A Life Course Perspective on Behavior and Health

Timothy P. Daaleman and John Preisser

The life course is a framework that provides a way to integrate macro-level factors – social, cultural, environment – with individual-level influences that collectively contribute to health by pointing to the trajectories and transitions of persons (Elder & Johnson, 2002; Elder, Johnson, & Crosnoe, 2003). The importance of this orientation is highlighted by the Patient Protection and Affordable Care Act, which has extended health-care coverage to millions of Americans and has concomitantly focused attention on social and behavioral determinants of health (Institute of Medicine, 2014). The Institute of Medicine (IOM) has responded to this legislation by a recent call to delineate and capture these determinants within emerging electronic health records, information that can ideally be used by individual clinicians, by health-care systems, and by public health officials and researchers (Institute of Medicine, 2014; Adler & Stead, 2015).

Social factors can be attributed at the individual level or larger contextual level (e.g., neighborhood and community), and both have a profound effect on the health and health care of patients. Individual-level social factors, such as race/ethnicity, exert a substantial influence on how people view and rate their health (Gibson, 1991; Kramarow, Lentzer, et al., 1999), in addition to how frequently they use health-care services (Phillips, Hamel, et al., 1996; Greiner, Perera, & Ahluwalia, 2003). Contextual factors are features of the social and physical world (Berkman & Kawachi, 2000), and geographic location and the local distribution of health-care resources are strongly associated with the intensity of services that patients receive (Fisher, Wennberg, et al., 2003a, 2003b). Although much prior work has studied the separate effects of individual-level and contextual determinants (Han, Phillips, et al., 2005; Wen, Cagney, & Christakis, 2005; Covinsky, Eng, et al., 2003), a conceptual framework to examine how these factors jointly contribute to health and health services has not been fully developed.

The recent IOM report recommended a panel of largely individual-level domains and measures, such as race/ethnicity, tobacco and alcohol usage, and social connectedness (Institute of Medicine, 2014). Unfortunately many of these measures do not fully capture or delineate the contributory and differential effects of key social and behavioral determinants on health outcomes (Braveman, Egerter, & Williams, 2011). The report also has a restricted view of contextual factors, such as community-level social and environmental data

(Bazemore, Cottrell, et al., 2015), a limitation that does not add understanding in how upstream factors contribute longitudinally to the health of populations (Braveman, Egerter, & Williams, 2011). In response, this chapter introduces the life course as a multilevel perspective that can frame how both contextual and individual factors jointly influence the health and health care of patients. This field of inquiry is characterized by locating people longitudinally along trajectories and characterizing their social contexts and situations as pathways in which their lives progress (Elder, Johnson, & Crosnoe, 2003). The life course has already gained wide acceptance across multiple disciplines, such as aging and gerontology, developmental psychology, and social epidemiology (Mortimer & Shanahan, 2003). A life course approach to chronic disease epidemiology, for example, examines the biological, behavioral, and psychosocial pathways that may be paved early in life and operate across an individual's life span, eventually contributing to the risk of developing chronic disease (Ben-Shlomo & Kuh, 2002; Kuh & Ben-Shlomo, 2004; Lynch & Davey, 2005). Conceptual models within life course epidemiology look at how the temporal ordering of exposure variables, such as stress, factor into later life risk of disease (Ben-Shlomo & Kuh, 2002).

Social Factors Contributing to Health and Health Care

The socio-ecologic model is addressed in many chapters throughout this book and underscores the importance of social and environmental influences within the life course perspective. Although individual-level social factors, such as race/ethnicity, are more commonly understood (Gibson, 1991; Kramarow, Lentzer, et al., 1999), contextual factors are less clearly defined features of the social and physical world (Berkman & Kawachi, 2000), but they account for many differences in the health-care experience of patients; geographic location and the local distribution of health-care resources are strongly associated with how much health-care services that patients receive (Fisher, Wennberg, et al., 2003a, 2003b). To illustrate these influences, this chapter will direct attention to the social and behavioral factors as they influence an important part of the life course, older adulthood, and the end of life.

As background, the overall health and health-care experience of older adults with serious chronic illness varies widely depending upon the local social and physical environment (e.g., geographic region, distribution of health-care resources) and individual-level factors (Dartmouth Medical School Center for the Evaluative Clinical Sciences, 1999). There are compositional and contextual explanations for such variation. A compositional explanation attributes area variation to differences in the characteristics of individuals in defined areas (Macintyre & Ellaway, 2000). For example, a larger concentration of frail, older adults in one geographic area would explain a higher rate of health service utilization when compared to another area. Contextual explanations, in contrast, suggest that there are features of the social and physical environment that influence the health of those exposed to it (Macintyre & Ellaway, 2000).

Older adults may be more influenced by their social environments and emotional ties to their communities (Diez-Rouz, 2002; Krause, 1996; Robert & Li, 2001). These place effects play an important role in health outcomes, especially near the end of life. This is illustrated by the finding that the chance of an inhospital death varies more than twofold among hospital referral regions in the United States, from as few as 20% of deaths to more than 50% (Dartmouth Medical School Center for the Evaluative Clinical Sciences, 1999). In addition, for older patients with Medicare, the number of days spent in acute hospitals and the chance of being admitted to an intensive care unit during the last month of life vary by factor of more than five (Dartmouth Medical School Center for the Evaluative Clinical Sciences, 1999). These variations in hospitalizations are associated with the per capita supply of hospital beds and physicians (Wennberg, Freeman, & Culp, 1987; Wennberg, Freeman, et al., 1989; Fisher, Wennberg, et al., 1994), health services that are unfortunately associated with aggressive technical interventions and are frequently undesired and at odds with elders' individual life situations and expressed preferences (Stein, Lynn, et al., 1989).

From an economic perspective, regional differences in Medicare spending are largely explained by more hospital and specialty-based patterns of care (Fisher, Wennberg, et al., 2003b). Intuitively, older adults residing in areas with high concentrations of health-care resources (i.e., hospitals, physicians) would expect better health outcomes than residents in low-resource areas. However Medicare recipients in high-spending areas do not have better quality of care or improved health outcomes, such as decreased mortality or improved functional status, when compared to lower-spending regions (Fisher, Wennberg, et al., 2003a, 2003b). The local supply of specialist physicians and hospital resources is a major driving force to the use of discretionary services – hospitalizations, physician visits – in a geographic area (Fisher, Wennberg, et al., 2003b).

Individual-level factors (e.g., race and ethnicity) also exert a powerful influence on outcomes, including perceived health status (Gibson, 1991; Kramarow, Lentzer, et al., 1999) and health-care utilization (e.g., hospitalization, hospice usage) (Phillips, Hamel, et al., 1996; Greiner, Perera, & Ahluwalia, 2003). Over 60% of African Americans prefer to die in the hospital, opt for more aggressive medical care for terminal illness (Garrett, Harris, et al., 1993; Gramelspacher, Zhou, et al., 1997), and are less likely to use hospice when compared to whites (Greiner, Perera, & Ahluwalia, 2003). In addition to health service utilization, race and ethnicity also exert a powerful influence on self-reported health status in older adults (Gibson, 1991). Among persons 65–74 years of age, non-Hispanic black persons and Hispanics are more likely to report fair or poor health, when compared to non-Hispanic white persons (Kramarow, Lentzer, et al., 1999). Further, self-rated health status and other health-related quality of life indicators have been found to be consistent predictors of how often health service are utilized (Hulka & Wheat, 1985; Wan, 1976; Wolinsky & Arnold, 1988). These global measures are representations of the physical, emotional, and social aspects of health and have been found to be an independent predictor of mortality (Idler & Benyamini, 1997) and life expectancy in older adults (Lubitz, Cai, et al., 2003).

The Life Course Framework

The life course provides a framework for understanding how social and behavioral factors impact health. Life course theory emerged from three intellectual traditions: social relations, age and temporality, and life span development (Elder, Johnson, & Crosnoe, 2003). From a social science perspective, roles are patterns of expected behaviors and attitudes that are commonly held and defined within groups or by social situations (Theodorson & Theodorson, 1979). A foundation for framing such a social and relational dynamic begins with the sociological relationship theories that surfaced in the 1960s and 1970s and continues with the life course theory of today (Kertzer, 1983; Clausen, 1968; Brim & Wheeler, 1966).

Socialization describes how individuals move into and out of social roles (e.g., parent, student) accompanied with a set of proscriptive and prescriptive expectations (Clausen, 1968). Patients may occupy a sick role which can release them from their usual obligations and responsibilities, such as work or parenting (Mechanic, 1978). These social roles, however, are not isolated sets of expected behaviors and attitudes but are often characterized by a graded sequence and transitions across different periods of the life cycle (Antonucci & Akiyama, 1995). Older adults rather than children and adolescents, for example, are more readily recognized and accepted by others in the sick role, although individual members within each group may be afflicted with the same serious illness.

Role-theoretical perspectives – social roles, life cycles – are limited in their ability to conceptualize relationships since they are timeless and fail to locate individuals within their larger social or historical contexts. Life course theory fills this void by incorporating constructs of age and temporality developed from social anthropology (Riley, Hess, & Bond, 1983; Neugarten & Neugarten, 1996). These elements recognize the multiple chronological meanings of age (e.g., historical time, social time, biological time) and the remarkable individual variability in the timing and scheduling of events along a life course (Neugarten & Neugarten, 1996). For example, the health effects of life events and transitions often depend on when they occur (e.g., whether bereavement and widowhood occur early or later in life) (Wortman & Silver, 1990).

A life span concept of development represents the final intellectual strand of the life course, drawing upon contributions from developmental psychology and life course sociology. Life span concepts such as life review and autobiographical memory emphasize the importance of narrative and memoir accounts within lived lives (Thomas & Znaniecki, 1958), while human agency views individuals as central actors and producers of their own development (Clausen, 1993). In the United States, patient-centered movements such as end-of-life care and complementary and alternative medicine can be viewed as attempts by patients to reclaim their own voice and individual human agency within a system of health care that is often depersonalized and grounded in technology (Daaleman, 2004).

Principles of the Life Course

Life course principles focus on individual choice and decision-making, promote an awareness of larger social and historical contexts, and foster an understanding of the timing of events and the various roles that change in a lifetime (Daaleman & Elder, 2007). These principles also think of human lives as embedded in relationships with significant others and help us consider a holistic understanding of lives over time and across changing social contexts (Elder, Johnson, & Crosnoe, 2003). As a whole, the principles are (1) *human development and aging as lifelong processes*, (2) *human agency*, (3) *historical time and place*, (4) *timing*, and (5) *linked lives* (Elder & Johnson, 2002).

The principle of *lifelong development and aging* embraces a longitudinal, often intergenerational, perspective that links earlier life influences with events and outcomes in subsequent years (Amick, McDonough, et al., 2002). Life course epidemiology, which was introduced earlier, is representative of this principle and examines the long-term effects of physical, environmental, or social exposures during childhood on subsequent health or disease risk in later life (Kuh, Ben-Shlomo, et al., 2003). This approach casts light on the behavioral, biological, and psychological processes that are in play across an individual's lifetime, or across generations, and that can contribute to the risk of developing disease or that can help maintain health and functional status (Kuh, Ben-Shlomo, et al., 2003). In its ideal form, life course epidemiology integrates the contributions of well-established risk factors for disease – smoking, obesity, and hypertension, for example – with the social and environmental processes (e.g., lower socioeconomic status) that may be operational. Consider, for example, the prevalence of heart disease, which peaked in the 1960s for a cohort of men born around the turn of the twentieth century (Lynch & Davey, 2005). After this decade there was a marked, progressive decline in heart disease, which reflects both the reduction in smoking and advances in blood pressure control in the general US population (Lynch & Davey, 2005). However the drop-off in heart disease in subsequent years was not uniform for all populations, illustrating the differences across subsequent birth cohorts in how early and later life exposures to smoking and hypertension – as well as to other social and psychological factors – predispose to developing heart disease (Lynch & Davey, 2005).

A life course epidemiologic approach looks at how socially developed and patterned exposures to risk factors in early life may account for marked differences and inequalities –which may not solely be attributable to genetic or biological factors – in later life mortality, disease, and health (Kuh, Ben-Shlomo, et al., 2003). Socioeconomic factors at different periods of the life course can function through an accumulation of risk or via a chain of risk (Kuh, Ben-Shlomo, et al., 2003). The accumulation of risk describes the gradual accrual of multiple behavioral risk factors (e.g., smoking, limited physical activity), adverse environmental conditions (e.g., limited access to clean air and water), and repeated illness or injury episodes that cumulatively cause physiological damage and subsequently increase the risk of disease and mortality (Kuh, Ben-Shlomo, et al., 2003). A chain of risk model, in contrast, is a sequence of linked exposures that raise the risk of disease; different types of social, biological, or psychological chains may mediate or moderate an increased or decreased risk of disease (Kuh, Ben-Shlomo, et al., 2003). In either risk model, there can be a critical period, which is a limited window of time in which an exposure can have a hazardous or protective effect on subsequent outcomes (Kuh, Ben-Shlomo, et al., 2003).

Agency is the second principle in the life course, and this reflects and characterizes the sense of control that people seek to gain over the events in their lives (Bandura, 1997). Human agency views individuals as active participants who construct their own life course through the choices and actions they take, given the opportunities and constraints of their personal history and social circumstances (Clausen, 1993; Bandura, 1997). Human behaviors, particularly health behaviors, are governed by a myriad of factors and individuals contribute to – rather than being the sole influencers of – what they do or what happens to them (Bandura, 1997). Agency is tied to individual actions that are done intentionally, and these actions are driven and guided by a person's personal efficacy (Bandura, 1997).

Self-efficacy beliefs are key in personal agency; if people do not believe that they are capable of executing a given plan of action and that the actions will produce a desired outcome, they will not initiate an activity or see it through to completion (Bandura, 1997). These beliefs can be drawn and developed from several sources: enactive mastery experiences that reinforce capability, vicarious experiences that promote efficacy beliefs through comparison with others, verbal and other types of social persuasion, and physiological and affective states through which people gauge their readiness and potential for change (Bandura, 1997). Personal agency does not operate autonomously and individually but emerges from a network of social structures that have both constraints and opportunities for personal growth and development (Bandura, 1997).

Personal agency and efficacy beliefs have provided the theoretical foundation for many interventions that have promoted health behaviors and enhanced the self-management of chronic disease. These beliefs that people can motivate themselves and regulate their health behaviors impact each phase of the personal change process, the contemplation and consideration of changing health behaviors, garnering the motivation and resources that are needed to be successful, and sustaining the desired change and dealing with setbacks (Bandura, 1997). One effective strategy that draws upon human agency is peer support or mentoring. Peer supporters provide the needed practical and emotional support of behavior change that can potentially facilitate and enliven the efficacy beliefs of people who live with comorbid disease by sharing a personal knowledge and an illness experience in authentic and meaningful ways (Solomon, 2004). There is a substantial evidence base – from patients living with chronic conditions such as diabetes, cancer, cardiovascular disease, mental illness, and HIV/AIDS – that has demonstrated the effectiveness of peer support in sustaining health behavior change (Davidson, Chinman, et al., 1999; Parry & Watt-Watson, 2010).

Peer support strategies offer emotional, social, and practical assistance on how to achieve and sustain complex behaviors that are essential for managing conditions and staying active and healthy (Brownson & Heisler, 2009; Dunn, Steginga, et al., 2003; Fisher, Brownson, et al., 2005). In addition, this approach often complements and adds value to existing health-care services that help people adhere to care management plans in daily life, to stay motivated and cope with the stressors of chronic illness, and to maintain continuity with their health-care providers, often in a cost-effective manner (Whitley, Everhart, & Wright, 2006).

Individual lives are located in a specific *historical time and place*, another core life course principle. The individual life course is embedded in and shaped by the places that a person experiences over a lifetime (Elder & Johnson, 2002). The same historical event may differ in impact and meaning across different countries or regions, as evidenced during the immediate postwar years of World War II which saw widespread devastation in parts of Europe but prosperity in the United States (Elder, Johnson, & Crosnoe, 2003). A more contemporary example is the social and economic effects of the current AIDS epidemic on African children. Homelessness, migration, malnutrition, and reduced access to health care and education are staggering problems which have greatly increased the probability of illiteracy, poverty, and chronic illness in subsequent adulthood for this population (Foster, 2002). These place effects can be viewed as historical and ecologic constraints that limit the range of potential opportunities and choices along the life course.

In health care, there has been longstanding interest in the geographic variations found in the distribution of health-care services and a growing recognition that many social determinants of health may operate at local levels through neighborhoods and communities (Diez-Rouz, 2001). A number of health problems, such as low birth weight and infant mortality, tend to be aggregated and studied at the neighborhood level (i.e., census tract or block) and are tied to the cumulative disadvantage and geographic isolation of many African American populations (Sampson, Morenoff, & Gannon-Rowley, 2002). Here it is important to clearly define the characteristics of geographic boundaries or areas in ways that are applicable to specific health outcomes (Diez-Rouz, 2001). The terms neighborhood, area, and community have frequently been interchangeably used, often referring to an individual's immediate residential environment (Diez-Rouz, 2001). Administrative boundaries (e.g., zip code or census block) have been traditionally used in many studies to operationally define neighborhoods and communities that are situated in a specific geographic location (Diez-Rouz, 2001).

Over the last decade, geographic information systems (GIS) have been increasingly employed as tools that have been more discretely used to define the social and physical environment of individuals, as well as a way to capture the distribution of health-care resources (e.g., physicians, hospitals) in a spatial context (Ricketts, 2003). Geographic software programs can now generate precise area coordinates that reflect more meaningful regions of human activity – rather than by administratively set boundaries – that are marked by commerce (e.g., markets and shopping centers), work locations, places of worship, and the sites of health-care services, such as hospitals and physician practices (McLafferty, 2003).

The life course principle of *timing* acknowledges that the concept of age has several meanings and interpretations (Neugarten & Neugarten, 1996). Similar events and life experiences can impact individuals in different ways depending on when they occur in the life course (George, 1993). For example, the differential experiences of young people who go through very early transitions from adolescence to adulthood (e.g., leaving home, marrying or cohabitating, becoming a parent) have detrimental effects on mental health (Elder, Johnson, & Crosnoe, 2003). Health-care providers commonly limit their understanding of time to strictly biological terms that are marked by developmental or physiological changes, such as childhood language acquisition, puberty, and menopause. However, the life course broadens this view to include other ways of thinking about time. For example, social time looks at how chronologic age (i.e., age in years since birth) distinguishes and differentiates role expectations among individuals, an understanding that is illustrated by ongoing discussions regarding the appropriate age for younger adults to have legal access to alcohol, to vote, or to serve in the military and for older adults to receive Social Security and Medicare benefits (Scanlon, 2006). Subjective time, in contrast, is a person's self-perception of how old they are or how old they wish to be (Neugarten & Neugarten, 1996).

Timing focuses on the assumptions and expectations regarding when life events should occur and are normative in areas such as childbearing and family life. Timing comes into greater play for patients and family members particularly around the beginning and end of life (Lynn, O'Connor, et al., 1999). This principle takes into account the developmental antecedents and consequences of life events and transitions which may vary according to their timing in a person's life (Elder, Johnson, & Crosnoe, 2003). In addition, it recognizes that the same events or experiences may impact individuals in differential ways, depending on when they occur in an individual's life course (George, 1993). For example, the very early transition to adult responsibilities (e.g., getting married or becoming a parent) at a relatively young age has been found to negatively impact subsequent mental health (Elder, Johnson, & Crosnoe, 2003).

The principle of timing also takes into account that individuals may view themselves as synchronous ("on-time") or asynchronous ("off-time") with their expectations regarding their social time (i.e., is the life event concordant with their age) or subjective time (i.e., is the life event concordant with how old they see themselves). This principle is illustrated by variations in the timing of a terminal illness, whether early or later in life. For example, a 35-year-old woman who is unexpectedly diagnosed with an aggressive breast cancer would be considered in a "too early" age group and asynchronous according to the timetable of her birth cohort.

The last principle in the life course, that of *linked lives*, refers to the interdependence and network of shared, social relationships that surround individual lives. Larger social changes can impact individuals through their interpersonal contexts on more microlevel settings, such as family units (Elder, Johnson, & Crosnoe, 2003). For example, economic hardships can negatively impact the mental health of parents, which in turn affects the growth and development of their children. Social relationships can be thought of as the relational ties between individuals (i.e., interindividual) or changes in these connections that take place within one individual over time (i.e., intra-individual) (Elder & Johnson, 2002). There are basic characteristics of social relationships, including the size of the personal network and the varying strengths of the social ties among network members (Antonucci & Akiyama, 1995). These ties and networks serve multiple functions, such as emotional and instrumental support, and often provide resources in the areas of caregiving and personal care services.

Social network is a conceptual approach which recognizes that individuals are embedded in a web of relationships and are influenced by the behaviors and activities of those around them (Christakis & Fowler, 2007). In analyzing social networks, the concept of a node is used to describe people who may or may not be connected to others in the network; the connection between two nodes is termed a tie (Christakis & Fowler, 2007). Social networks acknowledge the human tendency of individuals who choose relationships with others that have comparable attributes and behaviors, and the grouping of nodes – each of which is connected to at least another node – is called a cluster (Christakis & Fowler, 2007). A longitudinal study, for example, examined the linkage between the social network and obesity among 12,000 people who participated in the Framingham Heart Study and found that a person's risk of becoming obese increased by 57% if he or she had a friend who also became obese (Christakis & Fowler, 2007).

The convoy model is another organizing framework of social relationships, one that adds a life course dimension to the concept of networks. The model views relationships as a series of interactive sequences involving significant others (e.g., important family members, longtime friends) that aggregate and disassemble across different periods of the life course (Antonucci & Akiyama, 1995). This way of thinking emphasizes the longitudinal character of relationships and conveys a fluid aspect that is often not captured by social support or family network concepts (Broadhead, Gehlbach, et al., 1988). The social convey model views an individual as moving through their lifetimes surrounded by different groups of people who are close and important to them, an alliance of others who have a critical influence (either positive or negative) on their life and well-being (Antonucci & Akiyama, 1995).

Trajectories and Transitions

The concepts of trajectory and transition are central, unifying themes, and they represent both the long and short perspective of life course principles. Lived lives, for example, take place over an extended span of time, a social trajectory of work or marriage or a developmental trajectory of self-rated health. In contrast, a sense of agency or personal control may be developed within a short time span that is marked by the transition of specific life events, such as graduating from college and getting married. The life course emphasizes the importance of trajectories, as well as transitions and turning points, as core concepts in its framework. Trajectories are sequences or long-term patterns within a given area (e.g., health, family, or work situations) and are formed by linking states (e.g., health status, poverty) and transitions across successive years (Duncan, Brooks-Gunn, et al., 1998; Clipp, Pavalko, & Elder, 1992). Trajectories are not individual events in time, but are embedded in social pathways that are defined by social institutions and relationships that provide social support. That is, they are socially determined. Trajectories reflect the cultures and communities in which they evolve as well as the individuals whose lives they characterized. Transitions are inflections and changes in direction of the trajectory (Elder & Johnson, 2002).

Illness trajectories go beyond the physiological unfolding of disease to encompass the total organization of work done over the course of the illness and take into account the impact that this work has on those involved in the accompanying activities (Strauss, Corbin, et al., 1984). Work here refers to the physical and emotional tasks and activities performed by patients and caregivers. When a trajectory and its transition place people in new environments and alter behavioral and social patterns, they are referred to as turning points (Sampson & Laub, 1993). Turning points are individual or institutional sentinel moments that result in a change of direction along the life course (Clausen, 1998). For example, a seriously chronically ill patient who declines aggressive medical care has reached a turning point. The probable subsequent decline in health and functional status and entry into long-term care or hospice would constitute both a trajectory and a turning point. Trajectories are influenced by and directly impact social relationships (e.g., family caregivers) and provide a way to understand and conceptualize the important factors that potentially affect a patient's experience of health, illness, and well-being.

Trajectories have been mapped out to depict the patient experience of serious chronic illness and are distinguished by variations in their duration and shape (Glaser & Strauss, 1965; Pattison, 1977; McCormick & Conley, 1995). A report from the Institute of Medicine, for example, offered three plausible functional trajectories specific to serious illness and dying: (1) sudden death from unexpected cause, (2) steady decline from a progressive disease with a "terminal" phase, and (3) advanced illness marked by slow decline with periodic crises (Fig. 16.1) (Glaser & Strauss, 1965; Field & Cassel, 1997). A subsequent study of Medicare beneficiaries examined the degree to which these three trajectories accurately characterized

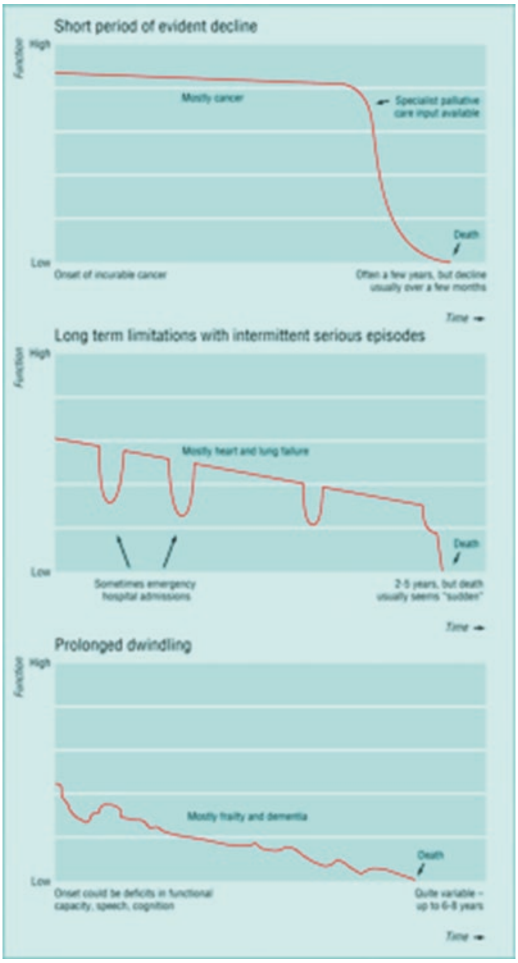

Fig. 16.1 Functional trajectories of serious chronic illness (Murray, Boyd, & Sheikh, 2005; Lynn & Adamson, 2003)

seriously ill and dying patients, and four trajectories were able to characterize 92% of individuals' pathways at the end of life: (1) sudden death, (2) terminal illness, (3) organ failure, and (4) frailty (Lunney, Lynn, & Hogan, 2002).

An Analytic Approach to Determining Trajectories

Statistical methods that integrate repeated observations over time and identify different paths of progression are central to characterizing trajectories. This analytical approach is different than simply using discrete observations at baseline and at one or more points in time. With trajectories, the focus is less on determining the outcome of interest as it is in describing the sequence of events that contribute to and sustain it. Since analytic strategies used in characterizing trajectories may not be commonly understood, the following section describes one approach by illustrating the functional trajectories of older adults with serious chronic illness (i.e., a subset of chronic diseases which are marked by a progressive loss in health and functional status leading to death) (Stein, Lynn, & Stein, 1989).

The primary strategy assumes a continuous-scale outcome and relies on the use of hierarchical linear models (HLM) to account for repeated measures; these are also known as linear mixed models. When the outcome is categorical or discrete, generalized linear mixed models may be used. The methods include: (1) equations for population-averaged trajectories and their corresponding residuals that are used to aggregate individuals into subgroups based on a specific outcome measure (e.g., older adults with a pattern of physical functioning over time), (2) explanatory models that identify factors associated with different outcome pathways, (3) estimating individual trajectories with prediction equations that include random individual-level effects to account for deviation of an individual's trajectory from the population-averaged trajectory for the group to which he/she belongs, and (4) validating the trajectories with respect to conceptually related measures.

Using our example, older adults with serious chronic illness (SCI) might be categorized into the following groups: (1) terminal illness (cancer, solid or hematologic malignancy, or malignant tumor of any type), (2) organ failure (ischemic heart disease, congestive heart failure, chronic kidney disease, chronic obstructive pulmonary disease), and (3) frailty (stroke, cerebrovascular accident). Life course principles, that were described earlier, can inform the selection of data elements to be used in modeling trajectories for specific patient populations and patients. The following section illustrates how analyses might proceed in differentiating and then describing these three groups and the extent to which they provide a representation of the variety of pathways among those with serious chronic illness.

Identifying the Pathways: Population-Averaged Trajectories and Residuals to Identify Resilient or Vulnerable Functioning

For each of the three groups with serious chronic illness, an average trajectory can be estimated by adjusting the intercept for baseline severity (and comorbid conditions, such as depression) and then identifying individuals for whom the model does not have a good fit. For simplicity, an analysis for a single group can be considered, although models can be specified to analyze all three groups simultaneously as this provides improved precision when regression parameters are shared across the three groups. Specifically, a longitudinal data model may be fit with up to a cubic effect of time (i.e., an individual's age is used instead of calendar time (t) in order to address age cohort effects):

$$E\left[Y\left(t\right)\right] = b0 + b1 * t + b2 * t^2 + b3 * t^3$$

In conjunction with this model for the mean value of functional status, an appropriate covariance model can be specified within the context of a hierarchical linear model (Cnaan, Laird, & Slasor, 1997) in the case of a continuous outcome or a generalized linear model (GLM) estimated by generalized estimating equations for a categorical outcome (Liang & Zeger, 1986; Diggle, Heagerty, et al., 2002). Once the regression parameter estimates have been obtained, a set of residuals can be computed, one for each observation that an individual contributes to the analysis. An individual with a particularly large (i.e., positive) residual (e.g., about the estimated mean regression line) is one who has functional status better than expected at that particular age. An individual with a particularly small (i.e., negative) residual is one who has functional status poorer than expected at that particular age. In this way, we can define so-called "resilient" (i.e., those who maintain their functioning) and "vulnerable" (i.e., those with declining functioning) older adults.

Practically, using longitudinal data from electronic health records can inform the categorization of an individual as resilient or vulnerable. This categorization will be time dependent, as an individual may have better functioning than expected at a younger age and subsequently poorer functioning than expected at an older age. At each of several ages, which can be determined based upon the distribution of ages in the data, the upper quartile of residuals can be defined as the resilient older adults, and the lower quartile of residuals as the vulnerable older adults. Two logistic regression analyses can be conducted, the first assessing whether individual factors, such as linked lives and agency, predict resiliency and the second assessing whether these factors predict vulnerability. These analyses (i.e., one for resiliency and one for vulnerability) can provide an assessment of individuals' longitudinal indicators in order to summarize findings across the life course. For example, do stronger social network ties with others explain resiliency across all ages or only for some age groups? To address such questions, modeling approaches for longitudinal binary data such as generalized estimating equations can be used (Liang & Zeger, 1986; Diggle, Heagerty, et al., 2002).

Understanding Differences Among the Pathways: Explanatory Models That Identify Factors Associated with Different Functioning Pathways

This approach, which extends that of the previous section, assesses directly, within the context of an HLM (or GLM, in the case of a categorical outcome), whether or not trajectories of functional status differ by individual characteristics. For simplicity, consider a covariate, X, and the longitudinal data model for a single SCI group:

$$E\left[Y(t)\right] = \left(b0 + a0^{*}X\right) + \left(b1 + a1^{*}X\right)^{*} t + \left(b2 + a2^{*}X\right)^{*} t^{2} + \left(b3 + a3^{*}X\right)^{*} t^{3}$$

If X is equal to 0 or 1, then a test that the regression coefficients, a0, a1, a2, and a3, are simultaneously equal to 0 is a test of whether or not the trajectory of functional status is identical for the two groups determined by X. A fully saturated model including several categorical covariates, informed by life course principles, would estimate intercept, linear, quadratic, and cubic time effects for each group resulting from the cross-classification of the covariates. In accordance with the richness of the data, a sequence of regression models can be fit.

The first set of models can include severity factors retaining main effects in order to adjust the intercept b0 above, but dropping nonsignificant polynomial time effect interactions as more complex but parsimonious models are built to describe varying trajectories. In this regard, the second set of models can additionally include individual factors, and the third set of models can add potentially protective factors, such as social networks. For example, do protective factors alter the group trajectories of functional status after controlling for symptom severity and other individual factors? The focus here is on estimating functional status trajectories for the three SCI groups and determining whether subgroups within those three primary groups have different trajectories.

Identifying Individuals' Pathways: Estimating Individual Trajectories Using Prediction Equations

Hierarchical linear models, also known as random coefficient models in the context of repeated measures, can be used to estimate a trajectory of a continuous outcome for each individual; generalized linear mixed models (e.g., logistic models with random coefficients) (Diggle, Heagerty, et al., 2002) could be used for dichotomous or categorical outcomes. In the parlance of linear mixed models, the individual-level trajectories can be based upon best linear unbiased predictors of model random effects. It would be possible to estimate a trajectory for each individual using only person-specific data, for example, a cubic polynomial curve for an individual with at least four data points. However, these trajectories can be poorly estimated if there is little data. The strength of the HLM approach is that individual trajectories can be estimated by also using information from a comprehensive data set from electronic health records via the particular model that is used. Ideally, random coefficients would be fit for each of the four polynomial terms in the model above. However, this model is very complex and it may not be computationally feasible to test it. Therefore, a simpler model that specifies a random intercept and linear term may be employed. Considering one of the mean models above, the model for the i-th adult at the t-th time is:

$$\mathrm{Y}\left(it\right) = \mathrm{E}\left[\mathrm{Y}\left(\mathrm{t}\right)\right] + bi0 + bi1^{*}\,\mathrm{t} + \mathrm{e}\left(it\right)$$

In the above equation, Y(it) is the observed functional status for the i-th adult at the t-th time, E[Y(t)] is the mean trajectory for a particular SCI group (or subgroups if individual-level factors are included), bi0 and bi1 are individual-level deviations from the overall group mean intercept and slope, and e(it) is a random error term. With the usual zero-mean normality assumptions of these random deviations, empirical Bayes estimation is used to provide estimates of bi0 and bi1 for each individual. Plugging these estimates into the above equation (with zero for e(it)) gives a predicted trajectory for each individual. For each SCI group, the individual trajectories can then be plotted to reveal their variation about the overall group mean trajectory, allowing characterization of variability of trajectories within each SCI group.

The potential contribution of using a life course approach in developing trajectories for older adults with SCI is highly relevant for both policymakers and care providers, since the number of older Americans continues to grow and will be facing disability, functional decline, and reduced quality of life (Merck Institute of Aging & Health, 2002). At the policy level, the striking geographic variation in health service utilization highlights that increasing services and resources do not improve mortality or quality of life, but result in less satisfaction with care for this population (Dartmouth Medical School Center for the Evaluative Clinical Sciences, 2006). And for providers, gaining a richer and longitudinal understanding of how individual-level social and behavioral factors contribute to the health of their patients can improve their care that they provide (Adler & Stead, 2015).

Caring for Patients and Populations Through the Life Course

The US health-care system is in the midst of a transformation to value-based care, which will focus on high-quality, cost-effective, patient-centered care for individual patients. In this new system, health-care providers will also be responsible for managing the care of populations of patients, such as those with type 2 diabetes mellitus, depression, and hypertension. The life course can provide both the intellectual and practical grounding for professionals who will be managing population in a system that seeks to optimize health and reduce disease burden not just in the short term but over the life span (Halfon & Conway, 2013). This orientation will shift the focus away from discrete, unlinked episodes of care, such as office visits, hospitalizations, and treatments for episodic or time-limited problems, to longitudinal trajectories of health and illness. In the foreseeable future, electronic health records and other sources will allow the measurement and creation of longitudinal data across the life course of patients, allowing the categorization of individual trajectories in specific health and wellness domains, such overall health and functional status.

A major challenge of health care in the twenty-first century will be a paradigmatic shift from an acute and largely communicable disease model to one that reflects chronic disease. Over a hundred years ago, communicable diseases –tuberculosis, diphtheria, and influenza – were the leading causes of death that largely contributed to infant and child mortality rates (Brim, Friedman, et al., 1970). The advent of antimicrobial therapy and major public health initiatives, such as vaccinations, have reduced mortality in these early years of life. As a result, chronic diseases – heart disease, cancer, stroke, lung disease – have displaced acute infectious diseases as the major causes of morbidity and mortality today (CDC, 2003; Jemal, Ward, et al., 2005). This shift may be illustrated in considering a 45-year-old woman who is newly diagnosed with diabetes mellitus and will require care over the next three to five decades. From a life course perspective, the biometric goal for her will not be a targeted level of glucose control at the next medical visit but a sustained trajectory of glucose control. The identification of major contributing factors – biological, social, and behavioral – in the early stages of her disease will confer an accumulation of risk providing a way to look at these trajectories that will inform treatment decisions and other interventions that last many years. Life course principles and trajectory analyses offer this way of thinking.

For health-care providers and public health officials, life course health data will allow a more complete understanding of how health is maintained or how disease develops over the life span. Practically, this information will transform the way health promotion and disease prevention programs are designed and implemented (Halfon & Conway, 2013). For example, predictive models using a life course approach may identify patients who are most likely to develop heart disease or diabetes, based on their cumulative individual (e.g., lack of exercise) and larger contextual (e.g., residence in a high-stress community) risk factors, facilitating the creation of targeted preemptive and preventive interventions (Halfon & Conway, 2013). At the same time, modeling pathways will support evaluation not in terms of "snapshots" of current status but of status and change in status over many years.

Health insurers and other payors will have greater incentives to promote health trajectories for populations of patients and to augment the longitudinal integration of health-care services, such as extending coverage and benefits from years to decades, creating incentives to manage risk and assume accountability for specified health outcomes (Halfon & Conway, 2013). An effective and efficient health-care system, as illustrated in Fig. 16.2, would ultimately require not only health-care services that are vertically integrated across medical, educational, and social service sites (e.g., worksites, schools) but also the

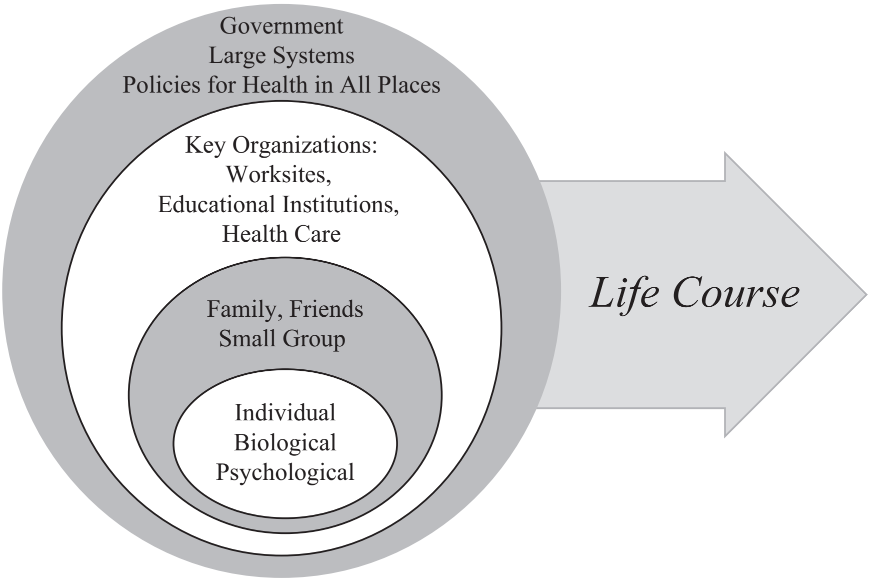

Fig. 16.2 Vertical levels of influence and the life course

horizontal integration across the entirety of the life course (Halfon & Conway, 2013; Halfon & Hochstein, 2002).

Part IV

Approaches to Changing Behavior Related to Health

17

Health Education and Health Promotion: Key Concepts and Exemplary Evidence to Support Them

Hein de Vries, Stef P. J. Kremers, and Sonia Lippke

The focus of this chapter is to summarize health education aimed at individuals and groups of individuals. We first briefly describe the history of health education. Next, we discuss the importance of identifying and systematically planning the various steps of health education. We then outline the constructs that are used in health education to motivate people to adopt health behaviors. Furthermore, we describe examples of approaches that are used in various settings. We outline the importance of taking a comprehensive and more ecological approach to health education by outlining the health promotion approach and contributions of ecological models for health education and health promotion, health behavioral change models, and diffusion models to illustrate the main concepts relevant for understanding how health education programs are developed, tested, and disseminated. We will also provide examples of programs that have been developed and were successful in various settings, such as mass media approaches, school-based programs, worksite programs, patient education programs, and eHealth and computer-based tailoring interventions.

Health Education

In 1948 the WHO acknowledged that health should be regarded as a state of physical, mental, and social well-being (WHO, [WHO definition of Health], 1946). An essential implication of this description is the fact that health is more than the absence of disease and that physical, social, and mental aspects are of equal importance. This view on health represents, in contrast with the medical disciplines, a more holistic view on health. This holistic principle was affirmed in the *Alma Ata Declaration* in 1978 (WHO, 1978) and the *Ottawa Charter* (WHO, 1986). These two documents outline that health should not be considered in an isolated context but as the result of the interplay between the individual and the context. In other words, health should be regarded as the result of an interaction between individual and environmental factors. Accordingly, the Ottawa Charter defines health promotion as strategy targeting the individuals and its environment.

Health education has a long history that dates before 1948 or 1986. Messages and interventions concerning hygiene were part of several ancient societies including the Roman civilization, where regular bathing was a hallmark. Messages about hygiene can also be found in many documents of several religions, such as the Bible, the Islam, and in Hindu documents. Yet, although issues of

health have always been a major concern for many civilizations, health education's significance has not always been articulated.

Generally, health education refers to the process of educating people about health and how they can influence their health. Health education methods thus pertain to methods used to educate people about health and how to achieve this. With regard to health education, several definitions can be found in the literature. For instance, health education aims at equipping people to enable them to make sound decisions regarding their health, safety, and welfare (Hochbaum, 1971), bringing about changes in individuals, groups, and larger populations to realize behaviors that are conducive to present and future health (Simonds, 1978).

An important concept in health education is *health behavior*. Health behavior often refers to an action taken by a person to reach and/or maintain good health and to prevent illness. These actions can be individual actions, such as quitting smoking and adopting a lifestyle with sufficient amounts of physical activity. We consider this action at the personal level.

Yet, groups can also undertake actions in order to promote good health or to prevent illness. We can think of parents helping their children to remain healthy but also of companies that start health promotion programs or regional and national governments that implement health-promoting policies. Hence, promoting health behavior can take place at the *micro level* (the personal level), the *meso level* (the organizational level, including e.g. families, schools and worksites) and at the *macro level* (the (inter)national level, including e.g. governments) (de Vries & van Dillen, 2007). This also implies that health education may be needed for several target groups in order to be able to comprehensively address a particular health problem.

Let us illustrate this with an example about the prevention of Lyme disease (de Vries & van Dillen, 2007). With regard to Lyme disease, several target groups can be identified. In the United States, the highest attack rates are in children aged 0–14 years and in persons 30 years of age and older. Several studies suggest a higher risk for children than for adults (de Vries & van Dillen, 2002). If one focuses on the prevention of Lyme disease in children, children are an important target group at the micro level. Target groups at the meso level can be, for instance, parents, siblings, relatives, and teachers but also sports trainers and peers. Examples of target groups at the macro level are institutions responsible for providing health education about Lyme disease. For addressing each target group effectively, it is relevant to know whether they are already engaged in the health education actions and what their motives are for engaging in it or not.

Health education is one of the methods used in health promotion. Health promotion refers to the process of enabling people to increase control over their health and its determinants and thereby improve their health (WHO, 1986). Health promotion implies the utilization of combinations of health education and organizational, political, and economic interventions designed to facilitate behavioral and environmental adaptations that will improve or protect health (USDHHS, 1980). Green and Kreuter define health promotion as the combination of educational and environmental supports for actions and conditions of living conducive to health (Green & Kreuter, 1991).

Green and Kreuter (1991) point out that health education – as a strategy for health promotion – should entail a systematic and planned approach. In achieving such an approach, various models and theories should be used. Different classes of models and theories can be distinguished. *Planning models* aim to outline the steps that can be taken in the process of identification of health problems up to the final stage of solving them. *Behavioral change models* aim to identify the factors that determine the adoption of a particular health behavior and to identify strategies to change these factors. These models are important for developing specific health education interventions. *Diffusion models* aim to describe the steps needed to disseminate effective programs on a larger scale. In the following we outline them in more detail.

Planning Models

One essential step in health education planning models concerns the analysis of the various steps that are important when trying to approach and solve a particular health problem (or sets of health problems), essential steps that need to be taken into account. Basically, the identification of these steps is characteristic for all health promotion planning models: they break down the complex process of health promotion into important steps that can be recognized.

An important conclusion from many of these planning models is that certain types of actions are needed in order to facilitate the conditions for a better health in a person, groups of persons, communities, and nations. Planning models can help to identify which types of health-promoting actions may be needed. The utilization of these models is important, since their application will help us to acknowledge important steps in the health promotion process, steps that we otherwise might have neglected. An important conclusion after investigating a particular health problem will probably be that we need to undertake actions in order to motivate persons to adopt a healthier lifestyle and to change our environment into a healthy environment.

The *PRECEDE–PROCEED Model*. In 1980 Green described the PRECEDE model for health education planning (Green, 1980). The PRECEDE model distinguishes five steps in the planning of health education strategies. The first step entails conducting a social diagnosis to determine people's perceptions of their own needs or quality of life and their aspirations for the common good. The *second step* is the epidemiological diagnosis which is conducted to determine which health problems are important. In the behavioral and environmental diagnosis, the *third step*, the main determinants of the health problem are analyzed. In the educational and organizational diagnosis, an analysis is made of the predisposing, reinforcing, and enabling factors that should be changed to initiate and sustain a process of behavioral and environmental change. These factors will become the immediate targets of a health promotion program (*step four*). The *fifth step* is the administrative and policy diagnosis, focusing on developing health education and health regulation actions.

In 1991 the PRECEDE model was amended and elaborated with a PROCEED part, describing the process that occurred after the development of health promotion interventions, thus describing the implementation of the actions (*step 6*); the changes of these actions on the predisposing, reinforcing, and enabling factors (process evaluation, *step 7*); the changes of the individual's behavior and the environment (impact evaluation, *step 8*); and the outcomes of the health promotion actions on health and the quality of life (outcome evaluation, *step 9*).

The PRECEDE–PROCEED model is still very influential in guiding health education and health promotion research and practice. One of the results of its utilization is the need for a slightly different organization of the planning model. Consequently, other planning models have been formulated which can be seen as various variations of the PRECEDE–PROCEED model, such as PATCH (see, e.g., McKenzie & Smeltzer, 2001, for an overview). In the United States, the *Planned Approach to Community Health (PATCH)* was developed in 1983 by the United States Centers for Disease Control (CDC) together with state and local health departments and community groups. PATCH was also intended to serve as a mechanism to improve links both within communities and between communities and state health departments, universities, and other agencies and organizations. PATCH integrates principles of community participation with the diagnostic steps of applied community-level epidemiology. The PATCH process guides users through five phases: (1) mobilizing the community, (2) collecting and organizing data, (3) choosing health priorities, (4) developing a comprehensive intervention plan, and (5) evaluation.

While applying the PRECEDE–PROCEED model, the Dutch I-Plan model resulted (also called ABC model (de Vries & van Dillen, 2007)). The I-Plan model is based on the three ABC's of the planning process: analysis, behavioral change, and continuation. The first *analysis phase* distinguishes five steps: (1) assessing quality of life, (2) assessing behavioral and environmental factors related to the problem, (3) defining the target groups, (4) analyzing factors that determine a person's behavior, and (5) access points analysis aimed at assessing how to best reach the target group and health intermediaries. The second *behavioral change* step involves (1) developing program goals and objectives, (2) developing the program, and (3) testing the program. The last phase, *continuation*, includes (1) establishing inter-sectoral collaboration and support, (2) developing diffusion strategies, and (3) developing supportive policies.

The *community organization model* by Bracht (1990) did not originate from the PRECEDE–PROCEED model. However, it has also similarities (Bracht, 1990). Since many health education and health promotion goals require active involvement of community citizens, leaders, and organizations, community organization is a central notion in this model. Community organization can be described as a planned process to motivate a community to use own resources and social structures to achieve the community (health) goals. The development of strategically planned interventions in which local groups or organizations are involved is therefore important to be able to realize relevant changes (Bracht, 1999). Community organization also implies community empowerment, capacity building, and partnership development. Bracht's model distinguishes five stages for the development of community programs, which are described in Table 17.1.

Table 17.1 The five stages of the *community organization model* by Bracht (1990)

First stage	Analysis of the community to obtain information regarding the community and its needs, resources, social structure, and values Establish citizen leader and organizational involvement to create collaboration and broad community participation
Second stage	Development of the design of the community program and the initiation of the development of an organizational structure and the preparation of plans
Third stage	Implementing the plans into action
Fourth stage	Program maintenance and consolidation Community members and staff gain experience and success with the program, and the problems that arose at the beginning of the project, have now been dealt with
Fifth stage	Dissemination of the program and the reassessment of activities Community analysis is updated, the effectiveness of interventions is established, and future directions and modifications are discussed

The *RE-AIM* framework was originally developed as a framework for consistent reporting of research results (Glasgow, Vogt, & Boles, 1999) but was later also used to organize reviews of the existing literature on health promotion and disease management in different settings. The acronym stands for *reach, effectiveness, adoption, implementation, and maintenance* which together determine public health impact. RE-AIM has been used to translate research into practice and to help plan programs and improve their chances of working in "real-world" settings. The framework has also been used to understand the relative strengths and weaknesses of different approaches to health promotion and chronic disease self-management – such as in-person counseling, group education classes, telephone counseling, and Internet resources. The RE-AIM model aims to guide planning and evaluation of evidence-based interventions that address different levels of the socio-ecological model, such as those that target individual health behavioral change by increasing intrapersonal, organizational, and community resource support; see Table 17.2.

Table 17.2 The dimensions of the *RE-AIM* framework (Glasgow, Vogt, & Boles, 1999)

Reach	Percentage and characteristics of individuals receiving the intervention
Effectiveness	Impact of an intervention on outcomes, including anticipated as well as unanticipated effects, quality of life, and economic outcomes
Adoption	Absolute number, proportion, and representativeness of settings that adopt the intervention
Implementation	Fidelity of intervention use and intervention costs
Maintenance	Long-term sustainability at both the setting and individual levels and thus involves the assessment of the extent to which a program or policy becomes institutionalized or part of the routine organizational practices and policies

The model has been used to evaluate programmatic and policy interventions addressing a wide range of health conditions (e.g., diabetes, obesity, hypertension) and health behaviors (e.g., physical activity, dietary behaviors, and smoking) and the built environment (Gaglio, Shoup, & Glasgow, 2013).

Dunton and colleagues, for instance, applied the RE-AIM model in order to examine the reach, efficacy, adoption, implementation, and maintenance of a physical activity and nutrition curriculum for Californian middle-school students (Dunton, Lagloire, & Robertson, 2009). They found that this particular program reached approximately 50% of applicable students and was adopted by 42% of the teachers to whom it was offered. The program had a strong influence on physical activity and sedentary behaviors, whereas positive effects for dietary intake were observed for some but not all of the outcomes measured. The majority of teachers delivered all of the lessons and implemented individual lessons in the recommended order. The program used by teachers remained relatively constant during the prior five school years, with approximately 51% of students reached. Taken together, these findings indicate that this program had a moderate to high public health impact among middle-school students.

Intervention mapping (IM) by Bartholomew et al. (2001) is an approach which was also inspired by the PRECEDE–PROCEED model. IM provides a protocol for the development of theory- and evidence-based health promotion programs. The purpose of IM is to provide health education program planners with a framework for effective decision-making at each step during the intervention development process. It provides guidelines and tools for the selection of theoretical foundations and underpinnings of health promotion programs, for the application of theory, and for the translation of theory into actual program materials and activities (Kok et al., 2011). IM suggests specific steps that guide problem-driven development, application and integration of nutrition, and behavioral change theories. IM proposes a systematic way for program development that results in the development of intervention matrices. These matrices finally develop into an "intervention map" that turns the translation of objectives to change strategies into actual intervention activities explicitly. IM describes the process of health promotion program development in six steps. Following an intervention map, six core processes are addressed (see Table 17.3).

Table 17.3 The six core processes of *intervention mapping* (IM) (Bartholomew et al., 2001)

1. Process	Needs assessment
2. Process	Identification of objectives
3. Process	Methods and strategies
4. Process	Program development
5. Process	Adoption
6. Process	Implementation

An application of intervention mapping is described by Van Stralen and colleagues (2008) that occurred for the development of a program on physical activity (PA) for older adults of at least 50 years of age. The needs assessment revealed that older adults who do not reach the international PA guideline of at least 30 minutes per day on at least 5 days of the week should become aware of their insufficient PA level and increase and maintain a new PA level. A list of specific objectives were identified, such as older adults need to (1) monitor their recreational PA level, (2) indicate reasons to be physically active as recreation, (3) identify solutions to take away the barriers to being physically active for recreation, (4) make clear decisions to become more recreationally physically active, (5) make specific plans to become more recreationally physically active, (6) increase their recreational PA, (7) make specific plans to cope with difficult situations occurring while being recreationally physically active, and (8) maintain their recreational PA by enhancing their routine and preventing relapses.

Concerning the methods, it became clear that methods were needed that would aim at, for instance, personalization, tailoring, feedback, argumentation, persuasive communication, self-monitoring, consciousness raising, active learning, and social modeling. These methods should provide tailored feedback on a person's awareness level, attitude, social influence beliefs, self-efficacy, and action plans. Program development thus resulted in the development of tailored letters that were sent to program participants three times, thus providing them with highly personalized and tailored feedback on how to become aware of their physical activity levels, on how to become or remain motivated, and how to best cope with the specific barriers that were relevant for this particular person. The sixth step resulted in the implementation of this program and evaluation of the effects. The results showed that the program was significantly effective in increasing physical activity levels (van Stralen et al., 2008).

In conclusion, planning models help a person to identify the relevant steps in the planning process. Most planning models share similarities: all of them identify a phase, step, or stage in which the problem and factors related to the problem are analyzed, one that focuses on program development and evaluation and one that addresses steps related to program adoption and implementation. Core differences can also be observed, which are mostly the result of the articulation of issues that remain more implicit in other planning models. For instance, the I-Plan model clearly recognizes the need to include three types of target groups at the micro level (individuals), at the meso level (families, schools, worksites), and at the macro level (organizations responsible for the development of policies), as well as an access point analysis to identify where the target groups can be reached as steps that should precede program development. The RE-AIM model, although initially intended to evaluate program implementation and impact, is now also increasingly used as an overall planning framework to guide program development. Intervention mapping has elaborated the PRECEDE–PROCEED model and stimulates the user to develop very clear ideas concerning the objectives that are needed for the development of programs, using an array of matrixes that can be used to summarize important information of the various steps. It also stimulates the user to clearly reflect on theories and theoretical constructs, as well as practical methods that can be used to change behavior. We will discuss these theoretical constructs in more detail below.

Concepts and Variables

In order to be able to develop health education interventions, health educators have used a variety of theoretical models and concepts within these models to develop their intervention. We will first start by outlining the main concepts. Later we will discuss various models and will see how these concepts were included (or not) in these models by various scholars and also obtain an indication of the differences and similarities between these models.

Knowledge Many health education programs provide information and facts about a certain topic. The idea behind this approach is that the provision of knowledge will increase awareness concerning a particular topic, for instance, the importance of hygiene, facts about pregnancy, the importance of eating sufficient portions of fruits and vegetables, etc. A smoking prevention program, for example, can provide information and facts about smoking by pointing at the health dangers of nicotine, tar, and carbon monoxide and by indicating that smoking is related to premature morbidity and mortality. Knowledge differs from beliefs, in the sense that knowledge items can be justified as true or false, whereas beliefs can be accepted or not. For instance, "cigarettes contain tar" is an example of a knowledge item. One reason why knowledge information is provided, is that it will increase risk perceptions and change attitudes in the receiver and attitudes in turn affect behavior. This chain is also referred to as the knowledge–attitude–behavior (KAB) chain. Better educated people possess more general knowledge on a broader range of public affairs topics (Price, & Zaller, 1993), which may also lead to better recognition and acquisition of new information (Bonfadelli, 2002).

A related concept, more often used in the area of patient education, is the concept of *health literacy*. Health literacy is defined by the WHO as the "The degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions" (WHO, 2010). Health literacy includes the ability to understand instructions on prescription drug bottles, appointment slips, medical education brochures, doctor's directions and consent forms, and the ability to negotiate complex healthcare systems. Health literacy is not simply the ability to read and know.

It requires a complex group of reading, listening, analytical, and decision-making skills and the ability to apply these skills to health situations. But also general literacy is related to risk factors: low (health) literacy in a population is associated both directly and indirectly with a range of poor health outcomes (Parker & Jacobson, 2000). Persons with lower reading (health) literacy levels have a greater likelihood of hospitalization and higher expenses for healthcare than those with better reading skills (Baker et al., 1998), and higher health literacy is related to better health behavior, higher well-being, and lower risk of morbidity and premature mortality (WHO, 2013).

Knowledge about certain health topics may be distributed skewedly. For instance, studies in the previous century already demonstrated that people with more formal education learned and knew more about many issues than people with less formal education (Hyman & Sheatsley, 1947), findings referred to as the *knowledge gap hypothesis* (Tichenor, Donohue, & Olien, 1970). The authors also pointed at the risk that information programs may be more likely to help groups of higher socioeconomic status (SES) than those of lower SES groups. The knowledge gap hypothesis implies a relative association as high SES and better educated groups will access, use, and acquire information faster and more effectively and thus yield a relative advantage. Yet, knowledge gaps may also decrease when information on a given topic becomes easily available to everyone. The rise of Internet use led to similar concerns, since differences in Internet access may lead to an increase in digital divide, resulting into a widened gap between individuals with and without much information about health-related topics (Hoffman & Novak, 1998). Knowledge differences, however, may exist between several groups. For instance, a Dutch study found differences between men and women about early detection of cancer: women recognized significantly more symptoms that could imply cancer than men did. Additionally, higher educated respondents recognized more symptoms than lower educated respondents (de Nooijer, Lechner, & de Vries, 2002).

In sum, health education programs targeting knowledge can thus lead to changes in knowledge, for instance, about HIV/AIDS (James et al., 2006), but these programs do not necessarily alter attitudes and behavior. Hence, several reviews concerning the effects of knowledge on behavioral change suggest that knowledge acquisition may influence attitudes, but is mostly insufficient to lead to health behavioral change (Hansen, 1992; Green & Kreuter, 1999). Yet, health education programs addressing knowledge can set the stage for developing risk perceptions concerning a certain health problem.

Risk Perceptions Studies of risk perception examine the judgments people make when they are asked to characterize and evaluate hazardous activities and technologies (Slovic, 1987). Risk perception derives from *threat appraisal*, which is considered to be a major motivating factor in preventive and protective health behaviors. Perceptions of risk can be an important motivator of a number of health-related behaviors. It is therefore important to understand them and their role in changing health behaviors. Risk perceptions (i.e., beliefs about potential harm or threat) are included in many health behavior theories (see, e.g., Lippke & Ziegelmann, 2008; Weinstein, 1988; Vernon, 1999). Core constructs that determine the development of risk perceptions are the *perceived susceptibility* to a particular threat and its *perceived severity*. The greater the perceived risk, the greater the chance will be that a person develops the motivation to protect oneself from the threat.

Studies analyzing the impact of severity and susceptibility perceptions on health behavior show small to medium effect sizes (Brewer et al., 2004; Abraham & Sheeran, 2005; Milne et al., 2000). Yet, many studies used cross-sectional designs and often found inconsistent contributions of risk perceptions to behavior. This does not imply that risk perceptions are not important. One explanation is that risk perceptions should be regarded as a more *distal cognitive process* influencing communication acceptance, awareness, and attitude change (Leventhal & Cameron, 1987; Schwarzer 2008; de Vries et al., 2003).

Recent findings also suggest that when communicating risk perceptions, it is better to describe conditional risks which describe clearly the probability that a certain event will occur given that the adaptive behavior is, or is not, performed (van der Velde et al., 1996; Janssen et al., 2011). For instance, "How likely is it that you will get disease X (e.g., skin cancer), if you would not perform behavior Y (e.g., sunscreen use)?" Additionally, recent research also points at the importance of the role of affect on risk perceptions. Affect can be regarded as an experiential system with reliance on quick "gut" feelings or reactions to respond to risk. This system encompasses biological and survival responses relying on the fight or flight autonomic nervous system, and is thus a different system than the more analytical and rational system, which relies more on slower pathways and cognitive reasoning (Slovic & Peters, 2006). Several studies increasingly support the importance of differentiating between cognitive and affective components of risk perceptions. For instance, in an attempt to assess potential differences between the two types of risk assessments, affective and noncognitive risk perceptions were found to be the only factor related to smoking, fruit consumption, and sunbed use in a Dutch study (Janssen et al., 2012, 2013).

In conclusion, as for knowledge (and probably for most factors) one can conclude that risk perceptions constitute an important factor in the process of behavioral change. Its role, however, may be more important in the early awareness phase than in later phases of the behavioral change process. Hence, health education programs should certainly address risk perceptions in populations that are not fully aware of the potential health risks of a particular behavior, and should not neglect the importance of emotional reactions of persons to risks.

Attitude Early persuasion studies by Hovland and colleagues at Yale were controlled experiments testing various conditions under which opinion or attitude change would occur in the context of such variables as source credibility, fear, organization of arguments, the role of group membership in resisting or accepting communication, and personality differences (Hovland, Janis, & Kelley, 1953). Several definitions for attitude can be found. Thurstone (1931) provided a now well-known definition of attitude as affect for or against a psychological object. Fishbein and Ajzen define attitude as the result of beliefs about the consequences of performing a particular behavior multiplied by the evaluation of these consequences (Fishbein & Ajzen, 1975). An example of a *belief* is "smoking increases popularity"; an example of an *evaluation* is "being popular is good." The notion that an attitude is constituted by several beliefs concerning the outcomes of a particular behavior has gained wide acceptance. The consequence of this notion also implies that attitudes can be changed by changing the underlying beliefs, beliefs that may differ from person to person. Consequently, a careful inspection of the most salient beliefs that constitute a particular attitude in a group is therefore important (Ajzen & Fishbein, 1980).

Yet, the multiplication of these beliefs with evaluation has received quite some criticism (Gagne & Godin, 2000). Consequently, many researchers decide to only assess the beliefs to measure the attitude. Beliefs about the consequences are described as outcome expectations in *Bandura's social learning theory* (Bandura, 1986). Outcome expectations thus refer to a belief that a given behavior will or will not lead to a given outcome. These outcomes can refer to all sorts of outcomes, such as *social outcomes*, *emotional outcomes*, or *health outcomes*. Another related concept is *decisional balance* (Janis & Mann, 1977) that describes to the weighing of advantages (pros) of a particular behavior with the disadvantages (cons). Furthermore, recent studies also outline the importance of distinguishing emotional versus more rational beliefs (Conner et al., 2013). In general, the different concepts of attitudes, outcome expectations, pros and cons, etc., refer to quite similar variables, and many theoretical models include them into their key constructs (Lippke & Ziegelmann, 2008).

Multiple studies have investigated the role of attitudes for several health behaviors. Studies have also examined which variables or beliefs distinguish a healthy group from an unhealthy group (Godin & Kok, 1996). For instance, Holm and colleagues (Holm, Kremers, & de Vries, 2003) found that non-smoking and smoking adolescents differed concerning their perceived pros and cons of smoking. Panday and colleagues (2005) showed that attitudes may also differ by ethnic group and demonstrated that Black African students were less convinced of the pros of non-smoking than colored students (i.e., the reference to colored people is used in South Africa to refer people with heterogeneous ethnic background) and white students, whereas colored students were least convinced of the cons of non-smoking, followed by Black African and, in turn, white students.

As attitudes are generally formed by multiple beliefs, and belief structures may differ per subgroup, it is important to acknowledge these differences when designing studies and programs targeting attitudes toward a particular health behavior. For instance, when discussing the need for smoking cessation, the importance of pointing at the consequences of smoking for the unborn baby becomes relevant for pregnant smoking women (de Vries et al., 2006). Moreover, smokers may not be equally convinced of all consequences. For instance, person A may not be convinced of the risks for cancer and thus may need information about the consequences of smoking for developing cancer; person B may be convinced of this aspect, but is not convinced of the consequences of passive smoking; person C may not be aware of the negative consequences of her smoking as a role model for her child; etc.

In sum, the identification of attitude beliefs is important when developing effective health education programs. Health education approaches need to tailor information as much as possible in order to be able to optimally address the specific attitude beliefs of one particular person.

Social influence beliefs pertain to the perceptions of a person to what others are thinking or doing. Social influences play an important role in the development of behavior (Bandura, 1986; Turner, 1991). Social influences can be described as the processes whereby people directly or indirectly influence the thoughts, feelings, and actions of others. Interventions aiming to change behaviors often focus on changing the impact of social factors. Social influences are associated with both beneficial and detrimental effects on other person's thoughts and behavior.

Well-known studies were performed by three different authors: First, Milgram (1963) demonstrated how conformity can develop. Second, Sherif (1935) indicated how acceptance of new beliefs can develop. Third, Asch (1956) revealed how compliance can develop. The *social comparison theory* (Festinger, 1954) argues that humans have a drive to evaluate their opinions and abilities. Hence, it is not only the mere exertion of social influences that impact people's behavior; at least as important are the ideas, perceptions, and expectations that a person has concerning other persons' behaviors.

An important factor in this context is referred to as *social norms* (Fishbein & Ajzen, 1975). Social norms refer to perceptions of the opinion of important referent persons. Social norms have been found to predict various behaviors. For instance, several studies in the former century document the role of social norms for understanding deviant behavior in adolescents (Presson et al., 1984; Grube, Morgan, & McGree, 1986; Oostveen, Knibbe, & de Vries, 1996; Newman, Martin, & Ang, 1982). For health education programs, the importance of social norms implies that one can develop programs to change social norms, as well as programs focusing on resisting social norms to engage in healthy behavior.

Other social influence constructs can be identified as well. Richard Evans suggested the importance of direct pressures to understand the process of uptake of unhealthy behaviors, such as smoking by adolescents (Evans, 1976). The difference between social norms and social pressure may be subtle, but distinct: pressures are exerted much more openly and clearly felt. Social modeling is a core construct in Bandura's *social learning theory*. Social modeling of a behavior by a person (the actor) can result in the perception of positive outcomes in another person (the receiver). This process is also referred to as vicarious or observational learning. This factor is sometimes also labeled descriptive norms (Rivis & Sheeran, 2003). De Vries and colleagues demonstrated the importance of both social pressure and social modeling (the behavior of others) as well as direct pressures (de Vries et al., 1995).

Social network theories describe the importance of a person's position in a social network and how persons are tied to each other, also in order to better understand the role of social influences. An important recent finding was that the onset of smoking does not only occur because of social pressure from peers but also by the selection of youngsters that have a similar profile (Mercken et al., 2010). These results indicate that conformity to behavior can also result as a consequence to fit in a particular group and thus leading to acceptance of certain deviant health behaviors (de Vries et al., 2006; Mercken et al., 2009). This implies that the influence of groups may have bi-directional effects. One the one hand, other persons may influence a person directly. On the other hand, characteristics of a group may prompt a person to conform to behaviors of this group in order to fit in.

Social support refers to the perceived help that a person receives from others. This help can be expressed in various ways, such as comfort, care, listening, and encouragements. Various types of social support can be given to a person (Sarafino, 1994; Taylor et al., 1986; Cohen & Wills, 1985). *Emotional support* encompasses showing concern, caring, and empathy toward the person and gives a person a sense of reassurance, comfort, and being accepted as a person. *Informational support* refers to actions of others that provide the person with information, advice, suggestions, or feedback about how the person is doing and what he might do. *Material* or *instrumental support* entails actual goods and services that other people can provide to a person. Berkman and Syme published in 1979 classical findings linking *social relationship quality* to mortality (Berkman & Syme, 1979).

Subsequently various studies showed that low levels of social support were associated with higher mortality rates due to cardiovascular disease but also to higher cancer rates and infectious diseases. Social support encourages the performance of health-promoting behaviors such as non-smoking, moderate alcohol consumption, adherence to medical regimens, etc. Kamarck et al. demonstrated that the mere presence of a friend was related to lower blood pressure reactivity to an acute psychological stress (Kamarck, Manuck, & Jennings, 1990). This led to the formulation of a stress-buffering hypothesis function of social support (see, e.g., Cohen & Wills, 1985; Uchino, 2006, for an overview). In sum, there are two explanations for the effects of social support on health: the *buffering hypothesis* and the *direct effects hypothesis*. The direct effects hypothesis predicts that social support is beneficial all the time, while the buffering hypothesis predicts that social support is mostly beneficial during stressful times. For health education programs, the results on social support imply that health education programs need to outline the importance of obtaining social support to individuals as well as to organizations (e.g., schools, hospitals, worksites) to optimize chances that social support can be given by others.

Social influences can thus impact health behavior in several ways, and assessing its impact can be realized using different constructs. Some of them, such as social norms, are quite proximal to the behavior. Others, such as social network structures and parenting styles, may also impact behavior but more at a distal level and exert their influence by, for instance, influencing attitudes. Huver and colleagues found, for instance, that parenting influences impacted smoking behavior via influencing the attitudes of their offspring (Huver, Engels, & de Vries, 2006).

Hence, a critical analysis of relevant social structure processes that impact on a particular health problem is crucial when designing health education interventions. This analysis helps to make decisions on how to best build health education programs for a particular problem. Consequently, health education programs can then address the impact of social influences in different ways by, for instance, including lessons (a) about how to resist social pressures, (b) for parents on how to communicate better with their children, (c) about how to provide social support, and (d) including strategies on how to change social norms.

Self-Efficacy Self-efficacy is defined by Bandura as people's beliefs about their capabilities to produce designated levels of performance that exercise influence over events that affect their lives in face of barriers (Bandura, 1977, 1986). In contrast to concepts such as self-confidence or self-esteem that refer to more general characteristics of a person, self-efficacy refers to a person's confidence to be able to perform one particular behavior. Self-efficacy expectations are thus different from self-esteem expectations in the sense that self-efficacy expectations are behavior specific: a person can have high self-efficacy not to smoke, whereas he may have low self-efficacy toward being physically active (de Vries et al., 1988). Self-efficacy expectations thus greatly depend on a particular behavior and the context in which it takes place. Self-efficacy influences all aspects of behavior, including the acquisition of new behaviors (e.g., a sexually active young adult learning how to use a particular contraceptive device), inhibition of existing behaviors (e.g., decreasing or stopping cigarette smoking), and disinhibition of behaviors (e.g., resuming physical activity after a myocardial infarction (Strecher et al., 1986)).

Furthermore, if a person has a high level of self-efficacy concerning a particular behavior or specific task, he or she will approach difficult tasks as challenges to be mastered rather than as threats to be avoided. High self-efficacy contributes to setting challenging goals, strong commitment to goals, and persistence toward reaching goals even if being confronted with temporary failures to attain these goals. People with high levels of self-efficacy attribute failure more rapidly to insufficient effort or deficient knowledge and skills than people with low senses of self-efficacy. Self-efficacy beliefs are cognitions that influence whether a certain health behavior will be planned and executed and how much effort will be expended to realize the behavior.

Self-efficacy is not only behavior specific but also context specific. A person can have a high level of self-efficacy toward being physically active, where he or she may have low levels of self-efficacy toward non-smoking. Yet and additionally, a person may also have different levels of self-efficacy depending on the context of the behavior. A person may have high self-efficacy to refuse from smoking after dinner, but may have low self-efficacy when being offered a cigarette by friends. Yet, this situation may be opposite for another person. Consequently, when aiming at increasing levels of self-efficacy, it is important to identify the specific situations that may put the realization of that behavior for that person at risk. In other words, the highest effects of health education programs toward increasing levels of self-efficacy will be attained when the assessment of the risk factors as well as the health educational feedback occurs as personalized and tailored as possible.

Consequently, within the construct of self-efficacy, different domains of self-efficacy have been identified defining specific types of self-efficacy related to different behavioral phases, such as action and coping self-efficacy and relapse self-efficacy, or to different types of self-efficacy for different challenging situations, such as social self-efficacy (for difficult social situations), skills self-efficacy (for difficult behaviors), or phase-specific self-efficacy (motivational self-efficacy imperative for adopting a behavior and volitional self-efficacy for maintaining a behavior and for coping with barriers) (see, e.g., Schwarzer et al., 2008; Dijkstra & De Vries, 2000; Pinto et al., 2008).

Self-efficacy expectations are influenced by the ability a person has to perform a behavior. Yet, ability is not a fixed attribute of a person, but the result of the interplay of cognitive, social, motivational, and behavioral skills (Bandura, 1993). This is also clearly illustrated by a classical experiment of Collins (1982) described by Bandura (1986) in which she selected children at three levels of mathematical ability – low, medium, and high. She found that at each level of ability, children who had higher levels of self-efficacy toward solving the math problems also solved the problems more quickly. These children also chose to rework more of the problems they failed and did so more accurately than did children of equal ability who were plagued by self-doubts. In sum, people who perform poorly may do so because of a lack of skills and/or because of a lack of self-efficacy. Skills are of course required to be able to perform a behavior, but high levels of self-efficacy to be able to execute the behavior facilitate learning new skills and coping with barriers that may hinder its execution.

The acknowledgment of the importance of self-efficacy led to adoption of specific self-efficacy-enhancing strategies in health education programs. These strategies often aim at increasing self-efficacy via *direct learning* of adequate healthy responses, *vicarious learning* (learning through observation), and *verbal persuasion* by which a person becomes stimulated by others to perform the adequate response. Via these strategies a person becomes aware of specific situations where efficacy may be low and how to react more effectively to these situations. Consequently, self-efficacy-enhancing strategies can be found in many health education programs for both healthy people and specific patient groups (see, e.g., Marks, Allegrante, & Lorig, 2005; Ashford, Edmunds, & French, 2010; Nichols et al., 2009).

Various studies demonstrate the importance of high self-efficacy levels for realizing various different health behaviors (O'Leary, 1985; Schwarzer, 1992), including smoking cessation (de Vries et al., 1995), reducing alcohol consumption (Oei & Burrow, 2000), smoking cessation and condom use (Hendriksen et al., 2007; Schaalma et al., 1993), fruit and vegetable consumption (Brug et al., 1995; Campbell et al., 1999), physical activity (Moritz et al., 2000), and skin cancer prevention (de Vries et al., 2005). Self-efficacy is quite similar to perceived behavior control and one of the two is included in most theories and models (Lippke & Ziegelmann, 2008). One older model, in which self-efficacy is not regarded, is the *theory of reasoned action* described in the following.

Intention and Stages of Change People may have positive or negative motivations to perform a particular behavior. The concept of motivation and motivational stage can be found in various theories. The concept of behavioral intention has become particularly popular since its introduction in Fishbein and Ajzens' *theory of reasoned action* (Fishbein & Ajzen, 1975). Behavioral intention is an indication of an individual's readiness to perform a given behavior. It is assumed to be an immediate antecedent of behavior. Intention scales assess the likelihood of whether people plan to engage in a particular behavior. Intention is considered to be the resultant of other motivational factors such as attitudes, social norms, and self-efficacy.

Some researchers categorize people into stages of readiness to change. Gollwitzer (1990) describes that the Rubicon model, for instance, posits four phases in the performance of behavior, the predisional action phase (characterized by wishing and deliberation), the decision-making phase (making new goal intentions), the preactional phase (characterized by action planning), and the action phase.

A related framework is described in the transtheoretical model of Prochaska and DiClemente. They developed a stage of change model with the following stages: *precontemplation* (people who are not intending to take action in the next 6 months), *contemplation* (people intending to change in the next 6 months but not within a month), *preparation* (intending to change within the next month), *action* (when people have already changed in the past 6 months), and *maintenance* (successfully maintained the change for at least 6 months) (Prochaska & DiClemente, 1983).

Weinstein and colleagues describe different stages: (1) *unaware of the health problem*, (2) *aware of the problem but not personally engaged*, (3) *engaged and deciding what to do*, (4) *planning to act but not yet having acted*, (5) *acting*, (6) *no action needed*, and (7) *maintenance* (Weinstein, 1988; Weinstein & Sandman, 1992). Several other strategies are possible as well. For instance, a Dutch model (de Vries et al., 2003) postulates three basic phases of change: *awareness* (determined by knowledge, cues to action, and risk perceptions), *motivation* (determined by attitudes, social influence beliefs, and self-efficacy), and *action* (determined by self-efficacy, action planning, and skills). Yet, other models have reduced the number of stages. For example, the health action process approach (HAPA) distinguishes three stages (unintentional, intentional, and action stage) without referring to a specific time frame (Schwarzer, Lippke, & Luszczynska, 2011).

Models using intentions as predictor of behavior without further recognition of stages are also referred to as *continuum models* (Weinstein & Sandman, 1992). In contrary, *stage models* imply that variables that are important for the transition from one stage to the next may be less or not important for the transition between other stages. Stage models can be subject to criticism and debate (see, e.g., Brug et al., 2005). For instance, concerning the definition of stages one may argue whether motivated persons should only include those who are willing to change within 1 month and not within 3 months. Furthermore, a person may misclassify his stage: for instance, a person who believes that he is sufficiently active may classify himself in maintenance, but actually may not be sufficiently active. Sutton (2000) questions why one needs to divide participants into stages of change, rather than their scores on the measure of behavioral intention (Sutton, 2000) and concluded that the stage of change algorithm underestimated motivation to quit smoking (Herzog & Blagg, 2007).

Yet, the application of the stage idea has found support as well. Studies have used experimental or longitudinal designs to assess whether social cognitive variables can predict transitions between the stages of change (de Vries et al., 1998; Plotnikoff et al., 2010a; Vries & Mudde, 1998). Authors like Weinstein and colleagues (1998) or De Vries and colleagues (2006) introduced the concept of match-mismatch studies. Match-mismatch experiments involve the development of interventions that are targeted at particular stages of change (for instance, a risk awareness intervention for those not being aware of a risk). The interventions are then matched, meaning that they are given to people in that particular stage of change (e.g., information about the pros of the health behavior for precontemplators), or mismatched meaning the interventions are given to people they were not designed for (e.g., information about action planning to precontemplators).

The hypothesis is that matched interventions should facilitate behavioral change, whereas mismatched interventions should not. In a study with the HAPA model by Lippke, Ziegelmann, and Schwarzer (2004) as theoretical backdrop, this matched-matched design was employed. The planning intervention was effective in terms of behavioral change only in intenders (matched) but not in non-intenders (mismatched; they would rather need a risk awareness intervention) and actors (mismatched they would require a maintenance intervention).

In one study 1540 smokers were randomized to one of the four conditions that provided information about the outcomes of smoking, self-efficacy, outcome beliefs, and self-efficacy or a no information control group. In comparison with the control group, contemplators benefited most from both sorts of information, whereas preparers benefited the most from self-efficacy-enhancing information only (Dijkstra et al., 1998), and results were repeated in another study (Dijkstra, Conijn, & De Vries, 2006). Yet, other studies using an experimental design did not find similar findings (Blissmer & McAuley, 2002; de Vet et al., 2008a; Quinlan & McCaul, 2000). In sum, the few experimental studies that have been conducted showed mixed findings, and much more experimental research is needed to be able to draw firm conclusions, as the studies also differed in how the matched feedback was given.

Practical advantages of a stage or phase approach are also described. For instance, health counselors can more effectively focus their attention when they identify the stage of their client, and health communication materials can be tailored toward the stage of the recipient. A similar conclusion can be drawn for brochures and leaflets. Instead of proving all the information at once, the reader may be guided to start reading segments that are most appropriate for this specific reader. Yet, further research is thus needed to determine whether the segmentation is most appropriate by using a stage of phase approach and how many stages or phases need to be distinguished.

In sum, the idea of stages has led to the development of stage-matched health education materials that sometimes show better results than nonmatched materials (Rakowski et al., 1998; Velicer, Prochaska, & Redding, 2006) although not all evidence is consistent (Aveyard et al., 2009;

de Vet et al., 2008b; Armitage, 2009). Yet, the idea of distinguishing different stages in the motivational process has been found helpful for researchers and in particular for medically trained specialists, that behavioral change cannot be summarized as a dichotomy (disease yes/no), but a complex process in which several steps are needed, each determined by different motivational factors.

Action Planning The significance of planning and execution of specific actions in order to realize a final outcome, such as a desired behavior, is an essential assumption in action planning notions that are derived from goal setting theories. Having a positive intention in itself does not necessarily guarantee actual realization of this behavior. Studies suggest that intention accounts for approximately 20–40% of the variance in behavior and behavioral change (Godin & Kok, 1996; Conner, & Armitage, 1998; Webb & Sheeran, 2006). People often fail to act on their intentions (Godin & Conner, 2008; Orbell & Sheeran, 1998) because the translation of intentions into behavior requires additional self-regulation strategies, strategies that we refer to as action planning (de Vries et al., 2003; Schwarzer, 1992; Bagozzi, 1992; Gollwitzer, 1999; Heckhausen, 1991).

Action planning implies the generation of a sequence of behaviors used to translate an individual's intention into actions aimed at goal achievement (Gollwitzer, 1999; Austin & Vancouver, 1996; Leventhal, Nerenz, & Steele, 1984; Handley et al., 2006; van Osch et al., 2008a, 2008b, 2010; Sniehotta, 2009; MacGregor et al., 2006). Action planning can be described as the process of planning and execution of several specific actions that may help to successfully adopt and maintain a new health behavior. Action planning is regarded as an effective way to overcome the so-called intention–behavior gap for both health and patient education. Effective action planning is more likely to occur when persons are motivated to change (Lippke, Ziegelmann, & Schwarzer, 2004; Gollwitzer, 1999; van Osch et al., 2010; Lippke et al., 2010; Sheeran, Webb, & Gollwitzer, 2005).

Action planning is related to goal setting. Both goal setting and action planning are directed toward realizing a specific goal. Goals can be regarded as internal representations of desired states (Austin & Vancouver, 1996). Goal setting thus refers to an end goal that one wishes to accomplish (Latham & Locke, 2006; Bandura, 1989) and may require considerable action planning (Abraham & Sheeran, 2003). Action plans thus pertain to the subset of actions needed to realize a final goal and can be regarded as setting proximal subgoals. Setting specific proximal goals further directs one's actions and enhances long-term motivation and performance (Stock & Cervone, 1990; Locke & Latham, 2002).

Action planning can entail at least two types of actions: preparatory actions and coping actions. Preparatory plans and actions pertain to the plans and actions that a person needs to undertake to prepare the behavioral change attempt (Bryan, Fisher, & Fisher, 2002; Goebbels et al., 2008; de Vet et al., 2011; Bagozzi & Dholakia, 1999). Coping plans refer to the types of plans and actions needed to maintain a behavioral change attempt and can contribute in a person's pursuit to cope and overcome obstacles and difficulties by anticipating how to address these obstacles and difficult situations (van Osch et al., 2010; Sniehotta et al., 2005; Lippke, Ziegelmann, & Schwarzer, 2005). Action planning may require much self-regulative effort since a person needs to identify which specific plans may be most effective for him or her.

Research by Gollwitzer led to renewed attention for a particular subset of action plans, *implementation intentions*. Implementation intentions are action plans that require little self-regulation, since they are linked to external cues that prompt the desired behavior (Gollwitzer, 1999). Implementation intentions are specific if-then plans that link a situational cue (e.g., a toothbrush) with a particular response (e.g., a health behavior, such as taking a vitamin pill). The idea is that a person acts according to the following schema: if situation Y is encountered, then I will initiate behavior Z in order to reach goal X. The assumption is that the linking of the behavior to a cue will increase the likelihood of an automatic reaction; this automatic reaction requires little self-management as its elicitation is then prompted by this external cue. Although implementation intentions are sometimes referred to as action plans, they thus imply a very specific type of action planning. An important precondition for implementation intentions is that the behavior will be under automatic control via a cue that prompts an individual to act. Not all action plans can be prompted automatically. For instance, planning to use nicotine replacement therapy (NRT) to quit smoking is an example of a preparatory action plan, but is difficult to be prompted automatically. Yet, after having made this action plan, a person can link regular NRT use to a specific cue (e.g., breakfast).

Action planning techniques can be effective for health education in the promotion of various health behaviors, such as physical activity (Milne, Orbell, & Sheeran, 2002; Sniehotta, Scholz, & Schwarzer, 2006; Ziegelmann, Lippke, & Schwarzer, 2006; Kwak et al., 2007), healthy dietary intake (Armitage, 2004; Verplanken & Faes, 1999), medical adherence (van Osch et al., 2010; Liu & Park, 2004; Sheeran & Orbell, 2000), cancer detection practices (Sheeran & Orbell, 2000), and several lifestyles (de Vries et al., 2008a). Implementation intentions and action plans can also lead to significant effects on behavior (Gollwitzer & Sheeran, 2006), although some studies did not find these effects (Jackson et al., 2005; Rutter, Steadman, & Quine, 2006; Skår et al., 2011). Perhaps this is because action planning and implementation intention formation outside the laboratory are realized by self-chosen plans instead of expert chosen plans (Sniehotta, 2009). Adding action plans to mass media campaigns is also possible: for example, the addition of action plans to the *Quit and Win campaign* led to more successful quitting. Van Osch found that addition of a coping planning intervention to the usual information about attitudes and self-efficacy increased conservative 7-month continuous abstinence rates from 10.5% to 13.4%, indicating that, if implemented correctly, coping planning can significantly reduce long-term smoking relapse (van Osch et al., 2010).

Health Behavior Models

As can be noted from the preceding section, many constructs can be identified as important in enhancing a person's motivation to adopt a healthy lifestyle. Research has demonstrated the importance of several motivational constructs of health behavior. These constructs include factors such as knowledge, risk perceptions, attitudes, social influence beliefs, self-efficacy, intention, and action planning. The identification of these factors is subject of research of many scholars. The mapping of these factors and how they operate together can be done in different ways, also depending on the type of health problem studied. Theories and models describe these mechanisms. Therefore, we focus on selected theories used for designing health promotion programs.

With regard to health behavior models, a distinction can be made between models that focus on *understanding behavior* versus models that (also) focus on *changing behavior*. The former type of models outlines the main factors that are related to health behavior, whereas the latter also provides strategies on how to change these factors. Since this distinction is not always clearly made, we will treat these models all as behavior (change) models in this chapter. Moreover, given the fact that many models are available, we need to be concise in giving this overview (see for other overviews other sources, such as Glanz, Rimer, & Viswanath, 2008; Conner & Norman, 2005).

Social Learning Theory Social Learning Theory (SLT) is a generic theory for both understanding and changing behaviors. It is one of the most frequently used and maybe the most influential theory for health education. Bandura outlines that a person's behavior influences personal factors and the social environment but is also influenced by personal factors and the social environment. Bandura (1986) outlines that these three factors (behavior, personal factors, and the social environment) operate interactively as determinants of each other. This interaction is known as reciprocal determinism. Reciprocal refers to the mutual action between these three causal factors. The environmental factors pertain to the factors that are physically external to a person. This factor is also called situation. A person's environment provides the social and physical context in which a person should function, as well as reinforcements or punishments for particular behaviors. Hence, important environmental factors are the level of reinforcement of behaviors by others and the extent to which others serve as a model (by modeling). The personal factors refer to the abilities of a person to learn from behavior through own experiences or observation of other's behavior ("vicarious learning"). The behavioral factor refers to the *capacities* a person has to be able to actually perform a behavior, for instance, specific skills, but also intellectual abilities or social support (Plotnikoff et al., 2008).

Learning can occur via several ways: enactive learning (learning by doing; observational learning, i.e., learning from others; and verbal instruction, i.e., learning via instructions). Social learning theory stresses the importance of learning from other persons. By observing others a person develops an idea of how new behaviors are performed and what the consequences of a particular behavior are. A person needs to have attention for a particular behavior and the model and remember the behavior and the consequences (retention), should be able to reproduce the observation, and should become motivated to perform this behavior him- or herself.

With respect to this motivational process, important constructs are self-efficacy, outcome expectations, and intentions. Self-efficacy beliefs play a pivotal role in a person's motivation to engage in a behavior. Self-efficacy expectations refer to a person's expectation whether he can perform the behavior and were described more extensively above. Bandura states that people are not motivated to act if they have low efficacy expectations. Hence efficacy expectations influence both behavior and the perception of outcome expectations (see also Strecher et al., 1986). Outcome expectations refer to a person's expectations regarding the positive and negative consequences of a particular behavior. Intentions or proximal goals refer to a person's determination to perform certain activities. Intentions are influenced by outcome expectations and self-efficacy expectations. Moreover, when a person has low efficacy beliefs, he/she is more likely to set relatively lower goals than when having high efficacy beliefs.

Social learning theory, or also referred to as *social cognitive theory* when referring to Bandura's elaboration of it, has influenced the development of many health education programs. As indicated earlier, one of its applications concerned the development of programs targeting self-efficacy. Another application of SCT concerned the utilization of modeling techniques (also referred to as peer modeling) to provide examples of healthy models. Additionally, SCT influenced the development of community health promotion programs in several countries (see, e.g., Farquhar et al., 1990; Puska et al., 2005; Perry, Kelder, & Klepp, 1994).

The Health Belief Model The Health Belief Model (HBM) was developed as one of the first social cognitive models in the 1960s in order to explain health behavior (Rosenstock, 1974; Janz & Becker, 1984). The HBM has been revised and expanded several times by adding other factors than those who were initially included in the model. Basic constructs in the HBM that determine health behavior are perceived threat, outcome expectations and barriers, cues to action, and demographical factors. The perceived threat is determined by a person's perception of the seriousness of the disease and his perceived susceptibility to this disease. The expected outcome expectations describe the perception of benefits of a particular action or health behavior and the barriers to taking that action (e.g., costs, danger, side effects). It is believed that the appraisal of threat and the perception of outcomes and barriers are dependent of other factors, such as cues to action (e.g., the perception of others who have a similar disease), but also demographic and psychological factors. At a later stage, the concept of self-efficacy was added to the theory by which the theory became more similar to the theory of reasoned action. The model has been applied to a variety of health behaviors and served as input for the development of several health education programs (see, e.g., Janz & Becker, 1984; King et al., 1994; Johnson et al., 2008; Brewer, Brewer,

& Fazekas, 2007; Vassallo et al., 2009; Skinner et al., 1998; Strecher & Rosenstock, 1997).

Theory of Reasoned Action (TRA) and Theory of Planned Behavior (TPB) TRA and its successor TPB are examples of a generic model which can be used to predict various behaviors over which an individual has (partial) volitional control (Fishbein & Ajzen, 1975; Ajzen & Fishbein, 1980; Fishbein & Ajzen, 2010). The theory states that behavior is predicted by the *behavioral intention*, although realization of the intention may not always be possible because of certain barriers. Intention is determined by the individual's *attitude* and the *perceived subjective norms* from other people. Attitude represents a person's general feeling of (un)favorableness toward a behavior (e.g., smoking is bad). Attitude is determined by (1) the beliefs ("b") about the behavior (e.g., smoking causes cancer) and (2) the corresponding evaluations ("e") of these beliefs (e.g., cancer is bad).

Attitude can be measured directly by asking how a person evaluates a particular behavior. Attitude can also be measured indirectly by measuring the specific beliefs and evaluations (Σ b*e). A person's subjective or social norm is his perception of whether the majority of important people thinks that the person should or should not perform a particular behavior. The subjective norm is determined by several normative beliefs ("nb"), which are perceived expectations of specific reference persons (e.g., my father does not want me to smoke) and by the person's motivation to comply ("mc") with these expectations (e.g., with regard to smoking, I do what my friends want me to do). The subjective norm can be measured directly by asking about the perceived opinion of other people about a behavior (e.g., most persons that are important to me think that I should (not) smoke). The subjective norm can also be assessed indirectly by measuring the combined impact of the normative beliefs with the corresponding motivation to comply: Σ nb*mc.

At a later stage, the concept of *perceived behavioral control* – very much similar to the concept of self-efficacy – was added to the theory by Ajzen (1988). Perceived behavioral control can be measured by asking direct questions about capability to perform a behavior or indirectly via a multiplicative function in which control beliefs are multiplied by frequency of occurrence of these control beliefs (Σ c*f).

The notions of Fishbein and Ajzen have been applied in multiple studies and served as input for many health education programs. Evidence for the importance of the constructs of their models is abundant (see, e.g., Godin & Kok, 1996; Montaño & Kasprzyk, 2008; Armitage & Conner, 2001; Plotnikoff et al., 2010b). Moreover, their constructs have been applied to a wide variety of topics, such as smoking, alcohol consumption, nutrition, physical activity, breastfeeding, sun protection, and health services utilization.

Protection Motivation Theory (PMT) was developed by Rogers (1975, 1983) who was inspired by the work of Lazarus (1966) and Leventhal (1970) who describe adaptive and maladaptive coping processes as a result to health threats. The PMT proposes that the protection motivation depends on four factors: (1) the *severity* of a certain threat (e.g., cancer); (2) a person's perception of his/her *vulnerability*; (3) *response efficacy*, referring to the perceived efficacy of the healthy action; and (4) *self-efficacy. Protection motivation* develops as the result of *threat appraisal* and *coping appraisal*. Threat appraisal occurs as a result of estimations of the severity of a threat and a person's vulnerability. Coping appraisal is how one responds to the situation. The coping appraisal consists of both response efficacy and self-efficacy. Threat appraisal develops as the result of vulnerability estimations of a certain estimation of the chance of contracting a disease (vulnerability) and estimates of the seriousness of a disease (severity). Coping appraisal consists of response efficacy and self-efficacy. Response efficacy is the individual's expectancy that carrying out recommendations can remove the threat. Self-efficacy is the belief in one's ability to execute the recommended courses of action successfully. Protection motivation is a mediating variable whose function is to arouse, sustain, and direct protective health behavior (Boer & Seydel, 1996; Smerecnik et al., 2011).

The protection motivation theory has been used to explain a wide array of health behaviors, such as smoking, alcohol consumption, nutrition, exercise, and health- and safety-related behaviors (see, e.g., Milne et al., 2000; Plotnikoff et al., 2010b; Norman, Boer, & Seydel, 2005; Floyd, Prentice-Dunn, & Rogers, 2000).

The Transtheoretical Model (TTM) Prochaska and colleagues suggest that the process of behavioral change can be divided into several stages (Prochaska & DiClemente, 1983; Prochaska et al., 1994). As described earlier according to the TTM people move from precontemplation, contemplation, preparation to action and then to maintenance or relapse. Movement through the stages involves a cycling and recycling process. Further distinctions within the precontemplation stage have also been proposed for other health behaviors such as smoking (Dijkstra, Bakker, & De Vries, 1997; Norman et al., 2000; Kremers et al., 2001).

The TTM also describes the importance of two other concepts: decisional balance and temptations. *Decisional balance* refers to a person's weighing of the advantages ("the pros") and disadvantages ("the cons") of a particular behavior. Research suggests that for a person who is not motivated to change (and is in precontemplation), the unhealthy behavior can be characterized by scoring high on the pros of the unhealthy behavior and low on the cons of the unhealthy behavior (or to state it differently: scoring low on the pros of the healthy behavior and high on the cons of the healthy behavior).

When a person is motivated to change (e.g., within a month when the person is in preparation), the person is much more convinced of the cons than of the pros of the unhealthy behavior. Moving, for instance, smokers from precontemplation to action thus implies convincing smokers of the advantages of quitting and of the disadvantages of smoking (Hall & Rossi, 2008), while also experiencing higher levels of self-efficacy. This pattern was also found in many different studies such as Dutch research (de Vries et al., 1998; de Vries & Backbier, 1994) and also other research groups (for a meta-analysis, see, for instance, Marshall & Biddle, 2001).

Temptations measure whether persons are tempted to fall back to their unhealthy behavior, and this construct is complemented with the *self-efficacy* scale; both scales refer to a person's level of self-efficacy. Both the self-efficacy and temptation measures have the same structure (Velicer et al., 1990). TTM research concerning smoking cessation often found three factors reflecting the most common types of tempting situations: negative affect or emotional distress, positive social situations, and craving. The temptation/self-efficacy measures are particularly sensitive to the changes that are involved in progress in the later stages and are also good predictors of relapse.

TTM furthermore postulates five cognitive and five behavioral processes that influence a person's motivation to change. The five *cognitive processes* (consciousness raising, social liberation, emotional arousal, self-reevaluation) are used mostly before behavioral actions occur. The five *behavioral processes* (commitment, countering, environmental control, rewards, helping relationships) are most used during the early phases of behavioral change (Prochaska & DiClemente, 1983). Yet, more research is needed to support the existence and importance of the TTM processes.

The TTM has been applied successfully to change and alter a variety of health behaviors, such as smoking, physical activity, alcohol consumption, and oral contraceptives (Adams & White, 2003; Horowitz, 2003; Dempsey, Johnson, & Westhoff, 2011; Noar et al., 2011; Prochaska et al., 2005; Babbin et al., 2011).

The Health Action Process Approach The Health Action Process Approach (HAPA; Schwarzer 2008) suggests a distinction between (a) preintentional motivation processes that lead to a behavioral intention and (b) postintentional volition processes that lead to the actual health behavior. Within the two phases, different patterns of social cognitive predictors may emerge. In the initial motivation phase (a), a person develops an intention to act. This intention is determined by risk perceptions, outcome expectations, and self-efficacy. After forming an intention, the volitional phase (b) is entered. The HAPA proposes five principles including a differentiation of the volitional phase into the preactional "intenders" and individuals already performing the behavior called "actors" (Schwarzer, Lippke, & Luszczynska, 2011).

The adoption and maintenance of a new behavior requires self-regulatory skills and strategies, such as action planning, social support, and recovery self-efficacy. Including planning and self-efficacy as volitional mediators and stages as moderators renders the HAPA into an implicit stage model because it implies the existence of at least a motivational and a volitional phase. Research using the HAPA model often employs path-analytic methods to assess and test these relations for several health behaviors (e.g., Lippke, Ziegelmann, & Schwarzer, 2005; Luszczynska & Schwarzer, 2003; Renner et al., 2008; Schwarzer et al., 2007; Ziegelmann et al., 2007). Not all of the five principles were tested so far (e.g., Lippke & Plotnikoff, in press) and much more research is needed.

The *I-Change model* (de Vries et al., 2003, 2008b) or the integrated model for explaining motivational and behavioral change is integrating ideas of Ajzen's theory of planned behavior (Ajzen, 1991), Bandura's social cognitive theory (Bandura, 1986), Prochaska's transtheoretical model (Prochaska & Velicer, 1997), the health belief model (Abraham & Sheeran, 2005), and goal setting theories (Locke & Latham, 2002). The I-Change model is a phase model rather than a stage model. The term phase is preferred as stages need to refer to qualitatively distinct stages (e.g., the transformation of a caterpillar into a butterfly, (Bandura, 1997)). Furthermore, the distinction between phases is not made on a time criterion but rather on the scores of the individual on several motivational factors. Together these scores are indicators of which phase a person is most likely to be. Three phases in the behavioral change process can be distinguished: (1) awareness, (2) motivation, and (3) action. For each phase particular determinants are specifically relevant.

Awareness of a particular problem in a person is the result of accurate knowledge and risk perceptions of the person about his own behavior. (Not all persons are aware of the level of their own behavior; for instance, many persons overestimate the amount of their physical activity.) Cues in their environment (e.g., a person with cancer) may also prompt a person to become more aware of a particular risk and the need to adopt a particular health behavior. Motivation to change a behavior is regarded to be dependent on a person's attitude (the results of perceived advantages and disadvantages of the behavior), social influence beliefs (norms of others, behavior of others, and support of others), and self-efficacy expectations (the perceived ability to perform a particular health behavior). The ultimate result in level of motivation to adopt a health behavior can be measured by intentions and related concepts such as the stage of change concept. Yet, intentions do not necessarily lead to behavior.

Factors determining action, besides a positive intention, are again self-efficacy, action planning and barriers. With regard to action planning, one can distinguish preparation planning (planning actions required to change), coping planning (planning the actions to cope with barriers and relapse in order to maintain the realized changes), and action enactment: the realization of the intended actions. Barriers are factors that may hinder the realization of the behavior and can be socially, economically, and environmentally determined. For instance, if a person wants to buy fruits, but has very little financial resources, this can be a barrier for realization of the desired behavior.

Finally, the I-Change model postulates that motivational processes are determined by various predisposing factors such as behavioral factors (e.g., lifestyles), psychological factors (e.g., personality), biological factors (e.g., gender, genetic predisposition), social and cultural factors (e.g., the price of cigarettes, policies), and information factors (the quality of messages, channels, and sources used). For instance, studies demonstrated that certain parenting styles and practices (a social factor) led to the development of attitudes in children concerning smoking (Huver et al., 2007; Harakeh et al., 2004) or that personality characteristics influenced the development of attitudes and behavior (Huver et al., 2006; de Bruijn et al., 2007).

The I-Change model has been used to explain and change several health behaviors, such as smoking, nutrition, physical activity, alcohol consumption, sunscreen use, participation in screening programs, breastfeeding, child abuse, oral health complaints, medication use, condom use, and adoption of interventions (see, e.g., de Vries et al., 2005, 2008b; Hoving, Mudde, & de Vries, 2006; Rosseel et al., 2010; Fransen et al., 2009; Dlamini et al., 2009; Segaar et al., 2007a, 2007b; Lotrean et al., 2010).

In sum, many models exist that explain health behavior and providing an overview of all models is impossible. Hence, we have not discussed models that explicitly focus on relapse processes (such as the *relapse prevention model* (Marlatt & George, 1984)) and models that explicitly focus on the importance of intrinsic and extrinsic motives (see, e.g., Hagger et al., 2011). Furthermore, several strategies can be used to change the determinants of behavior, which can be found in recent overviews (see, e.g., Bartholomew et al., 2011; Abraham & Michie, 2008; Webb et al., 2010).

When reading about these models, one other notion is important to consider. After reading the various models that outline how health behavior develops, one may get the impression that every person is carefully deliberating and comparing various behaviors. This may suggest that a person processes information very carefully and systematically when making decisions concerning executing a particular health behavior. However, the reality is more complex and suggests that health behaviors can be the result of such a deliberate process but may also be the result of less elaborate processing. The distinction between systematic and less systematic information processing is outlined in so-called dual process models. *Dual process models* outline that information processing can occur systematically but also peripherally (Fazio, 1990; Petty & Cacioppo, 1986). Well-known examples of dual process models are the *elaboration likelihood model* (ELM) by Petty and Cacioppo (1986) and Chaiken's *heuristic–systematic model of information processing* (Chaiken, Liberman, & Eagly, 1989). The latter describes two modes of processing of information, in which information processing can range from low to high. ELM refers to them as the central and the peripheral route whereas Chaiken refers to them as systematic and heuristic processing of information. In the *systematic mode*, a person processes information quite extensively and systematically and invests much cognitive effort into information processing and processes information quite extensively. In this mode people can spend a large amount of time, effort, and mental energy in systematically building beliefs and decisions. It is also believed that behavioral change is more likely to maintain when this mode is used. In the peripheral route, however, a person does not process the information elaborately, and decisions are based on, for instance, preexisting ideas and the persuasive qualities of the source that is providing the information. Behavior is then much more likely to be the result of direct automatic or unconscious responses to environmental cues (Bargh, 2005).

Habit strength is also one factor that may induce automaticity of environment–behavior processes. Repeated behaviors may be largely determined by habit rather than by reasoned action. When habits are formed, subsequent behavior can then be automatically triggered by specific environmental cues (Aarts et al., 1997; Kremers & Brug, 2008; Kremers et al., 2006).

The *dual mode perception of behavioral change process* implies that behavioral change can occur via both explicit and implicit processes (see, e.g., Epstein, 1994; Wiers et al., 2007; Hofmann, Friese, & Wiers, 2008; Strack, & Deutsch, 2004), chaotic versus cognitive processing (Resnicow & Vaughan, 2006), and automatic versus cognitively mediated environmental influences (see, e.g., Kremers, 2010). The existence of two different systems that influence behavior implies (1) a slow and reflective system which consciously regulates emotions and behavior-related processes and (2) a fast associative impulsive system which is responsible for automatic appraisal of stimuli and immediate behavioral action. There is increasing consensus arising that it may be unlikely that the fast associative impulsive system can be influenced by persuasive techniques.

Concerning the fast associative impulsive system, studies revealed that implicit approach tendencies and attentional biases determine behavior. Recent studies also demonstrated that retraining implicit associations can result in behavioral change (Schoenmakers, Wiers, & Field, 2008; Wiers et al., 2009). In other words, these findings imply that health education techniques for the future need to assess the conditions that determine the effectiveness of motivational reflective techniques on the one hand and implicit associative techniques on the other hand. Such an assessment is needed in order to be better able to best address a particular problem in a specific population and to determine which health education strategy may be more effective, an explicit and motivational strategy, an implicit associative technique, or maybe a combination of both.

Dissemination Theories

The previously outlined concepts and models typically relate to intervention development (i.e., the PRECEDE part of the PRECEDE–PROCEED model, cf. above). A systematically developed and evidence-based intervention, however, does not automatically lead to public health impact. In order to accomplish public health impact, the intervention needs to be disseminated successfully to the target group. In the next section, we describe several theoretical frameworks that describe how evidence-based practices are disseminated and how organizations realize changes such as the adoption of an evidence-based health education program. These theories are useful to understand the process of implementation and to guide the development of interventions to promote implementation.

Diffusion theory as described by Rogers describes that various stages within the process of the diffusion of an innovation can be distinguished (Rogers, 1983, 2003). The diffusion of a health promotion program can thus also be seen as an innovation. In most applications, five stages are proposed: (a) gaining knowledge about the innovation, (b) being persuaded to use the innovation, (c) deciding to try the innovation, (d) deciding to implement the innovation, and (e) confirming the decision, including integrating it into one's routine. When applied, these adoption stages are often referred to as *dissemination*, *adoption* (combining persuasion and decision), *implementation*, and *maintenance* or *sustained use* (Rohrbach et al., 2006).

A second tenet of diffusion theory that has been broadly applied is the concept that innovations have perceived attributes that affect their rates of adoption. These attributes include relative advantage, compatibility, complexity, trialability, and observability. Studies have shown that perceptions of these attributes are associated with adoption of evidence-based prevention programs (e.g., Hallfors & Godette, 2002).

Rogers defines an *innovation* as "an idea, practice or object that is perceived as new by an individual or other unit of adoption" (Rogers, 1983). Consequently, a critical component of an innovation (e.g., a health promotion program) is that the idea is perceived as new. *Diffusion* is defined as "the process by which an innovation is communicated through certain channels over time among the members of a social system" (Rogers, 1983). The *adoption* process differs, resulting in the discrimination of five different adopter categories: *innovators, early adopters, early majority, late majority*, and *laggards* with each group having different characteristics.

Diffusion theory has been useful in guiding research on methods to enhance or accelerate diffusion of prevention programs (Valente, 2002). For example, the theory suggests that multiple intervention strategies will be necessary, tailored to each stage in the diffusion process (e.g., Feifer et al., 2006; Parcel et al., 1989). The theory also suggests which features of a program could be marketed to speed its adoption (Rohrbach et al., 2006).

The model has been applied often to understand and explain why certain innovations occurred, for instance, individuals' or social networks' adoption of innovations (e.g., individuals and families adopting healthy dietary patterns) as well as organizations' adoption of health education programs. For instance, Rahimini used Rogers' diffusion theory to understand how the factors associated with the adoption of a computerized (Rahimi et al., 2009) provider order entry (CPOE) to reduce medication errors and increase safety in care settings and found, for instance, that (perceptions of) compatibility of such a system with existing methods may need to be improved in order to facilitate its adoption. Harting and colleagues (2009) assessed the determinants of guideline adherence for low back pain among physical therapists using Rogers' diffusion theory. They found, for instance, that physical therapists had rather unfavorable opinions about issues related to the dissemination of the guidelines, thus hindering the first phase of adoption. Segaar and colleagues (2007a, 2007b) integrated Rogers' diffusion theory with the I-Change model and found, for instance, that several nurses did not provide self-help guides on smoking cessations to cardiac patients that were smoking, thus hindering the adoption of these guidelines by patients.

Implementation Theories Implementation theories (Grol & Jones, 2000; Fleuren, Wiefferink, & Paulussen, 2004) build on Rogers' (2003) ideas, by putting additional emphasis on the user and the context that this user lives in. In general implementation theories define four broad groups of factors which determine the uptake and continued use of health education and health promotion interventions (Table 17.4).

Table 17.4 Features of implementation theories and what they include

(a)	*Features of the intervention*	Scientific basis (evidence) for the intervention and the source(s) of that evidence. The complexity of the change proposal is directly linked to its feasibility and its likelihood of uptake; presentation needs to be clear, logical, and attractive
(b)	*Features of the user (professionals)*	An understanding of and sensitivity to their knowledge, skills and attitudes, working practices, and personalities
(c)	*Features of the social context/ setting*	Expectations and working routines of professional colleagues and the culture operating within the target network, particularly the opinions of key individuals (opinion leaders)
(d)	*Features of organizational context*	Financial aspects of implementation (demand for resources, financial reimbursement), change in organization that implementation requires, structural aspects such as the availability of staff and equipment to implement the intervention, and legal and regulatory issues which might constrain the adoption of new, innovative practices

Organizational Change Theories Organizational change theories are in line with diffusion theory with respect to the assumption that change occurs in stages (Bartholomew et al., 2001). One example is the stage theory of organizational change, which describes multiple stages that organizations pass through as they accomplish an institution-wide change such as adoption of an innovation (Beyer & Trice, 1978). These stages range from *identifying the problem or need for change*, to *searching for solutions*, to *choosing a course of action and implementing it,* to *institutionalizing the change* so that it becomes part of the routine workings of the organization (Rohrbach et al., 2006).

Other theories suggest specific strategies for cultivating organizational change, such as forming a powerful guiding coalition within the organization, developing one vision and empowering members to act on the vision, planning for short-term wins, evaluating the change efforts, and providing feedback to members about their efforts (Senge, 1990). An important tenet of these theories is that in hierarchical organizations, innovations often require change by different levels of employees (e.g., managers, implementers, etc.) at different stages of the innovation adoption process (Bartholomew et al., 2001).

Health Education Methods and Settings

Various health education methods have been shown to have the potential to change behavior. Yet, health education can only have an impact at the public health level if it reaches the population. Hence, an access point analysis in the planning process is important (de Vries & van Dillen, 2007). Traditionally various settings are used for health education. When describing these settings for health education, we actually refer to channels that are used to reach our target groups. Below we will focus on different settings that address individual behavioral change, settings that have been traditionally used for health education such as schools, worksites, patients, and the general public. Other types of health promotion approaches that aim at communities will be discussed elsewhere in this book.

Schools

Children spend a large proportion of their waking life in schools (Kolbe, 1985). Schools can have a great impact on the health status of young people (WHO, 1985; Healthy people 2000: National health promotion and disease prevention objectives and healthy schools, 1991). Consequently, health education programs have existed in schools for many decades. Moreover, school infrastructure, school policies, curricula, and staff often yield an important potential to positively influence child health. The acknowledgment of school health education also illustrates the recognition that learning health-related attitudes and behavior is important at an early age.

School health education methods aim at the prevention of onset of unhealthy behavior and maintenance of healthy behaviors of individuals as well as stress management. Schools are often used for health education purposes since they are an important gateway to children but sometimes also to reach teachers and parents, which are important mediators between children and health educators. For instance, already in 1935 the *Health Education Section of the American Physical Association* described the school health program as consisting of three facets: (1) school health services, (2) school health education, and (3) healthful school environment. This example shows that an ecological approach, consisting of a health education program and the development of a healthy environment, has a long tradition.

Various methods have been used for developing school health education programs. Initially, many health education programs were based on the knowledge paradigm. After the Second World War, a gradual shift in focus emerged. Since the realization that other factors besides knowledge are also important, the focus of school health education programs shifted. In the 1980s, school health education became better grounded into health behavior theory. Consequently, many programs addressed attitudes, social influence perceptions, and self-efficacy and used a social inoculation approach (McGuire, 1985). Moreover, they taught children assertiveness techniques in order to cope with difficult (social) situations. In this aspect, the pivotal work of Evans and colleagues initiated a vast development of programs targeting social skills and resistance skills development (Evans, 1976). Other programs also addressed more generic lifestyle skills in order to address more factors, such as skills for enhancing self-esteem, learning creative problem-solving, reducing stress and anxiety, and managing anger, communication skills, and relationship-building skills (Botvin et al., 1980). Botvin's *LifeSkills Training* (LST) program has become a very frequently chosen drug abuse prevention program in the United States by elementary schools (Botvin et al., 2004).

Effective school health education programs have been developed for various health domains, such as the prevention of unhealthy habits as, e.g., alcohol, drugs, smoking, pestering, and gambling prevention on the one hand, and the promotion of healthy habits, such as physical activity, good nutrition habits, dental health, and sexual health on the other hand.

Although reviews of school health education program show inconsistent findings, an overall tendency for significant outcomes is often reported for various health behaviors (e.g., Hansen, 1992; Faggiano et al., 2008; Fletcher, Bonell, & Hargreaves, 2008; Evans-Whipp et al., 2004; Knai et al., 2006; Brown & Summerbell, 2009; Kirby, Laris, & Rolleri, 2007; Jurg et al., 2006). The results of various reviews provide a fairly consistent positive picture when short-term effects are concerned, but fail to show long-term effects after longer periods such as 5–10 years. For instance, many studies tried to realize long-term effects with regard to smoking prevention and – or but – were partly successful (Hansen, 1992; Bruvold, 1993; Peterson et al., 2000; Thomas, 2002; Elders, M.J. 1994). Yet, this does not necessarily imply that school health education is ineffective for delaying smoking onset. A pessimistic person could conclude that smoking prevention efforts are not effective at all in the long run. On the other hand, a more buoyant person would argue that it is unrealistically optimistic to expect huge effects from an approach with mostly a limited number of lessons for a problem that is reinforced by a multitude of smoking-promoting factors and that it may be naive to anticipate long-term effects of – for instance – only five lessons, since getting a driving license already requires many more lessons (de Vries et al., 2007). Although recommendations are available concerning a minimum amount of lessons needed (see, e.g., Glynn, 1989), no clear evidence exists concerning the minimal amount of lessons needed. Moreover, intensive school programs may not necessarily result in long-term effects. Lessons learned from the *Hutchinson trial* are that only school-based approaches – albeit very extensive – may not be sufficient in resulting in long-term effects (Peterson et al., 2000). On the other hand, other studies did realize long-term effects, for instance, with regard to smoking prevention (Bruvold, 1993). Hence, research is needed to identify which factors may foster long-term effectiveness, such as embedding them within a larger community perspective (Vartiainen et al., 1986), including addressing parents (e.g., parents do grocery and cook for their children and they are models) and environmental changes such as safe bike paths and sidewalks (Thomas & Perera, 2013).

One problem with school health education is that in many countries school staff may become overwhelmed by the supply of a great variety of school health education programs and time constraints. Low program fidelity has been found to be a serious problem (Dusenbury et al., 2003). Integrative programs addressing multiple risk behaviors may have the potential to overcome the burden on schools and teachers. Several authors have suggested that integrative programs can be efficient if the change processes or effective elements for different health behaviors are similar (de Vries et al., 2008a; Botvin, Eng, & Williams, 1980; Prochaska et al., 2008).

Several studies are also conducted to identify key factors of successful health education. For instance, a systematic review (Peters et al., 2009) identified five indicators of success for effective adolescent health education programs about substance abuse, sexual behavior, and nutrition: (1) grounded in social cognitive theory; (2) addressing social influences, especially social norms; (3) addressing cognitive-behavioral skills; (4) training of facilitators; and (5) using multiple components (e.g., school-wide elements, community involvement). Tentative evidence was found for the effects of (6) parent involvement and (7) a larger number of sessions.

In sum, what we can and should learn from our long history of school-based health education is that short-term effects can be realized. Yet, in the long period of childhood, adolescence, and early adulthood, several cues to act unhealthy will emerge to a child, an adolescent, and a young adult. Hence, school health education may and should serve as an essential ingredient to foster healthy conditions for a child. Yet, school health education is unlikely to be sufficient to guarantee a healthy continuation into adulthood.

Many reviews conclude that targeting social and environmental factors will be required as well. Hence, an integral approach including school, family, and the community as well as the environment may have the most optimal potential to foster healthy lifestyles in children (see, e.g., de Vries et al., 2003; Perry et al., 1996; De Meij et al., 2010), recommendations that are in line with basic principles of health promotion, as, for instance, outlined by Green and Kreuter (2005), Mc Leroy and colleagues (1988), and in Swinburn's Angelo model (Swinburn, Egger, & Raza, 1999).

Worksites

Worksites provide opportunities to reach many adults (e.g., more than 60% of adults in the United States; Nigg et al., 2010), including populations diverse in race, ethnicity, gender, age, occupation, income, and health status. A classic worksite intervention was conducted in 1974 in New York City which focused on screening employees for hypertension. Based on a screening of 180 employees, 94 were identified as hypertensive. Those were provided with a treatment lasting for 1 year which resulted in 81% achieving satisfactory blood pressure (Alderman & Schoenbaum, 1975). Over the past decades, the number of organizations and companies that offer a health promotion program for their employees at the worksite has increased (Aldana et al., 2005; Wilson, Holman, & Hammock, 1996). This is not only due to the fact that adults are spending increasingly larger portions of their waking hours at work but also because poor employee health comes at a cost to employers (Goetzel & Ozminkowski, 2008).

Worksite health education program can focus on primary, secondary, and tertiary prevention. *Primary prevention* efforts are directed at workers that are healthy and are aimed to maintain this level of health and to prevent diseases and disorders. Examples are programs encouraging smoking cessation, alcohol reduction, exercise and fitness, healthy eating, weight management, and stress management. Worksite health promotion can also entail *secondary prevention* aimed for individuals who are already at high risk because of their engagement in certain unhealthy behaviors (e.g., smoking, being sedentary, excessive alcohol consumption, high stress levels) and/or have abnormal biometric values such as high cholesterol, high blood glucose, overweight, and high blood pressure. Sometimes worksite health promotion includes elements of *tertiary prevention* which is also referred to as disease management. Then the programs are directed at workers with certain health problems, such as diabetes, cardiovascular disease, depression, etc. These programs can aim at improving lifestyles and/or optimal compliance recommendations (such as hand hygiene) and with medical treatment (Goetzel & Ozminkowski, 2008).

A review on the effectiveness of workplace health promotion (Harden et al., 1999) suggested that worksite health promotion interventions should include (a) visible and enthusiastic support for, and involvement in, the intervention from top management; (b) involvement of employees at all organizational levels in the planning, implementation, and activities of the intervention; (c) a focus on a definable and modifiable risk factor, which constitutes a priority for the specific worker group; and (d) interventions that should be tailor-made to the characteristics and needs of the recipients.

Various reviews have assessed the potential and effectiveness of worksite health education and health promotion programs (Harden et al., 1999; Ni Mhurchu, Aston, & Jebb, 2010; Groeneveld et al., 2010; Soler et al., 2010). Yet, these overviews report some methodological flaws in the designs used. Furthermore, they also do not demonstrate consistent findings for all interventions and all health behaviors. For instance, Groeneveld et al. found positive effects of workplace lifestyle-focused interventions on body fat, but not on other indicators for cardiovascular disease risk (Groeneveld et al., 2010). The effectiveness of a lifestyle intervention was shown to depend on whether the participants enrolled in the study had an elevated disease risk or not. One suggestion could be that studies aimed at high-risk populations may yield better results, have a larger health impact, and be more cost-effective than those targeting non-risk populations.

One other upcoming type of worksite health promotion programs is one that incorporates *health-risk assessment* or *biometric screening*. Assessments of health risks may be of interest to worksite health promotion planners, because they are easy to administer (computerized versions are available), convey a lot of information quickly, allow for access to a large number of people, provide workforce-wide estimates, and allow the potential for follow-up. A systematic review (Soler et al., 2010) showed strong or sufficient evidence for meaningful effects on the following outcomes: tobacco use, alcohol use, seatbelt nonuse, dietary fat intake, blood pressure, cholesterol, summary health-risk estimates, worker absenteeism, and healthcare service use. So far, there was insufficient evidence, however, to determine effectiveness for intake of fruits and vegetables, body composition, and physical fitness.

In conclusion, health education for worksites – as part of a more generic health promotion program – has the potential to reach many adults. It can reach both healthy workers, workers with elevated levels of risk, and workers who already have a particular disease. Additionally, it can be attractive for the worksite management to invest in worksite health education and promotion, not only to reduce costs (see, e.g., Goetzel & Ozminkowski, 2008) but also to increase the working climate in a company. Last but not least, worksite health education programs have the best potential in demonstrating effects when they are embedded in an ongoing, integrated program of health promotion and disease management that integrates specific components into a coherent, ongoing program (Pelletier, 2009).

HealthCare Settings

Patient education is a term typically used for educating, assisting, and empowering individuals in contexts of hospitals or clinical settings. Historically, educating patients has been considered a key feature of nursing (Henderson, 1966). Nurses, for instance, perceive patient education as an important part of their role today (Kruger, 1991). Patient education thus involves helping patients to become better informed about their condition, to inform them about the medical procedures that they may encounter during their process of treatment and choices they have regarding treatment.

Patient education entails the process by which health professionals and others pass on information to patients that will alter their health behaviors or improve their health status. When providing patient education, it is important to consider several important characteristics of the patient besides their specific disease and condition, such as a patient's literacy level, language skills, cognitive capabilities, social support, and economic situation, since the effects of patient education take place within a multifaceted context (Fox, 2009).

Patient education may imply helping to change a patient to adopt a healthier lifestyle. For instance, smoking cessation after the development of coronary heart disease (CHD) improves a patient's prognosis more than any other treatment (USDHHS, 1990). The hospital setting presents an excellent opportunity for cessation interventions. During hospitalization, cardiac patients are more aware of their personal vulnerability to the dangers of smoking, and their serious illness makes them more motivated to quit and more receptive to interventions. Consequently, the effects of providing patient education to smoking cardiac patients have been tested frequently and with some success. Rigotti and others conclude in their review that offering smoking cessation counseling to all hospitalized smokers is effective as long as supportive contacts continue for more than 1 month after discharge (Rigotti, Munafo, & Stead, 2008).

Another challenge for patient education is to foster *treatment adherence*. Several overviews describe the problem of non-adherent patients (see, e.g., Cramer, 2004; DiMatteo, 2004; Bolman, Arwert, & Vollink, 2011). For instance, daily use of prophylactic asthma medication (PAM, inhaled corticosteroids) is an effective medical treatment in preventing and reducing inflammatory reactions in asthma (Salpeter et al., 2006). Patient adherence to PAM is critical to successful asthma management because not taking the prescribed medication increases the risk of (severe) asthma attacks (Suissa & Ernst, 2001). Yet, often a minority of asthma patients take their PAM as prescribed, which can be caused by several factors that need attention in an intervention, such as breaking old habits, creating positive attitudes, and self-efficacy (Bolman, Arwert, & Vollink, 2011). Several studies have documented the effects of adherence-promoting interventions for patients, showing relatively positive results (McLean et al., 2010; Dean, Walters, & Hall, 2010; Cutrona et al., 2010) on the effectiveness of medication adherence intervention; the majority of all studies (88.9%) showed improved adherence. Studies show that improving patient's adherence can be hindered when they are confronted with comorbidities (e.g., depression, anxiety) and increased pain levels (McLean et al., 2010; Pomp et al., 2010).

When referring to the strategies used by patient education, a mix of strategies can be used for patient education, and several strategies are similar to those used by health education in general. These strategies can thus range from simply the provision of knowledge to counseling strategies, such as health counseling and motivational interviewing, and to more socio-ecological approaches that also address the larger environment of patients (Helmink et al., 2010). Besides the utilization of health education materials (such as brochures, self-help manuals, and more recently the Internet), patient education is often characterized by face-to-face interaction with a health counselor. Two health counseling strategies are often used in patient education: health counseling and motivational interviewing.

Health counseling refers to a strategy by which a health counselor aims to encourage patients to adopt healthy behavior, although such promotion of health behavior is not limited to this strategy. A well-known health counseling strategy for encouraging smoking cessation is the *5A's strategy* that stands for:

1. Ask: Identify and document tobacco use status for every patient at every visit.
2. Advise: Urge every tobacco user to quit in a clear, strong, and personalized manner.
3. Assess: Is the tobacco user willing to make a quit attempt at this time?
4. Assist: Use counseling and pharmacotherapy to help a patient willing to make a quit attempt plan specific strategies for quitting and resisting temptations for relapse.
5. Arrange: Schedule follow-up contacts.

Effects for smoking cessation are documented (Mays et al., 2012).

Motivational interviewing (MI) has also become popular and accepted as a method for patient education. It is a counseling technique, developed by Miller and Rollnick (2002), which is client-centered and based on the TTM. Accordingly, motivational interviewing acknowledges that persons may be in various levels of readiness to change their behavior. A key goal of MI is to assist individuals to work through their ambivalence about behavioral change. It appears to be particularly effective for individuals who are initially not ready to change (Resnicow et al., 2002). The approach attempts to increase the client's awareness of the potential problems caused, consequences experienced, and risks faced and to raise awareness what consequences of certain acts of a person may entail. At the same time, it entails unbiased discussion of the client's ambivalence about change and negative aspects of change. Through such balanced discussion of the client's own thoughts about the advantages and disadvantages of a particular behavior, the client is able to come to a greater awareness of the advantages and feasibility of a particular change.

Through this process, MI aims at mobilizing intrinsic motivation to change behavior. Effects of MI for patient education are, for instance, reported by Kemp et al. (1998) and van Keulen et al. (2011). There is evidence that MI patient-centered approaches to healthcare consultations may have better outcomes than traditional advice giving, especially when lifestyle change is involved (Britt, Hudson, & Blampied, 2004). Yet, MI is – as with most strategies – not a magic bullet, and reviews report mixed findings, most likely due to many variations in its implementation. Although often tempted to act otherwise, health counselors need to avoid a position in which they argue for change while the client argues against it (Hettema, Steele, & Miller, 2005). Yet, this may be a challenge that is not always easy to accomplish.

Adoption of recommendations by the patient requires actions from both the patient and the clinician. In the last decade, a trend can be observed showing that patient education and treatment decisions require indeed input from both patients and clinicians. An increasing emphasis on patient involvement in treatment decisions can be observed (Say & Thomson, 2003). Consequently, the patient-clinician relationship is moving more toward a *partnership* (Charles, Whelan, & Gafni, 1999).

Shared decision-making (SDM) is an approach in which the clinician and patient go through all phases of the decision-making process together and in which they share the preference for treatment and reach an agreement on treatment choice (Charles, Whelan, & Gafni, 1999). SDM involves clinician and patient, but often more since often the involvement of family members in treatment decision-making may be important as well. SDM requires that the patient and the clinician build a consensus about the preferred treatment. Therefore, the clinician needs to explain various treatment possibilities and their potential consequences for the patient. The patient and clinician together discuss and evaluate treatment options and together build a consensus on the treatment to implement. Joosten et al. report that SDM can be beneficial for improvements in patient satisfaction, treatment adherence, quality of life, and well-being. Also it may result in higher patient involvement and perceived control over their treatment. Results suggest that SDM may be particularly suitable for long-term decisions, especially in the context of a chronic illness, and when the intervention contains more than one session (Joosten et al., 2008).

The terms "patient education" and "self-management education" are closely related concepts (Coster & Norman, 2009). Self-management is the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences, and lifestyle changes inherent in living with a long-term disorder (Wilde & Garvin, 2007).

Bodenheimer and colleagues distinguish between patient education, which they suggest provides disease-specific information and technical skills, and self-management education which teaches problem-solving skills which allow patients to take appropriate actions to improve their health (Bodenheimer et al., 2002). They conclude that self-management education "complements, rather than substitutes for, traditional patient education."

Several reviews are available concerning the effectiveness of patient education. Coster and Norman studied several Cochrane Reviews of interventions designed to improve patients' knowledge and skills to manage chronic disease, with particular reference to nursing contribution and practice (Coster & Norman, 2009). Unfortunately, information on the professional delivering of the interventions was often not available, although 77% (23) of the reviews mentioned that nurses were involved in a proportion of studies. They concluded that educational programs resulted in benefits for several types of patients, such as patients suffering from asthma, diabetes mellitus, epilepsy, and mental health problems. However, they also outlined that it is still not clear what the active ingredients of many successful interventions were. This area thus definitely requires more systematic research.

Systematic reviews have shown that patient education intervention may be most effective when they (1) have motivational cognitive-behavioral approaches, (2) help patients practically to manage barriers, (3) improve factors related to healthcare providers and organizations, and (4) apply longer-term counseling strategies with regular reinforcement (McLean et al., 2010). Hence, the effectiveness of patient education is not only dependent on the quality of the health education materials used but also on the quality of the source providing the education. This implies that the behavior of the healthcare provider also plays an important role. Additionally, this conclusion also implies the importance of taking organizational and contextual factors into account. One important contextual factor concerns the level of social support that a patient encounters. DiMatteo found that practical social support had higher effects on adherence than emotional support (DiMatteo, 2004). When patients perceive their family as cohesive (e.g., warmth, closeness, acceptance climate), adherence was much higher than if the family was observed as conflicting. Thus, professionals working with patients should also try to involve the patient's social environment (such as family and friends) and improve the patient's ability to receive social support (Norris, Engelgau, & Narayan, 2001; Norris et al., 2002).

Although health education methods can be effective for patients, their public health impact is limited by lack of broad distribution and availability, implementation failure and/or underuse (Cranney et al., 2001; Glasgow et al., 2003), and reducing the intended health impact of these interventions. Segaar and colleagues investigated why cardiac nurses did or did not use an evidence-based protocol that was based on the 5A's. Ninety-four of 206 nurses did not fully apply the intervention in daily practice; they did not always provide patients with self-help guides, discuss smoking cessation aids, or provide follow-up care. Adherence was most likely if nurses consistently used an intervention card, perceived advantages of the intervention, had other nurses around them who used it, and had been involved in decision-making.

This example shows that effective patient education is not limited to the art of developing effective interventions but also to take into account a larger socio-ecological perspective. The use of effective patient programs may also be facilitated by linking patient education with *electronic patient files*. For instance, Bentz and colleagues found that *electronic health records* (EHRs) may be an effective tool to help clinicians address tobacco use more consistently (Bentz et al., 2007). They observed that during 12 months of follow-up, EHR-documented rates of advising, assessing, and assisting were significantly improved in the intervention clinics compared with the control clinics. A higher case mix index and the presence of a clinic champion were associated with higher rates of referral to a state-level quitline. EHR-generated provider feedback improved documentation of assistance with tobacco cessation.

In sum, patient education is an important area for health education. Significant effects can be found using various strategies. Yet, it is not clear what the active ingredients of many successful interventions are (Coster & Norman, 2009). It is therefore important to identify these ingredients in order to better be able to tailor the education to the needs of both the patient and others involved in the patient education process. Sometimes, this can imply very simple changes. For instance, nearly half of all American adults have difficulty understanding and using healthcare-related terminology and information, and there is a higher rate of hospitalization and emergency services utilization among patients with limited health literacy (Baker et al., 1998). Also, highly educated people may encounter trouble understanding instructions or other healthcare-related information. Hence, this illustrates an overall need for clear patient education strategies for all patients.

The communication challenges are also salient for our aging and growing portion of the population (Fox, 2009) as well as for certain at risk groups where health disparities are increasing, such as those with low levels of education. Additionally, since the process of patient education involves many stakeholders (such as the partner, families, healthcare providers, and hospitals), effective patient education has to acknowledge their needs and expertise as well. Given this, a socio-ecological approach for patient education, as for most if not all health education efforts, is important.

Mass Media Approaches

Mass media health education methods provide tools for providing health education to general and specific audiences. They are important tools in advancing public health goals. Communicating about health through mass media is complex, however, and challenges professionals in diverse disciplines. Yet, using the mass media to improve public health can be a very complex challenge if one does not specify specific objective and target groups (see, e.g., Winett & Wallack, 1996).

During the last decades, the types of mass media methods used for health education and health promotion have changed dramatically. In the late 1980s, mass media were thought of as "broadcast" media and aimed at reaching large segments of people. The old mass media concerns communication by, for instance, television, radio, newspapers, brochures, posters, billboards, etc. (Dictionary, 2010). Yet, the rise of the Internet resulted in the provision of a different type of new mass media communication, that also allows for interactive approaches that have the potential to also reach many people through personal computers, cellphones and smartphones, PDAs, tablets, etc. Health communication messages can now also be disseminated easily and rapidly via Web sites, blogs, discussion boards, RSS feeds, etc. (Abroms & Maibach, 2008). We will discuss this type of health education separately below.

Many examples of studies describing the effects of mass media programs can be found. For instance, mass media campaigns on health services utilization were regarded as effective, which is also concluded in the Cochrane Review by Grilli, Ramsay and Minozzi (2002). Mass media campaigns designed to raise awareness of HIV and AIDS have shown immediate significant but small effects in the promotion of voluntary counseling and testing for HIV (Snyder et al., 2004). Brinn et al. (2010) reviewed existing mass media interventions for preventing smoking in young people. They found seven studies, of which only three proved effective in terms of preventing the uptake of smoking in young people. Furthermore, studies also suggest that large-scale mass media interventions can be highly cost-effective as they target many people at relatively small costs compared to intensive one-to-one or group treatments (Morrison & Bennett, 2008).

The main advantage of both the traditional as the new mass media approaches is that many people can be reached, including through targeting those who are not initially motivated to participate in treatments. Health communication researchers tend to reach similar conclusions concerning the effectiveness of mass media interventions, namely, that they, by themselves or in combination with other programs, can significantly influence the health behaviors of populations, with different effects which are often rather modest. However, effective public health media campaigns have two important qualities: they feature well-designed messages, and those messages are delivered to their intended audience with sufficient reach and frequency to be seen or heard and remembered (Abroms & Maibach, 2008). In sum, mass media methods have the potential to promote public health by agenda setting, changing knowledge, attitudes, social norms, and behavior (Noar & Harrington, 2012). Moreover, they also can be used as powerful tool in broader health promotion strategies.

Internet and eHealth Methods

In general, *eHealth* refers to health services and information delivered or enhanced through the electronic devices, such as TV, telephone, and the Internet (Eysenbach, 2005). eHealth methods may concern any type of usage of health education and care via electronic and digital methods (Della Mea, 2001). Hence, eHealth may include the use of Internet, email, electronic patient systems, etc. In many national healthcare services, extensive eHealth infrastructures and systems are regarded as important for the provision of safe, efficient, high-quality, citizen-centered healthcare.

The advantages of eHealth programs are that they can reach much larger target groups than traditional approaches. With (mobile) telephone and the Internet, the distinction between mass media and individual health education has become less clear. For example, a web-based support network for those with diabetes may distribute material to thousands, may provide opportunities for dyads or small groups to exchange experiences and social support, and may provide information on obtaining individual health education and counseling from one's health provider system.

Another advantage of eHealth programs is that they provide options for *tailoring* intervention material to the needs of the recipients. In an early study, Kreuter and Strecher (1996) compared the effects of tailored HRA feedback with generic (non-tailored) feedback and found that individuals receiving the tailored feedback were 18% more likely to change at least one risk factor (usually cholesterol screening, dietary fat consumption, or physical activity).

People get questions and tasks, and on the basis of their responses a feedback report will be generated (Velicer et al., 1993; Strecher et al., 1994; de Vries & Brug, 1999; Kreuter et al., 2000). Hence, messages are based on the personal data that a person has given concerning his health behavior, the motivational beliefs related to this behavior, and other relevant personal characteristics (e.g., age, gender, disease profile). Most importantly, these characteristics are not only personal demographic characteristics, such as name, gender, and age, but rather motivational characteristics that determine whether a person does or does not adopt a particular health behavior (de Vries & Brug, 1999).

Computer tailoring can generate messages that are adapted to a person's beliefs about the advantages and disadvantages of a health behavior, how to cope with barriers and low self-efficacy, how to increase social support and/or cope with low levels of support, or how to develop specific action plans to translate intentions into actual behavior, all combining information and behavioral change strategies (Kreuter et al., 2000). Computer-tailored methods are more effective than generic health education messages due to the working mechanisms of computer tailoring. Because of the highly *personalized* nature of these messages, they are more likely to attract attention and to be read, appreciated, remembered, and regarded as personally relevant (Dijkstra & de Vries, 1999; Dijkstra, 2005; Ruiter et al., 2006; Hawkins et al., 2008) and thus are more likely to result in cognitive and behavioral effects. In fact, these outcomes provide support for one of the assumptions of the *elaboration likelihood model* (ELM) of Petty and Cacioppo (1986).

The ELM assumes that people may engage in two types of processing of messages, central and peripheral route processing, and suggests that the extent to which individuals are motivated to "elaborate" with regard to a message and engage in central processing is influenced by personal involvement with a message. Tailored messages clearly have the advantage of being personally relevant and thus increase the likelihood of central processing of these messages which will increase the chance for changing behavior.

Effects of computer-tailored messages have been demonstrated by several studies for various behaviors, such as smoking (Dijkstra & de Vries, 2000; Velicer, Prochaska, & Redding, 2006; Te Poel et al., 2009; Etter, 2009; Strecher, 1999; Strecher, Shiffman, & West, 2005; Borland et al., 2003), smoking prevention (Ausems et al., 2004; Dijk & de Vries, 2009), nutrition (Campbell et al., 1999; Brug et al., 1996, 1999; Kroeze, Werkman, & Brug, 2006; Oenema, Brug, & Lechner, 2001), physical activity (Kroeze, Werkman, & Brug, 2006; Smeets, Brug, & de Vries, 2008; de Vries et al., 2008), alcohol (Riper et al., 2008), screening (Strecher et al., 2008), and HIV prevention (Noar et al., 2009). Reviews and meta-analyses support the overall impression of positive outcomes of computer-tailored interventions (see, e.g., Noar et al., 2007). Additionally, eHealth programs offer substantial advantages in cost efficiency. A study by Lewis et al. (2010) compared an intervention delivered in a print format in comparison to be delivered as an Internet-delivered intervention. The Internet-delivered intervention appeared more cost-efficient relative to the print intervention but only if the total number of individuals receiving the intervention exceeded 352 (Lewis et al., 2010).

Internet-based health education has become very popular (Brouwer et al., 2010; Leung, 2008; Tu & Cohen, 2008) and can reach both large groups of recipients. For instance, the general public can receive via various Internet sites information concerning health-related topics. Additionally, Internet-based portals can help people make appointments, view laboratory results, refill medications, and communicate with their physician, pharmacist, or nurse online (Mulvaney et al., 2010; Armstrong & Powell, 2008; Grant et al., 2006).

Another advantage is that many people and especially adolescents spend much of their day using Web sites, social networking platforms, multimedia, and mobile media. Studies indicate positive aspects such as recruitment of teens who may not participate in other health education programs (Ito & Brown, 2010). However, despite these advantages, the actual potential of eHealth programs to attract people and to keep them interested in using eHealth programs can also fail (Eysenbach, 2005). It can be difficult to keep visitors engaged for a substantial time to participate in eHealth program and to become exposed to the most essential elements of a program (Eysenbach, 2005; Martinez, 2008; Tyler-Smith, 2006).

Future research should carefully assess the factors that determine its efficacy or inefficacy. Additionally, not everyone may profit equally from eHealth methods. Some researchers indicate that potential health inequalities may result from the differences in access and abilities to use the Internet and information technology, also referred to as the "digital divide" (Brodie et al., 2000; Wielm, 2004; Wagner et al., 2005). We speak of global digital divide when referring to differences in the Internet and information technology access between countries (Chinn & Fairlie, 2007). Studies suggest that the digital divide may particularly be affecting certain groups, such as the lower educated, the disabled, the elderly, and certain minority groups (Sarkar et al., 2011).

In conclusion, the rise of computer technology and the Internet has started a new type of health education methods that have the potential to reach healthy people and patients and to provide health education in a much more interactive way than traditional health education methods in the past. Yet, one of the disadvantages of Internet-based programs is that people may not remain highly motivated to use these programs. Research is thus needed to assess how to best use the potential of Internet and eHealth methods for health promotion.

Conclusions and Reflection

Health education and health promotion should be theory- and evidence-based. Therefore the knowledge of key predictors of behavioral change and how to address them is important. Key predictors are variables such as self-efficacy, intention/motivation, outcome expectancies, and action planning. Interventions can be tailored on these variables or matched toward the needs of the recipients. Such tailored and matched interventions are more effective than generic, non-individualized programs. New information technologies such as the Internet and mobile devices such as smartphones open avenues for designing interventions highly *personalized* to reach large groups of recipients.

However, in general too high expectations concerning its effects need to be tempered. This is not because health education might be ineffective. Rather, health education dosage is often minimal since programs do not last long. Moreover, health education programs are implemented in a broader context that may promote or impede on the intervention effects. Health education programs are therefore most effective when embedded in a broader health promotion approach that also targets the environment with the aim to make healthier choices easier. It is important to have a theory as backdrop when designing, implementing, and evaluating health education programs. Future research is needed for improving the reach and effectiveness of health education and health promotion programs.

Promoting Early Detection and Screening for Disease

David P. French, Suzanne E. Scott,
and Rachael Powell

Introduction

The outcomes of many diseases, in terms of morbidity and mortality, are much more promising when those diseases are identified and treated at an early stage. For instance, when a woman has ovarian cancer identified and treated at stage 1 (i.e. small and localised), her probability of survival is 92%, compared to only 6% survival when it is identified at stage 4 (i.e. large and metastatic) (Cancer Research UK, 2011). It has been estimated that by encouraging early diagnosis of cancer, potentially 5000–10,000 deaths that occur within 5 years of diagnosis could be avoided every year in the UK alone (Richards, 2009). Similarly, early intervention for depression may prevent impaired psychosocial functioning and reduce the risk of suicide, and prompt treatment of air-borne diseases such as influenza and tuberculosis will prevent further spread within the community. Thus, for many diseases, the timeliness of diagnosis and treatment is important. Early diagnosis of disease may occur before people experience symptoms and feel subjectively ill or may be dependent on the presence of symptoms.

The aim of this chapter is to provide an overview of various approaches that have been used to encourage behaviours that bring about early detection and treatment of disease, including a consideration of the likely efficacy of these approaches in reducing morbidity and mortality. It is therefore concerned with secondary prevention, which has been defined as 'actions taken to identify and treat illness or injury early with the goal of curbing or reversing the problem' (Sarafino, 2004, p. 9). Thus, it does not include primary prevention efforts such as vaccination programmes, nor tertiary prevention to rehabilitate function and reduce complications where a health problem has progressed beyond the early stages. This chapter will consider three broad categories of behaviour that are included in this definition of secondary prevention: (a) increasing screening uptake, (b) self-testing, and (c) seeking medical care in response to symptoms.

Screening is concerned with identification of people at high risk of disease, in a population of ostensibly healthy people, in order to further investigate and diagnose those people, and thereby treat their disease at any early stage. Screening may be considered as the classical example of secondary prevention, in that existing disease has not yet caused overt signs, symptoms

or dysfunction. Self-testing is a comparatively new phenomenon, whereby people attempt to identify the presence and nature of their own disease outside of organised healthcare systems. By contrast, when symptoms are experienced, promptly seeking medical care can result in disease being treated early, with good prognosis. Unfortunately, there is often considerable delay in seeking help from medical professionals in response to symptoms. Despite their common goal of early detection and treatment of disease, literatures on each of these categories of behaviours are fairly distinct: each does not seem to have been informed by insights derived from the other areas. In line with this, we will discuss each of these literatures in turn, before attempting to integrate common lessons from the three areas towards the end of the chapter.

Increasing Screening Uptake

What Is Screening?

The overall aim of screening is to maximise health benefits by identifying people with a diagnosable medical condition that would benefit from treatment. This is done by applying progressively more invasive tests, so that people who are judged by the earlier tests to be at low risk of the condition receive minimal testing, thereby minimising potential harms. By contrast, those who are judged to be at higher risk by the earlier tests then undergo more invasive testing, with the objective of diagnosing and consequently treating the condition. Screening is best conceptualised as a programme that identifies appropriate people to invite, offers screening, carries out screening tests, discusses the results of these tests, carries out diagnostic tests if required, discusses the results of these diagnostic tests and offers advice and treatment. Evaluations of screening should consider the whole programme, including likelihood of benefit from treatment, and not just the characteristics of the screening test.

Screening tests involve assessing or examining people without obvious symptoms to determine whether they are at high risk of having the disease for which they are being assessed. Those people who are identified as being at high risk by initial examinations or assessments, termed screening tests, are then invited to take a diagnostic test. This diagnostic test may then confirm a diagnosis of the disease, leading to treatment. However, many people identified as being at high risk by the screening test have no disease detected by the diagnostic test. These people are considered to be 'false-positives', in that they tested positive by the screening test, but were then found to produce negative test results on the more definitive diagnostic test; people who test positive on both screening and diagnostic tests are considered to be 'true positives'.

A key objective of screening programmes is to maximise the number of true positives, relative to the number of false positives (Morrison, 1998). The main benefits of screening programmes are accrued by people with true-positive results, as they receive early treatment of the disease detected, with the aim of preventing their disease progressing to cause morbidity and mortality. By contrast, the main harms of screening programmes are experienced by both people with true-positive results and those with false-positive results (Gray, 2004). People with positive screening test results undergo diagnostic tests, which may be invasive or painful, and may experience potential distress due to their screening test results, which would not have occurred had they not been screened (Shaw, Abrams, & Marteau, 1999; see also Collins, Lopez & Marteau, 2011). This distress may be at least partly due to uncertainty surrounding the meaning or implications of the screening result (see e.g. French, Maissi, & Marteau, 2004, 2006), although prolonged uncertainty does not necessarily lead to distress (e.g. Eborall, Griffin, et al., 2007). Many people with true-positive results will receive treatment that may be ineffective in preventing their disease progressing and, irrespective of this, may also have potentially severe side effects. They may also experience distress at an earlier time than would be the case if their disease had not been detected early due to screening.

Public Health Versus Informed Choice Agendas

The approach taken in this chapter is mainly concerned with a public health agenda which focuses on the nature and impact of interventions to promote screening to bring about early detection and treatment of disease, to improve prognosis. For example, a screening programme may attempt to detect people who have type 2 diabetes, but have not been diagnosed. The aim would be to alert such people by diagnosing their condition, so that changes in diet and physical activity, or in taking medication, may reduce the harms of this condition. An intervention may therefore focus on extending the reach of the programme, so that more people are diagnosed earlier with diabetes, receive treatment, and thereby public health is improved.

It should be noted, however, that other agendas exist. In particular, antenatal screening programmes tend to place considerable emphasis on informed choice, to ensure that women undergoing such screening understand that termination of pregnancy may be one possible outcome (Dormandy, 2007). This informed choice agenda is increasingly being endorsed for population screening programmes, not just antenatal screening. For example, in the UK the National Screening Committee (2011) trains health professionals with the explicit aim of 'ensuring individuals offered screening within the NHS are fully informed of their choices and receive the best possible care and experience along the screening pathway' (p. 15). For individuals to be considered fully informed they would need to be presented with information including the likelihood, meaning and implications of all possible test results, particularly the absolute probabilities of an individual benefitting or being harmed (Marteau & Kinmonth, 2002). Thus, to be considered informed, people invited to screening should be aware of the likelihood of receiving a negative result or a positive result, that both types of results could be in error (i.e. both 'false-positive' and 'false-negative' results are possible), and what procedures and future decisions might be involved in subsequent diagnostic tests were they to receive a positive test result.

Despite this drive for informed choice, invitations for population screening typically provide information about the prevalence and severity of the disease for which screening is being offered, and rarely provide information about the absolute chances of an individual benefitting or being harmed (Jørgensen & Gøtzsche, 2006). It therefore seems that despite the informed choice agenda many screening programmes explicitly endorse, the materials actually provided are implicitly based around a public health agenda. This may be due to a reluctance to highlight the potential harms of screening for fear of a reduced attendance rate. However, it is not clear that altering the materials used by screening programmes to provide a more balanced view of the likely benefits and harms of screening will have much effect on the attendance to such programmes (O'Connor, Bennett, et al., 2009). For instance, one recent trial found no difference in attendance for diabetes screening between a traditional screening invitation compared with a more balanced 'informed choice' invitation, even amongst more socially deprived groups (Marteau, Mann, et al., 2010).

Screening Programmes

The screening, diagnosis and treatment of people on a large scale is called mass screening or population screening, and is organised into screening programmes, which may be local, regional or national. Currently, throughout Britain there are several screening programmes which are offered to all people within populations defined by age and sex. These include programmes to detect and treat breast, cervical and bowel cancers and abdominal aortic aneurysm (UK National Screening Committee, 2013). In addition, there are antenatal and newborn screening programmes (e.g. to detect Down syndrome and cystic fibrosis), as well as a programme to detect retinopathy in all people with diagnosed diabetes. These programmes are free of charge to people offered them, publicly funded through taxation, and may achieve uptake rates of over 80% of the eligible population (National Screening Committee, 2011). Similar systems apply in many western European countries (e.g. the Netherlands). By contrast, in other countries, notably the USA, there is a charge for screening, usually paid for by health insurance, and access to screening is by self-referral or referral by a health professional (Miles, Cockburn, et al., 2004). Although bodies such as the American Cancer Society publish recommendations concerning screening, these do not constitute a national screening programme in the same sense as in the UK. In many low-income and middle-income countries, screening is even more patchy, and there are arguments that it may not be appropriate where the incidence of many conditions for which screening would be offered is lower than in wealthier countries, and attaining high levels of uptake of screening is challenging (Mittra, 2011).

The present section is concerned with evidence on promoting uptake of screening programmes, whether local, regional or national, rather than increasing informal screening by individual clinicians.

Contributions of Screening to Reduce Morbidity and Mortality

For any increase in screening attendance to translate into reduced population mortality, it is also necessary that screening programmes are effective at reducing mortality in those who attend. Although an evaluation of the effectiveness of screening is beyond the scope of this chapter (see Morrison, 1998), a brief overview of the evidence on this point is required.

Screening can be a controversial area (e.g. McPherson, 2010): although well-conducted screening programmes can prevent deaths, it is not clear that screening always does more good than harm (Gray, Patnick, & Blanks, 2008). An example of a well-conducted screening programme is the UK cervical cancer screening programme, which has been estimated to prevent 1300 deaths in England and Wales per year (Sasieni & Adams, 1999). However, it has also been estimated that about 1000 women would have to undergo cervical cancer screening for 35 years to prevent one death (Raffle, Alden, et al., 2003). It has been further estimated that less than 10% of cancer diagnosed is detected by screening (Hamilton, 2009a). So while this screening programme has saved many lives, it does not seem to have helped the majority of women who develop cancer, and also involves considerable resources.

In contrast to preventing mortality, screening is likely to be responsible for a considerable amount of harm. For instance, it has been estimated that for every death prevented by breast screening programmes, over 200 women will experience distress due to false-positive test results (Gøtzsche & Nielsen, 2011). Further, ten women will receive treatment who would not have been diagnosed without screening, and whose lives would not have been adversely affected, due to the cancer being slow-growing (Gøtzsche & Nielsen, 2011). This is at odds with the usual position in medicine: first, do no harm (Gray, 2004). Breast cancer screening is particularly controversial, at least partly because it has been proposed that the harms and costs associated with screening may outweigh the benefits (see McPherson, 2010). In addition, it has been argued that the likely individual benefit for any person invited for screening is often low, and crucially this information is not adequately communicated to the public (McCartney, 2010; Gøtzsche & Jørgensen, 2011).

Predictors of Screening Uptake

There have been a considerable number of studies which have investigated the correlates of screening attendance. Such correlates of screening attendance tend to be the targets for interventions to promote screening uptake. The pattern of results of these studies is somewhat mixed (Jepson, Clegg, et al., 2000), with many variables positively associated with screening uptake in some studies, and negatively associated in others, as well as not associated in yet further studies. Given the large number of studies, and often mixed results, the current section selectively reviews those variables which have been found to be correlated with screening attendance; the following section reviews the effects of interventions to increase screening uptake.

Demographic Factors and Health Inequalities

There is clear evidence that demographic factors are associated with screening uptake, although the precise pattern varies according to the condition for which a person is being screened and the country in which screening is taking place (Weller & Campbell, 2009; Allaby et al., 2009). For example, a national analysis in Britain showed that white British women were significantly more likely to have attended cervical screening than women from ethnic minorities (Moser, Patnick, & Beral, 2009). By contrast, women who lived in a household with a car and in owner-occupied housing were significantly more likely to have attended breast screening, but attendance was not linked to ethnicity (Moser, Patnick, & Beral, 2009). Generally, ethnic minority groups are less likely to attend screening; this difference remains even after statistically correcting for other sociodemographic variables (Szczepura, Price, & Gumber, 2008). Equally, socially deprived groups, e.g. as defined by education, are less likely to attend screening (Jepson, Clegg, et al., 2000).

Socioeconomic factors appear to be associated with screening uptake more strongly in countries without publicly funded national screening programmes, notably the USA (Breen, Wagener, et al., 2001). In the USA, lack of health insurance has a reliable association with lower uptake of screening (Jepson, Clegg, et al., 2000), even after controlling for other measures of deprivation, including education and income (Breen, Wagener, et al., 2001). Thus, not only is screening uptake higher where there are publicly funded screening programmes (Miles, Cockburn, et al., 2004), but publicly funded programmes appear to promote equality of access (Weller, Patnick, et al., 2009).

Social-Cognitive Predictors

It has been argued that demographic differences in screening uptake can be explained by social cognitive variables such as beliefs and attitudes (e.g. Weller & Campbell, 2009). Irrespective of whether this is true, it is certainly the case that social cognitive variables as assessed by the theory of reasoned action (Fishbein & Ajzen, 1975) and the theory of planned behaviour (Ajzen, 1988) are strongly predictive of attendance at screening programmes (Cooke & French, 2008). Across 33 studies identified in a systematic literature review, attitudes about the importance and benefits of the behaviour had a large association, and subjective norms (beliefs about others' expectations about engaging in the behaviour) and perceived behavioural control (beliefs about one's ability to engage in the behaviour) had medium associations, with intentions to attend screening (Cooke & French, 2008). Intention had a medium association, and perceived behavioural control had a small association, with actual attendance behaviour (Cooke & French, 2008).

The overall pattern of results for predictors of intentions to attend screening and of actual screening behaviour concealed substantial variation in these relationships according to the type of screening test (Cooke & French, 2008). For example, subjective norm was a strong predictor ($r = 0.69$) of intentions to attend prenatal screening, possibly due to the important ethical issues, such as potential termination of pregnancy, which are likely to affect people other than the woman attending screening (Michie, Dormandy, et al., 2004). By contrast, perceived behavioural control was a relatively weak predictor ($r = 0.17$) of intentions to attend prenatal screening, but there were strong associations between perceived behavioural control and intentions to attend screening for colorectal cancer and intentions to attend cervical screening ($r = 0.62$ and $r = 0.58$ respectively). Screening tests for both colorectal cancer and cervical cancer involve unpleasant and/or invasive procedures, which may act as a barrier to many people considering undergoing these tests.

How the Screening Programme Is Organised

There is clear evidence that how screening is organised can impact on screening uptake (Price, Zapka, et al., 2010). Screening programmes with centrally organised recruitment designed to ensure national coverage (as is the case in the UK) have higher rates of uptake than do programmes where recruitment is organised by individual providers or organisations (Weller, Patnick, et al., 2009). As noted above, national screening programmes also appear to promote equality of access and are likely to include more quality assurance measures to reduce harms of screening (Miles, Cockburn, et al., 2004).

Different methods of organising screening also appear to result in different social cognitive factors being associated with attendance. A systematic review showed that there is better prediction of intentions to attend screening within publicly funded programmes than when screening is paid for by the individual or their health insurance (Cooke & French, 2008). By contrast, the prediction of actual screening attendance is poorer where there are publicly funded programmes (Cooke & French, 2008). Thus, decisions about attending screening appear to be more 'reasoned' where it is free, but there is less of a 'gap' between decisions to attend or not to attend and behaviour where payment is required for screening.

Even within national screening programmes, organisational factors can affect uptake. For example, uptake of serum screening for Down syndrome was 73% in hospitals where screening was conducted as part of routine appointment, compared with 56% in hospitals where screening required a separate visit (Dormandy, Hooper, et al., 2002; see also Michie, Dormandy, et al., 2004).

Previous Attendance and Previous Test Results

Previous attendance at earlier waves of screening is a good predictor of attendance at subsequent waves of screening (Jepson, Clegg, et al., 2000). Further, social cognitive theories such as the theory of planned behaviour are much better at predicting attendance at the first wave of screening than at subsequent rounds, where previous attendance becomes the strongest predictor (Rutter, 2000; Drossaert, Boer, & Seydel, 2003). It has been proposed that the receipt of an invitation for subsequent waves of screening elicits a decision regarding screening attendance that has been previously made (Drossaert, Boer, & Seydel, 2003).

It is also clear that there is dropout over time, with higher rates of attendance at earlier waves of screening, compared with later waves (Steele, Kostourou, et al., 2010). One reason for this is that those who receive false-positive screening test results are less likely to attend for subsequent waves of screening. For example, 15% of women who were recalled for further examination after routine mammography did not attend their next routine breast screening appointment, compared with 8% who received a negative screening test result (Brett & Austoker, 2001). Further, amongst women who received a false-positive result, lower rates of reattendance were found for those who received more invasive diagnostic test procedures than for women who received less invasive diagnostic tests (Fitzpatrick, Fleming, et al., 2011). Receiving false-positive or ambiguous screening test results has been found to be associated with dissatisfaction with information provided (e.g. French, Maissi, & Marteau, 2004) and care provided (e.g. Hofvind, Wang, & Thoresen, 2003). Further, dissatisfaction with information provided is associated with anxiety and concern about test results for women who receive ambiguous cervical smear test results, even for those who subsequently received negative test results (French, Maissi, & Marteau, 2006).

Interventions to Promote Screening Uptake

There are several reviews of studies which have investigated the effects of interventions to promote screening uptake on screening attendance. These include a systematic review of all interventions (Jepson, Clegg, et al., 2000), interventions to promote equality of access to screening (Porter, 2008) as well as reviews of screening for cancers generally (Brouwers, De Vito, et al., 2011) and even particular cancers (e.g. Power, Miles, et al., 2009). The current section draws most upon the review of Jepson et al. (2000). Although now somewhat dated, this review is still the most comprehensive available of which we are aware, and used highly rigorous systematic review methodology, including examination of how study quality affected review conclusions. As with the literature on predictors of screening uptake, the results of interventions to promote screening uptake are often inconsistent, and somewhat mixed according to the type of screening programme being considered. Consequently, the following section is selective, and attempts to highlight where the evidence for the effects of interventions to promote uptake is most consistent, and considers likely explanations for these results.

Method of Invitation to Screening

It is generally found that where the usual route to attendance at screening is by physician recommendation, actively inviting people by letter, appointment card or telephone call to attend screening leads to higher attendance rates than usual care (Jepson, Clegg, et al., 2000). Such invitations may be where people are offered fixed appointment times, or where they are invited and asked to make an appointment time. The evidence is good that offering fixed appointment times leads to higher uptake (Jepson, Clegg, et al., 2000). For instance, a study of attendance at health checks in primary care found 70% attendance where invitation letters proposed a fixed appointment time, compared with 37% attendance where letters contained an open invitation to attend (Norman & Conner, 1993). This effect has been successfully replicated in subsequent studies (e.g. Hurley, Huggins, et al., 1994).

These studies highlight that even simple prompts to action may be effective in producing behaviour change. This may be explained by the phenomenon of 'inclined abstainers', which was demonstrated in the context of cervical screening (Orbell & Sheeran, 1998). Most women who intended not to attend for screening were successful in not doing so, but only 43% of women who were willing to attend managed to do so over the coming year. Thus, simple prompts may act as reminders to people who intend to attend screening, but would otherwise not get around to it. There may often be little need to persuade people to attend screening, by attempting to alter beliefs about disease and screening; instead, mere reminders may be sufficient where people are already positively inclined to attend. Further, the greater effectiveness of fixed appointments in achieving higher uptake may be due to this appointment system requiring little effortful decision-making over when to attend for screening.

The method of how people are invited to attend screening is a promising area of intervention, not least because the costs per person are likely to be much less than for other approaches to increasing uptake involving more in-depth contact.

Educational and Counselling Interventions

Another method of increasing uptake that has received considerable research attention is using educational materials to inform people of the potential benefits of screening. Generally, providing people with printed educational materials has been found to be ineffective at increasing attendance (Jepson, Clegg, et al., 2000). However, the results of educational interventions which were delivered during home visits, often to hard-to-reach groups, were more promising although still mixed (Jepson, Clegg, et al., 2000). One of the problems with interpreting studies that provided educational interventions delivered during home visits is that where such interventions are effective at increasing uptake, it is not clear whether the effects are due to the content of the educational intervention itself, or to simple prompts, or to the visits containing more than simple provision of information. The general lack of impact on attendance of 'pure' written educational interventions suggests that providing information is not sufficient to bring about changes in behaviour, although it is possible that these interventions may not change knowledge, due to literacy and numeracy issues in the target population.

There is reasonable evidence that interventions providing counselling produce increases in screening attendance, especially when such interventions are delivered via telephone, although there is heterogeneity (Jepson, Clegg, et al., 2000). In contrast to educational interventions, counselling interventions aim to change cognitions that social cognitive models propose act as barriers or facilitators to attend, rather than simply increasing knowledge (e.g. King, Rimer, et al., 1994). It is notable that in common with the broader literature on social cognitive models (e.g. Hardeman, Johnston, et al., 2000), the numbers of interventions based on social cognitive models lag behind the number of predictive studies using the same models.

Removing Economic Barriers and Health Inequalities

There is very good evidence that removing or reducing financial barriers to screening, e.g. by offering free screening, is effective at increasing screening uptake (Jepson, Clegg, et al., 2000). It should be noted that these results are most applicable in countries which do not provide publicly funded screening (e.g. the USA), and consequently where payment for screening is required from people attending screening or from their health insurance.

There is clear evidence of inequality of screening uptake across demographic groups in countries where there are publicly funded screening programmes as well as countries without such programmes (Allaby, Mulhall, & Lines, 2009). This suggests that these inequalities are not solely due to a lack of money, although transport and parking may still present a barrier. There have been comparatively few studies investigating interventions to reduce inequality in countries with publicly funded programmes (Porter, 2008). However, it appears that interventions which do not require literacy skills, such as face-to-face or telephone education and counselling, show more promise at encouraging people from lower socioeconomic status groups to attend screening than do interventions involving the distribution of letters (Porter, 2008). This finding contrasts with what has been found to be effective at promoting uptake for whole populations, suggesting that different interventions may be required to optimise screening uptake and reduce inequalities of screening uptake.

Interventions Aimed at Health Professionals and Organisational Change

A number of interventions have aimed to increase screening attendance by altering the behaviour of health professionals. For instance, reminding physicians to offer screening by tagging files or providing lists of people who are overdue for screening appears to be generally effective at promoting screening (Jepson, Clegg, et al., 2000). One study showed that computerised reminders to physicians increased the number of women attending cervical screening (from 13.7 to 16.1%), although not as much as when women were sent letters inviting for screening directly, where 25.7% attended (McDowell, Newell, & Rosser, 1989). This again suggests that providing patients with prompts to action is effective at increasing screening, although it is clearly not a complete solution on its own. Further, the effects may well be increased when such prompts are provided by physicians or health professionals.

It has been argued that interventions aimed at organisational change are more effective than interventions directly attempting to alter the behaviour of people to attend screening. One systematic review of interventions found that those interventions introducing organisational change were the most effective at increasing use of cancer screening services (Stone, Morton, et al., 2002). These interventions included setting up separate prevention clinics and designating specific staff as responsible for particular organisational tasks. These findings concerning the importance of organisational factors in producing high levels of screening uptake are supported by the observation that regions of France with organised programmes of colorectal screening have much higher screening uptake than do regions without such programmes (Eisinger, Cals, et al., 2008).

Future Directions in Developing Interventions

The section above has considered the effects of interventions delivered separately. However, it has been noted that multifactorial interventions employing more than one of these intervention approaches are most likely to be effective in promoting screening uptake (Jepson, Clegg, et al., 2000; Porter, 2008).

It is also essential when interpreting the literature on the effectiveness of interventions to promote screening uptake to bear in mind that the most consistent finding is the heterogeneity of the findings between studies. For example, a review of screening for breast, cervical and colorectal cancers found variation in apparent intervention effectiveness between the three cancers; it was not clear if this was due to genuine differences in effectiveness, or differences in the quality of evidence for the three cancers (Brouwers, De Vito, et al., 2011). The brief review above has attempted to identify the common results between studies. However, there are many conditions that can be screened for, with a variety of ways of organising programmes to carry out screening, with diverse and usually heterogeneous populations and varying and changing healthcare contexts. Consequently, it is not reasonable to expect that strategies that are effective for one screening programme will be effective in another programme for a different condition, in a different population, that is organised differently, and in a different healthcare system. In sum, although looking for commonalities of results across studies is a worthwhile endeavour, the bald fact of very high levels of heterogeneity of findings between studies makes it essential to consider how context moderates the effects of intervention.

Conclusion

In sum, there are a number of strategies for which there is good evidence that they are effective at increasing screening uptake. Further, increasing screening uptake to well-designed screening programmes results in fewer deaths in the people being screened. However, the likelihood of any one person benefitting is low, and less likely than experiencing a false-positive result or unnecessary treatment. Although a number of intervention strategies can improve screening uptake, there is increasing concern about merely increasing screening uptake, in line with a public health agenda, rather than promoting informed choices about screening. It is possible that when people make informed choices about screening, they will decide not to attend.

Self-Testing

Introduction

A range of devices are now commercially available with which members of the public can test themselves for illnesses without a doctor's recommendation and no or minimal contact with healthcare professionals. Ryan et al. (2006) identified 104 self-test kits available for purchase on the Internet to diagnose or screen for 24 health conditions without involving a health professional. Recent advances in genetics have also led to companies offering testing of genomes to detect individuals' hypothetical risks of a range of illnesses, from heart disease to melanoma.

There has been some debate about whether the development of self-test kits as a form of secondary prevention is a positive advance. On the one hand, self-testing could encourage people to test and identify illnesses for which they might not otherwise be tested, facilitating their access to healthcare in the event of positive results. On the other hand, questions have been raised as to whether receiving positive results in the absence of professional support would cause anxiety, and whether people would carry out and interpret tests accurately (Prasad, Wright, et al., 2008). It is particularly important that users are given adequate information to evaluate the accuracy of tests, including the likelihood of false-positive or false-negative results.

Important questions for secondary prevention are whether people find self-testing an acceptable and attractive method to screen or test for illness, what the impact of self-testing is on people and what factors may encourage or discourage people from using self-testing. If self-testing is acceptable, with minimal negative impact on users, then encouraging self-testing could be a useful strategy for screening programmes. Identifying factors predictive of self-test use would allow the effectiveness of such programmes to be maximised. On the other hand, if self-testing is acceptable only to a small proportion of the population and tends to cause unnecessary anxiety, then not only may it be of limited value to screening programmes but questions would be raised about the ethics of marketing such kits to the public.

Self-tests have been categorised into four groups (Ronda, Portegijs, et al., 2009): (1) tests where people conduct the test and obtain results themselves, with no outside support, which could be seen as true home-testing; (2) tests where people take their own sample but send this to a laboratory which returns results, for example, by Internet or post, which will be referred to here as self-sampling; (3) tests where people go to a laboratory for the sample to be taken with results returned by Internet or post; (4) tests available in public places such as supermarkets where a trained person takes a sample and delivers the results. It is tests within the first two of these categories which are addressed in this chapter (home-testing and self-sampling).

The use of self-test kits for sexually transmitted infections (STIs) is of particular interest for secondary prevention because these are illnesses where diagnosis is essential to allow people to access treatment and to limit transmission of the infection. Importantly, they are also highly stigmatised illnesses, so people may be deterred from accessing testing where contact with health professionals is required.

Three STIs that have received particular attention as potential targets for self-testing interventions to improve diagnosis and treatment are chlamydia, human immunodeficiency virus (HIV) and human papillomavirus (HPV). Issues surrounding acceptability, impact and determinants of self-testing vary between these three disease contexts. Self-testing in the context of these three diseases in turn is discussed to highlight the range of issues that have arisen in this emerging field.

Chlamydia

Genital chlamydia (caused by *Chlamydia trachomatis*) is the most commonly diagnosed STI in the UK but can be effectively treated with antibiotics (Cole, 2008; Horner, 2008). Chlamydia may be asymptomatic but, if untreated in women, can cause pelvic inflammatory disease, infertility, ectopic pregnancy or chronic pelvic pain (Horner, 2008). It has been estimated that for chlamydia transmission to fall, testing rates need to be maintained at above 35% (Hall, 2008); in 2009/2010, the testing rate in England under the National Chlamydia Screening Programme had reached just 22.1% (National Chlamydia Screening Programme, 2011).

Self-sampling kits for chlamydia are widely available to members of the public on the Internet and for purchase from pharmacies, allowing people who might be too embarrassed to go to a clinic to test and receive results without direct contact with a health professional. While many people who seek these tests are likely to do so diagnostically, and some online companies also provide treatment following a positive result, this technology has also been employed as a screening test by the National Chlamydia Screening Programme in England since 2003 (National Chlamydia Screening Programme, 2007). The programme has used strategies including distributing free self-sampling kits from general practitioner surgeries, pharmacies and non-medical settings such as university campuses to encourage 16–25-year-olds to test for chlamydia.

The kits provided by the National Chlamydia Screening Programme, and many commercial kits available to the public, require people to send urine samples or vulvovaginal swabs to a laboratory, and later being contacted with the result, for example, by text messaging. These are nucleic acid amplification tests (NAATs) and are currently considered the 'gold standard' measure because of their high sensitivity (extent to which the test identifies people who are infected as having the disease) and specificity (extent to which the test identifies people who are not infected as being disease-free) (Skidmore, Randall, & Mallinson, 2007). 'Point-of-care' tests have also been developed and can be accessed on the Internet, where test results can quickly be discovered without the need for posting samples away. However, there is not yet evidence of such tests meeting the standards of NAATs (Hislop, Quayyum, et al., 2010). In a systematic review, Hislop et al. (2010) found that while the point-of-care tests evaluated usually had good specificity, their sensitivity was generally lower than that of tests using NAATs, meaning that some people had infections that were not detected with the point-of-care tests and would have received false-negative results if they were tested with the point-of-care test alone. A false-negative result is particularly dangerous as the self-tester will not receive needed treatment and may infect other people. If members of the public are using these point-of-care tests it is vital that they are provided with good information about the risk of false-negative or false-positive results. In addition, in the studies reviewed, although participants may have self-sampled, the tests were professionally run, so the accuracy data does not take into account the risk of errors made by members of the public in conducting the test. It is crucial that the kits available to the public are accurate and reliable with sufficient information for people to both carry out the tests and understand the meanings of test results if self-testing is to form part of public health strategies.

Predictors of chlamydia screening behaviour in general (rather than screening specifically by self-testing) have been identified. Factors predictive of undergoing screening or of finding screening to be acceptable include perceiving chlamydia to be a serious condition (Chacko, Wiemann, et al., 2006; Pavlin, Gunn, et al., 2006), perceiving chlamydia to be common (Pavlin, Gunn, et al., 2006), having a new sexual partner (Pavlin, Gunn, et al., 2006) and wanting reassurance (Langille, Proudfoot, et al., 2008). Conversely, perceived barriers to screening include low perceived risk (Langille, Proudfoot, et al., 2008; Rose, Smith, & Lawton, 2008), being asymptomatic (Langille, Proudfoot, et al., 2008), fear, stigma and lack of knowledge (Rose, Smith, & Lawton, 2008).

There has been little research addressing self-testing for chlamydia outside of clinical settings. In these contexts, people take samples and receive test results without support from a healthcare professional but people who might not otherwise test may be more confident to do so. In randomised controlled trials, response rates to being posted home sampling kits were significantly higher than response rates to invitations to attend a medical clinic for testing (Cook, Ostergaard, et al., 2007; Østergaard, Andersen, et al., 1998; Xu, Stoner, et al., 2011). This suggests that, for this STI, a significant number of people prefer the privacy afforded by self-sampling to a face-to-face meeting.

One study examined the practice of inviting people aged 16–39 years to test for chlamydia using postal self-sampling kits (Low, McCarthy, et al., 2007). Invitations to take part were received by 14,382 people; 4731 people participated (39.5% women and 29.5% men). This level of uptake suggests that the process was considered to be reasonably acceptable given that, particularly within the wide age range, there were many people who were unlikely to consider themselves to be at risk. Qualitative interviews with a subsample of people invited to participate suggested that receiving the kit was acceptable to most. The privacy and convenience of the test were welcomed but the test method could cause concern; some worried that a urine sample might leak in the post and some (women) were put off by having to give a vulvovaginal swab. These findings are consistent with those of Ford et al. (2004): 120 black, Latino and white young adults aged 18–25 years were interviewed to elicit perceived advantages and disadvantages to using self-test urine STI kits. Privacy and convenience were seen as advantages, as were lower costs as it may be possible to avoid visiting a doctor. Perceived disadvantages included concerns about test accuracy and the potential for people with positive results to not receive treatment in the absence of immediate professional support.

There is a shortage of research incorporating psychological theory into the prediction of testing behaviour for chlamydia. Interviews with students about self-testing for chlamydia suggested that response efficacy (whether or not a test would give an accurate result) and self-efficacy (ability to correctly conduct the test) (protection motivation theory; Rogers, 1975, 1983) and subjective norm (the theory of planned behaviour; Ajzen, 1991) could be particularly relevant constructs in understanding the use of self-testing for chlamydia (Powell, Pattison & Marriott, 2016; see Powell, Pattison & Francis, 2016). The generalisability of these findings was tested in an online survey of individuals who were searching for, or reading about, chlamydia testing online (Powell, Pattison & Francis, 2016). Intention to self-test for chlamydia was predicted by perceptions of vulnerability and self-efficacy, with an almost significant effect for response efficacy ($p = 0.053$), supporting the use of protection motivation theory in this context. Further research is needed to examine factors that predict not only intention to test but also the actual testing behaviour carried out.

Low et al. (2007) also assessed the psychological impact of self-testing for chlamydia (Campbell, Mills, et al., 2006; Low, McCarthy, et al., 2007). Participants completed questionnaires at three time points: 1 month before kits were sent, when kits were received and after receiving a negative result. Screening did not seem to increase anxiety. A sample of participants with positive and negative test results were interviewed (Low, McCarthy, et al., 2007; Mills, Daker-White, et al., 2006). Some participants reported feeling anxious while waiting for test results and some were concerned about test accuracy, but severe anxiety was only experienced on receiving positive test results. Positive results were delivered by a nurse; people who learn of positive chlamydia status without such support may experience greater anxiety. Qualitative interviews with university students, some of whom had self-tested for chlamydia, suggested that a positive self-test result would lead to anxiety in the absence of professional support. Nevertheless, all 18 participants indicated that they would seek professional health advice under these circumstances (Powell, Pattison & Marriott, 2016). An online survey indicated that, of eight participants who reported receiving positive results after self-testing, all reported seeking treatment or help within a week (Powell, Pattison & Francis, 2016).

There is a need for further research to be conducted with people who choose to self-test for chlamydia outside of clinical settings to determine whether a positive result consistently leads to help-seeking. This is methodologically challenging when a key reason people would choose to self-test is privacy. Further research is needed to identify the factors predictive of self-test use so that programmes such as England's National Chlamydia Screening Programme can effectively devise interventions to increase uptake.

Human Immunodeficiency Virus

In the UK, 107,810 people had been diagnosed with human immunodeficiency virus (HIV) in 2009, including 5965 new cases within that year (Office for National Statistics, 2010). In the USA, at least 50,000 people are being detected with HIV each year, even though the availability of highly active antiretroviral therapy might have been expected to reduce transmission (see Moore, 2011). It is estimated that 21% of people with HIV infections in the USA are undiagnosed (Moore, 2011). Such individuals do not receive treatment and may unknowingly transmit the infection to others (Campbell & Klein, 2006). Increasing awareness of HIV status is therefore vital if HIV incidence is to be reduced.

The use of self-test kits for HIV could be one tool through which diagnosis rates could be increased, as some studies have suggested is the case for chlamydia. Self-sampling kits have been publicly available for some years, with the USA's Food and Drug Administration (FDA) granting approval to the first HIV self-sampling kit in 1996 (Nightingale, 1996). For this kit, an individual would send a blood sample to a laboratory for anonymous testing, receiving the result by telephoning the results centre with an identification number. In the UK, saliva self-sampling kits are available; again, the sample is sent to a laboratory and the results are received by telephone. With such self-sampling kits, professional support is available to individuals when they telephone for their results. Indeed, receiving results from a trained counsellor was a requirement of the FDA in granting approval (Food and Drug Administration, 1995).

Point-of-care tests have been developed for HIV and kits have been devised for home-test use, that is, where individuals not only take their own samples but also test those samples and gain results without professional support. However, home-testing for HIV infection has generated not only controversy and debate but also legislation governing its use; in the UK, it is illegal to sell point-of-care kits to the public ("The HIV Testing Kits and Services Regulations 1992" 1992 No. 460). With HIV being a particularly serious (and stigmatised) condition, concerns regarding testing errors and risks associated with absence of professional support seem more salient for HIV than with chlamydia self-testing.

An important specific concern for HIV testing is people testing within the 'window period' (FDA, 2005, 2006; Skidmore, Randall, & Mallinson, 2007). HIV tests detect antibodies to HIV; while these antibodies usually develop in two to eight weeks, it can take up to six months before they are detectable (FDA Consumer Health Information, 2008). It is therefore possible that people may test too soon after risky sexual behaviour for an infection to be detected, receive a false-negative result, and thus falsely conclude that they have no further need for concern. Nevertheless, not only may enabling people to use a wider range of tests increase accessibility to tests, but home tests can already be obtained over the Internet despite legislative restrictions.

The UK Government Response to the House of Lords Report of Session 2010–12 (2011) supported the recommendation that an alternative to the ban imposed in 1992 be developed such that home-test kits can be licenced where kits are of high quality and with appropriate advice being made available to individuals who use the kits. At the time of writing, the 1992 ban still stands in the UK, but in the USA, the FDA has recently for the first time approved an HIV home test (FDA, 2012).

One of the key arguments made by advocates of increasing self-testing availability is that by increasing access to testing they will allow people to be diagnosed with HIV who might not otherwise be tested. McQuitty, McFarland, Kellogg, White and Katz (1999) examined records of HIV antibody tests in San Francisco from August 1996 to December 1997. They found that the risk profile of people who tested at publicly funded sites was higher than those who self-sampled, that is, where people take their own sample but send this to a laboratory which returns results. However, a higher proportion of those who self-sampled had not tested in the past than those who tested at publicly funded sites (33.1% as opposed to 17.9%). Thus, while this study suggested that self-sampling had not made a large impact on populations with high-risk profiles, the procedure may have encouraged some people to test who would not otherwise have done so. Colfax et al. (2002) looked at reasons reported for not self-testing amongst 939 US adults who had heard of self-sampling kits but who had not used them. The most common reason for not testing was concern about the accuracy (56%). Other reasons included the lack of face-to-face counselling (47%), cost (34%) and perceived difficulty of use (30%). Although there is a lack of research directly applying theory to self-testing for HIV, the findings by Colfax and colleagues suggest that protection motivation theory (Rogers, 1975, 1983) may be relevant in this context, with concerns about accuracy (response efficacy) and perceived difficulty (self-efficacy) identified as barriers to testing.

Human Papillomavirus

Human papillomavirus (HPV) is a large group of viruses of which 30–40 types can infect the genital tract (Stanley, 2010). For majority of the people infected with HPV, up to 91% clear the infection without intervention within 2 years (see CDC, 2007). However, some HPVs cause genital warts, with which it is estimated that nearly one million people are diagnosed each year in the USA (Monk & Tewari, 2007). Other, 'high-risk' types of HPV are associated with cancers of the cervix (see Stanley, 2010). Unlike chlamydia and HIV, self-testing for HPV has received attention not as a method of reducing HPV itself, but because of its role in cervical cancer development.

Many countries in the developed world have effective cervical cancer screening programmes using Papanicolaou (Pap) smears, but allowing people to self-sample for HPV has the potential to increase access to screening for people who would not attend the clinic for a Pap smear. Findings suggest that screening for cervical cancer by HPV self-sampling may be less sensitive and specific than HPV screening by professional collection, but at least as sensitive as screening by Pap smears (if less specific) (De Alba, Anton-Culver, et al., 2008; Szarewski, Cadman, et al., 2007; Wright, Denny, et al., 2000).

While it may be unwise to market HPV self-sampling kits as diagnostic tests for cervical cancer, as a screening test they appear to be a valid alternative to Pap smears, especially in populations where women are reluctant to attend clinics for cervical screening.

A recent UK study randomised women who had not responded to invitations for cervical screening to either receiving a further invitation to attend for screening or to receiving a posted self-sampling kit (Szarewski, Cadman, et al., 2011). Significantly more women responded and screened in the self-sampling group than in the group receiving the invitation for screening (10.2 versus 4.5%). Two studies conducted in the Netherlands also found more positive responses in women invited to self-sample than those invited to attend a clinic for screening (Bais, van Kemenade, et al., 2007; Gök, Heideman, et al., 2010). These findings suggest that offering self-sampling to women who are reluctant to attend screening can increase screening uptake, although the large majority of women in this population still did not respond.

A systematic review examined 20 studies addressing acceptance, preferences and attitudes towards self-sampling for HPV (Huynh, Howard, & Lytwyn, 2010). Of the eight studies that addressed acceptability, self-sampling was considered acceptable by participants in seven. Thirteen studies considered preferences for test methods in women who had experienced both self-sampling and clinician-sampling; eight studies found women to prefer self-sampling. However, the authors note the important limitation that most studies only assessed the opinions of women who did self-sample. The one study that looked at responses from women who declined self-sampling found that women who declined were more likely to have concerns about self-sampling than those who did self-sample. Thus, while the studies, overall, suggest that many women find self-sampling acceptable for HPV testing, there is a high risk of bias in the data set.

Conclusions

There is clear potential for self-testing to increase the diagnosis rates of illnesses such as chlamydia, HIV and cervical cancer, with evidence suggesting self-testing may bring some people to test who would not otherwise do so. The studies that demonstrated higher levels of uptake where self-tests were offered suggest that this technology is acceptable, and indeed preferable to going to a clinic, for at least a proportion of the population. However, it is uncertain whether receiving positive results without the support of a healthcare professional would have a larger negative impact on people than if they received the results in a more formal setting. A particularly important group of people to study is those who have self-tested and received a positive result but these people are difficult to access, possibly because of the stigma associated with STIs, and those who test by self-testing may place a particularly high priority on privacy. It may be that more anonymous methods of recruitment, such as use of the Internet, could facilitate the participation of such individuals.

Test accuracy is a concern noted by both study participants and healthcare professionals. A false-positive result for an STI is likely to cause unnecessary distress, but a false-negative result is particularly dangerous, potentially resulting in people failing to receive treatment and unknowingly transmitting the infection to others. It is therefore concerning that some tests which may be available to the public have lower than optimal sensitivity. The technology for self-testing for a whole range of illnesses is developing rapidly and problems of test accuracy may reduce as a result. Nevertheless, it is vital that any publicly available test contains easily understandable information regarding test accuracy, in particular the risk of false-negative and false-positive results for that particular test.

The accumulating evidence suggests that there is a proportion of the population who would self-test as a preference to attending a clinic to be tested for an STI. There is therefore scope for self-testing to be exploited to a greater extent by public health bodies as part of secondary prevention strategies. It seems likely that different approaches will suit different people—for some, the desire for privacy may be of primary importance, making self-testing technologies more appealing. For others, knowing tests to be of high quality and the presence of professional support may be of higher value and testing at a clinic more appealing.

For chlamydia, health authorities in some countries already encourage people to self-test as part of screening programmes; in contrast, self-testing for HIV is legally restrained in countries, including the UK and USA. In order to support any such programmes, it is important to understand factors associated with self-test use, and to identify variables that could effectively be targeted with behavioural interventions. Evidence suggests that people welcome the privacy and convenience of self-test kits while concerns include test accuracy, perceived difficulty of testing and the lack of professional support on receipt of positive results. Remarkably little research has directly applied theoretical models to self-testing behaviour, but research has identified some factors (such as perceived test accuracy and difficulty of testing) which are highly relevant to psychological models such as protection motivation theory (as response efficacy and self-efficacy). An important avenue for future research is to directly incorporate theoretical models into research more to maximise the effectiveness of any interventions that are developed.

Seeking Medical Care in Response to Symptoms

Introduction

Despite the existence of screening programmes and the advent of self-testing, the majority of illnesses are diagnosed via people becoming aware of symptoms and subsequently seeking help from a healthcare professional. For example, Hamilton (2009a) estimated that in the UK over 90% of patients with colorectal, breast or cervical cancer enter the pathway to diagnosis via symptomatic presentation to healthcare professionals.

This section focuses on the processes that occur following the detection of symptoms and, in particular, symptom appraisal and the decision to seek healthcare. Throughout this section, the term 'symptom' is used to refer to any bodily changes or somatic information deemed to be abnormal (i.e. not the result of the environment or fluctuations of normal bodily processes) regardless of whether or not it can be observed by others, the meaning assigned to the bodily change or whether it turns out to be an indicator of disease. These bodily changes include both sensations (e.g. nausea, pain, thirst and fatigue) and visible alterations (e.g. rash, blushing, alteration of a mole). The detection of symptoms does not automatically mean a person will seek healthcare. In fact, upon noticing symptoms the majority of individuals will wait, do nothing or self-medicate (Patterson, Douglas, et al., 1992). This is usually an adaptive and beneficial response, as the majority of symptoms are indicative of minor illness or injury, or the result of fluctuations of normal bodily processes (e.g. indigestion after eating rich food). As such, most symptoms resolve naturally or with minimal intervention. The response of 'self-care' is also beneficial to the healthcare system: services would be overloaded should consultations occur for every symptom that arises. Stoller et al. (1994) found that the majority of respondents believed that their symptoms can be managed outside of the healthcare system (with the exception of certain symptoms such as chest pain and dizziness). Healthcare professionals therefore only encounter very few of the symptoms that occur. This phenomenon has been referred to as the 'symptom iceberg' (Hannay, 1979). A problem occurs when symptoms are due to an underlying pathology in need of medical treatment yet individuals continue to self-manage the symptoms rather than seek medical attention.

Understanding Help-Seeking Behaviour

Counter to what one might expect, the quantity and severity of symptoms are not strongly associated with the likelihood or timing of help-seeking behaviour. There does not appear to be a threshold of symptom severity that, once exceeded, will lead an individual to seek healthcare (Petrie & Weinman, 2003). Furthermore, some people will readily consult their doctor with what a healthcare professional would consider to be minor complaints. Different individuals with similar symptoms will also react in different ways. Yet this does not necessarily mean that people have a stable or dispositional pattern of help-seeking behaviour: individuals with similar symptoms at varying times often choose to seek help on one occasion, but not on another (Mechanic, 1982). This is supported by the finding that there is only weak evidence that sociodemographic factors (e.g. sex, age) are directly associated with different patterns of help-seeking behaviour (Leventhal, Easterling, et al., 1995). Instead, help-seeking behaviour is often reliant on the type of symptom, the context in which it occurs, and a number of cognitive, emotional and social processes (Macleod, Mitchell, et al., 2009; Petrie & Weinman, 2003). This is especially the case for symptoms that are vague or ambiguous (e.g. unexplained weight loss, fatigue, a change in bowel or bladder habits) as opposed to those that are striking (e.g. collapse, bleeding). As such, help-seeking behaviour has been defined as a process involving 'symptom perception, interpretation, appraisal and decision making in addition to having the ability and motivation to enforce the decision by visiting a healthcare professional' (Scott & Walter, 2010, p. 531). In turn, a biopsychosocial approach to help-seeking behaviour is required to understand the complex relationship between symptom experience and consultation with healthcare professionals.

Theoretical Models in the Understanding of Help-Seeking Behaviour

Research into help-seeking behaviour has been largely atheoretical [with the exception of a small number of applications of Leventhal's (1970) Self-Regulatory Model (see Cameron, Leventhal, & Leventhal, 1993, 1995)]. This has led to a disparate literature that often fails to build on existing knowledge. Rakowski et al. (1988) noted that it is difficult to establish the hierarchy of importance of the different variables that have been studied in relation to healthcare use, as different studies tend to investigate different predictors. Thus, more theory-based research in this area is vital.

Application of general models of (health) behaviour (see Compton & Esterberg, 2005; Hunter, Grunfeld, & Ramirez, 2003; Mulholland & Van Wersch, 2007) often fail to add to understanding of help-seeking behaviour. This may be because consulting a healthcare professional is not a frequent behaviour or a part of one's lifestyle such as exercise or smoking for which these models are normally used (Shaw, Brittain, et al., 2008). Instead, seeking help is an uncommon response to an event (detection of a symptom) that the individual may or may not have experienced before. A further explanation as to why these general models of behaviour have shown limited success in this field is that they tend to emphasise the rational side of decision-making and give little attention to emotional factors that may play a crucial role in help-seeking behaviour.

It may be useful to consider general models of health behaviour in combination with the specific models or frameworks for understanding help-seeking behaviour (Bish, Ramirez, et al., 2005). Building on the work of Safer et al. (1979), Andersen et al. (1995) developed a 'General Model of Total Patient Delay' which captured the decisional processes leading to healthcare utilisation. The model proposes a sequence of stages: 'appraisal delay' describes the time a person takes to evaluate a symptom as a sign of illness; 'illness delay' the time the person takes from the first sign of illness until deciding to seek professional medical care; 'behavioural delay' the time between deciding an illness requires medical care to acting on this decision by making an appointment; 'scheduling delay' the time between making an appointment and actually attending an appointment; and 'treatment delay' the time between the first appointment with a healthcare professional and the onset of treatment.

This model has been applied to a number of settings such as myocardial infarction (Hedges, Mann, et al., 1998), cancer (Walter, Humphrys, et al., 2010), paediatric services (Kaftarian & Safer, 1987) and sexually transmitted diseases (Pitts, Woolliscroft, et al., 2000). A systematic review of the application of the General Model of Total Patient Delay to the study of cancer diagnosis found that although there was evidence of identifiable stages, the differentiation between stages is not consistent (Walter, Webster, et al., 2012). Further, there is evidence that the process of help-seeking is more iterative and dynamic than this model suggests. For instance, 'individuals may go back and forth from symptom identification and monitoring to self-treatment to monitoring to consultation to self-treatment and monitoring again' (Burman, 1996). As such, a revised framework (the Model of Pathways to Treatment; Scott, Walter, et al., 2013; Walter, Webster, et al., 2012) has been developed which includes clear definitions and a dynamic representation of the pathway to treatment.

Process of Help-Seeking Behaviour

Two key aspects are involved in help-seeking behaviour. Firstly, the appraisal of the health threat or stressor (i.e. symptom perception and interpretation), and secondly the implementation of a response (i.e. seeking help) once the need to seek help has been recognised. These are each considered in turn with reference to research and theory that addresses the factors that influence these processes.

Symptom Perception and Interpretation

There is no close relationship between the presence of disease and awareness of symptoms. For vague bodily changes (such as fatigue, weight loss, stomach upset and muscle ache) people are relatively inaccurate at noticing their occurrence. Pennebaker and colleagues (see Pennebaker, 1982) have documented numerous laboratory studies that have found only low correlations between perceptions of physical symptoms and actual physiological states.

Awareness of and attention to bodily changes (symptom perception) are affected by expectations, emotions, beliefs, and biological, environmental, sociodemographic, and contextual factors (Broadbent & Petrie, 2007; Cioffi, 1991; Diefenbach & Leventhal, 1996; Geers, Wellman, et al., 2010; Kolk, Hanewald, et al., 2003). For instance, the quantity and quality of concurrent incoming information influence awareness of symptoms, with a competition of cues between internal (bodily) information and external information for our limited cognitive resource (Pennebaker, 1982).

Symptom interpretation (or appraisal) involves assigning meaning to a bodily change and this can include assessment of the need for healthcare. Symptom interpretation is different from (or beyond) perception as it does not just involve noticing a bodily change but also assessing whether the bodily change may be something wrong or abnormal (based on its expectedness and level of interference) and subsequently, whether it may require professional attention. Recognising the need for healthcare may not occur immediately as, for example, a person may attempt self-medication or ignore the symptom and only consider help-seeking following reinterpretation after the symptom has not resolved on its own or as a result of medication (Scott, McGurk, & Grunfeld, 2007).

Evidence of the importance of symptom interpretation is found across a wide range of conditions. For instance, the belief that symptoms experienced are those of a heart attack is a reliable predictor of early arrival in hospital (Clark, Bellam, et al., 1992; Horne, James, et al., 2000; Ruston, Clayton, J., & Calnan, 1998) and the predominant risk factor for patients' delaying seeking help following detection of cancer symptoms is 'lack of interpretation by patients of the serious nature of their symptoms' (Macleod, Mitchell, et al., 2009, p. S95).

The psychological processes involved in symptom interpretation have been explained using psychophysiological comparison theory (PCT; Cacioppo, Andersen, et al., 1989) and Self-Regulatory Model (SRM) (Leventhal, 1970). These theories stipulate that awareness of bodily changes will motivate an evaluation (a psychophysiological comparison) if they are not easily explained by the present context or expectations. Psychophysiological comparisons are made between the symptom experience and the concrete and abstract knowledge contained in an individual's illness schema. The result of the psychological comparison will generate hypotheses about the seriousness of their problem and the need for assistance. Previous symptom episodes and illness experience has a large bearing on symptom interpretation and help-seeking decisions (Leventhal, Weinman, et al., 2008). For instance, Smith et al. (2008) found men use previous bouts of ill health as a reference to monitor new symptoms. If new symptoms were similar to a previous episode then men decided not to seek help, whereas if they exceeded the duration of previous symptoms they caused concern and prompted help-seeking.

As an individual's explanatory models (illness schemas) reflect cultural beliefs and attitudes, experiences and responses, culture will play a role in symptom appraisal and responses to symptoms (Dein, 2004). Indeed, studies that addressed help-seeking behaviour of African and Afro-Caribbean women found lay beliefs that were particular to this population (Littlewood & Elias, 2000; Mathews, Lannin, & Mitchell, 1994). For example, Mathews et al. (1994) found that black women living in eastern North Carolina spoke about their advanced breast cancer as a disease arising from 'dirty' or 'bad' blood: blood that contained impurities which circulated through the system and tried to come out of the body through knots, lumps or boils called 'risens' or 'whiteheads'. These women often delayed seeking help as the idea of catching a lump early before it bothered them, and removing it before it started to grow did not make sense to them. In fact, surgery was considered risky as this would let air get to the disease, which in turn could increase the chances of it growing and spreading.

In both the SRM and PCT, the individual is seen as 'an active problem solver' (Diefenbach & Leventhal, 1996), with the appraisal of symptoms involving iterations of 'hypothesis generation, hypothesis testing and error correction' (Cacioppo, Andersen, et al., 1989). Indeed, in their qualitative investigation of how men self-monitor their health, Smith et al. (2008) reported that men talked about 'being a detective' in an endeavour to understand what was happening.

As the process of symptom appraisal is an idiosyncratic, psychological process, it is open to a number of biases. For instance, the nature and pattern of the symptom(s), the duration and familiarity will guide symptom interpretation (Jones, 1990; Pennebaker, 1982). Learnt heuristics also influence symptom interpretation and determine whether someone believes their symptoms are due to ageing, stress or illness (Cameron, Leventhal, & Leventhal, 1995; Prohaska, Funch, & Blesch, 1990). The process of symptom interpretation takes place within a social context and as such, significant others (e.g. friends and family) and heuristics involving social comparisons may contribute to symptom interpretation (Hay, 2008; Leventhal, Weinman, et al., 2008).

Seeking Help

Even though symptom interpretation plays a major role in a person's decision to seek help, it is not always sufficient for help-seeking to occur. Once a person considers seeking healthcare, a number of barriers exist that influence whether a person will actually seek help. These include cognitive, emotional, social, cultural and environmental factors.

Shaw et al. (2008) found that symptom appraisal and the need for treatment may be weighed against treatment appraisal. For instance, if treatments were thought to be too invasive or reliant on medication, then help-seeking was less unlikely to occur, especially if symptoms were appraised to be non-life-threatening and were having minimal impact on their quality of life. This observation concerning the importance of outcome expectancies is in keeping with many models of health behaviour, where it is a central construct.

Distress as a result of the symptoms or distress as a result of the perceived consequences can encourage or hinder help-seeking (Leventhal, 1970; Leventhal, Safer, & Panagis, 1983). A qualitative synthesis of help-seeking behaviour for cancer symptoms found a range of fears existed throughout the decision to seek help (Smith, Pope, & Botha, 2005). For instance, patients feared embarrassment through bothering the doctor with trivial symptoms, being seen as weak or unmasculine, or having symptoms in a sensitive or sexual area. Seeing cancer as a fatal incurable disease, having previous negative experiences of cancer, expectations of unpleasant treatment or the consequences of treatment (e.g. loss of sexuality) and shame were aspects of the fear of cancer. It is of note that fear occurred 'after patients had recognised symptoms'. As the appraisal of symptoms appears to be a key determinant of the time to seek help for symptoms of cancer, the impact of fear (although common) may be relatively small. However, the role of emotion is one area of research that still requires further investigation.

The decision and act of seeking help is also dependent on the perceived and real accessibility of the healthcare system. Penchansky and Thomas (1981) proposed a taxonomy to explain the varying dimensions of the concept of access. They suggested that access can be considered as the degree of fit between the patient and the healthcare system and comprises of several specific areas of fit: availability, accessibility, accommodation, affordability and acceptability. Availability refers to the volume and type of services/resources in relation to the requirements of patients. This can also refer to the availability of specialist equipment and healthcare professionals (e.g. surgeons, oncologists) necessary to treat disease. Accessibility refers to the location of services in relation to the location of patients. This is relevant to communities living in rural areas who may have to travel long distances to access healthcare. Accommodation is the organisation of the healthcare services (e.g. opening hours, walk-in facilities) in relation to the patients' needs. Inconvenience of making contact with a doctor can lead to substantial delays in seeking help (Paine & Wright, 1989). Affordability refers to the prices of healthcare services/insurance in relation to patients' income and ability to pay. Some research in the USA (Braun, Mokuau, et al., 2002; Underwood, Hoskins, et al., 1994) has found that time to seek help may be prolonged due to concerns about treatment costs whereas research in European countries (where healthcare is free at the point of delivery) rarely find this as a key influence on help-seeking behaviour (Smith, Pope, & Botha, 2005). Finally, acceptability refers to the individual's attitudes about the characteristics of the healthcare services/providers, the healthcare providers' attitudes about the characteristics of their patients and doctor–patient communication (Moore, Sickel, et al., 2004).

As with symptom interpretation, the decision to seek help occurs within the social and cultural context (Andersen, Paarup, et al., 2010). Cornford and Cornford (1999) found that patients spoke to up to 16 people prior to seeking help, with the average being 3–4 people. Further, 71% of patients reported that one or more conversations with others were important in their decision to consult a healthcare professional, with conversations with partners having the most influence. Relatedly, Smith et al. (2005) found that sanctioning of help-seeking by friends, family or wider social influences such as the media was important in legitimising use of healthcare when individuals were unsure as to the nature or importance of their symptoms. This played a key role in overcoming fear of being a 'time-waster'. Social approval was less necessary when individuals had appraised their symptoms as cancer or other serious illness, or when the symptoms interfered with one's ability to work. In these situations, it appeared that the appraisal itself or the impact of the symptoms sanctioned the need for consultation with a healthcare professional. Finally, for some cultures the norm may be to consult elders or traditional healers rather than formal healthcare providers and as such visiting a healthcare professional may be reserved for certain circumstances (Hay, 2008).

Delays Within the Health Care System

There are still challenges to early detection once a patient consults a healthcare professional: there is also a need for accurate and prompt diagnostic services. However, healthcare professionals may dismiss symptoms, fail to offer follow-up appointments to determine whether symptoms have resolved or may misdiagnose the condition. Misdiagnosis may result in inappropriate medication or management, referrals to an 'incorrect' specialist, or referral without the necessary urgency (Evans, Ziebland, & McPherson, 2007). This is particularly the case within healthcare systems in which healthcare professionals act as a gatekeeper to specialist services (i.e. systems in which patients do not have direct access to secondary care but instead require a referral from a primary care practitioner). There is also potential for delayed diagnosis and treatment if there are problems with access to services, for instance, due to administrative error, or lack of resources or long waiting times. Macleod et al. (2009) found that certain patient factors affected the speed at which referrals were made following presentation to a healthcare professional. Older patients with symptoms of breast cancer, upper gastrointestinal or colorectal cancer were referred more quickly than younger patients, yet older patients with symptoms of urological or lung cancer were referred more slowly than younger patients. The same systematic review found mixed evidence that a patients' socioeconomic status is related to practitioners' timely investigation and onward referral behaviour for cancer symptoms. Patients from lower socioeconomic groups may be referred more quickly than those from higher socioeconomic groups for gastrointestinal cancer symptoms but more slowly for colorectal cancer symptoms. Although patients from minority ethnic groups often wait longer before seeking help for some cancer symptoms, the systematic review found little evidence of the influence of patients' ethnicity on the time between first consultation with a healthcare professional and subsequent referral.

Due to the potential impact of the diagnostic interval (defined as the time between the first appointment with a healthcare professional and a formal diagnosis being made) on timely diagnosis and treatment, there is a growing body of research into healthcare professionals' responses to symptomatic patients, the diagnostic process (Baughan, O'Neill, & Fletcher, 2009) and symptom matrices that indicate potential pathology (Hamilton, 2009b). To facilitate appropriate design and targeting of interventions, detailed analyses of the pathways to diagnosis are required to establish which component is leading to late detection and what factors are behind delays in diagnosis.

Interventions to Promote Early Presentation and Diagnosis

Given the impact of delayed diagnosis, there is a strong rationale for developing ways to encourage early presentation of symptoms to healthcare professionals and prompt diagnosis. One challenge of such interventions is that the symptoms of serious disease are often not unique to that disease. For instance, dizziness can be a sign of acute myocardial infarction, but may also be a sign of anxiety, a drop in blood pressure, stroke or a common cold or influenza. Interventions aiming to encourage early presentation therefore face the challenge of avoiding an overload of healthcare services with those with benign or minor ailments and unwarranted anxiety amongst patients. A further challenge is the range of methodological issues that researchers face when evaluating interventions to encourage early presentation and detection of disease. The clinical impact of the intervention may take years to come into effect, and in the case of less prevalent disease, the required sample size to detect such changes may simply be unfeasibly large. As such, interventions often use proxy measures of impact such as knowledge/awareness of symptoms, risk perception and intention to seek help, resulting in a potential loss in external validity. Austoker et al. (2009) noted that standardised and validated measures of cancer awareness and duration of symptoms are needed to ensure reliable and valid outcome measures in the evaluation of interventions to promote early presentation, and some measures are now becoming available (see Stubbings, Robb, et al., 2009). Interventions also face problems in identifying a suitable control group, especially with mass-media campaigns. As a consequence, assessments of interventions are often not methodologically rigorous, and the effects are mainly only assessed in the short term (Burgess, Bish, et al., 2008; Caldwell & Miaskowski, 2002; Kainth, Hewitt, et al., 2004).

Interventions for Patients and the Public

Mass-media campaigns to encourage early detection of stroke and myocardial infarction have generally had a limited impact. For example, Becker et al. (2001) evaluated a community-based educational intervention in the USA involving public service announcements via television, newspaper advertisements and mail-outs. The intervention successfully improved knowledge of risk factors and symptom knowledge but not where in the body stroke occurs, or the intention to seek help (dial 911) in the event of a stroke. This demonstrates that an increase in knowledge and awareness alone may not be sufficient to result in earlier detection.

Austoker et al. (2009) systematically reviewed recent (2000–2008) individual-level interventions and community-level interventions that aimed to promote cancer awareness or early presentation. Both individual- and community-level interventions were found to increase cancer awareness at least in the short term, but the authors found no randomised controlled trials that assessed individual-level interventions promoting early presentation. The community-level interventions that promoted early presentation were found to have some promising effects for encouraging earlier detection of breast cancer, melanoma and retinoblastoma. These before-and-after studies have tested time-limited educational campaigns using a range of media such as community presentations, posters, leaflets and broadcasts. For example, a breast cancer educational program delivered by community health advocates in churches, workplaces and schools in Atlanta found the proportion of very early stage breast cancers increased from 12 to 26% and the proportion of very advanced stage breast cancers decreased from 17% to 9% (Gabram, Lund, et al., 2008). However, the review authors conclude that as the community-level interventions are often multifaceted, not theory-based and only evaluated in the short term, it is not yet clear what a campaign needs to make it work, make it work over the longer term or in different settings (Austoker, Bankhead, et al., 2009).

It is important that interventions reach those most in need (Bett, Tonkin, et al., 2005; Petti & Scully, 2007; Scott, Weinman, & Grunfeld, 2011; Waters, Nichols, et al., 1983). This may involve targeting interventions at those most at risk of developing the disease in question or those who currently delay seeking help. Interventions can also be tailored to those groups or individuals. For instance, de Nooijer et al. (2004) found tailored information to be more effective than general information in both knowledge of cancer symptoms, more positive expectations of the advantages of early detection behaviours, higher self-efficacy to paying attention to cancer symptoms and more positive intentions towards engaging in help-seeking for cancer symptoms. Importantly the intervention did not raise anxiety about cancer.

Interventions Involving Healthcare Professionals and the Healthcare System

In order to encourage early detection of disease there is also scope for developing interventions to change healthcare professionals' knowledge and behaviour, to alter aspects of the healthcare system or to involve healthcare professionals in the delivery of interventions to their patients. Surprisingly however, there has been minimal research into the impact of such interventions.

Where research has pointed to misdiagnosis or inappropriate management because of gaps in knowledge or proficiency (e.g. Greenwood & Lowry, 2001), then additional training and continued professional development may be warranted (e.g. Alberts, Perry, et al., 1992; Seoane-Lestón, Velo-Noya, et al., 2010). Kroenke et al. (2000) conducted a systematic review of interventions designed to improve diagnosis and treatment of mental disorders in primary care. The review concluded that educational strategies (e.g. lectures, seminars, self-study), interventions that target provider behaviour at the time of the visit (e.g. via memory aids for diagnosis and treatment, allowing longer clinic visits, supervision) or interventions that provide feedback on providers' actual performance can improve the process of care for mental disorders. However, this may not be the case for other diseases. For instance, Raasch et al. (2000) reported an educational intervention involving audit and feedback (e.g. a review of specific clinical performance highlighting specific deficiencies in physicians' performance) and found that the intervention did not improve practitioners' diagnostic performance of skin lesions.

Some attempts to encourage early diagnosis have focused on changing the pathways to diagnosis. For instance, in the UK, the National Cancer Plan (Department of Health, 2000) stipulated that no patient should wait longer than one month from an urgent referral for suspected cancer to beginning treatment. A 'fast track referral' (two-week wait) system was introduced, with referral guidelines for suspected cancer issued to primary care physicians by the National Institute for Health and Clinical Excellence (2005). The guidelines specify the symptoms for which an urgent diagnostic is warranted. However, there is continuing debate as to whether such initiatives are effective in improving patient outcomes (Hamilton, 2009a; Jiwa & Saunders, 2007). Other alterations to the healthcare system involve improving access to healthcare and diagnostic services, for instance, changing the opening hours of the healthcare centres or having diagnostic equipment available within primary care. Again, there is little research that has studied the effectiveness of these initiatives.

Finally, healthcare professionals can be involved in the delivery of interventions to promote early presentation. For instance, pharmacists and physicians are in a good position to provide education and counselling to reduce delay in seeking help for acute myocardial infarction in those patients with coronary heart disease and those who have previously experienced acute myocardial infarction (Dracup, Alonzo, et al., 1997; Holt & Hand, 1999). By explicitly encouraging early presentation, healthcare professionals may provide some sanctioning of seeking help and overcome patients' fear of wasting the doctors' time. Linsell et al. (2009) reported a randomised controlled trial of a psychoeducational intervention aimed to promote early presentation of breast cancer in older women. The intervention (a scripted one-to-one discussion and provision of a leaflet) was delivered by radiographers to women aged 67–70 years attending final routine appointment on the UK Breast Screening Programme. The training of radiographers was found to be feasible (Omar, Burgess, et al., 2010) and the intervention was found to increase breast cancer awareness, with the effect maintained after one year.

Conclusion

Many patients wait weeks or months prior to seeking medical care for symptoms of life-threatening diseases. This is not simply because patients do not want to seek help or have difficulty doing so, but more often because symptoms are dismissed or self-managed as the seriousness of symptoms is not recognised. The complex processes through which symptoms are detected and appraised and the subsequent decisions to seek help are influenced by psychological, social and cultural factors as well as the nature of the symptoms and the context in which they occur. Studying the pathways to diagnosis and the factors that influence the timeliness of diagnosis will help to identify targets for interventions to encourage early presentation and detection of disease. Such interventions could target healthy individuals who are at risk of developing disease, existing patients who are at risk of developing subsequent disease or healthcare professionals who may play a role in delays in diagnosis once patients have sought medical care. However, with some recent exceptions, existing interventions have shown limited success. This may be a result of the general lack of theory and techniques of behaviour change in the design and development of interventions, and/or a failure to reach or engage the target group. Furthermore, the evaluation of interventions requires better methodology, including use of valid and reliable measurement tools, assessment of the clinical impact of interventions and adequate control groups. These challenges are not insurmountable barriers, and thus there is huge potential for improving mortality and morbidity from a range of diseases through the development and implementation of interventions to encourage early diagnosis.

Summary and Future Directions

There is opportunity for improving the morbidity and mortality of a range of diseases by encouraging early detection and diagnosis, thorough screening, self-testing and timely healthcare use. Literatures concerning these three areas concerned with early diagnosis are often considered in isolation from one another, yet there are parallels amongst them. The main points regarding determinants, interventions and research required for each of these behaviours are provided in Table 18.1. There are a number of commonalities in each of these areas, but also notable differences.

Table 18.1 Summary of determinants, interventions to increase behaviours and research challenges and needs regarding key behaviours in promoting early detection and screening

	Screening	Self-testing (for STIs)	Timely response to symptoms		Diagnosis
			Symptom perception and interpretation	Seeking help	
Determinants of health behaviours	• Organisation of screening programme • Social-cognitive factors (differ by condition screened for) • Previous attendance (habit) • Previous (false-positive) test results • Demographic factors (especially income and ethnicity)	• Little current evidence addressing predictors, but social cognitive factors likely to be important, especially perceiving self to be at risk, self-efficacy, response efficacy) • Uptake also likely to be associated with wanting reassurance, knowledge about lack of symptoms • Not having to attend a medical clinic for testing	• Beliefs (e.g. expectations, individual's illness schema) • Context (e.g. environment, culture) • Nature of symptoms (e.g. pattern, duration, familiarity and interference) • Previous experience • Social input • Learnt heuristics	• (Mis)interpretation of symptoms (e.g. attribution to minor ailments) • Self-care • Emotions (e.g. fear, embarrassment) • Beliefs (e.g. outcome expectations regarding seeking care) • Context (e.g. environment, culture) • Previous experience • Social sanctioning • Accessibility of healthcare system	• Misdiagnosis by healthcare professional resulting in: dismissal of symptoms, inappropriate treatment, referral to incorrect specialty, failure to offer follow-up or lack of urgency in treatment/referral • Healthcare system barriers (e.g. lack of resources, administrative hurdles) • Demographic factors (e.g. age, ethnicity, socioeconomic status)
Interventions to increase health behaviours	• Organisational interventions (e.g. reminders for health professionals) • Methods of screening invitation • Counselling interventions, but not educational interventions • Removing economic barriers where payment for screening is required	• Currently lack of knowledge on how best to promote acceptability, impact and determinants of self-testing. • Different approaches suit different people, so self-testing useful additional option • Self-testing appears particularly important for stigmatising conditions such as STIs	• General lack of evidence and research on impact of interventions • Mass-media campaigns and community education programs may encourage earlier diagnosis and increase knowledge and awareness in the short term. • Provision of tailored information may be more effective than general information for increasing knowledge and awareness, self-efficacy and intention to seek help. • Promising results for interventions delivered by healthcare professionals		• Some evidence that educational interventions, memory aids lengthening duration of consultations, supervision and provision of feedback may improve diagnostic skills, but may differ between conditions
Research needed and challenges in research	• Need to assess impact of interventions at multiple levels, including population level interventions • Not clear what are the sources of variation between different screening programmes • Need to assess effects of interventions to promote informed choices, on both informed choices and screening uptake	• Little research has incorporated theoretical models into the study of self-testing behaviour; this is likely to maximise the effectiveness of interventions that are developed • Not clear if positive test results without health professional support have larger adverse impact; difficult group for research to access	• Interventions face a number of practical and methodological challenges (e.g. successfully reaching target group; incorporation of theoretical models; minimising potential for unwarranted anxiety or overuse of services; clinical impact may not be seen immediately; proxy outcome measures may lack validity; difficulty in identifying suitable control groups).		• Lacking research to determine impact of referral guidelines or other healthcare system factors on patient outcomes.

One notable commonality is that beliefs and other social cognitions appear to be related to all three behaviours of attending screening, self-testing and seeking medical help. However, the precise nature of the social cognitions examined appears to vary somewhat between the behaviours. There is good evidence that help-seeking in response to symptoms seems to rely heavily on expectations about symptoms and illness schemata, given that symptoms is the initial impetus for this behaviour, although outcome expectations play a key role in seeking help. For self-testing, appraisals can be important, but the evidence is stronger for the importance of constructs concerned with theories of risk, such as perceptions of susceptibility and self-efficacy and response efficacy. For screening attendance, more generic theories of behaviour such as the theory of planned behaviour have been successfully applied. This variation highlights that although each of these behaviours is concerned with secondary prevention through early detection of disease, the behaviours have different specific aims and will therefore have varying determinants. Thus, help-seeking is concerned with seeking an appropriate response to symptoms, self-testing is concerned with assessing health status where there is reason to suspect that one is at elevated risk, and screening is also concerned with assessing risk, but where there is typically no reason to expect elevated risk compared to the relevant screening populations.

It is notable that screening literature in particular has demonstrated the value of theory-based research. In contrast, theory has often been neglected in self-testing and help-seeking literatures and as such is an important avenue for future research (Rothman, 2004; Michie & Prestwich, 2010). As self-testing might be incorporated within a screening framework in some contexts (e.g. self-sampling for colorectal and cervical cancer screening programmes), the neglect of theory in self-testing literature is particularly unhelpful.

Another common theme is the association between behaviour and how services are organised. Where services are not free at the point of delivery and involve routinised appointment systems, interventions to facilitate invitations for screening appear effective at increasing coverage. Equally, features of medical systems appear to be important barriers to healthcare use and to appropriate diagnosis following patients seeking help. It is notable that even for self-testing, which is largely conducted outside of a healthcare setting, being able to avoid attending a medical clinic for testing is associated with uptake, where conditions are stigmatised.

Viewing the different literatures together could offer important insights for future research. For instance, screening literature has demonstrated the importance of demographic factors such as income and ethnicity in the uptake of screening, probably because the large numbers of people that can be identified prospectively at invitation facilitates examination of this area. Although the impact of these demographic factors has been explored in the context of diagnosis, there appears to be room for further examination of this in the areas of help-seeking and self-testing. This may indicate where there is a particular need for attention to identify and reduce health inequalities in certain groups.

The screening and help-seeking literatures indicate that a major concern is not providing people with full information due to concerns over causing anxiety. For instance, there is reluctance to describe potential harms in invitations for screening or outlining signs of symptoms of diseases for fear that this may cause anxiety and in turn delay help-seeking rather than encourage it. In contrast, the research evidence in both fields indicates that ensuring patients are fully informed does not raise anxiety, reduce screening uptake or hinder help-seeking. That is, although the steps one might take to increase screening uptake are different from those that one might take to promote informed choice (French & Marteau, 2007), it seems that these two aims are not necessarily antagonistic. Given the increasing promotion of informed choice, this is likely to become more of a research issue.

There are a number of methodological issues facing these areas, especially self-testing and help-seeking research, which is mostly retrospective, focusing on those who have undergone self-testing and used healthcare services. A focus on those who choose not to be screened or self-test or are unaware of self-testing opportunities or who choose not to seek help is rare, although it potentially offers considerable insight into the cognitive and emotional processes involved. However, researchers face the methodological challenge of finding ways of identifying and recruiting these samples, especially when studying stigmatised conditions.

A theme common to all three areas is the importance of context, where some constructs are predictive of behaviour and useful targets of interventions in one setting, but less useful in other settings. It is important that future work adequately theorises the different processes that are important in different contexts, based on evidence, to allow future interventions to benefit more from existing work.

Acknowledgements Rachael Powell is grateful to Helen Pattison for inspiring her interest in self-testing and the many interesting and influential discussions on this topic.

Adherence

Lora E. Burke, Yaguang Zheng, and Jing Wang

Introduction

Adherence has been described as a multilevel phenomenon, one that involves the individual, the provider, and the healthcare system (Hill & Houston-Miller, 1996). However, the provider and the healthcare system are only two components in the larger picture when adherence is viewed from the broader perspective of the social-ecological model (SEM) framework (Addison, 1992; Sallis, Owen, & Fisher, 2008). Adherence is the adoption and maintenance of recommended behaviors so that they are aligned or consistent with public health or clinical recommendations; to achieve long-term benefits to health, there is an emphasis on maintenance of those behaviors, e.g., following the recommended dietary or physical activity guidelines or taking prescribed medications (Burke, Dunbar-Jacob, & Hill, 1997). As suggested in the definition of adherence, we will focus on the alignment of medication, diet, and physical activity habits with guidelines to prevent as well as manage chronic diseases. Multiple interdependent factors influence these behaviors including the social context, the person, and the environment (Banks-Wallace, 2000; Streuber, Knoblich, et al., 2011). The SEM permits a conceptualization of the interdependence of these factors and how they influence the adoption and maintenance of new behaviors. Moreover, the underlying theory suggests that sustaining the behavior requires the support of programs that include numerous levels of influence (Emmons, 2000).

In this chapter, we will address adherence – its assessment within the SEM framework, particularly the individual, the social and contextual factors that influence the individual's adherence within the greater community, and the resources that can be called upon to improve or support adherence. Evidence-based strategies that have been demonstrated to improve adherence to chronic disease regimens (e.g., diet, physical activity [PA], medication taking, appointment keeping) will be discussed.

Assessment of Adherence

Using the SEM framework, we need to consider and assess the multiple levels of influencing factors. The exact terms used to describe the components or levels of the SEM vary, for example, the Centers for Disease Control and Prevention use *individual*, *relationship*, *community*, and *society* (Dahlberg & Krug, 2002). We will use the terms described in an earlier study (McLeroy, Bibeau, et al., 1988), which was recommended by the Institute of Medicine, as useful to examine levels of influence related to adoption of health-promoting behaviors (Smedley & Syme, 2000). Thus, assessment would involve four levels: *intrapersonal*, *interpersonal*, *community and environment*, and *organizational*.

Nonadherence is ubiquitous and is influenced by an array of factors that range from within the individual to a multitude of factors that interact with the different levels of the SEM framework, e.g., dietary adherence can be influenced by individual food preferences, family eating patterns, and access to healthy foods within the residential, work, and social environments (Gidding, Lichtenstein, et al., 2009). For other behaviors, such as taking medication or engaging in PA, the influence of intrapersonal factors and how these interact with the interpersonal, community and environment, and larger organizations, such as the healthcare delivery organization, can vary widely. Thus, adherence needs to be assessed in all settings with an emphasis on the different layers of factors represented in the SEM, depending on the behavior being assessed.

In assessing adherence, it is important to distinguish between adherence and therapeutic or clinical outcome, which can be affected by an array of other factors. For example, inadequate control of serum cholesterol may be due to inadequate drug dosage or individual variation in the drug's pharmacokinetic factors or personal factors. Inversely, the achievement of the clinical target or resolution of symptoms does not confirm adherence. Clinical outcomes are indirect measures of adherence, whereas patient behaviors (e.g., taking the medication or exercising) are direct measures. It remains difficult to measure behavior directly, and thus we rely on self-reported behavior in many situations.

In conducting an assessment of adherence, one could include the self-efficacy construct, which has been demonstrated as a predictor of adherence across multiple behavioral domains (Burke, Dunbar-Jacob, et al., 2005; Mielenz, Kubiak-Rizzone, et al., 2013; Warziski, Sereika, et al., 2008). One might view Bandura's distinction between efficacy expectation and outcome expectation as being similar. Efficacy expectation predicts if the individual will perform the adherence behavior, based on the individual's perceived self-efficacy to do so. Outcome expectation is the person's confidence in the treatment having a positive effect (Bandura, 1997). Thus, if the person has low outcome expectancy, he or she may choose not to adhere or engage in the treatment even if he or she has a high self-efficacy for performing the behavior.

A bias toward overestimation of adherence is a common flaw in adherence measurement (Miller, Alpert, & Cross, 2008). This can be partially explained by the period being measured, which often is not representative of the person's usual behavior, e.g., in a clinic appointment, the patient is asked to recall how he/she is following a recommended diet or a medication regimen. The person recalls the behavior close to the assessment encounter, which is apt to be better than usual, and consequently reports a better than usual behavior pattern. Research has shown that patients' adherence varies in relation to the clinical appointment, with adherence increasing immediately prior to and after the visit (Cramer, Scheyer, & Mattson, 1990). An array of methods are available to measure adherence to medication taking, appointment keeping, and therapeutic diet or physical activity, which include self-report, biologic and electronic monitoring devices or electronic diaries, accelerometers and pedometers, pill counts, and records such as pharmacy refills (Table 19.1).

Self-Report Measures of Adherence

Self-report measures consist of interviews, structured questionnaires, and diaries, which can be either paper and pencil or electronic. *Questionnaire*s or paper-and-pencil adherence

Table 19.1 Methods of adherence measurement, strengths, and weaknesses

Method		Behaviors	Strengths	Weaknesses
Self-report	Questionnaire	All behaviors	Extensively used; inexpensive; quick turnaround	Requires literacy; usually must be kept short; response rate may be low for mail and email questionnaires; measures need validation
	Diary	All behaviors	Provide detail of circumstances of behavior, no recall bias; the problem of day-to-day variation is reduced when multiple days are recorded	Time consuming; under- or overreport adherence; may have recall bias; may influence behavior; can be burdensome
	Interview	All behaviors	Inexpensive; provide details; quick turnaround	Interviewees may not recall important information; overestimate actual adherence
Objective	Biologic assays	Medication adherence, diet	Direct measure of adherence; may provide a validation of behavior	Expensive; limited assays available; other factors may influence the measure indirectly
	Technology supported, e.g., medication event monitoring system, accelerometers, pedometer, scales, smart cards for CPAP adherence, or continuous blood glucose monitoring	Medication taking, physical activity, weight, sleep disorder treatment, diabetes management	Provide real-time measures of adherence; easy storage of large amounts of information; ease of updating information	Loss of data if device is damaged or lost, can be quite expensive
	Pill count	Medication taking	Inexpensive; easy to conduct	Clients are able to manipulate the number of pills remaining prior to the visit
	Refill audit	Medication taking	Easy to conduct	Requires a closed or centralized pharmacy system; can be manipulated by patients

assessment is used most frequently, most likely due to the low cost and ease of administration. However, increasingly more, electronic diaries and monitoring devices are available for individuals to track their behaviors, e.g., downloadable apps to self-monitor diet or food intake. Although this is self-report, the use of the electronic diary may ease the burden of daily tracking and permit the patient to share a log with the provider for a review of recent behavior (Burke, Wang, & Sevick, 2011). *Interviews* are used frequently in clinical encounters and also in the research setting to assess adherence behavior at each contact or at specified intervals. Adherence to therapeutic regimens can also be ascertained through a 7-day recall interview by asking the patient to report the number of pills and the times at which these were taken for each day or the episodes of exercise and eating behavior for the past week. However, these tend to provide an overestimation of adherence

(Daniels, Goodacre, et al., 2011; Ross-Degnan, Pierre-Jacques, et al., 2010) and are biased to recall (Stone, Turkkan, et al., 2000).

Medication-Taking Adherence *Self-report* of medication adherence is assessed by questionnaire or by interview. The Morisky Medication Adherence Scale (MMAS), a four-item questionnaire about medication taking (Morisky, Green, & Levine, 1986), is the most often used instrument in medication adherence research (Morisky, Ang, et al., 2008). The MMAS-8 is an eight-item modified version of the MMAS (ter Bogt, Bemelmans, et al., 2011). Other self-report measures used to assess medication adherence include the Hill-Bone Compliance to High Blood Pressure Therapy Scale (Van Horn, 2011) and the Osteoporosis-Specific Morisky Scale (Urban, McCrory, et al., 2011). A systematic review of 58 studies focused on self-reported medication adherence for routine clinical practice recommended the development of a measure that can be completed by caregivers and also be used to differentiate between intentional and unintentional nonadherence (Garfield, Clifford, et al., 2011). Additionally, persistence in taking medication is considered as another indicator of adherence, measuring the duration from initiation to discontinuation of therapy (Caetano, Lam, & Morgan, 2006), e.g., proportion of days that the medication was taken during the specified period has been used to measure medication-taking persistence (Benner, Glynn, et al., 2002).

Dietary Adherence Assessing dietary adherence requires a determination of what the person eats and the degree to which the food intake approximates the recommended diet (Dixon, Subar, et al., 2007). The unannounced 24-h dietary recall is considered the gold standard for assessing dietary intake. In this *interview* approach, the individual is asked to recall food and beverage intake for the previous 24 h (Tucker, 2007). The unannounced assessment prevents individuals from changing their food intake in anticipation of the recall. The five-pass method permits a more exact description of foods (e.g., brands, degree of fat modification) but also requires interviewer skill for prompting recall and eliciting detail. Benefits of the 24-h recall are increased accuracy because of the shortened recall period. There may be reduced patient burden compared to recording in a food diary, but the 30–45 min interviews can also be burdensome. To reduce bias, it is important to collect the data for days on which the eating pattern is typical (Tucker, 2007).

Several techniques have been used to enhance accuracy of individuals' estimate of their food intake, e.g., the US Department of Agriculture (USDA) Automated Multiple-Pass Method (AMPM), a 5-step multiple-pass 24-h dietary recall method (Blanton, Moshfegh, et al., 2006). This is a computer-assisted 24-h dietary recall interview guide that provides cues to stimulate respondents' recall processes and has been shown to provide valid measures of total energy and nutrient intake among healthy normal-weight women (Blanton, Moshfegh, et al., 2006) and obese women (Conway, Ingwersen, et al., 2003), normal-weight men (Rumpler, Kramer, et al., 2008), and overweight/obese adults (Stote, Radecki, et al., 2011). Based on the AMPM approach, the well-established Nutrition Data System for Research (NDSR) is a comprehensive software program that is based on the AMPM approach and is available for assessment of dietary intake through 24-h dietary recalls, food records, menus, and recipes. The NDSR program, which contains over 18,000 foods, was developed by the Nutrition Coordinating Center at the University of Minnesota and is updated annually to reflect marketplace changes and new analytic data (NDSR, 2010, University of Minnesota, Minneapolis). It has been used in numerous large and small clinical trials (Burke, Hudson, et al., 2007; Kroenke, Caan, et al., 2012; Lin, Chen, et al., 2012). Additional software programs are available to collect dietary data, e.g., the USDA Nutrient Database for Standard Reference (Washington, DC), ProNESSy (Princeton, New Jersey), Food Processor (Salem, Oregon), and the more recently developed program in which the individual completes the recall online (Zimmerman, Hull, et al., 2009). Innovative approaches that are new include the eButton, which is a wearable computer that takes still photos of food being consumed and then uses computerized camera calibration to measure food portion size (Chen, Jia, et al., 2013; Yue, Jia, & Sun, 2012), the development of a mobile telephone food record in which image analysis and volume estimation are used, and another more objective approach being introduced (Six, Schap, et al., 2011). Each of these programs provides a comprehensive summary of dietary data with extensive detail of macronutrients and micronutrient intake.

Dietary adherence can be measured by several established *questionnaire*s. The Food Frequency Questionnaire (FFQ) is the most widely used measure to provide estimates of usual dietary intake over time (typically 6 months to a year) in large epidemiological studies (Boeing, 2013; Parr, Hjartaker, et al., 2013). FFQs include an extensive list of foods with a response requiring a report of frequency and amount of foods consumed. The commonly used ones include the Harvard/Willett FFQ (Weaver & Grunstein, 2008), National Cancer Institute's Diet History Questionnaire (DHQ) (Schmidt, Absalah, et al., 2008), and the Fred Hutchinson FFQ (Kong, Beresford, et al., 2012). The major limitation of FFQ is the number and types of items listed, which can limit its utility among ethnic groups (Tucker, 2007). FFQs have been adapted and validated to assess the diet of diverse populations (Matt, Rock, & Johnson-Kozlow, 2006), e.g., US-Chinese women (Tseng & Hernandez, 2005), elderly populations of low socioeconomic status (Quandt, Vitolins, et al., 2007), pregnant women (Vioque, Navarrete-Munoz, et al., 2013), and free-living elderly people (Pfrimer, Saes Sartorelli, et al., 2013). A regionally specific FFQ has been developed for white and black adults residing in the southern region of the USA (Tucker, Maras, et al., 2005).

Physical activity adherence measures include questionnaires, interview, and diary records. Each offers a simple and inexpensive estimate of habitual PA (Shephard & Aoyagi, 2012). Due to cost and convenience, the *questionnaire is* the most common measurement of PA. It assesses overall activity as well as intensity, frequency, duration, and type. The long version of the International Physical Activity Questionnaire (IPAQ-L) collects data on PA of the past week within leisure, transportation, occupation, and domestic domains (Cleland, Ball, et al., 2010). Godin Leisure-Time Exercise Questionnaire (LSI) is a four-item query of usual leisure-time exercise habits and average duration and frequency of light, moderate, and vigorous activity (von Gruenigen, Frasure, et al., 2012). The 7-day Physical Activity Recall and the Paffenbarger PA Questionnaire are widely used in various settings, e.g., African-American churches (Shuval, DeVahl, et al., 2011), the workplace (Gazmararian, Elon, et al., 2013), and with adolescents (Banks, Manlhiot, et al., 2012) and adults (Umstattd Meyer, Baller, et al., 2012). *Interviews* are often used in the research setting to assess adherence behavior at set intervals and can be conducted by telephone or in person (Hayden-Wade, Coleman, et al., 2003), usually guided by established questionnaires, e.g., Paffenbarger Activity Questionnaire (Burke, Choo, et al., 2006), Modified Activity Questionnaire (Conroy, Yang, et al., 2011), and 7-day Physical Activity Recall (Gazmararian, Elon, et al., 2013; Schoenborn & Stommel, 2011). *Diary records* may be used alone or with an accelerometer and include assessment of type of daily exercise and duration; these can be a paper-and-pencil or an electronic diary (e.g., downloadable program on a desktop or mobile computer platform) (Anton, LeBlanc, et al., 2012; Burke, Styn, et al., 2012; Shay, Seibert, et al., 2009).

Questionnaires, whether administered by interview or paper and pencil, are less susceptible to recall bias when the interval covered is brief. However, since lifestyle behaviors may change with the season, the shorter period decreases the likelihood of capturing representative eating and exercise behaviors. It is important to be aware that the individual's ability to store and retrieve information also affects the data's reliability and validity (Stone, Turkkan, et al., 2000). Additional concerns include the clinician's approach and how the question of adherence is posed. The individual needs to be given permission to be nonadherent, and the provider needs to be nonjudgmental in querying the person.

Diaries Daily diaries for food intake or exercise circumvent the bias of recall but require training and cooperation of the individual, which limits its use to motivated, literate individuals. Although diaries are also considered a centerpiece of interventions targeting behavior change, they may be used for assessment of adherence. Food and exercise diaries may cover a 3- or 7-day period, including one nonwork or leisure day. Recording for 3 or more days may reduce accuracy, and the recording may begin to influence the recorder's behavior. Several investigators have used diaries to measure adherence to the exercise and diet protocol (Acharya, Elci, et al., 2009; Burke, Choo, et al., 2006; Conroy, Yang, et al., 2011).

While self-report measures continue to be used most frequently, several measurement issues remain a concern, e.g., response biases due to social desirability and deliberate and nondeliberate errors in reporting, e.g., underreporting amount or types of foods consumed (Johnson, Friedman, et al., 2005; Yon, Johnson, et al., 2006) and overreporting physical activity (Colley, Hills, et al., 2008; Walsh, Hunter, et al., 2004); the latter two being common among overweight and obese individuals. Additional concerns related to eating behaviors include the difficulty individuals have in accurately estimating portion size; for medication taking, it is difficult to recall each individual episode. When using diaries to assess adherence, the individual needs to be assured that a full range of behaviors is expected to prevent less than truthful reports and also that it is important to record the behavior immediately after it occurs to avoid forgetting. Despite their limitations, self-report measures are common, easy to use, inexpensive, and provide information on the circumstances surrounding the good or poor adherence.

Objective Measures

Several objective measures are used to assess medication adherence that do not apply to eating or exercise behaviors, e.g., pill counts, pharmacy refills, electronic event monitoring, drug levels, and biological and physiological markers (Ho, Bryson, & Rumsfeld, 2009; Osterberg & Blaschke, 2005). *Refill audit* is defined as the percentage of doses refilled and is often used in a closed pharmacy or centralized system (Hudson, 2004; Olson, Gaffney, et al., 2008). *Pill count* can be easily conducted, through using telephone-based unannounced pill count (Kalichman, Amaral, et al., 2008) or counting pills during pharmacy refill visits. More recently, medication orders from electronic health records have been used as a measure of medication adherence (Conklin, 2006).

Biologic Measures These measures are at best indirect indicators of adherence; however, as stated previously, there are numerous factors that may be reflected in plasma levels of a pharmacological agent that do not reflect adherence behaviors. Biologic markers are often used as indicators of medication adherence, e.g., viral load as a measure of adherence to antiretroviral therapy (Kalichman, Amaral, et al., 2008). Medication adherence can be defined as a continuous level or by a cut point, e.g., of 80–100% (Benner, Glynn, et al., 2002; Ho, Bryson, & Rumsfeld, 2009). Clinicians often use glycosylated hemoglobin level as an indicator of patient's self-management of diabetes behaviors (Krapek, King, et al., 2004) which is interpreted as adherence to the overall regimen. Smoking cessation behaviors are often measured by assays that include saliva thiocyanate or cotinine level (Fuentes, Munoz, et al., 2010) or urine sodium for dietary sodium intake (Leiba, Vald, et al., 2005; Pärna, Rahu, et al., 2005). However, there are several limitations to measuring adherence through this approach, e.g., cost, daily variability in adherence cannot be detected, biological measures are not available for most dietary factors and drugs, and, finally, several other factors may influence biological assays (Charlton, Steyn, et al., 2005).

Electronic Monitoring The gold standard for electronic monitoring of medication taking is the use of the medication event monitoring system

(MEMS), a method that uses electronic microcircuitry embedded in the medication package, which generates a time and date stamp of the removal and replacement of the medication bottle cap (Jacqueline Dunbar-Jacob, 1996; Dunbar-Jacob, Sereika, et al., 2012). Another application of the electronic monitor for medication use includes the IDAS II (Intelligent Drug Administration System, Bang and Olufsen Medicom, Denmark) that accommodates blister pill packs (Santschi, Wuerzner, et al., 2007). This device uses visual and audible reminders to the patient to enhance adherence. Similar to the MEMS, the IDAS II has demonstrated acceptability and improved adherence with its use (Santschi, Wuerzner, et al., 2007).

Mobile devices that can collect data on food intake are undergoing development and testing, but none are available for use in clinical practice today. For example, a wearable computer referred to as the eButton captures digital pictures of food and permits portion-size estimation by the computer (Chen, Jia, et al., 2015; Yue, Jia, & Sun, 2012); others are using mobile phone-captured food images to identify food and volume that can be calculated to estimate portion size, energy, and nutrients consumed in real time (Aizawa, Maeda, et al., 2014; Six, Schap, et al., 2011). There are also several technology-based methods to assess physical activity, e.g., pedometers and accelerometers. Pedometers are used to measure steps during ambulatory activity and are the most inexpensive objective monitoring device for physical activity (von Gruenigen, Frasure, et al., 2012). Some limitations are that pedometer accuracy is influenced by walking speed, and it will not detect activities such as bicycling (Storti, Pettee, et al., 2008).The more recent models will store data up to 42 days permitting the individual to bring in the device to have the data uploaded and the memory cleared. Accelerometers are motion sensors that register body accelerations and decelerations and thus provide a direct and objective measure of movement intensity and frequency during physical activity (Pellegrini, Duncan, et al., 2012; Rogers, McAuley, et al., 2012). Sazonova and colleagues developed a footwear-based device with an embedded accelerometer, and insole pressure sensors showed this device can accurately estimate the energy expenditure associated with common daily postures and activities (Dannecker, Sazonova, et al., 2013; Sazonova, Browning, & Sazonov, 2011). The Actigraph accelerometer (Manufacturing Technologies Inc., Fort Walton Beach, Florida) and the Caltrac accelerometer (Muscle Dynamics Corp., Torrance, CA) have been used to assess physical activity levels among adults with congenital heart disease (e.g., corrected atrial septal defect) (Dua, Cooper, et al., 2007) and among individuals of all ages in the 2003–2004 National Health and Nutritional Examination Survey (Evenson & Wen, 2015). Typically, the person is asked to record their activities in a log to capture the activities not detected by accelerometer (e.g., swimming) (Rogers, McAuley, et al., 2012). The SenseWear® Armband (BodyMedia, Inc., Pittsburgh, PA) is a device worn on the upper right arm that contains an accelerometer and temperature sensors and monitors PA and energy expenditure. Data can be uploaded to a computer for analysis using the SenseWear® Software. This device has been shown to reliably determine energy expenditure in the active and resting state (Almeida, Wasko, et al., 2011; Villarini, Pasanisi, et al., 2012) and during resistance training (Reeve, Pumpa, & Ball, 2014).

Electronic Diaries Electronic handheld diaries are available to record eating and physical activity behaviors (Burke, Styn, et al., 2012; Burke, Wang, Sevick, 2011; Spring, Schneider, et al., 2012). Unlike the earlier version of diaries that were referred to as personal digital assistants that had to be brought into the clinic to have the data uploaded, the data on the currently available electronic diaries may be sent in real time to a server or have the data accessed through a portal on the Internet as these functionalities have been incorporated into mobile phones and tablets (Hutchesson, Rollo, et al., 2015). Mobile electronic diaries include software programs that facilitate recording, e.g., nutrient database for diet self-monitoring programs and databases of numerous forms of physical activity and exercise (Azar, Lesser, et al., 2013; Breton, Fuemmeler, &

Abroms, 2011). Recalling foods eaten and other events or symptoms is plagued by recall inaccuracies. Mobile devices facilitate immediate access and thus avoid this barrier by permitting individuals to record experiences close to the time of their occurrence. While these data are self-reported, they provide an excellent window into what the person is reporting in real time. Some of these devices include a date and time stamp so the provider can also measure adherence to the self-monitoring protocol, e.g., the Wi-Fi-enabled smart card for measurement of adherence to continuous positive airway pressure (CPAP) (Weaver & Grunstein, 2008). Previously, adherence to self-weighing was assessed by a digital scale that provided date- and time-stamp data and stored the weight data in the scale, which could be uploaded later at the center (Gokee-Larose, Gorin, & Wing, 2009). More recently, digital, Wi-Fi-enabled scales are available that can transmit the weight data in real time to a server (Music, Styn, et al., 2013).

Appointment Keeping Unlike adherence to the behaviors described above, there is a standard approach to monitoring appointment keeping, e.g., the attendance at PA sessions documented by research staff (Smith, Lanesskog, et al., 2012). It has been clearly demonstrated that in the context of research, attendance at intervention sessions decreases over time (Acharya, Elci, et al., 2009) and also that in longitudinal studies, it is increasingly more difficult to retain participants for completing assessments (Akl, Briel, et al., 2012; Page & Persch, 2013). Cancelation of appointments or not showing for a treatment session or assessment is a strong indicator of nonadherence.

Regardless of how adherence is measured, it is important to note that patient adherence to complex treatment regimens may vary across the treatment components (Atienza, King, et al., 2008), e.g., medication adherence may improve, while adherence to the dietary regimen could decrease. Acharya et al. reported varying levels of adherence to the five components of an intervention in a randomized clinical trial of behavioral treatment for weight loss (Acharya, Elci, et al., 2009). For example, while the highest level of adherence was to attendance of treatment sessions, adherence to the other components (self-monitoring of diet and exercise, daily calorie and fat gram intake goals, and weekly exercise goals) varied from 85% to 27% with varying patterns of adherence over 12 months. The largest decrease was in self-monitoring of diet and exercise, which was 85% initially and decreased to 26% at 1 year, which was performed with a paper diary.

In summary, adherence varies over time and often declines. Thus, ongoing and repeated assessments are essential. Moreover, repeated assessments convey to the individual that adherence is important. Furthermore, adherence should not be assumed, and when possible, the context of the behavior and its surrounding circumstances should be assessed, such as the components included in the SEM that go beyond the individual.

Determinants of Adherence

There are factors that are consistently identified as related to adherence, and, most importantly, they can be addressed through interventions. For this discussion, we have categorized them according to the SEM: intrapersonal, interpersonal, community and environment, and organization. There may be overlap across categories. Some of the determinants of adherence viewed in these categories may not be amenable to change, but one needs to be sensitive to their presence and develop interventions to improve adherence where feasible.

Pertinent to the SEM is an emerging topic, *social determinants* of health, a concept and term that was added to the Healthy People 2020 document. The 2020 plan emphasizes the need to consider all the aspects of social structure that not only influence the population's health but also the ability of many to achieve health equity (Koh, Nelson, & Cook, 2011; U.S. Department of Health & Human Services. Office of Disease prevention and Health Promotion, 2013). Additionally, it notes that the health of the individual is almost inseparable from the health of the larger community. Thus, this perspective emphasizes the ecological approach to health promotion and disease prevention and reinforces the need to assess and intervene to improve adherence across the different levels of the SEM.

Intrapersonal Individual characteristics are important factors that influence medication adherence and other adherence behaviors. Low health literacy is a major impairment to medication-taking and dietary adherence (Ownby, Waldrop-Valverde, et al., 2012; World Health Organization, 2003). Sociodemographic factors such as being older, having higher education, and a history of previous engagement in exercise have been shown to have a positive association with PA adherence (Courneya, Segal, et al., 2008; Courneya, Stevinson, et al., 2010; Tobi, Estacio, et al., 2012), while being a female and having a lower income, higher percent body fat, and reduced functional health status (e.g., osteoarthritis) are negatively associated with PA adherence (Courneya, Segal, et al., 2008; Trombini-Souza, Fuller, et al., 2012). Self-management, self-efficacy, and adherence can be notably affected by several factors, including the individual's perception of the severity of the disorder (DiMatteo, Haskard, & Williams, 2007), self-concept and the person's perception of the effect of medications (Thomas, 2007; Vlachopoulos & Neikou, 2007), or the benefits of exercising regularly (Cleland, Ball, et al., 2010; Gyurcsik, Brawley, et al., 2013; Seghers, Van Hoecke, et al., 2014). Other intrapersonal factors include prior adherence behavior, e.g., history of canceling appointments, the presence of supportive others, and satisfactory rapport with the health provider (Fuertes, Mislowack, et al., 2007). Skills for implementing the regimen are crucial, e.g., learning how to make dietary changes or follow a complex medication regimen demands that the individual receives training and a chance to practice and receive feedback.

Interpersonal Resources The absence of family or a social support network may negatively affect medication adherence. Culturally relevant social support (Stepnowsky, Marler, et al., 2006), family support (Mayberry & Osborn, 2012), and parental support for children (Conn, Halterman, et al., 2007) have been reported to impact medication adherence. The adoption of new behaviors, such as exercise, can be enhanced by supportive networks or even a partner (Aggarwal, Liao, & Mosca, 2010; Gorin, Wing, et al., 2008; Norton, Norton, et al., 2011). A study testing the role of types of support in diabetes management showed that nondirective support was associated with better metabolic control among those less than 30 years old, while directive support appeared counterproductive among those 30 or older (Fisher, La Greca, et al., 1997). A recent weight loss study using e-coach support showed that a directive support condition had more engagement than the nondirective support condition (Gabriele, Carpenter, et al., 2011). Both companionship and encouragement are important components to increasing PA adoption (Springer, Kelder, & Hoelscher, 2006). Reducing family conflict and improving communication are family-based behavior strategies that can enhance adherence (Koenigsberg, Bartlett, & Cramer, 2004).

Community and Environmental Resources The impact of the surrounding community or neighborhood is the center of extensive study that is rapidly growing (Cummins & Macintyre, 2006; Gordon-Larsen, Guilkey, & Popkin, 2011; Gordon-Larsen, Hou, et al., 2009b). The resources to which a person has access can greatly impact adherence to diet and prescription refill. Environmental influences on diet are partly considered to involve two pathways: access to foods from supermarkets and grocery stores for home consumption and access to ready-made food for home and out-of-home consumption (e.g., takeaways, restaurants) (Boone-Heinonen, Popkin, et al., 2010; Cummins & Macintyre, 2006; Gordon-Larsen, Boone-Heinonen, et al., 2009a). Living closer to fast-food restaurants led to more fast-food consumption, particularly among low-income men (Boone-Heinonen, Gordon-Larsen, Kiefe, et al., 2011), while increases in community-level prices of fast food and soda were associated with reductions in individual-level fast-food consumption (Gordon-Larsen, Guilkey, & Popkin, 2011). Supportive community and environmental resources are also associated with higher adherence to exercise (Boone-Heinonen, Gordon-Larsen, Guilkey, et al., 2011). Some examples of the supportive physical environments are availability, accessibility, and convenience of destinations; good urban design, e.g., good lighting of streets, presence of sidewalks and bike paths, and green spaces in community development; as well as safe streets, e.g., unattended dogs and safety from crime (Boone-Heinonen, Gordon-Larsen, Guilkey, et al., 2011; Gordon-Larsen, Nelson, et al., 2006; Pan, Cameron, et al., 2009).

Within the context of the SEM, the clinic setting is part of community resources. There is extensive evidence demonstrating that treatment-related factors can significantly impact adherence behavior (Ho, Bryson, & Rumsfeld, 2009; Natarajan, Santa Ana, et al., 2009). Several factors have been identified as having a negative impact on medication adherence; among these are the complexity of the regimen and the number of concurrent medications and the steps involved in mastering the treatment regimen, e.g., learning how to check blood glucose and administer insulin, make major dietary changes, or begin a walking program. Regimen-specific issues, such as the absence of immediate benefit, actual or perceived unpleasant side effects, and interference with one's lifestyle, have been identified as having a negative impact. The provider can control some factors that negatively impact adherence, e.g., reducing the number of medications taken per day.

Organizational Resources At this level, there are numerous factors related to system policies or management that can impact adherence, e.g., restricted formularies, high drug costs, long wait times, or inconvenient hours. Adherence can be influenced by the frequency of needing to refill a prescription, which may work in either direction, e.g., a 60-day prescription may result in better adherence than with a 30-day prescription (Batal, Krantz, et al., 2007); however, the cost of a 60- or 90-day refill may be prohibitive for some (Gellad, Haas, & Safran, 2007). Furthermore, availability of reimbursement after exceeding the cap amount among Medicare beneficiaries may lead to poor adherence (Hsu, Price, et al., 2006). There is evidence that high patient co-payments, inconvenience in accessing medications, and choice of initial therapy influence medication adherence (Budd, Mariotti, et al., 2011; Burke, Tuite, & Turk, 2009; White, Whisenhunt, et al., 2002). Lack of healthcare insurance, inability or difficulty accessing healthcare (Lafay, Thomas, et al., 2001), provider communication skills, disparity in health beliefs between providers and patients, lack of positive reinforcement, and lack of follow-up or continuity of care were all factors contributing to medication nonadherence (Krueger, Berger, & Felkey, 2005). Support from nonphysician health professionals can exert a strong positive influence on motivation for adopting a diabetes meal plan (Rosland, Kieffer, et al., 2008), while suggestions and information from professionals have been shown to have a positive influence on PA adherence (Schmidt, Absalah, et al., 2008). Health-oriented organizations can provide support and guidance for adopting healthy habits through online programs, e.g., the American Heart Association's My Heart. My Life.™ Another program is Heart360 that can facilitate sharing of data with one's primary provider (American Heart Association, 2013). Similarly, other nonprofit and government agencies provide programs that support adoption of a healthy lifestyle.

Models of Behavior Change for Adherence Enhancement

Various models of behavior change have guided interventions to improve treatment adherence. Earlier models included the theory of reasoned action, the theory of planned behavior, the health decision model, and the model of illness behavior, to name a few (Glanz, Rimer, & Viswanath, 2008). Currently, researchers are examining adherence from the perspective of cognitive-motivational models that focus on beliefs, intentions, self-efficacy, self-regulation, and readiness to change. Although these models focus on the individual's cognition and behavior and how they affect and are affected by the environment, they do not view the environment in the detail that the social-ecological model does. The SEM envisions the interdependence of the individual, those making up the person's social network, and the numerous components of the micro- and macroenvironment and how these factors influence the adoption and maintenance of new behaviors. The existing US environment has been termed obesogenic. As we learn increasingly more about the influence of the environment and the barriers it poses to health-related behaviors, e.g., limited access to healthy foods and safe places to engage in physical activity, interventions to support adherence need to incorporate the consumers and stakeholders at multiple levels in the greater community, e.g., drawing from the community and the organizational resources (Mozaffarian, Afshin, et al., 2012).

There is overwhelming evidence that poor lifestyle behaviors, e.g., suboptimal diet, physical inactivity, and tobacco use, are the leading causes of preventable diseases in nearly all countries (Mozaffarian, Afshin, et al., 2012), contributing 40% of preventable morbidity (Vogeli, Shields, et al., 2007). Further, potentiating these health risks, many of these behaviors often co-occur (Johnston, Buscemi, & Coons, 2013). Moreover, the presence of these poor health habits may also impact medication adherence. Thus, improving health behaviors, i.e., adherence to public health guidelines and prescribed treatment is a major component of chronic disease management. The following section describes the intervention strategies that have been demonstrated to be most robust in improving adherence across a wide range of settings that are consistent with the social-ecological model perspective.

Adherence-Enhancing Intervention Strategies

Multiple strategies have demonstrated efficacy to improve treatment adherence; however, greater improvement is observed using a combination of these strategies. Some may overlap, e.g., goal setting is intrinsic to many behavior change interventions, as well as self-monitoring and the provision of feedback. Thus, approaches that combine strategies targeting different components of behavior result in improved outcomes (Table 19.2).

Self-Monitoring The purpose of self-monitoring is to increase awareness of one's behaviors and the context in which the behaviors occur and to identify the barriers to changing a behavior. Self-monitoring also enables recognition of progress made toward a goal (e.g., taking a medication every day or reducing fat intake); thus, it provides feedback and supports self-evaluation, components of Kanfer's self-regulation model (Kanfer, 1990, 1991, 1996). This strategy has been described as the cornerstone of behavioral treatment for weight loss (Burke, Wang, Sevick, 2011) and an important therapy for diabetes patients' blood glucose control (Meetoo, McAllister, & West, 2011). Self-monitoring interventions can be simple, such as pencil-and-paper logs of foods eaten, medications taken, daily weights, steps taken, or distance walked (Burke, Wang, Sevick, 2011; Vasbinder, Janssens, et al., 2013). Self-monitoring is usually accompanied by feedback on the content recorded or when using mobile devices; an algorithm can read the data and deliver a tailored feedback message in real time (Ambeba, Ye, et al., 2015; Burke, Styn, et al., 2012).

Both observational data and evidence from clinical trials demonstrate the importance of self-monitoring in achieving behavior change. As part of an intervention, the frequency, consistency, and fidelity of self-monitoring can impact its effectiveness. In the Women's Health Initiative Dietary Modification Trial (Tinker, Rosal, et al., 2007), independent predictors of dietary change at 1 year included younger age, more education, being optimistic, greater treatment session attendance, and submitting more self-monitoring diaries. Notably, at 3 years, predictors of dietary maintenance were better attendance and submitting more self-monitoring records (Tinker, Rosal, et al., 2007). There is evidence that self-monitoring appears to be an

Table 19.2 Adherence enhancement strategies according to the social-ecological model framework

SEM level	Adherence enhancement strategies	
Intrapersonal	Self-monitoring	Self-monitoring consists of systematically observing and recording one's behavior and is positively related to successful weight control
	Goal setting	Teach participants the importance of setting goals for behavior change, which can lead to enhancement of motivation. They are instructed to set daily and weekly goals for calorie and fat consumption, exercise time, and behavior change, e.g., to eat breakfast daily and alter the content of snacks
	Psychological and motivational interventions	Self-efficacy enhancement strategies are based on the four sources of self-efficacy (mastery, modeling by a credible source, verbal persuasion, and physiological cues) and consist of providing opportunities for goal attainment or mastery, which is based on realistic goal setting
		Motivational interviewing is a directive, patient-centered counseling style for helping individuals examine and resolve ambivalence about changing a behavior. It is through reflective listening that the interviewer helps the patient identify and resolve uncertainty and ambivalence and thus increases self-motivation to change
	Relapse prevention	Teach participants to recognize situations that place them at risk for lapses from their dietary behavior change program. They learn how to use behavioral and cognitive strategies for handling these situations in the future
	Reinforcement	Providing positive feedback on progress made toward the goal of behavior change supports self-motivation by acknowledging accomplishments and instilling confidence in the individual's capability of attaining a goal
	Stimulus control	This strategy recognizes that multiple cues exist in the immediate and distant environment that can trigger behaviors, both healthy and unhealthy. The patient can be counseled to remove those stimuli and to restructure the environment to minimize the willpower needed to overcome strong stimuli
Interpersonal	Social support	Enlisting the support of others in one's environment includes work, social and home settings; sharing goals with those who can support one's efforts in behavior change
	Assertiveness training	The skill of being assertive in social situations that threaten desirable eating and physical activity behaviors is essential to behavior change in weight loss. Participants are taught three communication styles (aggressive, passive, and assertive) and how to use assertive skills in situations that may threaten their ability to meet their eating and physical activity goals
	Modeling	Modeling consists of having an individual observe another person performing the recommended behaviors, e.g., preparing healthy food or exercising
	Cueing	Develop a system of reminders or cues to perform activities that support one's goals, e.g., set out exercise shoes to remind one to walk and fresh vegetables prepared to eat in front of refrigerator
	Ongoing contact	Ongoing contact is through postal or electronic mail, telephone, or Internet to follow up the patients
	Habit building	The basic assumption is that often behavior is automatic and responsive to stimuli, but establishing a relationship between the triggers or stimulus and the target behavior can modify behavior
	Contracting	This strategy involves the person in the plan and specifies the details in writing, e.g., expectations of person, what will be accomplished, the steps that should be taken to reach the goal, and the time frame
	Tailoring the regimen	This approach entails being flexible to accommodate the needs of diverse patients and also being sensitive to cultural issues in recommending dietary change or other behaviors and being sensitive to literacy and financial constraints
	Teamlet model of primary care	An approach involving the clinician and health coach assistants and spending time with the patient before and after the clinical visit and also providing follow-up in the interval between clinic visits
Community	Safe walking areas	Including the community as the intervention setting. The community is primarily defined geographically and is the location in which interventions are implemented. Such interventions may be citywide, using mass media or other approaches, or may take place within community institutions, such as neighborhoods, schools, churches, work sites, voluntary agencies, or other organizations. Various levels of intervention may be employed, including educational or other strategies that involve individuals, families, social networks, organizations, and public policy
	Access to healthy foods	
Organizational	Medical home	Using patient-centered approach, establish partnerships among individual patients, families, and physicians through registries and health information exchange to facilitate patient-centered care
	mHealth interventions	Using mobile devices to collect information, facilitate communication between healthcare professionals and patients, or deliver an intervention, e.g., smartphone, tablets, accelerometers, SenseWear armband, CGMS

effective complement to behavioral intervention strategies in both white and minority populations (Burke, Wang, Sevick, 2011).

Technology Use With the growth of technology, behavior interventions are increasingly delivered through mobile devices, e.g., smartphones (Hutchesson, Rollo, et al., 2015; Turner-McGrievy, Beets, et al., 2013). For example, wearing the SenseWear armband demonstrated significant improvement in PA adherence (Almeida, Wasko, et al., 2011). More recent versions of the SenseWear armband can synchronize the energy expenditure data with an online dietary self-monitoring program that requires recording energy consumption (Chowdhury, Kulcsar, et al., 2012); this program then provides energy balance and feedback to the user. Recently, the armband was used to augment standard behavioral treatment for weight loss with improved outcomes compared to standard behavior treatment alone (Pellegrini, Verba, et al., 2012; Shuger, Barry, et al., 2011). Continuous glucose monitoring system graphs (CGMS) can also be used to teach individuals with diabetes about interactions between diet, PA, medications, and glucose levels; this feedback improved PA adherence in one study (Allen, Fain, et al., 2008). There are numerous advantages including the use of technology, e.g., ability to reach a larger number of people, easy storage of large amounts of information, ease of updating information, ability to provide personalized feedback, convenience for users, ability to reach people who are isolated or feel embarrassed or stigmatized, timeliness of access, and ease of adapting information for specific populations' intervention (Fanning, Mullen, & McAuley, 2012; Katon, Lin, et al., 2010; Reid, Coleman, et al., 2010). Other important features are that technology use can augment care delivered in the clinical setting (Blackburn, 2012) and that individuals can become reengaged with the programs when they are ready (Rao, Burke, et al., 2011).

Nonface-to-Face Approaches Considering the barriers to face-to-face intervention (work schedules, travel, childcare), recent studies have examined the effectiveness of interventions without in-person contact, such as telephone and the use of the Internet (Svetkey, Stevens, et al., 2008; Wing, Tate, et al., 2006). Advantages of Internet-based interventions are that they are available at any time, may provide tailored information and messages, and provide privacy and anonymity (Butryn, Webb, & Wadden, 2011; Kodama, Saito, et al., 2012). However, literacy, language, culture, and limited skills may preclude individuals from utilizing Internet-based interventions (Kaphingst, Zanfini, & Emmons, 2006). The use of the Internet can allow healthcare providers to reach a greater number of individual who could benefit from interventions targeting a healthy diet or regular PA in a cost-effective manner; however, several important questions remain unanswered, e.g., effectiveness of this approach in low-income and minority samples, utility for improving adherence to healthy lifestyle habits, and long-term sustainability (Almeida, Wasko, et al., 2011).

Goal Setting Evidence indicates that setting goals at the initiation of a program is important to achieve the desired behavior change (Pearson, 2012). In most situations, setting specific goals leads to better performance than having no goals or vague goals (Broekhuizen, van Poppel, et al., 2012). Goals may vary by degree of difficulty and specificity; for example, being adherent to once daily medication may be less complex than initiating an exercise program. Setting goals that are specific in outcome, proximal in terms of achievement, and realistic for the person's capability will lead to more successful outcomes (Donaldson & Normand, 2009). It is better to have the goals targeting a behavior the person can observe rather than a physiological outcome and also to have the level of challenge appropriate for the person (Broekhuizen, van Poppel, et al., 2012), e.g., setting a specific, attainable goal such as walking 15 min three times a week and then increase the duration as the person reaches the 15-min goal (Pearson, 2012). Goals that are too simple may be ignored, or overambitious goals are less likely to be attempted than a moderate, achievable goal (Strecher, Seijits, et al., 1995). To reinforce mastery, it is essential to provide regular reinforcement on goal attainment (Pettman, Misan, et al., 2008). Finally, goals need to be set in a collaborative manner with patient and provider. The more the provider engages in collaborative goal setting with the patient, the more likely it increases the patient's trust in the provider, which has been shown to improve patient adherence (Tate, Jackvony, & Wing, 2006). Monitoring progress toward goal attainment can be done through self-monitoring, a tool that can also be used to provide feedback and reinforcement on progress attained toward the goal (Burke, Styn, et al., 2012).

Reinforcement Providing positive feedback on progress made toward the goal of behavior change supports self-motivation by acknowledging accomplishments and instilling confidence in the individual's capability of attaining a goal (Lafata, Morris, et al., 2013). The feedback can highlight consequences of a dietary change such as energy reduction and weight loss, which may motivate individuals to persevere or provide direction for modifying the behavior to achieve the goal (Shuger, Barry, et al., 2011). There is extensive evidence supporting the role of feedback in successful behavior change interventions. Examples include provision of feedback about baseline status which highlights where the need for change is and subsequent assessments provide current information on progress and need for additional change (Bodenheimer & Handley, 2009).

Stimulus Control This strategy recognizes that multiple cues exist in the immediate and distant environment that can trigger behaviors, both healthy and unhealthy. Self-monitoring can help identify the triggers that lead to undesirable behaviors. Using this information, the patient can be counseled to remove those stimuli and to restructure the environment to minimize the willpower needed to overcome strong stimuli, e.g., place unhealthy foods where they are not readily visible (Foreyt & Goodrick, 1993), place exercise equipment in a place that is easy to access, lay out exercise clothes and shoes before going to bed (Epstein, Paluch, et al., 2004), and have morning medications near the coffee maker or bedtime medications near the alarm clock (Reeder, Franklin, & Bramley, 2007).

Social Support Counseling the individual to enlist the support of others in their efforts at behavior change can help ensure successful outcomes. This may include family and friends but also coworkers and the community, individuals who can be supportive allies at times of setbacks and success (Tamers, Beresford, et al., 2011). Parental support is positively associated with PA among children (Heitzler, Martin, et al., 2006) and adolescents (Peterson, Lawman, et al., 2012). Social support has been shown to be important in most types of behavior change and also can be instrumental in medication adherence (Kripalani, Yao, & Haynes, 2007).

Ongoing Contact The evidence supporting the decline in adherence as provider contact is decreased or withdrawn is voluminous (Acharya, Elci, et al., 2009; Artinian, Fletcher, et al., 2010; Forsman, Nordmyr, & Wahlbeck, 2011; Kottke, Battista, et al., 1988; Norris, Lau, et al., 2002; Wadden, West, et al., 2009; Wing & Hill, 2001; Wing, Tate, et al., 2006). Ongoing contact through postal or electronic mail, telephone, or the Internet has consistently demonstrated improved adherence (Marcus, Napolitano, et al., 2007; Wing, Tate, et al., 2006). Advancements in technology are moving this strategy forward in many important ways, particularly in terms of ease of use, access, cost, and convenience. Mobile devices support ongoing communication in real time, which can provide feedback and reinforcement to the individual on progress made or direction for change, e.g., several studies have implemented text messaging as a means to provide reminders to take medications, exercise, or follow a healthy eating plan (Patrick, Raab, et al., 2009; Shapiro, Koro, et al., 2012). Ongoing contact through community physicians and pharmacists or the use of handheld technology leads to improved adherence to medication taking (Heron & Smyth, 2010), adoption of healthy lifestyle habits (Wing, 2010), and weight loss maintenance (Perri, Limacher, et al., 2008; Svetkey, Stevens, et al., 2008). Accountability plays a role in the ongoing contact, a factor that patients identify as important for sustained adherence. Another approach to ongoing contact is the provision of healthy foods and access to PA facilities in the immediate neighborhood, resources that reinforce the healthful message.

Habit Building The stimulus control model is the underlying basis for this strategy. The basic assumption is that often behavior is automatic and responsive to stimuli and behavior can be modified by establishing a relationship between the trigger or stimulus and the target behavior. This strategy can be effective when a person is in a new environment, e.g., traveling. In this situation, it would be helpful to pair the behavior (taking a medication) with an established habit (brushing teeth) and place the medication bottle with the toothpaste.

Contracting This strategy involves the person in the plan and specifies the details in writing, e.g., expectations of person, what will be accomplished, the steps that should be taken to reach the goal, and the time frame. The contract needs to specify a behavior rather than the health outcome. If a contingency reward is included, it should be reinforcing to the healthier behavior.

Problem-Solving The standard approach to problem-solving entails five steps: identification or acknowledgment of a problem, defining the problem, generating potential solutions, and selecting one solution to resolve the problem, which is completed by evaluating the success of the problem-solving attempt (D’Zurilla & Goldfried, 1971). Use of this strategy is central to sustaining behavior change as the individual will encounter numerous barriers to sustaining healthy behavior changes (Allen, Whittemore, & Melkus, 2011; Chisholm, Atkinson, et al., 2011). Anticipating high-risk situations and problem-solving in advance can help a person prepare for an upcoming event, such as a holiday gathering. Having the person practice by actively engaging in role-playing can enhance successful outcomes.

Relapse Prevention Lapses or slips will occur during the course of any behavior change program. The work of Marlatt and Gordon (1980) demonstrated that slips or lapses are natural occurrences in the process of behavior change. The relapse prevention strategy makes a person aware that it is normal to deviate episodically from the program (Wells & Wells, 2007). It is helpful to teach individuals to recognize past situations that have placed them at risk for lapse and how to use behavioral and cognitive strategies for handling these situations (Burke, Dunbar-Jacob, et al., 2005). Because of the high rate of recidivism following intentional weight loss, this strategy is an important component of standard behavioral treatment for weight loss. Studies have demonstrated that individuals begin to lapse and regain weight after 6 months of treatment (Burke, Ewing, et al., 2011; Burke, Styn, et al., 2012; Wing, Tate, et al., 2006), which is similar to the lapse rates for exercise programs (Conroy, Simkin-Silverman, et al., 2007).

Tailoring the Regimen This strategy recognizes that not all individuals can meet the same goal or follow the same program to achieve their goals; it acknowledges what is realistic for the patient to achieve behavior change taking into consideration cultural diversity, socioeconomic status, preferences, support systems, and resources (Hawkins, Kreuter, et al., 2008). This approach entails being flexible to accommodate the needs of diverse patients and also being sensitive to cultural issues in recommending dietary change or other behaviors and being sensitive to literacy and financial constraints (Radhakrishnan, 2012). This strategy calls upon the social-ecological model and its implications. Numerous papers have addressed the diverse needs of the patient population in promoting behavior change and treatment adherence and the need for tailored approaches

(Almeida, Wasko, et al., 2011; Fleury & Lee, 2006; Stuart-Shor, Berra, et al., 2012). Current technology facilitates the development of sophisticated tailored algorithms that can collect personalized information and provide individualized feedback to individuals (Burke, Styn, et al., 2009; Lustria, Cortese, et al., 2009).

Use of External Cognitive Aids External aids include an array of reminders to enhance appointment adherence. Today, more of these reminders use technology, such as emails and text messages to remind individuals of appointments; however, the use of phone calls continues to be a primary form of appointment reminders (Forjuoh, Reis, et al., 2007). In clinical trials, a letter is often sent if a person has missed more than one treatment session (Burke, Choo, et al., 2006).

Other Strategies Unique for Medication Adherence Other strategies that have been shown to positively influence medication adherence included drug education, written instructions, special medication packaging, medication side effect monitoring, and dose modification (Conn, Hafdahl, et al., 2009). Intervention strategies targeting the healthcare system level for medication adherence have included reducing medication costs, providing free medications, and a multifaceted intervention incorporating collaborative care between pharmacists and primary care physicians (Ho, Lambert-Kerzner, et al., 2014). A study by Chisholm et al. revealed that 1 year of free medications did not improve medication adherence, as patients became nonadherent after 10 months, even when there was no charge for the medications (Chisholm, Vollenweider, et al., 2000). However, Gibson (Gibson, Wang, et al., 2011) found that a value-based insurance design program showed promise for cost savings for the insurance company by reducing patient cost sharing for asthma, hypertension, and diabetes drugs. The delivery setting of the medication adherence interventions also matters. While a meta-analysis (Conn, Hafdahl, et al., 2009) did not find the intervention delivery setting (home or clinic) to be a significant predictor of medication adherence, a pharmacist-led Web-based home monitoring program resulted in higher medication adherence (Martin, O'Neil, & Pawlow, 2006).

Psychological and Motivational Interventions *Self-efficacy enhancement* and *motivational interviewing* are covered in this section, strategies that have a strong theoretical basis. Strategies for enhancing self-efficacy are based on the four sources of self-efficacy (mastery, modeling by a credible source, verbal persuasion, and physiological cues) and consist of providing opportunities for goal attainment or mastery, which is based on realistic goal setting (Bandura, 1997). Providing feedback and reinforcement for progress can be conducted through a review of the self-monitoring record (Kanfer, 1970), conveying to the person that he or she is capable of performing the behavior through verbal persuasion and interpreting symptoms of physiologic response, such as reduced fatigue and diminished symptoms from exercising following weight loss and regular exercise (Bandura, 1997). Research has provided evidence across multiple behavior domains that increased self-efficacy is associated with improved adherence to healthy food choices, self-management in type 2 diabetes, and sustaining weight loss maintenance strategies (Bandura, 1998; Chapman-Novakofski & Karduck, 2005; Di Noia, Contento, & Prochaska, 2008; Di Noia & Prochaska, 2010; Warziski, Sereika, et al., 2008). Modeling, one of the four sources of self-efficacy enhancement, consists of having an individual observe another person performing the recommended behaviors, e.g., preparing healthy food or exercising. This strategy can be easily implemented by the use of in-person or video cooking demonstrations and personal PA training. The key is having credible individuals demonstrate the behavior; having the individual practice immediately afterward is an excellent way to reinforce the learning (Yanek, Becker, et al., 2001).

Motivational interviewing (MI) is a patient-centered counseling style for helping individuals examine and resolve ambivalence about changing a behavior (Rollnick, Miller, & Bulter, 2008). This strategy cannot always be used in its fullest extent in settings where time and possibly clinician expertise are limited; however, it is possible to follow the patient-centered focus and employ the four core principles: express empathy, develop a discrepancy, roll with resistance, and support self-efficacy. It is through reflective listening that the interviewer helps the patient identify and resolve uncertainty and ambivalence and thus increases self-motivation to change (Rubak, Sandbaek, et al., 2005). Behaviors that characterize the delivery of MI include seeking understanding of the person's perspective through reflective listening, expressing acceptance; eliciting and selectively reinforcing the person's own self-motivational statements, expressing recognition of stated problems, concerns, wishes, intention, and ability to change; observing the person's degree of readiness to change; ensuring that resistance is not generated by moving ahead of the person; and confirming the person's freedom to choose and self- direct the behavior. Motivational interviewing has been demonstrated to be effective across an array of health conditions and population groups, including treatment adherence and study retention (Smith West, DiLillo, et al., 2007), increasing physical activity (Hardcastle, Taylor, et al., 2008), improving medication adherence among hypertensive blacks (Ogedegbe, Schoenthaler, et al., 2007), and insuring minorities postcoronary stent placement (Palacio, Uribe, et al., 2014). A systematic review found that phone-based motivational interviewing shows promising evidence in promoting medication adherence (Teeter & Kavookjian, 2014). An integrative review also found that combing motivational interviewing with cognitive behavioral interventions led to improved medication adherence (Spoelstra, Schueller, et al., 2014). Training in the application of motivational interviewing strategy is essential.

Future Directions for Enhancement of Long-Term Adherence

Patient-Centered Medical Home (PCMH) PCMH is an emerging model for improving healthcare quality in the USA (Chowdhury, Kulcsar, et al., 2012). This model may provide an ideal way to integrate behavioral health and primary care services, particularly for persons with chronic conditions such as diabetes (Bojadzievski & Gabbay, 2011) and psychiatric disorders (Amiel & Pincus, 2011). At the organizational level, the PCMH includes several resources, e.g., evidence-based algorithms and care plans, electronic medical records, and referral to other community-based resources for patients (Marrero, Ard, et al., 2013). The central characteristic of the PCMH is the interdisciplinary, collaborative team, a key component of the PCMH. Reflecting an ecological perspective, the interdisciplinary team functions as an organizational-level intervention that influences the paired interactions of clinicians and patients (Marrero, Ard, et al., 2013). Evidence has demonstrated that patients in the medical home reported better care experiences, e.g., patient activation and involvement (Reid, Coleman, et al., 2010), were more likely to have one or more adjustments of insulin and antihypertensive medications (Katon, Lin, et al., 2010), and demonstrated increased adherence to antidepressant medication (Gilbody, Bower, et al., 2006).

New Models of Self-Management The Chronic Care Model (CCM) transforms the daily care for patients with chronic illnesses from acute and reactive to proactive, planned, and population based (Wagner, Austin, et al., 2001). The premise of the model is that quality chronic care is delivered by an integrated system involving six essential elements: health system leadership and support, community resources, self-management support, delivery system design, decision support, and clinical information systems (Coleman, Austin, et al., 2009). Bodenheimer et al. reported improved adherence resulting from their Chronic Care Model, an approach to self-management of chronic disorders (Bodenheimer & Laing, 2007; Bodenheimer, Lorig, et al., 2002). The model of care delivery involves the clinician along with health coach assistants who work with the patient prior to and after the clinical visit and also provide follow-up between clinic visits. The health coach engages the patient in collaborative goal setting and develops an action plan for the regimen that needs to be addressed (Chen, Thom, et al., 2010). Using a patient-centered approach, Calvert and colleagues found that a combination of enhanced inhospital counseling sessions, addressing adherence barriers, communication with community pharmacists and physicians, and continued adherence assessment by community pharmacists resulted in improved medication adherence after hospital discharge (Calvert, Kramer, et al., 2012).

Delivery of Multicomponent Interventions In contrast to single strategies, the majority of the clinical trials evaluate multicomponent interventions, e.g., the use of self-monitoring and self-efficacy enhancement. Today, multicomponent programs may include combinations of technology support or use of media (Burke, Styn, et al., 2012), group- and/or individual-based delivery strategies, telephone-delivered intervention sessions, or delivery of text messages (Patrick, Raab, et al., 2009). In most intervention studies, there are several components to the intervention, e.g., various behavioral strategies are implemented and may include goal setting, , feedback, social support, and problem-solving. The evidence suggests that the use of more than one strategy for all behaviors results in improved adherence outcomes (Almeida, Wasko, et al., 2011; Haynes, McDonald, & Garg, 2002; Hedegaard, Kjeldsen, et al., 2014). For medication adherence, the interventions with the strongest evidence include education combined with behavioral interventions (Dean, Walters, & Hall, 2010; Olson, Gaffney, et al., 2009; Osterberg & Blaschke, 2005; Stewart, George, et al., 2014). Nevertheless, a recent Cochrane review on medication adherence interventions revealed that multicomponent intervention studies generated the lowest level of bias, and while being effective and complex, these studies did not generate a large improvement in adherence or clinical outcomes. A suggestion for future interventions included targeting long-term feasibility and examining patient-centered clinical outcomes (Nieuwlaat, Wilczynski, et al., 2014).

Summary and Recommendations

Several factors may influence a person's ability to adopt and sustain new behaviors. When considering adopting a new behavior, the person needs to evaluate the anticipated benefits, which need to compare favorably to their current situation, and they need to have positive expectations regarding future outcomes. The decision to maintain a behavior is dependent, at least partially, on whether the outcomes achieved with the new behavior are sufficiently desirable to sustain the behavior. Most individuals have clear expectations about what a new lifestyle will provide; if their experiences do not meet those expectations, they will be dissatisfied and less motivated to maintain it, particularly in environments that often are not supportive of a healthy lifestyle.

Patient-Provider Interactions: Promoting Effective Behavior and Providing Optimal Care

Julia R. Van Liew, Jamie A. Cvengros,
and Alan J. Christensen

Patient-Provider Interactions: Meeting Patients Where They Are to Provide Optimal Care

Over the last several decades, there have been dramatic changes in patient-provider relationships, with a movement toward more patient-centered care and increased expectations for healthcare providers to play a central role in promoting patients' effective health behavior change. The overarching change has been a movement along a spectrum from paternalistic (or doctor-centered) to patient-centered care (see Fig. 20.1). With these changes, there has been increasing interest in the relationship between patient-centered care and healthcare outcomes. The present chapter reviews the evolution of the patient-provider relationship; the methods used to assess, understand, and modify the relationship; and the various ways patient-provider encounters may impact patient-oriented outcome variables such as satisfaction with care, adherence to treatment recommendations, and clinical outcomes.

Evolution of the Patient-Provider Relationship

Paternalistic Model of Healthcare

Rooted in the Hippocratic tradition, the patient-physician relationship, or more broadly patient-provider relationship, has historically been a paternalistic one. The paternalistic patient-provider relationship was based on the "expert role" of the provider and assumed that the provider was responsible for making healthcare decisions in the patient's best interest (Parsons, 1951; Pellegrino & Thomasma, 1988). The patient was expected to be passive in decision-making and trust in their provider to make appropriate healthcare decisions, even if these decisions were occasionally in contrast to the preferences of the patient. While this type of patient-provider relationship was clearly an autocratic one, it was not necessarily problematic. The paternalistic patient-provider relationship allowed the patient to assume a "sick role" and relived the patient of the "burden" of making healthcare decisions (Childress, 1982). While there is no standard

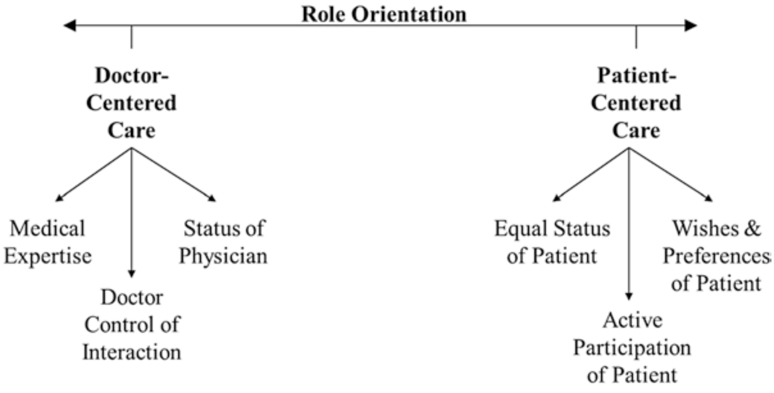

Fig. 20.1 Spectrum of patient-provider relationships

definition of the paternalistic patient-provider relationship, it is traditionally characterized by two factors: asymmetrical decision-making and a biomedical model of illness.

First, the paternalistic patient-provider relationship is characterized by decision-making that is directed by the provider (i.e., doctor-centered). The provider is entrusted to make decisions regarding diagnostic testing and treatment planning based on his or her professional expertise. For example, in the case of a patient with breast cancer, the decision to pursue surgical intervention, chemotherapy, radiation therapy, or a combination treatment would be at the discretion of the physician, based on his or her assessment of the patient's illness. In the doctor-centered model of decision-making, information regarding the various treatment options (e.g., side effects of each treatment, risks for treatment complications, and chances of remission) would not necessarily need to be presented to the patient in order for the patient to choose a treatment plan. Instead, the provider may present only the necessary amount of information about treatments to reassure the patient that the treatment plan is in the patient's best interest. One presumed benefit of doctor-centered decision-making is that patients are not overwhelmed by healthcare information and are not required to make decisions based on their limited medical knowledge and perhaps in times of emotional distress, such as immediately after receiving a diagnosis of cancer (Childress, 1982).

Second, the paternalistic model of healthcare is also associated with a biomedical model of illness. The reductionistic, biomedical model of illness assumes that illness is caused by a biological factor (e.g., virus, bacteria, genetic mutation) that can be treated using a medical intervention (e.g., medications, surgical interventions, radiation). The biomedical model generally ignores other factors that may contribute to illness, such as social and emotional factors. In the paternalistic model, healthcare decisions are often driven by a focus on ridding the body of an identified illness, without full appreciation of the patient as a "whole person" and consideration of the familial, social, behavioral, and emotional factors that may impact disease development, disease management, and treatment outcomes.

Patient-Centered Care: An Alternative to Paternalism

Over the last several decades, the standard model of healthcare has moved away from paternalism, or doctor-centered care, in favor of an alternative patient-centered model (see Fig. 20.1). A review of videotaped patient-physician interactions from 1986 to 2002 found that physicians engaged in significantly more information sharing behavior in 2002 compared to 1986 (Bensing, Tromp, et al., 2006). It is notable that in this study, while information sharing increased, process-oriented talk decreased. Specifically, physicians engaged in less talk about concern for their patients and less partnership building, which suggests that the movement from doctor-centered to patient-centered care has not occurred in a standard or uniform way. In 2005, the National Healthcare

Quality report found that patient-centered care was "always" or "usually" present in 89% of healthcare encounters (Agency for Healthcare Research and Quality, 2005). Patient-centered care has also come to represent a measure of quality care—in 2001, an Institute of Medicine report identified patient-centered care as one of the six aims of healthcare (National Institute of Medicine, 2001).

This rise in patient-centered care is likely due to several factors. First, with the ratification of the Patient Self-Determination Act (1991) and the Doctrine of Informed Consent, the ability for providers to make autonomous decisions has been reduced. Providers are now required to give patients sufficient information regarding treatment options and risks and benefits of treatments in order for patients to give informed consent for diagnostic and treatment procedures (Briss, Rimer, et al., 2004). Second, it has also been proposed that the rise in patient-centered care has been influenced by the development of direct-to-consumer advertising by pharmaceutical companies. In a recent survey, 35% of patients reported that they had asked their provider for more information about a drug because of an advertisement, and 19% had specifically asked for a prescription for an advertised drug (Wilkes, Bell, & Kravitz, 2000). Furthermore, when asked what they would do if their provider refused to prescribed the requested drug, 46% said they would be disappointed, 25% stated they would try to change their provider's mind, and 15% said they might switch providers (Wilkes, Bell, & Kravitz, 2000). Finally, it has been suggested that the changing demographics in the United States have contributed to the increased interest in patient-centered care. As more adults are living with chronic illnesses that require frequent patient-provider encounters and increased self-management, paternalistic or doctor-centered models of illness have become less applicable, in favor of patient-centered models of illness (Lambert, Street, et al., 1997).

Although there has been increasing interest in the provision of patient-centered care, a standard definition of this concept has not been established. Early work described patient-centered care as understanding an individual patient's perception of his or her work and illness (Balint, 1957; Roter & Stewart, 1989). Others have described patient-centered care as the opposite of doctor-centered (or paternalistic) care (Bensing, Tromp, et al., 2006). Lambert et al. (1997) posited that patient-centered care differs from paternalistic care in two key ways: a focus on information sharing and a focus on the socioemotional aspects of healthcare.

A review by Mead and Bower (2000) proposed perhaps the most comprehensive definition of patient-centered care and identified five key dimensions that distinguish patient-centered care from biomedical or doctor-centered care. Patient-centered care uses a biopsychosocial model of illness, focuses on the "patient as a whole person," emphasizes shared decision-making, and highlights the therapeutic alliance between patient and provider. Though sometimes overlooked, it also considers the "doctor as a whole person." Each of these aspects is explained in further detail below.

Biopsychosocial Model of Illness Patient-centered care utilizes a biopsychosocial model of illness. Engel (1977) proposed that illness develops as interaction of biological (e.g., a bacteria, virus), psychological (e.g., coping skills, stress), social (e.g., marital status, social support), and cultural (e.g., socioeconomic status, educational level) causes. In the biopsychosocial model of illness, these multiple causes of illness are identified and addressed as targets of treatment (Engel, 1977). For example, when treating a patient with hypertension, a provider utilizing the biopsychosocial model of illness would consider the way that the patient's current depressed mood, increased marital stress, and limited literacy may impact his ability to manage his hypertension. It has been suggested that the utilization of this biopsychosocial model of illness is the fundamental component of patient-centered care.

Patient as a Whole Person Patient-centered care focuses on the patient as a whole person (Balint, 1957), meaning that consideration is paid to the personal meaning or impact of an illness. The impact of a particular diagnosis may vary significantly between patients based on their personal and family histories, daily activities, and understanding of the illness. For example, one 35-year-old woman newly diagnosed with stage 1 breast cancer may feel very hopeful about her prognosis and treatment options if she had a sister with a history of cancer who completed treatment with few side effects and has been in remission for 5 years. However, another patient with a similar breast cancer may be devastated by her diagnosis if her mother died of cancer after a prolonged and difficult treatment process. Seeing the "patient as a person" also includes consideration of how a diagnosis and treatment may impact a patient's self-concept. For example, patients may experience feelings of embarrassment when diagnosed with a psychological disorder like depression and experience decreased self-esteem regarding decreased sexual function, a common symptom of depression and side effect of antidepressant medications.

Shared Decision-Making A third aspect of patient-centered care is shared decision-making and shared power between patient and provider. This dimension of patient-centered care represents a significant difference from the traditional paternalistic relationship, which was characterized by a power differential between the "expert" provider and the "uninformed" patient (Parsons, 1951). Several definitions of shared decision-making have been proposed, but perhaps the most comprehensive is the definition offered by the United States Preventive Services Task Force (USPSTF). According to the USPSTF, a shared decision-making process is one in which a patient (1) understands the diagnosis and the seriousness of the diagnosed condition, (2) understands the treatment options and the risks and benefits of the various options, (3) evaluates the options with regard to their personal values and preferences, and (4) participates in decision-making at the level at which he or she is comfortable. Shared decision-making requires input from both patient and provider during all stages of care throughout assessment, diagnosis, treatment, disease management, and relapse prevention. It also requires that the physician provides patients with information about the diagnosis and treatment options and requires that patients take an active role in eliciting necessary information (e.g., asking the questions they need answered in order to make treatment decisions) and making their provider aware of their preferences and values that impact their treatment planning.

Therapeutic Alliance Patient-centered care is characterized by an interest in the therapeutic alliance between patient and provider. Borrowing from psychotherapy literature, Rogers (1961) posited that providers need to express (1) empathy or understanding of a patient's personal emotional experience of illness, (2) congruence or genuine expression of their experience of the interaction, and (3) unconditional positive regard, that is, a positive evaluation of the patient as a person, despite the possibility of negative evaluation of a patient's actions, such as poor adherence to treatment. Rogers argued that these conditions lead to development of a positive therapeutic alliance, which is considered *necessary* and *sufficient* to elicit change in psychotherapy. With respect to eliciting healthcare changes, however, a positive patient-provider therapeutic alliance may encourage patients to take a more active role in their healthcare and increase adherence to treatment recommendations. It is notable that many interventions to improve patient-centered care are aimed at increasing provider communication skills consistent with Rogers' theory (e.g., active listening, empathic reflection of emotions, eliciting patient experience), in an effort to improve therapeutic alliance.

Doctor as a Whole Person The final aspect of patient-centered care includes consideration of the "doctor as a whole person." Just as a patient's participation in healthcare is influenced by his or her psychological and social state, a provider's participation is likewise influenced by his or her psychological and social state. Providers are subject to the same biases, subjectivity, and emotional reactions as patients. For example, a provider may be more likely to engage in shared decision-making with a patient whom they perceive as being collaborative, displaying more positive emotions, and having good communication skills (Street, Gordon, & Haidet, 2007). However, that same provider may be less likely to engage in shared decision-making with a patient whom they perceive as having poorer communication skills, displaying more negative emotions, or being more contentious (Street, Gordon, & Haidet, 2007).

Assessing Patient-Provider Relationships

Patient-provider relationships have generally been assessed using questionnaires (i.e., patients' reports on the type of interaction between patient and provider) or observation (i.e., coding of videotaped encounters). Although direct observation is likely to provide the most accurate categorization of the patient-provider relationship, it is often impractical given cost, equipment, and time constraints. However, questionnaire methods are also likely to yield important information about patient *perception* of and *satisfaction* with patient-provider interactions in a more cost-effective and time-efficient manner. As there is no standardized definition of patient-centered care, there also appear to be no standardized measures of patient-centered care. The following section will briefly review a few of the questionnaires and observational coding schemes used to assess patient-provider relationships.

Interpersonal Process of Care (IPC) Questionnaire (Stewart, Napoles-Springer, & Perez-Stable, 1999) The original IPC scale is a 41-item scale that assesses three domains consistent with patient-centered care: general communication, decision-making, and interpersonal style. Scoring allows for computation of 13 subscale scores across these three domains. General communication subscales include general clarity, explanation of condition, explanation of processes, explanation of self-care, explanation of medications, elicitation of patient concerns and responses, and empowerment. Decision-making subscales include responsiveness to patient preferences and consideration of patient's ability to comply. Interpersonal style subscales include friendliness and courteousness, respectfulness, discrimination, and emotional support. The original form of the IPC was developed and validated with an ethnically and racially diverse low socioeconomic status sample; however, a revised 29-item form and an 18-item short form have been developed for use across ethnic, racial, and socioeconomic status groups (Stewart, Napoles-Springer, et al., 2007).

Health Care Climate Questionnaire (HCCQ) (Williams, Grow et al., 1996) Rooted in self-determination theory, the HCCQ assesses patient perceptions of autonomy support from their healthcare provider. According to self-determination theory, autonomy is one of the fundamental needs that underlie motivation. In the case of healthcare, meeting the need for autonomy is necessary to promote patient motivation to participate in healthcare and engage in self-management of illness, consistent with the information sharing and shared decision-making aspects of patient-centered care. The long form of the HCCQ is 15 items and the short form is 6 items. Sample items include "I feel that my physician has provided me with choices and options" and "My physician listens to how I would like to do things." The HCCQ has been used to assess perceived autonomy support (and patient-centered care) in a variety of patient populations, including patients in weight management treatment, patients in smoking cessation treatment, and patients with diabetes (Williams & Deci, 2001; Williams, Freedman, & Deci, 1998; Williams, Rodin, et al., 1998; Williams et al., 1996).

Patient Assessment of Chronic Illness Care (PACIC) Scale (Glasgow, Wagner, et al., 2005) The PACIC was designed as a brief measure to determine if patients with chronic illnesses were receiving care that was consistent with the Chronic Care Model of illness (Wagner, Austin, & Von Korff, 1996). It was designed as a patient version to complement the Assessment of Chronic Illness Care questionnaire, a tool used by clinicians to evaluate their practices and improve quality of care. Specifically, the 20-item PACIC assesses patient perceptions of care in five domains: patient activation/involvement, delivery system/decision support, goal setting/tailoring, problem-solving, and follow-up/coordination. The PACIC was validated in several chronic illness populations, including patients with hypertension, diabetes, arthritis, pain, asthma, and depression, and was found to have adequate validity and reliability (Gensichen, Serras, et al., 2010; Glasgow, Whitesides, et al., 2005; Schmittdiel, Mosen, et al., 2008).

Bales Process Analysis System (Bales, 1950) Growing out of research on social interaction and small groups, the Bales method has been adapted to measure verbal interactions between patients and providers. Complex verbal interactions are divided into individual "units" of interaction, which are roughly equivalent to a simple sentence. Each of these units is then coded into one of 12 mutually exclusive categories. These 12 categories have been grouped into six affectively neutral categories and six affectively charged (either positive or negative) categories (Roter & Hall, 1989). Affectively neutral categories include task-related behaviors such as giving information and giving suggestions, whereas affectively charged categories reflect socioemotional behaviors such as agreeing or disagreeing with the patient or showing tension in the interaction. The Bales system has been widely used to assess and categorize provider behavior and to examine the relationship between provider behavior and outcomes, such as patient adherence with medications and patient satisfaction (Davis, 1968; Stewart, 1984).

Roter Interaction Analysis System (RIAS) (Roter & Larson, 2002) The RIAS is currently the most widely used system for coding provider behavior in medical encounters and includes assessment of 28 discrete categories of behavior. The various behaviors have been conceptually divided into two domains: a socioemotional domain and a task-oriented domain. The socioemotional domain is broadly defined as "affective" behavior and includes specific behaviors such as engaging in social conversation, making statements of concern, providing reassurance, and demonstration of empathy. The task-oriented domain is broadly defined as "behaviors that define the role of the physician" and "comprise the 'expertness' for which a physician is consulted" (Roter & Hall, 1989). This domain includes behaviors such as giving instructions, asking closed- and open-ended questions, and providing counsel. The RIAS system has been used to code interactions across countries, medical settings (e.g., pediatric medicine, emergency medicine, primary care), and patient diagnoses (e.g., asthma, hypertension, diabetes) (Hampson, McKay, & Glasgow, 1996; Roter & Ewart, 1992; Roter & Larson, 2002; van Dulmen, Verhaak, & Bilo, 1997; Wissow, Roter, et al., 1998; Wissow, Roter, & Wilson, 1994).

Four Habits Coding Scheme (4HCS) (Krupat, Frankel, et al., 2006) The 4HCS is a tool for assessing physician behavior in accordance with the Four Habits Model utilized to teach communication skills. The Four Habits Model encourages physicians to invest in the beginning of the encounter (e.g., show familiarity with patient medical history, greet patient, elicit patient agenda), elicit the patient's perspective (e.g., patient's understanding of the problem, goals for visit), demonstrate empathy (e.g., encourage patient emotions, accept patient feelings), and invest in the end of the encounter (e.g., offer rationale for tests, involve patient in decisions, encourage questions). The 4HCS includes 23 items that assess these core skills and includes instructions for coding both verbal and nonverbal physician behaviors. The 4HCS differs from other coding schemes in that the coder distinguishes between levels of performance in each of the domains, rather than simply providing frequency counts of observed behaviors. The 4HCS has been found to have adequate reliability and good convergent validity with other scales, such as the RAIS (Krupat, Frankel, et al., 2006).

Provider Behavior Questionnaire (PBQ) (Cvengros, Christensen, et al., 2009) The PBQ was developed to assess patient perceptions of provider behavior in three domains: information sharing and shared decision-making, patient self-management of illness, and provision of socio-emotional support. These domains were chosen to correspond to patient preferences for healthcare, as measured by the "Behavioral Involvement" subscale of the Krantz Health Opinion Survey (Krantz, Baum, Wideman, 1980) and the "Sharing" and "Caring" subscales of the Patient-Practitioner Orientation Scale (Krupat, Rosenkranz, et al., 2000) (these scales are discussed in detail later). Patients answer the nine PBQ items (three items per domain) using a true/false format, rather than a Likert format, to achieve provider behavior ratings that are as objective as possible. The PBQ was developed as a proxy for direct observation of the patient-provider interaction when this method is impractical or not feasible. The PBQ has been shown to have acceptable reliability and validity (Cvengros, Christensen, et al., 2009).

Factors Associated with Patient-Centered Care

Physician Correlates of Patient-Centered Care

Using various measurement methods, researchers have tried to identify which providers are more likely to utilize patient-centered care. Unfortunately, the data are limited and have yielded inconsistent findings. In a study of communication patterns between patients and physicians, physicians who tended to use a more biomedical model of communication (i.e., more physician-directed and focused on physical symptoms) were younger than those who tended to use a more psychosocial model of communication (Roter, Stewart, et al., 1997). In contrast, another study found that younger physicians were more likely to engage in shared decision-making, a behavior consistent with a more patient-centered approach to communication (Young, Bell et al., 2008). Roter et al. (1997) also found that male physicians were more likely to use a more biomedical model of communication, and female physicians tended to use a more psychosocial model of communication. A meta-analysis of almost 30 studies confirmed this gender effect on physician communication—female physicians were more likely to engage in partnership building, psychosocial question asking, and psychosocial counseling than male physicians (Roter, Hall, & Aoki, 2002).

Physician communication style is also influenced by observed or perceived patient characteristics. Johnson, Roter, Powe, and Cooper (2004) found that providers engaged in less patient-centered care with black patients compared to white patients. Cené, Roter, Carson, Miller, and Cooper (2009) found that this racial effect may be compounded by poor adherence with treatment, such that black patients who also had poorly controlled hypertension received particularly less rapport building and less psychosocial communication from their physicians. Finally, Street and colleagues (2007) found that providers were more likely to engage in patient-centered communication with patients they perceived to be "good historians," patients they perceived to be active participants in care, and patients they believed would be more adherent with treatment. These authors suggested that there may be a reciprocal effect between patient-provider communication and outcomes, such that good patient-provider communication may lead to positive outcomes, which may in turn lead to improved patient-provider communication.

Providers' engagement in patient-centered care may also depend on their perception of individual patients' interest in this type of care. As such, a systems or interactional approach may be a helpful framework for studying and promoting patient-centered care. For example, patients could be trained to initiate a more active role and draw out more patient-centered care from their providers. Patients with type 2 diabetes who received a brief, personalized training session to assist with formulating a strategy for shared decision-making immediately preceding a clinic visit were twice as effective in obtaining information from their physician during the visit than patients who received educational materials (Greenfield, Kaplan, et al., 1988). Moreover, these patients had better diabetes adherence (lower hemoglobin A1c levels) and fewer functional limitations. Interventions that change patients' behavior in clinical encounters can accordingly change providers' behavior in response.

Impact of Patient-Centered Care on Outcomes

Patient Satisfaction With the growing interest in patient-centered care, researchers have also begun to examine the impact of patient-centered care on outcomes. One of the most common outcomes studied is patient satisfaction with care. While this outcome may be considered a subjective or "soft" outcome, patient satisfaction continues to be an important patient-centered outcome. Indeed, patient satisfaction has been identified as a marker of quality care by both the Joint Commission on Accreditation of Healthcare Organization (JCAHO) and the United States National Center for Health Research and Development. Also, health systems are very concerned about patient satisfaction, as it is related to their overall position and market share in their communities.

Roter et al. (1997) audiotaped 537 interactions between patients and physicians and coded them into five communication patterns using the RAIS coding scheme. Interactions were categorized along the dimension of doctor-centered to patient-centered care. Patient satisfaction was highest among patients whose interactions were characterized as "psychosocial," where the physician spent equal time on psychosocial and biomedical talk and was positive and accepting of patient input, which reflects a more patient-centered approach to care. Similar results were found when assessing patient-centered care using survey methods. In a study of over 4000 patients receiving care for a chronic condition (e.g., diabetes, chronic pain, coronary artery disease), those who perceived their care to be patient-centered using the PACIC (described earlier) were twice as likely to rate their satisfaction with healthcare as "very high" to "best healthcare possible" (Schmittdiel, Mosen, et al., 2008). In pediatric medicine, parents' perceptions of greater patient-centered care have also been associated with greater satisfaction with their child's healthcare (Wanzer, Booth-Butterfield, & Gruber, 2004).

Despite the positive results using observational methods, intervention studies with the goal of promoting a more patient-centered patient-provider interaction have yielded equivocal results in terms of patient satisfaction. Kinmonth, Woodcock, Griffin, Spiegal, and Campbell (1998) conducted a randomized trial comparing patient-centered care to treatment as usual among patients with type 2 diabetes. Patients in the intervention group received care from nurses and physicians who had received up to a day and a half of specialized training in providing patient-centered care. Specific skills included education and practice of active listening and facilitating behavioral change (Kinmonth, Woodcock, et al., 1998). At one-year follow-up, patients in the intervention condition were more likely to report excellent communication with their physicians and greater satisfaction with care. Martin, DiMatteo, and Lepper (2001) compared outcomes for patients in an experimental inpatient unit that emphasized patient-centered care to patients in other traditional units in the same hospital. Patients in the patient-centered care unit reported significantly greater satisfaction with care than patients receiving treatment as usual (Martin, DiMatteo, and Lepper, 2001). On the contrary, in a study of general practitioners, subspecialists, and nurse practitioners (Brown, Boles, et al., 1999) and in a study of physicians only (Joos, Hickam, et al., 1996), training in patient-centered care led to observable changes in provider behavior, but these changes in behavior were not associated with patient satisfaction.

Patient Adherence In addition to satisfaction, research has examined the impact of patient-centered care on adherence to treatment. As discussed in the chapter by Burke, *infra*, adherence to treatment is suboptimal across many disorders, with only approximately half of patients demonstrating adequate adherence with treatment (DiMatteo, Giordani, et al., 2002). Rates of nonadherence are highest among preventive and chronic regimens, where patient-centered care may be of most importance (DiMatteo, Giordani, et al., 2002). Nonadherence is a costly problem for both the individual patient and larger society. Poor adherence with treatment is associated with increased disease burden, disease relapse, hospitalization, and treatment failure (Christensen, 2004). For example, poor control of diabetes is associated with neuropathy, retinopathy, and cardiovascular disease. Nonadherence to antiretroviral medications for HIV is associated with increased viral load and development of AIDS (Katzenstein, Lyons, et al., 1997). From a societal perspective, nonadherence to medication has been implicated in the development of drug-resistant strains of bacteria and viruses (Katzenstein, Lyons, et al., 1997). Annual costs of nonadherence are estimated at $100 billion, including increased healthcare costs and lost productivity costs (Berg, Dischler, et al., 1993).

In their seminal work on the Health Belief Model, Becker and Maiman (1975) found that aspects of the patient-provider relationship could impact patient adherence. Specifically, their review of early work suggested that "impersonality" of the physician and "less reciprocal interaction" between patient and physician were associated with poorer treatment adherence (Becker & Maiman, 1975). More recent studies using contemporary models of patient-centered care have supported these results. Piette, Schillinger, Potter, and Heisler (2003) examined the relationship between patient-provider communication and completion of self-care behaviors (e.g., foot care, medication adherence, activity) by patients with diabetes. Using an adaptation of the IPC as a measure of patient-centered care and general communication style, they found that the probabilities of daily foot checks and adherence to daily diet, daily exercise, and diabetes medication regimens were significantly higher among patients receiving communication reflective of more patient-centered care (Piette, Schillinger, et al., 2003). Using the PACIC measure, Schmittdiel et al. (2008) found that patients who felt they had received patient-centered care were significantly more likely to engage in five self-care behaviors: utilizing self-management services, eating five or more servings of fruits and vegetables daily, performing self-management tasks, exercising regularly, and participating in stress management. Unfortunately, PACIC scores were not significantly related to measures of medication adherence (Schmittdiel et al. 2008).

Intervention studies have shown that although providers can be successfully trained to increase patient-centered care, this increase is not robustly linked to improved outcomes. Kinmonth et al. (1998) compared patients with type 2 diabetes receiving care from providers with additional training in patient-centered care to patients receiving treatment as usual. The primary marker of diabetes regimen adherence, hemoglobin A1c, was not statistically different between groups. In the study by Joos et al. (1996), increased patient-centered care was not associated with medication adherence or compliance with follow-up visits.

Disease Outcomes Researchers have also studied the impact of patient-centered care on health outcomes such as self-reported health, objective markers of disease progression, and healthcare utilization. Patient report of greater patient-centered care was associated with decreased pain among patients with chronic fibromyalgia (Alamo, Moral, & Perula de Torres, 2002) and decreased symptom discomfort among patients in general medical practice (Stewart, Brown, et al., 2000). Ratings of greater patient-centered care following a heart attack were also associated with lower chest pain at one-year follow-up (Fremont, Cleary, et al., 2001). In an observational study, 315 patient-physician interactions were coded for patient-centered care on three domains: exploring the illness experience, understanding the whole person, and finding common ground (Stewart, Brown, et al., 2000). Patients also completed a questionnaire assessing perceptions of patient-centered care. Although patient-centered care coded from audiotapes was not associated with health outcomes, perceptions of patient-centered care were associated with patient-rated symptom improvement and overall health. In the Kinmonth et al. (1998) study, although the differences were small and of questionable clinical significance, body mass index (BMI) and triglyceride concentrations were significantly lower in the patient-centered care intervention group compared to the control group. Notably, blood pressure, cholesterol, and prescription of hypoglycemic medications did not differ between groups. A more recent study of primarily oncology patients utilized a patient-centered intervention that included up to 10 h per month of patient contact from members of the healthcare team (Sweeney, Halpert, & Waranoff, 2007). Patients in the patient-centered condition received significant education, frequent phone calls (average of 24 per month), home visits, and goal setting. Compared to patients who received treatment as usual, patients in the patient-centered condition had significantly fewer hospital admissions, fewer emergency room visits, and greater hospice and homecare days. Survival rates were not statistically different across treatment conditions (Sweeney, Halpert, & Waranoff, 2007).

Healthcare Costs If patient-centered care improves patient outcomes, such as patient adherence to treatment and disease outcomes, healthcare utilization costs may be decreased. However, only a few of the intervention studies reviewed in this chapter have directly examined the cost-effectiveness of the patient-centered intervention. In the Stewart et al. (2000) observational study of primary care patients, perceptions of patient-centered care were associated with fewer diagnostic tests and referrals. In the Sweeney et al. (2007) study of patients with life-limited disease receiving intensive patient-centered care versus treatment as usual, overall cost was reduced in the patient-centered care condition by 26%.

Summary A number of studies have developed protocols designed to promote providers taking a more patient-centered approach that emphasizes shared control and a highly active patient role in clinical encounters (Lewin, Skea, et. al. 2001). However, the literature on the impact of patient-centered care on outcomes such as patient satisfaction, adherence to treatment, and disease outcomes has failed to demonstrate a robust connection between patient-centered care and improved outcomes. Perceptions of patient-centered care appear to be associated with greater satisfaction with care, improvement in some health behaviors, and lower subjective disease burden. Interventions designed to improve patient-centered care through training of providers and utilization of a team approach to care have not consistently led to improved patient outcomes. This inconsistency in findings has led researchers to consider the role of patient preferences regarding patient-centered care. It has been hypothesized that the relationship between patient-centered care and positive outcomes may be moderated by patient preferences: patient-centered care may only improve outcomes for those patients that want or value it (Christensen, Howren, et al., 2010)!

Patient Preferences Regarding Healthcare

Variability in Patient Preferences

A study of nearly 3000 adults in the United States assessed patient preferences in three aspects of patient-centered care: seeking information, discussing options, and making treatment decisions (Levinson, Kao, et al., 2005). For each aspect of care, patient preferences fell at a different point along a dimension from patient-centered to physician-centered. For example, while 96% of respondents reported a preference to be asked about their opinions regarding healthcare, 52% of respondents reported that they preferred to leave the final decision to the physician (Levinson, Kao, et al., 2005). Swenson et al. (2004) found similar results by asking participants to view videotapes of simulated patient-physician interactions that varied from very doctor-centered to very patient-centered. Although the majority of respondents preferred the patient-centered interaction, a sizable minority (over 30%) preferred the very doctor-centered interaction (Swenson, Buell, et al., 2004). Two studies of actual patients yielded conflicting results. In a study of patients with asthma, roughly 25% preferred an active role, 35% preferred a collaborative role, and 40% preferred a passive role (Caress, Beaver, et al., 2005). However, in a study of primary care patients, nearly all patients showed high preference for a collaborative patient-centered approach (Little, Everitt, et al., 2001). Taken together, these studies highlight the wide variability in United States patients' preferred roles in their own healthcare and in the clinical encounter.

Within the United States, patient demographic factors have been associated with particular preferences for patient-centered care. A higher preference for patient-centered care has been found among patients who are younger (Caress, Beaver, et al., 2005; Coulter & Jenkinson, 2005; Levinson, Kao, et al., 2005; Swenson, Buell, et al., 2004), are female (Levinson, Kao, et al., 2005; Swenson, Buell, et al., 2004), have higher educational attainment (Caress, Beaver, et al., 2005; Swenson, Buell, et al., 2004), have better self-reported health (Levinson, Lesser, & Epstein, 2010), and have higher socioeconomic status (Caress, Beaver, et al., 2005). In terms of racial, ethnic, and cultural group status, African-American and Hispanic patients were more likely than Caucasian patients to prefer a more provider-centered approach to care (Levinson, Kao, et al., 2005), and Pacific Islander/Asian-American patients in Hawaii were less assertive and participated less in their healthcare encounters than patients who identified culturally as mainland Americans (Young & Klingle, 1996).

Though limited, international research in this area suggests that geographic and cultural factors also affect variability in patient preferences. In a multi-country European survey, patients reported a general desire for a more autonomous role in their healthcare and a higher degree of involvement in decision-making than they had been experiencing (Coulter & Jenkinson, 2005). Interestingly, preferences differed significantly across countries. Polish and Spanish patients proportionately preferred more paternalistic interactions, with the provider as primary decision-maker, whereas Swiss and German patients endorsed high preferences for patient involvement and Swedish, Slavonic, Italian, and British patients formed a middle group. Across all countries, however, younger patients (under age 35) expressed a desire for more patient-centered care and active patient involvement. This age-related effect mirrors that observed in the United States.

In a comparison of patients from Hong Kong, the Hawaiian Islands, and the mainland United States, cultural factors were associated with varying preferences for patient-provider communication (Kim, Klingle, et al., 2000). More individualistic/independent cultural characteristics were associated with positive beliefs about patient participation, including patient assertiveness and positive response efficacy. On the other hand, more collectivist/interdependent cultural characteristics were associated with more negative perceptions of patient participation and greater avoidance of communication with providers. As such, patients from Hong Kong were less willing to be assertive during a medical interview than patients from the Hawaiian Islands or the mainland United States. In addition to evaluating such broad cultural characteristics as individualism and collectivism, it is relevant to consider factors that are directly applicable to the healthcare interaction, such as cultural differences in communication processes. For example, Japanese, Korean, and Chinese cultures have more high-context communication, tending to value indirect communication and avoid self-disclosing, demanding, asserting, or openly criticizing others (Gudykunst & Kim, 1992). On the other hand, the United States culture has predominantly low-context communication, valuing more direct communication and self-disclosure (Gudykunst & Kim, 1992).

Notably, global variability in providers' behavior toward patients and in general cultural beliefs about illness also impact the patient-provider interaction. A recent qualitative analysis of Ghanaian medical students' experiences on a medical rotation in the United States described cultural differences in these domains. Regarding provider behavior, one student stated that "'in Ghana … the patient entrusts their life with you. Therefore you are God, you decide whatever—everything—for them'" (quoted in Abedini, Danso-Bamfo, et al., 2015, p. 164). In comparison, this student found that a patient in the United States is more like a "'customer'" and that the doctor's role is to "'listen to the patient, give options, let the patient make choices—which I think is very good medicine to practice'" (quoted in Abedini, Danso-Bamfo, et al., 2015, p. 164). In terms of patient attitudes toward illness, these students considered Ghanaian cultural taboos associated with illness (e.g., "The gods are angry") and Ghanaians' generally more limited access to medical information to be barriers to active patient engagement and illness self-management. Ultimately, these African students reflected that these cultural differences in both patient and provider behavior affect patients' degree of autonomy and shared decision-making in clinical encounters.

Notably, interindividual, intraindividual, intercultural, and intracultural variability in preferences exists. As reviewed, patients vary in their preferred interactions with providers. Moreover, an individual patient's preferences are not unifactorial or permanent. Rather, a patient's preferences may vary across one's stage of life or illness course or based on contextual factors such as the unique healthcare setting and presenting healthcare circumstance. For example, a patient may feel more comfortable having a primary role in making a decision about his or her diabetes regimen in a routine primary care appointment than they do deciding between treatments following a cancer diagnosis or making end-of-life decisions. Consideration of between- and within-patient variability in preferences may be critical in improving satisfaction with care and treatment recommendations, as will be reviewed later.

Matching Patient-Provider Relationships with Patient Preferences

Studies that examine the concordance, or match, between patient preferences for their role in healthcare and provider attitudes and behavior have found that greater concordance is associated with more positive outcomes. Early work in this area was conducted by Krupat and colleagues, who developed the Patient-Practitioner Orientation Scale (PPOS) to assess patient preferences regarding patient-provider interactions. The PPOS is a 33-item scale with two subscales: a sharing subscale (17 items) and a caring subscale (15 items). Items on the sharing subscale assess the degree to which patients believe "physicians should share power with the patient in terms of agenda setting and decision making, and the extent to which information should be shared with the patient" (Krupat, Yeager, & Putnam, 2000, p. 710). Items on the caring subscale assess the degree to which patients prefer that "physicians care about providing warmth and support to patients and the extent to which physicians should go beyond the patient's symptoms and care about the patient as a whole person" (Krupat, Yeager, et al., 2000, p. 710).

In the original measure validation study, college students completed the PPOS and were then presented with two simulated patient-doctor scenarios: one with a provider that demonstrated high levels of "sharing" and "caring" and one with a provider that demonstrated low levels of "sharing" and "caring." Students rated their satisfaction as if they were the patient in the scenario. Satisfaction was higher for interactions with the provider who demonstrated high levels of sharing and caring, but this relationship was moderated by students' PPOS scores. Those with preferences for greater sharing and caring were more satisfied when the provider demonstrated more, compared to less, sharing and caring (Krupat, Yeager, et al., 2000).

A follow-up study examined the role of congruence in actual practice (Krupat, Rosenkranz, et al., 2000). In the first phase of the study, physicians completed the PPOS and were categorized as having high, neutral, or low scores on the sharing subscale. Twenty physicians with high, low, and neutral information sharing scores, respectively, were chosen for the second phase of the study, during which patients of these physicians also completed the PPOS. Patients were divided into the same three categories based on PPOS scores. Overall, satisfaction was higher among patients whose physicians were categorized as high on information sharing. However, the match between patient and physicians was also associated with satisfaction. Satisfaction was significantly lower among patients who endorsed higher information sharing scores than their physicians. These data support the hypothesis that information sharing is associated with greater patient satisfaction; however, they also provide support for the congruence hypothesis. Satisfaction is significantly lower when there is a poor match between patient and physician, specifically when patients endorse a higher preference for information sharing than their doctors (Krupat, Rosenkranz, et al., 2000).

In their 2001 study, Krupat, Bell, Kravitz, Thom, and Azari examined the impact of PPOS congruence on visit satisfaction and trust in the physician. Prior to a specific outpatient visit, physicians and patients completed the sharing subscale of the PPOS. Patients also completed a measure of trust in their physician. Following the outpatient visit, patients completed measures of satisfaction with care and "endorsement of the physician" (e.g., I would recommend this physician to a friend). Rather than grouping patients based on tertiles (e.g., high, neutral, low), as in previous studies, PPOS congruence was computed using the difference between patient and physician raw PPOS scores. Analyses also controlled for clustering of patients within physicians. It is notable that the correlation between a given patient's PPOS score and their physician's score was extremely small and nonsignificant, suggesting that patients do not systematically self-select providers with similar attitudes. A greater absolute value of the difference in PPOS scores (discordance in either direction) was not predictive of patient satisfaction with the visit. However, larger differences in PPOS scores between patient and physician were predictive of lower trust in the physician and lower endorsement of the physician. Conversely, patients whose PPOS scores were congruent with their physician's scores were more likely to recommend their physician to others, more likely to follow their physician's advice, and more likely to make a special effort to see that physician (Krupat, Bell, et al., 2001).

Given the previous findings that congruence in beliefs as measured by the PPOS are associated with positive patient satisfaction outcomes, Krupat, Hsu, Irish, Schmittdiel, and Selby (2004) conducted an intervention that matched patients with primary care providers. Patients were randomized to an informed choice, guided choice, or usual care control condition. In the informed choice condition, patients were given information on provider demographics, training, personal interests, and openness to complementary and alternative medicine. In the guided choice condition, patients were also given a list of two to five providers whose PPOS scores were closely matched to the patient's scores. Patients in the usual care condition were assigned to providers using whatever method was usually used at that clinic (e.g., first available appointment). All patients were then surveyed after 1 year to measure satisfaction with care, trust in physicians, and attitudes toward the healthcare system. Contrary to the study hypotheses, there was not a significant difference in PPOS discrepancy across intervention groups. In other words, initially giving new patients additional information about providers did not result in patient-provider dyads with more congruent beliefs. However, results regarding congruence in PPOS were consistent with previous studies, such that PPOS congruence was a significant predictor of all outcomes (Krupat, Hsu, et al., 2004).

Effect of Congruence on Patient Outcomes

Christensen and colleagues have extended work on attitudinal congruence between patients and providers in a number of ways, including measurement of additional aspects of patient beliefs and healthcare preferences and conducting this work within a chronic illness model with a focus on patients with renal disease, diabetes, and hypertension (Christensen, Howren, et al., 2010; Cvengros, Christensen, et al., 2009). Finally, their work has examined patient outcomes, such as adherence to treatment, using both self-report measures and objective markers of clinical outcomes. A conceptual model for this work is presented in Fig. 20.2.

In a study of 16 primary care physicians and 146 of their patients, Cvengros, Christensen, Hillis, and Rosenthal (2007) examined the impact of attitudinal congruence between

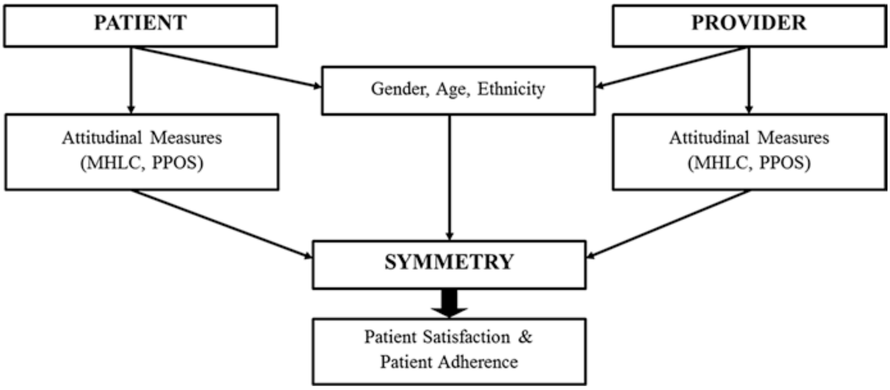

Fig. 20.2 Conceptual model of patient-provider congruence

patients and physicians on patient-reported satisfaction with care and self-reported adherence to treatment. Patients and physicians completed the PPOS as well as the Multidimensional Health Locus of Control Scale (Wallston, Wallston, & DeVellis, 1978). While the PPOS is designed to be administered to patients or physicians, the MHLC is designed for patients only. The authors developed a modified version that could be administered to physicians to assess their beliefs about patient locus of control over health. For example, a patient item from the MHLC is "I am in control of my health," representing a patient's internal control expectancies, and the corresponding physician item is "Patients are in control of their health," representing a physician's belief that patient outcomes are contingent on patient actions. Patient-physician dyads were categorized into three groups based on their congruence on each measure. One group represented patients with lower control expectations than their physician, one group represented patients with similar preferences as their physician, and one group represented patients with higher control expectations than their physician. Although congruence on the PPOS was not predictive of patient satisfaction or adherence, contrary to previous findings, congruence on the MHLC was predictive of both satisfaction and adherence. Specifically, patients whose beliefs about internal locus of control were congruent with their physician's beliefs reported significantly higher satisfaction with care and reported better adherence with treatment recommendations (Cvengros, Christensen, et al., 2007).

A follow-up study of patients with comorbid hypertension and diabetes found similar results using an objective marker of medication refill adherence (Christensen, Howren, et al., 2010). In this study, 18 primary care physicians and 246 of their patients completed the physician-modified MHLC and original patient-oriented MHLC, respectively. Adherence to treatment was derived from medication refill data for approximately 1 year prior to enrollment and defined as percentage of time patients had an undersupply of the medication (were not adherent in refilling and using medication) during that year. Values of hemoglobin A1c and blood pressure were also retrieved from the patient medical record. Using the same categorization of patient-physician dyads as in the previous study, Christensen et al. (2010) found that congruence in beliefs was predictive of medication refill adherence and blood pressure control. Specifically, patients in patient-physician dyads with similar beliefs about patient control over health outcomes (i.e., internal locus of control) demonstrated better adherence to medications and demonstrated lower diastolic blood pressure. Patient-physician congruence was not significantly associated with systolic blood pressure or hemoglobin A1c values.

The preceding studies examined congruence between patients' attitudes or beliefs regarding healthcare and physicians' parallel attitudes or beliefs. Another important dimension is congruence between what patients say they want and what they feel they have received from their healthcare. Cvengros et al. (2009) examined this congruence between patient preferences for patient-centered care and patient perceptions of received patient-centered care. In this study, 218 patients with diabetes completed measures of preferences for patient-centered care (e.g., information sharing and self-management of illness) prior to a target visit with their primary care provider. Within 2 days after the target visit, patients rated the degree of patient-centeredness of their received care and their self-reported diabetes medication adherence. Additionally, the hemoglobin A1c laboratory value closest to each patient's target visit was collected from the medical record as an objective marker of glucose control. This study was unique in that data were not collected from the providers; rather, the study focused on congruence between what patients *wanted* and what they *felt they received* with respect to the dimensions of information sharing and self-care. Consistent with previous work, congruence in preferences and perceptions of patient-centered care was associated with both subjective and objective adherence. Patients who had a high preference for behavioral involvement and self-management of their diabetes but felt that they had received a lower level of this behavior from their provider reported lower adherence to their diabetes regimen, compared to patients whose preference for and perception of this behavior were congruent. Similarly, patients who had a high preference for information sharing regarding their diabetes but felt they had received a low level of this behavior from their provider had higher A1c values (reflecting poorer glycemic control) than patients whose preference for and perception of information sharing were congruent (Cvengros, Christensen, et al., 2009).

Congruence in Patient Expectations for Care

The Cvengros et al. (2009) study raises the suggestion that patients may have specific expectations regarding the role they take in regard to their own healthcare when they present for a visit at their provider's office. Furthermore, when these expectations are met, patients are likely more satisfied and adherent with care. There is a growing body of literature that examines the role of patient expectations for other aspects of the patient-provider encounter. In a study using direct observation of over 500 patient-provider interactions, Kravitz et al. (2003) found that nearly 25% of patients made at least one request for a diagnostic test, specialty referral, or new medication. Nearly 15% of those patients who made requests had at least one request declined (Kravitz, Bell, et al., 2003).

This line of research is consistent with research on patient-provider congruence, in that failure to meet patient expectations for diagnostic tests, specialty referrals, and medications may also lead to lower satisfaction with care and poorer adherence with treatment. Bell, Kravitz, Thom, Krupat, & Azari (2002) used a checklist questionnaire to measure unmet patient expectations regarding collection of clinical data (e.g., questions the provider should have asked, parts of the physical exam that should have been completed), allocation of clinical resources (e.g., diagnostic tests that should have been ordered, medications that should have been prescribed), and information and counseling (e.g., information that should have been shared). The presence of one or more unmet expectations was associated with lower satisfaction with care, less improvement in symptoms, and lower intention to adhere to treatment recommendations (Bell, Kravitz, et al., 2002). In a similar study of over 900 patients, Kravitz et al. (2002) found that 84% of patients reported making explicit requests during their visits (e.g., requests for medical information, diagnostic tests, medications, or specialty referrals) and, of those making a request, 80% reported complete fulfillment of their request. Incomplete fulfillment or denial of requests were associated with lower satisfaction with care, higher health concerns at follow-up, and smaller improvement in symptoms at follow-up. Interestingly, those patients who made no requests had similar outcomes to those patients who reported complete fulfillment of requests (Kravitz, Bell, et al., 2002).

Promoting Patient Behavior Change

An increasing number of clinical treatment plans involve patient self-management and behavioral change efforts to improve health outcomes. Meeting patient expectations for the patient-provider interaction is just one way that healthcare providers play a potentially pivotal role in promoting and maintaining patients' effective health behavior. Understanding exactly how physicians can influence what patients do outside of the clinic, however, is less clear and can represent a formidable challenge to healthcare providers. Research from psychology and communication can help providers better utilize their central role in supporting patients' health behaviors. One psychological approach that has been adapted for use in healthcare settings is motivational interviewing. This approach involves a collaborative relationship between the patient and provider that addresses the patient's ambivalence toward change as a step toward increasing their motivation. Promotion of lifestyle changes and adherence has also been influenced by research in information processing and communication, which has been applied to health behavior change through the use of tailored healthcare communication. These customized, personally relevant health messages offer ways to inform patients, provide individualized feedback, encourage preventive health measures, and monitor progress. Motivational interviewing and tailored health communication each represent tools to help providers promote patient behavior change and will be reviewed in detail.

Motivational Interviewing

Making and adhering to health-conscious lifestyle changes remain challenging for patients (Stewart, 1995). A potential explanation for this is that providers' approaches to guiding behavioral interventions may fail to reflect their patients' readiness to change. For example, the typical approach to promote health behavior change (such as to decrease substance use or increase exercise) is for a health professional to provide action-oriented advice to the patient (Rollnick, Kinnersley, & Stott, 1993). When faced with a health issue and provided with medical rationale for behavioral changes, however, most patients are not immediately ready to transform their lifestyles (Rollnick & Heather, 1992). Rather, patients often experience ambivalence when called upon to make lifestyle changes. If this ambivalence is not addressed, individuals may become resistant to the behavioral change efforts (Britt, Hudson, & Blampied, 2004). Accordingly, such advice-giving encounters can be ineffective and frustrating for providers and patients alike, since action-oriented advice is premature without corresponding patient motivation, and resistance is counter-effective to change (Rollnick, Kinnersley, & Stott, 1993).

In contrast, the approach of motivational interviewing (MI) works explicitly with patients' ambivalence toward change and represents "something close to the polar opposite of advice-giving" (Rollnick & Heather, 1992). The interpersonal relationship functions in a reciprocal manner, in which practitioners provide facts related to objective health measures and patients provide personal interpretations of those facts (Emmons & Rollnick, 2001). This collaborative approach facilitates behavior change by helping patients explore and resolve their ambivalence toward the change. As such, these strategies affirm individuals' autonomy and self-determination while increasing their self-efficacy regarding behavior change. Instead of prescribing a set of techniques or a distinct treatment for providers to apply, MI entails overlapping collaborative processes and an underlying spirit with which to approach clinical work. The "collaborative, goal-oriented style of communication" at the heart of MI is approached through the processes of therapeutic engagement, focusing on a direction, evoking discussion of change, and planning change (Miller & Rollnick, 2013, p. 29). The underlying spirit of MI entails active partnership with the patient, acceptance of the patient, acting compassionately toward the patient, and evoking the patient's own strengths and motivation (Miller & Rollnick, 2013).

Rather than conceptualizing patient motivation as a stable personality trait, proponents of the motivational interviewing approach consider motivation to be a fluctuating state of readiness to change (Britt, Hudson, & Blampied, 2004). Importantly, motivation is evoked *in* the patient, rather than imposed *by* external influences (Rollnick & Miller, 1995). Motivation surfaces through a collaborative discussion of evidence for and against making a behavior change, with the practitioner helping to elicit and strengthen the patient's motivation (Miller & Rollnick, 2009). For example, a practitioner and patient may discuss how current health behaviors conflict with one's values and long-term goals, leading to an evaluation of the risks and rewards of making lifestyle changes. By applying the health information to one's own life, the patient discovers their own motivation to change, and their commitment is strengthened. As providers use an MI approach, over time the proportion of patient statements promoting change ("change talk") to those promoting maintenance of the status quo ("sustain talk") increases (Miller & Rollnick, 2013).

Although initially developed for working with patients with alcohol use problems, MI appears to be a highly face valid and generalizable approach that is now used internationally to address various lifestyle changes (Knight, McGowan, et al., 2006; see Rollnick, Miller, & Butler, 2007, for an in-depth discussion of the application of MI in healthcare settings). The integration of motivational interviewing into routine medical care is rapidly increasing, as patient behavior change is an essential aspect of disease prevention and adherence to medical regimens (Emmons & Rollnick, 2001). MI-informed approaches have been incorporated into many health behavior change efforts, including smoking cessation, diabetes self-management, medication compliance, HIV/AIDS risk reduction, increased fruit and vegetable intake, increased exercise, cancer screening, hypertension, asthma, and medical treatment retention (Emmons & Rollnick, 2001; Hettema, Steele, & Miller, 2005; Knight, McGowan, et al., 2006; Resnicow, DiIorio, et al., 2002).

The outcome research documenting the application of motivational interviewing to physical health issues has yielded promising, yet inconsistent, results (Burke, Arkowitz, & Menchola, 2003; Hettema, Steele, & Miller, 2005; Knight, McGowan, et al., 2006; Resnicow, DiIorio, et al., 2002; Rubak, Sandbaek, et al., 2005). A meta-analysis found that MI-informed treatments for alcohol, drugs, diet, and exercise were as effective as other active treatments and more effective than placebo or no-treatment controls for these health issues and had sustained long-term effects (Burke, Arkowitz, & Menchola, 2003). For decreasing alcohol and drug use, a motivational interviewing approach yielded the same 50% improvement rate in two sessions as psychotherapy attained in eight sessions, suggesting that MI could be a more cost-effective and time-efficient approach (Burke, Arkowitz, & Menchola, 2003). For smoking cessation, HIV-risk behavior reduction, and diabetes care, however, there is a lack of empirical support for the efficacy of motivational interviewing (Burke, Arkowitz, & Menchola, 2003; Heinrich, Candel, et al., 2010). One study found that adding MI techniques to existing diabetes self-management education was less effective than the diabetes education alone, as evidenced by a significantly lower mean change in hemoglobin A1c levels for patients who received motivational interviewing (Welch, Zagarins, et al., 2011). In another study, MI failed to offer advantages over usual nursing care for diabetes, and fat intake and HDL cholesterol were actually adversely affected in patients who received MI in addition to usual care (Heinrich, Candel, et al., 2010).

The variability in results of empirical analyses of MI in healthcare settings mirrors the overall MI research literature (Miller & Rollnick, 2013). The motivational interviewing approach is inherently difficult to evaluate empirically because its delivery is variable and reflects contextual factors in the provider-patient relationship (Miller & Rollnick, 2013). Perhaps it is not surprising that manualized MI interventions have been less effective than nonmanualized MI treatments, since MI is built upon meeting each patient at their own individual readiness level, and a manual purportedly provides each patient the same treatment (Hettema, Steele, & Miller, 2005). The highest effect sizes for MI have come from nonmanualized treatments in samples of ethnic minorities and samples of clients who are more angry, resistant, and less motivated to change (Heather, Rollnick, et al., 1996; Hettema & Hendricks, 2010; Hettema, Steele, & Miller, 2005). In a meta-analysis of clinical trials in the United States, MI studies with patients from minority populations (largely African-American and Hispanic) had effect sizes double those of MI studies with predominantly Caucasian non-Hispanic patients (Hettema, Steele, & Miller, 2005). These effects warrant further investigation, as motivational interviewing could represent a particularly effective approach for working with ethnic minorities and individuals whom more conventional approaches fail to engage.

Motivational interviewing is an attractive approach to integrate into healthcare settings because it can be employed by a variety of practitioners, such as doctors, nurses, and dieticians. While it remains unclear how much training is necessary for practitioner competence in motivational interviewing, 12–15 h of training, plus ongoing coaching and feedback, has been cited as the ideal training model (Britt, Hudson, & Blampied, 2004; Rollnick & Heather, 1992). The developers of motivational interviewing describe it as "simple but not easy" and insist that competency in its implementation necessitates disciplined practice and coaching (Miller & Rollnick, 2009). While in theory MI can be conducted by a variety of practitioners, doing so likely yields differential effectiveness. A meta-analysis reported that MI practiced by doctors and psychologists was effective in approximately 80% of studies, whereas MI done by other healthcare providers was effective in only 46% of studies (Rubak, Sandbaek, et al., 2005). Further research is required to support the claim that motivational interviewing can be integrated into the daily activities of primary care settings.

For patients, there is no empirical standard for the amount, frequency, and duration of motivational interviewing (Hettema, Steele, & Miller 2005). Importantly, practitioners can incorporate motivational interviewing strategies into regular clinical care or employ it as a brief stand-alone intervention (Miller, 2004; Rollnick & Heather, 1992). Although 64% of studies using an MI intervention of less than 20 min and 40% of studies with only one MI session were effective, effectiveness increases both with the amount of time spent on MI and the number of sessions of the intervention (Rubak, Sandbaek, et al., 2005).

Motivational interviewing aligns with patient-centered medical care efforts and offers a promising avenue for effective health behavior change. In approximately 80% of studies, motivational interviewing outperformed traditional practitioner advice-giving (Rubak, Sandbaek, et al., 2005). Because the approach is flexible and responsive to each patient's readiness to change, trained practitioners are prepared to work with a range of patients. MI also has the potential to effectively address multiple health behaviors that an individual is simultaneously facing (Prochaska, Butterworth, et al., 2008). Although clinical results yield preliminary support for implementing this approach in medical settings, further research on motivational interviewing is necessary to identify the active ingredients of change, type and amount of training required, and best ways to translate the techniques into medical settings.

Tailored and Targeted Health Communication

Other interactive and innovative approaches to the challenge of promoting effective health behaviors include providers' use of targeted and tailored health communication. Targeted health communication messages use a common approach to deliver health information to a segment of a population or members of a group (Kreuter, Lukwago, et al., 2003; Noar, Benac, & Harris, 2007). Examples include delivering smoking cessation information to pregnant women that emphasizes risks to the fetus and newborn child or providing cancer prevention materials to African-American males that emphasize underdiagnosis or delayed diagnosis of prostate and colorectal cancer in their group. Targeted health communications emphasize shared characteristics or concerns within a group and, therefore, implicitly assume a high degree of homogeneity among targeted group members. This may limit their effectiveness (Kreuter, Lukwago, et al., 2003).

Tailored health communication, on the other hand, improves customization by acknowledging known differences between individuals and addressing factors that are important to each recipient (Kreuter, Lukwago, et al., 2003; Kreuter, Strecher, & Glassman, 1999). Tailored health materials acknowledge that group or cultural membership does not necessitate uniformity of experience or belief (Kreuter, Strecher, & Glassman, 1999). Rather, it promotes individualizing tailored materials to focus on the most appropriate health information and strategies for an individual, based on his or her unique characteristics and preferences, as assessed by relevant psychological measures (Kreuter, Strecher, & Glassman, 1999; Rimer & Kreuter, 2006). The specific goals of these communications are diverse but generally aim to accomplish one or more of the following: enhance patient understanding of health information, facilitate informed clinical decision-making, increase motivation for health behavior change, provide strategies for behavior change, and provide evaluative or normative health feedback (Abrams, Mills, & Bulger, 1999; Rimer & Kreuter, 2006; Skinner, Campbell, et al., 1999). Among the health issues and lifestyle changes frequently addressed by tailored messages are smoking cessation, cancer screening, alcohol use, dietary change, exercise, and condom use (Kreuter, Oswald, et al., 2000; Sanderson, 2004). Targeted and tailored messages may address the same health behaviors, but targeted messages do so based on broader group membership and tailored messages do so on the basis of more fine-tuned individualized assessments.

The most influential theoretical underpinnings of tailored health communication are Cacioppo and Petty's (1984) elaboration likelihood model and Prochaska and DiClemente's (1983) transtheoretical (stages of change) model. According to the elaboration likelihood model, the perception of personal relevance of incoming information affects an individual's motivation to elaborate on it, with more personally relevant information leading to enhanced elaboration and processing (Cacioppo & Petty, 1984; Rimer & Kreuter, 2006). Since materials are tailored based on information from individual assessments, this customization increases "the chances that the message will be viewed as personally relevant, central processing will take place, and an individual will be persuaded" (Noar, Benac, & Harris, 2007, p. 684).

The transtheoretical model (TTM), which assesses an individual's readiness for health behavior change, is frequently used as a basis for tailored health communication (Rimer & Kreuter, 2006). Proponents of the TTM believe that patients cycle through five stages of change: precontemplation, contemplation, preparation, action, and maintenance (Norcross, Krebs, & Prochaska, 2011). Health communication can be tailored to reflect a patient's level of readiness for change, thus providing individuals with information consistent with the experiences at their stage. Using the example of stage-based tailoring for increasing physical activity, an individual in the contemplation stage may receive information regarding the health benefits of exercise, whereas someone in the preparation stage may receive information regarding exercise classes and gym memberships.

Tailoring based upon an individual's stage of change has been an effective approach for addressing various health behaviors, including smoking, stress, medication adherence, diet, exercise, and sun exposure (Prochaska, Butterworth, et al., 2008). In one smoking cessation study, abstinence rates were significantly greater at a six-month follow-up point for participants who received stage-matched tailored information compared to participants who did not (Prochaska, Velicer, et al., 2001). Furthermore, the difference between the two groups increased at each follow-up, eventually yielding a 24-month 25% abstinence rate for the stage-matched tailoring group, which was 30% higher than the abstinence rate for individuals in the control group

(Prochaska, Velicer, et al., 2001). Additionally, stage-based tailoring has been effective for simultaneously addressing multiple health behaviors in various populations, such as stress, inactivity, smoking, and BMI in a worksite sample and smoking, diet, and sun exposure in a parent sample (Prochaska, Butterworth, et al., 2008; Prochaska, Velicer, et al., 2004).

No universally accepted model or medium of tailoring exists. Rather, health messages have been tailored on an assortment of personal variables and delivered through multiple modes of communication. The choice of which variables to base tailoring on is still evolving, and an individual's stage of change is just one example. Criteria used to customize content include basic characteristics such as gender, age, education level, and culture (Sanderson, 2004). An individual's psychosocial characteristics, such as locus of control, coping strategy, need for information, self-efficacy, motivation, health practices, and risk factors, are also used to customize content yet require more in-depth individualized assessments of influential mediators (Abrams, Mills, & Bulger, 1999; Lustria, Cortese, et al., 2009; Sanderson, 2004). Modes of message delivery are constantly changing but include home mailings, phone calls, video, audio, pamphlets, and various computer programs (Kreuter, Strecher, & Glassman, 1999; Skinner, Campbell, et al., 1999).

A body of research has shown that tailored print materials are more effective in creating health behavior change than non-tailored materials (Kreuter, Oswald, et al., 2000; Noar, Benac, & Harris, 2007; Skinner, Campbell, et al., 1999). In a study comparing the effects of a non-tailored nutrition letter to a nutrition letter tailored on psychosocial variables, the tailored letters elicited significantly higher readership, discussion with close others, and relevance ratings (Brug, Glanz, et al., 1998). Furthermore, individuals who received the tailored letters consumed significantly less fat and more fruits and vegetables than individuals who received generic nutrition information (Brug, Glanz, et al., 1998). In another study comparing tailored and non-tailored mammography information, individuals who received the tailored information were significantly more likely to remember the content of the message than those who received non-tailored information (Skinner, Strecher, & Hospers, 1994). A recent meta-analysis found that tailored interventions have been 36% more effective than control conditions and that they have had a clinically significant impact on behavioral risk factors such as smoking (Krebs, Prochaska, & Rossi, 2010). No significant differences between communicating via print, telephone, or computer messages were found (Krebs, Prochaska, & Rossi, 2010). While the effects of tailoring declined after the intervention regardless of tailoring method, dynamic tailoring with iterative assessment and feedback was more effective over time (Krebs, Prochaska, & Rossi, 2010).

Current research seeks to optimize the effects of tailored health communication by assessing how and under what conditions tailoring works (Rimer & Kreuter, 2006). Effectiveness is difficult to empirically evaluate, as study outcome measures and specific methods of tailoring range across studies and health behaviors (Skinner, Campbell, et al., 1999). Some key features of successful tailoring, however, have emerged. Skillful customization is essential, since tailored materials will not be effective if patients fail to read them or to find them personally applicable (Kreuter, Oswald, et al., 2000). Additionally, design and layout are important, with more visual and brief print communication, such as pamphlets and magazines, more effective than letters and manuals (Noar, Benac, & Harris, 2007). Tailored messages regarding preventive and screening behaviors appear to be the most effective, yet particular participant variables being tailored to (e.g., age, culture, or psychosocial factors) do not influence the effectiveness of the message delivered (Noar, Benac, & Harris, 2007).

Currently, there is significant interest in electronic and Internet-based tailored health communication. Electronic tailoring expands the realm of tailored communication by providing instant adaptation and feedback in an interactive and iterative format (Lustria, Cortese, et al., 2009). The modalities for electronic and Internet-based tailored communication change as technology progresses but include electronic mailings, discussion rooms, electronic diaries, online quizzes and games, risk assessments, calorie counting programs, virtual reality experiences to view the consequences of health decisions, instant messaging with health professionals, and email reminders of appointments and self-examinations (Abrams, Mills, & Bulger, 1999; Lustria, Cortese, et al., 2009; Noar, Benac, & Harris, 2007).

An important dimension is the frequency of monitoring and messaging. Emerging developments include advanced interactive applications for cellular phones to enable instant and mobile interaction that monitor, say, eating, physical activity, and blood sugar levels among those with diabetes and deliver individualized messages responsive to changes during the day. Studies indicate their effectiveness on behavioral and clinical measures (Piette, Mendoza-Avelares, et al., 2011; Quinn, Shardell, et al., 2011; Williams, Bird, et al., 2012) and the potential for linking them with sources of live support (Aikens, Trivedi, et al., 2015).

Electronic tailoring appears to offer advantages over traditional tailored print materials. Of primary note are increased patient engagement in self-care, self-regulation, and self-monitoring (Lustria, Cortese, et al., 2009). Additionally, electronic tailored health communication holds the potential to efficiently reach a wider audience, such as those in rural areas, thus effectively eliminating geographic boundaries. Lack of access to technology is a potential barrier to the success of electronic communication. Efforts have been made to place computer kiosks in community locations, such as shopping malls and libraries, to address this issue (Lustria, Cortese, et al., 2009). Patients not only need exposure to the electronic material, however, but must also find it relevant in order for effective results.

While researchers suggest that tailored materials are cost-effective in the long run, there is an acknowledged lack of data to support this, making it a necessary subject for future research (Krebs, Prochaska, & Rossi, 2010; Kreuter, Oswald, et al., 2000; Kreuter, Strecher, & Glassman, 1999; Skinner, Campbell, et al., 1999). Initial development of tailoring programs represents a significant investment. Once developed, however, the continuing costs are minimal (Lairson, Newmark, et al., 2004). For example, the estimated total cost of developing a computer-generated tailored intervention used for mammography promotion was $264,390, 65% of which was spent on personnel costs (Lairson, Newmark, et al., 2004). If this intervention were used over 7 years with 10,000 participants, the average cost of developing the tailoring system would be $4.24 per person (Lairson, Newmark, et al., 2004). When considering both cost and adherence rates, another mammography promotion study found that a tailored letter was the most cost-effective strategy, when compared to a tailored phone call or a combination of a tailored letter and phone call (Saywell, Champion, et al., 2004). In 2008, the University of Michigan released a free, open source software package for individuals to use in creating and circulating their own tailored materials (available at http://chcr.umich.edu/mts/). The Michigan Tailoring System is an affordable way for researchers and health agencies to use tailored health communications for their noncommercial purposes.

Tailored health communication represents a versatile approach to health promotion. With implementation at the population level and tailoring at the individual level, such communication efforts are capable of having a great impact. Important considerations in tailored health communication include the timing of message delivery, comparative effectiveness for different behavioral topics and populations, and intricacies of various modalities of message delivery (Abrams, Mills, & Bulger, 1999; Skinner, Campbell, et al., 1999). As researchers seek a more precise understanding of tailored health communication, it will become an even more multifaceted and widely used tool in the future.

Summary and Implications for Clinical Practice

In summary, patient-centered care can be used as an umbrella term to represent several aspects of patient-provider interactions and patient and provider attitudes toward care. Three dimensions of patient-centered care that have received considerable attention are attitudes toward information sharing between patient and provider, preferences for self-management of illness by the patient, and preferences for provision of socioemotional support by the provider. The data to support the hypothesis that greater patient-centered care is associated with better outcomes is limited. However, recent studies conducted by the present authors and others have supported the congruence hypothesis. Specifically, greater *congruence in patient and provider attitudes regarding the healthcare encounter* is associated with more positive patient outcomes, such as greater satisfaction with care, higher trust in the physician, and greater adherence with treatment. This pattern is consistent with broader theory and research suggesting that patient individual differences and characteristics of the treatment delivery context interact to determine patient outcomes (Christensen, 2000).

Attitudinal congruence between patient and provider appears to be important and can be achieved in several ways. First, patients may “shop around” to find a provider with similar attitudes and preferences toward care. Second, patients may seek out providers that have been recommended by family or friends who endorse similar preferences as the patient. Third, providers may adapt their practice style toward a particular patient in response to that patient’s expressed preferences. Not to be overlooked is providers’ sensitivity in the moment to how circumstance (e.g., a new diagnosis) and personality may combine to make one or another interaction style appropriate. Finally, a match between patient and provider may arise through a combination of these methods. Future work in the area of patient-provider interactions should focus on identifying methods to improve congruence in patient and provider attitudes toward healthcare. This will include studies to determine effective algorithms for matching patients to providers, perhaps through the use of brief screening tools. This may also include studies of providers’ ability to adapt, or tailor, their care in response to patient preferences, perhaps through the use of “cheat sheets” which provide information on patient preferences for care.

As healthcare continues to evolve, providers will be increasingly called upon to play a central role in the promotion of positive patient health behaviors for disease prevention and management. Over the coming decades, the development of more treatment alternatives and more detailed algorithms guiding their use will continue to make patient-provider interactions more complex. With this evolution, providers will be called upon to play increasingly varied roles in guiding, serving, and collaborating with their patients. Further refinement of models, technologies, and other tools that facilitate patient-provider interaction and collaboration will play a pivotal role in this process (Howren, Van Liew, & Christensen, 2013). Recognition of the heterogeneity of target populations and the added value of customizing interventions to patients’ characteristics or readiness to change, such as through tailored health communication and motivational interviewing, allow healthcare providers and delivery systems to maximize the reach and effectiveness of their impact on patient outcomes. By meeting patients where they are with regard to readiness to change and preferences for information sharing, illness self-management, and socioemotional support, healthcare providers can impact patient adherence and satisfaction with care.

Child and Family Interventions

21

Persis Commissariat and Alan M. Delamater

This chapter considers intervention studies that are specific to children and families living with a chronic health condition. It is important to note that given the dozens of chronic diseases that can affect children and, by extension, their families, each is distinct in its own way. This chapter will cover trends for three chronic health conditions – obesity, asthma, and diabetes – along with evidence-based interventions targeting themes that are consistent in the treatment of these different conditions. The review is not exhaustive but focuses on well-regarded intervention studies that aim to improve regimen adherence and physical and mental health in medically compromised children and adolescents. The majority of intervention studies reviewed were conducted in the USA, although many techniques addressing family relationships, behavior change, coping skills, and social issues may be applicable to children and families worldwide. Child and family intervention approaches addressing these three common childhood chronic health conditions are reviewed, as well as their global prevalence, physiological complications, and related psychosocial issues. We review a number of evidence-based interventions that address educational, behavioral and psychosocial, psychological, peer, and digital technology approaches for managing these conditions, as well as psychosocial issues associated with them. The concluding section discusses and summarizes the findings and briefly considers future research needs.

Background

Chronic illnesses are conditions with a long duration and slow progression encompassing four main types: cardiovascular diseases, cancers, chronic respiratory diseases, and diabetes (World Health Organization, 2015). In 2012, about half of all adults in the USA – 117 million people – had one or more chronic health conditions (Ward, Schiller, & Goodman, 2014). Children are equally affected by chronic conditions: a recent study estimated that anywhere from 43% to 54% of children in the USA suffer from a chronic health condition (Bethell, Kogan, & Strickland, 2011). Such conditions increase the likelihood of comorbid physical and mental health conditions, complications from mismanagement, increased health-care costs, and reduced quality of life. For example, obesity in childhood has a high risk of persisting into adulthood and increases the risks for diabetes, cardiovascular disease, and cancer (Torpy, Campbell, & Glass, 2010).

Regimen adherence is essential for good management of these conditions. However, inadequate regimen adherence is a major problem among youth with chronic health conditions, with 50% average adherence across conditions (Drotar, 2000; La Greca & Mackey, 2009; Rapoff, 2010). Also among adults nonadherence rates for chronic illness regimens and lifestyle changes are about 50% (Haynes, Taylor, & Sackett, 1979).

To better understand regimen adherence difficulties in children and adolescents with chronic health conditions, it is helpful to use an ecological model: adherence may be determined by multiple levels of influence, including child characteristics (e.g., age, gender, temperament, psychological functioning), psychosocial factors (e.g., parental psychological functioning, family structure and socioeconomic status, parental monitoring and support of the regimen, family conflict, peer relationships), medical system factors (e.g., relationships with doctors, frequency of contact with health-care team), as well as cultural factors (e.g., culture-specific health beliefs) (Delamater, 2012; Marrero, Ard, et al., 2013).

With about one-half of children with chronic health conditions struggling with regimen adherence, researchers have focused considerable attention on the development and implementation of adherence-promoting interventions (Drotar, 2000; Graves, Roberts, et al., 2010; Kahana, Drotar, & Frazier, 2008; La Greca & Mackey, 2009). Interventions that improve regimen adherence among youth cover a wide variety of conditions; diabetes and asthma have been particularly well-studied (Kahana, Drotar, & Frazier, 2008).

Most interventions have been developed based on social cognitive theory (SCT) (Bandura, 1986). According to SCT, behavior is determined by environmental factors (such as modeling, family and peer influences, social reinforcement and support, social norms) and cognitive factors (such as self-efficacy, self-concept, beliefs). Individuals are more likely to engage in behaviors that they see others modeling or being rewarded for, as well as those they are directly reinforced for engaging in. Thus, a key component of intervention for youth is to involve parents in modeling health-promoting behaviors and providing social reinforcement for their children when they also engage in them. Self-efficacy for engaging in particular behavior is also integral to this theoretical model. This model additionally acknowledges the role of affective factors (such as depression and stress) as they may influence behavior. SCT-based behavioral and psychosocial interventions are reviewed below. These particular approaches have been integrated with family systems theory and therapy resulting in new interventions for youth in which behavioral interventions are employed within a family systems context (Robin & Foster, 2002).

Self-determination theory (SDT) is another approach that has been useful in the development of interventions. According to SDT, motivation is a key mechanism for understanding the drivers of human behavior (Ryan & Deci, 2000). In SDT, there is a distinction made between intrinsic and extrinsic motivation. Intrinsic motivation refers to incentives that are intrinsic to an activity such as better health and personal satisfaction, while, in extrinsic motivation, behavior is motivated by external incentives or pressures such as reduced insurance premiums for not smoking (Deci, Koestner, & Ryan, 1999). Individuals may be motivated both intrinsically and extrinsically, but SDT focuses on intrinsic motivation in order for individuals to achieve their best quality performance in various aspects of life. Development of intervention approaches based on SDT involves motivational interviewing, which has been applied to health promotion interventions (Resnicow, Dilorio, et al., 2002) by addressing intrinsic motivation for self-care.

Obesity

The global prevalence of obesity in children has been steadily increasing in recent years. A 2010 study found that 43 million preschool-aged children worldwide were estimated to be overweight or obese (de Onis, Blossner, & Borghi, 2010), and an expected 9.1% of preschool-aged children will be overweight or obese by the year 2020 (de Onis, Blossner, & Borghi, 2010). Throughout developed countries of the world, 23.8% of male children and adolescents and 22.6% of female children and adolescents were overweight or obese in 2013. However, recent epidemiological data indicate that in the USA, almost one-third of children are overweight or obese (Ogden, Carroll, et al., 2014). In developing countries, 12.9% of male children and adolescents and 13.4% of female children and adolescents were found to be overweight or obese in 2013 (Ng, Fleming, et al., 2014). Socioeconomic status and ethnicity have also been found to affect the prevalence of obesity. In middle-income countries such as China and Russia, members of higher SES households are more at risk for obesity due to a more sedentary lifestyle. However, in more developed, higher-income countries such as the USA, children in the lowest SES group have the greatest risk of obesity (Wang, 2001).

As with many chronic health conditions, obesity at an early age places the child at risk for comorbid physical conditions as well as psychological problems. Obese children and adolescents are at elevated risk for hypertension, high cholesterol, type 2 diabetes, and obstructive sleep apnea (Daniels, Arnett, et al., 2005), as well as obesity and obesity-related complications in adulthood (Freedman, Khan, et al., 2005). Furthermore, as obesity is a highly visible condition, children may also feel stigmatized by the fact that they do not look like their nonobese peers. Studies have found that obese children are consistently more stigmatized by other children than thin and normal weight children; when children have been shown drawings of other children with various forms of disability and asked to rank who they liked most, obese children were most often the least liked (Richardson, Goodman, et al., 1961; Latner & Stunkard, 2003). Early stigmatization may lead to low self-esteem and poor coping strategies later in life. For example, obese adolescents are more likely to suffer from low self-esteem and feelings of sadness and loneliness and more likely to cope through the use of substances such as cigarettes or alcohol (Strauss, 2000). These health- and mental health-related complications require early intervention and maintenance to improve child health during the current obesity epidemic.

Asthma

After obesity, asthma is one of the most common chronic health conditions of childhood. An asthmatic episode is characterized by lung sensitivity to various environmental stimuli, resulting in airway inflammation and constriction, causing the child to wheeze in an attempt to breathe normally (American Lung Association, 2014). Asthma can be life-threatening if not properly managed with both preventive measures to resist an attack and rescue measures to counter an attack. One of the most current global studies of asthma, conducted by the International Study of Asthma and Allergies in Childhood, found that the global prevalence for current asthma in the 13–14-year-old age group was 14.1%, while prevalence in the 6–7-year-old age group was 11.7%. Notably, asthma prevalence was widely variable even within regions of the same city; this suggests the importance of specific environmental factors that affect asthma attacks and diagnoses (Mallol, Crane, et al., 2013).

Given the traumatizing situation of being unable to breathe, it is not surprising that asthma is related to psychological issues in children and their caregivers. Poor asthma control has been found to be significantly associated with increased symptoms of depression, anxiety, and risky behaviors in children and adolescents in studies conducted in the Netherlands and the USA (Letitre, de Groot, et al., 2014; Peters & Fritz, 2010). Depression and anxiety symptoms have also been found to be higher in mothers of children with asthma than mothers of healthy children without asthma in Turkey (Ozkaya, Cetin, et al., 2010). Furthermore, from a social perspective, children in Norway with asthma have endorsed fear of a loss of control, exacerbation of their symptoms, and worry of how asthma affected their body, as well as fear of being ostracized by peers (Trollvik, Nordbach, et al., 2011).

Diabetes

The incidence of both type 1 (T1D) and type 2 diabetes mellitus (T2D) in children has also been increasing worldwide, leading to increased health-care costs and requiring complex treatments performed daily by the child and family. T2D, while much more common in adults, is caused by a combination of genetic and environmental risk factors. In T2D, the pancreas either produces an insufficient amount of insulin to counter glucose in the body, or the body becomes insulin resistant despite insulin production. Insulin resistance is often associated with excess adiposity (Lebovitz, 1999). The recent increase in childhood T2D is likely driven by the current obesity epidemic and decreased physical activity and increased sedentary behavior of children. A recent review conducted in the Netherlands of global trends for T2D in youth suggests incidence and prevalence rates of 0–330/100,000 person years and 0–5300 per 100,000 person years, respectively, depending on the population studied. T2D is far less prevalent in European countries, while Pima Indians in the USA have the highest incidence in children and adolescents. Overall, ethnic minorities have the highest incidence of T2D in the majority of countries studied (Fazeli Farsani, et al., 2013). However, relatively little behavioral intervention research has been conducted with youth with T2D (Pulgaron & Delamater, 2014).

T1D, the most common endocrine disorder diagnosed in childhood or adolescence, is an autoimmune-mediated chronic illness in which the pancreas becomes unable to produce insulin. In those with T1D, the body destroys its own beta cells in the pancreas, causing the body to become unable to produce insulin (American Diabetes Association, 2009). Without the production of insulin, children with T1D must manually replace insulin in their bodies through the use of insulin injections or a subcutaneous insulin pump. Without proper management, glucose levels rise in the blood and can cause severe complications, including acute symptoms of hyperglycemia or hypoglycemia, and with more chronic poor glycemic control, increased risks for nephropathy, neuropathy, retinopathy, and cardiovascular disease.

An initial report from the Diabetes Mondiale (DIAMOND) project described the incidence of T1D in children from 1990 to 1994 as approximately 4.5% of a population of over 75 million under the age of 15, through review of registries at 100 diabetes centers in 50 countries worldwide (Karvonen, Viik-Kajander, et al., 2000). An updated report from the DIAMOND Group (2006) reported that from 1995 to 1999, there was a 3.4% increase of T1D incidence in a population of 84 million children under the age of 15 in 57 countries. At present, data suggest that there are approximately 500,000 children under the age of 15 with T1D worldwide, with the majority from Europe and North America (Patterson, Guariguata, et al. 2014). This data demonstrates a marked increase in children with T1D worldwide compared to earlier reports from the DIAMOND group. Data on pediatric T1D incidence and prevalence are lacking in many countries in Africa and other developing countries worldwide, due to the lack of medical research, resources, and care and consequent early death of children with T1D.

Beyond the physiological complications, adolescents with T1D are twice as likely as their healthy peers to develop depression or anxiety (Grey, Whittemore, & Tamborlane, 2002; Hood, Huestis, et al., 2006). Depression has also been found to be more likely to contribute to regimen nonadherence (Hood, Huestis, et al., 2006), as well as poorer metabolic control and more hospitalizations (Lawrence, Standiford, et al., 2006).

Intervention Research

Each of the three chronic conditions described above has both psychological and behavioral issues that must be addressed in order to improve health outcomes and avoid health complications and reduced quality of life. Across conditions, interventions have aimed to improve disease management skills, regimen adherence, and psychological and family functioning through various approaches to treatment. While some interventions with older adolescents target personal motivation and self-management, others utilize support from parents, peers, and changes in the school environment or other community settings. Such interventions are markedly different from adult-focused work, as family functioning and peer interactions have significant influences on children's behaviors. Furthermore, interventions may vary based on the chronic condition being addressed. Several overarching themes emerge across health conditions including educational, behavioral, psychological, family and peer involvement, and digital technology intervention approaches.

Educational Interventions

Educational interventions rely on the assumption that patients and their parents lack important disease-specific knowledge and skills, and therefore increasing their knowledge of the illness will help to improve health outcomes (Delamater, Marchante, & Daigre, 2014). This section will focus primarily on asthma-focused education with which a number of studies have shown significant effects on asthma in the UK (Murphy, Rayman, & Skinner, 2006; Van Sluijs, McMinn, & Griffin, 2007).

A meta-analysis by Guevara, Wolf, Grum, and Clark (2003) found that educational programs for children with asthma were associated with improved lung function and self-efficacy, and with reduced number of missed school days, days requiring restricted activity, and visits to the emergency room. Given the technological sophistication of today's youth, interactive, computer-based programs to improve knowledge of asthma and its management have also been found to be helpful. For example, children who received routine patient education combined with the use of Interactive Multimedia Program for Asthma Control and Tracking (IMPACT) showed increased asthma knowledge, decreased symptoms and emergency room visits, lower daily medication doses, and less frequent urgent care (Krishna, Francisco, et al., 2003). The additional program provided interactive, online education of asthma pathophysiology, triggers, medication, and control strategies through the use of asthma-specific vignettes.

A preventive asthma intervention program targeted parents of inner-city children with asthma in making physical changes to the home environment (e.g., exposure to dust, pets, mold, etc.) in order to reduce asthma triggers in their children. Parents received six in-home modules with feedback from an environmental counselor who provided knowledge, skills, motivation, equipment, and supplies necessary to make environmental changes in the home. Results showed that this type of individualized, comprehensive evaluation and intervention significantly reduced asthma symptoms in children (Morgan, Crain, et al., 2004). Similarly, comprehensive education on triggers, symptoms and warning signs, and medication usage provided by a clinic nurse during initial allergy visits, as well as monthly follow-ups, resulted in significantly better health outcomes: children and caregivers who were provided with the educational intervention had a reduced number of emergency room visits, hospitalizations, and asthma-related health-care costs per year (Kelly, Morrow, et al., 2000).

Although increasing disease-related knowledge and skills is important and necessary, education alone does not always lead to behavior change. Research has determined that while education is effective in improving certain chronic conditions, provision of education-only interventions – without additional behavioral intervention – does not appear to significantly improve disease-specific management across conditions (Kahana, Drotar, & Frazier, 2008). It is important to note that many educational interventions focusing on self-management typically include some behavioral components (e.g., goal-setting and self-monitoring), which may have stronger effects on regimen adherence than education alone. This has been shown in the research literature on pediatric obesity, in which nutrition education (without behavioral intervention) has been utilized as a control condition in family-based behavioral intervention studies, and has consistently been shown not to be effective for behavior change leading to weight control (Epstein, Valoski, et al., 1994).

Behavioral Interventions

Chronic illnesses in childhood require long-term, sometimes lifelong care and treatment. As many chronic conditions involve disruptive, time-intensive treatment, regimen adherence is understandably difficult for many children and adolescents. As noted above, poor regimen adherence is a major concern among youth with chronic illnesses (Drotar, 2000; La Greca & Mackey, 2009; Rapoff, 2010). Diabetes provides an excellent example of how behavioral interventions can be used effectively to improve regimen adherence. Studies suggest that glycemic control is particularly difficult during adolescence, as adolescence marks a time of deteriorating metabolic control, poorer adherence, and heightened emotional distress (Helgeson, Snyder, et al., 2007; Korbel, Wiebe, et al., 2007). As adolescents mature, many diabetes-related tasks (such as proper insulin replacement and blood glucose monitoring) can interfere with the adolescent's ability to feel independent and fit in with peers and may result in poor adherence to treatment and lead to poorer health outcomes.

Behavioral interventions are problem-focused and address specific maladaptive behaviors and barriers to optimal regimen adherence. Systematic reviews indicate that behavioral interventions are effective in improving adherence in children and adolescents with T1D (Delamater, 2012; Delamater, Marchante, & Daigre, 2014; Hood, Rohan, et al., 2010). Typically, these interventions target families, as youth, particularly younger ones, depend greatly on parents or other adult caretakers for support and guidance with their diabetes management, and with older youth, there is often conflict regarding diabetes management tasks.

In attempting to improve children's health behaviors, it is essential to address the role of parent behaviors and family functioning. For example, parental involvement in diabetes care has been shown to be a very important factor in children's glycemic control (Delamater, 2012; Delamater, Marchante, & Daigre, 2014). Research has shown that supportive parental involvement was significantly associated with blood glucose monitoring adherence, which in turn was associated with better glycemic control (Anderson, Ho, et al., 1997). An early study by Satin, La Greca, Zigo, and Skyler (1989) demonstrated the necessity of involving parents in the treatment of T1D. Using a randomized control design, families were provided with either standard diabetes care, a multifamily intervention group that targeted improving communication and problem-solving, or a multifamily intervention plus parent simulation group in which parents engaged in the child's medical regimen (checking blood glucose and using saline injections). Adolescents in the group whose parents simulated diabetes care showed significant improvement in glycemic control and more positive attitudes toward diabetes, effects which were maintained at 6-month follow-up (Satin, La Greca, et al., 1989).

Behavioral family systems therapy (BFST) has also shown promise as an intervention to improve diabetes treatment adherence as well as family functioning. Designed by Robin and Foster (2002), BFST utilizes four major therapeutic skills: problem-solving training, communication skills, cognitive restructuring, and functional and structural family therapy. Though initially this intervention was not designed specifically for families dealing with diabetes, it addresses family functioning related to core issues of diabetes management in childhood and adolescence – conflict resolution, group decision making, effective communication of concerns and solutions, identifying and changing exaggerated beliefs, and cross-generational discordance. Wysocki, Harris et al. (2000) modified the BFST approach specifically for diabetes: behavioral family systems therapy for diabetes (BFST-D). In a randomized controlled trial, BFST-D was not only associated with improved family relationships, it also demonstrated significant improvements in glycemic control, mediated by improvement in regimen adherence (Wysocki, Harris, et al., 2007).

This theme of improving child health outcomes by improving family functioning has been demonstrated in many other studies. Notably, increased parental involvement in diabetes can sometimes undermine the child's personal self-care behaviors and increase conflict in the parent-child relationship, particularly if parental involvement and advice are construed as blaming or shaming the child's efforts (Anderson, Brackett, et al., 1999). However, Laffel et al. (2003) used a family-focused teamwork intervention to improve

T1D management in youths. Results indicated that teaching the family how to share responsibilities and avoid conflict by working as a team had a significant effect in improving glycemic control. Family involvement in diabetes management also increased and was maintained over time and was not associated with increases in family conflict (Laffel, Vangsness, et al., 2003).

Educational and psychoeducational interventions that help families to employ supportive behavioral strategies with their children with T1D have been successfully used to prevent later difficulties with disease management. For example, a psychoeducational program with children and their parents that promoted problem-solving skills and increased parental support and praise for child self-care behaviors resulted in improved long-term glycemic control of children when applied in the months after diagnosis of T1D (Delamater, Bubb, et al., 1990).

When integrated with routine clinic appointments, family-centered programs in the UK have improved parental involvement and glycemic control, particularly when families participated in such sessions more frequently (Murphy, et al., 2007). Similarly, American studies utilizing "Care Ambassadors" demonstrated improved frequency of outpatient visits and reduced adverse outcomes such as hypoglycemia and emergency room visits (Laffel, Brackett, et al., 1999; Svoren, Butler, et al., 2003). Care Ambassadors reached out to families to assist in scheduling appointments and encourage timely disclosure of concerns to medical providers between outpatient appointments (Laffel, Brackett, et al., 1999; Svoren, Butler, et al., 2003). In a more recent large multisite randomized controlled trial, a brief family teamwork intervention delivered during routine outpatient visits was associated with improved glycemic control for young adolescents; however, effects were not as strong for older children (Nansel, Ianotti, & Liu, 2012). Similarly, when the Care Ambassador role was combined with the delivery of a manualized intervention – focused on improving family teamwork in diabetes management through the use of problem-solving exercises and role-playing of realistic expectations for teamwork – results indicated that more youth in the psychoeducation group maintained or improved their glycemic control and increased parent involvement, without a negative effect on quality of life or increased family conflict (Katz, Volkening, et al., 2014).

However, while these intervention approaches may be helpful with many children and families who do not present with significant psychological or psychosocial issues, they may not be sufficient to improve outcomes in those youth who do have significant psychosocial difficulties. Many youth with T1D are at risk for poor glycemic control due to a variety of stressors that are more common in lower-income and single-parent families and among ethnic minorities (Delamater, de Wit, et al., 2014). Often these youth do not keep in close contact with the health-care team, and research has shown that youth with inconsistent health-care contacts have worse glycemic control (Kaufman, Halvorsen, & Carpenter, 1999). Therefore, additional intervention approaches are needed to reach them and intervene with them in effective ways.

Multisystemic therapy (MST) was developed particularly for high-risk youth and in recent years been applied with youth with T1D. MST utilizes strategies from cognitive-behavioral therapy, parent training, and behavioral family systems therapy to target adherence problems related to the family, peer network, and community (e.g., health-care system and extracurricular activities). This type of intervention offers a timeline-flexible intervention strategy, addressing issues within each of the youth's environments to individualize treatment for each child and family's specific needs and environmental factors. In contrast to BFST-D, MST is unique in its use of multiple behavior-focused interventions that are delivered in patients' natural environments (home, school, community) to improve diabetes management and glycemic control. By targeting every system in which the adolescent could encounter diabetes-related issues, controlled research with MST has demonstrated efficacy in improving self-management of T1D. Studies have shown that adolescents receiving MST increased the frequency of blood glucose monitoring, improved glycemic control, and reduced the number of hospitalizations for poorly controlled diabetes, resulting in reduced medical costs (Ellis, Frey, et al., 2005; Ellis, Naar-King, et al., 2008). Specific intervention strategies used in MST for T1D (Ellis, Frey, et al., 2005) are shown in Table 21.1. This is an excellent example of the application of an ecological approach for understanding the factors related to poor glycemic control and working with a high-risk group of adolescent patients (Marrero, Ard, et al., 2013).

Family-based behavioral interventions have also been successfully applied with overweight children in the USA and Israel, with significant weight loss maintained even 10 years after treatment in the US sample (Nemet, Barkan, et al., 2005; Epstein, Valoski, et al., 1994). Family-based interventions for weight loss include nutrition and physical activity education, daily self-monitoring of physical activity and dietary intake, goal-setting, stimulus control, and training parents in behavior modification for children's reduced caloric intake, increased physical activity, and reduced sedentary behavior (Delamater, Pulgaron, & Daigre, 2013). Multiple family members attend intervention sessions as the unit of change is the family, not just the child. Research indicates that parental weight loss is a robust predictor of child weight loss in family-based behavioral intervention programs (Wrotniak, Epstein, et al., 2004), attesting to the importance of parental role modeling and the adoption of healthy eating practices by all members of the family, not just by the overweight child.

A recent study compared the effects of a multicomponent family-based behavioral outpatient program to a brief family intervention in overweight children and adolescents (Steele, Aylward, et al., 2012). Significant improvement in body mass index and quality of life was observed for both treatment groups at posttreatment and maintained at 1-year follow-up for the children but not for the adolescents in the study. Similarly, both prescribed and self-directed approaches to

Table 21.1 Select multisystemic therapy techniques used to improve T1D adherence

	Individual	Family	Peer	School	Community
Cognitive-behavioral therapy	CBT for self-reported depressive symptoms		Have peers be actively involved in treatment (e.g., reminders)		Promoting self-care during extracurricular activities
Parent training		Monitoring of self-care, providing rewards and discipline to increase parent engagement		Working with school to monitor and provide more opportunities to engage in self-care (e.g., finding a private place to inject and test glucose)	
Behavioral family systems therapy		Creating scheduled meal times together, improving communication between caregivers and between parent and adolescent		Improving communication between family and school about adolescent's needs and adherence behaviors	
MST therapist addition		Attending medical appointments with families, resolving barriers to attending appointments			

Based on Ellis, Frey, et al. (2005)

family-based behavioral intervention for child obesity have resulted in significant weight loss up to 2 years after treatment (Saelens, Lozano, & Scholz, 2013).

Psychological Interventions

Psychological and psychosocial interventions addressing mental health issues are particularly useful in chronic illness as many conditions can affect mental health, which in turn may adversely affect disease management. As described above, health conditions such as diabetes, asthma, and obesity can affect self-esteem, mood, social skills, coping abilities, and treatment adherence. Interventions that target the emotional components of living with a chronic condition may be beneficial in improving mental health and long-term adjustment, as well as disease management. For example, a number of psychological intervention strategies have been shown to improve the quality of life, regimen adherence, and glycemic control of adolescents with T1D, including coping skills training (CST), communication skills training, social problem-solving, and stress management (Delamater, de Wit, et al., 2014; Grey, 2011). Thus, broader intervention approaches targeting stress management and coping skills may generalize to other aspects on life besides managing health conditions.

Cognitive-behavioral therapy (CBT), which includes strategies used in CST and stress management, has been used to improve a variety of psychological disorders in pediatric populations, including anxiety disorders (Heimberg, 2002), depression, eating disorders, and issues related to self-esteem and social competence. This would suggest that the application of such interventions would be helpful for youth with T1D among whom depression (McGrady & Hood, 2010) and anxiety (Herzer & Hood, 2010) have been shown to be associated with decreased regimen adherence. Similarly, given the high rate of eating disorders among youth with diabetes and the relationship of eating disorders to poor disease management (Neumark-Sztainer, Patterson, et al., 2002; Rydall, Rodin, et al., 1997), it would be worthwhile to examine the effects on regimen adherence of CBT interventions addressing disordered eating in youth. Nevertheless, CBT intervention studies to reduce depression, anxiety, or eating disorders among youth with T1D and evaluate the effects on regimen adherence have not yet been reported.

In applications to T1D, cognitive-behaviorally based interventions such as CST focus on general life issues as well as improving the behaviors and skills necessary to manage T1D and achieve better glycemic control and psychosocial outcomes (Grey, 2011). Controlled research with adolescents receiving intensive insulin therapy has shown that CST led to better glycemic control and improved self-efficacy, coping, and quality of life following the intervention (Grey, Boland, et al., 1998), and these improvements were maintained 1 year after completion of the intervention (Grey, Boland, et al., 2000). CST was used to increase adolescents' sense of competence and mastery by retraining them in more positive and effective coping styles and patterns of behavior. Thus, programs such as this may help many adolescents adapt to living with T1D as well as provide them with a generalizable strategy to cope with other life experiences, thereby improving self-efficacy and quality of life and reducing depression.

Psychological interventions have been shown to be effective in both asthma and obesity. Castés et al. (1999) created an intervention for Venezuelan children that included relaxation/guided imagery, cognitive stress management therapy, and a workshop to improve self-esteem. During the intervention, children showed a significant improvement in their asthma with a reduced number of asthmatic episodes, reduced use of bronchodilator medication, and an improvement in pulmonary function (Castés, Hagel, et al., 1999). Research also suggests that inpatient psychosocial interventions for Canadian children with asthma had a greater effect on asthma improvement than outpatient interventions, with better management of asthma symptoms and feeling better about having asthma (Brazil, McLean, et al., 1997).

In a recent review of interventions for adolescent obesity, it was shown that the majority of prevention programs with a mental health component took place in schools and resulted in mixed findings as to whether or not obesity prevention programs had any effect on mood, self-perception, and quality of life (Hoare, Fuller-Tyszkiewicz, et al., 2015). However, overweight and obese adolescents who participated in a group-based weight control intervention had significant improvements of social adjustment and self-concept (Jelalian, Sato, & Hart, 2011).

As adolescence is a time when teens strive to be independent from their parents, it may be important to develop interventions that provide guidance and structure without excessive importance placed on the role of parents. By targeting the developing adolescent alone, interventions can focus on encouraging and empowering adolescents to take control of their diabetes. One study paired youth ages 11–16 with a "diabetes personal trainer." Trainers worked with the adolescents to improve self-monitoring, goal-setting, and problem-solving related to their diabetes care. Results indicated that the personal trainer intervention had a significant effect on glycemic control among older adolescents in the study (Nansel, Ianotti, et al., 2007), an effect that was maintained at 2-year follow-up (Nansel, Ianotti, et al., 2009). This suggests that middle adolescence (typically defined as ages 14–16) is a particularly difficult time in the struggle for independence, and adolescents in this age group are more willing and receptive to help with diabetes that makes them feel empowered and supported while still in control. The use of an outsider acting as a "diabetes personal trainer" seems to provide the necessary structure and support for adolescents without the dual role of a parent, which may hinder the perception of independence and individual self-efficacy.

Similarly, motivational interviewing has been found to be an efficacious method for improving diabetes management in adolescents with T1D. The results of a randomized multicenter trial conducted in the UK indicated that adolescents receiving motivational interviewing improved their long-term glycemic control and quality of life (Channon, Huws-Thomas, et al., 2007). The use of motivational interviewing has also been efficacious with youth who have asthma. Research provides preliminary support for the use of motivational interviewing to improve regimen adherence in urban, African-American youth with asthma (Riekert, Borrelli, et al., 2011).

Peer Support Interventions

Peer relationships play a significant role during childhood and adolescence. Thus, developmental stage is especially important to take into account when designing interventions for youth that involve social support. For many young children, their closest relationship is with a parent or guardian. For adolescents, parental involvement may become less desired as they struggle to be more independent while achieving peer group identity. Along with these essentially normal challenges of adolescent development, living with a chronic health condition can make independence and fitting in with peers much more difficult. Some research has addressed the role of peers for youth with chronic health conditions. In a study assessing friend support for T1D, La Greca et al. (1995) found that friends provided useful emotional support by helping the adolescent feel accepted and companionship support by engaging in healthy eating or exercising behaviors together. Thus, interventions that involve peers would do well to allow active participation in education and treatment of the chronic condition.

A review of peer support interventions by Funnell (2010) demonstrated the concentration of peer-based interventions in adult populations rather than child and adolescent populations. This is a relatively underresearched area in pediatric health behavior research. Greco et al. (2001) found that when peers were included in a five-session, multisystemic, home-based intervention for children and adolescents with T1D, better glycemic control resulted. It is important to tailor peer support interventions to the individual child or adolescent, as perceptions of what constitutes "support" may differ between the parent and child (Pendley, Kasmen, et al., 2002).

In order to build more school and peer support for children with asthma, Clark et al. (2004) found that education for US students as well as school personnel resulted in significant symptom reduction in children with asthma, better grades, and less absenteeism. Peer involvement in asthma management has also been seen to positively affect quality of life. A peer education program in Australia in which older students taught younger students about asthma control resulted in less absenteeism and improved quality of life (Shah, Peat, et al., 2001). Similarly, when peers were trained as "peer leaders" in asthma management for their schools in the USA, the quality of life significantly improved in students with asthma within those schools (Rhee, Belyea, et al., 2011).

In diabetes research, peer-focused interventions generally include psychoeducation to deal with social situations that may impede optimal self-care. One study found that educating adolescents with diabetes and their best friends together resulted in increased knowledge of diabetes, increased social support, and decreased family conflict related to diabetes (Greco, Pendley, et al., 2001). Another study utilized a group format using only children with diabetes in group problem-solving sessions to counter the typical decline in glycemic control during adolescence (Anderson, Wolf, et al., 1989). Besides CST (Grey, 2011), there are a number of other examples of intervention studies for youth with T1D that used peer groups to deliver interventions. These studies indicate that stress management, problem-solving, and CST delivered in small groups of youths reduced diabetes-related stress in American children (Boardway, Delamater, et al., 1993; Hains, Davies, et al., 2000), improved social interaction in children in Spain (Mendez & Belendez, 1997), and increased glucose monitoring and glycemic control in American children (Cook, Herold, et al., 2002). It is important to note that, as discussed by Pendley et al. (2002), perceptions of support are subjective and relative. Adolescents in poor control of their diabetes may be more concerned with peer perceptions of their care and feel supported by friends who ignore their diabetes status. Interventions should be sure to properly educate both participants and peers in order to have a positive effect on health. Nevertheless, it is clear that intervention approaches that utilize peer groups may be beneficial for diabetes management in youth.

Obesity research has also done well to involve peers in treatment. One study compared "peer-enhanced adventure therapy" combined with traditional CBT for weight loss with the combination of aerobic exercise and CBT. Significantly more adolescents in the "peer-enhanced adventure therapy" group maintained at least 10 pounds of weight loss at 10-month follow-up. The peer-enhanced activity involved working together in a group to complete physical challenges (such as climbing and mazes) with mental exercises aimed at developing social skills and self-confidence. This proved to be an effective supplement to CBT for weight loss, particularly in older adolescents, who valued their peer support far more than exercise (Jelalian, Mehlenbeck, et al., 2006).

Another study implemented a school-wide, peer-led program to prevent obesity in Canadian children attending elementary schools. Older students were trained in nutrition, physical activity, and realistic body images before being paired with younger students. Results of this program indicated that those who participated in the intervention showed an increase in knowledge, healthy behaviors and attitudes, as well as a benefit in bringing children closer to recommended weight guidelines (Stock, Miranda, et al., 2007). Student-led programs may be especially useful as they may benefit both the leader and paired student.

Electronically-Based Health Interventions

Interventions delivered electronically to improve health behaviors and health outcomes are important to discuss given the growing number of children and adolescents who have access to the internet. Such interventions are referred to as eHealth or mHealth (mobile health) interventions. According to a review conducted in the UK, more than two-thirds of the world's population has a mobile phone (Free, Phillips, et al., 2013). Children are now given greater access to technological devices for games, online learning, and communication at a younger age than ever before. Mobile technology allows the user the opportunity to research, take breaks, respond at convenient times, and receive support from a huge network of users. This medium has great potential for delivering health information to youth.

For example, an Internet-based self-management intervention program for adolescents with T1D addressed barriers to effective self-management by targeting problem-solving skills. Adolescents who participated in the intervention showed significant improvements in self-management of their diabetes (Mulvaney, Rothman, et al., 2010). In another eHealth study, the effects of CST for adolescents delivered over the Internet were examined in comparison with an internet-delivered educational intervention. Results from this randomized controlled multisite trial showed clinical improvements for youth in both groups, supporting the idea that behavioral interventions can be effectively provided to youth with T1D using the Internet (Grey, Whittemore, et al., 2013).

Mobile health interventions have also recently been examined. One study in Canada developed a mobile app to improve diabetes management in adolescents with T1D, with input from youth in the design of the app. The app was able to transfer blood glucose meter readings, communicate with a community of other users, and reward routine diabetes management behaviors with tangible prizes such as iTunes music and apps. Results showed increased blood glucose monitoring in adolescents (Cafazzo, Casselman, et al., 2012).

The use of mobile technology to deliver evidence-based interventions has also proven effective. A recent study delivered BFST-D to two groups of youth with T1D through either live videoconferencing on Skype or in person at the clinic. Although there were no differences between groups, the Skype intervention had statistically significant improvements in self-management behaviors and glycemic control. This suggests mHealth technology is an effective medium for delivering therapeutic interventions that were previously only done in person. Youth may be more amenable to participating in treatment if given the option to participate in programs on their own schedules in a flexible way. Another study conducted in the UK demonstrated mHealth to be an efficacious medium to provide support to youth with T1D. "Sweet Talk" sent scheduled text messages to engage young people with diabetes in between clinic visits and allowed them to respond with questions and information for their health-care providers. Participants were also able to share their own tips and life lessons with the greater community, establishing the system as an effective way to provide support to youth with diabetes (Franklin, Greene, et al., 2008).

eHealth technology has also been beneficial in improving self-management of asthma in youth. The Health Buddy, an interactive device, was designed for children to monitor their asthma symptoms and report their quality of life securely to their health-care providers. After 90 days, children using the Health Buddy were less likely to report any limitation in activity or make urgent calls to the hospital and had improved their self-management behaviors for asthma symptoms (Guendelman, Meade, et al., 2002). Another computer-based program called Watch, Discover, Think, and Act provided education on asthma and its necessary management. Children and preteens who used the program scored significantly higher on questions assessing asthma prevention, regulation, and treatment. They also reported greater self-efficacy and importance of engaging in self-management behaviors (Shegog, Bartholomew, et al., 2001).

In obesity treatment, mobile technology and text messaging seem to be well-received by youth and their families. Parents of obese children have been enthusiastic about receiving text messages to offer suggestions for improving their child's health (Sharifi, Dryden, et al., 2013), and teens have reported that mobile technology that supports and reinforces healthy behaviors is useful to them (Arteaga, Kudeki, & Woodworth, 2009). A web-based family program for overweight children was demonstrated to be feasible and resulted in short-term weight loss (Delamater, Pulgaron, et al., 2013).

A recently created iPhone platform was used to motivate teenagers to engage in physical activity through the use of well-known iPhone games that require movement through GPS tracking or arm movement. Each user completed a brief, 10-question version of the Big Five personality test to help personalize the platform to each person. Based on their self-reported personality characteristics, users were offered specific games and motivational phrases through an "agent": a kind, supporting female or a stern, commanding male. Motivational statements were provided during the activities, encouraging the user to keep going or invite friends to join the game. Teens using the program were very responsive to the agents, thus utilizing the program as an effective tool to be more physically active (Arteaga, Kudeki, & Woodworth, 2009). Another study used tailored text messages in conjunction with a weight management program for obese adolescents. A large number of messages were created about weight-related behaviors and sent to individuals based on their difficulties with weight loss. Participants found the messages to be very personally relevant and useful, citing meal suggestions as most helpful. Thus, text messaging as a supplement to a weight-loss program was reported to be an enjoyable way to improve healthy behaviors (Woolford, Clark, et al., 2010).

Summary and Conclusions

Chronic health conditions in childhood can make physical and psychosocial development very challenging for the child, resulting in distress, poor mental health, and maladaptive coping strategies that adversely affect physical health outcomes. These conditions may also adversely impact family functioning and parental quality of life. In an effort to ease the burden on the child and family, a number of interventions have been developed for a variety of chronic conditions. This chapter summarized intervention approaches typically used with three common chronic health issues in childhood: obesity, asthma, and diabetes. The results of this research, conducted primarily in the USA and Europe, have shown that interventions typically have involved five approaches: (1) education for the child and family, (2) facilitating behavior change via psychosocial processes, (3) addressing personal and social psychological issues, (4) employing peers as part of the intervention to increase social support, and (5) utilizing digital, web-based, or mobile technology to deliver evidence-based interventions.

Using three health conditions as examples, research indicates that education is most useful when used in conjunction with other approaches. Behavioral interventions implemented through modeling, social reinforcement, cognitive-behavioral strategies, and modification of family functioning directed toward key health behaviors have shown to be a very well-developed and efficacious method for addressing chronic health conditions as they involve the family in addition to the child. Because they target changing family behaviors related to effective management of health conditions, this is essentially a psychosocial intervention approach. Psychological interventions often focus on personal adjustment and stress related to management of chronic illness and typically involve a behavioral component in an attempt to make care seem normal, routine, and less burdensome. Interventions to increase intrinsic motivation have also been employed to manage the complex regimens associated with these conditions. Technology-based interventions have shown great promise for interventions with youth, as many of today's youth are comfortable and familiar using digital technology, and reach to the population of youth can be significantly enhanced. Future research would do well to incorporate multiple approaches, using the child and family together, to address the management of chronic health conditions in a social context.

Despite the commonalities found in interventions across obesity, asthma, and diabetes, it should be noted that these conditions are distinct and unique in their physiological, emotional, and social effects on the child and family. Obesity poses long-term threats to health and organ function; however, in childhood and adolescence, concerns regarding body image and the possibility of social rejection are far more salient to youth. Intensive diet and exercise as treatment for obesity is difficult, and weight-loss progress can be slow, which may lead to a lack of motivation and decreased optimism regarding change.

T1D poses both immediate physiological and social difficulties in daily life. Youth with T1D often sacrifice their self-management routine for a variety of reasons: "burnout" from time-consuming self-care behaviors, fitting in with friends, or determining that other tasks may assume higher priority than diabetes care. Many youth with T1D may view self-management as a burden: as the body adjusts to chronic hyperglycemia, self-management no longer seems necessary to "feel better" and instead acts as a social hindrance and/or a trigger for family conflict. Many teens with T1D seem less affected by their providers' warnings of complications when complications are not immediately felt. Rather, the feeling of isolation and burden is immediate when treatment is so time intensive, and blood glucose is affected by physical activity, dietary intake, hormonal change, and emotions.

For children and adolescents with asthma, rescue bronchodilator treatment may be viewed as very valued given the fact that uncontrolled asthma can have life-threatening consequences. The inability to breathe causes panic in both the child and family members, as asthma attacks can be acute and without warning. It would then be understandable that a fear of asthma attacks may affect the child's self-confidence and increase anxiety.

Cultural factors are also important to consider when determining an intervention approach for families. For example, low-income families may find it difficult to manage obesity when their financial means only allow for high-calorie fast foods. Those who live in neighborhoods with high crime rates may not have the option of engaging in physical activity without a safe space nearby. Thus, ecological contextual factors are important to consider in treatment planning.

This review of child and family interventions for children with chronic health conditions revealed several themes applicable to the various conditions. Given the long-term duration of a chronic condition, most require time-intensive and often burdensome treatments that may affect a child's mental health, social status, and typical development. Education was noted to be an important aspect of many intervention programs, although in most cases is best thought of as a necessary but not sufficient condition to ensure optimal health behaviors for good health outcomes; often this approach has been used to supplement behavioral interventions.

Most intervention studies utilized a primarily family-based behavioral approach focused on the necessary health behaviors required by the child and family to manage the condition and ensure good health. Behavioral interventions usually involve parents and family members to facilitate encouragement and support of key health behaviors. Based on social cognitive theory, behavioral interventions use social reinforcement of key target behaviors, with clear expectations of what is required for success. Modeling is another key component of behavioral interventions based on SCT and has been particularly helpful in guiding intervention development. This approach has also been informed by family systems theory, and applications to diabetes management have been shown to be efficacious. Thus, these interventions typically focus on a key mediator of regimen-related behaviors – family functioning. These behavioral interventions appear to work by changing family behaviors such as clear communication about goals and responsibilities, modeling of effective self-care behaviors, and social reinforcement of behaviors key to ensuring good health.

Psychological interventions informed by SCT are important and necessary, since many chronic health conditions affect psychological functioning and quality of life. Psychological variables such as depression, anxiety, self-efficacy, and self-esteem are often assessed as outcomes rather than the focus of intervention. Research using cognitive-behavioral interventions to address stress and coping has shown promise in improving health outcomes and quality of life in youth with diabetes. More work is needed to address depression, anxiety, and eating disorders in youth with chronic health conditions, as studies have shown these psychological disorders may undermine effective self-care.

Another psychological intervention approach based on self-determination theory utilizes motivational interviewing, focusing on increasing intrinsic motivation for self-care. Although preliminary results are promising in applications to T1D and asthma, more research is needed using this approach to manage other chronic health conditions.

Interventions utilizing peers are another common approach to address chronic health conditions in youth. Researchers have employed peers in several ways for intervention: led by healthy peers, alongside peers with the same condition, or alongside healthy friends. Overall, the use of a paired or group format seems to provide the support necessary for children and teens to learn from each other in a way that feels less stigmatizing and less like a lecture than adult-led programs.

Technology-based, eHealth and mHealth interventions hold great promise for increasing reach to the populations of children living with chronic health conditions in order to effectively deliver interventions to improve health. It can be especially convenient for older adolescents and parents who may have busy schedules or other priorities, as it still allows them to engage and utilize services on their own schedules. Studies have already demonstrated the feasibility and efficacy of this approach in management of obesity, diabetes, and asthma in youth, but more work is needed to demonstrate effectiveness in larger scale trials.

Based on the benefits derived from each type of intervention, long-term programs to help youth and their families deal effectively with chronic health conditions may combine aspects of each type of intervention approach (i.e., education of the disease and associated psychological complications, behavioral and psychosocial, psychological, peer, and technology). After careful assessment, these approaches can skillfully address relevant issues at each level of the ecological model, including potential knowledge and skills deficits, problem-solving, coping and stress management skills, motivation for self-care, psychological disorders, peer and family support, as well as contacts and relationships with the healthcare team in order to provide effective follow-up support over time.

Peer Support in Prevention, Chronic Disease Management, and Well-Being

Edwin B. Fisher, Nivedita L. Bhushan, Muchieh Maggy Coufal, Sarah D. Kowitt, Humberto Parada, Rebeccah L. Sokol, Patrick Yao Tang, Diana M. Urlaub, and Jullie Tran Graham

Social support and the social bonds on which it is based are fundamental among primates (Harlow & Harlow, 1966; Harlow & Zimmerman, 1959) and extend to a variety of mammals including, e.g., elephants (Archie, Moss, & Alberts, 2006). Thus, peer support provided by "community health workers," "lay health advisors," "*promotores de salud*," and individuals with a number of other titles is built upon a fundamental and powerful dimension of human behavior. Reflecting this, peer support has been shown to play influential roles in health and the health-care delivery system (Gibbons & Tyus, 2007; Perry, Zulliger, & Rogers, 2014; Swider, 2002; Viswanathan, Kraschnewski, et al., 2010). Table 22.1 describes some of the benefits noted for peer support including encouraging appropriate regular care, providing practical and emotional support for complex behaviors that are critical to staying healthy, and helping individuals cope with the stressors chronic diseases and conditions so often entail (Brownson & Heisler, 2009; Cherrington, Ayala, et al., 2008; Colella & King, 2004; Dunn, Steginga, et al., 2003; Fisher, Brownson, et al., 2005; Fisher, Strunk, et al., 2009; Heisler, 2010; Parry & Watt-Watson, 2010; Rosenthal, Brownstein, et al., 2010; Solomon, 2004; Whitley, Everhart, & Wright, 2006). Accordingly calls to action and formal policy recommendations call for the implementation of peer support approaches (Bhutta, Lassi, et al., 2010; Bielaszka-DuVernay, 2011; CDC, 2015; Goodwin & Tobler, 2008), including in a joint position statement of the Society of Behavioral Medicine, the National Council of La Raza, the Harvard Law School Center for Health Law & Policy Innovation, and Peers for Progress (Sharp, Fisher, & Gerber, 2015) and in a strong emphasis on community health workers in the World Health Organization's Global Health Workforce Alliance (Global Health Workforce Alliance, 2010).

Table 22.1 Specific ways in which peer support contributes to health (e.g., Heisler, 2010; Rosenthal, Brownstein, et al., 2010)

- Link people to share knowledge and experience
- Provide health education at the individual as well as community level
- Provide practical assistance for how to achieve and sustain complex health behaviors that are needed in chronic disease management and prevention
- Provide emotional and social support
- Help people cope with the stressors that so often accompany health problems
- Help people get the clinical care and other services that they need; assist in navigating the system
- Build individual and community capacity for understanding health problems and promoting ways of addressing them
- Advocate for patients and their communities
- Build relationships based on trust rather than expertise
- Build cultural competence through peer supporters that often come from the communities they serve
- Above from the National Community Health Advisor Study (Rosenthal, Wiggins, & Brownstein, 1998)

Community health workers benefit from

- Shared experience with the people and communities they serve
- Shared life experiences, shared health condition or diseases
- Shared cultural, community ties, and social-economic status

As a result, the community health worker brings a special combination of expertise in the areas they address and deep experience with the perspectives of the individuals and communities they seek to serve

Ubiquity of Peer Support

Clearly, peer support contributes to or is part of broader approaches of self-management, self-management support, patient education, or patient engagement. The ubiquity of peer support, however, attests to its importance as a frequent component of each of these. A search of PubMed for papers with a variety of terms related to peer support (e.g., "community health worker," "*promotora*," "lay health advisor," "health coach") in their titles or abstracts yielded 431 hits for CY 2005, 936 in 2010, 1836 in 2014, and 2082 in 2015. Figure 22.1 presents the complete data for all years. There was a 483% increase for all papers with terms related to peer support between 2005 and 2015.

Evidence for Benefits of Peer Support

A review by Perry and his colleagues in the 2014 *Annual Review of Public Health* (Perry, Zulliger, & Rogers, 2014) identified contributions of community health workers to basic health needs (e.g., reducing childhood undernutrition), to primary care and health promotion, and to disease management.

Another review (Fisher, Boothroyd, et al., 2017) included peer support interventions from around the world that addressed a wide variety

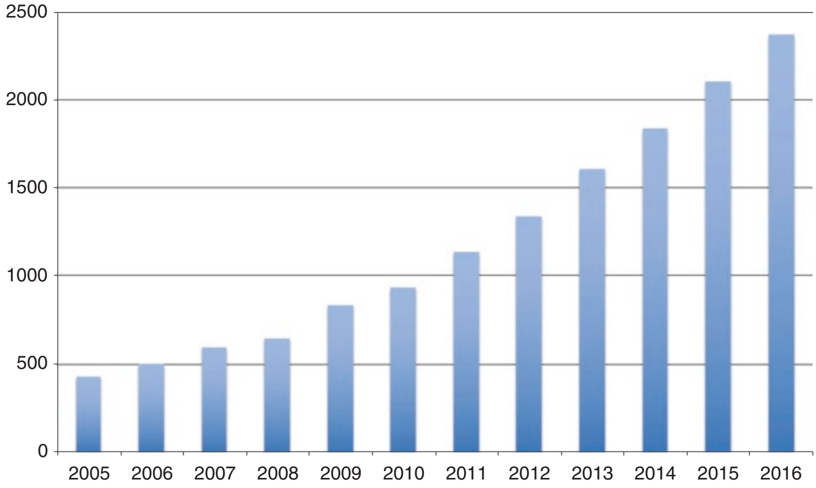

Fig. 22.1 Publications in PubMed with peer support and related terms in titles or abstracts, 2005 through 2016

of prevention and health objectives entailing sustained behavior change (in contrast to relatively isolated acts such as cancer screening) and using a broad definition of peer support entailing assistance and encouragement for those behaviors as well as linkage to appropriate care. It identified papers from the USA (34 papers), Canada (7), the Bangladesh, England, Pakistan, and Scotland (4 each), and Australia, Brazil, Denmark, Ireland, Mozambique, New Zealand, South Africa, and Uganda (1 each). The health issues papers addressed included pre- and postnatal care (17 papers), cardiovascular disease (10), diabetes (9), asthma (6), HIV (6), mental health (8), cancer (4), substance use (3), and chronic fatigue syndrome and chronic obstructive pulmonary disease (1 each). Across all 65 papers, 54 (83%) reported significant between-group or pre-post changes showing benefits of peer support. Among the 48 papers reporting RCTs, 39 (81%) reported significant between-group or pre-post changes.

The review by Fisher et al. also included summary of 24 reviews of peer support interventions (Andrews, Felton, et al., 2004; Ayala, Vaz, et al., 2010; Brownstein, Chowdhury, et al., 2007; Campbell, Phaneuf, & Deane, 2004; Chapman, Morel, et al., 2010; Dale, Caramlau, et al., 2008; Eysenbach, Powell, et al., 2004; Gibbons & Tyus, 2007; Giugliani, Harzheim, et al., 2011; Hoey, Ieropoli, et al., 2008; Hunt, Grant, & Appel, 2011; Ingram, MacArthur, et al., 2010; Kenya, Chida, et al., 2011; Lewin, Munabi-Babigumira, et al., 2010; Nemcek & Sabatier, 2003; Norris, Chowdhury, et al., 2006; Parry & Watt-Watson, 2010; Pfeiffer, Heisler, et al., 2011; Repper & Carter, 2011; Swider, 2002; van Dam, van der Horst, et al., 2005; Viswanathan, Kraschnewski, et al., 2010). Across these 19 reviews, a median of 64.5% of papers reviewed reported significant effects of peer support.

An ambitious 2015 review by the UK-based Nesta Health Lab and National Voices examined 1023 studies of peer support provided by a wide range of individuals, paid and volunteer; trained and not extensively trained; group and individual; phone, face-to-face, social media based; ranging from "one off" to over 1 year (Nesta Health Lab & National Voices, 2015). Recipients included:

- People at risk (e.g., smoking, alcohol, poor diet)
- People with long-term physical conditions
- People with mental health conditions
- Carers of people with physical or mental health conditions
- Parents, including breastfeeding mothers
- Children and young people
- Students
- Older people
- Employees
- Groups with specific experiences (e.g., veterans, sex workers)
- Healthcare professionals

Across this wide range of peer support and recipients, many reports found benefits in "experience and emotions," "behavior and health outcomes," and "health costs and service use." The report concludes cautiously that "the evidence available suggests that peer support is worth investing in, including commissioning more robust evaluations of the impacts and the reasons why peer support works better in some contexts and for some groups." Table 22.2 (Table 14, p. 23 from the report) summarizes recommendations for investment in peer support.

In addition to broad evidence of effectiveness, there is emerging growing evidence of cost-effectiveness of peer support, as summarized in Table 22.3.

Chapter Overview

Given the evidence for peer support in disease prevention and management, this chapter focuses on key considerations in developing scalable, disseminable models of peer support. The following section examines individual studies extending beyond efficacy to address the feasibility, reach, and sustainability of peer support. After that, the subsequent section reviews more fundamental psychological research related to social support and its implications for peer support. This chapter then turns to models of dissemination and, following that, key features of peer support pertinent to its success and its contributions to improving population health, including its ability to engage those too often "hardly reached" in

Table 22.2 Summary of expected benefits from various types of peer support

Type of peer support	Expected return on investment
One-to-one telephone support delivered by unpaid peers	• Inexpensive to set up and manage • May have variation in quality • Difficult to reach large numbers • Likely to reduce anxiety and isolation
One-to-one telephone support delivered by paid peers	• Potentially more costly • Difficult to reach large numbers • Likely to reduce anxiety and isolation • Moderate uptake rates
One-to-one in-person support delivered by unpaid peers	• Inexpensive to set up • Some management may be needed • High uptake rates • Likely to reduce anxiety and isolation • May improve health outcomes and behaviors
One-to-one in-person support delivered by paid peers	• Some costs for set up and management • High uptake rates • Difficult to reach large numbers • Likely to reduce anxiety and isolation • May improve health outcomes and behaviors
Support groups led by trained but unpaid peers	• Some investment in organization required • Likely to reduce anxiety and isolation • Easier to reach larger numbers
Educational groups co-led by paid peers and professionals	• Investment in organization required • Likely to reduce anxiety and isolation • Easier to reach larger numbers • May improve health outcomes and behaviors
Online support groups/forums	• Inexpensive to set up and manage • May have lower uptake rates and high drop out • Likely to improve knowledge and reduce anxiety by helping people feel less alone

Adapted from *Peer Support: What is it and Does it Work?* (Nesta Health Lab & National Voices, 2015)

Table 22.3 Examples of cost-effectiveness of peer support

In a community health center for low-income individuals in Denver, Colorado (Whitley, Everhart, & Wright, 2006)
• Shifted costs from urgent care, inpatient care, and outpatient behavioral health care
• Increase utilization of primary and specialty care visits
• ROI = 2.28:1.00
Diabetes initiative of Robert Wood Johnson Foundation (Brownson, Hoerger, et al., 2009)
• 3 of 4 projects in cost analysis emphasized peer supporters
• Cost per quality-adjusted life year (QALY) = $39,563 (well below $50,000 criterion for good value)
Asthma CHW project with Medicaid-covered children in Chicago (Margellos-Anast, Gutierrez, & Whitman, 2012)
• Three to four CHW home visits over 6 months and liaison with care team
• ROI: $5.58 saved per dollar spent
Lifestyle modification for low-income Latino adults with diabetes (Brown, Wilson, et al., 2012)
• CHWs and nurse educator: home visits, self-management education, individual counseling
• $10,995–$33,319 per QALY
• Especially cost-effective among those with HbA1c > 9%
Preventing rehospitalization in schizophrenia, depression, bipolar disorder (Sledge, Lawless, et al., 2011)
• Recovery mentors provided individualized frequency, mode, content of support
• Over 9 months: 0.89 vs. 1.53 hospitalizations, 10.08 vs. 19.08 days in hospital ($p < 0.05$)
Reducing depression/anxiety disorders in India (Patel, Weiss, et al., 2011)
• Education about psychological problems, ways of coping, and interpersonal therapy delivered by lay health counselors with primary care and psychiatric backup
• 30% decrease in prevalence, 36% in suicide attempts, 4.43 fewer days no work/reduced work in previous 30 days
• Lowered time costs resulted in intervention being cost-effective and cost saving

health care, integration of behavioral health, reaching populations and its role in primary care, integration with digital support, and organizational factors in implementing peer support. Given the wide range of programs, approaches, and models peer support entails, this chapter closes with discussion of peer support as a continuum cutting across many areas of health promotion and care.

Evidence from Individual Studies

Central to scalability is whether a program is feasible, reaches its intended audience, and is sustainable and adoptable (Glasgow & Emmons, 2007; Glasgow, Nelson, et al., 2006). Here and in much of the rest of this chapter, we include examples from the reports of investigators funded by and collaborators of *Peers for Progress*, a program dedicated to promoting peer support in health care and prevention (peersforprogress.org). Greater detail of these and similar studies is available through a supplement of the *Annals of Family Medicine* (Acheson & Fisher, 2015; Fisher, Ayala, et al., 2015).

Figure 22.2 portrays a general approach to thinking about program evaluation, from whether a program is feasible to whether it is adopted. This borrows from popular approaches to planning and evaluation such as Green and Kreuter's Precede-Proceed model (Green & Kreuter, 1999) and Glasgow's RE-AIM model (Glasgow, 2006; Glasgow & Emmons, 2007; Glasgow, Nelson, et al., 2006; Glasgow, Vogt, & Boles, 1999). In the following, we review evidence addressing these aspects of programmatic evaluation of peer support, drawn from Peers for Progress investigators and collaborators as well as select citations from the broader literature.

Feasibility

A global perspective provides an important frame for concerns about feasibility. In Thailand, Village Health Workers have been a part of the national health system since 1978, a system that spends the equivalent of $264 (US) per capita on health care (in 2013), relative to the US $9146 per capita (Global Health Observatory Data Repository). In Pakistan, an estimated 96,000 "Lady Health Workers" support maternal and child services through the primary care system that reaches an estimated 80% of Pakistan's rural population (Rahman, 2007; Rahman, Malik, et al., 2008).

- Across 14 projects funded by Peers for Progress in 9 countries on 6 continents, many in under-resourced settings, all were able to implement planned peer support programs. This speaks to the broad feasibility of these approaches in varied settings and populations.
- Among nine recipients of start-up grants from the Taiwanese Association of Diabetes Educators, all were able to develop and implement peer-led, ongoing support programs.
- Among African-American adults with diabetes in rural Alabama, intervention mapping was used to engage the community at multiple stages of program development. This iterative process led to the adoption of a flexible, client-tailored approach to providing ongoing support and the creation of a network for peer supporters to enhance teamwork, retention, and morale, minimize burnout, and permit case reassignment (Cherrington, Martin, et al., 2012).
- At the conclusion of a 2-month pilot in the UK, participants and peer supporters wanted to continue meeting, demonstrating that the

Fig. 22.2 General evaluation plan

peer support intervention was deliverable and acceptable to people with diabetes (Simmons, Cohn, et al., 2013).

- Training is central to peer support. Tang and her colleagues (Tang, Funnell, et al., 2011; Tang, Nwankwo, et al., 2014) have published several reports on training of peer supporters. In one program, 8 African-American adults with type 2 diabetes completed a 46-hour group training program. Attendance was 100%, and all 8 demonstrated competency objectives for diabetes knowledge, empowerment-based facilitation, active listening, and promoting self-efficacy. They also indicated willingness to facilitate subsequent peer support programs (Tang, Funnell, et al., 2011).
- In another project with African-American churches, Tang and her colleagues detailed the feasibility of training nonprofessionals to provide peer support for both diabetes prevention and ongoing diabetes self-management support (Tang, Nwankwo, et al., 2014).
- In prevention, a weight management program for immigrant Latino women in the USA was led by *Promotores*. It was well received and led to 2.1 kg losses (Cherrington, Willig, et al., 2015).
- A program for overweight African-American youth and families led by lay health leaders led to BMI reductions from 2.46 to 2.38 (Burnet, Plaut, et al., 2011).
- Mentors from the "Parents As Teachers" program improved weight management among postpartum adolescents through home visits and classroom and website activities (Haire-Joshu, Schwarz, et al., 2015).

Reach/Engagement

The 14 projects funded by Peers for Progress showed strong ability to reach and retain individuals for whom improved diabetes management was a priority. Across the projects, the number of participants in the peer support condition ranged from 46 to 810, and the average retention of these for follow-up evaluations was 78.6% (range from 45.7% to 99.4%). The average initial hemoglobin A1c (HbA1c) measure of blood sugar control for each site ranged from 7.1% to a high of 11.1% at one site. Overall, the average across sites was 8.41%, indicating these projects were reaching those for whom improved diabetes management was important. (For otherwise healthy adults, desired HbA1c is <7%. Goals of 7–8% are considered appropriate for those with limited life expectancy, long-standing diabetes, a history of severe hypoglycemia, or complications such as chronic kidney disease, nerve problems, or cardiovascular disease. National Diabetes Information Clearinghouse, 2014) Similarly, average systolic blood pressure across sites was 137.3 mmHg, and average BMI was 31.8.

- Among 102 entering a 6-month program in Vietnam, 86 completed it (Thanh, Deoisres, et al., 2013).
- In a 6-month program in Cameroon, only 1 of 100 participants dropped out.
- Emphasizing community partnerships, the peer support program for low-income African-Americans in underserved, rural Alabama communities exceeded its recruitment goals of 400 participants.
- In Cambridgeshire, UK, 1299 adults with diabetes enrolled for a peer support program, and 167 of these trained as peer support facilitators (Simmons, Prevost, et al., 2015).
- In Argentina, weekly phone calls were regularly maintained throughout a 12-month follow-up period (Gagliardino, Arrechea, et al., 2013).
- In China, the Beijing Diabetes Prevention and Treatment Association set objectives of enrolling peer supporters through each of 50 cooperating hospitals and community health centers to reach a goal of 5000. It succeeded in enrolling almost 5500 participants.

Efficacy/Effectiveness

- Among the 14 projects funded by Peers for Progress and using the sites as the unit of calculation, HbA1c declined from an average of 8.49% to 7.74%, systolic blood pressure from

137.0 to 133.6 mmHg, and BMI from 31.96 to 30.85 (Fisher, Ayala, et al., 2015).

- A "coach" intervention implemented as an extension of clinical teams caring for low-income and ethnic minority patients with diabetes in a large health center in San Francisco showed significant reductions in HbA1c measures of glucose control relative to controls (Thom, Ghorob, et al., 2013).
- A program for Latino adults with diabetes showed that volunteer peer leaders (PLs) could be as effective as staff community health workers (CHWs) in sustaining improvements in HbA1c over 12 months after a 6-month diabetes self-management education program (Tang, Funnell, et al., 2014).
- In *Clínicas de Salud del Pueblo* in southern California, the *Puentes* ("Bridges") program trained 34 volunteer peer leaders, each to provide support to 5–8 patients through telephone contact, in-person, individual, and group support. Among those randomized to the Puentes peer support condition, HbA1c decreased from 8.7% to 8.4%. This was significantly greater than among controls ($p = 0.05$) among whom HbA1c was unchanged (Ayala, Ibarra, et al., 2015).
- In Cameroon, peer support included group meetings and activities, such as group meals to demonstrate the possibility of healthy and tasty traditional meals, and frequent individual contacts – five times a month. Benefits included reductions in BMI (28.6–25.9 kg/m^2), systolic and diastolic blood pressure (142.0–124.4, 84.4–77.7 mmHg), and HbA1c (9.6–6.7%) (Assah, Atanga, et al., 2015).
- In Thailand, Village Health Volunteers were trained to include diabetes management in their work with individuals and communities. Baseline and post-intervention for 53 adults with type 2 diabetes showed declines in HbA1c from 8.64% to 7.91% ($p = 0.027$) and BMI from 26.66 to 25.17 ($p = 0.07$). Survey data included increases in measures of healthy diet, exercise, and self-efficacy and increases on the WHOQOL-BREF measure of quality of life (Fisher, Boothroyd, et al., 2012; Sanguanprasit, Leelaphan, et al., 2011; WHO Programme on Mental Health, 1996).
- In Uganda, individuals were paired in dyads and then linked by a telephone/text message network with each other and a clinic nurse who coordinated the program. Average diastolic blood pressure dropped from 85.39 to 76.27 mmHg, and average HbA1c declined from 11.1% to 8.3%. The number of participants with HbA1c values less than 7% nearly doubled, from 17% to 32%. Final evaluation feedback from participants also reflected perceptions of improved care from clinic staff, an important finding for enhancing linkages to care (Baumann, Frederick, et al., 2015).
- Among the first 110 participants entering the program of the Beijing Diabetes Prevention and Treatment Association, the percentage with HbA1C less than 7% has increased from 48% to 64% during initial 8 months of intervention.
- Three months' diabetes self-management education plus 12 months of ongoing peer support showed benefits in cardiovascular risk among African-American adults with diabetes. At 15-month follow up and in comparison to controls who received only the 3 months' education, the group that also received 12 months' peer support had significantly better measures of low-density lipoprotein cholesterol (−15 mg/dL, $p = 0.03$), systolic blood pressure (−10 mm Hg, $p = 0.01$), diastolic blood pressure (−8.3 mm Hg, $p = 0.001$), and body mass index (−0.8 kg/m2, $p = 0.032$) (Tang, Funnell, et al., 2015).
- Also identifying benefits for cardiovascular risk and extending previous findings of benefits of group support for blood pressure (Schulz, Pischke, et al., 2008), Simmons and his colleagues found reductions in systolic blood pressure through group peer support among middle-class, mostly retired adults with diabetes recruited through primary care in Cambridgeshire in the UK (Simmons, Prevost, et al., 2015).

Program Sustainability

Note on Terminology

Sustainability, dissemination, scalability, and adoption are overlapping and often confused. Here we have included sustainability of *individuals*' changes and benefits under efficacy/effectiveness because the provision of support for ongoing behavior change, e.g., diabetes self-management support (Powers, Bardsley, et al., 2015), is one of the primary rationales for peer support (Fisher, Earp, et al., 2010). We have then distinguished sustainability of individual programs *within their initial settings or organizations* from spread/adoption of programs to or by other settings or organizations. Thus, the ability of the program in Capetown, South Africa, to secure local funding to continue its activities is included under sustainability, while the adoption of the program of 15 sites of WellMed by all 23 of its sites in *other settings* is included under spread/adoption. Under spread/adoption, we have also included extension of programs from one problem, e.g., diabetes, to other problems such as childhood obesity.

- Four years after the end of funding from Peers for Progress, Village Health Volunteers in Thailand were still implementing diabetes activities, education, and support for which they had been trained. Local administrative offices in the provinces in which the program was developed committed to provide support to the project, both in cash and in-kind support, in order to ensure its sustainability. This is because the local administrative offices recognized the value of the project not only in terms of health but also in building unity and sense of belonging among people. In one community, Supan Buri, a member of the local administration who is also a Village Health Volunteer participating in the project, volunteered to work with other VHVs and local health staff to continue the activities and expand the coverage of the project.
- In light of successes with diabetes described later in this chapter, the Anhui Provincial Health Bureau in China has extended a peer support program to additional communities and to cardiovascular disease prevention and management (Zhong, Wang, et al., 2015).
- In Cambridgeshire, over 100 peer leaders and participants met in October, 2013, at the end of the formal study (Simmons, Prevost, et al., 2015) to discuss ongoing organizational structure for the program. This led to further funding from the UK government and collaboration with Diabetes UK to extend the program to six areas in the eastern region and West Midlands.
- Also in the UK, after a successful pilot funded by Nesta Health Lab and the Cabinet Office, the Royal National Institute for the Blind (RNIB) has embedded a new peer support service for people affected by sight loss into their core service offering. The service – called Time to Talk – is a series of four weekly telephone support sessions that give people affected by sight loss a safe space to (a) discuss their sight loss with others, (b) identify their needs, and (c) give and receive information around living with sight loss. Each session is led by a trained volunteer facilitator who helps the group to discuss a particular topic and exchange information and experiences. The pilot involved 1027 older people with sight loss as participants and included 4108 h of peer support contact. In the evaluation of the pilot, it was found that participants felt an increase in their knowledge of services and subsequent take-up of those services, increase in well-being measures including confidence, positivity and feelings of self-worth, and reduced isolation.

Experience in Uganda has led to an important perspective on sustainability. There, the nurse who had coordinated the program reported that the program as a whole had *not* been continued but that important elements of it had been incorporated into routine activities. For example, the nurse reported that she schedules patients who had been linked in peer support dyads for attendance at clinic on the same day, sustaining their relationship and utilizing it to support their care. It may be helpful to broaden our ideas about sustainability, not only to focus on maintaining whole programs but also to emphasize their *incorporation* into existing practices and procedures.

Spread/Adoption

- In Texas, WellMed originally agreed to implement a peer support diabetes program in 15 sites but, based on its own initial appraisal, extended it to all 23 of the clinical sites in its network (Knox, Huff, et al., 2015).
- In *Clínicas de Salud del Pueblo* in southern California, the *Puentes* program for adults with diabetes was used as a model for health initiatives among children and helped guide changes to the clinics system of care, including provider training and electronic health record changes to ensure documentation of peer support (Ayala, Ibarra, et al., 2015).
- In the USA, the Department of Veterans Affairs (VA) sets an example for spreading peer support at the national level. Since 2007, the peer workforce in the VA has increased more than 2.5 times and continues to grow; in 2013, the VA hired 800 mental health peer specialists in addition to the number originally planned for the year. In one national survey across the VA mental health system, 70% of sites reported hiring a peer specialist, 51% reported that implementation is "going well," and 96% stated that peer specialists are having a positive impact on veterans' care (Chinman, Salzer, & O'Brien-Mazza, 2012).
- In healthcare reform in the USA, the *Affordable Care Act* or "Obamacare" includes a number of provisions for support of community health worker interventions in prevention as well as chronic disease management and reducing avoidable hospital care such as among those recently hospitalized for problems like pneumonia, myocardial infarction, or heart failure (Peers for Progress, 2014b). The emphasis on team-based, patient-centered care has encouraged medical practices to begin employing community health workers as part of a strategy to improve patient-provider communication, reduce costs, and improve quality of care.
- In Kerala, India, Oldenburg and his colleague have extended peer support interventions for adults with diabetes and combined them with community approaches to health promotion to develop a community-based, peer support program for diabetes prevention (Sathish, Williams, et al., 2013). After the formal, 12-month intervention, a number of the peer supporters and community groups with which they have worked have taken the initiative to develop "extension activities" in their own neighborhoods and communities.

Fundamental Features of Social and Peer Support

The previous sections have described the broad evidence that peer support is feasible, beneficial, adaptable, sustainable, and cost-effective. The 550% growth from 2005 to 2016 in number of publications addressing peer support depicted in Fig. 22.1 (from 431 to 2369) also points to it being ubiquitous! There is a reason peer support is effective and gaining increased attention in health care and public health. As shown through a rich and varied base of research, social support and our connections with others are fundamental and important components of human biology, psychology, and community. The following sections review some of this research and its implications for peer support interventions.

Fundamental Value of Connection

As noted earlier, social support and the social bonds on which it is based are fundamental among many mammals (Archie, Moss, & Alberts, 2006) and primates (Harlow & Harlow, 1966; Harlow & Zimmerman, 1959). Reviews show the importance of this in that social isolation, the lack of social support, is as lethal as smoking cigarettes (Holt-Lunstad, Smith, & Layton, 2010; House, Landis, & Umberson, 1988). Evidence indicates that, in addition to a variety of benefits through health behaviors and psychological status (See Uchino et al., *infra*), social support "gets under the skin" as in the demonstration that the range of social relationships is associated with cold and flu symptom response to rhinovirus exposure (Cohen, Doyle, et al., 1997).

The implications of this for peer support are substantial. If those who have someone they can talk to about personal matters and call on for a favor (a simple indicator of connection) are better able to address a variety of life's challenges (e.g., Lowenthal & Haven, 1968), then peer support may provide benefit through its most fundamental features.

The value of simply "being there" is illustrated in a program of telephone-based peer support for those with diabetes in Hong Kong (Chan, Sui, et al., 2014). Developed to focus on diabetes self-management and implemented by telephone, participants had a median of 20 telephone calls with peer supporters, although the protocol anticipated only 12 over one year. Clearly, they saw value in talking with peers. Moreover, as will be detailed later in this chapter, those in the peer support condition with initially elevated measures of depression, anxiety, and/or stress (Szabo, 2010) showed substantial reductions in these, even though the intervention was designed to focus on diabetes management. Thus, it appears the simple provision of peer support is valued by those receiving it (the average of 20 calls instead of the 12 called for in the protocol) and is beneficial to emotional well-being.

The implications of this fundamental value of connection are important. Although knowledge about disease and its prevention or management and skills for caring for oneself are frequent and enduring themes of peer support programs, program managers and peer supporters themselves should recognize that their first task is simply to be someone who is interested in and has time to spend with those they would help. Even if they fail to convey helpful knowledge and assistance in prevention or disease management, simply "being there" for people may convey substantial benefit. Recent research by the Nuffield Trust on the Stroke Association's peer support model in the UK suggested that stroke survivors attending peer support groups appreciate the social aspect of these groups, this being often a motivation for attending. In the words of stroke survivors themselves, peer support groups gave them "an opportunity to spend time with others and offered a route back to having a social life" (Compiled by the Nesta Health Lab; http://www.nesta.org.uk/health-lab).

Secure Base

The Attachment Theory of Sir John Bowlby (1988), Mary Ainsworth (Ainsworth, Blehar, et al., 1978), and others provides an important framework for understanding peer support. Infants and those who parent them show remarkably reproducible patterns of interaction in which, optimally, the child uses his caregiver as a "secure base" from which to explore surroundings and to which to turn for comfort when stressed. In contrast to this securely attached pattern, an anxious and ambivalent pattern entails heightened arousal when stressed and both clinging to but inability to gain comfort from the parent. In an avoidant pattern, the child is aloof from the parent in both stressed and more routine circumstances. Research shows the securely attached pattern to be related to greater psychological and general well-being relative to the other types both in childhood and in adulthood (Mikulincer & Shaver, 2007).

These naturally occurring patterns of attachment may provide a template for peer support. Ideally, the peer supporter becomes something of a secure base from which the individual can explore ways to live in a healthier manner but also provides a source to which to turn when stress or unfamiliar issues arise. Some will interact with the peer supporter in an anxious-ambivalent manner. This may include appreciable emotionality expressed more quickly than might be expected, but also reactions of suspicion and annoyance over actions or words that the recipient feels indicate distancing or negativity. These reactions are thought to emerge from a history of inconsistent parenting or of relationships in which emotional support was directed more by the mood of the parent or significant other than the needs of the individual (Bowlby, 1988). For these individuals, the peer supporter's consistency, patience, and clear communication of interest and valuing of the person are paramount.

Those who have been frustrated in their attachments may develop an aloof, avoidant style in which they communicate little interest in emotional support and, perhaps, skepticism about peer support or social support in general. They may say things like "I don't want this to become a crutch" or "I only want information and answers to my questions." For such individuals, efforts by the peer supporter to encourage emotional sharing too early may discourage the relationship. Rather, interactions should stay within the range of topics with which the individual appears comfortable. At the same time, consistency is just as important as with anxious-ambivalent individuals who are often more colorful or exaggerated in their self-presentation. With consistent interactions that do not go too far beyond what the avoidant individual finds comfortable, the individual is likely to turn to the peer supporter when stressed, providing then the opportunity for broadening the relationship.

Consistency → Trust

As just discussed, consistency is a key feature in getting past individuals' difficulties in developing an effective and strong relationship with a peer supporter. In a program for low-income, unmarried mothers of children who had been hospitalized for their asthma, asthma coaches succeeded in reaching and engaging 89% of mothers (Fisher, Strunk, et al., 2009). For many, it took 3 months and several telephone calls before the mothers became engaged with the coaches. The coaches' strategy was flexible, nondemanding, but persistent effort to develop a relationship. If a mother indicated little interest in the coach's help, the coach would say something like, "That's fine. I'll just call back in a few weeks and check in with you." The coaches and study team felt the choice of words was important. "Check in with" suggests interest without intrusion or demand, in contrast to "Check up on" which, at least in US English, suggests surveillance.

Anecdotal reports of the mothers indicated this approach was noticed. They explained that, in their usual experience, those who call back usually have bad news or bothersome matters to discuss. The coaches, in contrast, called back without making demands or threats, just renewing an offer of help. Consistent, reliable, predictable, and persistent contacts were noticed by the mothers and, apparently, important in engaging them.

Nondirective and Directive Support

Social support can be conceptualized in different ways, including type (e.g., emotional, instrumental, informational, appraisal) (Cohen & Hoberman, 1983), role (e.g., functional vs. structural), and measurement perspective (e.g., perceived, received, provided) (See Uchino et al., *infra*). In addition to these, authors have considered how support may sometimes not be helpful. Problematic or unwanted support, for example, is support that is unsolicited or imposed upon the recipient (Boutin-Foster, 2005). In a study investigating the effects of social support among 197 patients with rheumatoid arthritis, problematic support was associated with greater depressive symptoms. Further, among patients receiving low levels of positive support, the relationship between problematic support and depressive symptoms was especially pronounced (Riemsma, Taal, et al., 2000). These findings regarding the detrimental effects of problematic support on health outcomes have been confirmed for other conditions, including HIV (Ingram, Jones, et al., 1999), cancer (Figueiredo, Fries, & Ingram, 2004), and acute coronary syndrome (Boutin-Foster, 2005).

Other research has developed a distinction between nondirective support (i.e., support that is accepting of the recipient's feelings and choices and cooperative with their plans) and directive support (i.e., support that prescribes "correct" choices and feelings). Nondirective support has been associated with reports of improved health behaviors, better disease management, and positive coping, whereas directive support has generally been found to have no effect or a detrimental effect on these outcomes (Fisher, Jr., Bickle, et al., 1997; Gabriele, Carpenter, et al., 2011; Harber, Schneider, et al., 2005; Stewart, Gabriele, & Fisher, 2012). For instance, in a community sample, nondirective support was associated with reports of greater physical activity, greater fruit and vegetable intake, and lower alcohol use after controlling for demographic variables (Stewart, Gabriele, & Fisher, 2012). In another study, nondirective support was associated with adaptive coping among those with non-small cell lung cancer (Walker, Zona, & Fisher, 2006).

All of the research on problematic as well as directive and nondirective support has examined associations among reports of support and various outcomes. This leaves how these distinctions might be pertinent to peer support interventions unanswered. Among five projects supported by Peers for Progress that administered a measure of nondirective and directive support that participants perceived from their peer supporters, nondirective support was significantly associated with reports of lower depression, while directive support was significantly associated with higher depression (Kowitt, Ayala, et al., 2017). This still leaves unanswered, however, how these types of support might be manipulated.

Jeanne Gabriele led an ambitious study to examine what happens when people systematically receive nondirective or directive support (Gabriele, Carpenter, et al., 2011). First was the challenge of how to manipulate them. Given the nuanced distinction between nondirective and directive support, it would be hard for an individual to be totally consistent in providing one or the other in live interactions. Instead, Gabriele and her colleagues utilized email messages that could be written and checked against protocols for nondirective and directive support before they were sent. She recruited university employees interested in an email weight loss program and then provided them 12 weeks of feedback and suggestions in response to their reports of eating patterns, physical activity, and weight.

Distinctions between nondirective and directive support included choices in the order of topics covered, for nondirective, and a fixed order for directive. Nondirective weekly messages provided choices among several observations as to what others or the research literature report as helpful, e.g., “Some people who have gained a pound or two find it helpful to….” Directive messages gave, instead, one specific suggestion for what the individual should do.

An important question was whether participants would even notice the fairly subtle distinctions between the nondirective and directive interventions. In ratings of the support provided by the e-coach, the two conditions differed in the pattern of nondirective versus directive support reported ($p < 0.01$). Those in the nondirective condition reported more nondirective support and a greater ratio of nondirective to directive support than those in the directive condition. So, nondirective and directive support could be manipulated through emails in a way that participants would notice. What about outcomes?

Women in the nondirective support condition lost, on average, 2.5 kg over the 12-week program in contrast to those in the directive condition who lost, on average, 4.5 kg ($p = 0.01$). (Men showed an opposite pattern, 6.57 kg loss in nondirective versus 3.35 kg in directive, but their numbers were too small to allow separate analysis or analysis of the interaction between sex and intervention.)

So, at least for women, a directive approach to weight management may be more effective than a nondirective approach. Note that participants signed up for a weight management program to be conducted by email. Presumably, they were looking for something to guide their weight loss, not to help them decide if they really wanted to lose weight. In terms of Prochaska’s *transtheoretical model* (Prochaska & Velicer, 1997; Velicer, Brick, et al., 2013), they were probably in preparation or action stages of change. It may be that directive support is more appropriate for those seeking help in enacting a change, while nondirective might be more helpful for those in precontemplation or contemplation, thinking about change, as well as for those in maintenance who may have learned what it is they must do, but whose challenge is to maintain motivation and performance. Other studies reviewed by Gabriele and her colleagues (Gabriele, Carpenter, et al., 2011) have indicated directive support may be more appropriate in dealing with acute or serious problems or those for which the individual is ill prepared.

The implications for peer support are important. Some data indicate that peer support is perceived as nondirective by those receiving it. Among low-income, unmarried mothers of children hospitalized for asthma, 66 of 80 chose "Help you to do what you think is right for your child's asthma" rather than "Push you to do what she thinks is right… " when asked to choose which best described their asthma coach. Additionally, 78 of 80 chose "Help you to 'take charge' of your child's asthma care" rather than "'Take charge' of your child's asthma care" (Fisher, Strunk, et al., 2009). In rural Alabama, on the other hand, 44% of participants reported that their peer advisor was most similar to a video portraying a nondirective style of counseling, but 56% thought their advisor most similar to a video portraying a directive counseling style (Lewis, Cherrington, et al., 2014). It seems clear that the relationships among nondirective and directive support, health and health behaviors, and peer support are not simple.

There may be occasions when people benefit from being given clear directions for how to do something. These may be when they are in the action stage of behavior change, when they are faced with stressful challenges, and/or when they are faced with challenges for which they do not know the skills required. At such times, peer supporters may provide direct assistance to those they would help, e.g., "I can make that appointment for you" or "I'll arrange for someone to watch your children, you just worry about keeping that appointment." At other times, perhaps most often, when challenges are more familiar or routine or when they are more a matter of motivation than learning skills, nondirective support may be the best approach for peer support.

Implicit Support

Many countries have expressions for talking about valued emotional support similar to "It wasn't anything she said or did, it was just knowing she was there."

- In Dutch this may be expressed as, "*Het was niet zozeer wat zij zei of deed, het was het besef dat zij er was*."
- In German, "*Es war nichts was sie gesagt oder getan hat, nur zu wissen, dass sie da war, reichte aus*."
- In Mandarin, "她怎么说或怎么做都不重要，重要的是知道有她在那里" (literally, "It did not really matter what she said or did. What mattered was to know that she was there").
- In Portuguese, "*Nao e' tao importante o que ela disse ou fez, o que importa foi saber que ela estava presente*."
- In Spanish, "*No importaba lo que ella dijera o hiciera, lo importante era saber que ella estaba allí*" (It didn't matter what she said or did, what mattered was that she was there).
- In Thai, "มันไม่ใช่คำพูด หรือ การกระทำ แต่มันคือการทีฉันรู้สึก ว่า เขาจะคอยอยู่ดูแลช่วยเหลือฉันเสมอ."

(Thanks to Associate Editors Ulrike Ehlert, Yan Guo, and Frank Snoek and to colleagues Silvana Barros, John Piette, and Chanuantong Tanasugarn, for translation assistance.) This suggests two things. First, emotional support can be very subtle and hard to describe. Second, emotional support can be conveyed without talking about emotions. Research indicates that in Asian cultures, for example, implicit support is more acceptable than explicit emotional support. This is linked to cultural emphases on the family and harmony and, consequently, individuals being reluctant to burden family or groups of which they are a part with their own, individual problems or concerns. Instead, the support of the family or group is conveyed and assumed without explicit discussion (Kim, Sherman, & Taylor, 2008), and, indeed, explicit support in such cultures may be ineffective or even counterproductive.

Representing programs in three distinct cultures (rural African-American women and urban Latinos in the USA, middle-class retirees in the UK) peer supporters described how emotional support emerges in their work with individuals. Peer supporters represented programs for low-income Latinos through an FQHC in Chicago, low-income, African-American women in rural North Carolina (Cummings, Lutes, et al., 2013) and retired, middle-class adults in Cambridgeshire, England (Simmons, Prevost, et al., 2015). They also identified implicit support as important (Kowitt, Urlaub, et al., 2015). Examples included showing interest and concern through attending a support recipient's art exhibit, "giving hugs," praying for/with people, group walks, talking about family, and playing cribbage with one another.

Implications for peer support include the sensitivity of the peer supporter to reluctance of some to engage in explicit discussion of emotions, but also the recognition that emotional support can be provided in numerous ways other than verbal discussion of emotions. Shared activities and sensitivity to instrumental or informational needs ("I thought you might find this interesting") can convey interest, concern, and liking that encourage the recipient and improve mood.

Emotional Support and Categories or Types of Support

Categories of social support often identified in research are emotional, informational, appraisal, and instrumental or tangible support (Cohen & Hoberman, 1983). Anecdotally, individuals frequently indicate interest only in information and answers to their questions from a peer support program, not emotional support. The structured interviews with peer supporters in the previous section explored how emotional support may emerge in the course of peer support interventions. In addition to the importance of implicit support, two important themes emerged (Kowitt, Urlaub, et al., 2015). First was the gradual evolution of emotional support out of informational support and after trust had been developed. Second was the interweaving of emotional and informational support. Rather than informational, instrumental, or emotional support being distinct categories, they appeared often to be different dimensions of the same actions and exchanges. These findings have important practical import. Where program planning to take at face value reports that individuals are only interested in information and answers to their questions, important dimensions of actual peer support interventions might be overlooked.

The importance of emotional support was reflected also in a program in Anhui province in China, described later in this chapter (Zhong, Wang, et al., 2015). A number of participants reported valuing the opportunity to share feelings with their peer supporters. The fundamental commitment of the family to its members in Chinese culture can engender a reluctance to obligate or place a burden on one's family with one's own concerns. Peer leaders however are not obligated to participants in the same way as family members and, so, provided an outlet for emotional expression free of concerns about "burdening" others.

In our penchant for categories, researchers have emphasized types of social support, including the categories of nondirective and directive of several of the current authors. It may be closer to reality to think of dimensions of support – instrumental, informational, appraisal, emotional, and, perhaps, nondirective and directive – with most all acts of support being some combination of these dimensions. For example, in a 2-year demonstration project in a community health center in Chicago (Alivio Medical Center, discussed in detail later), 8 *promotores* provided peer support contact to 3347 (90.8%) of the total of 3687 patients with diabetes Alvio served. This included 19,188 separate contacts. Of these, at least one dimension of instrumental, informational, appraisal, and emotional support was provided in 92% of contacts. Approximately 87% of contacts involved more than one dimension and 46% involved more than two dimensions of support.

Peer support programs should be planned, and peer supporters trained to be sensitive to the varied needs of participants and to recognize that, even when talking about some very concrete topic in prevention or disease management, the peer supporter's care and interest in the conversation will also convey important emotional messages. Conversely, emotional reassurance may have a central role in motivating and encouraging concrete disease management behaviors as well as lifting mood and enhancing quality of life.

Diversity of Social Networks and Total Institutions

In their provocative 1997 study showing that social ties were protective against infection with the "common cold" (rhinoviruses), Cohen and his colleagues examined what aspects of social connections were most strongly related to resistance (Cohen, Doyle, et al., 1997). Participants reported in which of 12 types of relationships (e.g., with family members as well as workmates, or members of religious organizations) they had contact with at least one person face-to-face or by telephone over the preceding 2 weeks. Diversity was assessed as the number of different types of relationships reported, 0–12. Also assessed was the total number of individuals with whom the participant spoke in the 2 week period. Results indicated that diversity strongly predicted greater resistance to infection, but number of contacts did not predict resistance at all. As Cohen and colleagues concluded, "The association between network diversity and susceptibility held even after controlling for the number of people in the social network indicating that it is diversity of the network (having multiple types of relationships) that matters not the sheer number of network members" (Cohen, Doyle, et al., 1997, p. 1944).

The importance of diverse networks and social roles was articulated by the anthropologist Erving Goffman in his writing on what he called "total institutions" such as prisons and mental hospitals and other *asylums* (Goffman, 1961). Goffman defined total institutions as limiting those within them to a single social role such as prisoner, patient, or inmate. All behaviors are interpreted in the context of that role so that, for example, a patient's complaint about mistreatment is construed as the complaint *of a patient* and as the manifestation of their pathology, not as a valid report of a staff member's behavior. In contrast, having several roles allow us to comment in one on the problems in others. With our family members, a complaint about our job supervisor is taken not as the predictable dissatisfaction of a marginal employee, but as a report about unfair or harsh treatment that should not occur. Discussions with our family about our friends and vice versa provide the opportunity to think about important relationships without challenging those relationships directly.

An important part of peer support may be the opportunity to talk about relationships that are challenging to us without fear of reprisal or immediate dismissal of our thoughts. This may include concerns about one's healthcare providers. In this regard, there may be advantages to peer supporters being closely linked with but not part of the clinical team, so that individuals may feel they can share concerns with their peer supporter without those immediately being conveyed to doctors or nurses. That peer supporters and those they serve may have much in common demographically or in the communities in which they live will tend to place the recipient of support not in the role of patient but rather in other roles as parent or university graduate or resident of a particular neighborhood. This may help the individual make sense of their health and health care in a way that is not easy within the clinical setting.

Context: "It Always Depends"

Across a number of the topics discussed above, the importance of context emerges. One might assert that there are no absolutes in social or peer support. Whether nondirective or directive support is more beneficial may depend on the seriousness or threat posed by a problem, on the skills of the individual for coping with it, and, no doubt, on the provider of support (e.g., La Greca, Auslander, et al., 1995). Consider again the email delivered support for weight loss of Gabriele (Gabriele, Carpenter, et al., 2011). How might the context of email have been important in the effectiveness of directive support? Although we may think of it as impersonal, email may be an essentially nondirective medium. We control its access to us. If someone is predictably annoying or harsh in their emails, we can leave them unopened or erect a filter to send their messages to a separate folder or even delete them unopened. We can delay responding until a time we choose. In contrast, directive support provided in a live encounter is hard to avoid and will tend to demand response. So, the directive email support in the weight loss intervention of Gabriele may be seen as directive messages delivered through a nondirective medium.

This contingency on context extends beyond nondirective and directive support. Whether emotional or more instrumental support is called for will depend on the situation of the recipient and the ability or position of the provider. In his writing on attachment, Bowlby described key features in the development of secure, health attachments, emphasizing that “the ordinary sensitive mother is quickly attuned to her infant’s natural rhythms and, by attending to the details of his behavior, discovers what suits him and behaves accordingly… Ainsworth and her colleagues have noted that infants whose mothers have responded sensitively to their signals during the first year of life … cry less during the second half of that year … (Ainsworth, Blehar, et al., 1978)” (Bowlby, 1988, p. 9). Emphasizing the sensitivity of the parent to the child’s changing needs and circumstances in the earliest of relationships reflects the importance of sensitivity and responsiveness to differing contexts across relationships and individuals’ activities throughout the lifespan. Context matters!

Contextual differences are apparent also among the varying approaches to delivering peer support. Heisler and colleagues showed impressive benefits among adults with diabetes exchanging support in dyads (Heisler, Vijan, et al., 2010). A similar intervention was not effective among those with heart failure who appeared not to have the energy to engage in dyadic support (Heisler, Halasyamani, et al., 2013). Another study with heart failure examined factors associated with engaging in group or dyadic support. Older European American women with better health status, functioning, social support, and confidence in their ability to manage their disease and less difficulty with the physical and emotional aspects of living with heart failure were most likely to engage in support (Mase, Halasyamani, et al., 2015).

Peer support does not occur in a vacuum but rather within the context of other sources of support. Spousal support, for example, moderated dietary outcomes with pregnant Latino women (Shah, Kieffer, et al., 2015). Regarding a common question of the advisability of delivering peer support to groups or individuals, Latino adults recruited through churches preferred group to individual telephone coaching, although they saw individual coaching as a possible supplement to the group (Baig, Locklin, et al., 2012).

Dissemination Models

The importance of contexts poses challenges for dissemination. On the one hand, adaptability to varying contexts and populations is very important. On the other hand, adoption is also advanced by identification and standardization of important features of peer support. Such identification of important features of support should still allow flexibility to accommodate contextual and population differences (Fisher, Earp, et al., 2010). Given these challenges, Peers for Progress initiated a consultation organized through the WHO in 2007 (World Health Organization, 2008). Representatives from over 20 countries encouraged a view that, although programs would have to be tailored to individual health systems, cultures, and patient populations, nevertheless, key aspects of peer support could be generalizable across those differences in settings.

Accordingly, Peers for Progress has pursued a strategy of defining peer support not by specific implementation protocols or details but according to four “key functions of support” (Fisher, Earp, et al., 2010). This follows a strategy of “standardization by function, not content” (Aro, Smith, & Dekker, 2008; Hawe, Shiell, & Riley, 2004). The four key functions are (i) assistance in daily management, (ii) social and emotional support to encourage management behaviors and coping with negative emotions, (iii) linkage to clinical care and community resources, and (iv) ongoing availability of support because chronic disease is for the rest of one’s life (Boothroyd & Fisher, 2010). Pursuing standardization in this way also has the advantage of defining peer support in terms of what it does, not who is doing it.

With tailoring according to needs and strengths of a specific setting or health challenge, the four key functions become a template for planning and evaluating peer support programs (Fisher, Boothroyd, et al., 2012). The hardiness of this approach was documented through programs in Cameroon, South Africa, Thailand, and Uganda and benefits they achieved across clinical, self-management, and quality of life indicators (Fisher, Boothroyd, et al., 2012). These documented both the feasibility and early impacts of peer support as well as how each program tailored the template of key functions to its own population, healthcare system, and organizational setting.

The Four Key Functions in China

Dissemination in China needs to respect preferences that programs include Chinese contributions to planning, development, and implementation. The four key functions have provided a strategy for dissemination in China, in which great value is placed on things being "made in China." Emphasizing the four key functions rather than a concrete product has created a base for a number of collaborations. In conjunction with leaders of the Chinese Diabetes Society and in healthcare settings in several cities, over 600 program managers, clinicians, and diabetes educators have been trained to develop and implement programs. Training includes large workshops in conjunction with national meetings but then, very important, ongoing consultation by conference call and online forum to facilitate coping with problems in developing and implementing peer support programs.

Interestingly, when promoting the four key functions, two of them, "social and emotional support," and "ongoing availability of support," seem to resonate the most among Chinese healthcare professionals. Individual programs have reported intentionally utilizing peer support groups to strengthen social support among participants. They have also taken advantage of online chat utilities (QQ and WeChat) and naturalistic settings such as grouping participants from the same communities to facilitate ongoing support in their communities.

Outcomes have included over 35 programs being developed, the expansion of the section on patient education and management of the Chinese Diabetes Society, and the demonstration project of the Beijing Diabetes Prevention and Treatment Association, described above, engaging 50 hospitals and community health centers and over 5000 individuals with diabetes.

Setting a model for adaptation of peer support to China was a demonstration project in community health centers in Anhui province. The program trained mostly retired adults with diabetes to co-lead monthly informational and educational meetings with staff of community health centers. The peer leaders also led discussion groups that provided greater opportunity for participants to talk about self-management plans, obstacles encountered, and successes. The peer leaders also promoted informal groups within housing complexes such as for tai chi, morning walking, shopping, and even fishing. Reported advantages included peer support as a "bridge" between community health centers and their patients. In two sites in which it was implemented, a "peer leader" program achieved significant benefits relative to controls for knowledge, self-efficacy, BMI, SBP, DBP, and both fasting and 2-hour postprandial blood glucose (Zhong, Wang, et al., 2015). In light of these results, the Anhui Provincial Health Bureau has extended the peer leader program to other communities and to cardiovascular disease prevention and management (Zhong, Wang, et al., 2015).

Success Factors

In addition to key functions of peer support, there are a variety of important characteristics of how peer support is delivered (Funnell, 2010). These include an emphasis on empowerment and the encouragement of self-efficacy. In most cases, peer support should also take a person-centered approach, addressing not only clinical issues or prevention but also reflecting the values, interests, and other problems of the individual, e.g., problems with an adolescent child that may take precedence over personal health. This reflects the wide variety of social, economic, and community stressors that influence chronic disease management. In the intervention that reduced hospitalizations among children with asthma, described earlier (Fisher, Strunk, et al., 2009), asthma coaches' contact records indicated discussion of a variety of issues including stress around moving residence (39.6% of parents), social service resources (34.4%), housing (11.5%), illness or other problems of the parent (24.0%), and new jobs (6.3%), with only 9.4% of parents discussing no such topics.

Articulating these and other success factors was a landmark survey of community health workers, the National Community Health Advisor Study (Rosenthal, Wiggins, & Brownstein, 1998). Table 22.1 contains important features of peer support as identified through it and others. Shared experience with the people and communities they serve is an important base for the benefits of community health workers. That shared experience includes life experiences, health conditions or diseases, as well as culture, community ties, or socio-economic status. With training, then, the community health worker brings a special combination of expertise in the areas they address and deep experience with the perspectives of the individuals and communities they seek to serve. The central role of the community health worker in linking communities, individuals, and organizations like health centers is widely recognized in the USA (Reinschmidt, Hunter, et al., 2006). It was also noted by a community health center director in a program in Anhui province, China, who commented that peer leaders serve as "the bridge to link our [clinic] with patients in their served neighborhood."

Proactive Contact

Papers reporting failure of community-based peer support often have failed to engage individuals in peer support, e.g., an average of 5 of 9 meetings attended and 18% attending none at all (Smith, Paul, et al., 2011a, 2011b) or 50% with one or fewer contacts and 32.3% with none (Hunkeler, Meresman, et al., 2000). There is little evidence however about the types of engagement strategies utilized by peer supporters and the impact of these engagement strategies on intervention outcomes.

A systematic review of 47 peer support interventions for breastfeeding identified proactive engagement strategies: face-to-face interaction (89% of papers), active initiation of peer support (81%), both prenatal and postnatal contact (62%), and contact initiated within 72 h of birth (52%). The odds of reporting significant differences in breastfeeding outcome between groups, those who received peer support and those who did not, significantly increased with each additional engagement strategy utilized (OR = 4.5, *p*-value = 0.002). No unique combination or "magic bullet" of engagement strategies emerged – it was the *number* of *different* strategies that mattered. This reflects other findings in behavioral medicine (e.g., Kottke, Battista, & DeFriese, 1988) that it is the number and variety of intervention strategies, not any particular critical ingredient that is most related to success.

Reaching the Hardly Reached

Varied "high-risk" groups account for disproportionate avoidable and expensive care but are often not reached by clinical and preventive services. In addition to the 83% of "high-need" patients at Alivio Medical Center, discussed later, published papers show peer support to be effective in reaching and engaging "hardly reached" populations. For example, in the project described earlier, asthma coaches pursuing a nondirective, flexible, stage-based approach were able to engage 89.7% of mothers of Medicaid-covered children hospitalized for asthma. The coaches sustained that engagement, averaging 21.1 contacts per parent over a 2-year intervention and reducing rehospitalization by 52% (Fisher, Strunk, et al., 2009). Similarly, home visits from community health workers led to clinically significant increases in symptom-free days among children with asthma in low-income neighborhoods of Seattle (Krieger, Takaro, et al., 2009).

Remarkably, studies have shown peer support to be most successful among “hardly reached” groups among whom one might expect least success. In a peer support intervention for diabetes management among ethnic minority patients of safety net clinics in San Francisco (Thom, Ghorob, et al., 2013), participants were categorized at baseline as low, medium, or high on medication adherence and on self-management. The relative impact of peer support versus usual care was *greatest* among those initially in the low-adherence and low-self-management groups (Moskowitz, Thom, et al., 2013). In support exchanged between pairs of veterans with diabetes (Heisler, Vijan, et al., 2010), improvements in blood glucose measures were greatest among those with initially low levels of diabetes support or health literacy (Piette, Resnicow, et al., 2013).

In parts of Bangladesh with low care utilization and high infant mortality, pre- and postnatal home visit by community health workers reduced neonatal mortality by 34% (Baqui, El-Arifeen, et al., 2008). In a novel approach among HIV+ individuals who also were active drug users, each individual took separate roles of both receiving and providing peer support, receiving support from one participant and providing it to a different participant (Broadhead, Heckathorn, et al., 2002). Of 15 participants in this pilot study, 14 engaged in the reciprocal support, keeping 80% of the appointments with each other. Positive outcomes included clinic appointment keeping and reduced needle sharing.

Another way to think about disparities is to analyze their socioeconomic determinants. If a program reduces the effect of low-income status on some important outcomes, for example, then it would be reducing disparity related to low income. Preliminary studies for an intervention for postpartum depression in Pakistan, discussed in detail later, showed that household debt and lack of financial empowerment (managing daily expenditures) were associated with greater depression. An intervention delivered by Lady Health Worker subsequently reduced the extent to which these variables were associated with depression (Rahman, Sikander, et al., 2012). That is, the intervention offset factors that, otherwise, would have inclined individuals to worse outcomes.

Two systematic reviews have examined how those hardly reached are identified and how peer support may reach and benefit them. In a first review, Sokol and her colleagues evaluated whether cultural/environmental, demographic, or individual characteristics were used to distinguish those hardly reached. Of 334 papers identified, 74.9% used characteristics from at least two of these domains, and only 25.2% used characteristics from only one domain to identify hardly reached individuals (Sokol, Fisher, & Hill, 2015). Thus, being hardly reached is not a reflection of one or a few troublesome individual characteristics but is rather associated with a range of social, organizational, and demographic as well as individual characteristics. A subsequent review then identified 47 papers reporting peer support interventions with hardly reached groups. Of these, 44 (94%) showed significant benefits. Additionally, papers that reported the use of strategies to promote trust and respect within peer support interactions reported greater retention, 82.8% than those that did not, 48.1% ($p = 0.0027$) (Sokol & Fisher, 2016). Across these studies emerges a very important feature of peer support, its apparent value in reaching and benefitting those whom healthcare and promotion initiatives too often fail to reach.

Integration of Behavioral Health and Peer Support

As indicated in the review of characteristics associated with being hardly reached, psychological distress plays a prominent role. Among all characteristics used to identify hardly reached groups, “psychological and/or cognitive factors” was the most common, included by 38.92% of papers reviewed (Sokol, Fisher, & Hill, 2015). Additionally, attention is focusing increasingly on psychological characteristics associated with chronic diseases and complicating their management and associated quality of life (Fisher, Chan, et al., 2012, 2015). Depression has been most extensively investigated, especially as it coexists with diabetes. Individuals with diabetes are twice as likely to suffer from depression as patients without diabetes, and it is estimated that the prevalence of elevated symptoms of depression among individuals with diabetes is 31% (Anderson, Freedland, et al., 2001). Among those with coronary heart disease, 15–20% are estimated to meet criteria for major depression (Lichtman, Bigger, et al., 2008), and an additional 20% are estimated to have elevated symptoms of depression. But concern is not limited to depression. Hostility and anxiety are major risks for and complications of cardiovascular disease (Blumenthal, Sherwood, et al., 2012). Among cancer patients, the prevalence of anxiety is estimated to be 10%, and the prevalence of any mood disorder is estimated at 38% (Mitchell, Chan, et al., 2011).

As described in greater detail in the chapter on "Psychology, Mental Health, and Quality of Life" (Snoek et al., *infra*), broad social and economic contexts of family and social relationships, organizational, economic, and cultural factors influence both psychological and biological functioning. Those disadvantaged in a number of these areas are much more likely to develop some chronic disease and some psychological disorder. The particular diseases and disorders may be varied, but their likelihood is high. This "complex of developmental, biological, and psychosocial determinants" and the diseases and disorders to which it leads are, in turn, major contributors to avoidable emergency and hospital care in most health systems around the world.

If individuals are disadvantaged with regard to a number of factors in the "complex of developmental, biological, and psychosocial determinants," then developing some chronic disease and some psychological disorder are highly probable. The phenotypic expression of the complex may be varied, but the likelihood of expression is high. Thus, an important strategy is to develop interventions that address this underlying complex in order to reduce unnecessary burden of disease and associated costs (Fisher, Chan, et al., 2012, 2015).

There is much reason to think that peer support can be helpful in this area. In addition to psychological problems complicating other health problems, they are also themselves the object of peer support. Both the social isolation or lack of a confidant that often accompany psychopathology and distress (Fisher, Chan, et al., 2012, 2015) and the importance of simple social contact and emotional support discussed at the beginning of this chapter (Harlow, 1958) suggest that simple, frequent, affirming, and pleasant contact from a supporter may be especially helpful to those with emotional distress.

Data support this expectation. A meta-analysis by Pfeiffer, Heisler, and their colleagues found a pooled, standardized mean difference between peer support for depression and usual care of −0.59 favoring the peer support (Pfeiffer, Heisler, et al., 2011). The emotional benefits of peer support were illustrated in a study commissioned by the UK-based Stroke Association. Having a stroke can negatively impact on emotional well-being both in the immediate aftermath of a stroke, and in the longer term. In a small-scale study of the Stroke Association's peer support groups, supported by Nesta Health Lab and the Cabinet Office, some stroke survivors talked about "loss of the life and the person they were before their stroke." They highlighted significant changes to their personal and role identity, including a loss of independence and reduced ability to do things they had previously done, including taking care of others in their lives. For these stroke survivors, attending a group alongside supportive peers had a positive impact on their mental well-being. This was variously attributed to being among friends, to the creation of a supportive and social group atmosphere and to groups creating a space in which people could make sense of the ongoing emotional "ups and downs" that can follow a stroke.

In a striking cluster randomized evaluation in Pakistan, Lady Health Workers implemented a cognitive-behavioral, problem-solving intervention for women who met criteria for major depression during the third trimester of their pregnancies. Relative to controls, the intervention substantially reduced depression 12 months *postpartum* ($p < 0.0001$) (Rahman, Malik, et al., 2008). In India, peer support for depression, anxiety, and other mental health problems included education about psychological problems and ways of coping with them (e.g., deep breathing for anxiety symptoms) as well as interpersonal therapy (de Mello, de Jesus Mari, et al., 2005), all delivered by lay health counselors with backup by primary care and monthly consultations from psychiatrists. Results included a 30% decrease in prevalence of depression and other common mental disorders among those meeting criteria at baseline, 36% reduction in suicide attempts or plans, as well as reductions in days out of work (Patel, Weiss, et al., 2011).

A population-based study in the USA evaluated Medicaid enrollees who had made a claim for both community mental health and peer support services. A comparison group who had made only claims for community mental health services was matched by gender, race, age, urban/rural residence, and principle diagnosis. Those who had received peer support were more likely (OR = 1.345) to achieve crisis stabilization than the comparison group, and those who did not achieve stabilization were still less likely to be hospitalized (OR = 0.766) (Landers & Zhou, 2011).

Peer support also reduced distress and related hospitalizations among adults with diabetes in Hong Kong. The base of the program was JADE (Chan, So, et al., 2009a, 2009b), a standardized, systematic model of care incorporating many of the same emphases as Wagner's Chronic Care Model and the Patient-Centered Medical Home, e.g., quarterly reports to patients providing appraisal of clinical status and self-management recommendations. In addition to JADE, half of participants were randomized to receive PEARL, telephone-based peer support provided by trained peer supporters.

Reflecting patterns familiar to most in health policy and services, patients with elevated levels of depression, anxiety, and/or stress were more likely to be hospitalized (34%) than those without distress (20%). Among the group with heightened distress, the peer support intervention improved distress scores relative to standardized, high-quality care alone ($p = 0.03$) and reduced overall hospitalizations (relative risk =0.15, $p < 0.001$), a reduction to the "normal" level of those low on distress measures (Chan, Sui, et al., 2014). That is, among the fifth of patients with high scores on distress and who account for greatly disproportionate hospital care, the addition of peer support to standardized, high-quality clinical care reduced distress and lowered associated hospitalization rates to normal levels.

One of the striking aspects of these results of Chan and her colleagues is that the peer support intervention was designed to assist diabetes management, not to reduce emotional distress. Yet it had substantial effects on distress and associated hospitalizations. As discussed in an earlier section on the "Fundamental Value of Connection," the provision of peer support itself may have emotional and quality of life benefits, regardless of the particular curriculum or behavior changes the peer supporter is promoting.

Reaching Populations and Peer Support in Primary Care

Although exceptions are becoming more numerous (Bhutta, Lassi, et al., 2010; Patel, Weiss, et al., 2011; Perry, Zulliger, & Rogers, 2014; Rahman, Malik, et al., 2008), many studies of peer support continue to be based on samples of populations of interest. As much as these may illuminate important principles and intervention approaches, they are unable to address the challenge of reaching entire populations.

One approach to reaching populations is through primary care, therefore an especially important setting for peer support (Daaleman & Fisher, 2015). A number of the projects already cited have been conducted through primary care (Ayala, Ibarra, et al., 2015; Safford, Andreae, et al., 2015; Simmons, Cohn, et al., 2013; Simmons, Prevost, et al., 2015; Tang, Funnell, et al., 2014; Thom, Ghorob, et al., 2013). In one study, 12 group-based primary care office visits plus 12 individual phone contacts with peer coaches led to 4.5 kg losses among African-American adults with initial BMIs over 30.0 (Dutton, Phillips, et al., 2015). Recent development of the "Patient-Centered Medical Home" (Stange, Nutting, et al., 2010) emphasizes understanding individuals' in the context of their lives and comprehensive care addressing the person, not just the disease. This provides a context highly congruent with peer support (Bielaszka-DuVernay, 2011; Findley, Matos, et al., 2014; Volkmann & Castanares, 2011) as explored in a 2015 conference addressing varied approaches to applying peer support within the medical home (Fisher, Hacker, et al., 2015).

Turning to reaching populations through primary care, a program of Alivio Medical Center, a primary care, community health center in Chicago funded by the government to provide care for indigent people, set out to identify ways to provide peer support to the entire population of 3787 adults with type 2 diabetes whom Alivio serves. The project was also a collaboration with the National Council of La Raza and Peers for Progress.

In the program, *Mi Salud es Primero*, the intended audience of 3687 was divided into two groups. About 10% with elevated HbA1c values, apparent psychosocial distress, or who were referred by their primary care providers as needing extra support were placed in a "high-need" group. *Compañeros En Salud* reached out to these individuals through individual contacts and a protocol focused on self-management objectives and psychosocial and environmental barriers and implemented initially through biweekly phone calls, reduced to monthly and then quarterly as progress warranted. The balance of the population of 3687 with diabetes were approached with a less intensive protocol, including quarterly contacts by phone or group classes, activities, and contacts through regular clinical appointments. All participants were encouraged to participate in group classes and support groups and to contact the *Compañeros* when they felt that might be helpful. After 28 months, *Compañeros* had reached 90% of the high-need group of 468 and 91% of the balance of those with diabetes. This was associated with modest reductions in HbA1c ($p < 0.001$), from 9.36 to 9.12% in the high-need group, and from 8.05 to 7.94% in the rest of the population. Although modest, it is important to note that these were changes across the entire population, not just a selected study sample.

The program included nine *Compañeros* who worked with individual patients, yielding a case load of about 410 patients for each. At an annual salary of about $50,000 (including fringe), this yields a cost of $122 per patient per year, *not including* administrative and other expenses. Clearly, the challenges of reaching populations are substantial, but not insurmountable. As discussed earlier, for example, well-established peer support programs in Thailand with its Village Health Workers and in Pakistan with its Lady Health Workers show the feasibility of broad implementation of such programs.

Digital Peer Support

An important opportunity for extending peer support may lie in digital health applications. Through telephone, text, web-based, social media, and automated technology, digital resources can allow peers to deliver support across geographic distances, to larger numbers, and with more efficiency. As a complement to live peer support, digital tools can provide routine monitoring and even health messaging, using algorithms to prompt live outreach for those individuals or circumstances that may need it. Digital tools also respond in real time, making support more accessible and convenient. For patients with rare diseases, digital tools may present their only opportunity to find other patients with the same condition. Providers and researchers are pressing for the integration of e-applications and electronic medical records, which promises to improve patient monitoring and generate actionable data.

In the UK, Body & Soul, a charity working to promote the dignity and well-being of children, young people, and families living with or affected by HIV was funded by Nesta Health Lab and the Cabinet Office to expand their face-to-face peer mentor approach with young people through a new peer support digital offer. The grant has allowed the team to reach 435 young people across 74 local health authorities by mobilizing 25 volunteer peer mentors through over 3700 peer support calls. The digital peer support intervention showed positive impact including participants experiencing:

(a) Increased feelings of well-being and thinking about the future
(b) Less loneliness and isolation among young people living with HIV, with some clients highlighting an increased number of people whom they could talk to for support
(c) Increased confidence in their knowledge of HIV and their ability to communicate openly with health professionals, friends and romantic partners

Texting and telephone contact were used extensively in a peer support program in Uganda (Baumann, Frederick, et al., 2015), and automated text prompts were used in a South African program (Rotheram-Borus, Tomlinson, et al., 2012). In another study, automated telephone self-management support for low-income English-, Spanish-, and Cantonese-speaking adults improved reported self-care and SF-12 physical status (Ratanawongsa, Handley, et al., 2014).

In remote areas of Australia, Oldenburg and colleagues developed "Telephone-Linked Care" (Williams, Bird, et al., 2012). This provided messages and reminders that were personalized according to individual self-management and clinical measures, all monitored through data entered in patients' smartphones. HbA1c values declined from 8.8% to 8.0% and were accompanied by improvements on mental health indicators that exceeded those in a control condition. Medication costs were lower as well ($1542 vs. $1821 on average).

The four key functions of peer support provide a useful template for understanding the value of interventions such as the Telephone-Linked Care program. Consider the following ways in which features of the program fit with the four key functions:

- Assistance in Daily Management – Dialogues and individualized messages around self-management behaviors and medication adherence from among over 2000 prerecorded messages in the program library, facilitating great sensitivity to the nuances of users' reports, reminiscent of Bowlby's identification of the parent's sensitivity to the child's needs as key to attachment relationships (Bowlby, 1988).
- Linkage to Clinical Care – Program coordinator monitors patients' data to connect them with clinical providers as necessary
- Ongoing Support – Costs of adding additional users and extending use are quite modest once the system is put in place.
- Social and Emotional Support – Surprisingly, users reported that the system seemed to provide substantial social and emotional support; in addition to improvements in mental health outcomes, 79% strongly agreed that it gave them confidence to manage their diabetes better (Oldenburg, 2014).

Recent years have seen a boom in the release of smartphone apps for any number of chronic diseases. Though they began as tools to educate and build skills for self-management, the latest smartphone apps are designed around social connectivity. Developers of digital tools have realized that the main selling point of health smartphone apps is giving users the ability to connect with an online community of peers. App users trust the collective knowledge and experience of "patients like me," and they use these apps to actively seek out opportunities to give and receive support. For direct-to-consumer digital apps, endorsements from and coaching provided by peers can help patients overcome common barriers to initiating and maintaining app utilization.

Social Networking

Digital tools can recruit social networks and supports from individuals' family and friends. For example, in Piette's CarePartner program, patients received calls from an automated system, including information about ways to improve self-care. Information was then disseminated to (1) clinics, which received alerts about patients' signs and symptoms, and (2) family members/friends who received an email, IVR call, or SMS with updates on the patient's status. Results demonstrated significantly greater medication adherence among patients with a support person, as well as greater emotional benefits (e.g., fewer negative emotions) compared to those without a support person (Aikens, Trivedi, et al., 2015; Piette, Marinec, et al., 2016).

In another example, Valle and colleagues (2013, 2015) conducted an RCT of a behavioral intervention to increase moderate-to-vigorous intensity physical activity (MVPA) among young adult cancer survivors ($n = 86$) compared to a self-help comparison condition. Delivered primarily through Facebook, intervention participants received weekly Facebook messages with behavioral lessons, a pedometer, moderated social support discussion prompts within a Facebook group, and access to a goal-setting and self-monitoring website. Comparison group participants also received Facebook messages with general exercise information and a pedometer, but discussions within the Facebook group were unprompted (not moderated), and they did not have access to the website. After 12 weeks, the intervention participants significantly increased self-reported light physical activity compared with the self-help group. Both groups posted a comparable number of comments to their respective Facebook groups and increased weekly minutes of self-reported MVPA. Among all participants, social support from friends was associated with changes in MVPA. Overall findings from the study demonstrate the feasibility of messages and group functionalities of Facebook, the emergence of social support (both among intervention and comparison group participants), and the potential to enhance support for behavior change using social media, perhaps incorporating peer-led options as well.

Gamification

A promising digital approach entails embedding health messages and promotion within game formats (DeSmet, Shegog, et al., 2015; Miller, Cafazzo, & Seto, 2016). Gamification applies the elements of games in nontraditional gaming contexts in order to improve user engagement and experience (Deterding, Björk, et al., 2013; Deterding, Dixon, et al., 2011). In response to HIV disparities among young men who have sex with men, Lisa Hightow-Weidman and colleagues worked with the technology company Caktus Group (caktusgroup.com) to develop a technology-based "game" to increase HIV medication adherence. The result, *Epic Allies*, is a smartphone app for Android and iPhone platforms that utilizes game mechanics (mini-games, points, rewards, story-line, levels, competition, collaboration), behavioral tracking, tailored feedback, and social networking elements to increase uptake of and adherence to antiretroviral therapy (LeGrand, Muessig, et al., 2016). From 2015 to 2017, the efficacy of the app at achieving these goals will have been tested in a randomized controlled trial with men who have sex with men age 16–24 at 5 US sites (Florida, Illinois, Louisiana, New York, North Carolina). The app – including the main superhero theme – was iteratively developed through rounds of testing and feedback with end users (young, HIV-positive men who have sex with men). This process resulted in important changes and refinements to the app's gamification design features in order to draw clearer connections between the end user's actions in the game and their health behaviors (LeGrand, Muessig, et al., 2016). With the promise of promoting individual tailoring, 24/7 access, greater interactivity, and integration of gaming and social features, the *Epic Allies* app offers many benefits to participants, especially given the stigma surrounding HIV. Continued challenges for future researchers include gaining and maintaining user engagement and navigating how to capitalize on web/app development, especially given the rapidly evolving technology field and the different language and goals between researchers and developers.

Integrating Digital and Peer Support

"High tech" may be complementary to, not a replacement of, the "soft touch" of peer support. One can easily imagine individuals receiving both digital and live support interventions, the former addressing routine, redundant information and monitoring, and the latter engaging in problem-solving and attention to individual concerns. A current study (Tang, Peeples, et al., 2016) offers a digital tool for diabetes management, *BlueStar*®, as an enhancement of peer support. Participants took advantage of the flexibility with which peer support and the digital tool were offered. Some regularly used both and others used predominantly one or the other.

The blending of both digital and peer support may be advantageous. Patients at risk for nonadherence to antidepressant medication were offered support for adherence and symptom reduction through weekly interactive voice response technology. Among these, 61% opted for participating with a support person. Analyses indicated that only those who participated with a support person improved adherence and symptom remission (Aikens, Trivedi, et al., 2015).

The integration of digital and peer support suggests ways to enhance patients' choices, to titrate care and support according to patient need and preference, and to reach populations. All patients might be offered peer support, digital tools, basic diabetes self-management education (Powers, Bardsley, et al., 2015), online resources, and varied activities and promotional initiatives. Among these, combinations of digital and peer support might be actively promoted according to need. For those doing well (as gauged by blood glucose control, psychosocial status, and clinician appraisal), little more than offering the digital support might be indicated. For those doing only moderately well (again, gauged by clinical, psychosocial, and clinician indicators), the digital resource might be promoted more vigorously, perhaps through peer support contacts. For those not doing well (e.g., poor blood glucose control, abnormal values for blood pressure, lipids, heightened depression, anxiety or diabetes distress, and/or clinician identification), peer support might be offered proactively with digital tools as a resource within the peer support relationship. There are many ways in which such a plan might be varied by population, setting, and healthcare system, but the general model of combining intervention approaches to reach populations, meet varying needs, and support patient choices and preferences is an important direction for future research and program development.

Organizational Niches and Peer Support

A key issue for peer support is the organizational niche in which it should be placed. In what part of a community or clinical setting will peer supporters be housed, both organizationally and physically? Who will supervise the peer supporters? How will their work be linked with other services of the organization? How will they identify those to help? How and in what office will records of their work be developed and kept, and with whom will they be shared? The best answers to these questions will depend on the problems, settings, and populations to be served. They are, however, important to address.

In a program of New York-Presbyterian Hospital and Columbia University Medical Center, funds are given to cooperating community-based organizations to hire peer supporters who then work through those organizations while linking the organizations and those they help with the medical center's clinical resources (Center for Community Health Navigation). This supports the role of the community organizations as active collaborators in the program. In contrast, the Rhode Island Parent Information Network in the USA is based in the Rhode Island Department of Health and funds trained peer supporters who work out of cooperating pediatric practices (Rhode Island Parent Information Network). The program in New York is based in the clinical setting, but funds peer supporters in community settings, while the program in Rhode Island is funded through state government but places peer supporters in clinical settings.

In the program at Alivio Medical Center, described earlier, *Compañeros En Salud* was not part of clinical teams, but a separate group within the organization. The leader of the *Compañeros* reported directly to the head of the organization, not the medical director. At the same time, *Compañeros* were linked to clinical teams and spent part of their time in clinic to see patients during routine clinic appointments and coordinate with clinical care. This was intended to coordinate the peer support with clinical care but also provide patients a sense that the peer supporter was someone with whom they could comfortably share concerns, even about their clinical care. No doubt, what model best fits a setting may vary. What is important is that planning considers such organizational issues and their advantages and disadvantages for a particular program.

A number of other reports have raised valuable questions for consideration in developing a plan for the organizational home of a peer support intervention. Instead of setting up a new program, objectives can be incorporated into existing programs and structures. Haire-Joshu and her colleagues pursued this in several programs. One incorporated energy balance interventions into adult mentoring of disadvantaged, ethnic minority children (Haire-Joshu, Nanney, et al., 2010). A second incorporated obesity prevention and control into a program of home visiting and parent mentoring for adolescent mothers (Haire-Joshu, Schwarz, et al., 2015). Others also have pursued this strategy, including integrating healthy nutrition and physical activity into an after-school setting (Choudhry, McClinton-Powell, et al., 2011).

With its strong ties to broader community organization and community health promotion approaches, peer support has often been linked with community programs. The program among low-income African-Americans in rural Alabama in the USA, described earlier, drew heavily on community input for program planning (Cherrington, Martin, et al., 2012) and went on to exceed recruitment goals (Andreae, Halanych, et al., 2012) and achieve improvements on several clinical measures (Safford, Andreae, et al., 2015). A prominent community-oriented approach is to organize peer support through churches (Samuel-Hodge, Keyserling, et al., 2009; Simmons, Fleming, et al., 1998; Tang, Nwankwo, et al., 2012, 2014).

In Birmingham, Alabama, Cherrington and her colleagues established a searchable, interactive web-based resource providing details about local programs for diabetes prevention and management, intended both for individuals as well as peer supporters and professionals (Cherrington, Agne, et al., 2015). They then went on to develop a fee-for-service program through which local provider groups or other organizations may contract for peer support services (Fisher, Hacker, et al., 2015). Clearly, there are many ways in which peer support can be organized and sustained through community and healthcare settings. Implementation and dissemination research needs to articulate alternative approaches to enable programs to find those that best suit their purposes, settings, cultures, and populations served.

Peer Support as a Continuum

In February, 2016, representatives from diabetes peer support programs in Denmark, Finland, France, Holland, and the UK met in London, hosted by the Nesta Health Lab, by the Steno Diabetes Center of Copenhagen and by Peers for Progress. Although sharing a focus on diabetes, the range of programs was striking. It included individual, group, telephone, and web-based programs, those focused on newly diagnosed individuals and their families, those focused on sharing experiences among those with diabetes, and many more approaches. (A report from the meeting is available at peersforprogress.org.) Some might be viewed as "pure" peer support in which an individual with diabetes but no professional training or a family who has dealt with type 1 diabetes helps another family to cope with their new challenges following diagnosis of a child. Others, such as a mutual support website, or an automated digital app, or a peer support group facilitated by a trained nurse might be seen as including elements of peer support.

Toward the end of the day's discussions, one individual pointed out, "peer support is really a continuum." Expanding on this, it appears more worthwhile to examine the many ways peer support can be provided and woven through prevention and care than to spend effort worrying about what is and is not "real" peer support or who is and is not a "real" community health worker or *promotora*. This lays the ground for a robust view of peer support as a set of intervention emphases that can be integrated into a variety of settings and services, rather than a highly demarcated service that risks isolation and marginalization. A narrow definition would also tend to limit health system support to a similarly narrow range of interventions. The potential of other forms, varieties or levels of peer support to grow and reach and benefit those they may would be regrettably constrained.

That we best view peer support as a continuum is also suggested by the observation from Uganda, above, that the peer support program was not maintained as a distinct program but, rather, was incorporated into ongoing clinical routines such as in making appointments for patient dyads to encourage their continued mutual support.

Viewing peer support as a continuum encourages exploration of how it can be included in a wide range of programs and interventions and how a wide range of individuals, not just "real" peers, can adopt peer support strategies and approaches in their work, even if they do so as professionals, counselors, or in other roles. Just as promoting psychology is not limited to psychologists and promoting health is not limited to health professionals, so promoting social and peer support can reach far beyond those with titles denoting peer support.

Conclusions and Policy Implications

A 2014 international meeting hosted by Peers for Progress and addressing much of this work (Peers for Progress, 2014a) noted that, in addition to its contributions to effectiveness, reach to populations, including those often hardly reached, and benefits for quality of life as well as clinical status and prevention, peer support fills a critical role in *humanizing health care*. If not unique, this dual role of combining effectiveness and humanizing care is an important feature of peer support for prevention and health care of the future.

Beyond showing that "it works," emerging research shows that peer support is broadly feasible and sustainable. Dissemination can combine standardization, such as through the four key functions emphasized here, and adaptability to local circumstances. Keys to its success are becoming clear, including both person- and community-centered implementation, proactive offering of services, and attention to emotional as well as instrumental support. Most important, perhaps, peer support shows strong potential for addressing key priorities in "bending the curve" through healthcare reform (Rosenthal, Brownstein, et al., 2010): reaching those whom conventional services too often fail to engage, mitigating and reducing costs associated with co-occurring physical and psychological problems, and providing intervention models adaptable to diverse settings and populations. Future work should expand the individuals and groups providing support, the concerns and objectives for which it is useful, the organizational arrangements through which it can be implemented, the modes and channels by which it is delivered, the nuance with which it is employed, and, thereby, the individuals, families, and groups who benefit from it.

Acknowledgments The development of this chapter has been supported by Peers for Progress, a program of the Department of Health Behavior in the Gillings School of Global Public Health at the University of North Carolina at Chapel Hill. Much of the work of reported in this chapter was supported through Peers for Progress while it was administered through the American Academy of Family Physicians Foundation (2006–2015) and through contributions from the Eli Lilly and Company Foundation and the Bristol-Myers Squibb Foundation. Additional support is provided by the Michigan-UNC Peer Support Research Core of the Michigan Center for Diabetes Translational Research (P30DK092926 from the National Institute of Diabetes and Digestive and Kidney Diseases, PI: William Herman) and by the Merck Foundation, Sanofi China, and Novo Nordisk.

In particular, this chapter would not be possible without the work of investigators supported by grants from Peers for Progress. In alphabetical order according to organization, they are:

Engaging Communities to Improve Health: Models, Evidence, and the Participatory Knowledge Translation (PaKT) Framework

Shoba Ramanadhan and K. "Vish" Viswanath

Introduction

A 1988 report from the US's Institute of Medicine (IOM) suggested that much decision-making in public health was driven by "crisis, hot issues, and concerns of organized interests" (Institute of Medicine Committee for the Study of the Future of Public Health, 1988). More than 25 years later, that concern still resonates, leading to repeated appeals to better link research evidence with community needs and preferences to improve population health in a systematic and strategic manner (Kohatsu, Robinson, & Torner, 2004). The process of leveraging evidence to promote changes in population health is often referred to as knowledge translation (KT). As described by The Canadian Institutes of Health Research (2004), KT encompasses the "exchange, synthesis, and ethically-sound application of knowledge – within a complex set of interactions among researchers and users – to accelerate the capture of the benefits of research for [populations] through improved health, more effective services and products, and a strengthened health care system." That is, effective KT is not simply a cognitive or intellectual process but entails action on the part of systems, groups, organizations, and diverse individual behavior. Effective KT approaches are expected to yield diverse benefits including increased utilization of successful programs and policies, increased program sustainability, heightened organizational efficiency/use of limited resources, and greater impact on health outcomes (Brownson, Baker, et al., 2011; Brownson, Fielding, & Maylahn, 2009; Canadian Institutes of Health Research, 2004; Rychetnik, Hawe, et al., 2004). Despite their potential, KT approaches are not the norm in public health settings at this time, resulting in lost opportunities and wasted resources (Brownson, Baker, et al., 2011).

A significant arena for the application of evidence to public health challenges is within local community institutions and organizations. Community-based organizations (CBOs) and nongovernmental organizations are vital – but often underutilized – channels and partners in the delivery of health promotion programs to the general public (Kerner, Gruiguis-Blake, et al., 2005; Maibach, Van Duyn, & Bloodgood, 2006; World Health Organization, 1999). These organizations are also the front line in translation of many large-scale efforts that reflect policymaking at the local, state, or federal levels and thus

are vital to the success of those programs. CBOs targeting underserved populations are of particular importance as improved links between research and action in these organizations may be an important support for reducing and eliminating health disparities (Institute of Medicine, 2001, 2008; Viswanath, 2006).

Despite tremendous interest in the field, it is still unclear how best to leverage KT in community settings to create sustained social change (Owen, Glanz, et al., 2006). Important challenges include:

1. Limited practitioner access to and skills to use knowledge in a timely manner
2. Gaps between practitioner expertise related to the problem and researcher expertise related to potential solutions
3. A mismatch between evidence-based strategies/programs and adopting organizations (e.g., resource demands, lack of capacity within adopting organizations for implementation, problems defined based on academic divisions, rather than real-world issues)
4. Barriers related to implementation context (e.g., political opposition, lack of leadership, competing tacit knowledge from practitioner experience, complex program delivery environments, organizational inertia, lack of resources, etc.)
5. Inability to translate research results to practice settings (e.g., results that are not relevant to practice settings, lack of capacity among researchers to engage in translation activities) (Brownson, Colditz, & Proctor, 2012; Glasgow & Emmons, 2007; Harrop, Nelson, et al., 2012; Landry, Amara, et al., 2006; Stamatakis, Vinson, & Kerner, 2012; Woolf, 2008)

A major challenge with existing KT models is that most rely on top-down, centralized approaches, which restrict the ability of local institutions to leverage their expertise and underemphasize the fact that evidence-based strategies are being adopted in increasingly diverse settings. Translational efforts are often hindered or even halted by challenges of addressing local context or practice settings (Brownson, Fielding, & Maylahn, 2009). This is a particular challenge as an important part of the KT process is implementation or the integration of evidence-based strategies into practice settings. Most implementation occurs at the local level even if policies are formulated at the national or regional level. In this way, variation in local capacity to leverage the evidence base can lead to variation in outcomes, which can create or exacerbate disparities. Yet another challenge with current orthodoxy is that it does not always account for dynamic changes occurring at the local level, resulting in rigid prescriptions instead of taking an iterative flexible approach. Finally, assessments of implementation tend to focus on the movement of a given program or strategy through a system (with a treatment of the system as a fixed entity).

Following these considerations, this chapter seeks to review important approaches to creating change in communities, highlight gaps in current approaches, and propose a novel approach to creating social change in communities. In the section "Community Organization and the Evolution of Participatory, Ecological, and System Approaches to Creating Change", we draw on early community trials for cardiovascular health and describe recent advances in participatory, ecological, and systems approaches to KT. In the section "The Participatory Knowledge Translation (PaKT) Framework", we present the participatory knowledge translation (PaKT) framework and provide examples of its application. Finally, in the section "Conclusions and Next Steps", we discuss opportunities for future research and practice based on the PaKT framework.

Community Organization and the Evolution of Participatory, Ecological, and System Approaches to Creating Change

The Initial Cardiovascular Health Programs

The early community trials focused on cardiovascular health offer acute insight into the opportunities and challenges of creating social change in communities. In the 1970s and 1980s, the reduction of cardiovascular disease (CVD) and related risk factors were gaining attention as major public health priorities. In light of evidence that primary prevention through behavior change could be a feasible population-wide solution to lower CVD rates, in conjunction with the growing popularity of using community settings for behavior change, programs began using larger-scale strategies that intervened at the community level. The North Karelia Project was one of the first of this group of programs, and is one of the most well known, given its successes. The project was started in 1972 as a community-based project to address cardiovascular disease in North Karelia, a county in Eastern Finland (Puska, Nissinen, et al., 1985). The main objective of the program was to reduce coronary heart disease (CHD) mortality in the population, with intermediate objectives to reduce levels of major risk factors such as smoking, elevated serum cholesterol, and elevated blood pressure. Dietary changes to reduce cholesterol were an important target of the intervention. The program utilized a wide range of strategies, including mass media-based education, training of community residents, and provision of materials necessary for residents to implement simple, sustainable activities promoting lifestyle changes, with an emphasis on smoking and dietary habits. Training activities also targeted doctors and nurses and also social workers, representatives of voluntary health organizations, and informal opinion leaders. Attention to the health system included treatment guidelines and reorganizing treatment for hypertension as well as care following myocardial infarction (Puska, 2009). The intervention developers strategically involved the health services, voluntary, media, business, and policy sectors to create broad-based change. The breadth of these involvements was striking, including in the food industry, for example, not only grocery stores but dairies and sausage factories. Also, there was substantial interaction among the components of the campaign so that, e.g., mass media interventions interacted with local newspapers and community organizations.

The program resulted in significant changes in smoking, cholesterol, and blood pressure in North Karelia compared to the reference area, although differences by gender were observed (Puska, Nissinen, et al., 1985). About 20 years after program inception, CHD mortality among men declined significantly between the preprogram assessment (1969–1971) and 1995, with a decline of 73% in North Karelia compared to 65% across Finland. A similar decline in CVD mortality was also found. Among men, lung cancer mortality decreased significantly more in North Karelia in the 1980s and 1990s versus all of Finland. Among women, a marked reduction in CVD mortality and a small reduction in lung cancer mortality were detected (Puska, Vartiainen, et al., 1998). An assessment at the 35th anniversary of the program inception provides a sense of the scale of possible changes. In Finland, serum cholesterol levels declined strongly between 1972 and 2007. Blood pressure also declined through 2002. Smoking rates declined among men but increased among women until 2002 (at which point they leveled off). For body mass index, levels increased between 1972 and 2007 for men. For women, they decreased, until 1982, but increased through 2007. Overall, changes in risk factors were linked to a 60% reduction in CHD mortality for middle-aged men (in the context of an overall 80% decline) (Vartiainen, Laatikainen, et al., 2010).

Due in part to the broad community model and successes of North Karelia, the US National Heart, Lung, and Blood Institute (NHLBI) funded a series of large research and demonstration programs in the USA to explore the feasibility of implementing large-scale community programs targeting activities to lower both risky behaviors and subsequently CVD morbidity and mortality rates in the community (Viswanath, Finnegan, et al., 1991). These studies are described in rich detail elsewhere; key attributes of the projects are presented here:

- Stanford Five-City project: The program was funded from 1978 to 1996 and covered five California communities. The two treatment communities received 5 years of intervention, which focused primarily on delivering health education for behavior change through print and broadcast media programs, with other educational opportunities provided in community settings. The long-term goal was to establish locally-run programs that were tied to the investigators, but not supported by them, so that the programs could be maintained by the communities (Farquhar, Fortmann, et al., 1985). The program produced change in smoking rates, cholesterol, blood pressure, resting pulse and CHD risk (Farquhar, Fortmann, et al., 1990).

- Minnesota Heart Health Program (MHHP): Funded from 1980 to 1993, the program covered six communities in Minnesota, North Dakota, and South Dakota (Murray, 1995). The three treatment communities received 5–6 years of intervention, and strategies included the use of several mass media channels to deliver messages on healthy behaviors, a strong emphasis on building community advisory boards, and educational programs in schools, worksites, and community settings (Jacobs, Luepker, et al., 1986; Luepker, Rastam, et al., 1996). Community analysis and organization were important strategies used to engage community leaders and organizations, resulting in active involvement of groups to support risk reduction (Murray, 1995). Impact was demonstrated on smoking prevalence among women and increased physical activity for men and women (Luepker, Murray, et al., 1994).
- The Pawtucket Heart Health Program (PHHP): Funded from 1980 to 1996, the program covered two communities in the New England region of the USA. The treatment community received 7 years of intervention, with programming focused on targeting CVD risk factors (including smoking cessation, cholesterol reduction, and maintenance of a desirable body weight), building skills for behavior change, and fostering community activation (Carleton, Lasater, et al., 1995). The PHHP emphasized involvement of community volunteers to carry out program activities (Lefebvre, Lasater, et al., 1987). Reductions in obesity and CHD risk were the major outcomes (Carleton, Lasater, et al., 1995).

These trials had a number of common features, including the emphasis on harnessing the power of the community to create large-scale change. These trials also tended to rely explicitly on theories of behavior change, communication, and diffusion of innovations. As a group, the trials emphasized the complex, multilevel drivers of CVD and accordingly developed multilevel intervention strategies. Strategies included mass media campaigns, network interventions, community organization and mobilization, environmental changes (e.g., changes in supermarket offerings or clinical services), and policy change (e.g., encouraging the implementation of smoke-free policies for public areas, schools, and worksites). They utilized quasi-experimental controlled designs and utilized baseline surveys, panel follow-ups, and cross-sectional surveys (Viswanath & Finnegan, 2002).

Despite these similarities, the three US-based trials utilized different strategies in engaging communities and creating system change. Broadly, the Stanford project utilized mass media (television, radio, and print materials) and group programs implemented in community settings to support behavior change, whereas the MHHP emphasized face-to-face communication, community events, and television, and the PHHP emphasized community organization and action, health promotion campaigns, and activities supporting screening, counseling, and referral to services (Flora, Lefebvre, et al., 1993; Lefebvre, Lasater, et al., 1987; Winkleby, Feldman, & Murray, 1997).

The community prevention trials demonstrated the importance of using multiple interventions to influence individuals' knowledge, attitudes, and behaviors as well as institutional and environmental supports to promote and sustain behavior change (Finnegan, Bracht, & Viswanath, 1989; Finnegan & Viswanath, 1999). Another important strength of the four large cardiovascular prevention programs is that they were better able to approximate "real-world" environments than laboratory-based trials. Data from such trials are expected to be more relevant to practice than data from tightly controlled trials. Another advantage of the community intervention approach is that it does not require activated participants, such as those who might enroll in a clinic-based intervention. Instead, community members are exposed to the intervention and system changes as they go about their regular lives. Accordingly, these interventions may reach a broader audience than those served by the healthcare system directly (Fortmann, Flora, et al., 1995). Yet, these theoretical advantages were not always realized. Taking the Stanford project as an example, the protocol required intensive evaluation activities for some participants more characteristic of a laboratory trial, which may have altered the received dose of the program and also impacted participation rates, negatively impacting the expected population-wide reach (Leventhal, Safer, et al., 1980).

Ultimately, the early cardiovascular trial projects were deemed of limited success in terms of cardiovascular health-related outcomes, due at least in part to secular trends in comparison communities obscuring program effects. In fact, the lack of sufficient dose to overcome secular trends may have affected all three programs, a problem not uncommon with most public health programs (Viswanath & Finnegan, 2002; Hornik, 2002). A careful analysis suggests that changes in comparison communities may have been due to improved clinical diagnosis and treatment of heart disease, as well as increased adoption of preventive behaviors among the public. These changes in behavior may have resulted from mass media campaigns and increased attention to heart disease among the media due to the ability of scientists, policymakers, and others to place this issue on the media's and thus the public's agenda (Viswanath & Finnegan, 2002). Additionally, the traditional evaluation models were built under the assumption of little change in comparison communities and media systems (Viswanath, Finnegan, et al., 1991). Another evaluation challenge relates to the expected effect size and statistical power. The three US-based trials were powered to detect what may have been overly ambitious reductions in risk factors (10–20% declines) and also assumed very low rates of change in comparison communities (Viswanath & Finnegan, 2002; Winkleby, Feldman, & Murray, 1997).

From an outcomes standpoint, it was clear at the end of the trials that assessments should have included a wider range of targets, i.e., moving beyond immediate change in biological markers and risk factors. In many of the demonstration projects, although changes in CVD risk and biochemical measurements such as blood pressure and cholesterol were smaller than expected, focusing on these specific endpoints may have missed the range of positive change that rippled through the communities, setting the stage for change at a later time. The need for long-term monitoring to see change in population-based CHD mortality was noted in the North Karelia Project (Puska, Nissinen, et al., 1985). As critics of the Stanford project highlighted, the emphasis on clinical markers, rather than behavior change among individuals and communities, limited the impact of the trial on the field of preventive health (Leventhal, Safer, et al., 1980). Although intermediate markers, such as knowledge and awareness, and community impact markers, such as organizational or environmental changes, were included in the assessments of each of the three trials (Pirie, Stone, et al., 1994), greater emphasis on the impact of intervention components on behavior change processes would have supported greater application of the findings. While the overall findings may have been less than expected, several components of the interventions often interacted to produce parental involvement, increased social networks, and other positive changes within groups of the community; however, the challenges in testing many combinations of these components on a broader scale may have led to an underestimation of their success (Mittelmark, Hunt, et al., 1993; Schooler, Fortmann, & Flora, 1997). For example, at the close of the MHHP intervention, greater social connectedness was found in worksite organizations providing health promotion services (Weisbrod, Pirie, & Bracht, 1992), although this finding was not included as a main outcome to gauge study success.

Another challenge to the trials may have come from the way communities were defined and integrated into the theoretical base of the intervention. Researchers affiliated with the MHHP note that the working definition of the community may have been too narrow to achieve the program goals. The program focused intensively on residents of three selected communities but did not/was unable to control the larger social environment that impacted these communities. Investigators noted that changing the behavior of whole communities may require changing their broader social environment as well, which was beyond the scope of this program, but may have limited the program's ability to create change in community-level outcomes (Luepker, Murray, et al., 1994). An example of broader social change assessed, but not addressed, by the MHHP relates to state-level restrictions on tobacco use. Assessments of opportunities to change policy and public support for policy change were conducted, though the findings were not translated into action during the course of the initial trial (Mittelmark, Hunt, et al., 1993). For the Stanford project, critics highlighted the mismatch between the community trial goal and the predominance of individual-level behavior change theories in the intervention design, with insufficient attention to community processes and outcomes (Hawe, Shiell, & Riley, 2009; Leventhal, Safer, et al., 1980).

Based on the experience and findings of the early cardiovascular trials, suggestions for improving community-level interventions include the following:

1. A greater emphasis on creating interventions that suit the local context in terms of the population, culture, and social/political climate
2. An increased emphasis on multi-sectoral partnerships (particularly among non-health sectors) to allow for a sufficiently multilevel and integrated effort
3. Coordination of intervention activities across levels of influence
4. Ensuring a sufficient reach and dose across the target audience
5. Allowing sufficient time for community needs assessments, networking, and relationship development before the intervention starts
6. Tailoring programs for community characteristics, such as leadership, community participation, capacity, networks, community values and unification, and community ability to address problems (Goodman, Speers, et al., 1998; McLaren, Ghali, et al., 2007; Mittelmark, Hunt, et al., 1993; Papadakis & Moroz, 2008; Schooler, Fortmann, & Flora, 1997)

Overall, the initial cardiovascular trials highlighted the importance of multilevel, multiprong action to create change in communities. They also highlighted the potential to leverage the evidence base for large-scale program development and planning. At the same time, the modest results and challenges to sustainability point to the need to take a broad, long-term perspective on creating social change in communities. The required intensive investment and long-term solutions cannot be achieved simply through external agents' action. An important potential solution to these challenges lies in the use of participatory approaches to creating change in communities.

Participatory Approaches to Knowledge Translation

Many of the challenges with bringing research evidence to bear in community settings stem from the distance between research and practice settings. Early attempts at leveraging the evidence base often focused on a "push" from the research and funding communities. Current strategies proposed also include a "pull" approach, driven by the needs and capacity of practitioners and "system capacity" for supporting the use of evidence in practice (Green & Mercer, 2001; Lavis, Lomas, et al., 2006; Orleans, 2007). Another way to bridge this gap is to engage communities and other stakeholders using a participatory approach so that research produced is more relevant to communities and more widely disseminated (Glasgow & Emmons, 2007; Minkler & Salvatore, 2012; Woolf, 2008). Importantly, a participatory approach, such as that described by community-based participatory research (CBPR), can engage the end users of the knowledge early in the process, thus enhancing the probability of successful translation. That is, practice may influence the nature of research questions, study designs, and interpretation of results plausibly leading to more relevant research and sustained social change.

CBPR is an approach to research that is collaborative and involves all partners in a process of co-learning and capacity-building to create change and link knowledge and action to improve health and reduce health disparities (Israel, Schulz, et al., 1998; WK Kellogg Foundation, 2001). CBPR is vital for translational research as it allows researchers to leverage the rich knowledge of practitioners and community members and potentially improve intervention impact in a wide range of settings (Minkler & Wallerstein, 2008). By increasing the relevance of the research conducted and insights gathered, there is potential to increase the application of research evidence to practice settings. CBPR is particularly relevant for KT work as it emphasizes multidirectional flow of information between researchers, communities, organizations, and policymakers, not the typical unidirectional flow from researchers to communities (Minkler & Salvatore, 2012). In this way, the approach directly addresses a number of challenges related to translational research, including issues of external validity, privileging of academic versus practice-based knowledge, power dynamics in universities, limited attention to sustainability, difficulties with communication between academics and practitioners, and historical lack of trust between researchers and practitioners (Wallerstein & Duran, 2010). An example that addressed each of these issues comes from work conducted by Duran and colleagues in New Mexico (Wallerstein & Duran, 2010). Using participatory approaches, a team of researchers, service providers, and community partners integrated evidence-based, culturally appropriate services for Native Americans with/at risk for HIV into a new care center. The engaged approach was credited with leveraging indigenous knowledge, increased health impact, increased acceptability of services, and improved potential for sustainability.

An important aspect of CBPR for KT is its roots in action research, or the approach to research that studies the impact of a range of social actions, with the goal of producing practical knowledge to support further action (Lewin, 1946). The action research approach emphasizes democratic, participatory processes to develop practical knowledge to address important issues for individuals and communities. Researchers are expected to approach a problem with the understanding that others will know as much, or more, as they do about the issue and potential solutions (Brydon-Miller, Greenwood, & Maguire, 2003). The work proceeds in a "spiral of steps" composed of cycles of planning, action, and evaluation that feed the next set of steps in the spiral. The evaluation, or "fact-finding" components, is essential to understanding the impact of one set of actions and setting the stage for refinement for greater success in the next iteration (Lewin, 1946). The emphasis on iterative steps and feedback of the results into the system as well as to involved parties are seminal components of this approach. Outputs of research from this perspective allow individuals and communities to set up systems to create the change they value (Bargal, 2006; Brydon-Miller, Greenwood, & Maguire, 2003).

Ecological and Systems Perspectives

An important complement to the participatory approach to KT is the adoption of ecological and systems perspectives. As described by Bronfenbrenner (2005), the ecological perspective emphasizes the embeddedness of an individual in his/her environment and the mutual influence between the individual and environment. In typical public health applications for individual behavior change, the perspective prompts attention to micro-level influences, such as biology or interpersonal influences of individuals, family, friends, and colleagues; meso-level influences, such as community structures and organizations; and macro-level influences, such as policies and governing institutions. In the context of KT in community settings, we must consider the multilevel drivers that support or hinder the application of evidence to solve public health problems, as well as the multiple levels at which KT can have impact. Change requires individual change as well as linked social and structural supports. Change can be created more quickly and more sustainably if multiple actions work independently and interdependently to move a system toward a desired set of outcomes (Trickett, 2009). Accordingly, we take into account multiple influences and impacts of action by individuals and organizations charged with creating social change. We also consider interactions within and between levels, both directly and indirectly (Bronfenbrenner, 2005; Schensul, 2009; Trickett, 2009).

An evaluation of an international effort for diabetes prevention highlights the challenges and supports for an ecological approach to KT. A range of projects across the KT continuum were conducted in the USA, Vietnam, the Philippines, Sri Lanka, India, Australia, Guinea, Cameroon, and Jordan. Key barriers and facilitators to translation of diabetes prevention efforts existed at the following levels: target population, staff, and organizational/interorganizational. Potential solutions highlighted the importance of engaging end users in a different manner than traditional outreach efforts, investing time in relationship building and capacity building (among staff and supporting organizations), and preparing for dissemination activities to a diverse set of stakeholders as knowledge was gained. The review highlighted the complexity of intervening in systems but also highlighted the potential to create sustainable change if the challenges were met (Garcia de Quevedo, Siminerio, et al., 2012).

Ecological approaches can often be supported via community mobilization. Community mobilization refers to processes by which community groups and institutions convene and collaboratively identify health topics, create action plans, and then take action to support change (Minkler, Wallerstein, & Wilson, 2008; Roussos & Fawcett, 2000). The potential for community mobilization and collaboration in the arena of health promotion has been of great interest to private and public sector actors, resulting in an intense focus on the formation of coalitions, alliances, and other forms of interorganizational partnerships (Butterfoss, Goodman, & Wandersman, 1996; Lasker, Weiss, & Miller, 2001). A useful example comes from the Canadian Heart Health Initiative. For a provincial project in Prince Edward Island, the leaders of the initiative utilized techniques of community mobilization to engage coalitions to promote heart health. With this perspective, the effort increased research and programming capacity in the community, strengthened partnerships, increased investment into the activities by the community, and expanded the scope of the project to a multilevel effort (Robinson, Elliott, et al., 2005).

Intersectoral partnerships – relationships among actors from diverse sectors, such as education, public health, and criminal justice – offer an important target for creating sustainable change. This is in line with the social determinants of health perspective that acknowledges the contribution of different sectors – health and non-health to health outcomes. Intersectoral partnerships can marshal human and social capital from a wide range of partners and are one solution to problems that cannot be tackled by an organization or sector in isolation (Lasker, Weiss, & Miller, 2001; Provan, Nakama, et al., 2003; Provan, Veazie, et al., 2005; Roussos & Fawcett, 2000). Inclusion of diverse partners can increase the range of resources available, not only in terms of pooling of resources or resource exchange but creation of new and effective resources and the potential to impact a broad set of influences on health (Burt, 1992; Lasker, Weiss, & Miller, 2001). Despite the potential benefits of partnership in community settings, there are many barriers, including interorganizational differences in values, missions, goals and norms, competing interests, and challenges of competing for scarce resources (Provan, Nakama, et al., 2003). Thus, the challenges with creating interorganizational partnerships is non-trivial, though such efforts have successfully been applied to address health disparities overall (Hennessey, Smith, et al., 2005) as well as specific behaviors and diseases, such as diabetes (Giachello, Arrom, et al., 2003), HIV/AIDS (Parker & Aggleton, 2003), and substance abuse (Shults, Elder, et al., 2009).

An important challenge posed by ecological models and intersectoral partnerships relates to the scope of efforts to create change. For example, a comprehensive approach to obesity might include families, schools, neighborhood business, and local government. Yet, supporting and coordinating action among such diverse constituents would probably call for more resources than the typical local organization can bring to bear. Or, competition and conflict may derail or inhibit efforts to mobilize different sectors. This is particularly the case in large heterogeneous communities where conflict is part of the system (Tichenor, Donohue, & Olien, 1980). One important solution is in the form of broad-based coalitions that bring together public, private, and nonprofit sectors. These can be government sponsored or locally commissioned and can spread the burden of coordination across a range of agencies, rather than attempting to have a single organization attempt the task. For example, a recent partnership among researchers, community groups, and service providers in Tampa, Florida, highlighted the power of a diverse coalition to assess local needs related to mental health and substance abuse, identify appropriate evidence-based practices, and support their implementation. Through engaging with potential stakeholders from the needs assessment onward, the group was able to identify and implement acceptable and sustainable solutions (Rugs, Hills, et al., 2011).

The field of systems science is also vital to KT efforts in community settings. This area of inquiry focuses on complex systems, or those in which the functioning package of parts, or the whole, is different than the sum of its parts due to interplay between parts. A useful definition from the World Health Organization (WHO) highlights the following features of systems: self-organizing, nonlinear, dynamic, history-driven, tightly linked, counterintuitive, feedback-driven, and resistant to change. The WHO vision of systems science is inherently participatory, with explicit guidance for inclusion of diverse stakeholders in understanding systems, defining success and goals, and devising systems-based solutions to public health problems (de Savigny & Adam, 2009). An important idea is that the outcomes are durable and adaptive (Luke & Stamatakis, 2012). Given the complex and important interplay between elements, the study of KT thus requires a study of the whole system to understand opportunities to create change. This perspective addresses limitations in behavioral science that stem from roots in the biomedical tradition, which prompt seeking of results that are highly generalizable, assume linearity, and mask, rather than delve into, differences between groups (Livingood, Allegrante, et al., 2011). These ideas parallel the idea of complex/systems interventions, in which the overall impact is not a simple addition of the components (Hawe, Shiell, & Riley, 2004). A useful example of the application of systems science approaches for KT comes from the Prevention Impacts Simulation Model (PRISM), developed by the Centers for Disease Control and Prevention, with co-funding from the US National Institutes of Health. PRISM allows communities to model potential impacts of health policies that target chronic diseases, project time and effort required to create a given change, and assess the potential impacts of partially implemented changes. By integrating evidence and modeling capabilities and making them accessible to decision-makers, the tool is able to leverage the power of systems modeling for supporting evidence-based policy change (Homer, Milstein, et al., 2010).

Clearly, it is a complex task to intervene in communities and systems. The motivation to engage in work at the intersection of KT, CBPR, and multilevel/systems interventions is summed up nicely as follows by Brydon-Miller et al. (2003):

> Messes are complex, multi-dimensional, intractable, dynamic problems that can only be partially addressed and partially resolved. Yet most action researchers have disciplined themselves to believe

> that messes can be attractive and even exciting. We try not to avoid messy situations despite knowing that we do not have the 'magic bullet' because we believe that, together with legitimate community stakeholders, we can do something to improve the situation.

The Participatory Knowledge Translation (PaKT) Framework

Clearly, there are a number of challenges to creating evidence-driven, broad-based change in communities to improve health. It is our contention that a system that allows for ongoing translation of evidence/data into sustained community change efforts will address many of the barriers to improving health and addressing health disparities in communities. The success of such a system hinges on sustained engagement in a community with community stakeholders. Thus, we outline a *process* by which individuals and organizations can engage with communities to leverage KT and develop systems that promote social change over the long term. In this way, the framework we offer explicitly addresses a major challenge of many past efforts, which have typically relied on outsiders to kick-start or even attempt to control the change process. Lack of user engagement and ownership for these outsider-driven changes has been a major cause of failure for change efforts. We focus here on community engagement and mobilization, not just participation, with KT processes as the engine that fuels ongoing change. The framework also explicitly includes attention to health disparities and social/contextual drivers of those disparities, which also prompts a long-term perspective that addresses differing targets as health profiles and disparities shift. The goal of the outlined process is to build multilevel infrastructure for promoting change in communities to improve health. Our experiences with successes and challenges to application of this framework have served to refine it, and we discuss these experiences in detail below.

As seen in Fig. 23.1, there are three major inputs to the framework: institutionalized participation, investment in communities, and knowledge production/transfer, which are linked to infrastructure impacts by iterative Plan-Do-

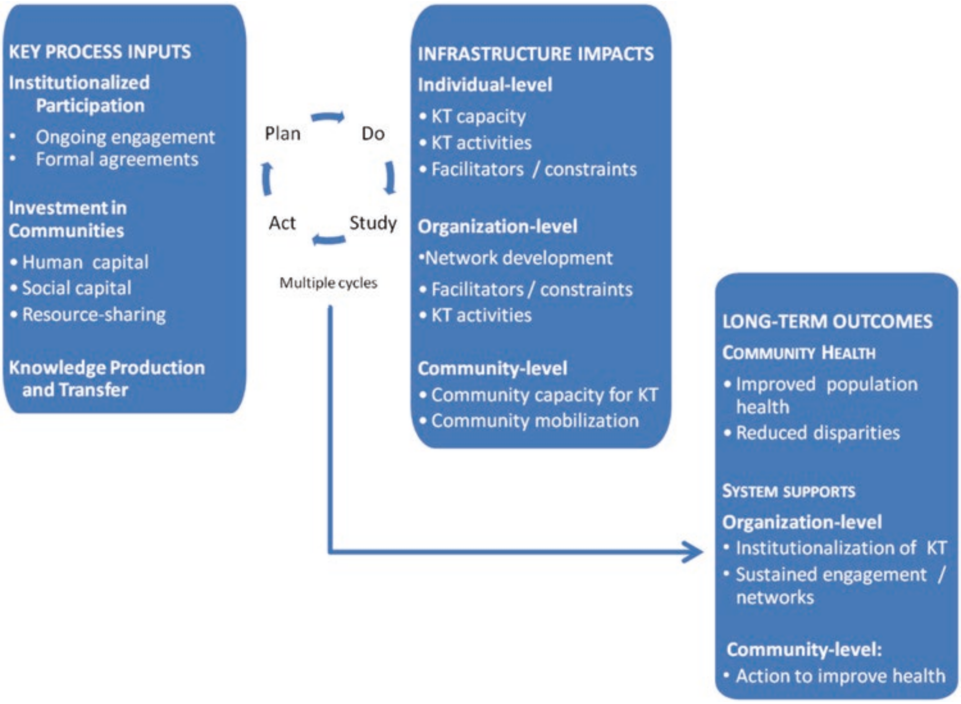

Fig. 23.1 The participatory knowledge translation (PaKT) framework

Study-Act cycles, which ultimately lead to long-term outcomes. At a high level, institutionalized participation refers to the activities and *infrastructure* that allow diverse partners to engage successfully to address a priority health issue. The focus on investment in communities emphasizes opportunities to share resources and build capacity and structures within communities that have sustained benefits that may extend beyond a given effort's focus. Finally, the emphasis on knowledge production and transfer highlights opportunities to produce and spread knowledge that is relevant, accessible, and useful for diverse partners. The infrastructure impacts, or initial markers of change, are expected to accrue at the individual level (e.g., capacity for KT), the organization level (e.g., intersectoral network development), and the community level (e.g., capacity for using KT to improve health). As noted in the figure, there are a series of Plan-Do-Study-Act cycles in the process. These cycles emphasize action-oriented learning through four steps: Plan (determine a course of action), Do (execute the plan), Study (assess outcomes), and Act (utilize the findings by acting upon them) (Deming, 2000; Institute for Healthcare Improvement, 2004). In the PaKT framework, the Plan-Do-Study-Act cycles provide the link between key process inputs and infrastructure impacts, which change through the iterative cycles. As cycles progress, we expect to see changes in long-term outcomes, such as improved community health and system supports to promote social change for improved health.

Background on Three Key Projects

We draw from our experiences with three recent participatory research projects to illustrate the components of the PaKT framework.

2005–2012: Massachusetts Community Network for Cancer Education, Research, and Training (MassCONECT)

MassCONECT was a transdisciplinary collaboration based on CBPR principles. This initiative was funded by the US National Cancer Institute (NCI) as part of the Community Networks Program. The program focused on reducing and eliminating cancer disparities in low SES communities through infrastructure development. The program utilized a social determinants approach and brought together relevant stakeholders – academics from a number of disciplines, policymakers, community leaders, coalition leaders, media, and local and state government – together to create sustainable solutions to reduce cancer disparities. This was achieved through making public health data available, engaging local media about health inequalities, supporting the dissemination of evidence-based strategies/programs, supporting coalition efforts related to health insurance, and training CBO staff to engage media about health inequalities. The program leveraged existing infrastructure and connections of four community coalitions in Boston, Lawrence, and Worcester, MA (Emmons, Viswanath, & Colditz, 2008; Koh, Oppenheimer, et al., 2010).

2008–2014: PLANET MassCONECT

PLANET MassCONECT was a KT project that grew out of the MassCONECT effort. The project was initially based in the MassCONECT communities – Boston, Lawrence, and Worcester and leveraged the existing connections and relationships between researchers and academics that were built during the MassCONECT project. The program infused three types of capital into partner communities. First, we focused on *human capital* – the program built capacity among staff members of community-based organizations (CBOs) to find, adapt, and utilize evidence-based programs (EBPs). Capacity-building efforts included a 2-day workshop and a tool kit that included a website (www.PLANETMassCONECT.org), a training manual, handouts, and case studies. Second, we focused on *financial capital*, including pilot grants to apply newfound knowledge, as well as financial support for partner institutions. Third, we focused on *social capital*, including networking opportunities to promote learning networks in which trainees could support each other. By enhancing capacity among local CBOs to use EBPs, the project was expected to improve programmatic quality and impact, ultimately reducing disparities. The original project was funded by the National Cancer Institute; additional funding allowed for the expansion of the intervention to two additional Massachusetts communities: Lowell and Brockton. Across the five communities, over 250 individuals were trained. The discussion in this chapter focuses on the intervention developed with and for the initial three communities.

2010–2015: Influencing the Media and Public Agenda on Cancer and Tobacco Disparities (Project IMPACT)

In contrast to the very broad infrastructure development of PLANET MassCONECT, Project IMPACT was created to build capacity among community groups in Lawrence, to change the public agenda on health- and tobacco-related disparities by changing the media agenda. The project started with a needs assessment, a community leadership analysis, and an assessment of the media environment, related to health disparities broadly and tobacco disparities specifically. The second step of the initiative was a capacity-building program for CBO staff members to help them advance their agendas, through strategic communication, around health disparities with special focus on tobacco-related disparities. About 60 individuals were trained through this program.

Description of Settings

The initiatives described here are set in three Massachusetts communities, Boston, Greater Lawrence, and Greater Worcester, constituted as a part of regional community health network areas (CHNAs). CHNAs are local coalitions that link public, private, and nonprofit sectors to engage in prevention and health promotion with the broad goal of building healthier communities. The CHNA effort was started in 1992 by the Massachusetts Department of Public Health and includes all Massachusetts towns and cities, organized into 27 CHNAs (Massachusetts Department of Public Health, 2013). These communities are diverse in terms of size and demographics and thus present a useful range of settings for KT activities. Table 23.1 summarizes the racial/ethnic composition of the three communities.

Component 1: Institutionalized Participation

Developing and maintaining partnerships that support sustained community action to improve health can be challenging, but a structured approach to participation can provide the scaffolding to support such an effort. One of the key ideas espoused by the participatory approach is stakeholder participation throughout the research process to leverage the strengths diverse partners bring to the table and ensure that the efforts meet the needs of diverse stakeholders (Israel, Schulz, et al., 1998). Joint infrastructure development has been identified as an essential element for success across a diverse set of CBPR projects (Lencucha, Kothari, & Hamel, 2010). Institutionalized participation, including plans for ongoing engagement and the use of formal agreements, is key to supporting the growth of effective, collaborative, sustained partnerships.

Ongoing Engagement

The process outlined by the PaKT framework assumes that engagement among those attempting to create change in communities and important stakeholders must occur before, during, and after a discrete project is conducted. This supports the goal of creating long-term collaborative structures to create change in a given community. Often, models focus on mobilization with the elite. The PaKT framework focuses explicitly on a wide range of stakeholders. This addresses challenges highlighted earlier with the potential disconnect between those creating and those required to adopt new solutions.

One opportunity to promote and sustain engagement comes from the formation of advisory committees that include diverse stakeholders, a strategy often used in participatory research. For each of our projects, we formed Community Project Advisory Committees (C-PACs) that

included community partners, investigators, and study staff. The C-PACs are key decision-making platforms that ensure all stakeholders have input into and agree with all phases of a given project. C-PACs for each project meet in person quarterly to review progress, solicit feedback from all members, and make important decisions. Each C-PAC conducts additional business through conference calls or email as needed.

C-PACs are often complemented by project-specific *working groups* in each community. Each working group is time limited focused on a defined project and involves academic, community, and project-specific partners. Two coalitions (in Lawrence and Worcester) created a MassCONECT Working Group when the grant period began. These working groups brought together local CBOs working on cancer and health disparities. They met monthly to discuss the MassCONECT work occurring in their communities, as well as how best to work together to reduce disparities. Even though the grant has ended, these working groups still convene regularly to sustain the work started by these efforts.

Community assessments provide an additional opportunity for partners to engage actively as a new project starts or early in the project life course. This type of assessment is useful for collecting necessary data to inform an approach that is evidence-based and reflects the needs, goals, and resources of the community (Brownson, Baker, et al., 2011; Minkler & Hancock, 2008). An ecological assessment addresses the health profile of the community, the underlying power structures, the network structure of the community, norms that influence health-related behaviors, and community history and trajectory (Trickett, 2009). Community assessments also present an opportunity to support and develop partnerships. Though it comes in many forms, the ultimate purpose of the assessment is to highlight targets of intervention and identify resources and opportunities.

Engaging in a participatory needs assessment has a number of benefits, including codevelopment of priorities for action. Our research suggests that CBOs often face challenges leveraging data for priority setting (Ramanadhan, Crisostomo, et al., 2012; Ramanadhan & Viswanath, 2013). Key challenges include (1) integration and utilization of data along with community values and local social, cultural, political, and economic contexts; (2) the fact that CBO staff members may use different definitions of data and evidence and have different understandings of the role and utility of evidence, compared to academics and funders; and (3) barriers to using data for priority setting and decision-making, such as challenges in finding, accessing, and using relevant data. By negotiating these challenges as partners, the team can negotiate and cocreate a set of acceptable priorities, rather than approaching the process from separate directions.

Although needs assessments may provide the impetus for a project, communities have often already identified issues to be addressed, and there is an opportunity for collaboration where appropriate. For example, the PLANET MassCONECT project was developed based on a request from community partners to fill a gap in capacity at the community level for finding and using evidence-based programs. Community partners highlighted an important need, and a team of academics and community partners collaborated to create a research program around this need. Certainly, challenges exist in issue selection, including tensions between funding streams and community interests (Minkler & Hancock, 2008). However, long-standing partnerships with institutionalized participation provide a forum for resolution and mutual accommodation of interests and needs. Participation related to remaining phases of the research process (after the partnership has been created and the issue identified) are discussed under Component 3, knowledge production and transfer. Also, given the emphasis on long-term engagement in the framework, it is unsurprising that in each of our partner communities, we have one to two partners (leaders of organizations or coalitions) with whom we consistently collaborate, adding additional stakeholder partners as the projects dictate. In this way, ongoing engagement refers not only to participation throughout a given project but also across and in between projects, to ensure continuity of effort toward social change.

Formal Agreements

Formal agreements are a useful way to support institutionalized participation. At the beginning of each new project, we have signed a memorandum of understanding (MoU) with each of our partners, clearly detailing roles and responsibilities related to the project. These agreements provide a useful reference for all stakeholders. Again, given our interest in engagement beyond the life of a given project, these formal agreements provide an opportunity to renew the commitment to collaboration but also to define appropriate boundaries for a particular effort. Another important formal agreement is the Publication Policy. Often, community partners find that partners contribute different skills at different times, but in many cases, the academic partners are the only ones recognized in formal publications. To avoid this issue, we have developed a publication policy that ensures that diverse contributions are recognized, whether through individual contributions as authors or through a list of all members of the advisory committee in the acknowledgements section.

Component 2: Investment in Communities

Human Capital

Investment in human capital is essential to an engaged, systems-focused approach to using KT for improving health. For CBO staff members and leadership, to understand the value of leveraging the best health promotion evidence and to have the skills to do this supports not only health impact in the short term but inherently prompts ongoing attention to opportunities to apply the changing health promotion science to new efforts. Successful capacity building thus results in the improved ability of community partners, and local structures, to address current health issues, as well as those that the community is likely to face in the future (Hawe, Noort, et al., 1997). It is useful to consider Lewin's metaphor of action, research, and capacity building as the three points of a triangle that must be linked to remain whole (Lewin, 1946). It is clear that KT efforts require a great deal from CBO staff members; thus, it is vital to plan for the necessary support.

One example of capacity building for KT in community settings comes from the PLANET MassCONECT intervention, which tested a participatory model for knowledge transfer. By developing abilities to find, use, adapt, and evaluate evidence-based programs and strategies, CBO staff members were expected to be able to provide higher-quality services to the communities they serve. The program did not emphasize a specific health issue but instead focused on a broad set of skills that apply across disease categories. This was an important decision based on C-PAC guidance so that the program would best meet the needs of CBOs in the partner communities. Trainees were introduced in a 2-day workshop to the systematic approach to program planning, summarized in Fig. 23.2. As indicated by the funnel metaphor, the process supports organizations as they take stock of the large universe of potential EBPs available and systematically narrow this down to a set of strategic options for the adopting organization.

In addition to skills built during the training workshop, the program emphasized ongoing use of the skills through use of a customized website with resources to support each step of the process. Finally, trainees had opportunities to apply skills gained in the training to apply for pilot grants and were given detailed technical assistance throughout the application process, including post-decision feedback.

As we engaged in this capacity-building effort, the limits of applying highly prescribed EBPs in practice settings became evident, and we shifted toward the idea of evidence-informed programs and strategies, which is an important conceptual distinction. Rather than promoting a fixed, static EBP, which may or may not meet the needs of CBOs, we instead began to promote the incorporation of evidence and data throughout program planning processes. This is consistent with the evidence-based public health approaches put forth by Brownson and colleagues (Brownson, Baker, et al., 2011).

The PLANET MassCONECT systematic approach to program planning was developed to link evidence and action in community settings. First, when reviewing data, CBOs may face sev-

Fig. 23.2 The PLANET MassCONECT systematic approach to program planning

eral challenges in finding the data they need, based on issues of accessing relevant data or interpreting and acting upon the data that are found (Ramanadhan, Crisostomo, et al., 2012). We delivered explicit training focused on finding, evaluating, and using a range of data to support program planning. The second step of the process, finding partners, provides a useful example of the interactive exchange that drove program content. Our goal was to emphasize strategic selection of partners, with an emphasis on multilevel change and opportunities to select partners that brought needed resources to the partnership. We incorporated a tool codeveloped with partners for partnership assessment; the tool is discussed in detail in the section on social capital.

In the third step of the systematic approach, we introduced the US Centers for Disease Control and Prevention's (CDC) *Community Guide*, a resource that provides high-level guidance about evidence-based approaches to health promotion. Through this resource, trainees were introduced to ideas of systematic reviews and opportunities to make decisions about the appropriate strategies for their work based on large amounts of data. One challenge is that many reviews consider randomized control trials (RCTs) as the gold standard for evidence-based practices and exclude studies using other designs (Livingood, Allegrante, et al., 2011). This makes finding relevant data for strategies housed in community organizations a particular challenge. For example, trainees attempting to partner with schools often found that there are a number of strategies for which there is "insufficient evidence" to support the use of that strategy in schools. However, upon closer examination, the challenge with the data was often that there were too few trials conducted in schools to allow for a determination to be made. Trainees were encouraged to read the "insufficient evidence" marker as a situation in which the "jury was still out," but this required intensive discussion and support to move practitioners away from their initial reading that they should avoid strategies with this label. We also encouraged trainees to remember that an EBP could exist in a nonsupported category of strategies. As noted by Fisher (2008), compilation reviews present a few important challenges. First, a finding of "insufficient evidence" may simply reflect the challenge (in terms of design, expense, ethics, etc.) of conducting a certain type of study. However, the "insufficient evidence" finding may lead to concerns that there are no evidence-based actions to be taken, with the result of no action taken. Additionally, the designs of these reviews (e.g., categories used to distinguish one group of intervention settings from another) may be a function of the available eligible data, rather than an underlying scientific question of interest. Thus, while the findings have a place in evidence-based decision-making, they reflect a summary of a tightly restricted set of studies and should be applied accordingly.

In the fourth step, we supported staff members as they attempted to find an appropriate program or strategy. Through rich experience with over 250 trainees, we have found that an important challenge relates to finding a program that meets enough criteria for selection (e.g., program match with resources and target audience, availability of evaluation materials, and customization requirements). However, once we shifted toward ideas of evidence-based strategies and programming efforts, we found that we were able to point trainees to resources that summarized the best available evidence. At that point, they were charged with making the information usable locally, which brings us to the process of customization or localization, also called program adaptation. CBOs face the challenge of making a program relevant to the CBO's target audience, which may be quite different from the population with which a given program was developed. Mismatches between study and target populations are likely to become the norm in countries that are becoming increasingly diverse in terms of race/ethnicity, national origin, religious background, and other attributes, as is the case in the USA (Castro, Barrera, & Holleran Steiker, 2010; Humes, Jones, & Ramirzez, 2011). This is also a challenge when attempting to use a program that was effective in one country in another. Insufficient or ineffective adaptations can result in decreased participant engagement or a program that is not relevant to the participant, which can lead to program failure (Lau, 2006).

An important set of solutions for program adaptation focus on preserving the function, rather than the form, of the program. Drawing on the idea of interventions as events that take place in a system (rather than something that happens to a defined organization), it is clear that context is key, and the way a program interacts with the context will lead to success or failure. Rather than thinking of a static program, if one thinks of the program as a dynamic and complex entity, the underlying processes by change is achieved can be standardized across sites, even if the program looks quite different across sites (Hawe, Shiell, & Riley, 2004, 2009). At this time, the challenge is for program developers to identify core processes, or the function of the intervention, and develop methods for sharing those processes with CBOs, a marked shift from the earlier stance of packaged interventions that were to be implemented with exacting fidelity (Fixsen, Naoom, et al., 2005).

The final piece of the PLANET approach to program planning relates to evaluation. Again, the program promoted continuous evaluation and feedback loops to drive further action. While funders often require evaluations as a condition of funding, CBOs do not always see the utility of this often resource-intensive process (Ramanadhan, Crisostomo, et al., 2012). In our trainings, we emphasized quality improvement perspectives, highlighting the potential for evaluation to allow CBOs to maximize limited resources and increase impact. Given that KT requires a new way of work and organizational change, it is important to use evaluation as a tool to focus on quality and organizational improvement, as well as a means by which to bring about organizational change (Senge, 1990). In this context, the idea of connecting KT with improvement science to improve the quality of care and public health is increasingly gaining currency (Improvement Science Research Network, 2014; Institute for Healthcare Improvement, 2014). The same PDSA cycles highlighted in our framework were the focus of our efforts to encourage CBOs to leverage organizational data as part of continuous quality improvement processes.

Another example of investing in human capital comes from Project IMPACT. As part of this project, we planned to conduct a baseline survey and found that in order to get a sense of the depth and breadth of the community, we would need to do a door-to-door survey, rather than a phone- or web-based survey. While door-to-door surveys have been replaced by telephone-administered surveys for the reasons of cost and efficiency, the increasing penetration of cell phones is posing a significant challenge to the reliability and representativeness of usual random digit-dial surveys. This is particularly true in minority and low-income communities (Blumberg, Ganesh, et al., 2013). We therefore opted to administer face-to-face surveys. Rather than hiring an outside company, we recruited, hired, and trained 16 young adults from Lawrence High School and Northern Essex Community College to administer the survey. Not only were these young people engaged in the process (and supported by leaders at their institutions), but they also quickly built the necessary research and survey administration skills to field over 900 surveys. The survey administrators were paid and were also given opportunities to visit the Dana-Farber Cancer Institute/the Harvard School of Public Health and network with leading oncologists, nurses, and public health professionals. A subset also attended a voluntary meeting and performed a series of analyses on the preliminary data, which they presented to public health professionals in the community. Through participation, the survey administrators reported gaining professional and communication skills, learning about health disparities, and gaining self-confidence. Although the financial costs of hiring young people were within the expected range for costs for a survey research firm, this nontraditional approach required a much greater investment on the part of staff and community partners (Ramanadhan, Nagler, et al., 2016).

Social Capital

In addition to human capital, the PaKT framework also explicitly focuses on social capital. We take a network-based view of social capital, emphasizing the "resources embedded in a social structure that are accessed and/or mobilized in purposive actions" and focused on individuals and groups (Lin, 2001). Given our interest in supporting multilevel action, partnerships among diverse stakeholders become a vital target for action. A useful distinction comes from the concepts of bonding versus bridging capital. Bonding capital comes from similar others and helps organizations get their work done and maintain effectiveness. On the other hand, bridging capital comes from connections with dissimilar others and helps organizations move ahead, particularly when organizations have different levels of power. In this way network members gain access to a wide range of capital through their connections (Kawachi, Subramanian, & Kim, 2008) as well as enabling the flow of information (Viswanath, 2008).

Broadly, a network approach emphasizes the potential to leverage the knowledge and resources of diverse stakeholders in the development of practical and effective solutions to health problems (Israel, Schulz, et al., 1998; Lasker, Weiss, & Miller, 2001). Staff social networks can also be important to support a new way of work (Institute for Healthcare Improvement, 2004), here the use of KT approaches in community settings. Informal knowledge transfer can be particularly important in low-resource settings, such as the environments many CBOs operate in, to allow for diffusion of information without great expense related to training (Ramanadhan, Wiecha, et al., 2009, 2010).

Social capital should be viewed as a strategic investment. Resources must be invested to develop and maintain network connections, so there is an important opportunity to identify the network structures and members that will support the desired social change and then work toward that setup. One way in which to uncover a strategic set of partners is to use community leadership analysis. This technique draws on community reconnaissance, a set of methods that uncovers underlying power dynamics in communities (Nix, 1977; Nix & Seerley, 1971). In a recent study for Project IMPACT, we conducted such a leadership analysis to understand power dynamics in relation to health inequalities in the intervention community. We started with a seed group of community leaders and conducted a snowball sample, interviewing other individuals who were often nominated as leaders in the community. We conducted a total of 33 semi-structured interviews with participants from six sectors in the city. We analyzed the qualitative data (interview transcripts) and then mapped the resulting nomination network using UCINET (Borgatti, Everett, & Freeman, 2005), dedicated network analysis software. By combining the qualitative and quantitative data, we were able to create a number of network maps that (a) identified a core leadership group for the city, (b) assessed the extent to which a range of sectors were represented in the power structure of the city, and (c) highlighted connections that could be leveraged by our community partners to engender multi-sector collaboration to support their goals (McCauley, Ramanadhan, & Viswanath, 2015). This type of assessment is vital as public health practice efforts may include wide-ranging actors and systems including community members; community-based/nongovernmental organizations; entities from a range of sectors, such as housing and transportation; and governmental structures at local and higher levels (Trochim, Cabrera, et al., 2006). A major challenge is in translating this assessment process from an academic to a practice context, so that it is accessible and feasible for community partners.

In addition to conducting our own network assessments, we have developed a tool for CBOs to consider interorganizational networks in a selective and strategic manner. Working with the PLANET MASSCONECT C-PAC, we developed the "Assessing and Maximizing Partnerships (AMP) Tool," a four-step strategic planning process that allows CBOs to analyze their current and required partnerships for a given health promotion goal. The tool is meant for use by a team of CBO staff members and includes four steps: defining the health promotion goal, creating a partnership snapshot, analyzing the partnership snapshot, and developing an action plan to create a network of partners that will allow the organization to meet the targeted goal. The novelty of the partnership snapshot is that it prompts CBOs to assess partners' resources and determine what aspects of the relationships are/could be leveraged effectively. Resources are defined by the CBO and may range from granting access to space to providing access to a new or hard-to-reach population or even facilitating connections to policymakers.

Another example of explicit network development efforts comes from PLANET MassCONECT. We arranged a series of networking events for capacity-building trainees in our intervention communities and facilitated connection development both within and between the three communities where the intervention occurred. These events included additional trainings on requested topics, such as network analysis and evaluation and always included time for networking as part of the event. These activities supported our goal of building a network of KT specialists in each of the communities. This network was intended to be a sustained resource in the community long after the intervention concluded. We also wanted to take a network perspective because changing the "way of work" around EBPs is a difficult process, and staff members need support from their peers and opportunities to exchange information and resources to sustain the effort.

In addition to targeting networks, an important focus of our work has been to leverage existing networks. As mentioned, the members of the initial MassCONECT coalitions were selected because of their strength and activity. Through partnership with academics, a rich network was developed. Similarly, for PLANET MassCONECT, the team hired community health educators based in each of the three communities. These individuals were well connected in their communities and served as the face of the academic institution in the community. At the same time, they served as the face of the community in the academic institution. By hiring respected and connected staff members, we were able to build and strengthen relationships much more quickly than if the team had hired outsiders. In all of our participatory projects, our team also focuses on what is often referred to by partners as the "power of showing up." The investigators and study staff visited our three communities on a regular, almost weekly, basis at the outset of partnership development, and in-person engagement with community partners remains a part of our standard operating procedure despite staff turnover. As discussed elsewhere in the chapter, hiring local staff is also an investment in the community, a way of transferring resources by employing local people and investing in human capital by training them.

Another opportunity to encourage social capital development is through facilitating partnerships. For example, through MassCONECT, the academic team was able to link the City of Lawrence Mayor's Health Task Force with the Boston Mammography Van and fill an unmet need for mammography services. Additionally, a Mammography Working Group was created at the Task Force. This working group brought together representatives from each of the four hospitals and health centers in Lawrence with imaging centers. The partnerships were facilitated by the research project but then continued to flourish on their own.

Resource Sharing

Another key input in the PaKT framework is resource sharing. Key resources shared may include funds or other material resources, staff, and access to knowledge or individuals. Consistent with our emphasis on agreements, we plan for the sharing of funds and material resources during the grant application stage. In the series of meetings in which potential grant ideas are discussed, we also include opportunities to discuss the budget and ways in which funds can be distributed. We also plan for honoraria for partners who are engaging outside a funded partner organization, as well as stipends for travel to meetings. A great challenge often relates to the differences in funding allocation among partners. The research partners' budget is often inflated by indirect costs (the charge levied by many academic institutions to cover facilities and other expenses) as well as expenses related to formal research activities. Long-standing partners have come to appreciate the perspective our group takes to allocate as much as possible to community partners, both directly in the manner of funds that go to the organizations but also in other ways, such as directing resources into the community whenever possible. An example of this, described earlier in the capacity-building section, was the training of local survey administrators for Project IMPACT. The additional flow of resources into the community was important both in terms of sharing resources but also in generating capacity and strengthening relationships in the community.

Another important strategy within the resource-sharing approach has been the sharing of staff time. For example, with the PLANET MassCONECT project, we hired three full-time community health educators, one in each city. These individuals served as local study staff to support the program, conduct surveys, etc. on behalf of the research team, but a portion of their time was also allocated directly to a partner coalition in that community. In this other role, they provided project and programmatic support to community partners as needed. This had the advantage of further maintaining the integration of our staff members into the community. Finally, resource sharing has often included access. From a network perspective, one vital resource a network connection can provide is access to other individuals or additional resources (Lin, 2001). As an academic partner, we were often able to facilitate connections to researchers or experts in an area of interest for community partners.

Component 3: Knowledge Production and Transfer

Knowledge production is an important component of the PaKT framework and emphasizes the creation of practice-focused evidence. A participatory research process includes engagement throughout the research process, including problem definition, data collection and analysis, interpretation of results, and dissemination and application of results (Israel, Schulz, et al., 2008). The first activity (problem definition) was addressed in Component 1; we discuss the other phases of the research process here. Our engaged research process starts with the development of the research protocol and the evaluation plan. Through codevelopment of evaluation tools and plans, the key stakeholders' interests, needs, and definitions of success are incorporated explicitly. After all, there are diverse "ways of knowing" which have value to different parties (Minkler & Salvatore, 2012). In some cases, this may result in additional evaluation activities that have meaning to different parties, but the goal is to compare and contrast the variety of evaluation vehicles to determine what the broad picture looks like. This is a marked shift from traditional clinical trials methodology, in which a primary outcome is specified at the outset and success or failure rests on tests of that outcome. Instead, outcome assessment in this tradition is conducted with an emphasis on context, emphasizing assessment of what works, for whom, and under what circumstances (Pawson & Tilley, 1997). This is not to suggest that findings cannot be applied elsewhere in the field but instead that sufficient attention is paid to context to support spread of effective processes and strategies. This type of evaluation is necessary for action research, to ensure that stakeholders participate in, benefit from, and have needs met by the evaluation effort, with the goal of improving the situation.

A major challenge for leveraging KT to create change in communities is the evaluation of multilevel, systems-focused efforts. As described by McGrath (1981), the choice of study design often reflects a tension between generalizability to populations, precision of measurement related to behavior, and emphasis on measuring systems/context. Given the complexity of public health systems and the need to focus on external validity and the impacts of context and multilevel drivers, designs such as the traditional randomized controlled trial may not be appropriate choices (Luke & Stamatakis, 2012). Instead, multilevel modeling, social network analysis, agent-based modeling, geographic information systems, and mixed-methods designs may be better choices (Luke & Stamatakis, 2012; Trickett, Beehler, et al., 2011). These designs can allow researchers to disentangle patterns of interaction between heterogeneous, multilevel elements that make up the system, address context explicitly, and study nonlinear and long-term effects (Green, 2006; Schensul, 2009). The study of interactions between levels of influences is underscored by ecological approaches (Bronfenbrenner, 2005). Another important element in the design (that reflects action research and systems science) is the emphasis on continuous feedback loops so that KT activities can be refined through the life course of the effort, to adapt to changing context, new knowledge, and other inputs, with the goal of increased impact.

Mixed-methods approaches may be of particular use for assessing change in complex systems. This approach prompts collection and analysis of quantitative and qualitative data in response to research questions, with an emphasis on integrating the two types of data to develop novel and more complete understandings of the issue than possible from quantitative or qualitative data alone (Creswell & Plano Clark, 2007). This approach is particularly appropriate for efforts to create change in community settings given that new methods of creating change are being tested, and mixed-methods approaches allow for exploratory and confirmatory work to support the development of new hypotheses and the subsequent testing of those hypotheses. Additionally, mixed-methods approaches allow for the integration of end users' voices (Palinkas, Aarons, et al., 2011), which is vital for participatory, action-oriented approaches. Drawing on diverse data sources is also important for incorporating context into the assessment, which is an important driver of success (Berwick, 2008) and has been a major challenge for KT initiatives. Finally, mixed-methods approaches support development of a wide range of dissemination products that can meet the needs of the diverse stakeholders and consumers of project-related products.

For Project IMPACT, the research team developed a survey that focused on media use, perceptions of social determinants of health, and general health and well-being. Our partners noted that they were engaged in a series of obesity prevention activities but were unable to find necessary local data to support their efforts. Through collaboration, a series of obesity-related items were added to the questionnaire. This resulted in some items of interest to the research team being dropped from the survey to avoid increasing respondent burden. Preliminary obesity-related data were shared with community partners in a timely fashion, though scientific publications took much longer to produce.

Once data have been collected, we leverage the strengths of team members to analyze the data. Typically, because of resource and capacity constraints, the academic partners on the team shoulder the responsibility of analyzing the data. Then, the C-PAC participates in the interpretation of results for all key studies and relevant minor studies. As noted above, we take an inclusive approach for all major study publications and solicit participation from all C-PAC members in some format. Similarly, the C-PAC members jointly determine the appropriate dissemination vehicles.

The MassCONECT project provides an example of the benefits of engaging in evaluation in a participatory manner. As noted above, we conducted a social network analysis to assess network development and its impact for this infrastructure-building grant. The stimulus to use this analytic method came from a subset of the community partners on the C-PAC. They subsequently participated in the development of the research instruments, guided fielding of the study, and participated in the analysis, interpretation, and dissemination of data. These individuals found the tools of network analysis extremely useful for their work with coalition-building and partnership development and wanted to share this work with other colleagues in their communities. To support this goal, the group conducted a daylong training on social network analysis targeted at CBO staff members. This introductory workshop focused on potential applications and prompted the group to create the AMP tool, described earlier, which provides a structured method for CBOs to examine the resources they have/need within their organizational partnerships.

For academic partners, at the end of an intervention, typical dissemination vehicles often include scientific presentations and publications. However, these vehicles are not necessarily relevant or accessible to community partners, who may determine additional channels that can effectively reach intended audiences (Minkler & Salvatore, 2012). For the MassCONECT project, we created a Dissemination Working Group to support creation of useful products. A popular format for dissemination was a two-page "brief" that summarizes a project activity. For example, we created a brief to share results of the network analysis mentioned above.

The brief was written for CBO staff members and contained three sections, as seen in Fig. 23.3. The first section provided an overview of the project. The second section provided highlights of the study. The third section emphasized the ways in which the findings might influence practice. Professional writers transformed academic findings into accessible, practice-focused information, presented in an appealing and easily digestible format. Another popular format was a poster. The academic team created a poster template, including background information about the project. Then, partners were able to adapt the template to suit their needs, which often included local conferences. A generic version of the poster also made the rounds in the three communities, displayed at venues for the public, such as public libraries. The poster template, as well as all project training materials, and additional content were put onto a CD and distributed to partners. Another strategy that has been effective is the joint presentation of results by academic and community partners at local and national events. Finally, the coproduction of journal articles has been another important strategy to ensure that the voices of diverse stakeholders are shared. Ultimately, the reach and application of the information contained in briefs, posters, and presentations are the markers of interest, and these provide an important area for future study.

Iterative, Action-Oriented Cycles

A broad goal for this approach is infrastructure development to create multilevel, ongoing change in communities that improves health and reduces disparities. As seen in Fig. 23.1, the key process inputs and a set of infrastructure impacts are linked by iterative cycles. Drawing on the spiral metaphor from Lewin (1946), evaluation is an ongoing process that leads to incremental improvements. For this reason, the framework includes the Plan-Do-Study-Act cycles (important feedback loops) so that the process inputs and infrastructure impacts work in concert to create a set of system-level changes driven and chosen by stakeholders and beneficiaries. Consistent with a systems science approach, planning is not something that simply happens at the outset of a program. Instead, continuous feedback loops allow for constant reevaluation and tinkering with strategies and inputs, and system action is understood to be a series of events over time (de Savigny & Adam, 2009; Trochim, Cabrera, et al., 2006). This continual adjustment reflects the importance of knowledge management and transfer to improve organizations' ability to keep up with and react to rapidly changing environments (Senge, 1990).

Infrastructure Impacts

The multilevel assessment captures progress toward the goal of creating change at multiple levels to support the use of KT to create change in communities. At the individual level, the framework highlights impacts among diverse stakeholders, such as researchers, practitioners, and/or other external change agents, depending on the project. An important impact is capacity for KT or the ability to generate and incorporate knowledge (Canadian Institutes of Health Research, 2004). In the tradition of capacity building, the goal is to support the ability to address current and future health problems (Hawe, Noort, et al., 1997). For practitioners, this may include understanding the value of the evidence base broadly as well as identifying needs, finding partners, choosing evidence-driven targets for action, adapting programs to local needs, and evaluating the results. For researchers and change agents, improved capacity may relate to deeper understanding of partnering communities, realities of practice, and realistic solutions (Glasgow & Emmons, 2007; Green, 2008). These outcomes will have important impacts on participatory processes, an example of the iterative interactions contained within the framework. The measures of capacity will shift based on the target of the effort and may reflect participatory decision-making

Analysis

About MassCONECT

Fig. 23.3 Dissemination brief created to share results of MassCONECT social network analysis regarding markers of success. At the same time, stakeholders must be increasingly sensitized to issues related to health disparities and ideas of social determinants of health. After all, the causes of health disparities are myriad and complex. Moving beyond attention to healthcare access and individual behavior choices, researchers have identified key social determinants of health, such as race/ethnicity, income, education, social networks, neighborhood conditions, work environments, and social policies, that drive health outcomes and potential inequalities (Berkman & Kawachi, 2000; Phelan, Link, & Tehranifar, 2010). Although this conversation has taken root in academia, this perspective needs to be shared with other stakeholders to prompt attention to broad, multilevel change. One example of this conversation outside the academy are the workings of the World Health Organization's Commission on Social Determinants of Health – one way of using the knowledge transfer to promote policymaking among nation states (WHO Commission on Social Determinants of Health & World Health Organization, 2008).

Other individual-level impacts include increased application of research-based knowledge among knowledge users. In other words, success is defined as the application of scientific knowledge in practice settings. Measures that assess efforts to spread that knowledge are useful process indicators but are not sufficient to demonstrate success in this realm (Canadian Institutes of Health Research, 2004; Straus, Tetroe, & Graham, 2009). Finally, there are a range of individual-level facilitators and constraints of engaging in a given KT effort, such as their knowledge and beliefs, self-efficacy for required activities, identification with the organization, and other personal attributes (Damschroder, Aron, et al., 2009).

At the organizational level, we are prompted to assess networks between and within the range of key organizations and institutions in the system, which may include local agencies from a range of sectors, government entities, and others deemed vital to creating multilevel, sustainable change. The goal is to create strong, productive networks that include partners from multiple levels/sectors and support collaboration and collective action. As noted in the discussion of the Community Leadership Study from Project IMPACT, part of the goal for network development is to effectively engage with power structures, such as policy- and decision-makers. Through such network development, the flow of evidence and resources between key stakeholders can be improved (Canadian Institutes of Health Research, 2004).

As demonstrated earlier, social network analysis can be a useful tool by which to evaluate infrastructure development. Network analysis allows for assessment of relationships between parties of interest, such as members of a coalition or community group, as well as the impacts and outcomes of these relationships (Scott, 2000; Valente, 2010; Wasserman & Faust, 1994). Despite the potential utility of using network analysis to evaluate and intervene on community partnerships, this application is still underutilized for this purpose (Provan, Veazie, et al., 2005). A detailed description of potential measures is beyond the scope of this chapter. Instead, we highlight key questions of interest for building networks to support KT in communities, including the following: identifying central (or key) network members, assessing ways to leverage central members' position and power (such as access to external resources and influence on other members to support KT), determining whether or not relationships are formalized between organizations and thus sustainable, assessing trust among members and strength of relationships, examining subgroups of members and opportunities to mobilize them, identifying key benefits and drawbacks of partnership, and assessing the impact of external influences on the network (Provan, Veazie, et al., 2005; Shortell, 2004). By assessing networks, organizations can proactively shape and structure networks to reach their goals and increase impact.

An example of using social network analysis for assessing progress with partnerships comes from the MassCONECT project (Koh, Oppenheimer, et al., 2010). Again, the goal of this program was to develop an infrastructure to support collaborative research and practice efforts targeting cancer disparities in Boston, Lawrence, and Worcester, MA. Key stakeholders included community coalitions, researchers, policymakers, and others. At the end of the fourth year, the team conducted a social network analysis as one method of documenting the impact of the program. We studied the whole network of MassCONECT participants and were particularly interested in the impact of intersectoral connections or the relationships between network members from different sectors, such as CBOs and policymakers. The analysis demonstrated an increase in connections within the network, as well as the number of intersectoral connections and the extent to which intersectoral connections were reciprocated. Intersectoral connections were positively associated with outcomes of interest to diverse partners, including community activities, grants and publications, and policy engagement (Ramanadhan, Salhi, et al., 2012). Findings such as these underscore the importance of multilevel and multi-sectoral connections but also highlight the tremendous investment required to build and sustain such relationships.

At the organizational level, it is also important to assess impact in terms of organizational facilitators and constraints, such as the organization's structure, communication patterns, networks, culture, creation of internal systems for KT, climate for change, and readiness for change (Damschroder, Aron, et al., 2009; Fixsen, Naoom, et al., 2005). As with the individual level, engagement in KT activities is another important marker of infrastructure change. Examples of activities at this level include using data for programming and policy development, supporting policy changes, and interacting with the media. KT activities must also be assessed in terms relevance of solutions and creation of local change (Brydon-Miller, Greenwood, & Maguire, 2003).

At the community level, an important impact is the capacity of the community to use KT to improve health. The concept of community capacity includes (a) the characteristics (with an emphasis on assets) of communities that impact their ability to identify and address health and social issues of interest and (b) the capacity and resources to create change at the individual and community levels to support public health goals. In this application, community capacity specifically relates to the use of KT activities to improve health. Important components include citizen participation, leadership, skills, resources, networks, sense of community, understanding of community history, community power, community values, and critical reflection (Goodman, Speers, et al., 1998). Consistent with participatory and action research perspectives, we expect to see increased community capacity for advocacy and generating system changes that reduce disparities (Viswanathan, Ammerman, et al., 2004). Additional markers of interest may include social cohesion and social influence, trust, reciprocity, social capital, civic engagement, collective efficacy, and empowerment (Minkler, Wallerstein, & Wilson, 2008).

Community mobilization is another important community-level infrastructure impact. Mobilized communities can leverage existing social structures and resources to create change with varied goals, including increased access to services, improved health outreach, reformed policies, and a more health-promotive environment (Bracht & Tsouros, 1990). Mobilization around a particular set of health-related goals or in support of a population subgroup can provide the necessary support for taking action based on research evidence. Finally, as described earlier, a subset of community-level outcomes relate to development of necessary intersectoral networks, particularly connections with policy- and decision-makers who can support the translation of the community's agenda into change. Strengthening community capacity to change public agenda on health is an important strategy in mobilization such as we did in IMAPCT.

Long-Term Outcomes

The goal of the PaKT framework is to support systems-level change that has an impact on both health outcomes and health disparities. Thus, there are two types of long-term outcomes in this framework. One set of long-term outcomes includes community health impact, which can include markers such as community members' satisfaction, function, and symptomatology (Proctor, Silmere, et al., 2011). In addition to improved health, reduction of health disparities is an explicit goal of the processes described in the framework. Consistent with the iterative nature of the framework processes, it is understood that as disparities and underlying causes are addressed in relation to one issue, others will arise, prompting the next cycle of action in the community. As evidenced by the community heart health trials, these outcomes may require lengthy follow-up to demonstrate change.

The other set of outcomes are related to systems change, particularly within organizations and communities. These changes are expected to support sustainable efforts to change communities and improve health, including addressing social determinants of health (Wallerstein, Oetzel, et al., 2008). At the organization level, an important outcome is the institutionalization of KT approaches and activities in practice settings. These activities will create changes that improve health and address disparities and will sustain momentum in communities for continuous improvement. In this way, communities will be expected to yield the benefits ascribed to KT practices, including greater health impact and more efficient use of resources (Brownson, Baker, et al., 2011). Other important organization-level outcomes include networks to support KT activities. These networks must include a diverse group of engaged and committed stakeholders to providing the multilevel support required for sustainable change. The network structure can be a resource that is developed and strengthened as a community asset. The final set of long-term outcomes, found at the community level, focus on action to improve health. Through an engaged and participatory process, communities are expected to be able to identify and address pressing issues, leveraging the best available evidence from external and internal experts.

Conclusions and Next Steps

The PaKT framework offers a framework for a systems-focused, action-oriented, participatory approach to KT in community settings to drive multilevel, collaborative action for social change. The emphasis on institutionalized participation, investment in communities, and knowledge production and transfer is expected to lead to sustainable systems change to support the ability of communities to leverage existing knowledge to tackle health problems. Consistent with the participatory approach described, the framework is not highly prescriptive. Instead, it acknowledges the organic, evolving nature of engaged social change projects and highlights key areas for consideration. Those applying the framework are charged with adapting as needed to suit the change effort at hand.

Given the high-level, process-oriented nature of the framework, it can be utilized as a complement to other frameworks for the study of KT. There are over 60 frameworks and models addressing knowledge translation (Tabak, Khoong, et al., 2012). Many of the models assess the dissemination and/or implementation of a specific program or strategy in a defined setting, which is often clinical. The PaKT Framework provides a complementary perspective, placing a given study or implementation effort in the context of a strategic, long-term effort to create change that is driven and owned by those who will ultimately sustain the effort and benefit from it.

The framework highlights the intense investments required to create social change in communities. Although the examples presented in this chapter mostly come from research settings, a major strength of the framework is that social change efforts driven by others (whether internal or external change agents) can utilize many of the same principles. The framework highlights key areas for development to support the creation of change in communities to improve health. First, a systems approach is vital, which impacts not only the ways in which change efforts are constructed but also how they are evaluated. The use of multilevel assessments, systems modeling, network analysis, community leadership analysis, and mixed-methods approaches represents an important shift away from highly standardized randomized control trial designs, which are likely inappropriate for assessing the far-ranging impacts of systems change efforts. These methods of evaluating interventions are also an important way to gauge success with intermediate outcomes and project potential impacts on long-term outcomes. Second, a mindshift is needed to move away from external change agents conducting discrete projects in communities to long-term engagement of change agents (whether internal or external) with diverse stakeholders (from multiple sectors and with different levels of power). Such engagement not only will address existing barriers to creating practical, sustainable solutions but will also address the high cost of large-scale change efforts. Coordinated allocation/redirection of community resources provides an opportunity to engage in projects that would be far beyond the scope of a small number of organizations. As seen earlier, coalitions and networks of engaged stakeholders are key to the development of coordinated action. As highlighted in an IOM report on prevention-oriented interventions, the future of the field lies with collaborative development and execution of multilevel interventions (Smedley & Syme, 2000).

Training of researchers, change agents, and practitioners who can engage in a participatory KT process will address some of these challenges. On the research side, training in participatory approaches is limited, but steadily increasing, particularly with the recommendation by the IOM that CBPR be included as a core public health competency. As a complement, on the change agent and practitioner side, we have provided extensive details in an earlier section about the promise of building capacity among community partners to engage with scientific evidence more actively and ensure that available knowledge benefits their communities and constituents.

Conclusion

KT efforts are widely acknowledged as an essential part of promoting social change. While the mechanisms of knowledge transfer and utilization vary, resorting to classic "top-down" approaches to disseminate and implement evidence-based strategies and promote social change is unlikely to yield effective outcomes. It is increasingly recognized that involving the end user of the knowledge generation process may be a more effective approach. Leveraging the long and powerful history of community organization and engagement (including current manifestations as CBPR and other participatory approaches to research) presents an important opportunity to increase the impact of KT efforts. To this end, we propose the participatory knowledge translation (PaKT) framework, which emphasizes institutionalized end user participation, investment in human and social capital with resource sharing, and explicit end user engagement in knowledge generation and transfer as the means to develop sustainable systems to improve health and address disparities. The framework emphasizes the pacts made among stakeholders to address complex public health problems collectively and is intended to serve as a complement to top-down approaches. A return on investment in billions of dollars in research and developmental aid will come to naught if the change promoted lacks community buy-in and is not sustainable. This is particularly important in population health promotion where the disease burden is faced disproportionately by vulnerable groups. Though initial costs and timelines may be larger than traditional endeavors, such alternative models that promote infrastructure development and sustainability show great promise for creating effective and efficient change in the long run.

Funding Acknowledgments MassCONECT was funded by the US NCI (5 U01 CA114644, Viswanath PI). PLANET MassCONECT was funded by the US NCI (5 R01 CA132651, Viswanath, PI) and the NIH via the Harvard Clinical Translational Science Center (R01 RR025758-Supplement). Project IMPACT was funded by the US NCI (5P50 CA148596, Viswanath, PI).

Using Genomic Knowledge to Improve Health Promotion Interventions in the Developing World

Colleen M. McBride, Hendrik D. de Heer,
Fasil Tekola Ayele, and Gail Davey

Introduction

Completion of the Human Genome Project has informed rapid advancements in technologies and discovery in the last decade. These advances have generated optimism that accumulating genetic discovery could be used to improve disease prevention efforts globally with many forecasting that affordable health applications will be available in the near-term (Burke, Burton, et al., 2010; Collins, Green, et al., 2003; Hingorani, Shah, et al., 2010). Much of this optimism rests on the potential to identify disease susceptibility early in life and the possibility to target interventions to *prevent* the occurrence of many health conditions. Indeed, the future is envisioned where health promotion applications could be targeted to improve health behaviors based on genetic susceptibility. However, the feasibility of these developments and the time frame for their realization continue to be widely debated (Burke, Burton, et al., 2010; Hingorani, Shah, et al., 2010).

Improved understanding of gene-disease associations indicates that most disease arises from the interrelationships of genes with each other and with the environment (including health-related behaviors) (Mabry, Olster, et al., 2008). Here we will refer to this perspective as "genomic." It also is widely agreed that the translation potential of most genetic discovery has yet to be established (Burke, Burton, et al., 2010; Hingorani, Shah, et al., 2010; McBride, Bowen, et al., 2010a). Thus, the immediate charge going forward for applying new genomic knowledge to health promotion interventions will be agnostic consideration of whether derived innovations add value to existing intervention approaches. This will be of particular importance in global health contexts with constrained resources and diverse social and cultural contexts (Daar, Singer, et al., 2007).

Current Knowledge of Genetics and Role of Genetics in Health

The past two decades have witnessed impressive accomplishments in genomic discovery. For example, completion of the sequence of the human genome has now established that a remarkable 99% of the human genome is shared across individuals. Thusly, it is the 1% of unique code that accounts for most of the observable differences between individuals in height, skin and hair color, and innumerous other traits. The majority of this variation is accounted for by differences between individuals in code at specific sites in the genome, that is, single nucleotide polymorphisms or "SNPs." Genome-wide association studies (GWAS) have shown that common SNPs (>5% prevalence) are associated with the development of many common chronic diseases (such as diabetes, heart disease, high blood pressure, asthma). However, each of these SNPs individually conveys only small to moderate increases or decreases in disease risk (odds ratios 1.2–1.4) (Hindorff, Sethupathy, et al., 2009). Indeed, risk for common chronic diseases is influenced by many different genes (i.e., polygenic) interacting with each other and the environment (Frazer, Murray, et al., 2009; Mabry, Olster, et al., 2008).

Consider the example of the exceedingly high prevalence of Type 2 diabetes observed among Pima Indians. Yet, the prevalence of Type 2 diabetes is fivefold higher among Pima Indians living in the USA compared to those living in Mexico (Schulz, Bennett, et al., 2006). The two groups share common ancestry and a similar gene pool that is distinct from other Native American populations. This disparity in risk aligns with significant differences in lifestyle factors associated with weight (i.e., diet and physical activity) and the substantially higher prevalence of obesity among Pima Indians living in the USA compared with those living in Mexico.

Recent evidence is revealing how these environmental exposures "get under the skin," that is, interact with genes to influence disease development. Current evidence supports that exposures encountered in the environment and over a lifetime prompt chemical processes in the genome that turn gene expression on and off (Dolinoy & Jirtle, 2008). Emerging evidence is showing that these "epigenetic" processes are highly responsive to a broad array of environmental exposures that include health behaviors such as diet, physical activity, tobacco, and alcohol use (Mabry, Olster, et al., 2008; Wild, 2012). Add to this that the plasticity of one's "epigenome" is especially heightened at some stages of development including prenatally and in early childhood. Thus, environmental exposure may exact greatest harm and confer greatest during these periods.

Epigenetic modifications in gene expression can be passed down intergenerationally such that the influences of exposures on one generation can be conveyed to children and grandchildren (Adamo, Ferraro, & Brett, 2012). So-called natural experiments show how maternal exposures can influence epigenetic processes in the fetus and increase the offspring's disease risk in later life (Vaiserman, 2011). The Dutch Famine (1944–45) prompted by an embargo on the transport of food supplies in World War II. The Dutch population experienced a two-thirds drop in daily calories. This "Hunger Winter" was sandwiched between periods of optimal food availability. In addition, to a concordant drop in birth weight among babies born during the time frame of the famine, this cohort also experienced an increased likelihood of developing metabolic and heart disease later in life. Epigenetic explanations for this phenomenon build upon "mismatch theory" (Jackson, Niculescu, & Jackson, 2013). According to this line of thinking, the fetus's highly plastic epigenome has the ability to "retune" its metabolic needs to respond to anticipated food scarcity based on the mother's experience of famine and its effects on the uterine environment. Indeed, evolutionary pressure selects for those individuals who can adapt gene expression patterns (via epigenetic mechanisms) to a fluctuating environment. However, when the infant is born into an environment of privation (i.e., a nutritionally rich environment that characterized the time after the Hunger Winter), there is a mismatch in which the metabolic adaptations are not well suited to maximize fitness. This increases risk for pathological metabolic responses to adequate nutrition, responses that accrue over a lifetime and can lead to metabolic and heart disease.

With growing understanding of the complexity of the relationships among genes, epigenetics, environment, behavior, and health, there is optimism that genomic information could be applied to prevent and manage disease and promote health (Hingorani, Shah, et al., 2010). As knowledge of gene by environment increases, consideration of behavioral influences on gene expression and disease development will be the norm, rather than the exception. Genomic information is now being considered for use in risk communications to motivate individuals and families to take preventive actions to reduce disease risk (McBride, Bowen, et al., 2010a), for guiding screening schedules and treatment decisions among patients at high risk for a variety of health conditions (McBride, Koehly, et al., 2010b; Myers, Manne, et al., 2011), as well as for chemoprevention and surgery-based prevention options (Burn, Gerdes, et al., 2011; Rebbeck, Friebel, et al., 2004). However, it is important to note that utility has not been established for all new genetic information. For example, it has been argued that the utility of common disease genetics, an arena with the greatest potential for public health benefit, is years away from being demonstrated (Haga, Khoury, & Burke, 2003).

Genomics and LMIC

Skepticism is particularly high in applying genomic technologies in low- and lower-middle-income countries (LMICs) (Howitt, Darzi, et al., 2012), countries categorized by the World Bank to have gross national incomes ≤4035 dollars per capita (Price, 1976). As of 2008, over 100 countries met the criteria for LMIC. The list includes most of the continent of Africa, Central America, and East Asia (International Congress for School Effectiveness and Improvement, 2011). The World Health Organization (WHO), the United Nations, and other international organizations have generated several consensus reports to identify "grand challenges" and priorities for applying genomic advances to disease prevention in LMICs (Dandara, Adebamowo, et al., 2012). For example, over a decade ago, Singer and Daar (2001) recommended that genomics-based biotechnologies should be harnessed to improve global health equity. Most recently, the World Health Organization initiated plans for a list of policy and research priority target areas for genomics-informed innovations. These priorities included consideration of the ease of delivery of interventions in resource-poor clinical settings and the potential impact of genomics-based interventions for disease reduction and improving health equity (Singer & Daar, 2001).

However, these consensus-building efforts have heavily emphasized prevention of communicable diseases. For example, consistent with the World Health Organization's priorities, considerable effort already is underway to evaluate whether new understanding of the genomes of insect vectors can be used to develop vaccines for malaria (Prachi, Biagini, & Bagnoli, 2012). Similarly, increased evidence is suggesting the heritability of susceptibility to *Chlamydia trachomatis* infection, a sexually transmitted disease prevalent among adolescents in some LMICs. This research is informing new vaccine development and targeted prevention activities (Bailey, Natividad-Sancho, et al., 2009; Obasi, Balira, et al., 2001). Optimism about extending these approaches to prevent other communicable diseases also is high (Robinson & Hort, 2012).

Steep increases occurring in noncommunicable diseases worldwide, particularly chronic diseases (e.g., Type 2 diabetes and heart disease), are prompting the call for innovation in health promotion interventions (Yach, Hawkes, et al., 2004). Sixty-three percent of global mortality is from cardiovascular disease, cancer, chronic respiratory disease, and diabetes, of which 80% was in LMICs (Robinson & Hort, 2012). In LMICs, cardiovascular disease will kill five times more people than HIV/AIDS (World Health Organization 2012). By 2030, it is estimated that these chronic diseases will be the leading causes of death in LMICs (Robinson & Hort, 2012). Experts point to the globalization of industry including fast food, soft drinks, and the increasing reliance on motorized vehicles that together are shifting diets and activity patterns among those living in LMICs (Daar, Singer, et al., 2007).

Individuals in LMICs also develop chronic diseases at younger ages and die earlier than those living in high-income countries (Robinson & Hort, 2012). Increasingly, there is a call to maximize prevention efforts by targeting pregnant women and young children in LMICs, for promotion interventions (Hanson, Gluckman, et al., 2012). If these prevention efforts are to succeed in LMICs, applications of new genomic knowledge must consider and align with health behavior change interventions (Howitt, Darzi, et al., 2012; Yach, Hawkes, et al., 2004).

In this chapter, we describe how emerging genomic knowledge could lead to improvements in health promotion interventions that target risky health behaviors in the context of LMICs. We focus on two possible potential opportunities for genomics-informed health promotion efforts in LMICs: (a) risk stratification and health resource allocation and (b) targeted risk communications that heighten motivation to adhere to behavioral recommendations. We also consider these opportunities against the backdrop of social challenges presented by LMICs (Howitt, Darzi, et al., 2012; Yach, Hawkes, et al., 2004). To do so, we draw from the experiences of an ongoing program of research among genetically high-risk families in rural Ethiopia. We conclude with recommendations for future formative and comparative effectiveness research to consider potential opportunities for applying new genomic knowledge to health promotion globally. We provide working definitions of the terminology we use in Table 24.1.

Table 24.1 Key terms

Gene variation: the genetic differences within and among populations
Genetic variant: a difference in DNA code at a single location of the genome and often referred to as a "single nucleotide polymorphism" (SNP)
Genome sequencing: a laboratory process that determines the precise order of the complete DNA sequence of a person's genome at a single time
Stratification: where individuals are grouped based on genetic risk (e.g., family health history or genetic variant test results)
Targeted intervention: using a group characteristic to inform what type of intervention is provided
Genetic determinism: belief that genes determine, to the exclusion of environmental influences, a health outcome
Literacy: a complex set of abilities to understand and use the dominant symbol systems of a culture for personal and community development

Applying Genomics-Informed Risk Stratification in the Context of LMICs

Rose in his seminal article "Sick Individuals and sick populations" (Rose, 2001) was among the first to consider the relative value of targeting interventions to those at highest risk (often termed a clinical or high-risk approach) versus intervening with an entire population, the majority of whom would be at average risk (often termed a public health approach). The question Rose considered is whether there is greater public health benefit in achieving substantial risk reduction within a proportionately small, high-risk subgroup or to achieving modest health improvement (e.g., small blood pressure reduction) across an entire population.

The advent of improved multivariable risk algorithms is prompting new thinking that there may be utility in both approaches with the decision resting in the context under consideration (Ahern, Jones, et al., 2008; Zulman, Vijan, et al., 2008). For example, high-risk approaches may not be optimal when risk assessment must occur in clinical settings. However, the concern is that under these circumstances, targeted interventions may not reach those with inadequate access to health care (Frohlich & Potvin, 2008). On the other hand, public health interventions are highly in variable in cost, efficacy, and potential for adverse effects, all factors that influence their benefits (Ahern, Jones, et al., 2008; Zulman, Vijan, et al., 2008). Paradoxically, in contexts with limited resources, a low-intensity approach that is less expensive but also less efficacious may not be preferable to targeting a more effective intervention to those at higher risk (Frohlich & Potvin, 2008; McLaren, McIntyre, & Kirkpatrick, 2010; Zulman, Vijan, et al., 2008).

The post genomic era offers the capability to use genetics to guide risk stratification. Genomic research conducted internationally tells us that populations are not genetically homogeneous (Zimmern & Khoury, 2012) and accordingly, that disease risk is not equally distributed within a population. A study conducted in the USA (Williams, Hunt, et al., 2001) is frequently cited in which 14% of families ("high-risk families") accounted for more than 70% of early coronary heart disease (CHD) and 11% of families accounted for 86% of early strokes. Consider this scenario was occurring in an LMIC setting with limited health resources. Consider also that a portable approach to risk assessment is available that accurately identifies those at high risk, and adherence to moderately intensive behavioral recommendations (e.g., dietary restrictions, cholesterol-lowering pharmacotherapies, shorter screening intervals) has been shown to be efficacious in reducing risk. Given these considerations, targeting an intervention to high-risk families, particularly the children, arguably could be more effective than a population-based approach. Moreover, risk stratification will identify groups at especially low risk who will benefit less from some health promotion efforts.

Such stratification could be particularly useful in LMICs such as those in Africa, where the level of genetic diversity is exceptional (Tishkoff & Williams, 2002). Sub-Saharan Africa, for example, comprises 46 countries with enormous cultural, linguistic, geographic, and genetic diversity. This diversity of population genetics along with varying environmental exposures increases the likelihood that LMIC populations could be effectively stratified into risk categories, and the value of targeting interventions could be evaluated rigorously. However, these assertions rest on the assumption that reliable and valid risk assessment tools exist.

LMICs present unique opportunities and challenges for applying new genomics knowledge to health promotion that must be considered. A recent Lancet report (Howitt, Darzi, et al., 2012) outlines the complex nexus of infrastructure in which health promotion must occur in LMICs. Over two billion people lived on less than $2 a day (Howitt, Darzi, et al., 2012). Additionally, the number of health-care workers is extremely limited, with sub-Saharan Africa which accounts for 11% of the world's population, and 24% of global disease burden has only 3% of the world's health-care workers (Howitt, Darzi, et al., 2012). Intervention approaches that are portable and inexpensive, so-called frugal technologies, are required in these settings (Howitt, Darzi, et al., 2012). Concerns are that genomic applications will be too costly to be feasible (Burke, Burton, et al., 2010).

In the next section, we suggest a few examples of currently available genomics-based risk stratification tools, and we consider their potential utility for health promotion in LMICs and the challenges they present in these social and cultural contexts.

Potential Uses of Available Genomic Applications

Chronic disease risk clusters within families. Indeed, as an intergenerational set of related members, families share genetic, environmental, social, and behavioral factors. One genomics application that is widely available now is the Family Health History (FHH) assessment. While there is a considerable range of applications used to assess FHH, in principle, FHH comprises a systematic characterization of disease occurrence and age of onset among first- and second-degree blood relatives. Almost 60 studies have shown FHH to be predictive of disease onset across a variety of health conditions (Berg, Baird, et al., 2009; Qureshi, Wilson, et al., 2009). An individual's risk is highly predictive of disease risk for all members of a family (Claassen, Henneman, et al., 2010; Uusitupa & Tuomilehto, 2011; Yoon, Scheuner, & Khoury, 2003). FHH could be regarded as a "frugal technology" for identifying high-risk families.

However, an AHRQ review conducted in 2009 found that despite the ubiquity of its use, there were few examples and sparse empirical evidence concerning whether FHH assessment prompts individuals to adopt preventive behaviors (Berg, Baird, et al., 2009; Heideman, Middelkoop, et al., 2011; Qureshi, Wilson, et al., 2009). Like any risk assessment, the usefulness of the FHH also depends on the accuracy of the information obtained. In the case of FHH, individuals must be able to accurately report the occurrence and age of onset of diseases in their family members. However, the advantage of interview-based FHH is that it can be portable and adapted to the context.

For example, in the study of Utah families with coronary heart disease, Williams and colleagues (Williams, Hunt, et al., 2001) engaged students in health education classes to take home a FHH assessment for the family to complete. Students as part of the assignment transferred the FHH data to machine-readable data forms. The estimated cost of these assessments was $6.50 per survey. In the same way, lay health workers could be trained to collect FHHs. Thus low-cost administration of FHH assessment is feasible. Moreover, new applications of FHH are now being facilitated by smart technology where interactive computer increases the speed and ease of data collection. These innovations also could lower cost and extend their reach.

A few studies conducted in the USA have used FHH assessments with low-literacy populations to discuss inherited disease risk for chronic diseases (Ashida, Wilkinson, & Koehly, 2012; Kaphingst, Lachance, et al., 2011). Results suggest that risk reports generated using these tools are understandable to low-literacy target groups (Kaphingst, Lachance, et al., 2011) and feasible for use in low resourced settings (Ashida, Wilkinson, & Koehly, 2012). However, despite the strong predictive value of FHH in disease risk, and portability of the applications, FHH information has been underutilized for risk screening in public health practice (Berg, Baird, et al., 2009).

Genetic testing also is being used to characterize disease risk. Genetic tests for rare genetic mutations that cause familial cancer syndromes have been available since the mid-1990s. However, an ever-growing number of common gene variants associated with a host of common health conditions also are now being identified. Currently there are over 2000 genetic tests available related to health outcomes (National Library of Medicine, 2013). Some of these are panel tests that test for hundreds of genetic variants, and feedback is given to individuals on their disease risk and response to pharmacotherapies (Bloss, Darst, et al., 2011). These studies are also providing insight into how genetic variation may influence disease susceptibility and whether individuals with specific gene variants are more reactive to environmental exposures (Gilliland, 2009).

The availability of genomics-based risk information has raised concerns about whether the public will be able to accurately comprehend the meaning and limitations of this information. Concerns have been particularly heightened for genetic risk information related to common chronic disease where risk estimates will convey relatively low probabilities (Lea, Kaphingst, et al., 2010). Despite these concerns, there also has been considerable optimism that the high degree of personalization inherent in genetic risk information will make it especially salient to recipients and as such likely to motivate efforts to reduce risk.

Offerings of genetic testing in an array of contexts have evaluated whether individuals can understand the implications of having a risk variant of a single gene (McBride, Halabi, et al., 2000; Sanderson, Humphries, et al., 2008; Smerecnik, 2010) and having variants for multiple genes (Kaphingst, McBride, et al., 2012). Measures of comprehension have differed across these studies, ranging from assessments of whether an individual can recall results accurately (Lipkus, 2007) to indicators of misunderstanding reflected by attitudes endorsing genes as sole determinants of health (Smerecnik, 2010). These studies are consistent in showing that when evidence-based communication strategies are used and consideration is given to the literacy level of the target audience, lay audiences can understand the implications of genetic risk for common diseases. Studies showing the best outcomes in comprehension have used strategies including pictorial renditions of risk estimates (Lea, Kaphingst, et al., 2010), metaphors to convey the interplay of genetic susceptibility and exposure (McBride, Halabi, et al., 2000), and written material geared to the fifth grade level of literacy (Kaphingst, Lachance, et al., 2011).

Two systematic reviews have considered the evidence base concerning whether providing genetic risk information increases motivation and prompts concordant behavior change (Marteau, French, et al., 2010; McBride, Koehly, et al., 2010b). Both conclude that there is little evidence to support the assertions that genetic risk information alone will prompt behavior change. However, each also describes the numerous limitations of the research to date. By and large, most of the studies have targeted cigarette smoking, an addictive behavior. The study samples have been relatively small, and baseline levels of motivation for behavior change have been high in the targeted samples. Participants have been older individuals who are already experiencing health outcomes that are behavior-related. One future direction encouraged for this nascent field is to evaluate genetic risk communication with target groups such as young families where motivation levels for behavior change are low, and parent-child shared risk could be leveraged to motivate behavior change (McBride, Bowen, et al., 2010a).

It also is noteworthy that the common genetic variants identified in these studies each alone account for only modest increases in disease risk (e.g., 10–40%) (Frazer, Murray, et al., 2009). However, it is forecast that in the future these variants in aggregate could identify subgroups who are at substantially increased or decreased disease risk (e.g., as much as 2–5 fold). The rapid decrease in cost of such testing is also prompting efforts to consider whether integrating genetic variant testing with existing risk assessments including FHH could add value to risk stratification and inform targeted health promotion efforts (Pharoah, Antoniou, et al., 2008). Advancements too in technology enable genome-wide assessments to be conducted using saliva samples (without requiring refrigeration). Such developments further increase the feasibility for using genetic testing to assess disease risk in rural and often remote field settings that characterize LMICs.

Potential Challenges Presented by LMIC Contexts

The social-cultural context of LMICs presents numerous challenges for health promotion efforts. However, two key challenges quickly come to the fore as we consider evaluating whether integrating genomics-informed risk stratification and targeted risk communications could increase the effectiveness of health promotion interventions. First, widespread illiteracy, common in most LMICs, will present sizable communication challenges. Second, misperceptions about genomics (e.g., beliefs that such conditions are unpreventable) could foster social distancing and other stigmatizing behaviors and undermine adherence to behavioral recommendations. These challenges operate at multiple levels of influence to create a nexus of barriers that must be addressed in genomic translation research. Each of these challenges is discussed in turn below.

Literacy Challenges

The challenges of promoting genetic literacy in countries with *high* literacy rates are well documented (Pearson & Liu-Thompkins, 2012; Smerecnik, Mesters, et al., 2008; Syurina, Brankovic, et al., 2011). Thus, the challenges for promoting genomic literacy in LMICs are likely to be sizable (Nielsen-Bohlman, Panzer, et al., 2004; Raz, 2003; Tomatir, Ozsahin, et al., 2006; Wonkam, Njamnshi, & Angwafo, 2006). Literacy comprises skills that extend beyond the acquisition of knowledge and includes having the competencies to process, understand, and use information to make decisions and take requisite preventive actions (Rudd, 2013). World experts from 58 countries have identified public education in genomics as a high priority for LMICs (Daar, Singer, et al., 2007). Yet, an informal review of education programs for genomics-related diseases occurring in LMICs found few examples of programs.

In one study conducted in Tanzania, youth affected by albinism (McBride & Leppard, 2002) were provided with a health booklet describing the role of heredity as a cause of albinism and the importance of sun protection among those affected. Home visits were conducted in which health workers provided participants with sunscreen and hats. Unfortunately, few of the participants read the booklet and among those who did, the information was poorly retained and adherence to sun protection was quite low. Health promotion interventions have a long tradition of employing print-based education strategies that can be successful when designed specifically for low-literacy audiences (Michie, Jochelson, et al., 2009). However, high rates of *illiteracy* coupled with the high value placed on oral traditions of knowledge exchange may make print-based approaches less suitable for LMIC contexts.

High-income countries also rely on one-to-one genetic counseling services to accomplish educational objectives. However, genetic counselors are a limited resource internationally, and the majority of LMICs have no in-country genetic counselors (Pang, 2009). Thus, these efforts will likely fall to lay health advisors who themselves will have limited genetic literacy. How best to use oral education strategies to convey genomic information is largely unexplored.

Three decades of evidence suggests that bottom-up community involvement will be required in fostering genomic literacy in LMICs. It will be important when designing interventions to engage the community in advance in defining the primary objective for any literacy building efforts. For example, strategies may be targeted to improve a target community's capacity to appreciate the potential benefits and risks of participating in genomics-related research as a means to empower informed decision-making. Alternatively, literacy building may be directed to improve understanding of the role of heredity in disease risk as a means to justify resource allocation and motivate preventive actions. Thus, organized efforts involving the community in identifying conceptual knowledge needs, opportunities for using new knowledge, and fostering these essential competencies will be needed. Moreover, these processes likely will differ across LMICs and health contexts (Bhuyan, 2004).

In LMIC contexts of limited resources, systematic efforts to enhance genomic literacy also have the potential to divert limited resources away from other health promotion endeavors. Thus, health and community leaders will be important target groups for promoting genomic literacy. Again, information needs will differ based on the health context. For example, information needs may center on helping leaders develop skills to evaluate how and to what extent genomics-based innovations might be integrated with ongoing health education programs. Currently, there is sparse evidence to support what individuals, lay health workers, and community leaders need to know in order to build sufficient context-specific genetic literacy.

Labeling and Stigmatization

Another challenge of using genomic information to guide health resource allocation centers on the propensity for genetic risk to be misunderstood as signifying certainty, that is, deterministic of health outcomes. Misperceptions that health conditions with hereditary underpinnings are *unpreventable* are well documented and consistent throughout the developing world (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). There also is mounting evidence in LMICs that such misconceptions increase social ostracism and other stigmatizing behaviors of families affected by conditions such as sickle cell disease, albinism, spinocerebellar ataxia, and certain neglected tropical diseases (Balgir, 2008; de Villiers, Weskamp, & Bryer, 1997; Kromberg, Zwane, & Jenkins, 1987; Lund, 2001; Lund & Gaigher, 2002; Marsh, Kamuya, & Molyneux, 2011).

Most of what is known about the association of these deterministic beliefs and increased stigmatizing behaviors is in high-income countries and based within the context of mental illness. Indeed, a review of 32 of these studies showed that beliefs in biogenetic explanations of mental illness tended to increase social distancing of those affected by mental illness and their families (Angermeyer, Holzinger, et al., 2011). Characteristics of LMICs present some additional and unique challenges that may intensify these consequences. Target groups in LMICs live predominantly in rural areas, often in remote settings where interpersonal affiliations have significant impact on daily living and economic livelihood. Thus, concerns that genomic risk-based resource allocation could result in social labeling and, in turn, could prompt associated social distancing behaviors with the potential for negative social consequences for affected families are justified.

Formative analysis of endemic causal beliefs about locally relevant disease caused by hereditary and environmental factors is needed in LMIC contexts. Novel health education strategies that convey the interplay of genes and environment in disease occurrence designed for oral delivery will be of particular import in reducing the likelihood that target groups will develop these misconceptions. Strategies most likely to be successful will layer new information about the combined contributions of heredity and environment on health onto individual's existing mental models, that is, the web of their beliefs and perceptions about the causes of a health condition (Fisher, Walker, et al., 2002; Roter, Rudd, et al., 1981). Accurate perceptions can be reinforced, and prevalent misunderstandings that discourage preventive actions could be corrected (Fisher, Walker, et al., 2002; Newman, Seiden, et al., 2009).

Use of Genomics-Informed Risk Stratification in LMICs

To identify examples of using genomics-informed risk stratification for health promotion efforts in LMICs, we conducted a literature search from 1960 to 2011 using keywords *genomics, genetics and family history* crossed with *health promotion, intervention, global health, and behavior change* and a third level of keywords including *allocation, stratification, effectiveness, adherence, equity, and social justice*. Studies were included if they used genomic-based knowledge or tools for health promotion. A total of 18 papers and 17 unique intervention studies were identified. Half described studies that targeted family members of patients with Type 2 diabetes or heart disease for improvements in diet and physical activity; half focused largely on promoting screening behaviors for early detection of cancer. The majority used FHH assessments, and a few relied on genetic testing for risk stratification. All publications were fairly recent (1999–2011), and none were conducted in LMICs.

Several of the identified studies targeted families at high risk for Type 2 diabetes (Kujala, Jokelainen, et al., 2011; Qureshi & Kai, 2008). Consistent with the broader literature, these studies relied on FHH assessments to identify target populations for health promotion interventions. FHH of Type 2 diabetes is associated with a doubling of individual risk; risk increases fourfold when both parents are diabetic (Heideman, Middelkoop, et al., 2011). There is evidence that those who report having a FHH of Type 2 diabetes have high levels of worry about their risk for the disease (Zlot, Bland, et al., 2009). Additionally, several studies of high-risk families show evidence that when adherence to dietary and physical activity recommendations is achieved, there are concordant improvements in disease risk factors (e.g., weight and blood glucose) (Kujala, Jokelainen, et al., 2011). However, these studies have not evaluated the relative benefits of informing high-risk families about hereditary risk as a means to enhance and motivate adherence, and average-risk comparison groups have not been included (Heideman, Middelkoop, et al., 2011).

Epidemiologic investigations also illustrate possible opportunities to stratify populations based on genetic testing for common variants and targeting interventions accordingly. One example comes from research with a cohort of asthmatic children recruited from families in Mexico City where exposure levels to air pollution are high (Romieu, Sienra-Monge, et al., 2004). The cohort was tested for gene variants in the *glutathione* *transferase (GST)* family of genes that influence the lung's ability to metabolize air pollution particulates. Evidence suggests that children with a null-null genotype for *GSTM1* may be especially vulnerable because their lungs are less efficient at metabolizing air pollutants (Gilliland, 2009; Yang, Fong, et al., 2009). Nearly 40% of children in the cohort had the null-null genotype. These children also had the most severe asthma symptoms (Romieu, Ramirez-Aguilar, et al., 2006). Antioxidant supplementation (vitamins C and E) improved forced expiratory flow levels more strongly among children with the high-risk genotype (i.e., *GSTM1* null-null) compared to children with at least one copy of the gene. This association was strongest among children with moderate or severe asthma (Romieu, Sienra-Monge, et al., 2004).

Again, this research has not evaluated how parents and affected communities might respond to risk stratification or targeted recommendations for antioxidant supplementation. It is also unclear how genetic testing and risk education might be integrated into existing asthma prevention programs. Moreover, even if deemed to be acceptable to target groups, it is unclear whether there would be cost savings and more efficient distribution of resources.

In summary, research in high-income countries suggests the feasibility of using genomics-informed risk assessments to identify those at highest risk and target health promotion resources accordingly. However, rigorous evaluation of these opportunities has yet to be conducted. Formative research will be required to consider how to communicate about genetic and environmental contributors to health conditions, to ensure adequate understanding of genomics, and to understand how to use genomic information in ways that motivate adherence to behavioral recommendations and reduce stigmatizing behaviors. This formative work also will require partnerships with communities to consider how best to integrate genomic innovations with existing health promotion interventions in varying social and health contexts. Lastly, comparative effectiveness research will be required to evaluate whether these efforts add value to health promotion efforts.

Genomic Translational Research in Ethiopia

In the sections to follow, we describe an ongoing program of translation research that began with formative research aimed to understand community members' receptivity to genetic research participation and their understandings and beliefs about the role of heredity in the development of podoconiosis, a nonfilarial elephantiasis. We applied these insights in a second phase of research to develop and pilot test health education materials about genetic susceptibility aimed to motivate consistent shoe wearing among genetically high-risk children. The research culminated in a community-based study to evaluate whether enhancing genomic literacy regarding the role of inherited susceptibility and environmental exposure as conjoint causes of podoconiosis improves upon standard health promotion intervention approaches. Each phase of the research is described below to illustrate how we built on opportunities and tackled inherent challenges of integrating genomics into efforts to promote foot health in rural Ethiopia.

Podoconiosis: A Neglected Tropical Disease

Podoconiosis, also known as "mossy foot," is a geochemical noninfectious lymphedema of the lower legs caused by prolonged barefoot exposure to red clay soil derived from volcanic rocks in highland areas (see Fig. 24.1) (Davey, Tekola, & Newport, 2007; Price, 1990). It is characterized by a gradually progressive and usually asymmetric swelling of the lower legs, with skin changes that include hyperkeratosis, papilliform ("mossy") lesions, and nodules. As the disease progresses, the lower legs become increasingly swollen and deformed, and the individual becomes increasingly disabled. Podoconiosis is an extremely stig-

Fig. 24.1 Podoconiosis, also known as "mossy foot," showing skin changes that include hyperkeratosis, papilliform ("mossy") lesions, and nodules

matized health condition in endemic areas (Tora, Davey, & Tadele, 2011; Yakob, Deribe, & Davey, 2010). The swelling in podoconiosis is disfiguring, and in the absence of deep cleaning, the oozing lymph fluid produces an unpleasant odor. Affected adults are often banned from churches, employment, and social events. Ostracized by peers and teachers, children drop out of school. Young people from affected families have very slim chances of finding a marriage partner, whether they themselves are affected or not. Those who get married and go on to develop the condition are likely to be discriminated against and divorced by their husbands.

Podoconiosis is an important public health problem in more than ten countries; there are at least four million people with the disease across tropical Africa, Central and South America, and northwest India (Davey, Tekola, & Newport, 2007; Price, 1990). In endemic areas, the number of people with podoconiosis outnumbers those with other diseases including HIV/AIDS, tuberculosis, malaria, and filarial elephantiasis (Alemu, Tekola Ayele, et al., 2011).

Most of the research on podoconiosis has been conducted in Ethiopia. With an estimated one million cases, Ethiopia bears the largest disease burden of any country (Destas, Ashine, & Davey, 2003). Podoconiosis develops in young adulthood when individuals are generally most productive economically and thus has catastrophic economic consequences. In Ethiopia it is estimated that the disease costs more than 200 million USD per year in lost productivity. In one quarter of patients, disease is advanced, substantially limiting their ability to work (Alemu, Tekola Ayele, et al., 2011; Tekola, Mariam, & Davey, 2006) Complications of the disease such as superinfection and acute lymphadenitis are associated with morbidity, reduced quality of life, and destitution aggravated by lost productivity in affected families. Most patients experience these acute episodes during the seasons of the year when agricultural activity is more intense (Alemu, Tekola Ayele, et al., 2011; Molla, Tomczyk, et al., 2012b; Tekola Ayele, Alemu, et al., 2013). For communities where an entire year's worth of income must be made in a matter of months, loss of a few days of work because of morbidity is a serious threat to their weakened economy and hurts the agricultural sector of endemic countries.

Genetic and Environmental Risk Factors for Podoconiosis

Podoconiosis is an example of a disease resulting from the interaction of genetic and environment risk factors (see Table 24.2). Areas endemic for

Table 24.2 Risk factors for podoconiosis in endemic areas

Factor	Description	References
Geography	Altitude: high altitude >1000 m above sea level Rainfall pattern and volume: seasonal rainfall, >1000 mm per year Soil: irritant red clay soil derived from volcanic rock	Davey, Tekola, and Newport (2007), Price and Plant (1990)
Socioeconomic status	Occupation: the majority are farmers Literacy: the majority are not educated Household economy: the majority are poor Gender: males and females are equally affected	Destas, Ashine, and Davey (2003), Kloos, Bedri Kello, and Addus (1992), Mengistu, Humber, et al. (1987), Price and Plant (1990)
Shoe-wearing behavior (lifestyle)	The majority of patients are barefoot	Davey, Tekola, and Newport (2007), Price and Plant (1990)
Familial factor/ genetics	Familial clustering, high heritability (63%), high sibling recurrence risk ratio (5.1), the most parsimonious genetic model being autosomal codominant major gene with age and footwear as significant environmental covariates. Genome-wide association study revealed significant susceptibility loci in the HLA class II loci (HLA-DQA1, -DRB1, -DQB1 genes)	Davey, Gebrehanna, Adeyemo, Rotimi, Newport, and Desta (2007), Price (1972), Tekola Ayele, Adeyemo, et al. (2012)

Adapted from Tekola Ayele, Adeyemo, and Rotimi (2012)

podoconiosis are characterized by altitude >1000 m above sea level and annual rainfall >1000 mm, factors that are important in the formation of the brownish red clay soil that contains mineral particles small enough to penetrate the skin of barefoot individuals (Price, 1974).

Barefoot exposure to the soil is common. Most do not regularly wear shoes from childhood and this habit begins in childhood, primarily because they cannot afford shoes (Yakob, Deribe, & Davey, 2008). The majority of people in highland Ethiopia are uneducated. Furthermore, the livelihood of adults in endemic areas predominantly depends on working the fertile clay soils for food crop production, which when practiced barefoot increases exposure to the environmental culprit.

Not all individuals who are exposed to red clay soil develop podoconiosis. Accumulating evidence shows the role of genetic predisposition in podoconiosis. Individuals in endemic areas enriched for the genetic risk factor(s), for example, through positive family history and barefoot exposure to clay soil, are at high risk for podoconiosis (Tekola Ayele, Adeyemo, & Rotimi, 2012). Familial clustering of podoconiosis in areas of red clay soil was first described by Price and based on his observations of high disease burden in some families in the tropical African countries of Ethiopia, Rwanda, and Burundi (Price, 1976). His segregation analysis of families with more than one affected child indicated significant familial aggregation and the possibility of a genetic factor(s) with an estimated risk genotype frequency of 15–40% (Price, 1972). Other community-based surveys since have also reported familial aggregation in a third to one-half of affected individuals in Ethiopia (Kloos, Bedri Kello, & Addus, 1992; Molla, Tomczyk, et al., 2012a; Tekola Ayele, Alemu, et al., 2013).

In 2005 a pedigree study conducted in multigenerational and multiple affected Ethiopian families showed that podoconiosis has a strong genetic basis. Siblings of an affected person were at five-times increased risk of developing podoconiosis when compared to a person in the general population, and 63% of the variation in development of podoconiosis was accounted for by genetic factors. The “best fit” model in the study revealed the contributions of a major gene, age, and history of use of footwear (i.e., genetic and environmental factors) to the pathophysiology of podoconiosis (Davey, Gebrehanna, et al., 2007).

In 2012, a genome-wide association study (a genomic approach that compares the frequency of common genetic variants in the genome between cases and controls) was validated using a family-based study method. This study confirmed that podoconiosis has a strong genetic basis and suggested that it is a T-cell-mediated inflammatory condition (Tekola Ayele, Adeyemo, et al., 2012).

Social Stigma and Its Effect on Genetic Research Participation

An initial qualitative study of podoconiosis-endemic areas showed that two-thirds of community members believed that the disease is hereditary and unpreventable (Tekola, Bull, et al., 2009a). Affected community members who reported experiences of social stigma and concern about being stigmatized were reticent to participate in genetics-related research on podoconiosis.

Community Engagement to Develop Informed Consent Processes

High rates of illiteracy in endemic areas make conventional informed consent processes virtually impossible. Yet little research is ongoing to guide alternatives. To this end, qualitative investigations were undertaken in podoconiosis-endemic areas prior to seeking consent for genetic research in Ethiopian families affected by podoconiosis. Results of focus groups with a variety of community groups showed that several social and cultural issues, if not properly handled by a research team, could affect the consent process for genetic research (Tekola, Bull, et al., 2009b). Among the concerns raised that were unique to participation in genetics research is that it was critical to have a comprehensive understanding of local terminologies and contexts for describing the hereditary nature (genetics) of podoconiosis. For example, the local vernacular term for podoconiosis, *gediya kita*, is a derogatory term (Tekola, Bull, et al., 2009a). Moreover, lay descriptions of genetics and heredity included concepts of “having it in the blood” or “the bone.” Given the strong social value of the bloodline in these communities, individual’s beliefs inclined them to associate genetic susceptibility with “unclean” blood. Additionally local decision-making structures and family ties needed to be considered in obtaining consent. And lastly, a more complete characterization of the stigma experienced by podoconiosis-affected families was needed to help the research team avoid exacerbating existing stigma.

The findings suggested the importance of using a hierarchical consent process in partnership with a local community health provider (CHP), the Mossy Foot Treatment and Prevention Association. The first part of the consent process involved community education and training of the CHP’s field workers. The components of the training emphasized providing information on genetic susceptibility to podoconiosis given environmental exposure. Results of the developmental study indicated that research involvement had to first be considered at the family level before an individual could agree to or decline participation. This was regarded as especially important in the context of podoconiosis because the stigma of research participation in a genetic study extended to the family as a whole. Moreover, affected individuals perceived that there would be increased stigma associated with participating in related research and felt strongly that they would have to consult their families before deciding. Thus, individuals were enrolled in the study only after they had discussed study participation with their family. Families were given information and adequate time to deliberate thus respecting complex intra-household decision-making processes. This comprehensive approach yielded great dividends during the recruitment process as most families reported less concern about privacy and social stigma, and 98.5% of approached individuals consented to enroll in the genetic study (Tekola, Bull, et al., 2009a).

Qualitative Research to Guide the Development of Interventions to Promote Shoe Use

Footwear may appear a relatively simple behavior to target to prevent podoconiosis. However, as with other behavioral interventions, the reality is complex. Recent evidence indicates that shoe-wearing prevalence is low and inconsistent (Yakob, Deribe, & Davey, 2008) and that the majority of school-aged children in these rural settings in Ethiopia wear inappropriate shoes that do not adequately protect the feet from exposure to the soil (e.g., flip-flops) (Tadesse, 2005).

Consistent with the PRECEDE-PROCEED approach to program development and evaluation (Green & Kreuter, 1991), we conducted a two-phase process for considering intervention strategies to promote consistent shoe wearing. The PRECEDE phase involves qualitative activities that enable diagnostic planning and focused on assessment of social, behavioral, environmental, educational, and ecological issues that may influence whether and when high-risk children wear shoes. In the PROCEED phase, information gleaned in the PRECEDE phase is used to guide and tailor program implementation and evaluation. The model has been used widely in developing and evaluating public health interventions across a wide variety of public health settings including interventions for rural populations in sub-Saharan Africa (Mbonu, Van Den Borne, & De Vries, 2011). Each phase of our activities is described in turn.

PRECEDE: Understanding Beliefs About Heredity and Their Effects on Shoe Wearing

As suggested earlier, we considered it critically important to understand individual's mental models about the role of genetics in health conditions. To this end, we undertook a second series of qualitative research activities including focus group discussions, semi-structured in-depth interviews, and extended case studies with community members. A total of 306 adults and children participated in these activities that explored participants' beliefs about the causes of podoconiosis, attitudes toward individuals affected by podoconiosis, attitudes toward wearing shoes, and optimal settings for promoting footwear among high-risk populations.

Heredity was spontaneously and frequently mentioned in participants' renditions of the cause of podoconiosis (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). Those who believed podoconiosis was solely hereditary also tended to perceive that the condition was not preventable. Endorsement of heredity as a sole cause also aligned with acknowledgment that affected families experienced stigmatizing behaviors as well. However, denial that heredity had any role influenced stigmatizing behaviors. Those who perceived no role for heredity were concerned that podoconiosis was contagious and were concerned about being in close proximity to affected families (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). Both belief systems led community members to conclude that interactions with individuals and families affected by podoconiosis should be avoided, thus exacerbating social stigma.

Beliefs about the involvement of heredity in the development of podoconiosis also were associated with shoe-wearing behaviors. Believing the condition to be inherited and thus not preventable diminished the perceived importance of wearing shoes; whereas believing that heredity was not involved and that contagion was at play also diminished the importance of wearing shoes in favor of avoiding physical contact with those who were affected. These misconceptions and attitudes were present among affected and unaffected families. Thus, improving community levels of genetic literacy will be required to shift attitudes and motivation to adopt foot protecting practices.

Adherence to most behavioral recommendations is impeded by a host of social and contextual factors as well. Indeed, our qualitative work identified a range of barriers to compliance among those who considered it important to wear shoes (Ayode, McBride, et al., 2013). Financial barriers were among the most important, but other issues such as suitability for farming activities, fit of shoe, and fear of labeling were also significant deterrents (Ayode, McBride, et al., 2013; Yakob, Deribe, & Davey, 2008). Several investigations have documented reluctance to wear shoes while farming or in the rainy season (Alemu, Tekola Ayele, et al., 2011; Molla, Tomczyk, et al., 2012b; Yakob, Deribe, & Davey, 2008) and use of poor-quality sandals or low-cut shoes likely to afford little protection from the soil (Alemu, Tekola Ayele, et al., 2011; Molla, Tomczyk, et al., 2012b; Yakob, Deribe, & Davey, 2008). These findings suggested that interventions to promote footwear will need to build participants' confidence and skills to overcome these barriers.

Shoe Distribution Targeting High-Risk Families

Promoting foot protection practices in podoconiosis-endemic areas of Ethiopia also is limited by the availability of health workers to distribute shoes. In turn, demand for shoes is high – half of the Ethiopian population is under the age 12 and could benefit from wearing shoes. Accordingly, the community health provider, Mossy Foot Treatment and Prevention Association, has used FHH to identify children at high risk of podoconiosis (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012; Davey & Burridge, 2009) and target them for distribution of shoes. This service delivery model that uses the limited infrastructure to distribute free shoes to genetically high-risk families is defensible given that podoconiosis is a highly prevalent disease, with an identifiable phenotype and high heritability, and that shoes are a relatively scarce resource (Tekola Ayele, Adeyemo, & Rotimi, 2012). However, the efficiency of targeted shoe distribution must be balanced against concerns that in the absence of programs aimed to improve understanding of the rationale for targeting, these approaches could backfire by exacerbating stigmatizing behaviors toward affected families.

Thus in the PRECEDE phase of the research, we solicited community members' beliefs and attitudes regarding targeted shoe distribution and their association with understanding of the role of heredity in the development of podoconiosis. Our focus groups suggested that perceptions that inherited diseases were not preventable needed to be countered by efforts to reinforce and deepen understanding of individual variation in susceptibility, a concept acknowledged by many participants, but only superficially understood (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). Our results also suggested that this could be used to bolster target groups' confidence that risk can be reduced. Indeed, these initial findings suggested that education strategies were needed. However, it was not clear how best to convey a nuanced understanding of the interaction of inherited susceptibility and environment as joint causal factors in podoconiosis or whether these efforts would decrease the occurrence of stigmatizing behaviors.

PROCEDE: Developing a Theory-Based Genetic Susceptibility Education to Motivate Consistent Shoe Wearing

Theory Considerations

There is consensus that public health interventions that are most effective are grounded in social and behavioral theory (Michie & Johnston, 2012). Theory may be especially important for developing interventions for LMICs where public health infrastructure is limited and literacy levels are low. In these contexts, theory can be useful for considering how best to incorporate emerging genomic knowledge into existing health promotion efforts and to attain parsimony in assessments of intervention response. Theory also could be informative in deciding what genomic information could uniquely bring to behavior change interventions aimed for LMICs' specific health promotion challenges.

Accordingly, we drew on several theories in designing an intervention to promote shoe wearing among high-risk families. We first considered individual-level conceptual models including social cognitive theory (SCT) of self-regulation (Bandura, 1986). SCT argues for the importance of targeting individual's beliefs and attitudes about genetic susceptibility and its association with shoe wearing, how these beliefs about genetics influence their perceived capabilities to prevent podoconiosis, and whether wearing shoes can be effective in reducing their risk for the condition.

Additionally, we considered interdependence models including the concept of "communal coping." Interdependence theory argues that an individual's motivation to engage in health behaviors may be influenced by their affective relationships (e.g., spouses, parent-child relationships) (Lewis & McBride, 2004). Motivation may be enhanced in circumstances in which a health threat is perceived to be shared or that remediation of the health threats is a relational responsibility. Indeed, individuals will take preventive actions on behalf of important others that they may be less willing to adopt on their own behalf. In this line of thought, understanding of shared genetic risk could be capitalized on, for example, to motivate parents to encourage their children to wear shoes.

Misunderstandings that inherited diseases are unpreventable also are socially influenced. These misconceptions represent shared beliefs about illness that are maintained through interpersonal communication in social contexts (Landrine & Klonoff, 1992; van Oostrom, Meijers-Heijboer, et al., 2007). Intervention activities can capitalize on interpersonal relationships at the family, neighborhood, and societal level to correct misconceptions and empower community members to communicate accurate information within their social networks. Engaging community members in this way also would increase the potential for the intervention to be sustained over time.

Intervention Target Groups

Interdependence theory also guided the selection of our target group for the intervention. Our qualitative work suggested that parents from affected families felt strongly that wearing shoes could improve their children's chances for social advancement by offering them opportunities to attend school (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). Thus consistent with interdependence theory, we proposed to capitalize on parent's desire to improve their child's social standing to encourage and empower parents to help their young children wear shoes consistently.

Also consistent with interdependence theory, our qualitative work suggested that community misperceptions were reinforced within the community by those who were unaffected by podoconiosis. Affected and unaffected individuals had similar misperceptions about the role of heredity in the development of podoconiosis. However, the two groups were not comfortable discussing these beliefs in mixed groups (Ayode, McBride, de Heer, Watanabe, Gebreyesus, et al., 2012). Thus, we concluded genomics education would be targeted to affected families and their neighboring unaffected households. However, this would require that separate health education sessions be conducted with affected and unaffected families.

Additional efforts to promote broader public awareness of the shoe distribution would be conducted by distributing posters and other promotional materials and development of a song to provide a supportive context to the educational efforts. Lastly, it was decided that to maximize long-term sustainability, the intervention should be delivered by local individuals identified by community leaders as lay health advisors.

Inherited Susceptibility Education

Our choices for discussing inherited susceptibility as a means to motivate high-risk individuals to take preventive actions were limited by high rates of illiteracy in the target population. Additionally, residents of the targeted communities speak a variety of different dialects, making it difficult to standardize text. Thus, we concluded that our health education materials would have to rely on oral delivery with visual aids used to support key learning objectives. Under these circumstances, use of visual metaphors has been recommended to enhance the cultural sensitivity of the messages (Freimuth, Linnan, & Potter, 2000). We drew on one example used to characterize genetic susceptibility to mental illness (Peay & Austin 2011). The metaphor for genetic susceptibility relies on a jar of marbles where one color of marble is used to represent individual's genetic risk and another color represents environmental risk. The notion conveyed is that individuals who start out with their jar holding more genetic risk marbles require less environmental exposure (fewer marbles) to significantly increase their risk for a negative health outcome.

Building on this metaphor, we first considered examples of environmental sensitivities that were not stigmatized in the targeted Ethiopian communities. The high elevation of highland Ethiopia, limited tree cover, and necessity of walking long distances to get water or travel to market mean that individuals experience long spells of sun exposure. It is common to see variability in individuals' sensitivity to this sun exposure. Some use umbrellas to shield from the sun, others wear scarves, and some walk without any sun protection. We used this example of variation in sensitivity that is well accepted by the community to illustrate how subjective sun sensitivity might influence the use of sun protection. We then linked this example to inherited sensitivity to soil. The development of foot and leg swelling among family members was an indication that individuals may have inherited this sensitivity to soil exposure, and these individuals would benefit from consistently wearing shoes to protect the feet. We tested this conceptual approach with the target audience in sessions with community health leaders and found it to be well accepted.

Skills Training to Overcome Barriers

Consistent with SCT, it was also clear that parents would benefit from having the opportunity to develop requisite skills to overcome key barriers to their child wearing shoes. Thus an important component of the intervention was to conduct oral educational sessions in households and give parents' the opportunity to build confidence to overcome impediments to their child wearing shoes. A booster education session and shoe distribution were included to sustain intervention benefits. The developed intervention is currently being evaluated with parents of young children who are receiving free shoes from MFI in six communities in highland Ethiopia.

Implications of Podoconiosis for Using Genetics to Promote Health Globally

The case of podoconiosis offers a valuable example of the opportunities and challenges of using genetic information for risk stratification and targeting scarce resources to those at highest risk for negative health outcomes. Results of this project suggest the critical role that genetic education strategies can play in promoting health and reducing the stigma of preventable hereditary health conditions. This example is relevant to the broader global health context as world experts from 58 countries have recommended the development of public engagement strategies to inform and educate the public about genomics (Daar, Singer, et al., 2007). These activities are being given priority in recognition of their potential to build the capacity needed to weigh the ethical, social, and cultural issues that come with efforts to apply emerging genomic knowledge for health improvements (Daar, Singer, et al., 2007). Currently there are very few examples of health education interventions in development or that have been evaluated in the developing world. Indeed, there are few examples of these approaches in developed countries (see, e.g., (Kaphingst, Lachance, et al., 2011)). Development and evaluation of health education approaches that can be readily incorporated appropriate to the needs of LMIC settings will be critical in the coming decade.

Additionally, the conditions for whether and how to use genomics in risk stratification and for targeting intervention also need more careful consideration and evaluation. The risk stratification approaches employed in the podoconiosis project were based on extensive efforts to build relationships with the communities and target groups. At each step of the research, the community was consulted about the approaches being taken. Even so, community members were frustrated that footwear could not be made available to all. Thus, reliance on targeting those at high risk will have social costs and could influence the likelihood that interventions are sustainable for the long term. Considering the optimal complement of targeted interventions and population-wide activities will be especially critical for promoting health in LMIC settings.

Conclusions and Recommendations

In this chapter, we have suggested examples of what may be unique opportunities and challenges for applying genomic discovery to promote health in LMICs. We specifically considered how targeting genetically high-risk families for health conditions in LMICs might be used to allocate scarce health promotion resources and to motivate adherence to behavioral recommendations. We suggested how social and behavioral sciences could be brought to bear in conducting formative research to develop and evaluate genomics-informed innovations in interventions to promote health. We considered this potential alongside concerns about high rates of illiteracy in LMICs and the potential that community misunderstandings about inherited susceptibility to health conditions could exacerbate stigmatizing behaviors. We described our formative research in developing novel approaches to conveying information about genomics to a low-literacy audience in the context of podoconiosis. We described our efforts to develop a footwear promotion intervention aimed to reduce the likelihood of social stigmatization arising from targeting shoe distribution to genetically high-risk families.

Our discussion of opportunities and challenges for genomic translation research touches on only the tip of the iceberg. Predictions of increased technological capacity to generate large volumes of genetic data faster and at lower cost have been largely on track (Green & Guyer, 2011). However, the global health research, that is, the "collaborative transnational research and action for promoting health for all" that is being called for to apply new genomics knowledge, is nascent (Beaglehole, Bonita, et al., 2011; Dandara, Adebamowo, et al., 2012). Moreover, it is being argued as a matter of social justice and commitment to fundamental human right to health that LMICs should be in the vanguard of receiving the benefits of genomics (Bozorgmehr, Saint, & Tinnemann, 2011). However, to be in the vanguard, LMICs must be fully engaged in translation research now.

Most agree that the agenda for genomic translation research must align with critical public health needs in LMICs (Williams & Tishkoff, 2011). As the epidemic of noncommunicable diseases like Type 2 diabetes and other chronic diseases grows, the health priorities of LMICs are converging with the priorities of high-income countries. This provides both the impetus and ideal social climate for the transnational collaborations in disease prevention efforts (Dandara, Adebamowo, et al., 2012).

Efforts to foster these collaborations will face numerous challenges. First and foremost will be the need to build scientific capacity in LMICs. Initially it will be critical that LMIC leaders see a clear path to concrete applications of genomic advances that lead to health improvements where ethical, social, and legal implications have been thoroughly considered (Dandara, Adebamowo, et al., 2012). Programs like the Human Heredity and Health in Africa (H3Africa) Initiative are beginning to lay the groundwork for these transnational collaborations (Williams & Tishkoff, 2011; Wonkam, Njamnshi, & Angwafo, 2006). The Initiative aims to develop expertise among African scientists and establish networks among these investigators to build needed research infrastructure (Price, 1976). Currently, these efforts are focused largely on the development of biorepositories and engaging target populations to participate in epidemiologic research to explore gene-disease associations (Williams & Tishkoff, 2011). Social and behavioral science perspectives will be essential in these efforts. However, the prevention of chronic disease, with the goal to promote healthy behaviors as the cornerstone, is *the* pressing issue internationally.

The case of podoconiosis is just one of an increasing number of health contexts in which health behavior change is needed. The charge for any genomic translation research in health promotion interventions will be to consider agnostically whether genomics-informed innovations add value for unit of cost to existing approaches. The knowledge base and tools for advancing this research agenda are well within the purview of social and behavioral scientists. They include community engagement strategies, state-of-the-science risk communication approaches, understanding of social and behavioral theories, and evidence-based behavior change approaches. Early involvement of an international cadre of social and behavioral scientists in translational research is critical if we are to shape genomics-informed innovation to promote health globally with maximal benefit and minimal negative social impact.

Acknowledgments The authors would like to acknowledge the contributions of Ms. Emily Schiller and Ms. Leah Abrams in assisting with the preparation of this chapter.

Policy and Policy Research for Behavioural Medicine

Vivian Lin, Bronwyn Carter, and Yan Guo

Introduction

Health behaviours are shaped by a multiplicity of forces. The policy environment is one of the factors that can influence behaviour, either for better health or to damage health. In other words, the right set of policies can make healthy choices easier choices, and policy instruments – such as financial subsidies and incentives, regulation, information and service provision – are commonly used to address behavioural health issues. While these same instruments can provide incentives for better health through better use of health services and adoption of health-promoting behaviours, they can also act as disincentive for health service use and healthy behaviours.

This chapter will be concerned with the design and research of policy interventions that positively alter health behaviour. How healthcare policies and intersectoral policies for health influence behaviour will be considered. However, insofar as policy research in relation to behavioural health is a relatively new and evolving field, the chapter will focus on policy research methods for behavioural health, as policy research methods are important both for assessing policy impact as well as helping to design policy interventions.

What Is Health Policy?

The term policy is commonly used in relation to how we are governed but does not have a clear and unambiguous definition. 'Policy' may be used to mean a broad orientation, an indication of normal practice, a statement of values or a specific commitment. The work of government is understood by Colebatch to involve 'managing… problems by means of explicit courses of action – its policies' (Colebatch, 2009). The term 'policy' is used in this chapter in reference to how governments manage the course of events in order to solve and prevent health problems.

The World Health Organization conceives of health policy in two respects (World Health Organization, 2000): policies for delivery of healthcare services and policies to protect and improve population health and well-being. Healthcare policy is primarily concerned with the health sector and the service delivery system, whereas policy for health, as defined by The Ottawa Charter for Health Promotion (World Health Organization, 1986), proposes actions on both population level interventions by the health sector, as well as public policies in all sectors that

shape health and well-being. As a core action in the Ottawa Charter, healthy public policy puts health on the central agenda of government, making policy choices in support of health easier choices at the macro level. The Charter makes policy-makers in all sectors aware of the health consequences of their decisions, directing them to accept their responsibilities for health and making it easier for them to make policy decisions in support of the health of the population. The determinants of health are addressed specifically as a core action in the Bangkok Charter (World Health Organization, 2005), which requires governments to regulate and legislate to protect from harm and enable equal opportunity for health and well-being for all people.

Process of Policy-Making

All governments have formal processes of policy-making, although the specific institutions and processes vary depending on the constitution and structure of government, including the relationship between the legislative and executive arms of government. Governments will typically express their policies through instruments such as plans, legislation and regulation, budgetary allocations, service provision and financial subsidies and incentives.

While formal institutions of policy-making are important, in most countries, policy-making is the result of complex interaction among a wide array of stakeholders which takes account of the formal process of policy-making, the specific technical issues involved in a policy arena and the context within which policies are being proposed and debated (Buse, Mays, & Walt, 2012). The moment of policy decision relies on the confluence of major streams of policy-making: (1) the definition of the policy problem, (2) the agreement on the appropriate policy solutions and (3) the political window of opportunity (Kingdon, 1984). Evidence is important in policy-making. However, policy-makers rely on a broad range of evidence – from scientific research to political polling to budgetary projections for government to community acceptance. The uptake of research evidence into policy occurs when there is concurrence of interests and understanding among the researchers, the policy-makers and the community at large (Lin & Gibson, 2003).

Policies have effect – whether using financial, regulatory or information instruments – when they are implemented. Implementation, however, rests not only on government capacity but also on the extent of stakeholder ownership. This points to the importance of participatory processes – both across sectors and with non-state actors – in policy-making, as well as having sound evidence. For public health advocates within and outside of government, policy advocacy strategies become important, as well as getting the appropriate governance structures for policy-making. Whole-of-government and whole-of-society approaches are recognized as important for health policy-making (World Health Organization, 2013a), with six models for ‘smart governance’ proposed including collaboration with sharing of power between at least one public agency and non-state stakeholders; formal partnerships among different government departments and other sectors; formalized citizen engagement in decision-making to facilitate innovation; a mix of regulation and persuasion; independent expert bodies to provide evidence and watch ethical boundaries; and governance by adaptive policies, foresight and resilient structures to enable flexibility and timely response by stakeholders to issues as they arise (World Health Organization, 2011b).

How Is Policy Relevant to Behavioural Medicine?

Policy measures that shape health behaviour may relate to primary prevention at the population level as well as healthcare for individuals and communities. Policy measures directed at healthcare provision are needed to ensure access to quality health services, for at-risk and for ill populations with targeting for disadvantaged communities. Policy measures outside the health sector are also needed for primary prevention, particularly to address the social determinants of health.

Figure 25.1 provides a framework for policy interventions related to behavioural medicine. The framework shows how policy is used for behavioural medicine in sectors other than health, to provide interventions at the population level. The main policy instruments for behavioural medicine in use across sectors are 'health in all policies' (HiAP) initiatives and policies to reduce harmful behaviours and increase healthy behaviours at the population level. Such policies provide financial disincentive/incentive, regulation or information. The framework shows how policy is used for behavioural medicine in the health sector, to provide interventions at the level of the individual and for targeted groups. Within the health system, policy instruments for behavioural medicine relate to financing – for screening and referral, access to services, service models and workforce development. Health policies are, however, distal (rather than proximate) interventions. They do not have the same effects on all persons. Policies designed for health purposes interact with, and may be in contradiction with, policies in other sectors. Policy research for behavioural medicine therefore relates to agenda setting, policy design, policy implementation and evaluation of the impact of policy, within the health sector as well as other sectors.

Healthcare Policies

Access to health services is a policy area relevant to behavioural medicine as this influences care seeking and adherence. This is particularly important for disadvantaged groups. For healthcare policies, the key question is what policies are most likely to encourage appropriate care seeking and adherence – policy measures and research questions are therefore likely to be related to system characteristics such as financing incentives, service models and workforce competencies, and demand side issues such as health literacy, and social and cultural influences on access. Policies in relation to financial barriers to access are important, as are policies that are non-discriminatory and promote diverse service models and diversity in the health workforce

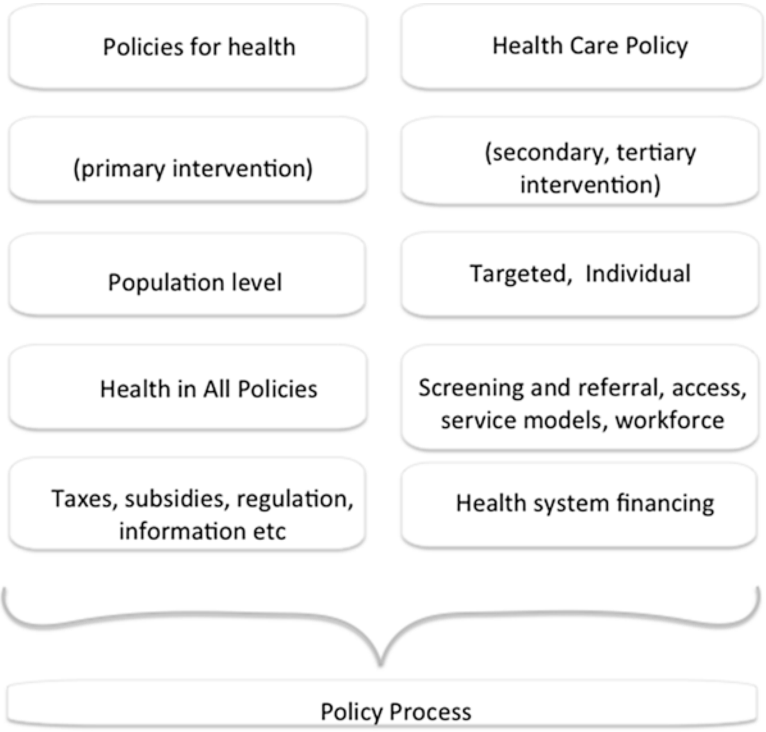

Fig. 25.1 Organizational framework for examining policy and behavioural medicine

which engender trust by the community. In the post-2015 development agenda, policies for ensuring universal health coverage will be a core concern globally (Lin & Carter, 2014; World Health Organization, 2013b, 2014).

Financing Incentives

Key policy areas for health system financing relate to health insurance, patient and provider incentives for preventive care and the effects of out of pocket costs. Policy questions for behavioural medicine include Is there a health insurance system that assures people having access to care, including both preventive services as well as treatment and rehabilitation services? Is there specific financing for systems to underpin preventive care, such as screening registries and recalls, or social marketing campaigns? Does the payment system for the provider give incentive for preventive interventions such as regular screening, lifestyle advice and referral to counselling and support services? Does the financing or payment system require substantial out of pocket payment from consumers such that they can fall into poverty, or delay care seeking, or not take the necessary drugs? One example of a financing incentive to promote access to services is blended payment systems which increase access to care by combining capitation, allowances and fee-per-item payments. A study of oral healthcare found that blended payment systems promote balance between over-provision or under-treatment, patient selection or 'cherry picking' by dentists and overconsumption and equitable coverage and access for patients (Woods, 2013). Public funding of family planning services for low-income women (Gerstein & Markus, 2013) is an example of financial incentive to promote access to care and preventive services.

A review of systematic reviews of financial incentives for health-related behaviour examined characteristics of effective programmes (Lynagh, Sanson-Fisher, & Bonevski, 2013) and proposed the following principles:

- Reliable, accurate and acceptable measures of behaviour change should be used such as uptake of immunization, participation in screening and treatment programmes, smoking cessation and physical activity (validated by pedometer readings).
- Incentives are more likely to be effective with disadvantaged or vulnerable groups, for example, low socioeconomic groups, drug users and teenage mothers, but more studies are needed of the general population.
- Incentives need to be sufficient in size, for example, return visits to a tuberculosis clinic were higher in patients receiving a larger cash incentive.
- The size of the incentive required may vary with financial status, for example, more favourable results were achieved in treatments for obesity with incentives greater than 1.2% of personal disposable income.
- A frequent and incremental reinforcement schedule with reset contingency is needed (when a relapse in behaviour occurs the size of the incentive returns to its initial value), particularly for behaviours where maintaining an initial change is critical to sustaining change over the longer term, such as with smoking abstinence.
- Minimal delay between behaviour and reward is needed, for example, in drug treatment programmes immediate rewards have been shown to be more effective.
- Carrots work better than sticks because negative incentives may reinforce personal failure and may be viewed as punishing the most vulnerable.

Service Models and Workforce Policies

Policy for healthcare service models for behavioural medicine relate to policies which encourage services to be patient and community centred and offering seamless care that links community health and hospital care (World Health Organization Western Pacific Region, 2007). Prevention of unnecessary admissions, health maintenance in the community setting and satisfaction with services are some of the major policy objectives. Improved service coordination and responsiveness to the needs of patients will be achieved through further development of models of care, such as integration of patient education, family involvement, self-management and counselling. So policies need to encourage multidisciplinary teamwork, involve families/carers and recognize the use of complementary healthcare. The use of e-health records to promote continuity of care and web-based services to promote self-management (Ramadas, Chan, et al., 2014) is a recent example of service models for behavioural medicine.

People-centred healthcare rests, in part, on healthcare providers who can communicate effectively with patients and their families and work effectively in teams and on institutions that are trusted by the community and can develop tailor-made interventions. Policies are required to ensure the health workforce has the requisite competencies to practice behavioural medicine – to provide counselling and brief interventions and to refer to other disciplines for support services. With recognition and support, clinical educators and role models who espouse professionalism and humanism in healthcare can transfer to trainees such values and skills important in behavioural medicine. So workforce policies for behavioural medicine are about leadership, curriculum, multidisciplinary education, clinical training in community settings and cross-cultural awareness training. For example, workforce policies for curriculum support inclusion of training in socio-behavioural medicine as well as biomedical paradigms (Ding, Zhong, et al., 2014) and development of specialist postgraduate training in particular areas of need such as public health nutrition (Hughes, 2006). Additional measures to promote non-discrimination of particular patient groups may also be important for access, such as targeted information or workforce competency development.

Policies for Health

Policies which address social determinants of health – the conditions in which people are born, grow, live, work and age – are important in behavioural medicine. There are multiple examples of the use of policy to address behavioural health issues such as smoking, alcohol and nutrition. Key policy areas for sectors other than health relate to financial incentives, regulation and information.

Legislation and regulation are core policy instruments used by governments around the world to promote population health. For example, the National Alcohol Strategy enacted in Chile in 2012 increases regulation of drunk driving (found to be in charge of a motor vehicle while over the legal blood alcohol limit) (Pena, 2012). Other examples of the use of regulation in behavioural health policy include limits placed on advertising, promotion, sponsorship and sales of tobacco, alcohol and unhealthy food, tobacco plain packaging laws, increases in smoke-free public places and worksites, bans on tobacco flavourings, regulation of salt content of foods, replacement of trans fat with polyunsaturated fat, labelling of ingredients, and policies to support breastfeeding such as breastfeeding rooms (Framework Convention Alliance, 2015; Lin, Jones, et al., 2014). Besides well-established measures in tobacco control, there is increasing experimentation with regulation such as bottle-size bans for sweetened drinks (Mytton, Clarke, & Rayner, 2012), zoning to control fast food and ensure access to quality early childhood education (Friedman-Krauss & Barnett, 2013).

Governments also exert influence through the use of financial tools. Examples of financial incentives in policy for behavioural health include tobacco and alcohol taxes (Framework Convention Alliance, 2015; Lin, Jones, et al., 2014; Pena, 2012), subsidies to increase availability and access to healthy food and health insurance incentives for keeping physically active (Lin, Jones, et al., 2014). 'Fat taxes' such as tax on sugar sweetened drinks have also been trialled in Denmark (Mytton, Clarke, & Rayner, 2012).

Examples of behavioural health policy supporting the provision of information and persuasion include warnings on tobacco packets, mass media and public education to raise awareness of tobacco harms and the benefits of diet and physical activity in disease prevention (Framework Convention Alliance, 2015; Lin, Jones, et al., 2014).

For policies for health relevant to behavioural medicine, the concern is to effect the adoption of healthy public policies across all sectors involving policies and programmes that have an impact on the social and behavioural determinants of health. Increasingly, health in all policies approaches are becoming a focus for action on social determinants of health (European Observatory on Health Systems and Policies, 2006; Howard & Gunther, 2012; Government of South Australia, 2013; McQueen, Wismar, et al., 2012; Shankardass, Solar, et al., 2011).

Healthy public policies can be adopted at various levels to address behavioural health issues. Well-established examples include broad-based healthy settings policies such as 'health-promoting schools', 'age-friendly cities', 'safe communities' and 'healthy cities'. Healthy city policy enables local policies such as for green spaces and physical activity as part of housing development, active transport and policy for maintaining land for agriculture and local food production (Lin, Jones, et al., 2014).

The importance of acting at multiple levels is recognized in policy areas related to behavioural medicine including tobacco control, nutrition and physical activity, alcohol-related harm, drug dependence, healthy ageing, preventing accidents and injuries and sexual health (Lin & Carter, 2013). In 2007 European Union (EU) health ministers recognized the importance of behavioural and lifestyle factors in determining the health of the population and committed to addressing such health issues at local and international levels through adopting the HiAP approach. HiAP is defined as a policy principle to improve population health by including, integrating or internalizing in the policies of other ministries and sectors, health policies that shape or influence the social determinants of health (McQueen, Wismar, et al., 2012).

Getting appropriate policies adopted and implemented for behavioural health is often a challenge for public health advocates, particularly in the face of either industry power or lack of understanding of the evidence base on the part of policy-makers.

The importance of policy governance for behavioural health can be seen particularly in HiAP. In South Australia, the key governance elements included state strategic plan with key performance indicators that held government agency heads accountable, a process coordinated by the cabinet office and supported by analytical work of the health department (South Australia Health, 2012). Intersectoral governance structures effective in achieving HiAP were examined by the European Observatory on Health Systems and Policies (McQueen, Wismar, et al., 2012) and shown to include committees at the levels of parliament, government and the public service, engagement with stakeholders and particular funding arrangements. Achieving policy coherence across agencies and across all levels of the system has been shown to be important in addressing behavioural risk factors (Lin, Jones, et al., 2014).

Policy Research: Why and What?

Behavioural health policy can prevent potentially harmful effects and minimize unintended adverse consequences of policy in the health sector and other sectors, as well as address inequalities in behaviour-related health issues. Hence the importance of policy research for behavioural medicine. The current evidence base for behavioural medicine policy is stronger, however, than achievements to date in implementation would indicate (European Observatory on Health Systems and Policies, 2006). At the same time, there is still much research to be done to understand the impact of specific policy measures. Challenges in policy research in relation to the availability and appraisal of evidence for policy-making, including the requirements of the evidence-based medicine and evidence-based policy movements, are discussed later in the chapter.

What Does Policy Research Focus On?

Policy research aims to understand the nature of policy work: how policies are made, how policies are implemented, how policies might be designed and how policies can be influenced – these central concerns apply to both healthcare policy and policy for health. Policy research can focus on both the content and the processes of policy-making. A critical problem for policy-makers is under what conditions will policies be effective in delivering desired policy objectives. The preconditions and the infrastructure necessary for policy interventions are also important for understanding policy effectiveness.

Policy Content and Design

Typical questions in relation to the content and design of policy can be oriented towards analysis *of* policy or analysis *for* policy (Parsons, 1995). Key aspects of analysis *of* policy are concerned with policy determination – how policy is made, why, when and for whom and also policy content – which may describe a particular policy and how it developed or may be informed by a theoretical framework which offers a critique of policy. In the case of analysis *for* policy, this relates to advocacy intended to influence the policy agenda and also to information that may provide evidence for policy decisions. Policy analysis also includes policy monitoring and evaluation, which examines the impact on the population and decides what works.

Questions asked by health researchers when examining the content of policy for behavioural medicine may include Did health or access to services improve? What is the appropriate mix of interventions? Which policy instruments are the most cost-effective? What level of coverage or targeting of funding is necessary to have an impact? What processes and resources would assure effective implementation? Who benefits and at a cost to whom? What is the equity or distributional impact?

Policy Analysis/Policy Evaluation

Policy evaluation studies are comparable to programme evaluation studies, but the attribution of result is often more difficult given the interaction of policy measures with other complex societal forces, including other policies, social institutions and locational differences in any jurisdiction.

Nonetheless, tools are being developed for use in studying what health impacts may arise from various public policy measures. Such tools include, for example, health impact assessment (HIA) (the systematic screening, scoping, appraisal, reporting and monitoring of anticipated health impacts) (European Observatory on Health Systems and Policies, 2006), Health Lens Analysis (a cross-sectoral process of gathering evidence of health impacts, generating policy recommendations aimed at mitigating health impacts, navigating recommendations through decision-making and governance processes and evaluating the effectiveness of the health lens process) (South Australia Health, 2012) and health equity gauge (a community development and social justice approach including social/political/economic assessment, advocacy and community empowerment) (Pauly, MacDonald, et al., 2013). One example of a tool developed to evaluate equity impacts of behavioural health interventions is the framework used to identify whether smoking cessation programmes reduce or exacerbate inequities in smoking rates between socio-disadvantaged and affluent smokers (Pauly, MacDonald, et al., 2013). The application of this equity evaluation tool in a programme in the United Kingdom demonstrated that although overall smoking rates dropped, affluent smokers benefited more from the programme, so the programme was not contributing to a reduction in health inequalities.

Policy Process

Typical questions in relation to the processes of policy-making revolve around agenda setting, decision-making and implementation (Parsons, 1995). The focus is on the key issues related to the policy process – the underlying factors and actors in policy-making, such as how power is exercised, how decisions are made, how values/knowledge/ideas have been used, how advocacy and negotiations have been undertaken, what contextual influences are important and what roles are played by diverse stakeholders and networks.

Research related to agenda setting seeks to explain stability and change in policy-making.

Topics in agenda setting relevant to behavioural medicine include the role of a mixture of empirical information and emotive appeals, termed 'policy images', in dampening or exacerbating mobilizations against entrenched interests; how policy change is born out of belief systems common to participants in the policy process and also results from shifts in attention, as described by the Advocacy Coalition Framework and Punctuated Equilibrium Theory; how and why political agendas change as a result of the unequal agenda-setting power of different political parties; as well as timing of changes in agenda according to how governments respond to and process new information about changes in their environment (Sabatier & Weible, 2014).

Using the Advocacy Coalition Framework, studies of how advocacy is undertaken have shown that substantial compromises and important changes in public policy can be achieved through 'opposing groups …modifying… certain elements of their belief structures through policy learning born of continual interactions within policy subsystems' (Sabatier & Weible, 2014). Such policy-oriented learning is understood to occur when there is an intermediate rather than extreme level of informed conflict between the coalitions; accepted quantitative evidence exists in relation to the policy question; and due to the feasibility for controlled experimentation, when the problem relates to a natural system rather than a purely social or political system. Even when the views of the opposing coalition are not changed in the face of the available evidence, important impacts on policy can be achieved through alterations achieved in the views of policy brokers – actors who act as intermediaries between opposing coalitions mitigating conflict and seeking agreement on common ground. Such achievements indicate potential for the prioritization of policy to address behaviour-related public health issues.

Studies of policy decision-making seek to understand how changes in policy occur. 'Policy shifts' are understood by researchers to spring from shifts in attention, and non-incremental shifts or rapid changes termed 'serial shifts' are described as resulting from two shifts, the first shift occurring when a decision rule is temporarily set aside (called a deviant case) and the second shift occurring when a new decision rule is adopted (called a shift point).

Understanding of policy implementation has received less attention from researchers but is a central concern for practitioners, as seen through the recent rise of implementation science (Glasgow, Vinson, et al., 2012). Early policy implementation studies revealed how policies are not always implemented as designed or intended. The notion of 'street bureaucrat' (Pressman & Wildavsky, 1984) has been very important in highlighting the role of front-line workers in any policy and service delivery system in exercising discretion.

The need for further research of the policy process in relation to behavioural health is recognized as a core action of the Bangkok Charter, which declared a commitment to build capacity for research to address the determinants of health.

What Are the Common Approaches Used in Policy Research?

Methodologies commonly used in policy research include controlled/quasi-experimental, comparative or historical analysis and participatory action research (PAR). Both quantitative and qualitative methods may be used or used in combination. Common study designs used include rigorous impact evaluation and case study, using survey and interview as data collection instruments. A prospective approach to the study of the policy process is not commonly undertaken due to difficulty accessing information in relation to the processes which occur in policy-making. With retrospective studies the difficulty is access to key players and their memories (or the need to construct history).

The appropriate study design and methods to be used will be determined by the research question under investigation. This approach is well recognized in public health and public policy research (Baum, 2008a; Carter, 2009; Dunn, 2012; Saks & Allsop, 2013) and is consistent with good political science (Moses & Knutsen, 2007). For example, in studies of the cross-sectoral policy process, the use of an empirical methodology provides access to the various actors involved and provides insight into the various roles of different sectors and the importance of leadership in developing and implementing policies for health. The use of intensive methods such as case study and interview enables the collection and analysis of relevant data. The integrated use of both qualitative and quantitative data enables recording of the views of various actors and stakeholders as well as demonstration of changes occurring over time (Shankardass, Solar, et al., 2011). The strengths and limitations of each of the approaches commonly used in policy research are discussed below and summarized in Table 25.1.

Before describing policy research methods in detail, it is important to note that these methods are not mutually exclusive but may be used with each other and in varied combinations. Examples in the following pages recur as illustrative of several methods. This reflects an important aspect of policy, that is, its need to bring together and integrate diverse evidence, observations, as well as perspectives and interests of varied individuals, groups, and organizations.

Experimental and Quasi-Experimental Methodologies

Rigorous impact evaluation is a quasi-experimental methodology used in research to inform public health policy. Quasi-experimental and other controlled methodologies are used, often in combination, due to the capacity of these approaches to minimize bias. Experimental methodologies and study designs such as randomized controlled trials (RCTs) are not used due to issues with feasibility and/or ethical barriers often present in studies of policy interventions. Also, the plausibility of extrapolation of evidence produced by RCTs across complex causal chains underlying public health interventions is considered insufficient to inform policy decisions regarding such interventions (Victora, Habicht, & Bryce, 2004).

Policy evaluation using rigorous impact evaluation approach may use randomized and controlled study design features when feasible. However, other design features are used in conjunction with these, such as observational and analysis techniques, in order to generate evidence of plausibility. Evaluation studies using such a study design can inform policy decisions in relation to ongoing funding, changes to or cancellation of public health programmes. The World Bank, for example, uses this approach to measure the effectiveness of development programmes in poor and vulnerable populations in the areas of child development and nutrition, education, health systems, water supply, sanitation and hygiene. This type of study design is used to investigate how health-related behaviours can be improved by reforms and interventions that focus on areas such as social norms and practices, education, economic assets and cash transfers, reducing violence and accountability mechanisms (World Bank, 2015b).

The key advantage of this approach is the strength of the evidence provided through the use of baseline data and a control group. Without the use of such a rigorous approach to programme evaluation, health improvements in developing countries, for example, may be attributed to improvements in economic growth and public service delivery rather than to programme interventions (World Bank, 2015c). Studies undertaken of such programmes have demonstrated that rigorous impact evaluations can be conducted in a cost-effective and timely manner. However, this approach requires that the relevant evaluation is planned in advance, prior to programme implementation, including the methodology to be used. Such forward planning allows for collection of baseline data, identification of study groups with similar characteristics and random allocation to programme implementation and non-intervention groups.

A natural experiment methodology may be adopted, where random or controlled allocation of population groups is not feasible (Des Jarlais, Lyles, & Crepaz, 2004). In such studies, standardized reporting of results is important, in order to facilitate synthesis of findings to inform policy decisions.

Table 25.1 Common approaches in policy research: advantages and limitations

Policy research approaches	Advantages	Limitations	Examples
Rigorous impact evaluation Compares programme outcomes with outcomes of control group	Provides rigorous evidence of programme effectiveness to inform policy decisions regarding ongoing programme funding. Can be conducted in a cost-effective and timely manner	Allocation to control and programme recipient groups must be in place prior to programme implementation and a systematic and transparent method must be adopted	• Strategic Impact Evaluation (World Bank, 2015b) • Building Parental Capacity to Help Child Nutrition and Health: A Randomized Controlled Trial (World Bank, 2015a)
Comparative and historical analysis Identifies and explains differences and similarities among cases using shared concepts and seeks to make inferences in relation to generalizability	Enables comparison of policy initiatives in different contexts and sheds light on implications for application in other contexts	Inferences drawn in relation to policy factors in one setting may not apply in other contexts/populations, managing complex data can be a limitation	• Getting Started with HiAP: Results of a Realist-Informed Scoping Review (Shankardass, Solar, et al., 2011) • Towards the integration of HiAP: a Québec–South Australia comparison (Department of Health South Australia, 2010)
Participatory action research (PAR) All participants and researchers work together as fellow subjects in a collaborative and cyclical process, reflecting on their own experience and taking action based on understanding of context in order to achieve common goals	Allows for development and refinement of new policy based on issues arising during policy design, implementation and evaluation, by policy-makers and other stakeholders working together	May require long and complicated negotiation and reflection to reconcile values and demands of various participants – community members, practitioners and policy-makers	• Using participatory action research to build healthy communities (Minkler, 2000) • Participatory action research on public health policy development for physical activities in local administration organizations, Chiang Mai Province, Thailand (Sarobol, 2012) • Challenging HiAP, an action research study in Dutch municipalities (Steenbakkers, Jansen, et al., 2012)
Literature review and systematic review Primary studies relevant to the particular research question are identified and appraised	Generates evidence to inform policy decisions, can also identify need for further primary studies to address particular policy questions	Primary studies may not have been conducted or may not have produced evidence which answers particular policy question	• Effective drunk driving prevention and enforcement strategies: approaches to improving practice (Australian Institute of Criminology, 2014) • Effectiveness of Mass Media Campaigns for Reducing Drinking and Driving and Alcohol-Involved Crashes: A Systematic Review (Elder, Shults, et al., 2004) • Increased police patrols for preventing alcohol-impaired driving (Review) (Goss, Van Bramer, et al., 2008) • Interventions in the alcohol server setting for preventing injuries (Review) (Ker & Chinnock, 2008)

Case study Empirical research drawing on multiple sources of evidence in context, can be descriptive or explanatory	Provide detailed view of policy in context, can describe complexities of how particular policies are developed or implemented and explain how and why they are effective. Allows development of research methodology, as more is known about the context	Inferences drawn in relation to policy factors in one setting may not apply in other contexts/populations	• Case studies of HiAP implementation from South Australia, Finland, Norway, France, Wales and Thailand (Department of Health South Australia, 2010) • A case study of the role of HIA in implementing welfare strategy at the local level (European Observatory on Health Systems and Policies, 2006) • Case study South Australian HiAP Initiative (Government of South Australia, 2013) • Case studies of HiAP as a strategic policy response to NCDs (Lin, Jones, et al., 2014) • Case studies of governance mechanisms for HiAP (McQueen, Wismar, et al., 2012) • Case studies of equity-focused HiAP activities (Shankardass, Solar, et al., 2011)
Quantitative methods Data on single variables expressed in numbers, useful for understanding cause and extent of behaviour-related public health issues	Descriptive data can be summarized graphically, inferential statistics can be used to support generalization	Provides limited contextual data, missing data can introduce error or bias, sparse categories can limit basis for comparative analysis	• Using social network analysis to examine decision-making on new vaccine introduction in Nigeria (Wonodi, Privor-Dumm, et al., 2012)
Qualitative methods Data on multiple variables expressed in words, enables detailed exploration and increased understanding of issues effecting population groups	Allows for description, understanding and interpretation of complexities, such as roles of multiple stakeholders and variations in political, economic and social context	Missing data can introduce error or bias and limit generalizability	• HiAP: An EU literature review 2006–2011 and interview with key stakeholders (Howard & Gunther, 2012)
Mixed methods Integrated use of qualitative and quantitative methods	Allows for measurement of complexity and variation inherent in public health policy processes and content	Methodologically complex	• Racial and Ethnic Approaches to Community Health project (REACH) United States (Blas & Kurup, 2010; Institute for Family Health, 2014) • Developing and Evaluating Best Practice in User Involvement in Cancer Services (Tritter, 2013) • North Karelia Cardiovascular Study (Baum, 2008a) • Evaluation National HIV/AIDS Strategy (Feachem, 1995)

Sources: Halperin and Heath (2012), Baum (2008a), Padgett (2012)

For example, in evaluation studies of interventions for HIV prevention, a non-randomized trial design is used together with agreed guidelines for reporting research design, theories used, intervention and comparison conditions and methods of adjusting for possible biases.

Comparative and Historical Analysis

Comparative and historical research is also increasingly recognized as important in health policy research. Policies are often context specific yet there are features and dynamics that are shared across countries and communities, so comparative analyzes can help tease out the context specificity and universality (Halperin & Heath, 2012). Comparative studies have examined policies to promote behaviour to prevent non-communicable chronic diseases such as heart disease and diabetes and to control the spread of communicable diseases such as HIV and SARS.

In comparative research the purpose of comparison may include exploration, explanation or evaluation (Saks & Allsop, 2013). Explanatory studies make best use of the analytical potential of the comparative research design, although exploratory comparative studies indicate differences and similarities observed. Evaluation

HiAP: Results of a Realist-Informed Scoping Review of the Literature

The comparative analys`is of HiAP cases conducted by the research team at St Michael's Hospital Canada (Shankardass, Solar, et al., 2011) compared the success of the implementation of particular HiAP activities across 16 different countries. This study was commissioned as part of a broader set of studies and consultations by the Ministry of Health and Long-Term Care to assess the feasibility of a government-wide HiAP approach to reducing health inequities in Ontario.

An international scoping review of scholarly articles and grey literature on equity-focused policy initiatives produced 163 documents describing intersectoral health policies in 43 countries. A total of 16 cases of the use of specific HiAP approaches were identified in the following countries: Australia, Brazil, Cuba, England, Finland, Iran, Malaysia, New Zealand, Northern Ireland, Norway, Quebec, Scotland, Sri Lanka, Sweden, Thailand, and Wales.

Adopting a comparative analysis approach as well as a systematic realist approach in this study facilitated comparison of programmes in different countries and discussion from an explanatory perspective, unpacking how implementation of HiAP policies had been found to work in addressing 'lifestyle or behaviour' factors and working and living conditions. The researchers reported that no single design feature leads to successful implementation of the HiAP approach, but the following trends were observed:

- HIA or other tools or mechanisms were used to assess impact and evaluate interventions in the health sector or other sectors outside healthcare.
- Midstream interventions were aimed at reducing behavioural factors, and the effects of these factors were also mitigated by healthcare service-related interventions (downstream interventions).
- Universal policy initiatives were combined with targeted policy initiatives, but most policy activity was related to the target group.
- Recognition of the social determinants of health at the level of government enabled involvement of sectors outside healthcare and non-governmental stakeholders.
- Interdependence across sectors such as sharing of budgets was considered important rather than simple information sharing or cooperation.
- Use of purpose developed and existing tools and structures to support coordina-

tion for HiAP including formal intersectoral committees, budget development processes and decision support tools.

- HiAP appeared feasible for improving population health inequities in both strong and weak welfare states.
- Fewer HiAP cases focussed on outcomes across the entire population, most were focussed on reducing health disparities between subgroups.
- A mix of horizontal and vertical integration management strategies were used, approaches were varied but tended to be linked to the management and delivery of primary health care where this was aimed more broadly, that is, towards social and economic development, or in other cases intersectoral strengthening was itself a government goal, for example, in UK Health Action Zones.
- The leadership role played by the health sector varied, as did rationale for improving health inequity, including national development goals to address political turmoil, a tradition of cross-sectoral approaches to development as part of political ideology and a drive for state efficiency.

The researchers recommended that more studies of HiAP are needed, using interview and case study methods, in order to understand variations in roles of different sectors and the importance of leadership in HiAP and to examine the types of relationships and mechanisms that support HiAP in particular settings, which can then inform the initiation and implementation of HiAP in other settings.

studies assess the implementation or impact of particular policies of interest such as HiAP.

In another study comparative analysis was used to benchmark jurisdictions with the highest levels of health and the best health behaviours in Canada and internationally (Manuel, Creatore, et al., 2009). Studies of the Racial and Ethnic Approaches to Community Health (REACH) programme in the United States and the Communities for Health programme in England provide an example of the use of comparative analysis for evaluation of behavioural health programmes (Blanchard, Narle, et al., 2013). This comparative analysis resulted in suggested priority areas of action for policy to address behavioural risk factors for NCDs and provided strategies and actions for NCD reduction globally.

The comparative analysis of HiAP in Quebec and South Australia identified similarities in both settings (Department of Health South Australia, 2010). In Quebec HIA is a legislative requirement, and in South Australia the State Strategic Plan gives the Department of Premier and Cabinet a key role in health. Through the use of the comparative analysis method, the implementation of HiAP was shown to benefit from similarities of context in the two countries, including (a) high-level government mandate, (b) engagement of a central government agency, (c) high-level cross-sectoral governance structures and actors, (d) working ‘upstream’ as early as possible in the policy process and (e) policy focus based on a determinants approach to health.

Policies are often path dependent and therefore an understanding of history can explain not only the present but potentially predict dynamics into the future. A study of alcohol policy in the European Union (European Observatory on Health Systems and Policies, 2006) is an example of the use of historical and comparative analysis to inform policy for health. This study was undertaken following policy developments which had been taking place over a number of years including loosening of EU alcohol policies and opening up of alcohol markets in Nordic and Baltic states. The researchers analyzed the history of policy developments leading to increased alcohol consumption and compared potential policy options to limit alcohol consumption including ‘hard law’ such as legislation and regulations and ‘soft law’ such as recommendations and strategies.

Policy studies are often event or decision based as they may be the embodiment or culmination of a set of policy processes. The study of alcohol policy in the European Union discussed above is such an example, as this study was undertaken to address increasing alcohol-related harm in Finland and to inform a submission on the EU alcohol strategy.

Recognized limitations of comparative studies include (Saks & Allsop, 2013):

- When choosing comparable cases, using cases with functional equivalence is important. This depends on the particular framework of the research design, cases with multiple characteristics which are identifiably similar or different. Countries with broad similarities are best – similar economic wealth, stable democratic political systems and developed welfare states.
- Identifying comparable units for comparison can be problematic, for example, specific health policies, health outcomes and health services.
- Managing complexity of data can be problematic.
- The use of ideal types and typologies; these need to be employed cautiously.

Participatory Action Research

Participatory action research (PAR) has been increasingly adopted as a way of engaging with and improving policy interventions as they unfold. Realist approaches framed around theories of change are an important underpinning of participatory action research, straddling the natural and social sciences and naturalist and constructivist methodologies (Moses & Knutsen, 2007). This method allows for the development and refinement of new policy based on issues arising during policy design, implementation or evaluation (Baum, 2008a). This approach is used in policy research to understand how policy works in context and the mechanisms at play in policy implementation and policy outcomes, focusing on necessity and contingency.

Using this methodology in social research, various stakeholders, such as academics and community members, work together for mutual benefit. The contradictory role of power and privilege is recognized in this approach, which can challenge these issues and integrate education and social action to improve health and reduce health disparities (Wallerstein & Duran, 2006). When using this participatory methodology, fellow researchers work in a collaborative and cyclical process, reflecting on their own experience and taking action based on understanding of context in order to achieve common goals. The cycle is described as a spiral of processes involving planning, acting, observing and reflecting (Baum, 2008a).

Examples of the use of the participatory action research method are found in the Healthy Cities and Healthy Communities Projects. This method has been used in many of these projects, with ‘experts’ and citizens working together incorporating high-level community participation in various aspects of the research process (Minkler, 2000). The usefulness of the participatory approach is recognized in cultural competency research. Community input to design, implementation and evaluation of programmes was recommended by the US Office of Minority Health and Agency for Healthcare Research and Quality in the report on research on cultural competence in healthcare (Fortier & Bishop, 2003). However, in order to measure and validate elements of culturally competent health promotion programmes (CCHP), controlled studies are also recommended.

The work of the National Health Assembly in Thailand is another example of PAR. This legislative body acts as part of a learning process as well as an instrument to develop participatory public policies on health at local and national levels (Lin, Jones, et al., 2014). Behavioural health issues considered in the 2012 National Health Assembly include food safety, air pollution, systems to support walking and cycling, children and IT, among others. The NCD prevention project conducted in Chiang Mai Province in Thailand is a particular example of the use of participatory action research. Public health policies to promote physical activity were developed, as well as a model for development by the community of public policies for health. Local community members and local organization officers in two municipalities used PAR at all steps of the process to develop policy to address NCDs in working and elderly people (Sarobol, 2012). In Holland PAR was used in the evaluation of implementation of HiAP interventions targeting obesity and showed that coaching for municipalities by the regional public health service stimulated the development of HiAP (Steenbakkers, Jansen, et al., 2012).

Limitations of participatory action research as a method in policy research include the long and complicated negotiation and reflection required to reconcile values and demands of various participants – community members, practitioners and policy-makers (Baum, 2008a).

Case Study

The usefulness of the case study method in policy research is recognized (Baum, 2008b; Halperin & Heath, 2012) as this method can provide a detailed view of policy in context, describe complexities of how particular policies are developed or implemented and explain how and why policies are effective. The case study method also allows development of research methodology as more is known about the context. The intensive methods used in case studies are recognized as useful in providing much needed information about the practicalities of implementing the HiAP approach successfully. For example, the findings of the global review of 16 cases of HiAP activities described above (Shankardass, Solar, et al., 2011) highlighted the importance of budget sharing and tools and structures to support HiAP. The case studies of governance mechanisms for HiAP in the European Union, North America and Australia (McQueen, Wismar, et al., 2012) found that structures effective in achieving HiAP include committees at the levels of parliament, government and the public service, engagement with stakeholders and particular funding arrangements. Such structures were found to facilitate governance actions in relation to planning, implementation and management, research and legal mandating.

Case studies conducted of HiAP initiatives worldwide have examined policy for behavioural health in the European Union, the United Kingdom, North America, Australia and Thailand (Department of Health South Australia, 2010; European Observatory on Health Systems and Policies, 2006; Government of South Australia, 2013; Lin, Jones, et al., 2014; McQueen, Wismar, et al., 2012; Shankardass, Solar, et al., 2011). Case studies have addressed topics related to behavioural health including:

- The use of the HiAP approach to address behavioural health risk factors such as physical activity, healthy eating, alcohol and tobacco
- Recognition of social determinants of health in addressing behaviour-related health issues
- HiAP case studies from health, work, digital technology, food and agriculture, alcohol and environment sectors
- Benefits of the HiAP approach for sectors other than health
- Systemic approaches to policy-making
- Equity-focused intersectoral policy initiatives
- Implementation challenges, effective strategies, governance structures, mechanisms and instruments for HiAP
- Mobilizing community action for healthy policy

Case studies demonstrate the utility of tools such as HIA and Health Lens Analysis in implementing HiAP. For example, the case study of the use of HIA to implement welfare strategy in a city in Finland (European Observatory on Health Systems and Policies, 2006) highlighted the importance of a procedural link between HIA and the decision-making process.

Case studies are also often undertaken as a way of using particular instances to elucidate the general. For example, the study of 158 cases of the use of HIA concluded that, in principle, it is possible to use HIA as a tool for implementing the HiAP approach, although due to the limited activities observed at national level, it was difficult to assess the effectiveness of HIA for this purpose (European Observatory on Health Systems and Policies, 2006). This research for HiAP policy analyzed case studies from the health, work, food and agriculture, alcohol and environment sectors in the European Union and identified benefits of HiAP for sectors outside

Health in All Policies Prospects and Potentials

This report forms part of a project under the auspices of the European Observatory on Health Systems and Policies, exploring the prospects and potential of HiAP to improve population health in Europe. The project took place against the background of the Lisbon Agenda which recognizes the importance of population health for economic stability and social cohesion in Europe and in the context of decreasing fertility rates, the ageing population, the obesity crisis, increasing chronic disease and healthcare costs and health workforce shortages.

This work was undertaken in the context of the Finnish Presidency of the European Union and aimed to emphasize the unique mandate and obligation of the EU to protect health in all its policies and to examine principles and challenges of the use of HIAP in moving health higher up the European agenda. The scope of the studies reported includes review of the theories, concepts and challenges in regard to HiAP in the European context, analysis of concrete examples of the use of HiAP in various fields and review of governance mechanisms used for HiAP with particular focus on HIA.

Methods used included reviews and case studies. Case studies were conducted of the use of HiAP in various fields including heart health promotion, working life, food and agriculture, alcohol policy and the environment. A review was conducted of governance mechanisms for implementation of HiAP, and challenges of horizontal health policy were examined. The Finnish experience of the preparation of national health reports was reviewed as an example of getting other sectors involved with and committed to intersectoral cooperation. Case studies of the use of HIA as a tool for HiAP were analyzed in 158 instances across Europe, with a focus on the implementation and institutionalization of HIA. A Finnish case study describes the role of HIA in implementing welfare strategy at the local level.

The findings of the project identified benefits of HiAP for sectors outside health as well as challenges and barriers to HiAP. Mechanisms and instruments for HiAP required to keep health high on the agenda are also discussed. Benefits of HiAP identified include healthier workforce, increased productivity and economic benefits – policies can affect the relationships among health, work and productivity, and health is a prerequisite for the latter two; advances in health made through policies in other sectors including education, environment, water and sanitation, planning, labour, housing, traffic, agriculture and nutrition. In principle, HIA was found to be a useful tool for implementing the HiAP approach, although the researchers concluded that further development of the use of HIA is needed. The study of heart health concluded that population health can be improved through policies, legislation and regulations in relation to tobacco smoking, physical activity levels and food quality.

Challenges and risks identified for the use of HiAP include conflicting priorities of other sectors in relation to agriculture, food and alcohol; the need to strengthen the analyzes of health impacts as well as the consideration of impacts on policy-making; the impact on costs of healthcare of other policies, for example, international trade; the need to consider health equity and the distribution of the impact of policies of other sectors across populations such as alcohol on low SES groups; the need for policy coherence – sectoral and organizational barriers need to be addressed; public support for HiAP is needed so public information and knowledge, civil society consultations and involvement of NGOs are all important, and in order to secure necessary political support, political ownership of HiAP is required at the highest level.

Mechanisms and instruments needed for HiAP include legal mandates for HIA and health surveillance to keep health high on the agenda; partnership and alliance building such as permanent intersectoral committees for transparency of policy process, timely HIA and comment and dialogue on policy proposals; availability of relevant knowledge and evidence; and identification of alternative policy options (European Observatory on Health Systems and Policies, 2006).

health including healthier workforce, increased productivity and economic benefits.

Another example of the use of the case study method to develop useful generalizations is the collective evaluation of five cases of the use of Health Lens Analysis for HiAP conducted in South Australia (Government of South Australia, 2013). This study enabled identification of common themes in implementation of the HiAP approach including:

- Policy changes which impact on the social determinants of health
- Greater understanding and stronger partnerships between health and partner agencies
- Increased understanding by policy-makers of the impact of their work on population health and health equity
- Development and dissemination of policy-relevant research
- Willingness to use the Health Lens Analysis process and adopt HiAP philosophy in future work
- Learning for all involved about redefining goals for HiAP, problem definitions and strategies, as well as dialogue and interaction among stakeholders.

One of the case studies described the use of the Health Lens Analysis in a project aimed at raising parental engagement with literacy to improve literacy outcomes for children and ultimately improve their health, with a focus on low socioeconomic families. Another of the Health Lens Analysis case studies demonstrated that the use of the HiAP approach enabled consideration of the health and well-being implications within the core business of a non-health government sector. Working together, the health department and the department of education, science and technology considered social and equity issues associated with increasing broadband uptake, together with the associated technological issues. Both positive and negative health impacts were associated with the use of digital technology, and use was linked to socioeconomic indicators such as education and literacy, employment status and income. Even when there was access, use was limited by individual capacity, digital literacy and confidence and insufficient financial resources.

Limitations of the case study method recognized in public policy research relate to transferability of findings, as inferences drawn in relation to policy factors in one setting may not apply in other contexts/populations (Halperin & Heath, 2012). The use of various pattern-matching methods (Dunn, 2012) such as comparative analysis discussed below enhances potential for generalizability of case study findings. Selection bias can be an issue in case studies. For example, as only 13 of 18 invited countries participated in the study of opportunities and barriers for the implementation of HiAP (Howard & Gunther, 2012), the researchers recognized that selection bias may have occurred, as those countries with more positive experiences of implementing HiAP may have been more likely to participate.

Systematic Reviews

Reviews of primary studies are often conducted in order to generate evidence to inform policy decisions, for example, in relation to behaviour-related health issues such as tobacco (Fichtenberg & Glantz, 2002) and drink driving. The Australian Institute of Criminology reviewed Australian and international literature on drunk driving countermeasures with the aim of identifying implications for policy and practice. This review made recommendations in relation to policy for random breath testing, publicity campaigns, penalties and targeted interventions for the general population and for recidivist drink drivers (Australian Institute of Criminology, 2014).

Systematic reviews are used to inform policy for behavioural medicine. For example, systematic reviews of studies of effective interventions to prevent alcohol-impaired driving are used to inform policy to reduce road trauma (Elder, Shults, et al., 2004). Systematic reviews include studies of various types, depending on the particular research question and also depending on the availability of evidence. Evidence is drawn from primary research studies and also potentially from a broad range of other sources. Other types of evidence may include policies and opinions of experts and consumers and other stakeholders, depending on pragmatic and contextual relevance (Carter, 2009; Lin & Gibson, 2003). For example, evidence drawn from various sources is to be included in the impact assessment of the World Health Organization Framework Convention on Tobacco Control, such as reviews of changes in legislation, as well as reviews of published studies and also stakeholder interviews and country case studies (WHO Framework Convention on Tobacco Control, 2014).

Systematic reviews are reviews conducted with the aim of summing up the best available evidence in relation to a particular research question. Essential to this process is the use of an explicit search strategy, coding and analysis of included studies, peer review and where possible meta-analysis of findings. The Cochrane Collaboration and the Campbell Collaboration conduct such reviews in fields related to behavioural medicine, such as healthcare, consumer advocacy, education, crime, social welfare and international development. The reviews which are freely available online are conducted by a global independent network of researchers, experts and stakeholders.

The capacity of systematic reviews to inform policy can be limited, however, due to lack of available or applicable evidence, particularly as published research tends to be focused on high-income (and often English-speaking) countries. Nevertheless, one key advantage of the use of this approach in policy research is the capacity of the systematic review to identify the need for further research in relation to a particular policy question. For example, systematic reviews of police patrol programmes and interventions in alcohol server settings identified insufficient evidence and recommended that further studies were required (Goss, Van Bramer, et al., 2008; Ker & Chinnock, 2008).

For policy research, the best available evidence includes evidence from the most rigorous studies, integrated with the most relevant evidence from other related sources, including the views of stakeholders. For this reason, the use of systematic reviews in which evidence is included from academic as well as colloquial sources is the preferred approach in health policy decision-making (Carter, 2009; Lin & Gibson, 2003). Policy research is complex and the key question is 'under what conditions will a policy intervention deliver the desired result'. This central concern for conditional effectiveness means that the questions of what is the best available evidence and what evidence is relevant must be considered in relation to any particular policy question.

Qualitative Methods

Using qualitative methods in policy research, data can be collected at organizational, community and individual levels through observation, interview or by accessing policy-related documents. Data analysis can be done using various approaches (Padgett, 2012) such as case study or participatory action research as discussed above, ethnography, grounded theory, phenomenological analysis, a mix and match of different qualitative methods or narrative approaches discussed in more detail below. Examples of the use of grounded theory in policy-related research are found in the review conducted of qualitative studies relating to tobacco control (Schultz, Bottorff, & McKeown, 2009). This method has also been identified as useful in the study of social determinants in women's health (Wuest, Merritt-Gray, et al., 2002). Phenomenological analysis has been used to identify factors that influence the utilization of research findings by policy-makers (Albert, Fretheim, & Maiga, 2007).

Textual analysis can also be done through a range of narrative analysis approaches (Padgett, 2012; Saks & Allsop, 2013) such as thematic coding for describing content, or through attention to form by identifying distinctive forms or stories for interpretation of meaning, or by meta-synthesis. Meta-synthesis of data is achieved through systematic review and can include integration of both qualitative and quantitative data. In some approaches qualitative data is converted into quantitative data to enable aggregation of the two different types of results, which can both then be interpreted in the meta-analysis. Different approaches to meta-synthesis are used for systematic reviews in policy research, depending on the underlying aim, particular research question, nature of the evidence and stage of policy development. Examples of systematic reviews in policy research for behavioural medicine include the Bayesian synthesis of qualitative and quantitative evidence for factors affecting the uptake of childhood immunization, the use of meta-ethnography in the study of medicine-taking behaviour, the quantitative case survey method used in the evaluation of crime prevention programmes and

Intersectoral Governance for Health in All Policies: Structures, Actions and Experiences

This project examined how countries in Europe, the Americas, Asia and Australia use intersectoral governance structures for HiAP and explains the processes that lead to health in all policies. The project was undertaken by the European Observatory on Health Systems and Policies (EOHSP) in partnership with the International Union for Health Promotion and Education (IUHPE) and encapsulates the research on how intersectoral governance structures for health operate.

The project involved an initial planning phase allowing for development of the study proposal and research framework to be adopted. During this phase fundamental conceptual issues in relation to methodological issues and governance for HiAP were discussed and clarified. Multiple qualitative methods were used including consultations with international experts, snowballing methods, an author's workshop, literature reviews, internal and external reviews of all case studies and critical reflection, revision and modification of the methodological framework developed for the study. Potential authors and HiAP cases to be included in the study were identified via the networks of the IUHPE and the EOHSP policy dialogue group.

Challenges and opportunities presented by the cultural and political diversity of the contexts of the authors and the case studies were discussed and taken into consideration. More than 20 mini case studies from Europe, the Americas, Asia and Australia were analyzed and reviewed in the context of the relevant literature; reviews were conducted by internal and external stakeholders in order to gain both perspectives. The validity of the methodological framework developed for the study was confirmed by the editors and other partners, following revision and modification based on the reflection and critical perspective of the authors and their cases.

The findings of the project include how governments and ministries can initiate action and how intersectoral governance structures can be successfully established, used and sustained; examples for policymakers of the governance tools and instruments available; and case studies which show how countries currently use intersectoral governance for HiAP. Key intersectoral structures and how they facilitate intersectoral action were identified including cabinet committees and secretariats, parliamentary committees, interdepartmental committees and units, mega-ministries and mergers, joint budgeting, delegated financing and public, stakeholder and industry engagement (McQueen, Wismar, et al., 2012).

the qualitative and quantitative narrative review of barriers and facilitators of health-related behaviour in young people (Mays, Pope, & Popay 2005).

Another example of the use of multiple qualitative methods is the study of HiAP implementation in the European Union (Howard & Gunther, 2012). Interviews provided a perspective not gained from the literature review on how things operate in practice and on the role of culture and values. Culture and values were not widely commented on by stakeholders, although in the literature review culture and values were recognized as an important factor in HiAP, with alcohol consumption shown to be higher in male study participants with less education. Also, notwithstanding the low rate of comment by stakeholders on culture and values, interview data did show that some stakeholders did see how

Health in All Policies: An EU Literature Review 2006–2011 and Interview with Key Stakeholders

The study of HiAP implementation in the European Union was undertaken as part of the Equity Action programme which aimed to develop an action plan to address increasing health inequalities in Europe. The programme aimed to identify what works and why for implementation of HiAP, build capacity in EU member states and develop practical guidance and consensus for adopting a HiAP approach to address health inequalities in the EU.

Following a decade-long reduction in poverty in Europe, in 2010 major health inequalities had been identified within and between countries in the WHO European Region. In 2011 the European parliament resolved to tackle the problem, calling upon all European Union member states to prioritize policy action to address health inequalities, taking into account the social determinants of health as well as lifestyle-related risk factors, such as alcohol, tobacco and nutrition. In keeping with this 'HiAP' approach, the response to such a call required action in policy areas such as consumer policy, employment, housing, social policy, the environment, agriculture and food, education, living and working conditions and research.

The literature review and stakeholder interviews were undertaken as a first step in the programme, in order to review the evidence in relation to opportunities and barriers for implementation of HiAP, to assess opinion on the implementation of a HiAP approach across a range of member states, countries and regions and in particular to assess how heath inequity was being incorporated within the HiAP approach and the use of HIA as a tool to implement HiAP.

The conclusions reached in the study in relation to opportunities and barriers to the implementation of HiAP related to political commitment which is needed at the highest level especially given the economic climate, the need for overarching strategies and action plans that endorse a HiAP approach and the use of dedicated people and resources to implement HIAs, the need for more partnerships particularly with communities, more skill development not only technical skills but also the softer skills such as negotiation and relationship building, prioritization of HiAP initiatives with an equity focus and a truly collaborative approach – 'health *for* all policies as well as 'health in all policies' (Howard & Gunther, 2012).

In this study use of interviews together with literature review provided fuller insight as interview findings provided a richer description of barriers and solutions for implementation. Specific pleas for support were heard, including simpler tools to support implementation and recommendations and tips for progress including the use of case studies to help raise awareness and sell the concept of HiAP. Also, few concrete examples were found of successful HiAP work undertaken with a strong equity focus. It was identified that a better understanding is needed of the difference between health inequity and health inequality/disparity (health inequity exists when population groups with differing health needs do not have fair and equal access to the basic requirements to address their particular health needs such as appropriate health services, healthy food and drink and effective help to quit smoking, whereas health inequality or disparity refers to unavoidable differences in health status among population groups). The findings of this study also identified the need for more case studies of HiAP to address behavioural health issues.

the history and tradition of public health could influence the acceptability of an interventionist approach to social determinants of health.

Another qualitative method used in policy research is realist systematic review. This model of research synthesis is used to evaluate complex social interventions (Pawson, Greenhalgh, et al., 2005) and has been recognized as particularly suitable for understanding complex policy processes such as HiAP. The realist methodological lens adopts an explanatory perspective rather than a judgemental one, unpacking how 'x' works and under what circumstances rather than asking how well did 'x' work. The use of this method facilitated identification of trends for successful implementation of HiAP interventions to address 'lifestyle or behaviour' factors and working and living conditions in 16 countries and subnational areas worldwide (Shankardass, Solar, et al., 2011).

In summary, advantages of the use of qualitative data in policy research include (a) the measurement of multiple variables and expression of the data in words, (b) detailed exploration and increased understanding of issues effecting population groups, (c) description, understanding and interpretation of complexities such as roles of multiple stakeholders and (d) variations in political, economic and social context (Baum, 2008a).

Quantitative Methods

Quantitative data in policy research can be collected at the organizational, community, network and individual levels (including polling). In the United States social network analysis was used to study how alcohol addiction is influenced by social environmental factors (Rosenquist, 2011). In Kenya, this method proved a useful instrument in understanding the social and health status of scavenging street children (Ayuku, Odero, et al., 2003).

Social network analysis has become increasingly important in understanding actor influences on policy decision-making. It can be used to identify how information is exchanged and who is included or excluded from the decision-making process. For example, in the study of vaccine decision-making in Nigeria, using data culled from interviews with government officials, as well as from partner organizations and other stakeholders such as health providers and the media, relationships were mapped and analyzed to show the distribution of influence among decision-makers and to explore linkages and pathways to stakeholders who can influence critical decisions in the policy process (Wonodi, Privor-Dumm, et al., 2012).

Quantitative methods are also important in rigorous impact evaluation and the use of big data for understanding policy impact. For example, in the evaluation of the North Karelia Project, large-scale quantitative methods were used to measure the impact on behaviour-related NCDs. Methods used included population prevalence rates for specific behaviour-related risk factors, mortality rates for particular NCDs and life-expectancy projections (Puska, 2002).

Cross-impact analysis (Dunn, 2012) is a quantitative method used in the analysis of public policy-related to behavioural health. This method has been used to study interdependent relationships among economic and health policies and outcomes. Cross-impact analysis is used to identify events that will facilitate or inhibit the occurrence of other related events, taking into account three aspects of any linkage including mode of linkage (positive or negative direction), strength of linkage and elapsed time of linkage. For example, this method was used to study the impact of increased motor vehicle production on family and community relationships, crime and alcohol addiction and identified linkages among these involving elapsed times of several decades. Some of the recognized advantages of this method include the ability to discern interdependencies that otherwise may go unnoticed and the revision of probabilities based on new evidence. Recognized limitations of this method include exclusion of relevant interdependent events due to the pragmatic problem of including a greater number of events and costly and time-consuming complex process, even with the use of high-performance computer technology. To address such limitations Dunn (2012) recommends the use of problem structuring methods to expose and debate conflicting assumptions and arguments, theory mapping and relevance trees.

In summary, advantages of the use of quantitative data in policy research include the expression of variables and factors in terms of numbers, portrayal of descriptive data such as in graphical summary and use of inferential statistics to support generalizations (Halperin & Heath, 2012). This approach can contribute to understanding the causes and extent of public health issues that are related to behaviour. The usefulness of quantitative data, however, can be limited by a lack of contextual data needed for understanding of policy processes and social determinants of health-related behaviour. Also, missing data can introduce error or bias and sparse categories can limit basis for comparative analysis.

Mixed Methods

Both qualitative and quantitative methods are used in policy research, and often it is important to use a combination of these methods. Mixed methods, the integrated use of qualitative and quantitative methods, allows for the measurement of the complexities and variations inherent in public health policy issues such as health-related behaviours. In a study of HiAP in South Australia (Government of South Australia, 2013), qualitative methods were used to include community views in policy development. The study then integrated qualitative and quantitative methodologies to identify solutions for complex policy issues such as behaviour-related health issues. In mixed methods studies, one or other methodology may dominate or the methods are used equally, in sequence or concurrently (Padgett, 2012).

Both qualitative and quantitative methods are used in the evaluation of the *Racial and Ethnic Approaches to Community Health* project in the United States. A community-based participatory approach is used that incorporates quantitative methods such as surveys and analysis of programme records as well as qualitative methods such as interviews and focus groups (Blas & Kurup, 2010; Institute for Family Health, 2014).

Well-known examples of studies using mixed methods to study behavioural health-related issues include the *North Karelia Cardiovascular Study* (Baum, 2008a) and the *Evaluation of the National HIV/AIDS Strategy* (Feachem, 1995). Another example of the use of mixed methods research to inform behavioural health policy is the study *'Developing and Evaluating Best Practice in User Involvement in Cancer Services'* (Tritter, 2013). Drawing on the expertise of the academic and voluntary sectors and health service partners, the study used a range of qualitative and quantitative methods to map and analyze user involvement, attitudes and experience.

Access to valid and reliable data of both types, qualitative and quantitative, is a challenge in public health research (Padgett, 2012). Do answers to a limited number of open-ended questions provide sufficient and valid data? Will a scale or index used in the quantification of qualitative data obtained in in-depth interviews produce descriptive statistics of limited value? Triangulation of data can present a conundrum, either when results from both sides are in accord or disagree. Despite the advantages of the use of mixed methods in policy research in allowing for the measurement of complexities and variations, this approach is methodologically complex. Researchers are advised to exercise caution and practice transparency. Trade-offs and opportunity costs involved in the use of multiple methods are recognized in public policy research, particularly in relation to time and financial constraints (Dunn, 2012). Knowledge gaps in research methods for HiAP may also be an issue, given the observation made by Dunn, that economists traditionally are not trained in data collection and the consideration of context, which is enabled through the use of qualitative methods.

What Are the Challenges in Policy Research for Behavioural Medicine?

Approaches to Policy Research

Challenges faced globally in approaches to policy research for behavioural medicine relate to approaches to research including theoretical understandings of the policy process, the use of applicable methodologies and methods and issues with data, as well as the use of evidence to inform policy.

Theories of the Policy Process

Policy theory is often derived from empirical studies rather than theoretical or review articles (Sabatier & Weible, 2014). As such, policy studies may be context dependent – so a flexible and synthetic approach to theory is advisable. The need for empirical studies of policy-making processes is recognized in the policy research literature. The findings of the international survey of policy work undertaken by Colebatch have highlighted that more empirical research is needed to study how policy workers (and which sort) get a place at the table, how the question is framed, what discourse is accepted as valid and how this work relates to the outcome at any point in time (Colebatch, 2006).

Methodology

In order to address the ‘wicked’ problems posed by the social determinants of health, countries must work together (European Observatory on Health Systems and Policies, 2006) to further develop methodologies for assessing impacts of proposals on health systems and determinants of health, such as the impact on nutrition and public health of policies which influence food supply and demand. Development of methodology for surveillance of determinants is also needed.

To address the ‘wicked’ nature of behaviour-related public health problems, researchers have identified the need for new forms of learning and knowledge management and can draw upon the foundation of HiAP in public health sciences to further develop methodology for the study of HiAP (European Observatory on Health Systems and Policies, 2006). The International Meeting on Implementation of HiAP (Department of Health South Australia, 2010) has highlighted that new approaches to health policy must encompass the global industry of health-related products and services, with consideration given to trade regimes, and industry approaches to innovation and corporate responsibility. Therefore there is a need to study a ‘different logic’ – the logic of the decisions of other sectors – as described by the World Health Organization’s 2008 World Health Report on Primary Healthcare, so that working within their frameworks, using their language, and based on their desired outcomes, equity and social determinants of health can be addressed.

Further development of evaluation methodology is needed, and methodology that captures HiAP’s need to be flexible, sensitive and responsive (Department of Health South Australia, 2010). The development of policy evaluation methods needs to be done before policies are introduced (European Observatory on Health Systems and Policies, 2006) – this is important from a logistical standpoint. Also, future studies need to accommodate lack of consensus on fundamental concepts and definitions and where possible build consensus (McQueen, Wismar, et al., 2012).

The use of more intensive research methods is needed, such as case studies to evaluate equity-focused HiAP initiatives (Howard & Gunther, 2012) and interviews and case studies to understand variations in roles of different sectors and the importance of leadership in HiAP (Shankardass, Solar, et al., 2011). The integrated use of qualitative and quantitative methods is needed to capture changes in sectors outside health and also to include community views in policy development (Government of South Australia, 2013). Methods are also needed to capture less tangible outcomes of HiAP work, outcomes such as long-term changes in policy culture in agencies outside of health, including relationship building and knowledge transfer among project group members (Government of South Australia, 2013). Improved access to relevant data and wider consultation with stakeholders have been identified as important, as well as increased capacity and capability in data analysis (McQueen, Wismar, et al., 2012) (Howard & Gunther, 2012).

The most critical lesson from policy research is to draw out what may be generalized from one setting to another. Policies can seldom be replicated, transferred or scaled up as if realities were comparable everywhere. Consideration of the use of appropriate methodology and research methods, together with consideration of context, social determinants of health and the involvement of health users, are all important. A pragmatic integrated approach is needed in policy research, using methodologies drawn from both constructivist and positivist paradigms. A constructivist approach understands knowledge to be a human construct and sees the researcher as an active participant in the research process, drawing conclusions by induction, moving from specific observations to broader generalizations and theories. A positivist approach understands knowledge as obtained through independent observation of naturally occurring phenomena. Together these approaches are capable of generating rigorous evidence including sufficient relevant detail in relation to the particular intervention or policy under evaluation. A description of the research methods used and the context of the intervention/evaluation are also required (Lin & Gibson, 2003).

Use of Evidence to Inform Policy

For policies to have the desired effect on behaviour, research evidence needs to underpin policy development and implementation. However, research evidence in relation to the prevalence and cause of behaviour-related health issues – and even evidence for effective interventions – is no assurance for policy adoption or implementation. For this reason key challenges for policy research for behavioural medicine include knowledge translation. Numerous strategies including knowledge brokerage, change agendas, diffusion networks, long-term liaison and communication training can be used to promote the uptake of research findings by policy-makers and policy managers charged with the implementation of innovative policies for behavioural medicine (Lin, 2008).

Good information infrastructure is important to track policy impacts over time and to understand the complex interactions among policy measures and other social, economic, environmental, cultural and political factors that affect behaviour of individuals, communities and social institutions.

Besides the importance of information, end users of policy research (be they politicians, bureaucrats, community leaders or health service providers) must be engaged – to inform prioritization of research questions, to shed light on potential unanticipated consequences of policies, to contribute to interpretation of results and to deliberate on implications of research for action.

The Nature of Evidence

Policy-makers are typically concerned with making decisions of a practical nature at a community level and so look to the available evidence as to what interventions are most likely to work in the population in question (Lin & Gibson, 2003). Given the realities and constraints of situations in which policy-makers are required to intervene, and the need for immediate resolution, the relevance of the available evidence at hand is of most importance. So the nature of evidence required by policy-makers is not what works or does not work on average for individuals with particular conditions derived from research and irrespective of context, as constructed in the study of clinical interventions. For this reason the adoption of a narrow application of evidence-based medicine to health policy may not accord with the reality of different communities and population groups. For example, according to the 'what counts is what works approach' adopted under NICE policy in the United Kingdom, there is an expectation that funding will not be continued where there is no evidence of effectiveness. Yet, policy interventions are typically adapted during implementation to suit the needs and contexts of different population groups. Furthermore, policy evaluation may not address the complexities of policy implementation (Pressman, Wildavsky, & Oakland Project, 1979). Evidence in relation to why particular policies are not effective can be used to make recommendations for further policy development. For example, the evaluation of coordinated care trials in Australia identified failures in both policy design and implementation and made recommendations for health system reform in order to improve care coordination (Segal, Dunt, & Day, 2004).

In adopting an evidence-based approach to health policy, cross-discipline thinking is required within the health sector, and beyond the health sector, cross-sectoral thinking is required, in particular, economic thinking. Increasing costs to the health sector as well as other sectors are attributed to issues in the delivery of healthcare, such as lack of cost/benefit analysis in terms of gains in quality of life, employer-funded insurance, overdiagnosis and lack of attention to patient preferences (Kaplan & Porzsolt, 2006). More empirical research is needed to study how policy workers (and which sort) get a place at the table, how questions are framed, what discourse is accepted as valid and how this work relates to outcomes at any point in time (Colebatch, 2006).

Involving Health Users in Research

Involving health users and community interest groups in research is another challenge for behavioural health policy research. The benefits of including healthcare users in research that aims ultimately to change their behaviours may appear self-evident. Research findings demonstrate that including the perspective of health users in research is important in increasing compliance with medical advice (Tritter, 2013). Involvement of healthcare users in research is also recognized as improving health outcomes, through improving the relevance, applicability and implementation of findings (Hill, 2013). Involving health users in research is recognized as important in generating evidence required by policy-makers in relation to the values and interests of community groups, as well as the relative efficacy of different policy options and the distribution of costs and benefits across different interest groups. A further challenge is to strengthen community capacity to engage in policy dialogue and demand evidence-based health policies (Lin & Gibson, 2003).

Involving healthcare users in policy research is recognized as a complex process, which may require some reorganization and structuring within the health sector, expansion and diversification of health consumer groups and associated organizations, as well as workforce training in particular research knowledge and skills (Hill, 2013).

Agendas in Policy Research for Behavioural Medicine

There are many issues about policies for behavioural health that warrant further research. These include policy process, policy tools and policy designs and impact. The global epidemic of chronic, non-communicable diseases is central to this agenda. Although it is important to consider best buys in interventions for specific diseases and risk factors (World Health Organization, 2011a), it is important also to consider the equity impact of interventions. The need for more case studies of policy initiatives targeted to address health inequalities and with a particular focus on determinants has been highlighted by both the review of implementation of HiAP in the European Union (Howard & Gunther, 2012) and the global review of equity-focused intersectoral initiatives (Shankardass, Solar, et al., 2011). Similarly, while there is much interest in adopting HiAP as a whole-of-system approach, there are many research gaps about the process and the effectiveness.

As part of the process, there are tools being developed, such as health impact assessment, but their use and effectiveness still need to be better documented and understood. Besides policy process, there is still a need to understand the policy advocacy dimensions better. The challenge for behavioural health policy is to understand how decisions to change priorities are made and how to raise the profile of the social determinants of health on the central agenda of government.

Policy research can be focused on policy as an intervention or as a context for other interventions, so sorting out complex intermingling relationships is difficult. There is a need to be clear about the circumstances, the relationships among actors, the frames of reference of actors, the object of intervention and the relationships among various interventions.

The mandate and responsibility of organizing health services exists at national or even local level; however, the framework in which it can be done is increasingly determined at levels beyond the national. For example, policies on international trade, markets, competition, industry and linked policy objectives on taxation and the size of the public sector and its services may all have important direct consequences for the health sector and its costs.

Addressing Chronic Diseases

One central challenge in behaviour-related health research is to develop an assessment approach for chronic disease. One possible model is the World Health Organization assessment approach, suggested by the policy think tank, Mitchell Institute in Australia (Mitchell Institute, 2014). The selected approach would be adopted to report quantitative trends in behavioural risk factors for chronic disease and provide qualitative assessments on the infrastructure required to prevent chronic diseases, such as public commitments, funding and the range of interventions including future priorities for action. The use of such an approach which could assist in turning theory into practice in health behaviour for chronic diseases such as cardiac disease presents the greatest challenge (European Observatory on Health Systems and Policies, 2006).

HiAP Policy Processes

Understanding policy processes is important when new policy approaches are adopted, such as HiAP. The key issues relate to governance structures and actions and degree of policy coherence and design of effective policy interventions – including return on investment and distributional consequences (Department of Health South Australia, 2010; European Observatory on Health Systems and Policies, 2006; Lin, Jones, et al., 2014; McQueen, Wismar, et al., 2012). Examples of policy research for HiAP are summarized in Table 25.2.

Design of Effective HiAP Interventions

No single design feature has been found to lead to successful implementation of the HiAP approach. Instead, a variety of trends have been observed such as in the review of 16 cases of HIAP interventions to address 'lifestyle or behaviour' factors, described in detail earlier (Shankardass, Solar, et al., 2011).

Preconditions for effectiveness of intersectoral policy interventions have been identified (Lin, Jones, et al., 2014). Factors essential for success of HiAP interventions include political context, horizontal governance, leadership, political commitment, human and financial resources, information and research, policy analysis tools, health sector role, partnership management, stakeholder engagement including across portfolios as well as outside government including civil society, immediacy of the problem, political importance, expectations and prospects of a workable policy solution, entry points and monitoring and evaluation of policy effectiveness.

Research has highlighted potential returns on investment offered by effective HiAP interventions, including improved productivity, economic growth and stability (European Observatory on Health Systems and Policies, 2006). The European Public Health Programme study to address the considerable burden on the economy attributed to obesity, tobacco use and

Table 25.2 Studies of health in all policies (HiAP)

Title	Policy focus	Findings in relation to HiAP policy processes	Findings regarding challenges in policy research
HiAP as a strategic policy response to NCDs. Health, Nutrition and Population discussion paper (Lin, Jones, et al., 2014)	Review of recent developments in HiAP policy initiatives including intersectoral mechanisms and partnerships to address NCDs including behavioural risk factors	HiAP offers an approach to secure coordinated action on behavioural health risk factors such as physical activity, healthy eating, alcohol, tobacco and also mobilizing community action for healthy policy	In order to effect and secure HiAP, there is a need to better understand: governance actions and their relationship to governance structures and processes, agenda setting, policy formulation, implementation and evaluation and effectiveness of interventions
South Australian HiAP Initiative Health Lens Analysis Case Study (Government of SA, 2013)	This case study aimed to evaluate the effectiveness of the Health Lens Analysis model in identifying evidence-based public policy to address social determinants of health and build capacity for HiAP implementation and also to benchmark with other models	Outcomes of Health Lens Analysis included policy changes which impact on social determinants of health, stronger cross-sectoral partnerships, development and dissemination of policy-related research and willingness to adopt HiAP in future work	Need to integrate qualitative and quantitative methods to capture changes in sectors outside health, need to identify ways to include community views in policy development and also to adopt HiAP at programme and service delivery levels
Intersectoral Governance for HiAP. Structures, Actions and Experiences (McQueen, Wismar et al., 2012)	An analysis of effective intersectoral governance mechanisms for HIAP in the European Union, North America and Australia	Identified intersectoral governance structures effective in achieving HiAP	Access to information is an issue, either limited information or too much. Future studies need to identify factors influencing action in and on HiAP and accommodate lack of consensus on fundamental concepts and definitions and where possible build consensus
HiAP: An EU literature review 2006–2011 and interview with key stakeholders (Howard & Gunther, 2012)	Identifies opportunities and barriers to HiAP implementation in the European Union in order to tackle health inequalities by addressing social determinants of health and lifestyle-related risk factors	Policies are needed which support development of overarching strategies and action plans which endorse a HiAP approach and promote working in partnership particularly with communities	Wider consultation and increased capacity and capability in data analysis and interpretation may strengthen findings. More case studies are needed, in particular, examples of equity-focused HiAP
Report to the Ministry of Health and Long-Term Care. Getting Started with HiAP (Shankardass, Solar, et al., 2011)	Global review of initiation and implementation of equity-focussed intersectoral health activities, to inform policy for Ontario	Behavioural factors addressed by midstream interventions, findings highlighted importance of recognition of social determinants of health, budget sharing and tools and structures to support HiAP	Intensive methods needed such as interviews and case studies to understand observed variations in role of different sectors and types and importance of leadership in initiation and implementation of HIAP

(continued)

Table 25.2 (continued)

Title	Policy focus	Findings in relation to HiAP policy processes	Findings regarding challenges in policy research
HiAP prospects and potentials (European Observatory on Health Systems and Policies, 2006)	Analysis of the benefits of the HiAP approach for sectors other than health and the whole of society	Benefits of intersectoral action identified, HiAP contributes to 'win-win' opportunities. Risk assessment methods are effective for HIAP but have limitations	Need to develop specific methodology for assessing impact of proposals on health systems, need to work together on methodological issues related to determinants of health
Implementing HiAP (Department of Health South Australia, 2010)	Analysis of HiAP implementation – discusses concepts and provides practical examples of national and sub national country case studies	Need to identify how and why other sectors would share HiAP goals, find a new balance among responsibilities, identify roles and accountabilities	New forms of learning and knowledge management required to address 'wicked' problems, encompassing global industry of health-related products and services, considering trade, industry innovation and corporate responsibility

alcohol-related conditions recognized that investment in health contributes to a 'virtuous cycle' of improved heath as well as economic outcomes.

Examining distributional consequences of policy interventions is a topic for healthy public policy research. As detailed in the descriptions of European studies of HiAP earlier in this chapter, HIA studies of distributions of impacts point to the value of HiAP in reducing inequities (European Observatory on Health Systems and Policies, 2006) The researchers concluded that HIA could be used to predict how different segments of the population would experience health impacts if different policy options were implemented. The review concluded that this approach has potential to address inequities between countries as well as within countries. A subsequent study (Howard & Gunther, 2012), however, found few examples of successful policy work undertaken with a strong equity focus. This research identified the need for better understanding of the differences between health equality and health equity and the need for better data to understand health inequities at a national and local level.

In healthcare policy as well as policy for health, the question of elites, including industry influence, is important, as is the question of the conditional effectiveness of policies. An example of the importance of industry influence is found in the study of HiAP for non-communicable diseases (NCDs) (Lin, Jones, et al., 2014). Opposition from industry and property developers was identified as potentially limiting the effectiveness of policy interventions such as excise duty on tobacco and alcohol, advertising bans and restrictions, promotion of healthy food products and planning restrictions to increase recreational space and promote active transport.

Infrastructure for HiAP

More research is needed of infrastructure to support HiAP, to better understand governance actions and their relationship to governance structures and processes, agenda setting, policy formulation, implementation and evaluation and effectiveness of interventions (Lin, Jones, et al., 2014). Researchers also report the need to identify ways to adopt HiAP at program and service delivery levels (Government of South Australia, 2013). Additionally, future studies are needed to identify factors influencing actions to develop HiAP initiatives as well as actions within HiAP initiatives (McQueen, Wismar, et al., 2012).

Conclusion

Policy measures are increasingly being advocated for and adopted for behavioural health. Policy instruments such as regulation may have a direct influence on health behaviour. Policies such as financial incentives can create enabling conditions for behavioural interventions to be effective or ineffective. However, evidence about policy effectiveness for behavioural health is still evolving. Research about policy effectiveness is challenging due to the complex nature of the policy-making process. For this reason, research about policy effectiveness needs to be concerned about policy process as well as policy impact. Understanding about policy process can help with better policy advocacy and better policy implementation. For example, better understanding of policy advocacy can help with placing the social determinants of health on the central agenda of government.

Development of good information infrastructure is required to gather evidence over time to inform policy development and revision, including evidence from a range of health disciplines and health users, as well as from across industry and government sectors. To address global factors in behavioural health issues, the development of cross-national infrastructure for comparative analyzes will be required. Such developments in approaches to policy research and information infrastructure will enable the generation of evidence required to inform future policy for behavioural medicine.

Key Areas of Application in Prevention and Disease Management

Tobacco Control: Preventing Smoking and Facilitating Cessation

26

Ron Borland and Hua-Hie Yong

Introduction

Tobacco became the single largest cause of premature death and disease in the second half of the twentieth century, and unless stronger action is taken, it is on track to prematurely kill one billion people in the twenty-first century. It is currently estimated to kill over five million people each year (WHO, 2008). On average, it takes more than 10 years off the life of the smoker, and even more if they smoke heavily (Jha, Ramasundarahettige, et al., 2013). This means that smokers lose more lifetime than the total time they actually spend smoking (i.e., with a lit cigarette).

Tobacco is a product grown and manufactured for human consumption, and thus the harms it causes can be seen as an epidemic of harm created in large part by human activity. As such, it should be easy to solve, by reversing some of the harmful innovations and finding technological fixes for others. One of the aims of this chapter is to analyze why, even though considerable progress has been made to reduce the death and disease it causes, progress has been slower than desirable and may be slowing further. Behaviors can be very hard to change when they meet immediate human needs. Tobacco control is a story of how concerted action can make a difference, but also of the need to adapt strategies as the nature of the problem changes, changes that are in part generated by our attempts to control it.

The approach taken in this chapter is one that requires an ecological model of behavior change (Sallis, Owen, & Fisher, 2008). It requires consideration of broad environmental determinants that can nudge people away from smoking (Thaler & Sunstein, 2008); but this is not enough, it also needs to consider intrapersonal factors, both conscious beliefs and more reactive process (Friese, Hofmann, & Wiers, 2011; Borland, 2014). The factors that are available to consciousness include beliefs about self-efficacy, outcome expectancies, goals, and other beliefs. The more reactive aspects include consideration of how conditioning, both classical and operant, can influence behavior in response to the person's immediate environment.

Tobacco control has some unique features as well as some commonalities with other preventive activities. Because tobacco contains nicotine, it is a form of drug use, but unlike alcohol and some other drugs, it is not intoxicating, so the harms are virtually all associated with long term, not short-term use. In this, it is similar to the health harms associated with diet and physical activity. However, unlike diet, physical activity, and alcohol use, there is no desirable level of use (at least of smoked tobacco), so the aim is to

reduce or preferably eliminate use, rather than find the appropriate level of use (moderation). Like diet, overuse has been stimulated, at least in part, by mass marketing. Finally, unlike some other behaviors, there are no user groups advocating for help. All of this should be kept in mind when relating the lessons learned in this chapter to other areas of prevention.

The way science has responded to behavioral challenges like tobacco control has been largely reactive. Science tends not to study easy-to-change behavior (except in the field of commercial marketing), so many scientists hold the false perception that behavior change is difficult. In fact, much behavior change is easy – think about the changes in behavior associated with the uptake of mobile phones and other technologies. However, the exceptions, the hard-to-change or more correctly hard-to-maintain behaviors like quitting tobacco use are the ones where change does not just happen (Borland, 2014). The way science develops is by developing an increasingly sophisticated understanding of the problem, a process that will continue until the understanding is sufficient to produce the interventions that allow us to effectively eliminate the problem.

The Addictive Nature of Tobacco Products

Tobacco use, particularly of cigarettes, is addictive; i.e., a proportion of the people who start to use regularly find that it is extremely difficult to stop even when they commit themselves to trying. Researchers and clinicians have tried to define addiction more clearly, and to find indicators that will predict future failure to abandon the behavior, but have had limited success. While there have been many scales developed to measure aspects of nicotine dependence, the only measures that have reliably predicted future quit success are two measures of habit strength: the amount smoked per day and the time to first cigarette of the day (Baker, Piper, et al., 2007; Borland, Yong, et al., 2010a). To these might be added reported strong cravings, particularly if measured after quitting (Herd, Borland, & Hyland, 2009) and a past history of failed attempts, especially short-duration ones (Partos, Borland, et al., 2013). All these measures only predict weakly, so none should really be thought of as a measure of addiction, but more as indicators of some of its characteristics. Currently, the only way to really measure addiction is after the event, i.e., still smoking in the face of prolonged interest and attempts to quit. There is much we do not know.

Addiction is a biopsychosocial phenomenon, meaning that smoking is maintained by a complex mix of biological, psychological, and social factors (West & Brown 2013, for a good summary of many of the theories of addiction). The biological component relates to the effects on the brain of nicotine, the main chemical responsible for tobacco's appeal (Henningfield & Benowitz, 2010). These effects differ as a function of how the nicotine is delivered, particularly how quickly it gets to the brain. If it is delivered rapidly, it provides a "hit" which many find pleasant. This hit is not present (or is much reduced) when the nicotine is delivered slowly, as is the case with nicotine patches (used to help smokers quit), and thus users do not develop an addiction to nicotine patches. It appears to be the sudden pulse of nicotine that provides the experiences that support addiction.

Two main factors influence the rate of uptake of nicotine: the pH of the environment and where in the body the nicotine is delivered. Cigarette smoke is mildly acidic and results in ionized nicotine that is absorbed into cells with difficulty. However when delivered into the lungs, it can be taken up rapidly. At higher pHs (mildly alkaline), nicotine is more readily absorbed, so enough can be absorbed through the oral mucosa to provide a psychologically satisfying dose. Cigar and pipe smoke can achieve this, but still at rates lower than for lung inhalation. The acrid smoke is harder to inhale; however, cigarette smokers, who have become expert in inhaling cigarette smoke, tend to inhale even when smoking pipes or cigars, while never cigarette smokers tend only to puff on these products. Unfortunately, for cigarette smokers, lung ingestion of smoke is the most harmful form of tobacco use because it delivers highly toxic and carcinogenic tar to the sensitive tissues of the lungs.

The immediate biological effects of nicotine provide rewards that are the basis for conditioned associations developing to the act of smoking, and the act gradually comes to be enjoyed – it typically starts out as being experienced as unpleasant, or at least some aspects are experienced that way, but this adjustment is usually rapid and most users come to experience positive effects quite quickly. From the perspective of behavioral theory, the addiction to smoking develops as a result of a combination of classical and operant conditioning. Cues associated with use, from the sight of cigarettes, through the act of lighting up to the experiences of taking in a puff of smoke, all of which occur before any desirable physiological effects of the nicotine are felt, become conditioned and over time become rewarding in their own right, especially those closest to the physiological response, such as the experience of the smoke on the back of the throat. Operant conditioning processes then build on these desired outcomes (rewards) by acting to find and use cigarettes more frequently. Indeed, according to some contemporary theories of addiction (Robinson & Berridge, 2003), the repetition of the behavior is reinforced more by the positive emotions associated with the anticipation of getting the drug, than by the actual effects of the drug itself. Because of these cues associated with regular use, drug users, *including* smokers, tend to prefer to use their drug in regular situations even though this means that the physiological effects of the drug are lower (something known as tolerance). That is because using in a novel situation leads to a stronger physiological response as the body is less prepared for the drug, because it is not expecting it. Part of the anticipatory response involves the body preparing to counter the effects of the drug, so if the drug effect was primary, smokers should prefer to smoke in unfamiliar context, but they do not.

Desire to smoke is not just determined by contextual cues, it tends to be greatest when the person is in a negative mood state. Thus both internal and external cues can come to trigger the desire to smoke, which is experienced as a craving, when the desire cannot be immediately fulfilled.

Initially addiction is simply experienced as a desire to smoke, but from the time smokers decide they should quit but are unable to do so, they can become aware that smoking is no longer a simple choice. However, addiction is much more than a simple conditioned habitual response. The biological aspects are associated with particularly strong rewarding consequences of use, which help maintain the behavior, and social and psychological aspects are also important. The social factors maintaining addiction range from the effects of social norms (both of the society as a whole and of friends and family), through any relevant laws and cultural traditions (e.g., in some parts of the world it is still considered polite to offer cigarettes as a gift). As tobacco control efforts have developed and the social determinants of smoking have been reduced in strength, we think conditioned and biological factors (and their interactions) are becoming more important factors maintaining smoking, although social context and beliefs can still have some influence.

The psychological aspects of addiction include the largely unconscious build-up of habits associated with the drug which create regular desires to smoke and beliefs about the utility of use, which when combined with conscious beliefs about the harms associated with long-term use create conditions of ambivalence about use. The habitual aspect of smoking is critical to its maintenance: By the age of 40, the average smoker will have smoked around 150,000 cigarettes (15–20 per day, by 365 days, by 25 years) and, if they take around ten puffs on each, will have inhaled tobacco smoke 1.5 million times. No other habits are anywhere near as practiced, and even if smoking were not addictive, suddenly eliminating this habit would still be likely to be difficult. The ambivalence is manifest in the rational self-being committed to quitting to avoid the adverse effects, but part of the emotional self, the part driven by the physiological need for the drug, wanting to smoke whenever cues to smoke trigger cravings. This conflict results in oscillations in reported motivation to quit, to avoidance of the issue, and to beliefs such as that if one really wanted to quit (e.g., resolved the essential psychic conflict) then quitting would be straightforward (Balmford & Borland, 2008). This last "excuse" focuses attention on the extremely difficult task (at least while still a smoker) of resolving the psychic conflict, and distracts attention away from strategies that are known to be effective, such as use of cessation aids. We think it is not possible to understand addiction from a purely social or behavioral perspective, but it requires an analysis that incorporates both operational (reactive) functions and executive or conscious deliberative ones along with the influences of environmental conditions. Stopping an addictive behavior can be seen to belong to a class of hard-to-maintain behaviors, which are those for which the simple desire to engage or desist is not enough to result in sustained change (Borland, 2014). In this regard, addictions should not be thought of as an all or none phenomenon, but one where the strength of the urges to engage in the problematic behavior varies across individuals, and within the individual it varies as a function of the person's underlying physiology, his/her beliefs and emotional states, and the environmental conditions he/she is in.

A Brief History of Tobacco Control

Tobacco had been used in North America for many generations before it was brought to the rest of the world in the sixteenth century following the European colonization of the Americas. It was used in a variety of forms, among which, what we would today recognize as, a cigarette (all hand-rolled, either by the user or in factories) was only a minor form of use. This all began to change in the second half of the nineteenth century.

The rise in tobacco use is a story that mirrors the rise of capitalism and, in particular, mass production and mass marketing as means of growing the market for certain kinds of products. Many of the standard techniques of modern marketing were pioneered by the tobacco industry (Brandt, 2007; Proctor, 2012). The invention of the automated cigarette rolling machine by Bonsack in the 1880s provided the basis for mass marketing. One other factor that was also important to the growth of the cigarette was the development of flue-curing of tobacco (Proctor, 2012). Flue-cured tobacco retains more sugar than traditionally cured tobacco and produces smoke with a lower pH, making it less acrid and allowing it to be inhaled into the lungs relatively easily. Lung inhalation is necessary as the lower pH reduces the uptake of nicotine from the oral mucosa. Absorption of the nicotine into the lungs results in it getting to the brain faster – within seconds of inhalation, providing a more powerful psychological experience and thus one that over time most tobacco users came to prefer. With mass production, it became cheaper to provide cigarettes and enterprising companies started making a lot of money from it, and gradually cigarettes came to dominate the tobacco market. Tobacco companies in the USA promoted their products extensively and had them included in rations for World War I soldiers, which hastened their spread. After the war, tobacco use expanded rapidly. The growth of factory-made cigarette use per capita in the USA is shown in Fig. 26.1. Note that in the early years, most tobacco use was of loose tobacco, often used in pipes, but there was still growth in overall tobacco use. Other Western countries had similar growth. Growth slowed at the start of the Great Depression, but then increased again over the period of World War II and beyond, until people started to become concerned about its harms.

Concern that tobacco smoking might be associated with serious health harms began to grow from the 1930s, albeit slowly. Two of the biggest and most influential studies were published in 1950, one by Doll and Hill in the UK and the other by Wynder in the USA, both showing compelling evidence of strong links between smoking and lung cancer. Publicity associated with these studies was considerable, but there was no consensus as to whether the harms were real, a debate artificially flamed by tobacco-related interests with a vested interest in undermining the evidence.

Institutional acceptance of the harms from tobacco can be dated from the 1961 report of the UK Royal College of Physicians and the 1964

Fig. 26.1 Annual adult per capita cigarette consumption and major smoking and health events – United States, 1900–1998 (Reproduced from MMWR, November 5, 1999, p. 986)

Report of the US Surgeon General. The problem could no longer be denied. The first international conference on tobacco or health was held in New York in 1967 and was addressed by US Senator Robert Kennedy. In the 1970s, led by Nigel Gray, the UICC (*Union for International Cancer Control*), supported by the American Cancer Society, built the framework for the global tobacco control movement. However, there was little coordinated action to stem the epidemic until the late 1970s and 1980s, and even then such effort took place only in a few countries.

Countries have varied greatly in terms of their response to the epidemiological evidence demonstrating the nature of the problem. It is impossible in one chapter to cover all of this diversity or the reasons for the varying levels of action, so what follows are largely generalizations. Two key reasons for the lack of concerted action were the counter-response of the tobacco industry, which contested the evidence and was successful in maintaining a debate over the harms for several decades, and the lack of expressed concern by smokers, those most directly affected. Indeed it was not until the end of the last century (nearly 50 years after the first definitive studies) that major tobacco companies were prepared to publicly acknowledge, something they had known at least as early as health researchers, that smoking was extremely harmful to health. Prior to this, tobacco companies took extraordinary steps to deny the evidence, create misleading evidence, and to challenge all attempts by governments to control use (Proctor, 2012). The false controversy, probably exacerbated by the reality that smoking does not seem dangerous, has meant that smokers have been reluctant to believe it is as harmful as scientists have claimed, and since most smokers who tried to quit found it too difficult to do so, they developed an ambivalent relationship with smoking even when they accepted that it was harmful. Without pressure from smokers, and with strong advocacy from a politically powerful and rich tobacco industry, and also perhaps diverted by the large income they receive from taxes on tobacco, governments largely failed to act.

For the first decade or so following the first conclusive reports in the early 1960s there was little governmental action in most places, although warnings were placed discretely on cigarette packs in some countries and some restrictions were placed on tobacco advertising, mainly in the electronic media (in those days, TV and radio). Over this time it also became clear that smoking was even more harmful than the early reports indicated. Links between smoking and heart disease were established as were links with a range of other diseases (several other cancers, stroke, and peripheral vascular disease being among the most important). Estimates of premature mortality from smoking started off at around one in four smokers, but grew as the epidemic matured to around one in two, and more recently the best estimates are more like two in three smokers will lose on average 10 years or more of productive life if they smoke (Doll, Peto, et al., 2004; Pirie, Peto, et al., 2013).

As the evidence grew, pressure for more action began to build. In some countries, the need for action was galvanized by a mixture of nongovernmental organizations (NGOs) advocating for action and activists taking high publicity action. One well-known example is the organization BUGA-UP (Billboard Utilising Graffiti Against Unhealthy Products) in Australia which defaced tobacco company billboard advertisements in often humorous ways to highlight some of the harms the advertisements were designed to ignore (see Fig. 26.2; Chapman, 1996).

Starting mainly in the 1980s, some countries began to take more comprehensive forms of action, with strategies varying somewhat by country. Most of this action was in affluent countries, including English-speaking countries (e.g., the USA, the UK, Australia, and Canada), much of Scandinavia, and small places like Singapore and Hong Kong. Most began to tighten up legislation, imposing restrictions on the ability of the tobacco industry to advertise its products, initially focusing on electronic media, but subsequently spreading to other forms of promotion. In the USA and Finland, a lot of initial action was stimulated by large community-based trials to reduce smoking, in some cases in conjunction with an integrated effort to encourage healthier lifestyles.

Fig. 26.2 Examples of the activities of the Australian activist group BUGA-UP. This was a group of mainly health professionals concerned about the ongoing promotion of tobacco products (Photo provided by Simon Chapman)

As the success of these initiatives became known, momentum for more action began to build. This was stimulated greatly by institutional conclusions that passive smoking was harmful, most notably in the conclusions to this effect in the 1986 US Surgeon General's report. This galvanized many nonsmokers to be concerned and validated tobacco control efforts as involving the protection of innocent bystanders, including children, rather than one of protecting smokers from their own behavior. This was closely followed by the 1988 Surgeon General's report concluding that smoking was addictive. Together, they helped change the discourse away from the position the industry had adopted of a freely chosen activity to one that smoking is not freely chosen and that it can also harm others. Tobacco control forces in those countries that were already trying to take actions became stronger, and other countries began to take action. One notable case was Thailand, which began with strong restrictions on promotion and attempts to prevent international tobacco companies from entering the market under the provisions of international free-trade agreements.

Since then, the impetus for tobacco control was stimulated by regular World Conferences on Tobacco or Health, and more recently by scientific journals: first *Tobacco Control*, then *Nicotine and Tobacco Research* following the formation of the Society for Research on Nicotine and Tobacco (SRNT). Both provide dedicated outlets for research to complement publication in more generalist journals. This has helped strengthen and disseminate the evidence base, while also facilitating sharing of advocacy successes. These developments have strengthened the case for tobacco control and for specific strategies, and thus increased the influence of tobacco control advocates, leading to increased action.

From the mid-1980s, Australia pioneered the extensive use of regular mass media campaigns and was able to demonstrate their benefits. In 1994, US researcher and activist Stanton Glantz received a box of tobacco industry documents sent anonymously (Glantz, Slade, et al., 1998), which was the start of a mass of such material becoming public in various ways, mainly through the US Courts and through a negotiated settlement by the government with most tobacco companies to pay for costs incurred in treating tobacco-related diseases. Among other things, this showed that the tobacco industry concealed research they had done showing that tobacco smoke was both carcinogenic and addictive. These documents have greatly enhanced our understanding of the industry and have helped convince decision-makers that they are no longer a respectable part of corporate society. They had been one of the most powerful lobby groups, but publicity about their unethical behavior has considerably weakened their power with politicians who now run considerable risks to their reputations if they are publicly identified as supporters of the industry. They still retain considerable power behind the scenes as they are large and profitable enterprises. Their power means that many governments still feel constrained from doing all that is needed to properly tackle the problem. The other main challenge for governments is that while so many people continue to smoke, prohibition is not a viable option.

Major Institutional Responses Shaping the Future: WHO FCTC and US FDA

In February 2005, the World Health Organization's (WHO) first piece of international law, the Framework Convention on Tobacco Control (FCTC), came into force for those countries that were party to it. As of January 2015, 180 of the 195 countries of the world are parties, the main exceptions being the USA and Indonesia. This convention calls for, and in some instances mandates, actions that represent an integrated approach to dealing with this major public health problem. The implementation of the FCTC has been complemented by WHO's MPOWER framework which picks up on several key articles and provides guidance for countries on implementation of tobacco control policies and programs that complement the formal text of the treaty and its negotiated guidelines. Implementation has also been supported by civil society through a coalition of NGOs called the Framework Convention Alliance, allowing the voices of tobacco control activists and researchers to be heard independent of governments.

The other major recent event that is likely to have international significance was the passage of legislation in the USA to give its Food and Drug Administration (FDA) powers to regulate tobacco products, but not to prohibit them. Even though the USA has not ratified the FCTC, the FDA legislation means that it will soon become compliant with FCTC requirements. Perhaps more importantly, it provides an agency that has the capacity to begin to properly regulate tobacco products, something that most FCTC parties lack the resources to effectively tackle.

Trends in Tobacco Use

Most of the tobacco used in the world today is in the form of factory-made cigarettes. However, in some places hand-rolled tobacco is an important source of smoked tobacco, and in others smokeless tobacco is also important. The greatest diversity in tobacco use is probably in India, where a wide range of tobacco products are either smoked, sucked, sniffed, chewed, or even used in toothpaste. In South Asia and parts of Africa, women who use tobacco predominantly use forms of smokeless tobacco. In Sweden and Norway, smokeless tobacco is the dominant form of use among men, but not used much by women.

Smokeless tobacco is less harmful than smoked tobacco, and smokeless forms can be reduced in toxicity far more than smoked forms (Foulds, Ramstrom, et al., 2003). In some parts of the developed world, there is some evidence of increased use of cleaner forms of smokeless as a consumer-initiated harm-reduction strategy. This chapter focuses on cigarette use, but does discuss the potential of cleaner forms of smokeless as part of the solution to the huge epidemic of tobacco-related harm, which is mainly due to the use of smoked tobacco.

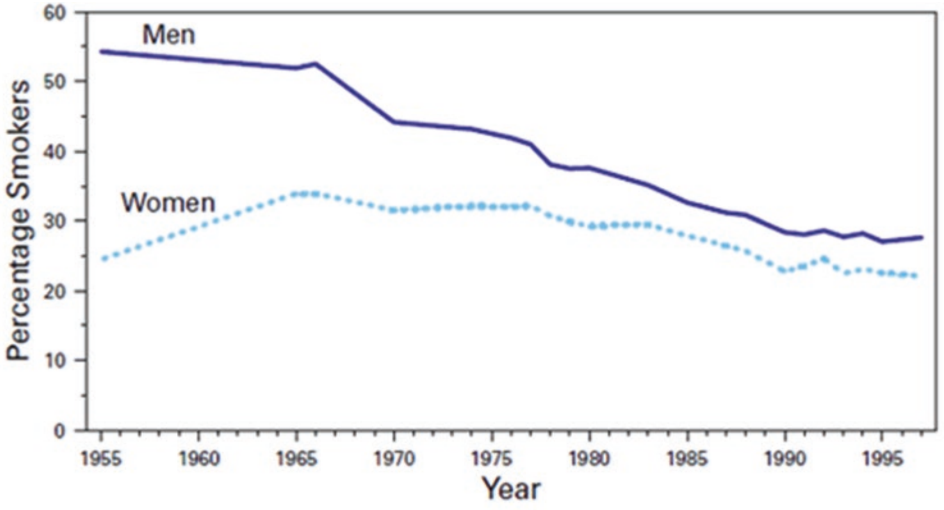
In this section, we have selected examples to illustrate both the diversity and the potential for progress of tobacco control efforts. We first focus on the early adopter countries, then briefly consider the early adopters among the less developed countries, and then describe the situation in two of the largest tobacco markets in the world: China and India.

Trends in Tobacco Use in Early Adopter (and Affluent) Countries

In the USA, tobacco use increased almost exponentially from the 1800s to the mid-1960s (DHHS (US Department of Health and Human Services), 2000). The dramatic rise in tobacco consumption was largely fuelled by the invention of the factory-made cigarette and cigarette smoking quickly outpaced the use of any other forms of tobacco product (Brandt, 2007). At the peak of tobacco use in the mid-1960s, more than 40% of the US adult population smoked cigarettes, more men than women (National Center for Health Statistics, 2005). However, starting from the early 1950s, cigarette consumption in men began to fall, perhaps as a result of health scares associated with tobacco use. The publication of the first US Surgeon General's report in 1964, concluding that smoking caused lung cancer, was associated with an increased decline for men and the start of a decline for women.

To mollify the public's growing concern about the health effects of smoking, tobacco companies introduced filtered cigarettes in the 1950s and the so-called low-tar cigarettes in the 1960s. As a result, the market share of both filtered cigarettes and so-called low-tar cigarettes increased dramatically. By 1960, more than half of all cigarettes consumed had filters (Giovino, 2002) and by 2005, 99% had filters (FTC (Federal Trade Commission), 2007). Similarly, the market share of low-tar cigarettes increased from 2% in 1967 to 85% of cigarettes distributed within the USA (Giovino, 2002). Menthol, an additive with an anesthetizing effect that was claimed to sooth the throat, was also added to cigarettes in the 1960s and its market share peaked in the 1980s when just under 30% of all cigarettes sold in the USA contained menthol (Giovino, 2002).

US adult smoking prevalence fell from 42% in 1965 to 21% in 2009 (see Fig. 26.3), with the rate for men (21%) being higher than for women (16%) in the latest estimate (Centers for Disease Control and Prevention, 2014). Among those who smoke, daily cigarette consumption began to fall around 1979 and smokers, on average, are smoking less than they did three decades ago.



*Before 1992, current smokers were defined as persons who reported having smoked ≥100 cigarettes and who currently smoked. Since 1992, current smokers were defined as persons who reported having smoked ≥100 cigarettes during their lifetime and who reported now smoking every day or some days.

Sources: 1955 Current Population Survey; 1965–1997 National Health Interview Survey.

Fig. 26.3 Trends in cigarette smoking* among persons aged ≥18 years, by sex – United States, 1955–1997 (Reproduced from MMWR, November 5, 1999, p. 988)

Most of the fall in daily consumption is due to reduced smoking among heavy smokers. This picture is replicated in other early adopter countries, with some doing better, particularly those that have complemented public education with the stronger forms of restriction on tobacco promotion, and restrictions on where smokers could smoke. Australia has done particularly well in this respect (overall, at least weekly smoking prevalence has more than halved from 34% in 1980 to 14% in 2013), as have the city states of Singapore and Hong Kong (2010, overall smoking prevalence of 14% and 12%, respectively), where because of historically low levels of smoking among women (about 4% in both countries), overall prevalence is even lower than countries like Australia.

In the UK, like the other early adopter countries, the overall smoking prevalence among adults (aged 16 and over) fell steadily between the mid-1970s and early 1980s. After 1982, the rate of decline slowed and between 2007 and 2012, overall smoking prevalence leveled out at 20% (Action on Smoking and Health (ASH), 2013).

Among youth in the UK, smoking prevalence has declined more recently. From the 1980s, where the first surveys occurred, uptake of smoking in youth fluctuated, but did not overall decline much till the mid-2000s (Action on Smoking and Health (ASH), 2013). However, in the USA from 2000, smoking rates among middle-school students almost halved by 2009 (see Fig. 26.4), and the rates of older students also declined from a higher baseline by a similar amount (but less proportionately) (Centers for Disease Control and Prevention, 2010). In Australia, the same pattern of decline occurred, but it may have happened slightly earlier.

Trends in Developing Countries

Thailand was among the first developing country to take action. As a result, it has reduced its smoking prevalence among those aged 15 years and older from around 35% in 1981 to 24% in 2011 from the latest available estimate (Global Adult Tobacco Survey (GATS), 2011). Rates in

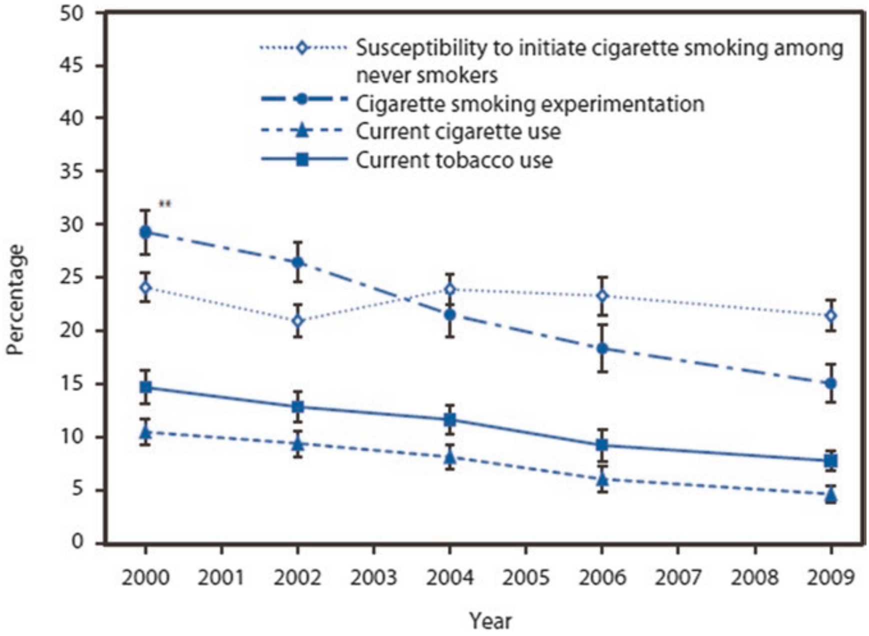


Fig. 26.4 Susceptibility to initiate cigarette smoking among never smokers, cigarette smoking experimentation, current cigarette use, and current tobacco use among adolescents in middle school. National Youth Tobacco Survey, United States, 2000–2009 (Reproduced from MMWR, August 27, 2010, Vol. 59, No. 33, p. 1066)

men fell from 63% to 46.6% and among females fell even further from the low 5% in 1981 to 2.6% in 2011 (GATS, 2011).

One stand-out case is Bhutan, a small Buddhist country in the Himalayas, which banned the sale of tobacco products in 2006 (but not possession or use), completing a process that began in one district in 1989 (ITC Project, 2011). Action in Bhutan was largely due to long-standing discouraging of smoking by the dominant Buddhist sect in Bhutan, with the legislative action triggered by publicity about the epidemiology. Bhutan has had very low tobacco use, with smoking rates estimated at less than 4% in 2010, making it relatively easy to implement a ban. Smuggling of tobacco remains a problem, although stronger laws were enacted in 2010 to try to reduce it. How successful they will be remains to be seen.

While the trend of tobacco use is on the decline in many developed Western nations, there have been concerns that this may not be happening in many developing countries like China and India. China has 350 million smokers representing about a third of the world's smokers. China ratified the FCTC in October 2005 and has slowly begun to take steps toward implementing the FCTC. Based on a 1996 survey, overall prevalence rates for Chinese smokers were around 67% for males and 4% for females, with an overall prevalence of 38% among those older than 15 years of age (Yang, Parkin, et al., 2004). The GATS conducted in 2010 estimated the current smoking prevalence of around 53% for men and 2% for women with the overall prevalence at 28.1%, an overall decline of nearly 10%. This reflects the early progress that can be made with public education in encouraging (mainly) less addicted smokers to quit.

The Chinese population is now better educated about the harms of smoking with smokers reporting higher levels of information from most communication channels (Li, Borland, et al., 2013), although levels of awareness still remain far too low (Yang, Hammond, et al., 2010). However, some interventions may not have been as effective as desirable. For example, in October 2008, the Chinese government introduced the new larger text-based health warnings on cigarette packaging to replace the old warnings, but unlike most other countries, they remain text only and do not require a standard background, and on one side are in English (which very few Chinese read). Experimental studies show that these warnings have low immediate impact as compared with stronger graphic or text-only warnings as used elsewhere (Fong, Hammond, et al., 2010), so the population-level effects are likely to be small. In May 2009, tobacco tax was increased by 3.4%, but the China National Tobacco Corporation (CNTC, the national monopoly) simply kept prices constant by absorbing the tax increase, thus it can have no effect on consumers (Hu, Mao, & Shi, 2010). Despite the efforts made to date, the FCTC commitment has not been fully fulfilled. There is also no national ban on tobacco use in public places, and in cities with restrictions, many do not cover all indoor work and public spaces. The restrictions on tobacco advertising, promotion, and sponsorship are also far from comprehensive. That said, there continues to be progress with many places becoming smoke-free and some rules being enforced more effectively.

China also has a problem of conflicting interests in the way it administers tobacco control policy. It has given its State Tobacco Monopoly Administration responsibility to lead the implementation of the FCTC. However, this agency also has responsibility over the CNTC, which is the largest single manufacturer of tobacco products in the world (Hu, Mao, & Shi, 2010). There is genuine concern that the interests of CNTC sometimes take precedence over the interests of public health, so administration of tobacco control policy in China needs to be changed to give health interests priority.

As a country that has only recently begun to educate its population about the harms of smoking, China still has smoking embedded in aspects of its culture. It is common to have tobacco products offered as gifts to reinforce friendships and relationships (Pan & Hu, 2008). Similarly, when men meet, it is customary for everyone to offer cigarettes to signal respect and hospitality, providing a barrier to quitting (Zhang, Chan, et al., 2012). These normative influences are likely to gradually disappear as they have in countries that have taken tobacco control seriously for years, but while they persist, they are likely to keep some more socially cued smokers from quitting.

Tobacco use in India is very different to China. India has an estimated 120 million smokers, the second largest number after China. It has also ratified the FCTC and is beginning to put in place strong policies. In India, cigarettes comprise just 19% of tobacco consumption, while bidis (a mix of tobacco and other products wrapped in a leaf) account for 53% and are the main form of smoking among women, with most of these produced by hand (GATS, 2010). However, in most states the main form of tobacco use for women is smokeless, in a variety of forms, while overall smokeless use among men, while at similar rates to women, is lower than for smoked tobacco. Data from GATS India gathered in 2009–2010 estimated that more than one-third (35%) of adults in India use tobacco in some form or other. The prevalence of overall tobacco use is 48% for males and 20% for females. Prevalence of smoking is 24% and 3% for males and females, respectively. Prevalence of smoking and chewing tobacco varies widely between different states and is associated with sociocultural characteristics. Tobacco chewing is more common in the Central, Eastern, Western, and Northeastern states compared to the Northern and Southern states. Smoking of tobacco is relatively higher in the Northern states (except in Punjab where tobacco prevalence is one of the lowest because the Sikh religion prohibits tobacco consumption). As in China, India's rapid economic growth and increase in people's disposable incomes are expected to increase smoking consumption. Less is known about the early impact of the strengthened tobacco control initiatives in India; they are likely to have some positive effects, but difficulties in implementation and the largely unregulated cottage industry for much of the tobacco production are major challenges to any rapid progress.

Sociodemographic Patterns of Use

Historically, uptake of smoking occurred first among more advantaged groups, but they were the first to give up when informed of the health effects. In countries like the USA, smoking is now much more prevalent among disadvantaged groups, although there are some cultural differences. For example, Hispanics in the USA have lower smoking rates in spite of lower average socioeconomic status (SES) than other groups (Centers for Disease Control and Prevention, 2010; Siegel & Faigeles, 1996).

In most countries, smoking began as a predominantly male practice, only being taken up by women later, particularly in countries from Europe or European origin. In much of the developing world, rates of smoking among men are far higher than among women, reflecting greater sex-role differentiation in those cultures. In Asia, in particular, smoking has remained socially unacceptable for women and rates have typically remained low. In countries with strong tobacco control policies, rates among women have remained low, or even reduced, while in countries without strong policies, such as in Japan, they were increasing, until those countries began to take action. The increases, where they occurred, tended to be in the more affluent countries, or among the more affluent elite in less developed countries, and have been linked to the capacity of the tobacco industry to link their products to modernity and to the desirable aspects of Western lifestyles.

In developed countries where tobacco use has declined to around 20% or lower, the rates are much higher among the most disadvantaged sections of those societies, including the marginalized minority groups (e.g., American Indians, Australian aboriginals), people with mental illnesses (including other drug problems), and others who have fallen off the social ladder (e.g., the homeless) (Barbeau, Krieger, & Soobader, 2004). These pockets of high prevalence are going to be a major challenge for the future, especially as rates of smoking in these groups may not be declining as fast as in the broader community.

In Western countries, and increasingly in developing countries, smoking is linked to social disadvantage as the educated and the well-off get the message and quit, and also protect their children from becoming smokers. Smoking rates are very high among the dispossessed in rich societies, and where they exist, among their indigenous peoples. That said, there is increasing evidence that being poor or poorly educated is not directly related to tobacco use. The high use is among those who are disadvantaged in other ways, especially related to the negative experiences associated with disadvantaged positions in society or with impaired mental health. For example, we are finding that peasants (the poor with limited education) in some Asian countries are at least as willing and able to quit smoking as their more affluent urban cousins. In some countries, where tobacco use is more recent, use is also overall greater among more affluent urban dwellers, as this is the group that tends to be early adopters as they have the financial resources to afford it. Over time, the use of tobacco tends to spread down into the disadvantaged, who as a result of their disadvantage may get proportionately more immediate benefit from use, but over time tobacco use actually leads to a reduction in overall wellbeing.

The strong association of smoking with some forms of disadvantage means that tobacco control efforts should be seen as part of making a more equitable society. There is now compelling evidence that smoking increases financial stress (due to the cost) and exacerbates other causes of distress. Further, smoking makes a major contribution to the higher levels of ill health and premature mortality experienced by the dispossessed (Jha & Chaloupka, 1999).

Elements of a Comprehensive Approach to Tobacco Control

To effectively deal with a problem as complex as tobacco use requires an integrated and comprehensive approach as no single intervention will solve the problem. Solutions to the problems of tobacco use can range from influencing the harmfulness of the product through to influencing patterns of use. They need to attack one or more aspects of the chemistry of the products, the way it is marketed, psychological responses to use, aids to support cessation, and various aspects of the context of use, through to the motivations of various groups including tobacco companies which profit from trade in tobacco. Change can occur at various system levels: at the level of the person, their family (or friendship network), the community to which they belong, and the broader societal influences (both national and international). The relative importance of these factors is a function of where the locus of power exists for enacting changes to facilitate the desired behavior outcomes, i.e., the organizational level of the state (local through to national) that controls the key determinants of interest. Most of the environmental conditions that need to change to facilitate effective tobacco control (beyond what the person can do themselves) require action at societal (usually national, but sometimes state or provincial) or international levels. The main exception is the regulation of smoke-free places as in some countries local government have considerable power. In the USA, local governments led the move to smoke-free places and were important pioneers in setting the scene for larger-level jurisdictions to follow.

The critical issues to consider in controlling tobacco use are to what extent the environment can be modified to reduce cues to smoke tobacco and the extent to which individuals need assistance to enact desired changes. To the extent that tobacco use is socially determined, social change needs to be an important part of the solution. However, because of its addictive nature many individuals are going to need help to change, even if social conditions could be optimized for discouraging use. In this section, we consider both social and individual approaches to tobacco control.

Tobacco control is strongly grounded in science. It is only through epidemiology that we know how harmful smoking is. Science is also increasingly contributing to the development and evaluation strategies to control tobacco. Tobacco control researchers are leading the development of new research methods (or creative adoption of existing methods) (Borland & Cummings, 2010; IARC, 2008) that are providing a paradigm for understanding population-level behavior change that is being increasingly considered for other health behaviors. Examples of this include the adaptation of methods from marketing to evaluate mass communications and the International

Tobacco Control Policy Evaluation (ITC) project which is conducting parallel cohort studies in a range of countries to explore both:

- the impact of population interventions using other countries as controls (Fong, Hyland, et al., 2006; Thompson, Fong, et al., 2006) and
- cross-country differences that might reflect differential effects of policies either as a function of progress in tackling the problem or cultural differences (see the later section on denormalization).

Good science is built on and aids the development of good theory. Tobacco control has been conceptualized by some as a simple fight between good and evil, with responsible social forces working to remove an evil industry. While this may be a useful perspective for antismoking advocates to take, it is an unduly narrow conceptualization. More sophisticated models are needed. We have attempted to reconceptualize the problem using open-systems thinking (Borland, Young, et al., 2010b) – see Fig. 26.5. In most of the world's countries, it is useful to think of the current system as a tobacco use management system, with a regulatory core putting some constraints on the ability of the tobacco industry to market its products and some, typically poorly resourced, organizations providing information about the harms and supporting cessation. The way social forces act can be changed in two ways. First, by tilting the playing field toward one set of forces (e.g., supporting antismoking forces against the tobacco industry). This can be done by imposing constraints as to what the tobacco industry can do by way of laws (e.g., laws restricting tobacco advertising) and/or via the availability of resources (e.g., taxes on producers) or by helping the opposing forces (e.g., funding to antismoking groups). The second way is by changing the nature of the forces or institutions operating in the area, which changes what they are motivated to do. An example of this from the regulatory arm is the policy changes that led to governments moving from a model of regulating tobacco products like any other consumer product to one where the goal was changed to discourage its use. To change the nature of the tobacco industry would require either transforming tobacco companies into something other than profit-maximizing corporations, or finding a substitute for smoking that they could market more profitably (either of which would transform the landscape if it occurred). The set of societal forces created by the three kinds of forces within the system is the major determinant of the context in which individuals act, modulated by interpersonal social forces and the extent to which they have become dependent on tobacco or have otherwise integrated it into their lifestyle.

Systems analysis helps organize a range of major issues facing tobacco control. First, the current system is not structured to eliminate tobacco use, merely to manage it, either downward or at worst to reduce its growth. Until recently, very few people within tobacco control have called for an end to tobacco sales, and where they have, details as to how this could be achieved without unacceptably high levels of illicit trade have been conspicuously missing, making them aspirational statements more than plans (see special issue of Tobacco Control (2013) on Endgame issues) ("The Tobacco Endgames," May 2013).

Second, most of the costs of tobacco control are treated as externalities (costs that are not managed within the system), meaning there is no effective feedback mechanism for ensuring that tobacco control efforts are properly funded. Currently, only a very small proportion of the resources that most governments get from tobacco-specific taxes are returned to programs to support tobacco control, and overall levels of funding are far less than for many other public health and public safety issues, which are objectively much less destructive to health. Thus, while most public health problems represent a net cost to governments, tobacco is often a net source of revenue, even after accounting for the costs to governments of tobacco-related illness.

Third, continuing to allow tobacco companies to market their products to consumers while they are structured as for-profit corporations is

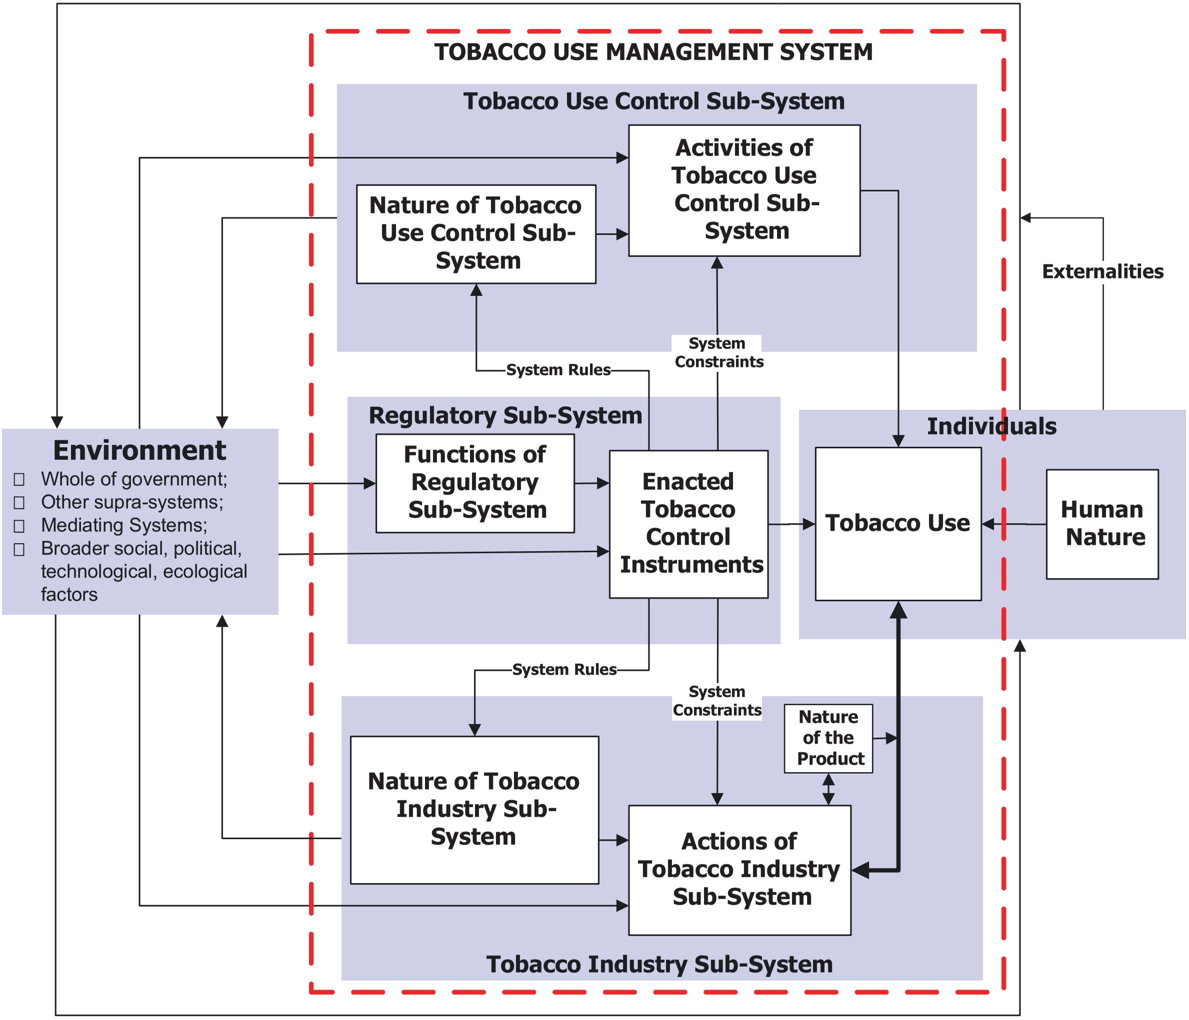

Fig. 26.5 A schematic diagram of the tobacco use management system (Adapted from Borland et al., 2010). This diagram shows how three conceptually different sets of institutional forces act on individuals. It does not show the normative influences of others acting as individuals

making resolution of the problem more difficult and it institutionalizes powerful forces within the system that have goals inconsistent with the system as a whole.

Fourth, the regulatory capacity of the system is limited, with most regulatory control still held by central government, meaning that the system is slow to respond to changing conditions. In the USA, from 2009, the Food and Drug Administration (FDA) has been given the power to regulate tobacco, so more concerted action is likely in the future, although early attempts to reform health warnings on packs have been thwarted by industry-led litigation leading to injunctions. Regulation in ways designed to reduce the level of a profit-making activity is bound to attract opposition from forces that profit. However, over time we might expect a more rational set of rules governing tobacco manufacture and sale.

Fifth, the current espoused goal of eliminating tobacco use precludes rational appraisal of harm-reduction strategies, something that should be intrinsic to any use management system. This is an important issue which is covered in more detail in the section "Harm Reduction and Product Regulation."

Finally, related to several of the above points, aspects of tobacco use have implications beyond the health system; thus attempts to change need to take into account a broad range of social forces, including the implications for other unrelated industries of regulating tobacco. In this regard, there would be considerable benefits if tobacco control forces were to join with other social movements for more socially responsible public policy, but unfortunately there is a tendency to treat tobacco as a completely separate issue.

While a systems approach is critical for analyzing the problem and testing the viability of potential solutions, it is not a useful framework for negotiating the needed change. Young, Borland, & Coghill (2010, 2012) have used a version of Actor Network Theory (ANT; a theory of the sociology of sociotechnical change) to organize the complex of individuals, organizations, facts, and arguments that together form the negotiated process that creates change in contested situations (see Fig. 26.6). ANT conceives of four broad sets of forces, usefully conceived of as two pairs that come together and interact in complex ways to determine outcomes. The original version of Latour (2005) was primarily concerned with the institutionalization of material things, while our adaptation is to ideas and policies with physical resources taking a more peripheral role. One pair has the possibilities for actions and the evidence and arguments used to support the various options, and related to this, the activities of organized interests who act to support and push particular positions. In a clearly contested issue like smoking, it can be useful to separate out the arguments and influence of pro- and antiforces. This pairing interacts with another, that covers public acceptance and support at one pole, and at the other, the responses of institutionalizing powers, be they scientific bodies to accept the nature of issues and problems or governments which legislate or regulate and control implementation and enforcement. Resolution of an issue requires that the institutionalizing responses are congruent with public desires and the absence of issues to generate sufficient opposition to potentially overturn or disrupt the operations of institutionalized responses.

The negotiated nature of social change is a key reason why solutions are often rationally flawed and some potentially powerful solutions are not achievable. The compromises necessary to get sufficient support for an innovation to be adopted often mean that the intellectual integrity of the innovation needs to be compromised. ANT considers the powers of various forces and of the frequent need to enact change through indirect paths. For example, in many countries early efforts to achieve smoke-free places used the systems of occupational health and safety. Although this provided the needed support, it meant nothing could be done about exposures outside workplaces. In time as workplace-oriented bans were seen to be beneficial, there was sufficient support to tackle the remaining areas as is now happening. Thus far, it has not proved possible to negotiate the regulatory changes required to properly tackle tobacco (although there are signs that this is changing). In the absence of sufficient support within government for strong action, other forces, such as community activism and litigation, have been

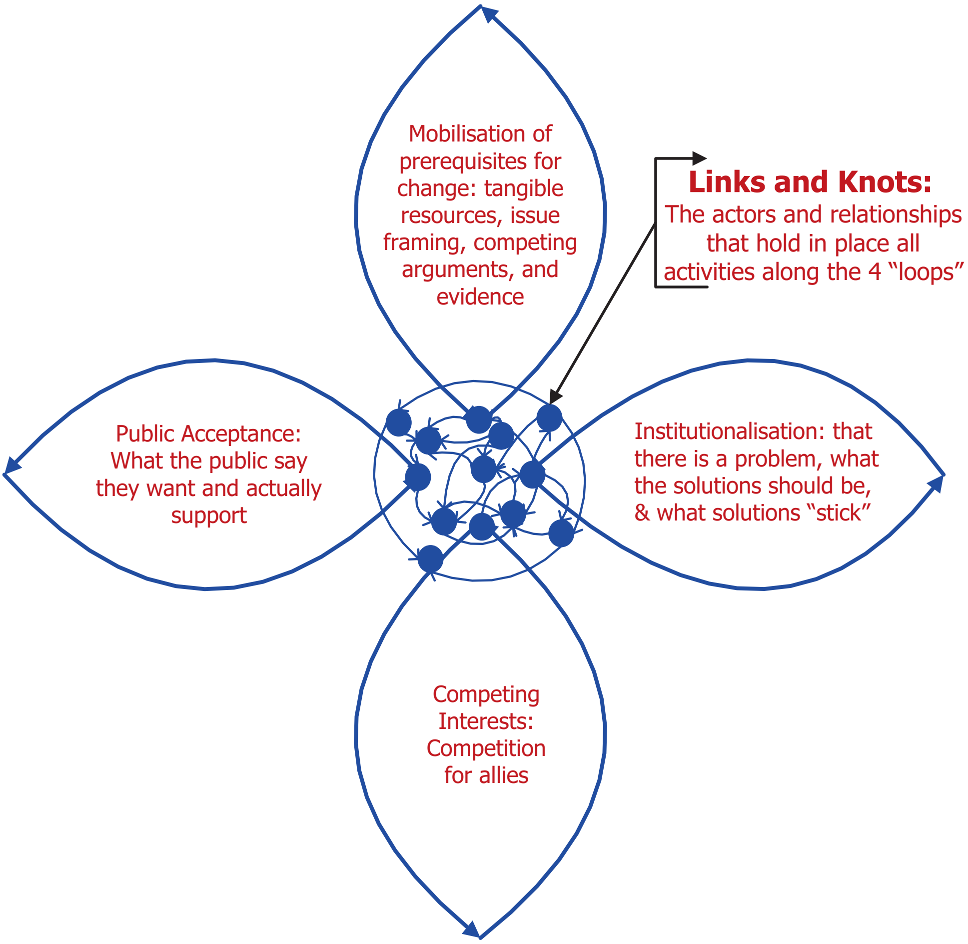

Fig. 26.6 The four kinds of interaction that influence the adoption and institutionalization of policy innovations (Adapted from Young, Borland, & Coghill, 2010)

successfully used to force government action, and at the same time they have changed the way society views tobacco and the tobacco problem.

Some lawyers argue that aggressively marketing tobacco might be technically illegal, given tobacco harms when used as intended and the appalling record of the industry in not unambiguously warning about those harms (Liberman & Clough, 2002). There have been a number of successful prosecutions of tobacco companies, primarily in the USA for failure to properly warn. However, the deep pockets of tobacco companies and the complexities of the cases make this a difficult strategy to implement. That said, none of this goes to the basic legitimacy of selling a product known to shorten the lives of as many as two-thirds of its long-term users, when used as intended (Pirie, Peto, et al., 2013). The failure to confront big tobacco may be motivated by a fear that successful litigation would result in the tobacco industry being made illegal overnight and the social dislocation that it could cause given the large numbers of tobacco addicts. The social problems that resulted from prohibition of alcohol in the USA are often given as an example of the inadvisability of prohibiting smoking.

As alternative solutions to the tobacco problem begin to gain acceptance as viable, it may be that litigation rather than legislation will be the tool that brings about the major changes to the industry many believe are needed. However, even

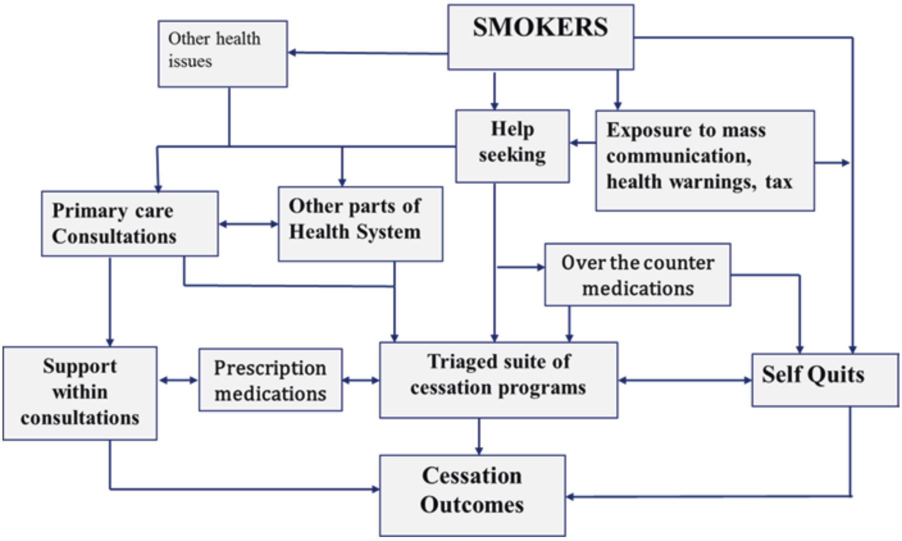

Fig. 26.7 A comprehensive smoking cessation system showing a pathway of self-quitting stimulated by population-level strategies, strategies that also stimulate activity to support quitting within the health-care system

if litigation forces action, systematic government action (regulation and/or legislation) will still be required to create a workable system.

Within this broader context there are a range of specific interventions that can occur to further tobacco control (see Fig. 26.7).The main ones are briefly discussed in the following subsections.

Informing the Public

Central to a rationality-based society is that people have adequate information to make decisions about products and activities that affect their lives. Strategies to achieve a better informed public range from provision of information by health authorities to mandated warning and product information (on packaging, at point of sale and on advertising, where it is allowed). Public information campaigns utilize the mass media, in both paid and unpaid form, and for young people, through education programs in schools. However, mere knowledge is not enough, people need to have an emotional engagement with the knowledge and understand that quitting smoking is a viable strategy for reducing their risk. People experiencing tobacco-induced diseases have this level of engagement, if they do not think action is too late, but we cannot wait until diseases occur to motivate quitting. This is why it is important to use vicarious learning techniques to generate this sense of need for action in those who are not at immediate risk of the problems. Graphic depictions of the harms is one way of doing this, sometimes using media to bring the cases of others to the attention of the at-risk population.

Health Warnings and Product Information on Packaging

There is now compelling evidence that warning labels on packaging improve knowledge and generate concerns about the harms of smoking, and through this, stimulate increased quitting (Borland, Wilson, et al., 2009, Borland, Yong, et al., 2009), although their net effect on cessation is probably small. Warnings with graphic photographs of smoking-related harms, first introduced in Canada in 2001, are the current state of the art in this area.

It is also now clear that strong warnings that lead to some degree of avoidance of warnings by smokers are effective. However, many psychologists believe that “scare tactics don’t work.” This belief is based on research which shows that punishment does not change behavior, but merely suppresses it, and the belief that such stimuli result in avoidance of the issue. There are a number of reasons why this belief turns out to be wrong. First, graphic communications are not punishment. They are better thought of as discriminative stimuli, as indicators about the harmfulness of the product than as noxious in themselves. As cues they act to remind the person that the behavior is dangerous, and this is what leads to increased action to desist. As long as the source of the concern persists, which it does for a genuinely risky behavior, the warning is likely to continue to have the effect of reminding us of the harmfulness of smoking. The issue of avoidance is somewhat different. There is a lot of evidence that avoidance leads to reduced engagement with an issue in experimental studies (Peters, Ruiter, & Kok, 2013), but these almost always entail isolated presentations of risk. However, avoidance is a temporary solution. Mandated warnings of risk remain present on the packs. It should also be noted that avoidance, when it does occur, is motivated by the evasiveness of the risk information and, so, is an expression of concern about the issue. On the occasions when the person avoids a graphic warning, they are unlikely to contemplate change; however, over time those who avoid most also tend to be confronted and think about the risks most (Borland, Yong, et al., 2009), and it is on these occasions when they fail to avoid that they are more likely to act. Finally, for young people and those not at risk from the behavior, graphic images do not appear to evoke fear, but disgust. The association of smoking with disgust may have a preventive value in combating images of smoking as attractive. Thus, prevention effects of graphic warnings among adolescents may function in very different ways to the ways they stimulate concern and thoughts of quitting among smokers.

Mass Media

The mass media is the main source of health information for many people, and even with the Internet, it remains the main source of unsolicited information. It is important for conveying new information and for reminding people about things they already know, but have either forgotten or are ignoring. This is why it is important to ensure that as much as possible of the scientific research on tobacco and its harms gets into the mass media. US research has shown a strong link between the number of media stories and quitting-related activity (Pierce & Gilpin, 2001). This can be done at very little expense as the media have a voracious appetite for news and human-interest stories. To maximize uptake it is important to frame the stories in ways that attract the reader's interest, often by including a personal angle. Getting stories into the media is likely to be less effective in countries where interests associated with the tobacco industry have influence over content.

Similarly, well-constructed advertisements about the harms of smoking, and possibly about the devious behavior of tobacco companies, raise the profile of the issue and make the issue more personally relevant, and thus encourage smokers to quit and sometimes motivate them to seek help. While advertising is expensive, it reaches large numbers, so it is actually quite a cheap form of intervention based on per person influenced.

The health effects ads appear to have their effects by essentially the same mechanisms as the way health warnings on packs work. Because TV ads are mini-films, they can convey a much more graphic and nuanced message than a picture with a small amount of accompanying text, but on the other hand, they may only be seen a few times, unlike the pictures on the packs which can be seen several times a day. Graphic mass media communications also contribute to discouraging youth from tobacco use. Part of the prevention effect seems to stem from disgust associated with linking the unattractive and disfiguring aspects of disease to smoking, rather than the anxiety about future harms to them that drives smokers.

To be effective, messages need to deliver on or be part of a larger campaign that makes the case that smoking is too harmful to continue (or to engage in) and that cessation or avoidance of it is the best solution. This requires gaining an affective engagement with the issue. Mere knowledge is not enough, and to achieve this affective engagement, as noted above, vicarious learning can be an important strategy (Hill & Dixon, 2010).

In the coming years, there is likely to be increased international coordination of efforts to get important tobacco stories into the media, and continuing pressure on governments to continue to warn against the harms. While most people have heard that tobacco is harmful, because it does not seem harmful, the level of harm is widely underestimated, and thus the need for action is similarly underestimated. This rationalizing or underestimation of risk is common to most addictions and often seen as indicative of the psychological processes associated with addiction. Keeping the issue before the public and making the harms emotionally salient will remain important strategies for discouraging use.

The mass media is also a good way to reach lower-SES smokers. Especially when the advertising is both designed to be seen as relevant and shown in programs they tend to view, it is at least as effective at influencing them as more advantaged smokers. Further, as they utilize mass media for health information more than other groups, they are more likely to be influenced here than from sources that one has to actively seek out. Having the issue of smoking prominent in the mass media can also motivate health professionals by making them both more aware of the issue and more aware that their clients have been similarly informed, and thus making them more likely to discuss smoking with their clients, something known to motivate quitting and/or be better prepared to respond to increased queries from smokers.

School-Based Programs

Programs targeted at preventing the uptake of tobacco use have generally not been shown to have marked long-term effects although they can slow the rate of uptake temporarily The more effective programs seem to incorporate information about the harms (i.e., reasons for not smoking), understanding of dependence/addiction, skills training (especially refusal skills), plus information countering the common misperception that more young people smoke than actually do (Buller, Borland, et al., 2003).

A key part of the problem is that in telling people not to do something there must be a mention of what not to do (Wegner, 1994). This generates interest in the behavior, which the preventive message needs to overcome before it can play a positive role. Thus prevention programs that do not adequately convey the reasons for avoiding the behavior can be counterproductive. There is evidence that the tobacco industry has exploited this dilemma in the way it has provided prevention programs in schools. On the face of it, these may appear to be admirable acceptance of responsibility. However, these programs notably deemphasize the health harms and focus on individual choices that smoking is not for children, but a choice some adults make. The limited evidence available suggests that these industry programs encourage some tobacco use by helping frame tobacco use as a legitimate (thus sensible) choice and a sign of adult independence (Landman, Ling, & Glantz, 2002). Whatever their reasons, the tobacco industry has no place in tobacco education. It is not reasonable to expect commercial tobacco interests to make the necessary, strong, unequivocal, negative statements about a product they profit from selling.

Many experts in the field believe that good public education plays a useful and probably necessary role. It is better to have the discussion in the classroom where the arguments against use can be presented, than out of class where they occur in the presence of the product and often no countervailing messages. However, unless accompanied by strong societal policies discouraging all harmful tobacco use, and thus primarily focusing on adults, it is unlikely to have much effect. Our experience in Australia, mirrored elsewhere where it has been studied, is that when you ask young people about what has influenced them, it is strong antismoking messages directed at encouraging adult smokers to quit. By contrast, they see messages directly focusing on youth as less effective for them (some think they could work for younger children). This may be because it treats tobacco as something no one should do, while youth-targeted ads run the risk of having a subtext of wait till you are an adult, something that acts as a magnet for many young people (Landman, Ling, & Glantz, 2002). Young people in modern societies, at least, are motivated to behave like adults and are resistant to the idea that there are some things open to adults that they should not do. This is consistent with research that finds that even the most effective school programs to prevent smoking tend to have modest impacts, and with the success in smoking prevention in countries like Australia which have for the most part focused communications on encouraging adults to quit, with school- and youth-oriented messages consistent with this, i.e., you should not smoke because it is not good for anybody, and as it is very addictive, you run a risk of not being able to stop if you take up the habit.

Other Media

The new social media (the integration of interactive elements of the Internet with mobile telephony) provide both huge challenges and opportunities for tobacco control. The threat comes from the potential of the industry to seed pro-smoking groups, given that such activities are hard to regulate. The opportunity is that it allows the potential for more genuinely interactive engagement with the issue and the opportunity of well-informed members of the community to become active partners in getting the messages out. The Internet will be most effective for those seeking information or help, but mass media will continue to play an important role for motivating people to seek information or help as people need to be sufficiently motivated before they will proactively seek things out. Also, because of interactive capacities, the Internet makes it easier to interact with the potential audience, to hear their views and understand the ways they frame the issue, and thus provides the capacity to respond appropriately, rather than expect the audience to adapt to the frame provided by experts speaking to them through the mass media.

Countering Tobacco Industry Marketing

Modern marketing is framed around the four Ps: Product, Promotion, Place, and Price. Tobacco control activities to date have tended to focus on promotion, and, through taxation, price, all of which we consider in this section, with product modifications reserved for the section "Harm Reduction" because it raises issues beyond product innovation as a marketing tool.

Many of the techniques that are now ubiquitous in mass marketing were first used, or first perfected, for selling tobacco, in particular the manufactured cigarette (Proctor, 2012). The tobacco industry continues to be a leader in the development of new marketing techniques, motivated, at least in part, by the constraints put on them from using established methods.

Restrictions on Promotion

Legislative bans, or other agreements, to eliminate tobacco advertising have been an important strategy since the 1970s. Bans on television often led the way. In many countries, bans now extend to all electronic media, newspapers and magazines, and billboards, and all forms of sponsorship by tobacco companies. Increasingly, advertising is also being eliminated at point of sale. Reviews of the impact of such laws indicate that when they are relatively comprehensive, they do reduce tobacco use, but if they are weak, tobacco companies can compensate by spending more on areas that are still allowed (Jha & Chaloupka, 1999). A number of countries, including early adopters France and Thailand, now require cigarettes to be kept under the counter to eliminate the promotional aspect of cigarette displays. There is evidence that this policy can reduce spontaneous purchases (Li, Borland, et al., 2013), so it is likely to have a small positive impact on cessation outcomes, although the likely small size will make finding direct links difficult. Display bans should restrict storage to cabinets where the contents are not clearly visible to the public when opened, as is the case of large cabinets behind the seller, a set-up which draws attention to the products inside when opened.

Tobacco promotion has not been eliminated. The essence of modern marketing is the brand, and tobacco products are all attractively branded. This results in smokers becoming unpaid brand promoters each time they publicly display the brand they are smoking. The closest any country has come is Australia. Since the end of 2012, all tobacco products sold in Australia are in plain, standardized packaging. Apart from the large colorful health warnings that are mandated on 75% of the front, 90% of the back and generic contents information on one side, the rest of the pack is a dull dark olive-brown color and the names and variant descriptor (where relevant) of the brand are only allowed in a standard font (see Fig. 26.7). In addition, all branding on cigarette sticks has been prohibited. This goes a long way to reduce the capacity of companies to use brand imagery, but while they can retain brand names (especially those with existing connotations due to past promotion), there will still be some capacity to promote brands. While for-profit companies can continue to compete against each other, there must be marketing potential in the brand names and whatever else they can use to add value to the basic products. If active promotion of tobacco products is to be eliminated, it may be necessary to stop for-profit tobacco companies from marketing their products directly to consumers. Banning sale of cigarettes for profit does not mean prohibition as not-for-profit mechanisms can be used to supply the demand (Borland, 2003), but in a way that does not degenerate into "the more you sell the more you make," something unacceptable for products as harmful as cigarettes. The nonprofit agencies (either arms of governments or through some other mechanism) could take control of the marketing of the products. Similar mechanisms have been used to control the sale of alcohol in various countries including North America and Scandinavia, although many of these have focused on controlling distribution without addressing marketing. Nevertheless, these strategies have been shown to reduce consumption compared to for-profit distribution and marketing. As modern marketing is at the core of product sales, and marketers largely control the distribution network, if marketing is controlled, most of the benefits of such an approach would be achieved.

A major promotional strategy still used by the tobacco industry is known as relationship marketing. One key aspect of relationship marketing is to position the desired activity as part of a broader lifestyle. This involves building and helping to sustain a lifestyle where the product, in this case cigarettes, is designed to fit – just one of the things you do and have. Linkages to brands are through colors and design elements, and/or through strategic product placement. The best-known example of this is color (Coombs, 2013). The brand Luck Strike packet design was a red bull's-eye on a green background. Research found that many women found the green color clashed with their clothes. Instead of changing the design, Edward Bernays, the father of public relations (and a nephew of Sigmund Freud), was consulted and decided to make green fashionable. The American Tobacco Company started promoting fashion events (e.g., balls, cocktail parties) using the same base green color in the design of the setting for the event and encouraged people to fit in. The green Lucky Strike pack acted as a complement to attempts to be fashionable and both green and Lucky Strike became fashionable for a time. As an aside, Bernays became embarrassed by his success in getting more women to smoke and became an antismoking activist in later life. The lesson here is clear, where the context happens to fit the product, there is less need for overt product advertising because the context itself and other people using the product in those contexts are powerful forms of promotion. It is extremely difficult if not impossible to impose legislative controls on such indirect promotion, especially if the events that are designed to promote the image (i.e., the desired fashion) are funded by legally independent third parties. In the future, plain packaging will make brand-specific relational marketing more difficult as all brands look very similar.

A remaining challenge, and one the FCTC convention of parties may develop a protocol on (an extension of the international laws), is cross-border advertising, which is occurring through satellite broadcasting and, increasingly important, the Internet, both to promote the products and to facilitate product sales.

Price and Taxation

Tobacco use is price sensitive, even though it is addictive. Increased prices (in real terms) increase cessation and reduce consumption

(Jha & Chaloupka, 1999). The best estimate of the elasticity of price is that a 10% increase in price reduces consumption by around 4% (IARC, 2011). That is, smoking is relatively inelastic, but nevertheless still somewhat sensitive to price. Moreover, its price elasticity may vary in different groups. Price appears to have a stronger effect on uptake than on consumption by existing regular users, at least in part because adolescents have less disposable income and perhaps because many of the young people are not addicted, or at least are less addicted than those who have smoked for longer. For existing smokers, reductions driven by price changes are due to some combination of cessation and reductions in consumption among continuing smokers. It should be noted that reduction in cigarettes per day does not necessarily translate into reduced consumption of nicotine (or of the accompanying tar and carbon monoxide) as each remaining cigarette could be smoked harder.

The onset effects of price increases are virtually instantaneous, making them easy to detect, but less is known about how long they are sustained if prices are kept constant in real terms.

Governments use tax on tobacco as an important source of revenue. In recent years, tobacco control advocates have pushed for tax increases as a means of controlling use. Tobacco taxes are one of the few popular taxes (even among smokers in countries where they understand how harmful it is and know they should quit). Countries with strong tobacco control policies have up to around 75% of the retail cost made up of taxes. High taxes can also have the effect of limiting tobacco companies' flexibility to use price as a marketing tool, as it creates an effective minimum price.

Price differentials between jurisdictions and high taxes do provide incentives for illicit trade, something that can have other social harms such as the institutionalization of crime and corruption, as well potentially providing access to cheaper (tax not paid) tobacco products. However, a range of other factors, particularly level of institutional corruption and quality of enforcement mechanism, are important in determining whether an illegal trade will develop and how extensive it is likely to be.

Price can lead to a reduction in tobacco use, but it can also result in changes in patterns of consumption if there are price differentials between tobacco products. For example in the UK in the last 20 years, the percentage of smokers using mainly hand-rolled tobacco (RYO) has more than doubled, particularly among women. This increase has been attributed to tax differential between factory-made (FM) and RYO cigarettes, and increased overall tax rates, coupled with easy access to duty-free rolling tobacco from continental Europe. This may have been further advanced by efforts by the tobacco industry to market it as a cool and natural choice. Similarly in Sweden, the move from smoked to smokeless tobacco use (especially among men) has been attributed to the lower cost of smokeless. That use is much less among women highlights the fact that cultural factors can diminish the motivational force of price.

High prices, while providing a greater incentive to the poor to quit, can cause problems for those unable to quit, because the costs of smoking can result in them skimping on essentials which can result in families going hungry, eating poor quality food, and/or being poorly clothed. In some countries there is evidence of this happening, while in other, more affluent countries, only the most economically disadvantaged seem to suffer in this way, and they are often able to access cheap illicit supplies. There can be no complete solution to the tobacco problem that does not attend to the needs of these groups, as smoking rates are particularly high among the most disadvantaged.

Place of Sale

Tobacco remains one of the most readily available consumer products on the market. Many countries have prohibited sales to minors, and a few, like France, limit its sale to specialist retailers; however, in most countries tobacco is still available in places where children buy sweets. Density of tobacco outlets is related to the prevalence of smoking in the area (Chuang, Cubbin, et al., 2005). Based on experience in restricting sale of other products, e.g., alcohol (Campbell, Hahn, et al., 2009), it is likely that reducing the number and type of outlets, and/or hours of purchase would reduce consumption.

Restrictions on Use: Smoke-Free Places

There has been major progress in many countries in the move to smoke-free environments. This has been motivated by the evidence on the harms of passive smoking, especially to nonsmokers. After implementation, we generally find high levels of compliance and increased support, including among smokers. The most difficult places to make smoke-free have been bars and gambling venues, two activities that are strongly associated with smoking. However, as Ireland demonstrated in 2004, totally smoke-free pubs (bars) are not only achievable but strongly supported by the community (Fong, Hyland, et al., 2006). As smoke-free policies are being implemented in countries with little history of public education about the harms (of both passive and active smoking), compliance has sometimes been a problem. In many cultures, it seems that people need to believe that a policy is in most people's interests before they comply.

Mandated smoke-free public places (including work places) lead to reduced cigarette consumption among continuing smokers and a small temporary increase in cessation (IARC, 2009). Smoke-free public places seem to have a small positive effect on people making their homes smoke-free, which, in turn, seem to be an aid to successful cessation. There is also some evidence that having smoke-free public places, particularly recreational venues like bars and clubs, inhibit uptake of smoking.

Supporting Cessation

So far this chapter has focused on environmental factors which can be influenced at a societal level, or at least at the level of lower-level jurisdictions within countries. However, these strategies can only get us so far, as we pointed out earlier. Many existing smokers remain unable to quit even in countries which have adopted most of the possible strategies to nudge their populations away from smoking. This section focuses on helping individuals who need or seek help to quit.

Cessation Aids

There is now overwhelming evidence (www.treatobacco.net) (Treatobacco.net) that a range of medications can be effective aids in smoking cessation when used for periods of around 6–12 weeks (Cahill, Stevens, et al., 2013). These medications, including nicotine itself (as nicotine replacement therapy, NRT), plus two other drugs Bupropion and Varenicline which work on different aspects of the brain's reward system, are all demonstrably effective. There is also some evidence that using medication for longer can at least delay relapse, but only during the period the drug is being used. Anecdotally, some ex-smokers continue to use NRT long term, but it is not clear whether this is necessary for preventing relapse or a choice due to presumably positive effects of use.

There is also evidence that a wide range of behavioral interventions from structured self-help manuals, through tailored self-help resources, through Quitlines to face-to-face individual or group programs, all help smokers to quit, with the success rates increasing with increased length up to several sessions (see a number of Cochrane reviews for the evidence: http://tobacco.cochrane.org/our-reviews, accessed April 28, 2014). Although limited in their ability to sustain nonsmoking, as discussed next, across the variety of modes of delivering cessation services, a common behavior change methodology has evolved over 40 years of research on smoking cessation that provides an important model for behavioral medicine in general (stated here in general terms – exemplified by how they apply to smoking cessation):

1. Reviewing reasons for the behavior change. This involves both enhancing an understanding of the cons of smoking and challenging the pros, which combine to influence the person's motivation to quit and, by challenging

the pros, is designed to reduce ambivalence about doing so.
2. Setting a concrete, specific plan for behavior change – This may involve decisions as to whether to use medications, professional guidance, through to choosing a quit date.
3. Acquiring any necessary resources, skills, and supports. For example, purchasing stop smoking medication, enrolling in a quit course, practicing relaxation skills, asking one's partner for support, and asking your smoking friends not to offer you cigarettes.
4. Identifying and developing concrete plans for addressing issues that may compromise success – identifying predictable temptations for relapse and making specific plans for avoiding or mitigating them. A useful strategy is to rehearse statements of the kind "If in a specific situation, use a particular strategy to deal with the problem" (e.g., "If I feel myself becoming stressed, I will take three long deep breaths, and leave the situation if I am still having problems.") These framing statements are known as Implementation Intentions (Gollwitzer, 1999; Gollwitzer & Sheeran, 2006) and is one promising way to improve the likelihood of appropriate actions being triggered when in problematic situations.
5. Encouraging sustained vigilance and efforts to maintain new behaviors. It is this last part that is most difficult. As in many other areas of behavioral medicine, the challenge is helping people sustain healthy behaviors.

More intensive advice-based programs are increasingly delivered via the telephone rather than face-to-face. There has also been an upsurge of use of automated advice programs, consisting of either or both tailored personalized advice on the Internet or short frequent advice messages to mobile phones. Both forms of automated intelligent programs have been shown to be effective. These are computer programs that tailor advice to the smoker based on their responses to relevant questions. They were first developed by Prochaska and associates in the early 1990s (Prochaska, DiClemente, et al., 1993) based around the Transtheoretical Model of Change, but have now expanded to be provided from other conceptual models (see www.QuitCoach.org.au for one example). More recently, interventions have been developed which send short pieces of advice via text and/or graphics to mobile phones. These are generally less tailored than those delivered via the Internet. In principle, the provision of detailed advice, coupled with the potential of providing regular prompts, and also of rapidly responding to relapse crises, should have additive effects, but while each has been shown to be effective in its own right, the evidence for additive effects is currently weak.

While both cognitive-behavioral interventions and pharmacotherapy help quitting and when combined their effects are greatest (Stead & Lancaster, 2012), all of the benefit appears to occur during the time the interventions are actually being provided, and there is little evidence of interventions having persistent effects beyond the point where they are being actively delivered (Hajek, Stead, et al., 2013). Evidence is also emerging that the factors that determine short-term success in quit attempts may be different from those that affect long-term maintenance, suggesting that different strategies may be needed to help some of those who survive the difficult early weeks to stay quit longer term. Clearly most ex-smokers already have what it takes, the challenge is to find signs of vulnerability and develop strategies to overcome them. Unfortunately, at present there are no demonstrably effective cognitive-behavioral *intervention* strategies that have been reliably shown to sustain maintenance of smoking cessation. As a result, some people have turned to a consideration of using clean forms of nicotine long term as an alternative approach to sustaining abstinence, particularly for those who find staying quit particularly difficult. We discuss this possibility in more detail in the later section "Harm Reduction and Product Regulation."

The Challenge of Getting Smokers to Quit

Earlier in the chapter, we pointed out how addictive smoking is and some of the challenges associated with successfully quitting. This section begins from that knowledge base and considers the kind of system we need to facilitate getting smokers to quit and to make the most use of effective cessation aids.

Uptake of help, particularly advice-based help, remains low, even when subsidized or free. This is probably due to a combination of beliefs that one “should be able to do it myself” and the deep ambivalence about change that characterizes tobacco use and other dependencies. It is also influenced by the way the services are provided. For example, contradicting talk about the importance of paying for a service in order to value it, free cessation assistance offered to members of a health plan, although less effective among participants, recruited sufficiently more participants to generate a greater net impact on overall numbers quitting (Curry, Grothaus, et al., 1998). Accessibility is important. In the UK, there is much greater use of face-to-face services as there is a well-organized and readily available network of services. However, in most other places, telephone-based Quitlines are generally preferred to face-to-face services, at least in part due to the convenience.

The effect of interventions is not just a matter of how effective they are when used, it is also a function of what proportion of smokers is prepared to use them in their quit attempts. As noted above, promotion of the issue in the media drives people to seek help, as does product-specific advertising. However, unless interventions are seen as desirable, the effects of promoting them will be limited. To maximize cessation requires both a population of smokers who are motivated to confront the challenge and universal access to systems that will maximize success, with such interventions being seen as desirable to use. This requires the complex mix of population strategies to support activity and aids to facilitate success.

While seeking support might seem sensible, the ambivalence that smokers feel, a belief that they should be able to just quit, coupled with a widespread distrust of both pharmaceuticals, and even more of counseling approaches, results in an over reliance on ineffective strategies and strong tendencies to avoid action as much as possible.

Ambivalence does not just affect the smoker, it affects those around them. Ambivalence toward health-enhancing change is not something most health-care providers feel comfortable dealing with. The current health-care system is focused on curing illness and generally expects its patients to be motivated to act in ways their advisers tell them will improve their health. Smokers’ ambivalence about being advised to quit is transmitted to health professionals, in part by negative reactions when they are not “ready” for the information. As a result, health professionals often avoid the issue of cessation unless it is central to the presenting problem, to both avoid feeling uncomfortable themselves and because of fears of making their patients feel uncomfortable. The tendency to avoid is further motivated by the reality that most health professionals lack the skills to help smokers and there are few systems in place for referral to sources that can assist. Recommendations by health professionals that smokers seek help are not enough to get most to act. Active referral where the person is directly put in touch with the service is needed. Active referral to Quitlines which offer a callback counseling scheme is feasible and is available in some places. It is acceptable to both smokers and health professionals and leads to more successful quitting (Borland, Balmford, et al., 2008).

Because smoking cessation involves a lifestyle change as well as overcoming a dependence, and treatments only support short- to medium-term behavior change, unless ex-smokers discover that they can cope and enjoy life at least as well as when they smoked (if not better), they remain at ongoing risk of relapse, even years after successfully quitting. For example, if ex-smokers continue to believe that smoking helps them cope with stress, they are more prone to relapse, especially when they are subject to high levels of stress (Dijkstra & Borland, 2003). Beliefs about emotional regulation appear to be the important ones, as beliefs about social and other functions of smoking do not appear to influence relapse.

This brief analysis suggests two major challenges: finding ways to confront or cut through ambivalence and that would encourage smokers to use the sort of help that will maximize their chances of success; and finding ways for health professionals to raise the issue with smokers that maximize the likelihood of action.

Smokers may come into contact with options for help in different ways (see Fig. 26.7). They may seek help directly from specialist cessation services (Quitlines and face-to-face services), perhaps motivated by strong and regularly presented antismoking messages; they may seek help from their own health-care provider who may provide it or refer them on; or they may be referred to help by other parts of the health-care system. Of these, the first is likely the main way when smoking cessation is widely promoted in the mass media and other community communication channels. However, the health-care system has obligations to do as much as it can to facilitate smoking cessation as well. We are still some way off providing all the encouragement and support many need to quit successfully. Unless we can find such strategies, we will need to consider substitution as the most attainable alternative, even though that may result in the persistence of addictive nicotine use. The upside is that there will be far fewer adverse health effects.

The Denormalization of Smoking

Smoking, being a socially embedded behavior, is subject to normative influences, which vary across cultures, and as a function of the way the society responds to the problem. In many countries today, smoking is no longer seen as socially desirable for any group in the community, and is widely accepted as being highly detrimental to health. However, in other countries it is still normative, as little effort has been put into educating the public.

Cultural differences may determine the extent to which subjective norms influence smokers' quitting behavior. In more individualistic cultures such as the USA and Australia, smokers may be more influenced by their own attitudes toward smoking than by antismoking norms, whereas in more collectivistic cultures such as in Asia, societal norms against smoking may play a greater role and somewhat different role (Hosking, Borland, et al., 2009). Religion is another cultural factor that can influence normative beliefs about smoking especially in countries where religion is central to the lives of people. Different religions or modes of their expression may lead to them influencing smoking in different ways (Yong, Hamman, et al., 2009), and they may vary in the extent to which they dominate broader societal norms (Yong, Borland, et al., 2012).

The process of changing what is normative in a social group is not something that can be simply imposed from outside. Normalization is an emergent property of the ways people think, talk, and act around a topic or activity. External agents can seed discussion with information and encourage people to challenge problematic practices, but unless the people accept the need for change, it will be resisted. Even within a society, laws that do not achieve community support are widely ignored or broken. This can be seen with some drugs that are currently illegal, such as marijuana, where in some places use is reported to be greater than for drugs like tobacco-delivered nicotine which is legally allowed.

Initially, attempts to challenge normative behaviors are often resisted, but at some point there can be a rapid transformation, and what was previously normative becomes unacceptable (Rogers, 2003). Attitudes to smoke-free policies tended to change in this way, with the change in attitudes further supported by the experience of complying with imposed bans on smoking in public places. As smokers found that they could readily comply and that they also often enjoyed the smoke-free environments, they not only complied but became supportive of the restrictions. In other words, discovering that compliance was not a major problem, then led to a virtuous cycle of increased support or, at the very least, reduced active opposition, and the new behavior patterns became rapidly normalized. Similarly, as smoking becomes denormalized it should be easier for smokers to quit, but this effect may be masked by the addictiveness of the product, meaning that the remaining smokers are more physiologically and psychologically addicted than those who have quit. If so, it would suggest that much of the quitting that occurs in relation to the reduced normativeness of smoking might be among those who were less biobehaviorally addicted.

It is notable that the progress in movement to smoke-free places has been much faster than the move away from active smoking. We think this is for two main reasons. First, societies are more active at solving problems where other people are affected (by passive smoking), than where the harm falls on the person engaging in the behavior. People are seen as having some rights to make their own choices and own mistakes as long as it does not adversely affect others. Second, we think it is partly because where people smoke is largely determined by social factors, which are relatively easy to change, while smoking is more determined by addiction and thus is more difficult to shift. Combined together, this explains why some countries have largely solved the problem of passive smoking, although it really only became an issue in the late 1980s following the publication in 1986 of the US Surgeon General's report concluding that passive smoking caused lung cancer and some other conditions. This can be contrasted with the situation with active smoking, where a similar level of scientific consensus as to its harms has been known since the early 1960s, yet it remains a big issue today. This shows that many of those addicted to smoking (via nicotine delivery) can alter their patterns of use to fit in with environmental constraints, but find it much harder to quit altogether.

Denormalization has played a central role in the decline in smoking driven by the knowledge of its harms. This can be seen by reconsidering Fig. 26.1 and noticing that the large decline in smoking in the USA started with the widespread publicity afforded by the conclusions of the 1964 US Surgeon General's report. However, the effects of knowledge do not have an instantaneous effect as do price changes, so the impact of knowledge has been hard to pick up in empirical studies that only covers a brief period. This is particularly the case now that almost everyone knows that smoking is harmful, and educational interventions are mainly reminding them of this and trying to get them to realize *how harmful* it is. That so many people continue to smoke in this denormalized climate is proof that denormalization and knowledge of themselves are not enough.

Harm Reduction and Product Regulation

The regulation of tobacco products brings us into the area of harm reduction. The main aim of tobacco product regulation is to reduce the harmfulness of the products, ideally at a population level, although most regulators tend to focus on harm to each exposed individual and tend to neglect the issue of the impacts on total population use. It is important to understand that a product that is somewhat less harmful, but used by many more people, could do more population-level harm although it does less harm, on average, to each of its users.

To understand the potential for harm reduction it is important to know the sources of harm. Although nicotine is the component of smoke that is responsible for its sustained use, it is other components that are causing the health harms. This separation of what is addictive from what is harmful raises the possibility of less harmful ways of delivering nicotine.

The tobacco industry has invested large amounts of money in attempting to develop cigarettes that are less toxic and/or carcinogenic (herein collectively referred to as toxic or toxins), while still being attractive to consumers. To date, they have failed. The first attempt was the introduction of filters. However, filters do not change the mix of chemicals much, they filter out nicotine at a similar rate to other toxins, and as smokers smoke primarily for the nicotine, they adjust and take in more of the filtered smoke, ending up with similar levels of nicotine along with the other harmful chemicals (Kozlowski & O'Connor, 2002). Filters have not provided any major reduction in cigarette harmfulness, but by giving the impression of reduced harm, may have helped allow the market to grow and thus they have been net counterproductive.

Before the evidence was in on the effects of filters, several governments set limits on the amount of tar, nicotine, and often carbon monoxide produced by cigarettes. This led to marketing opportunities to promote cigarettes which delivered lower levels of these chemicals. These were the so-called "Light" and "Mild" cigarettes. They were designed to taste less harsh and delivered lower levels of toxins when smoked by a machine with a fixed intake of smoke. The industry used filter ventilation, small holes in the paper surrounding the filter, to allow air to mix with the smoke. The industry knew what we now know, but see Kozlowski et al. (Kozlowski, Frecker, et al., 1980) who warned us at a time when we were not listening that smokers compensated for this dilution effect: they blocked some of the holes and took larger and deeper puffs. This is easier to do with the cooler, more diluted smoke, thus ending up with similar levels of inhaled toxins and the same levels of disease (including new kinds of cancer deeper in the lungs).

The FCTC mandates prohibiting the misleading use of the terms "mild" and "light" and recommends removing misleading yield measures from packaging where they had been mandated. These bans have had a limited impact (Yong, Borland, et al., 2011). Consumers experience the "lights" as slightly less harsh and interpret this reduced averseness as evidence of reduced harmfulness, helping to reduce concerns about the potential harms to them of smoking (Shiffman, Pillitteri, et al., 2001). The core problem has not been addressed, that of filter venting, and thus the problem remains.

It has become clear that there is no prospect of reducing the harmfulness of smoked tobacco to acceptable levels. The main problem is that the combustion creates new toxins, and filters have not proved selective enough to remove enough toxins to make a large difference. Currently, marketed cigarettes vary considerably in the levels of toxicants they produce (WHO, 2007). There is a moral imperative to force companies to clean up or stop producing the more toxic cigarettes, even if the net reduction in toxin load to smokers is modest. The importance of targeting harmfulness has been heightened recently with the 2014 US Surgeon General's report (U.S. Department of Health and Human Services, 2014) concluding that cigarettes may be causing more lung cancer. The most plausible culprit for this is filter venting, and thus the case for banning this engineering feature has become much stronger.

In contrast to smoked tobacco, smokeless tobacco products can be cleaned up to have low levels of toxins. As a result, some public health people and some tobacco companies have explored the potential of smokeless tobacco as a harm-reduction strategy. The Swedish experience has been important in fueling support for this strategy. Sweden's then government-owned tobacco monopoly was the first group to develop low-toxin forms of smokeless tobacco. The Swedish government allowed smokeless to be sold at a cheaper price than smoked, but until recently, allowed no health claims. In the 1970s, use of Swedish oral snuff ("snus" in Swedish) was a dying habit of old men. Use has recovered: there are now more snus users among Swedish men than smokers, among whom the smoking rate is low, indeed lower than for women where few took to snus. Epidemiological research indicates that levels of smoking-related disease are notably low in Swedish men and are largely comparable to nonsmokers for snus users. Expert panels have estimated that snus and products like it are at least 90% less harmful than cigarettes, perhaps more so (Levy, Mumford, et al., 2004; Royal College of Physicians, 2007).

One recent product development that has excited interest as a harm-reduction option is of vaporized nicotine products (VNPs). These create an aerosol containing nicotine when puffed on in a way analogous to smoking e-cigarettes (electronic cigarettes). These products vaporize nicotine in a solution of typically propylene glycol and/or glycerin using a battery-powered heater, which is switched on either manually or by starting to puff on a mouthpiece linked to the heated liquid. They are known by various names, including e-cigarettes (electronic cigarettes), and more recently, especially among those who want to differentiate them from smoking, other names such as personal vaporizers, with the behaviour called vaping. There are other similar devices being developed or in the early stages of dissemination that heat rather than burn tobacco to create the aerosol to be inhaled, and other devices that do not require heating, but release metered doses of an aerosol containing nicotine from a pressurized chamber each time the person puffs on the mouthpiece. Some VNPs look like cigarettes, but others look completely different to any smoked product. There are now a number of groups of ex-smokers who use and promote the use of VNPs as low-harm alternatives to smoking – so-called Vaper groups. The evidence to date is that VNPs are by far the most attractive alternative to smoking to date, and that they can help smokers to quit (Hartmann-Boyce et al., 2016); however, whether they are good enough to migrate most smokers away from smoking is less clear.

We know that a small percentage of ex-smokers continue to use NRT long term, and studies from Sweden show that some smokers have successfully quit by switching to smokeless tobacco, and more appear to be doing so using VNPs. Indeed, in the UK in 2013, VNPs were the most used form of drug for smoking cessation, even though they are not approved as medicines and cannot be promoted as cessation aids, and those using them were more likely to be successful than those using approved nicotine replacement products (West, Brown, & Beard, 2014).

There is currently a vigorous, and sometimes acrimonious, debate within the tobacco control community as to the appropriateness of a harm-reduction approach, rather than continuing to pursue an abolitionist agenda. Those opposed to a harm-reduction approach fall into two broad camps, those who see any form of addiction as bad and are concerned that harm-reduced products might lead to more people using nicotine-containing products. The second group is concerned about the workability of the approach and sees the possibility of just as many smokers and lots of other nicotine users, thus potentially leading to more harm (the extreme version of this concern). By contrast, those sympathetic to harm reduction (a group that includes the authors), see it as having a huge, as yet untested, potential to reduce or eliminate the most harmful form of nicotine dependence, that of smoking cigarettes, especially if it can be done in a way that minimizes the possible downsides. This means adding harm reduction onto the existing set of tobacco control strategies, not treating it as an alternative.

Taking a comprehensive population-approach perspective not only involves all of the strategies discussed above, it also requires consideration of characteristics of tobacco products that encourage and/or sustain use and the extent to which they are intrinsic to the product or are potentially removable or modifiable. Australia through its Plain Packaging legislation has already legislated to make cigarettes look less appealing, and Canada and Brazil have legislated to remove additives from tobacco, particularly flavors that make them more appealing to use, in part by tempering the naturally aversive taste of inhaled smoke. These actions should make cigarettes less attractive to novice users and should be encouraged more widely. In addition to the extent that suitable alternatives are available, it becomes much more feasible to reduce the nicotine in cigarettes, so that they become overall less satisfying and addictive. Having viable alternatives to cigarettes for delivering nicotine should mean less risk of a black market in unregulated products developing (i.e., the types of cigarettes available now). Making cigarettes less attractive and/or less addictive could thus help shift the balance toward VNPs, compensating for their current lower levels of psychologically attractiveness.

Based on all we know about addictive substances, the more potent the initial reaction to the use of the drug, the more likely it is for an addiction to develop; thus it is easier to quit current nicotine replacement products than it is for smokeless tobacco, which in turn is easier than quitting smoking (Fagerstrom & Eissenberg, 2012). If we apply this principle to VNPs, they are likely to fall in addictiveness between smokeless tobacco and cigarettes. However, technological advances in e-cigarettes are likely to result in them becoming closer to cigarettes in their capacity to deliver nicotine, and to the extent that the experience is similar to smoking should have increased potential to be acceptable substitutes for smoking. If a product was invented that was as good as smoking, then smoking would be likely to rapidly disappear as smokers do not want to die prematurely, and all other things being equal (e.g., price and availability), the problem of smoking would solve itself. Unfortunately, we are far from being in this situation at present, although we may be approaching the situation that if we were to tilt the playing field enough in favor of VNPs, we might be able to prohibit or heavily restrict cigarettes without it producing a societally unacceptably sized black market (Borland, 2013). We simply do not know where we are with current products, partly due to rapid product innovation and partly due to the paucity of good research.

It is extremely likely that if VNPs were allowed and encouraged as a cessation aid, it would increase the numbers of smokers successfully quitting even if VNPs prove no more effective as it is likely that some smokers who would not otherwise quit would use them to quit. This is likely, given the spontaneous enthusiasm some ex-smokers have shown, even to the extent of setting up Vapers clubs (as they are known) which encourage use and educate smokers on how to best use them to gain the greatest satisfaction, and thus be the best possible replacement for cigarettes.

It is likely that the more attractive the product, the greater the impact on existing smokers. However, it is also likely to be more attractive to nonsmokers, both ex-smokers who miss the experiences associated with smoking but have been able to forgo them in the face of the high risks and nonsmokers who would not otherwise have taken up smoking. That is, we are faced with the uncomfortable situation that the better the solution the greater the risks.

The evidence from Scandinavia is that the availability of snus there has led to more tobacco use, particularly among males, but snus has not been a gateway to smoking among those who would not otherwise have smoked (Foulds, Ramstrom, et al., 2003; Ramstrom & Foulds, 2006). There is increasing evidence that VNPs are attracting the interest of youth, and some unscrupulous companies are actively promoting these products to youth, but no evidence yet on whether there will be progression to smoking that would not otherwise have occurred.

We think it unlikely that use of VNPs or other low-harm nicotine products will lead to more regular smoking as youth are aware of the harms of smoking, but we acknowledge that it might lead to more experimentation with cigarettes, especially if they remain readily available. Unless it facilitates uptake of smoking, it will have a beneficial effect to the extent that it can get smokers to quit cigarettes.

At present VNPs are banned in some countries (either altogether or only if they contain nicotine), while they are allowed in others with regulators working to develop appropriate frameworks to minimize health and other risks. Thus we are facing a great natural experiment as to what contribution they can make and to what extent the fears of some will be realized. We would like to see governments that allow VNPs support extensive postimplementation research to help us most rapidly find out what their effects are on smoking, what uptake occurs among nonsmokers, and ultimately whether they are as low in harm as we would expect extrapolating from what we know about other similar products.

Conclusions and Challenges for the Future

Reducing the harm from use of a dependence-inducing substance that has been, and in many ways still is, deeply embedded in national cultures and economic activities is a complex and difficult task. No single strategy has had much potency of itself. The mix of strategies that has been used today has reduced the prevalence of cigarette use from over 40% or 50% to less than 15% of the population in the most successful countries – a remarkable public health accomplishment given its addictiveness and the need to change social, cultural, and economic climates which until recently had been supporting smoking. To make further progress is likely to require greater application of the existing known strategies as well as new strategies based on a more fundamental appraisal of the role of the tobacco industry and the marketing of tobacco products. It is becoming clear that more is required than environmental and associated policy changes leading to the denormalization of smoking, although this is an important part of the solution. We believe that there needs to be a renewed focus on biobehavioral factors. In this regard, dual-process models of psychological functioning may provide the best framework for understanding this complexity (Borland, 2014). Dual-process theories postulate two sets of factors within the individual to jointly determine behavior in conjunction with contextual (environmental) conditions. These two sets of factors are first, bottom-up, reactive, operational responding to environmental cues, and top-down, language-based, executive functions that act to arbitrate conflicts between operationally generated action tendencies and which can operate in relation to linguistically defined propositional goals and as such can apparently transcend the contingencies of the moment (Borland, 2014). Dual-process models are leading to the development of innovative new interventions based on principles of conditioning that may provide powerful new tools to modify complex resistant behavioral patterns like smoking (Wiers, Gladwin, et al., 2013). However, we need to be open to the possibility that the lure of mind-altering drugs like nicotine may be too strong to resist permanently. It may also require society to decide whether the ultimate goal of tobacco control should be the elimination of all nicotine use, or the less ambitious effective elimination of smoked tobacco as an addictive behavior and condoning the use by adults of low harm, but psychologically rewarding forms of nicotine.

Promoting Physical Activity Behavior: Interventions and Mediators

Edward McAuley, Sean P. Mullen, and Jason Fanning

Introduction

The demographic landscape of the United States is undergoing a transformative shift. As a nation, we are becoming older (Goulding, Rogers, & Smith, 2003; Center for Disease Control and Prevention, 2015a), less active (Pleis & Lucas, 2009), and more overweight/obese (Center for Disease Control and Prevention, 2010). For example, the proportion of the population aged 65 years or older is projected to increase from 12.4% in 2000 to 19.6% in 2030 (Goulding, Rogers, & Smith, 2003; Center for Disease Control and Prevention, 2015b) with the number of adults aged 65 years or older estimated to increase from nearly 35 million in 2000 to approximately 71 million in 2030. The rapidity of this trend is even more pronounced in the segment of the population aged 80 years and older. Additionally, in spite of the well-documented benefits of regular physical activity (see below), participation rates have either remained stagnant at alarmingly low levels, or have declined. Most recent estimates suggest that 21% of adults aged 18 years and older engage in regular leisure-time activity at sufficient levels of physical activity to reach public health guidelines. As one might predict, there is a consistent decline in activity with age, with only 16% of those 65 and older being inactive (Behavioral Risk Factor Surveillance System, 2013). Paralleling these levels of inactivity, not surprisingly, are the national statistics associated for overweight and obesity. Obesity levels have steadily risen in adults 20 years and older from 19.5% in 1997 to 35% in 2011–2012 (Ogden, Carroll, et al., 2014; Center for Disease Control and Prevention, 2010), and these numbers are higher for Hispanic and African American adults. It is of considerable concern that these gradient increases are also demonstrated in children and adolescents (Ogden, Carroll, et al., 2014).

These issues are not unique to the United States and similar trends have been documented internationally. European populations report comparable activity rates as the United States with only 31% of the population reporting sufficient physical activity (Sjöström, Oja, et al., 2006). Regionally, 54.1% of men and 45.3% of women from Greece are physically active (Filippidis, Tzavara, et al., 2011). In Scotland, about two-thirds of the population is failing to meet the equivalency of CDC physical activity guidelines (Physical Activity Task Force, 2005). Australian data suggests that less than 30% of adults met physical activity recommendations in 2008 (Australian Bureau of Statistics, 2009). Inoue et al. (Inoue, Murase, et al., 2009) reported

that only 21% of Japanese adults were sufficiently active.

The extent of objective physical activity data from low- to middle-income countries is less than from higher income countries, but several reports (Dugas, Harders, et al., 2010; World Health Organization, 2012) indicate that physical inactivity, especially in growing urban areas, is a problem in these countries and accounts for appreciable burden of noncommunicable disease. It is apparent, however, that among less developed countries walking (rather than moderate to vigorous physical activity) accounts for a much greater volume of exercise. This may be attributable to infrastructure and culture that supports walking as exercise and/or transportation (Bauman, Bull, et al., 2009).

Overall these health statistics paint a rather bleak picture for society at large. Advances in modern medicine, better living conditions, and environmental and worksite health improvements in developed countries all contribute to the population living to an unprecedented age. However, such increases in lifespan are accompanied by an increase in chronic health conditions such as cancer, stroke, and disability. Taken together these outcomes are likely to seriously jeopardize quality of life. Similarly, the health consequences of being overweight or obese in adults are equally deleterious. Obesity-related medical costs were estimated at $147 billion in 2008 (Finkelstein, Trogdon, et al., 2009), and this figure may increase by as much as $66 billion per year by 2030 (Wang, McPherson, et al., 2011). Obesity and overweight-related conditions in adults include heart disease, diabetes, cancer, arthritis, and a host of other conditions (Jensen, Ryan, et al., 2014). In children, obesity is associated with increases in cardiovascular risk factors, Type 2 diabetes (previously classified as an adult disease), and social discrimination (Pratt, Arteaga, & Loria, 2014; Surgeon General's Report, 2007).

It is well established in the scientific literature that physical activity plays an important role in the accrual of physical and psychological health benefits. Unfortunately, as noted earlier, participation rates across the lifespan are typically quite poor and appear to decline as we age. The present chapter provides an overview of the various approaches that have been adopted by behavioral scientists in an effort to increase adoption and maintenance of physical activity. These approaches range from center-based to home-based interventions and from media-based strategies to considerations relative to altering the built environment. We begin with a brief overview of the physical and health benefits that have been reliably associated with regular physical activity participation. We then provide an overview of the main findings derived from several different approaches to influencing physical activity and include detail on some exemplar studies. Where meta-analytic data are available, we report overall effect sizes determined across studies. We then provide a brief summary of what is known in terms of the theoretical mediators of physical activity intervention approaches reviewed and conclude by highlighting important targets for future research. Although we will not provide in-depth discussion of the topic, it is important to acknowledge a growing field of research concerned with the reduction of sitting behavior. Though clearly related to physical activity, sitting behavior is conceptually distinct, as it is independently associated with obesity, metabolic health, and mortality when controlling for physical-activity level (Matthews, George, et al., 2012). Over the last several years, researchers have identified long, unbroken bouts of sitting time, rather than total amount of sitting time, to be the most deleterious to health (Healy, Dunstan, et al., 2008). See Owen, Baumen, and Brown (2009), Van Uffelen et al. (2010), and Biswas et al. (2015) for reviews.

Physical and Psychological Benefits of Physical Activity Participation

Physical inactivity has consistently been identified as a modifiable risk factor for a host of chronic conditions including cardiovascular disease (CVD), diabetes, some cancers, disability, and compromised psychological health (Blair, Kohl III, et al., 1995; Keysor, 2003; McAuley &

Rudolph, 1995; U.S. Department of Health and Human Services, 2000; Taylor, Cable, et al., 2004a; Taylor, Brown, et al., 2004b; Warburton, Nicol, & Bredin, 2006). Indeed, CVD is the leading cause of death in the United States, where approximately 1 in 3 adults suffer from this disease (Rosamond, Flegal, et al., 2008). Numerous longitudinal, observational studies have provided convincing data that physical activity and fitness are associated with reductions in CVD and all-cause mortality (Blair, Kohl III, et al., 1989) and that this effect holds true for men (Myers, Kaykha, et al., 2004) and women (Hu, Willett, et al., 2004). Moreover, these associations appear to operate in a dose-response fashion, as those with lower activity and fitness levels have the greatest risk of premature death (Erikssen, Liestøl, et al., 1998).

Similar findings have been reported relative to physical activity as both a preventive behavior for type 2 diabetes and as a management modality for the disease (Warburton, Katzmarzyk, et al., 2007). For example, Williamson, Vinicor, and Bowman (2004) reviewed the scientific evidence from randomized controlled trials involving lifestyle intervention effects for the prevention of type 2 diabetes in high-risk individuals. Weight loss achieved through physical activity and dietary changes reduced incidence rates over a 4-year period by up to 60%. Similarly, reductions in mortality risk in those with diabetes can be brought about by relatively modest increases in physical activity (Gregg, Gerzoff, et al., 2003). Indeed, over 2.8 years, the Diabetes Prevention Program demonstrated that physical activity, and particularly weight loss achieved through physical activity, can yield a dramatic reduction in onset of type 2 diabetes (58%) (Diabetes Prevention Program Research Group, 2002).

The most consistent and well-documented associations between physical activity and cancer appear to be relative to breast cancer and colon cancer. Although the evidence has been identified as somewhat inconsistent (Ibrahim & Al-Homaidh, 2011), it has been reported that the risk reduction for breast cancer incidence ranges from 20 to 40% in favor of active versus sedentary women (Lee, 2003; Vainio, Kaaks, & Bianchini, 2002). However, whether physical activity is implicated in survival for those women with breast cancer has proven to be a contentious issue. A recent meta-analysis, Ibrahim and Al-Homaidh (2011) suggests that an inverse relationship exists between physical activity level and all-cause mortality. Specifically, prediagnosis physical activity was associated with reduced breast cancer mortality in women with a BMI <25 kg/m^2. In addition, intermediate-to-high levels of physical activity were associated with an 18% reduction in all-cause mortality. Moreover, participating in physical activity, at any level, was associated with a 30% reduction in mortality from breast cancer and 41% reduction in all-cause mortality. Wolin, Yan, Colditz, and Lee (2009) report the magnitude of risk reduction for colon cancer in a meta-analysis suggesting that being physically active affords a 24% reduction in risk and was similar for both men and women. Although it was not possible to determine the exact nature of the dose-response relationship, Wolin et al. (2009) previously reported that the equivalent of 5-6 h per week of brisk walking resulted in a 23% reduction in risk among women.

As well as having favorable and consistent effects on physical health, engaging in physical activity has been associated with a host of psychological benefits. These include reductions in anxiety (Herring, O'Connor, & Dishman, 2010; Petruzzello, Landers, et al., 1991) and depression (Phillips, Kiernan, & King, 2003; Ströhle, 2009) and enhancements in quality of life (QOL; McAuley & Morris, 2007; Rejeski & Mihalko, 2001) and cognitive function (Hillman, Erickson, & Kramer, 2008). For example, Petruzzello et al. (1991) reported that the overall effect of physical activity on anxiety was modest ($d = -.24$), and this effect was similar for both acute ($d = -.23$) and chronic activity ($d = -.25$). The effect is, however, moderated by a number of factors including exercise mode (aerobic activity, $d = -.26$; anaerobic activity, $d = -.06$). In a more recent meta-analysis, Herring et al. (2010) reported an overall change in patients with chronic illness receiving exercise as a primary treatment or as an adjuvant for nonanxiety related medical conditions. This effect was increased when exercise programs lasted up to 12 weeks, sessions were greater than 30 min in duration, and the reporting period for anxiety was greater than 1 week. Thus, the evidence suggests that the anxiolytic effects of physical activity, although modest, are quite consistent across healthy and diseased populations.

The physical activity and depression relationship has been reviewed quite extensively in meta-analytic and narrative review format. Although the consensus is that depression is reduced as a function of being physically active, this literature is plagued by methodological inconsistencies and lack of rigor (Lawlor & Hopker, 2001). However, in those studies employing true randomized designs there appears to be evidence to support the relationship (see (Phillips, Kiernan, & King, 2003), for a review). For example, randomized studies of clinically depressed patients suggest that exercise is as effective in reducing depressive symptoms, and possibly more so, than interventions such as medication, meditation, and psychotherapy (Babyak, Blumenthal, et al., 2000). As Phillips et al. (2003) state, the literature suggests that exercise may be a feasible, inexpensive, nonpharmacological option for the treatment of depression.

However, randomized trials examining aerobic exercise effects in those individuals who fall within the normal range for depressive symptoms have consistently failed to find any depression reduction effects of exercise interventions (Phillips, Kiernan, & King, 2003). A 6-month randomized trial compared the effects of aerobic (walking) and nonaerobic (stretching/toning/balance activities) on depressive symptoms in nondepressed older adults (Motl, Konopack, et al., 2005). Using latent growth analyses, they reported a small but significant decrease in symptoms at intervention end ($d = -.26$), a reduction that was maintained at 12-month ($d = -.18$) and 60-month ($d = -.29$) follow-up. This effect was not moderated by exercise condition. As previously noted, physical inactivity can lead to chronic disease, obesity, and disability, ultimately compromising QOL. It is therefore unsurprising that a considerable literature focuses on the physical activity and QOL relationship (see (McAuley & Morris, 2007; Netz, Wu, et al., 2005; Schuch, Vasconcelos-Moreno, & Fleck, 2011) for selected reviews). Although the construct of QOL has been defined and assessed in many ways, there does appear to be a consistent effect of physical activity on QOL. In a meta-analysis of the effects of physical activity on psychological well-being in older adults, Netz et al. (2005) reported an overall effect size of $d = .24$ with stronger effects for aerobic activity ($d = .29$) and moderate-intensity activity ($d = .34$). More recent examinations of this relationship have suggested that physical activity effects on more global indices of QOL (e.g., satisfaction with life) are indirect rather than direct (McAuley, Konopack, et al., 2006). In these models, physical activity is proposed to have a significant effect on more proximal physical activity outcomes such as self-efficacy (Bandura, 1986, 1997), which in turn has a direct effect on indicators of physical health status (e.g., function, disability) and mental health status (e.g., perceived stress, affect, self-esteem). These latter factors, often measured under the rubric of health-related quality of life, are proposed to be determinants of global QOL. Cross-sectional (White, Wójcicki, & McAuley, 2009) and longitudinal studies (McAuley, Morris, et al., 2007b; White, Wójcicki, & McAuley, 2012) have provided preliminary support for this pattern of relationships.

An intriguing and rapidly expanding literature focuses on the effects of physical activity and cardiovascular fitness on cognitive function (see Hillman, Erickson, & Kramer, 2008; Kramer, Erickson, & McAuley, 2008; McAuley, Kramer, & Colcombe, 2004; McAuley, Mullen, & Hillman, 2013a; Smith, Blumenthal, et al., 2010; Voss, Nagamatsu, et al., 2011 for reviews). This literature has focused primarily on older adults, given the well-established association between age and declines in cognitive processing. However, increasing attention is being paid to this association in children and adolescents (Davis & Cooper, 2011; Hillman, Pontifex, et al., 2014). Building on the findings from an extensive animal literature (e.g., (Cotman & Berchtold, 2002; van Praag, Shubert, et al., 2005), data from randomized controlled trials suggest that fitness-induced change, as a result of aerobic exercise interventions, is associated with improvements in executive function (e.g., planning, decision making, error correction, response inhibition). However, there is some debate as to the size of this effect with Colcombe and Kramer (2003) suggesting it to be moderate to large (g = .68), whereas Smith et al. (2010) report a much more modest effect (g = .12). However, it should be noted that the Smith meta-analysis included participants aged 18 years and above likely attenuating the strength of the effects reported by Colcombe and Kramer (2003), whose meta-analysis focused only on randomized controlled trials with older adults. Importantly, evidence suggests that fitness change brought about by aerobic exercise is associated with both brain structure and function (Colcombe, Kramer, et al., 2004; Kramer, Erickson, & Colcombe, 2006). Indeed, a recent study, Erickson et al. (2011) reported that a 12-month aerobic exercise intervention resulted in significant increases in the volume of the anterior hippocampus, leading to improvements in spatial working memory. Exercise training increased hippocampal volume by 2%, effectively reversing age-related loss in volume by 1–2 years. Such findings reflect a very exciting direction for exercise and well-being.

The mechanisms through which physical activity brings about these benefits are varied. For example, enhancement of domain-specific, physical activity-related self-perceptions have been implicated in improvements in quality of life and self-worth and reductions in functional limitations. Physiological benefits are believed to occur as a result of metabolic adaptations. Social benefits are enhanced through increased exposure to supportive social networks. Finally, mechanisms theorized to be at the heart of the physical activity effects on brain structure and function include increased blood-flow to the frontal cortex and up-regulation of neural growth factors (Churchill, Galvez, et al., 2002).

Taken collectively, there can be little doubt that the effects of regular physical activity on physical and psychological health are well established and our understanding of these relationships continues to grow. Unfortunately, as noted earlier, the proportion of the population meeting public health guidelines, no matter how modest, is declining or has stagnated at levels likely to have continuing serious implications for the health and well-being of the population and society. To this end, behavioral scientists have been testing an array of approaches designed to promote adoption and maintenance of physical activity. The remainder of this chapter is devoted to providing an overview of this literature.

Levels of Approach to Promoting Physical Activity

Most approaches to physical activity promotion have been conducted at the individual level, albeit in different ways. Until the turn of the millennium, the physical activity research tradition mainly involved evaluating the effectiveness of center-based interventions and features of the research setting were generally overlooked or recognized as barriers to future wide-spread dissemination. More recently, researchers have begun testing the feasibility of delivery within natural settings, such as the home and work, where features of the environment may facilitate physical activity adoption and maintenance. The most successful interventions are likely to be those that incorporate multiple levels of approach targeting individual, social, and environmental influences. The following section describes some of the advances in this area, and outlines the advantages and disadvantages of each application.

Center-Based Interventions

Much of the evidence for the efficacy of physical activity interventions has been based on behavioral interventions delivered within university and healthcare settings (for reviews, see Eakin, Glasgow, & Riley, 2000; Eden, Orleans, et al., 2002; Marcus, Williams, et al., 2006; Petrella & Lattanzio, 2002; Smith, 2004). We refer to all of these interventions as “center-based” approaches to physical activity promotion. These approaches have unique advantages, including the ability for participants to interact directly with highly trained healthcare professionals and to use specialized equipment. In addition, center-based approaches offer far greater levels of control over the intervention environments, affording more rigorous examination of specified hypotheses.

There is consistent evidence that interventions delivered within these structured environments have a positive effect on physical activity (Conn, Hafdahl, et al., 2008; Conn, Valentine, & Cooper, 2002). For example, Conn et al. (2002) applied meta-analytic procedures to examine the overall effect of 43 interventions (33,090 participants) on physical activity and to explore the moderating features of interventions that influenced effect sizes across the studies. The studies reviewed included symptomatic and asymptomatic adult samples, involved in center and home-based studies, and were limited to interventions that focused on aerobic exercise only. Conn et al. (2002) reported a modest overall effect (d = .26) of interventions for increasing physical activity and a greater effect for center-based interventions relative to home-based interventions (d = .47 vs. d =. 24). Several design features were associated with greater effect sizes including center- and group-based delivery (vs. home- and individual-based) and having a self-monitoring component (i.e., participants recorded their physical activity). In a separate meta-analysis of patient education programs for chronically ill adults, Conn and colleagues (2008) also found that effect sizes were larger for programs which featured self-monitoring components. Interestingly, their meta-analytic reviews have consistently shown that the presence or absence of cognitive modification strategies (e.g., reframing, goal-setting, decision balancing) and socially mediated strategies (e.g., modeling and support) had no moderating effect on physical activity behavior.

There is evidence to suggest that tapered intervention intensities at the end of a program can improve adherence to study protocols. An exemplar study involving a transition from center to home is the Lifestyle Interventions and Independence for Elders Pilot (LIFE-P) physical activity intervention (Fielding, Katula, et al., 2007). In the LIFE-P study, sedentary older adults were randomly assigned to an intervention condition (i.e., multicomponent center-based exercise training plus behavioral skills training) or to a health education control. The intervention condition was tapered from three sessions per week for the first 2 months, to two per week for the following 4 months, to one per week for the remaining 6 months. Participants in the intervention condition had significantly more change in self-reported physical activity from baseline to 6 and 12 months relative to participants in the control group. Also, participation in the center-based intervention for the last 6 months of the trial remained relatively high (49.8% of classes attended) given that the majority of exercises were conducted at home. Attendance rates were even higher among those who completed home-based physical activity logs (79.5% vs. 45.9%). However, it must be considered that the tapered schedule was combined with behavioral skills training leaving the possible independent contributions of each of these to future research. This intervention served as the foundation for a larger recently completed intervention of 1635 older adults with physical limitations which proved successful against major mobility disability and persistent mobility disability (Pahor, Guralnik, et al., 2014).

A recent trend has been to utilize interventions aimed at increasing physical activity while simultaneously improving other health behaviors (e.g., dietary behaviors, smoking cessation, stress management). For example, Toobert, Strycker, Glasgow, Barrera, and Angell, (2005) conducted a 6 month, multiple behavior change intervention with postmenopausal women with Type 2 diabetes, focusing on physical activity, eating patterns, stress management and social support. Participants were required to attend a 2 ½ day nonresidential retreat, followed by weekly 4-h meetings targeting each topic for 1 h. Participants were randomly assigned to either a Mediterranean Lifestyle Program (MLP) or a usual care (UC) condition. Throughout the course of the intervention, the MLP group exhibited a more favorable behavioral profile, including significantly more self-reported physical activity than the UC condition. However, in a 7-year follow-up study, Toobert, Strycker, Barrera, and Glasgow (2010) found that most of the lifestyle changes returned to pretreatment levels, including physical activity.

Center-based interventions are often expensive to maintain given the costs of equipment and personnel. Additionally, it takes substantial time to deliver these programs and to train intervention providers. There are also significant population-specific barriers that may emerge, especially for older adults, including lack of transportation to the site of the intervention (Schutzer & Graves, 2004). In fact, center-based interventions rarely involve representative samples, and this may be due to the fact that they fail to reach people outside of university environments through conventional recruitment procedures. Although there is evidence that center-based interventions are effective for increasing physical activity, at least in the short term (Marcus, Williams, et al., 2006), one particular problem is that participants often return to their preintervention physical activity levels when they are no longer receiving professional guidance. Intervention providers have taken many innovative approaches to bolster adherence to study protocols postintervention, including adding "booster strategies" (Müller-Riemenschneider, Reinhold, et al., 2008). In some studies, multiple forms of media (e.g., phone, Internet) have been used to deliver supplemental information to participants, whereas additional intervention sites (e.g., worksite, home) are also used to encourage lifestyle change within more natural environments. As we discuss later in this chapter, center-based approaches continue to be used, although integrative approaches and "booster" interventions may be more effective at facilitating long-term behavioral change.

Workplace Interventions

As behavioral scientists have come to realize, the workplace offers a unique environment in which to influence the health behaviors of large numbers of employees and their families. There are a number of reasons for this including the potential for significant reach across an extended period of time and the fact that worksite settings offer a variety of resources to encourage adoption and maintenance of physical activity. These can include corporate policy, multimedia interventions, activity-related signage, departmental teams, etc. (Pronk, 2009; Pronk & Kottke, 2009). Engaging individuals to be active in their work environment has proven to be a popular strategy for enhancing physical activity and several reviews of this literature exist (Conn, Hafdahl, et al., 2009; Engbers, van Poppel, et al., 2005; Matson-Koffman, Brownstein, et al., 2005; Proper, Koning, et al., 2003; Shephard, 1995).

Conn et al. (2009), summarizes the status of what we know about the success of workplace interventions in increasing physical activity in a recent meta-analysis in which they report a modest overall effect for worksite interventions employing an intervention and control group with post-test design (d = .21) which corresponded to a difference of 612 steps per day in favor of the intervention group over the control condition. Interestingly studies assessing fitness changes as a function of the intervention fared better with an overall effect size of d = .51. When transformed to maximal oxygen consumption this effect reflects a mean difference between groups of 3.5 mL/kg/min in favor of the intervention condition. However, it should be noted that there was considerable heterogeneity across studies. In addition, worksite physical activity interventions appeared to have effects on other work-related factors such as reduced absenteeism (d = .19), lower job stress (d = .33), and greater job satisfaction (d = .20).

Abraham and Graham-Rowe (2009) reached similar conclusions in a systematic review and random effects meta-analysis analyzing studies reporting workplace interventions between 1997 and 2007. They report the overall effect for fitness and physical activity changes as a function of such interventions to be modest (d = .20). However, the reviewers note that evidence points to more recent studies being more rigorously designed and in those studies which evaluate physical activity only interventions (as opposed to including other lifestyle change elements), the effect size for fitness change was *d* = .27. As Abraham and Graham-Rowe (2009) point out, the public health impact of such an effect, if applied across the population, could be considerable. Studies which targeted walking or step counting were more effective (*d* = .54*)* than interventions which targeted overall lifestyle changes (*d* = .14).

Like Abraham and Graham-Rowe (2009) and Conn et al. (2009), several recent systematic reviews have concluded that better designed studies of worksite physical activity promotion programs should be an important priority (Malik, Blake, & Suggs, 2014; To, Chen, et al., 2013). Still, over the last several years a number of exemplar studies have emerged that reflect a more rigorous approach to such interventions. For example, Dishman, DeJoy, Wilson, and Vandenberg (2009) evaluated the efficacy of the *Move to Improve* program; a systematic 12-week group-randomized intervention incorporating a social ecological approach to enhancing physical activity in 16 Home Depot Inc. worksites. The intervention specifically targeted organization action and goal-setting (both personal and team goals). The organizational action component consisted of endorsement and support from management, committees consisting of both management and employees to implement the intervention, group goals and incentives, and use of environmental signage as prompts to physical activity. The intervention was compared to a standard of care control group which received a health risk approval and monthly newsletters regarding the benefits of physical activity. The primary outcomes were physical activity assessed by questionnaire and daily steps assessed by pedometer.

The intervention resulted in approximate increases of 29, 24, and 50 min per week spent in moderate activity, vigorous activity, and time spent walking, respectively, compared to an approximate increase of 19 min in each for the control group. Intervention participants also increased their pedometer steps to greater than 9000 per day by week 5. Further analyses examined the extent to which participants met public health guidelines for physical activity. At baseline, about a quarter (24%) of control participants met recommended levels of activity as compared to 31% of the intervention condition. Whereas the control condition did not change across the 12-week period, over half (51%) of the intervention condition met the guidelines at study end. Thus, the *Move to Improve* intervention, combining organizational action and both individual and team goal-setting, appears to reflect an encouraging, well-designed, and efficacious intervention for promoting worksite physical activity participation.

Warren, Maley, Sugarwala, Wells, and Devine (2010) reported findings from *Small Steps are Easier Together,* a study designed to improve walking in women in rural worksites. The target population is of importance given that lower income, rural women are the least likely segment of the population to meet physical activity recommendations. The 10-week intervention incorporated local support from cooperative extension educators, locally determined behavior change strategies, goal-setting, online monitoring of walking progress, and e-mail support and feedback. Pedometer step counts were the primary outcome measure. Findings indicated significant increases in weekly steps for every week beyond baseline ranging from 24.9% to 45.8% increases; however, daily steps on average did not meet public health guidelines (M = 7342), although the average weekly increase represents approximately 90 added minutes of walking per week. Although smaller in scope than the Dishman et al. (2009) study, these findings attest further to the efficacy of more social ecological approaches to enhancing physical activity in worksites.

With few exceptions, the studies examining worksite intervention effects on physical activity have restricted the length on their interventions to 12 weeks or less (e.g., Chan, Ryan, & Tudor-Locke, 2004; Dishman, DeJoy, et al., 2009; Gilson, McKenna, et al., 2007) and there have been calls for implementing longer interventions to determine whether effects are maintained beyond the 10–12-week period (De Cocker, De Bourdeaudhuij, & Cardon, 2009; Malik, Blake,

& Suggs, 2014; To, Chen, et al., 2013; Warren, Maley, et al., 2010). De Cocker et al. (2009) conducted a 20-week quasi-experimental intervention with a social services company in Ghent, Belgium. Participants in the intervention worksite were provided with educational materials, a pedometer, e-mail information and tips on a weekly basis, social support via a worksite step competition, goals, and promotion of staircase use and walking circuits. The comparison worksite participated in baseline and follow-up assessments only. Physical activity, as the primary outcome was assessed by questionnaire and step counts.

Interestingly, in contrast to other studies in this area, De Cocker et al. (2009) reported an overall, nonsignificant ($p = .07$) decline in mean steps per day. However, there were significantly different decreases between conditions with the control worksite having a twofold greater decrease in daily steps (−1389) than did the intervention condition (−618). There was no significant change in self-reported physical activity overall, and the two conditions did not differ significantly. At first glance, one might consider that this intervention had the opposite effect of what had been intended. However, the findings need to be considered in the context of a seasonal effect whereby the intervention began at the end of summer (September) and concluded in winter (February). Therefore, one might argue that although the intervention failed to increase physical activity across the 20-week period, it potentially attenuated the greater declines that were exhibited by participants in the control condition.

It appears that the majority of interventions designed to improve physical activity behavior in worksite populations are moderately successful in the short term, but it remains to be determined whether these effects can be maintained. The methodological rigor of many of worksite physical activity studies has been criticized (Conn, Hafdahl, et al., 2009; Malik, Blake, & Suggs, 2014; To, Chen, et al., 2013), yet some studies, while continuing to embrace social ecological approaches, have strengthened the rigor of their designs (e.g., Dishman, DeJoy, et al., 2009). Using social ecological approaches to change physical activity behavior allows individual worksites to tailor the intervention to their site to maximize success. Unfortunately, this type of design does not lend itself well to identifying which strategies are the "active ingredients" for change. However, they do have the distinct advantage of including input and support from all constituents involved in the intervention.

Clearly, worksite interventions have numerous advantages which, if effectively harnessed could have considerable public health impact in the future. As Pronk and Kottke (2009) and others have noted, the workplace is an arena where the promotion of physical activity initiatives can be delivered to large numbers of people, on a repeated basis, over long periods of time. The literature is encouraging in that there appears to be a consistent effect of worksite interventions increasing physical activity and related outcomes. The effect appears stronger in well-controlled studies. Continued efforts are needed to refine interventions, integrate successful interventions into best practice approaches to health promotion, and, where possible, compare the efficacy and effectiveness of selected intervention components (Dishman, Oldenburg, et al., 1998).

The same properties that make the workplace appealing as a venue for physical activity intervention make it an important point of intervention for the reduction of sitting behavior. Unfortunately, technological advancements have made unbroken bouts of activity ubiquitous in the workplace (Healy, Dunstan, et al., 2008; Owen, Healy, et al., 2010): Some estimates indicate that many employees spend more than 75% of their time seated, and much of this is in bouts of at least 30 min (Evans, Fawole, et al., 2012). Healy and colleagues (2013) implemented a 4-week multicomponent intervention aimed at decreasing workplace sitting. The research team worked with those in the workplace to develop strategies to reduce sitting. At the environmental level, workstations were installed that allowed individuals to easily alternate between seated and standing positions. Finally, each participant underwent a 30-minute face-to-face consultation with health coaches to identify various behavior change strategies, and these were followed by weekly telephone calls. When compared with a control condition, those that received the intervention decreased the amount of time spent sitting by 2 h, and increased the time spent standing by 2 h. Additionally, the intervention condition had two more transitions from a seated to a standing position per hour, and one less hour per day of prolonged sitting time. These early findings are promising, but much like workplace interventions for improving physical activity, research using longer intervention periods is warranted.

Home-Based Interventions

Home-based interventions offer an alternative intervention approach to overcoming common barriers to center-based research such as having to travel to a facility or scheduling difficulties. Delivering intervention materials in-home provides the individual with a safe, convenient exercise environment. In a summary of home-based physical activity interventions for middle-aged and older adults, Atienza (2001) stated that those interventions that targeted moderate to vigorous physical activity improved physical functioning in normal and special populations (e.g., those with COPD, arthritis) alike. Unfortunately, at the time, few studies addressed the need to maintain physical activity postintervention. Additionally, poor adherence was common among trials yielding null effects, possibly due to the lack of researcher supervision. However, a few trials have maintained contact with participants, thereby increasing adherence, and yielding stronger effect sizes.

In one such study, King, Haskell, Taylor, Kraemer, and DeBusk (1991) maintained contact with participants in a home-based intervention via telephone calls during a 1-year randomized controlled trial. They compared high-intensity group-based training, high-intensity home-based training, low-intensity home-based training, and an assessment-only control. At month 6 and month 12, both home-based conditions reported significantly higher adherence rates than did the group-based condition (78.7% ± 33.9%, 75.1% ± 31.8%, and 52.6% ± 29.9% respectively). Cox, Burke, Gorely, Beilin, and Puddey (2003) used a two arm design comparing the effects of a center-based exercise program to a home-based program with adult Australian women. In the center-initiated arm, participants attended regular exercise sessions three times per week for 6 months followed by 12 months of home-based exercise. The second arm exercised at home for the duration of the 18-month program. At each time point, adherence rates were higher among participants in the center-based condition. More recently, McAuley and colleagues delivered a 6-month progressive exercise program targeting flexibility, strength, and balance designed to be delivered in the home (McAuley, Wójcicki, et al., 2012). Those randomized into the intervention condition received six exercise sessions delivered via digital video disks (i.e., digital versatile disc, DVD), and were encouraged to use each of the six sessions at least three times per week for 1 month. Those in the control condition received a commercial healthy aging DVD. Both groups received telephone support calls from the research staff with the same frequency and duration. Individuals that received the intervention reported higher levels of physical activity (Gothe, Wójcicki, et al., 2014) and improved physical function and quality of life (McAuley, Wójcicki, et al., 2013b) at the end of the 6-month intervention, and enhanced physical function was maintained after 6 months postintervention (Wójcicki, Fanning, et al., 2014a).

Clearly within the context of prescribed activity programs, home-based interventions appear effective. However, as Atienza (2001) noted, engaging individuals in physical activity postintervention remains an issue. In response, some investigators have chosen to focus on the accumulation of physical activity within daily life. These “lifestyle” interventions are similar to home-based interventions in that both seek to provide convenient physical activity that avoids common barriers; however, they are typically less structured than home-based interventions, encouraging participants to self-select activities that can be accumulated throughout the day (e.g., walking to the bus stop, using stairs rather than taking elevators). Behavioral and environmental cues, such as signage prompting stair use or educational sessions teaching behavioral skills, aid in incorporating these activities into daily life. For example, Opdenacker, Boen, Coorevits, and Delecluse (2008) conducted a 2-year study in which they randomly assigned older adult participants to a structured exercise intervention, a lifestyle intervention, or a standard care control group. Participants in the lifestyle group attended an educational session in which the research staff taught behavioral strategies, supplied participants with a pedometer, and information and brochures on various forms of exercise and active transportation. These individuals then met with an instructor, receiving a set of exercises tailored to their preferences. The staff maintained contact with "booster calls" once or twice each month. The structured exercise intervention met three times per week, completing 60–90 min of endurance, strength, flexibility, and balance training. After 1 year, participants in both groups increased physical activity significantly relative to control. However, only the lifestyle group maintained daily steps and active transportation after 2 years; the structured exercise group showed no differences in step counts compared to the control. By integrating physical activity into daily routines, participants were successful in maintaining an active lifestyle 1 year postintervention.

These comparative studies help to evaluate the efficacy of various interventions, allowing investigators to identify which are most effective in the initiation and maintenance of physical activity behavior. In a landmark 2-year study, Dunn et al. (1999) compared a typical structured (i.e., center-based) intervention to a lifestyle intervention. During the first 6 months, the structured group attended three to five sessions of exercise each week. For the remaining 18 months, participants met quarterly to participate in group activities. The lifestyle group was instructed to accumulate 30 min of moderate-intensity physical activity on most days of the week for the first 6 months. They also met weekly in a classroom format to learn behavioral skills (e.g., problem-solving) during this time, meeting monthly for the remaining 18 months. Both groups significantly increased energy expenditure at 2 years; however, the lifestyle group increased primarily in energy spent in moderate-intensity exercise, in contrast to the structured group which primarily increased energy spent in vigorous intensity exercise. The authors note that for those individuals whose perceived barriers to exercise might include lack of time, lack of access to facilities, or a dislike of vigorous activity, lifestyle interventions are more efficacious than more structured trials. Additionally, the lifestyle group was significantly more cost-effective, an important consideration often ignored in physical activity intervention studies.

Overall, the evidence suggests that home-based interventions are effective for increasing physical activity whether they are delivered as stand-alone interventions or in combination with other approaches. It should also be noted that home-delivered interventions have been found to be more cost-effective than structured exercise programs (e.g., Kahn, Ramsey, et al., 2002). However, further research efforts are needed to determine whether and how intervention effects might be maintained without professional guidance. The success of home-based programs may be due to participants feeling more comfortable at home, as well as providing a viable alternative to center-based approaches to promoting physical activity in certain populations. For instance, some individuals may have difficulty attending programs conducted at larger facilities due to functional limitations, whereas others may simply have a strong preference to exercise alone. Tailored information with constructive and motivational feedback also appears to facilitate adherence at home (Artinian, Fletcher, et al., 2010; Lustria, Cortese, et al., 2009).

Phone-Based and Print-Based Interventions

Telephones have been used both as a sole delivery method to promote physical activity and in conjunction with other methods, such as printed materials (e.g., newsletters) which are mailed to participants. Telephone contact has been used for well over two decades and found to be effective for increasing self-reported and objectively measured physical activity (Castro & King, 2002). There are unique advantages to these media-based methods, including overcoming barriers such as geographic distance and travel time for participants. Phone and mail-delivered interventions also increase time efficiency for intervention providers. Such methods may be applied as primary interventions alone or together, or delivered as separate "booster strategies" to supplement other interventions.

In Castro and King's (2002) review of telephone-assisted counseling interventions, they found consistent evidence that these approaches are more effective than standard care. They also appear to be equally effective for increasing physical activity in both healthy and special populations. Castro and King (2002) suggested that including a telephone-counseling component within other physical activity interventions may facilitate adherence. Indeed, Dishman and Buckworth's (1996) review of physical activity interventions suggested that involving some form of media-based delivery (i.e., print, telephone) was associated with greater effects on increasing physical activity than face-to-face interventions. In a review of tailored print interventions, 7 of 12 studies reported positive effects on physical activity 3–18 months postintervention (Short, James, et al., 2011). These effects may be a function of such approaches being perceived as more personalized, as Napolitano and Marcus (2002) reported that participants who received personalized and motivationally matched materials had greater levels of physical activity than participants who received more generic information.

There is also evidence to suggest that print and telephone interventions are effective methods for increasing physical activity without any additional supervised or structured intervention. Marcus and colleagues (2007) compared these two intervention methods in a 12-month randomized controlled trial. Participants receiving telephone calls (*M* duration = 13 min) and printed materials (i.e., feedback, manuals, and tip sheets) showed an increase in self-reported physical activity at 6 months relative to the control group. At 12 months, participants receiving printed materials reported significantly more minutes spent engaging in physical activity than those receiving phone calls. Additionally, the print-based group was three and five times more likely to achieve 150 min of physical activity at 6 and 12 months, respectively, relative to the control group. The telephone only condition reported identical levels of physical activity to the print condition at 6 months, but no differences from the control group at 12 months.

Interestingly, Humpel, Marshall, Iverson, Leslie, and Owen (2004) reported that printed materials with and without follow-up phone calls were equally effective at increasing self-reported walking behavior after 3 weeks, but a higher percentage of participants reported reading the brochures in the mail plus phone intervention. When used as a "booster strategy," telephone counseling and print-delivered materials may be even more effective. For example, following 2 months of weekly physical activity classes, sedentary, low-income women, were randomly assigned to receive physical activity telephone counseling plus printed newsletters, or newsletters only (Albright, Pruitt, et al., 2005). After 10 months, participants in the phone plus print condition showed significantly greater energy expenditure compared to the group who received newsletters only.

Although print and telephone approaches have been shown to be fairly consistent methods for increasing physical activity, there are some inconsistencies in reported effects of these interventions. For example, Greaney et al. (2008) randomly assigned older adults to either a combined phone and print-based intervention or a contact-control group. The intervention included a manual detailing exercise benefits, guidelines and safety, newsletters, a multipage report with individual and normative feedback based on assessments, and three coaching calls. After 12 months, no significant increase in self-reported physical activity was found. In a similar 12-month study, with diabetic and hypertensive patients, Eakin, Reeves, Winkler, Lawler, and Owen (2010) compared a telephone-counseling condition with "usual care" (i.e., primary care visits). Both groups received feedback on assessments by mail, but the telephone group also received counseling, a pedometer, and a workbook with information on physical activity and healthy eating. At 12 months, both groups increased self-reported physical activity and also fruit and vegetable intake but exhibited a declining trend at 18-month follow-up.

Eakin and colleagues (2010) suggested that telephone counseling may be most effective in changing behavior if it is the sole delivery method or if it is used as a follow-up treatment after a more intensive mode of intervention delivery. Alternatively, longer-lasting effects may have resulted from titrated person-to-person contact. In an evaluation of TeleWalk, a telephone-counseling program designed to increase walking behavior among older adults (Kolt, Oliver, et al., 2006), participants indicated that both the counselor and printed materials encouraged them to be physically active, and 14% wanted to be paired up with others of similar ability who lived within the same neighborhood. In other words, transitioning from less contact with professionals to more face-to-face contact with supportive community members may be necessary to maintain the positive effect of these programs.

An important trend in communication over the last decade has been the movement away from dedicated landline telephone use. According to CDC (Center for Disease Control and Prevention, 2014) data and PEW (Smith, 2015) estimates, between 43% and 46.5% of adults in the United States live in a wireless-only household (i.e., do not use landline telephones). Global cellular phone adoption is consistent with these trends and text messaging via short message service (SMS) is the most widely used feature on cell phones. These trends may offer an important advantage to those attempting to influence health behavior, as voice and individualized text content can be provided in any location, and indeed researchers have begun to test these features. Fanning, Mullen, and McAuley (2012) published a meta-analysis of the effects of mobile device-delivered interventions on physical activity. The majority of the studies included involved text messaging, and there was a significant moderate effect (g = .54 [95% CI = .17 to .91]) on physical activity outcomes, indicating that this is may be an effective method for influencing behavior. Note that intervention designs utilizing smartphone devices is discussed in the following section.

In summary, it appears phone and print-based interventions are effective for increasing physical activity behavior among adults, although further work is necessary to determine their long-term impact. Phone-based approaches are likely to be more cost-effective, particularly for large-scale interventions, compared to mailing printed materials or conducting onsite interventions (e.g., center, work), as printing and postage costs, and personnel fees grow exponentially with increases in sample size. However, there is the potential for nontailored, telephone and mailed materials to be perceived as impersonal (Napolitano & Marcus, 2002). As tailored interventions grow in popularity (see Short, James, et al., 2011) and coupled with the increasing capabilities of SMS via cellular phones, there is exciting potential for information to be highly individualized, delivered with increasing regularity, and to be accessible on-demand (e.g., Hurling, Catt, et al., 2007).

Computer and Internet-Based Interventions

In the last decade, advances in Internet technology have allowed users to interact with website content, to generate and share text and video, and to receive instantaneous customized feedback (Vandelanotte, Spathonis, et al., 2007). Additionally, Internet accessibility has increased dramatically. From 2000 to 2014, adult Internet access in the United States increased from 46% to 87% (Perrin & Duggan, 2015). Internet access continues to rise internationally as well, with approximately 40% of the global population having Internet access and use has increased by approximately one billion individuals since 2010 (Internet Live Stats, 2014). This trend has been driven in large part by increasing access to the web via mobile phones. In the United States, 63% of all mobile phone users access the Internet with their phone, and 34% of all Internet users access the Internet solely by their phone (Smith, 2015). Altogether, improvements in Internet accessibility should contribute to an extended reach of intervention content to nearly any location with larger, more representative samples.

Webb, Joseph, Yardley, and Michie (2010) conducted a meta-analysis, evaluating the success of Internet interventions for changing a host of health behaviors including physical activity. They reported a small positive mean effect for those studies specifically addressing physical activity ($d = 0.24$); however, there was substantial heterogeneity across studies. Additionally, they reported a small effect for those studies using theory to guide selection or development of behavioral techniques ($d = 0.19$) and a stronger effect for studies using theory to select participants ($d = 0.33$) across all health behaviors. Unfortunately, the authors failed to provide the corresponding effects for individual health behaviors such as physical activity. In a comprehensive review by Joseph et al. (2014), 44 out of 72 (61.1%) Internet-based interventions had positive effects on physical activity. The majority of these were theory-based (68%) but similar to the Webb et al. (2010) meta-analysis, there was considerable heterogeneity in study design (e.g., intervention durations lasted 2 weeks to 13 months). Consequently, it is difficult to determine the extent to which individual theories offer promise for guiding the design and implementation of Internet interventions for physical activity. Results of a systematic review conducted by Joseph and colleagues (2014) indicate that theory-based, Internet-delivered RCTs have become more common in recent years; however, they found that the use of behavioral theory did not lead to better outcomes in the included studies. The researchers posit that this may be due to the manner in which the studies target important theoretical constructs.

The ability to provide instantaneous, automatically generated and individualized feedback is one of the unique and appealing features of Internet interventions (Marcus, Ciccolo, & Sciamanna, 2009; Wanner, Martin-Diener, et al., 2009). Indeed, these tend to be more effective at increasing physical activity relative to nontailored interventions (De Vries, Kremers, et al., 2008; Ogilvie, Foster, et al., 2007). In a meta-analysis of computer-tailored interventions to promote health behavior change, Krebs, Prochaska, and Rossi (2010) found a modest effect ($d = 0.16$) for interventions that included physical activity outcomes, with 43% of participants adherent to physical activity recommendations at follow-up as compared to 34% who received nontailored interventions. It is, however, important to consider the content of the feedback. In a 3-month study, Slootmaker, Chinapaw, Schuit, Seidell, and Van Mechelen (2009) provided Dutch office-workers with an accelerometer and access to the study website where participants could upload activity data, plan and evaluate activity relative to their goals, and receive feedback customized to these goals. The intervention, however, was unsuccessful at increasing physical activity levels, and the authors noted that only a small proportion of the participants (39%) found the content of the feedback useful or appealing. Internet-delivered interventions are able to provide personalized content and feedback that previously required face-to-face interaction (Kroeze, Werkman, & Brug, 2006), thus creating a customized program to the participant, and reduced hours for research staff. However, these findings underscore the fact that creating content that is relevant to the individual is necessary to realize these benefits.

Internet interventions may be particularly useful for promoting physical activity in those individuals with physical or mental health concerns. Mailey et al. (2010) used a 10-week Internet intervention to increase physical activity in college students receiving mental health counseling. Participants in the intervention group were given access to a website providing information on the benefits of physical activity and strategies for maintaining physical activity behavior. Additionally, participants met with activity counselors on two occasions to set goals and outcome expectations and to assess progress and discuss barriers. The control group received usual care relative to mental health counseling. The researchers reported a significant effect for increased activity in the intervention group relative to control (*d* = 0.68 and *d* = 0.05 respectively). A process evaluation suggested that participants desired a higher level of interaction with the website, a preference that is line with recent recommendations to design more interactive, dynamic user interfaces (Glasgow, 2009). Finally, Motl, Dlugonski, Wojcicki, McAuley, and Mohr (2011) adapted the Internet intervention developed by Mailey et al. (2010) for individuals with relapse-remitting multiple sclerosis (MS). They found a significant increase in physical activity in the intervention group (*d* = 0.72) as compared with control (*d* = 0.04).

In recent years, some researchers have sought to incorporate relatively new technologies, including popular social media platforms, e.g., Facebook, Twitter (Cavallo, Tate, et al., 2012; Wójcicki, Grigsby-Toussaint, et al., 2014b), and smartphone-based applications (apps), in behavioral interventions. One particularly interesting feature of both technologies is their broad adoption and ubiquity within the daily lives of many individuals. For example, 1.4 billion individuals used Facebook on a monthly basis in 2014, and daily users numbered nearly 900 million (Facebook, 2015). Regarding Twitter, in 2015 monthly users numbered greater than 288 million, and roughly 500 million tweets are sent each day (Twitter, https:/twitter.com/). Similarly, smartphone apps have become a daily staple for many individuals. As of the third quarter of 2013, adults in the United States spent more than 30 h per month with their smartphone apps, an increase from 18 h per month in the fourth quarter of 2011 (Nielsen, 2014). Such broad reach may allow researchers to better disseminate evidence-based health interventions that include elements that would otherwise require a visit to the research center, such as one-on-one counseling (e.g., Alley, Jennings, et al., 2014), targeted and thematic group-based discussions (e.g., Wójcicki, Grigsby-Toussaint, et al., 2014b) and highly tailored instantaneous feedback (Glynn, Hayes, et al., 2014). Still, like any emerging trend, it is important that practitioners continue to evaluate the use of these platforms to determine which features are most effective. Conroy and colleagues (2014) underscored this point in their review of commercial physical activity smartphone apps that had received top consumer ratings. The authors found that evidence-based behavior change techniques were not common in these apps, and users may have to interact with multiple apps concurrently to initiate and maintain behavior change.

In addition to identifying effective features of emerging technologies, researchers have had difficulty designing, funding, conducting, and publishing research in the face of the rapid evolution of consumer technologies (Glasgow, Phillips, & Sanchez, 2014; Riley, Glasgow, et al., 2013). Some estimates indicate that this research cycle often takes 7 years to complete (Riley, Glasgow, et al., 2013). Accordingly, a study published in 2014 is likely to have been conceptualized the same year that the first iteration of the Apple iPhone was released. It has, therefore, been suggested that research methodologies adapt to allow for more rapid evaluation and publication (see Boudreaux, Waring, et al., 2014; Riley, Glasgow, et al., 2013). Doing so will provide essential data for behavioral scientists and practitioners who wish to replicate and refine activity-enhancing features.

Environmental Influences on Physical Activity

It is well-recognized that in order to reverse declining or consistently low physical activity rates, it is important to identify those correlates of activity that are most amenable to change. To this end, most interventions have relied upon underlying theoretical approaches that emphasize individual level change variables. There have been several important reviews of this literature with Humpel, Owen, and Leslie (2002) identifying 19 early studies examining the relationship between physical activity and five categories of subjective and objectively assessed environment. These early studies suggested that certain elements of facility accessibility (e.g., cycle paths, access to local parks), opportunities for being active (e.g., home equipment, local area opportunities for physical activity), safety (e.g., neighborhoods safe from crime), and aesthetics (e.g., enjoyable scenery) all had weak to modest associations with physical activity participation.

Wendel Vos, Droomers, Kremers, Brug, and Van Lenthe (2007) have made the case that identifying those environmental factors that facilitate and impede physical activity is necessary, if promoting physical activity at the local and national levels is an important public health goal. They systematically reviewed 47 studies conducted between 1989 and 2004 primarily in the United States and Australia. They used the ANGELO framework (Swinburn, Egger, & Raza, 1999) to group environmental influences along physical (i.e., what is available for physical activity), sociocultural (i.e., attitudes and beliefs of the community/society), economic (i.e., cost of health behavior), and political (i.e., the regulations and rules that influence physical activity) environments. Using a minimum of three records for each class of environment, evidence was considered "convincing" if more than half of the records for each environmental category reported a significant association in one direction and a "possible" association was reflected by 40–50% of the records reporting a significant association in the same direction. Further, they examined these associations from the perspective of general, moderate, and vigorous activity; a sedentary lifestyle; commuting activities; bicycling; and walking.

Their findings indicated that 75% of the records within the review reported no associations with physical activity suggesting that environmental characteristics are less important to physical activity than has been argued in the literature. Alternatively, it could be that the constructs were inappropriately defined and/or measured (Wendel Vos, Droomers, et al., 2007). No evidence was found for relationships between economic environment and physical activity. Relative to each of the classes of physical activity behavior, findings were mixed. For example, only social support (sociocultural environment) was positively associated with general physical activity whereas there was no evidence at all for any environmental category as a correlate of either a sedentary lifestyle or moderate activity. Relative to vigorous activity, there was convincing evidence for access to physical activity equipment and social support and possible support for the convenience of facilities. When vigorous and moderate activity were combined, there was convincing support for social support and having someone to exercise with and a possible association with recreation facility accessibility and the availability of trails for activity. This latter correlate was the only environmental factor associated with activity for transport and no reliable environmental correlates were identified for bicycling. Additionally, there was supportive evidence for social-environmental determinants (i.e., having someone to be active with and having social support) being associated walking. A possible association was reported between walking and the availability of sidewalks.

The consensus from reviews such as those summarized above is that the relationship between the built environment and physical activity is promising (Humpel, Owen, & Leslie, 2002) but that more evidence is needed to determine the efficacy of environmental influences in changing this complex behavior (Giles-Corti & King, 2009). Indeed, a number of authors have noted that, if environmental determinants are to be effective in engendering policy change, then it is incumbent on the scientific community to provide evidence based upon intervention studies (Humpel, Owen, & Leslie, 2002; Sallis, Owen, & Fotheringham, 2000). With that in mind, we now provide an overview of two interventions for enhancing physical activity by changing the environment.

Nicoll and Zimring (2009) adopted an innovative approach to improving stair climbing by designing an office building with "skip-stop" elevators. The California Department of Transportation building in Los Angeles is comprised of two vertical circulation cores; one core has main elevators for able-bodies users which stop at every third floor (skip-stop) and an American Disabilities Act compliant elevator which stops at every floor and is accessed by a security pass. The other core had six traditional elevators which stopped at every floor. In addition, the "skip-stop" core has an adjacent open and aesthetically pleasing staircase between floors. This intervention core was contrasted with the other building core where the elevator stopped at every floor with an enclosed fire exit stairwell. Stair use was assessed over a 24-week period using infrared monitors for the skip-stop stairs and access reports from card readers on the traditional enclosed stairs. The results showed a 33-fold greater use of stairs in the skip-stop core than in the traditional core. Although it may be difficult to generalize these findings, they certainly represent a promising architectural approach to modifying existing and building new structures that would encourage stair use in both industrial and residential buildings. As the authors note, current elevators can be reprogrammed, stairwells can be open access, and accommodations can be made for persons with disabilities to permit elevator access on any floor.

Whether retrofitting a neighborhood to provide more connectivity by building an urban greenway/trail has an impact on physical activity was recently investigated by Fitzhugh, Bassett Jr, and Evans (2010). In this quasi-experimental study, physical activity at the neighborhood and school level in a retrofitted intervention neighborhood was compared with two control neighborhoods matched on socioeconomic parameters. Direct observation of physical activity was conducted at baseline and then 14 months later after completion of an urban greenway/trail in the intervention neighborhood. Physical activity counts increased significantly in the experimental condition across the intervention period whereas the activity counts in the two control neighborhoods declined significantly across the same period. There were no significant changes in active transport to school activity across the period in either the intervention or control conditions. However, control neighborhoods at both baseline and postintervention had higher levels of active transport to school activity, and this was significant at follow-up. It is encouraging that once again, in a study that adopts more stringent methods and design, it appears that modifying the built environment can have positive effects on physical activity behavior.

In conclusion, there appears to be a wealth of cross-sectional data suggesting modest associations between the built environment and physical activity behavior. Also, aggregation of multiple small effects can lead to substantial public health gain (Jeffery, 1989). However, only a few rigorously designed, prospective studies of this relationship exist. Moreover, it is important to keep in mind that the built environment-physical activity relationship constitutes only one aspect of the social ecological model. Indeed such models are founded on the premise that behavior change emerges from influences at the individual, sociocultural, physical environment, and policy levels (Sallis, Cervero, et al., 2006). Thus, a focus solely on the built environment as a determinant of physical activity is as inconsistent with the ecological model as a focus exclusively on intraindividual factors (Satariano & McAuley, 2003).

Understanding Intervention Effects on Physical Activity: Key Constructs and Processes

Understanding why interventions do or do not influence physical activity behavior is crucial to effectively bringing successful interventions to scale. This can be achieved by effectively designing interventions that capitalize on known and consistent relationships with key theoretical processes and mediators. Unfortunately, much of the physical activity literature examining theoretical associations has been cross-sectional, and true tests of the intervention-mediator-physical activity effect have been scarce (Rhodes & Pfaeffli, 2010). Moreover, the focus of much of this literature has been on individual level factors (i.e., attitudes, expectations, intentions), although more recent endeavors have adopted multilevel approaches. Clearly, progress in understanding this complex health behavior will come from studying neither individual or environmental levels alone but from an integrated approach. In this section, we present a brief overview of factors that appear to underlie physical activity behavior change.

Individual Level Factors and Processes

Although there are a host of individual level correlates of physical activity, we have restricted our discussion to the role played by individual expectations, as they are perhaps the most often studied factor in this literature. One important type of expectations is self-efficacy, a central component of Bandura's (1986, 1997) social cognitive theory (SCT). Self-efficacy expectations reflect one's beliefs in his or her ability to successfully carry out a course of action (Bandura, 1997). Such perceptions influence the activities in which individuals choose to engage, the amount of effort they will invest in those activities, and the extent to which they will persist when they encounter barriers and/or failures. Self-efficacy has been consistently identified as a determinant of an array of health behaviors (Bandura, 1997) including physical activity with evidence to suggest that it is both an antecedent and a consequence of this health behavior (McAuley & Blissmer, 2000).

McAuley and his colleagues (2010; McAuley & Mihalko, 1998) have observed that in several interventions, self-efficacy has actually declined across the time course of the trial. Thus, baseline measures may be artificially inflated, possibly obscuring any mediating effect of self-efficacy on physical activity. They propose that inactive adults entering exercise interventions may not have the appropriate previous experiences to formulate accurate efficacy expectations and, therefore, overestimate their capabilities at baseline. Furthermore, as they become exposed to the intervention they recalibrate their personal efficacy. Additionally, they suggest that not all efficacy measures might be expected to have similar trajectories (McAuley, Mailey, et al., 2010). For example, measures which assess self-efficacy to overcome barriers or to adhere to exercise prescriptions over time may not fare as well as those measures which assess confidence to complete progressive gradations of specific tasks (e.g., walking further or longer). Indeed, Rhodes and Pfaeffli (2010) noted that of the SCT studies that they reviewed, only Blanchard et al. (2007) conducted mediator analyses and found a mediating effect for task-related self-efficacy but not barrier efficacy.

To examine whether trajectories of self-efficacy measures differentially changed across time, McAuley et al. (2010) examined four different efficacy measures across a 12-month exercise trial. Using latent growth curve and latent class analyses, they reported that baseline efficacy measures declined significantly after 3 weeks into the trial and then increased significantly at 6 months before declining to baseline levels at 12 months. These findings suggest that efficacy-boosting strategies may need to be planned at multiple time points of an exercise intervention. It may be especially important to teach self-regulatory strategies for boosting efficacy toward the end of a program as participants are facing the prospect of exercising on their own. In short, we need to rethink how and when we measure self-efficacy in physical activity interventions, if we are to effectively test whether or not it is a significant mediator of intervention effects on physical activity. Additionally, considering how self-efficacy may interact with other nonindividual-level factors may provide important information for the design of interventions and exercise programming.

Consistent evidence exists for the mediating role that self-efficacy has on long-term physical activity behavior (McAuley, Morris, et al., 2007b) and on outcomes associated with physical activity participation such as quality of life (Rejeski & Mihalko, 2001; White, Wójcicki, & McAuley, 2009) and functional limitations (McAuley, Morris, et al., 2007a). However, there needs to be further systematic attempts to determine whether self-efficacy and other SCT variables are influenced by interventions and in turn whether they influence physical activity. Again, to do so will require rigorous attention to matters of research design, and the timing and accuracy of the measurement of SCT and physical activity variables.

Perceived behavioral control (PBC) is another element of the expectations construct that has received attention in the physical activity domain. PBC is a component of the theory of planned behavior (Ajzen, 1991) and reflects the perceived ease or difficulty of adopting or engaging in a behavior. It is important to note here that many individuals have considered perceived behavioral control to be the conceptual equivalent of self-efficacy. This is erroneous given that believing a behavior to be easy or difficult (perceived behavioral control) is conceptually and theoretically distinct from beliefs in one's capabilities to successfully execute a behavior (self-efficacy). Indeed, in one of the few meta-analyses to test the utility of self-efficacy and perceived behavioral control in predicting intention and behavior, Armitage and Conner (2001) suggest that both play independent roles in predicting health behavior. Moreover, they note that self-efficacy and perceived behavioral control may differentially influence behavior depending upon the behavior under scrutiny. Especially pertinent to the concerns of this chapter, it is clear that control beliefs such as PBC and self-efficacy are particularly pertinent to challenging health behaviors such as physical activity, weight management, and smoking cessation, in contrast to behaviors that are generally viewed as requiring considerably less effort (e.g., a simple medication regimen).

In the context of individual processes that may influence physical activity, researchers have used the transtheoretical model (TTM; Prochaska & DiClemente, 1982) to understand how people move through various stages of change, typically from precontemplation through contemplation, preparation, action, and maintenance. Movement through the stages is posited to be influenced by decisional balance (i.e., weighing the pros and cons of being active), experiential (e.g., self-evaluation) and behavioral processes (e.g., reinforcement management), and self-efficacy. For example, Marcus et al. (2007) and Napolitano et al. (2008) found that behavioral processes mediated the effect of telephone and print-based interventions on physical activity, whereas self-efficacy and decisional balance had no effect. In a meta-analysis, Marshall and Biddle (2001) found that the most robust changes in TTM constructs occurred from the preparation to action stages as evidenced by increases in perceived pros ($d = .97$), decreases in perceived cons ($d = -.46$), and increases in use of processes of change ($d_{\text{range}} = .55–1.18$). Rhodes and Pfaeffli (2010) have noted in a recent review that 50% of the interventions studies using TTM constructs failed to find any effect of the intervention on physical activity. Of the four that did find an effect, half of them reported that TTM constructs did not mediate the relationship. As previously noted, Napolitano and her colleagues (2008) did find a true mediating effect of some TTM constructs between the intervention and behavior. Clearly, further research is warranted before definitive conclusions can be drawn as to the efficacy of TTM-based interventions for influencing physical activity and those constructs that would be expected to mediate such an effect.

Multilevel Approaches

Recognizing that individual level approaches to understanding health behavior change are insufficient, scientists have embraced social ecological models (Bronfenbrenner, 1979). These models are characterized as frameworks for understanding roles played by intrapersonal, interpersonal, organizational, community, and policy factors and the interactions among them in changing health behavior (Sallis, Owen, & Fisher, 2008). Sallis and his colleagues (2006) proposed an ecological model specifically for creating more physically active communities. Their model places interpersonal factors (i.e., demographics, biological, psychological, family) at the center and branches outward from more to less proximally influential factors such as the perceived environment, active living domains, behavioral settings (i.e., access, characteristics), and policy environment (i.e., health care policies, park policies, community zoning regulations).

Given the scope of such models, there have been few attempts at intervening at all levels, and many studies which claim to have taken a social ecological approach to understanding physical activity in adults have focused almost solely on elements of either the built or perceived environment (see an earlier section for examples). As noted earlier, these studies are predominantly cross-sectional and account for relatively modest amounts of variance in the physical activity behavior (Giles-Corti & King, 2009). For example, Haughton McNeill, Wyrwich, Brownson, Clark, and Kreuter (2006) used social cognitive theory (Bandura, 1986, 1997) and the social ecological model to make specific hypotheses relative to the potential mediators of the environment and physical activity relationship in a community sample of adults. Haughton McNeill et al. (2006) took the perspective that social and physical environmental factors would influence physical activity through the mediation of individual level factors. In addition, they proposed a direct relationship between the physical environment and physical activity.

Using structural equation modeling, they tested separate models for walking, moderate-intensity activity, and vigorous intensity activity. Although they found support for social and physical environments having indirect influences on all types of physical activity and for some elements of the physical environment having direct effects on physical activity, the most interesting findings were for self-efficacy. This individual-level correlate had the strongest association with physical activity and, of most interest, evidenced a positive gradient dose-response. That is, the association became stronger as the degree of physical activity became more challenging; supporting a fundamental theoretical tenet of social cognitive theory that self-efficacy has the greatest utility in challenging situations (Bandura, 1997). Although there are numerous strengths associated with this study, the cross-sectional nature of the design precludes causal statements. Nevertheless, Haughton McNeill et al. (2006) offer an interesting platform from which to potentially design interventions linking individual, social, and physical environmental influences on physical activity.

Although there are a significant number of published articles that espouse adoption of a social ecological model to understand physical activity, few interventions incorporate all of the individual, social, and physical environments that constitute such a model. Indeed, even the cross-sectional studies which have attempted to examine individual contributions of these environments have come to the conclusion that individual level variables, and in particular self-efficacy, are the strongest correlates of physical activity (Azar, Ball, et al., 2011; Ball & Crawford, 2006; Cleland, Ball, et al., 2010; Haughton McNeill, Wyrwich, et al., 2006). A number of considerations are important here. First, conducting interventions that manipulate, change, or seek to influence each of these environmental levels is a daunting task. Second, more efforts are needed that replicate or extend structural models such as that proposed by Haughton McNeill et al. (2006) to determine the reliability of those factors which may mediate overall social and physical environmental influences. Third, if factors such as self-efficacy are consistently found to mediate the effects of other factors, then interventions which manipulate efficacy with respect to more expansive social and physical environmental factors may serve to integrate social cognitive and social ecological models (Cleland, Ball, et al., 2010). Finally, Giles-Corti and King (2009) recommend that to optimize environments that promote physical activity, researchers from all disciplines need to "think outside of the square," and to adopt a systems theory approach to understanding how different components of the complex social ecological model of physical activity can influence and be influenced by other parts of this system.

Where to Next?

Numerous narrative, meta-analytic, and systematic reviews have come to similar conclusions relative to what we know about the benefits of a physically activity lifestyle and how to change this behavior. An array of intervention approaches has met with success in getting adults to adopt physical activity over the relatively short term of the intervention. However, much less is known about what constitutes the best intervention for maintaining this behavior. In large part, it has been argued that effective behavior change may best be brought about by targeting mediating variables (Baranowski, Anderson, & Carmack, 1998). Unfortunately, the extent to which these relationships have been tested, yet alone supported, is disappointingly low (Baranowski, Anderson, & Carmack, 1998; Lewis, Marcus, et al., 2002; Rhodes & Pfaeffli, 2010). As Rhodes and Pfaeffli (2010) note, we live in a world that has socially and environmentally ingrained a physically inactive lifestyle into our existence. This recognition points to the importance of social ecological approaches that address multiple layers and channels of influence on physical activity. These may ultimately stand the best chance of changing the behavior of large numbers of people over continued periods of time (Sallis, Owen, & Fisher, 2008). It is recognized that this may be both costly and difficult to implement. However, the escalating physical, mental, economic, and societal costs of inactivity and sedentary behavior are problems of such magnitude that multidimensional approaches to sustained physical activity may be not only what is required for population-level effectiveness, but also the most cost-effective.

Behavioral Management of Obesity: Enduring Models, Applications to Diabetes Prevention and Management, and Global Dissemination

Craig A. Johnston, Pilvikki Absetz,
Elezebeth Mathews, Meena Daivadanam,
Brian Oldenburg, and John P. Foreyt

Despite countless promises from the popular media of "miracle cures" for obesity, the prevalence of obesity continues its relentless increase in both developed and developing nations (Ng, Fleming, et al., 2014). In the USA, the rapid increase in the prevalence and incidence of obesity was initially noted in the 1980s (Flegal, Carroll, et al., 1998). The prevalence of obesity had increased from 14.5% to 22.5% over the course of about 15 years (Flegal, Carroll, et al., 1998). As early as 1992, attention was being given to the number of children who were overweight or obese. An article in *Science* included obesity with issues such as teenage suicide, pregnancy of unwed mothers, and declines in college aptitude test scores as one of the pressing conditions facing children in the USA (Fuchs & Reklis, 1992). By the early turn of this century, considerable attention was being given to the obesity epidemic not only in adults but also in children (Robinson, 2000). To demonstrate the early consequences of excess fat mass, studies demonstrated that obese children were suffering from hyperlipidemia and hypertension (Freedman, Dietz, et al., 1999), at increased risk for type 2 diabetes (Pinhas-Hamiel, Dolan, et al., 1996), and developing atherosclerotic lesions (Berenson, Srinivasan, et al., 1998). Currently, 69% of adults and 31.8% of children in the USA are classified as overweight or obese (Ogden, Carroll, et al., 2014). Globally, it is estimated that 671 million individuals are obese (Ng, Fleming, et al., 2014). Not only is this a substantial increase compared to 30 years ago, the increase has accelerated in the last decade (Stevens, Singh, et al., 2012).

The obesity epidemic has occurred relatively recently, but the issue of weight loss has been

discussed for a much longer period. Cases of individuals engaged in weight loss have been dated back to at least the fourth century A.D. (Lacey, 1982). For example, in the Middle Ages, several cases of religious women were reported to have existed on very little food over extended time periods only by virtue of spiritual power (Bell, 1985; Halmi, 1982; Hammond, 1879; Lacey, 1982). However, many of these early instances may more closely resemble eating disorders. In terms of the behavioral management of weight, William Banting developed a diet to promote weight loss in 1863 (Banting, 1863). Diets had been developed before this to address health concerns including diabetes, but Banting was among the first to develop a diet strategy that resembles the dieting of today. In the 1800s, obesity was neither a focus of medicine nor an area of scientific inquiry. It was almost 100 years later when the first behavioral studies were conducted to address obesity (Ferster, Nurnberger, & Levitt, 1962; Stuart, 1967). Studies on the "self-control of overeating" described behavioral principles (e.g., stimulus control, shaping) that are still used in obesity management today (e.g., to promote changes in diet and physical activity). In 1973, a conference on obesity was held at the National Institutes of Health in order for obesity experts to discuss "the need for heightened research on psychological, physiological, and biochemical determinants of this important health derangement" (Leavitt, 1973).

Though behavioral strategies showed promise in reducing weight, their use has not led to long-term weight maintenance (Laddu, Dow, et al., 2011). In fact, the promise of behavior modification has always been that inappropriate lifestyle behaviors could be self-controlled after patients receive training in the use of these techniques. If behavioral techniques are successful, they should be self-reinforcing because they would lead to weight loss and a sense of self-control (Foreyt, Goodrick, & Gotto, 1981). Patients who undergo behavioral training do lose weight, typically around 8% after 6 months of intervention but do not ordinarily continue weight loss following treatment. Despite the theoretical underpinnings of behavioral theory, the state of behavioral obesity treatment in the 1970s was summarized as follows:

> *Although behavior therapy has advanced the treatment of obesity, its results are still of limited clinical significance. Weight losses have been modest and the variability in results large and unexplained. Even long-term maintenance of weight loss which, it was originally hoped, would be of particular benefit of the behavioral approach, has not yet been established.* (Stunkard, 1978)

Sadly, this statement still reflects the state of behavioral weight management in most cases. However, several behavioral treatments recently have been and are being studied that suggest the long-term maintenance of clinically significant weight loss is possible (Diabetes Prevention Program Research Group, Wadden, et al., 2009; Look AHEAD Research Group, 2014a). The Diabetes Prevention Program (DPP) and Look AHEAD are models of behavioral programs that focus on lifestyle change and provide important answers on how best to treat this intractable and punishing condition.

Behavioral Treatments for Obesity

Although many necessary components (e.g., diet and physical activity-related behaviors) to treat obesity have been identified, behavior modification remains the bedrock of weight control programs (Foreyt & Pendleton, 2000). In its guide to selecting treatments for obesity, the National Institutes of Health recommends behavior modification for all individuals receiving treatment for overweight and obesity (National Institutes of Health, 2000). Changes in diet and physical activity remain the ultimate goals, but it is the behavioral strategies used that can help patients to overcome barriers that are associated with making these changes. Even in the case of bariatric surgery, behavioral management is needed to promote the lifestyle changes that are necessary for short- and long-term weight control. Behavior modification strategies with the most success take a lifestyle change approach aimed at helping patients adhere to healthy diets and sensible physical activity regimens.

The DPP and Look AHEAD studies had similar lifestyle interventions for overweight and obese adults that incorporated a tailored problem-solving approach that includes self-monitoring, goal setting, contracting, problem solving, stimulus control, cognitive restructuring, stress management, and social support (Poston & Foreyt, 2000). The goal of DPP was to determine the role of lifestyle intervention and medication in the prevention of type 2 diabetes (Diabetes Prevention Program Research Group, 2002). Along with the complementary objective of 150 min per week of moderate physical activity, the principal objective of the DPP lifestyle intervention was to assist participants at risk for diabetes in achieving and maintaining a weight loss of at least 7% (Diabetes Prevention Program Research Group, 2002). In order to achieve this objective, the lifestyle intervention of the DPP program included a comprehensive array of behavioral techniques, individual case management by "lifestyle coaches" who also delivered the intervention, frequent contact with participants throughout the duration of the study, and ongoing intervention which started with a 16-session initial core curriculum and continued with personalized maintenance sessions (Diabetes Prevention Program Research Group, 2002). Moreover, this array was flexibly tailored within sites to individual needs and across sites to site-specific cultural or regional factors.

The Look AHEAD study adapted the DPP lifestyle protocol to participants who have already been diagnosed with type 2 diabetes. It differed, however, in several ways. During the first year, the Look AHEAD treatment was provided primarily in a group rather than in an individual setting, and the use of liquid meal replacements was encouraged (Look AHEAD Research Group, Wadden, et al., 2006). The Look AHEAD study examined the impact of intentional weight loss as it relates to reduced cardiovascular morbidity and mortality (Look AHEAD Research Group, Wadden, et al., 2006). Specifically, the principal goal of the Look AHEAD study was to determine the combined effects of deaths from cardiovascular diseases, nonfatal heart attacks, nonfatal strokes, or hospitalization for chest pains during the study period of 13.5 years (Look AHEAD Research Group, Wadden, et al., 2006). Participants were randomized to either a diabetes support and education (DSE) or an intensive lifestyle intervention (ILI) condition. The DSE condition received three 1-h group meetings per year focusing on diet, physical activity, and social support (Wesche-Thobaben, 2011). Information was provided, but behavioral strategies to promote adherence were not taught. Participants in the ILI condition were encouraged to achieve a sustained weight loss of 10% of initial weight and to increase moderately intense physical activity to at least 175 min per week (Look AHEAD Research Group, Wadden, et al., 2006).

The ILI, however, utilized meal replacements as a form of portion control (Look AHEAD Research Group, Wadden, et al., 2006). Participants were given a daily calorie goal which varied (1200–1800 calories a day) depending on the individual's calorie needs (Look AHEAD Research Group, Wadden, et al., 2006). During the initial phase of treatment, participants were encouraged to replace two meals a day with a liquid shake (meal replacement) and one snack with a bar, as well as increase intake of fruits and vegetables. After month 7, calorie goals were adjusted based on weight loss during the first 6 months and individuals' future weight loss goal. A gradual shift of replacing one meal and one snack a day with a shake or bar and increasing consumption of low-energy-dense foods was encouraged.

The intervention included gradually increasing physical activity to a specific number of minutes per week, engaging in at least 10,000 steps daily, and incorporating exercise into daily lifestyle (Look AHEAD Research Group et al., 2006). Specifically, during the first 6 months of the intervention, participants were encouraged to increase activity to 125 min per week by week 16 and to 175 min per week by week 26. For the remainder of the study, participants were encouraged to engage in at least 175 min of exercise per week.

Behavioral Strategies

The following sections detail the behavioral strategies common to DPP, Look AHEAD, and most other state-of-the-art weight loss programs, including commercial applications such as Weight Watchers.

Self-Monitoring Self-monitoring is an essential component of behavioral weight loss treatments (Berkel, Poston, et al., 2005) and involves raising self-awareness through observing and recording behaviors (Kanfer, 1970). Participants in the Look AHEAD study used various self-monitoring techniques. Specifically, participants recorded their daily food intake and monitored their physical activity by totaling calories consumed and recording minutes of activity and step count, respectively. Additionally, at each weekly meeting, participants' weights were recorded in order to provide feedback about their progress and increase motivation. All of the self-monitoring methods used in Look AHEAD were strongly correlated with one another, with self-reported physical activity being the strongest correlate of weight loss at the end of the first year (Wadden, West, et al., 2009). Additionally, increased self-monitoring was related to greater treatment attendance. These findings provide clear support for the importance of self-monitoring. Even though reporting of behavioral changes may not have been accurate, self-monitoring, especially of physical activity, was still associated with weight loss. A clear example of the importance of the act of self-monitoring and not necessarily the correctness of the information recorded was demonstrated with food records. Specifically, participants who engaged in self-monitoring to a greater degree by keeping more detail on their food record at screening lost more weight at year 1 than individuals who were less detailed (Tsai, Fabricatore, et al., 2014).

In general, at the outset of treatment, self-monitoring involves observing and recording behaviors without requiring individuals to change diet or physical activity habits. Other variables that may be recorded include the time of day a food is eaten, the type of exercise completed, and the emotional state of the patient before, during, and/or after those activities. This feedback process is a significant aspect of intervention. Several studies have demonstrated a correlation between self-monitoring of food intake and one's weight with long-term weight loss and maintenance (Epstein, Valoski, et al., 1995; Williamson, Anton, et al., 2010; Israel, Guile, et al., 1994; Wing, Tate, et al., 2006).

Self-monitoring involves three processes that influence behavior change. First, self-monitoring records serve as a guide as they provide important information to individualize treatment. For example, records provide insight to patterns of behavior which can then be targeted as part of the intervention. The second process is one of increasing awareness. Even if individuals overestimate or underestimate their behaviors, the act is still effective because it is a persistent reminder of weight-related goals (Lichtman, Pisarska, et al., 1992; Trabulsi & Schoeller, 2001). A third process is that self-monitoring, especially if carried out before food is eaten, can help to break up chains of almost automatic eating that may have developed such as in eating snacks.

Goal Setting A goal-based approach for weight loss was used in both the Look AHEAD and DPP programs (Diabetes Prevention Program Research Group, Knowler, et al., 2009; Look AHEAD Research Group, Wadden, et al., 2007). Specifically, both programs used a tailored approach by identifying strategies that would be most appropriate for the specific situations of their participants.

All aspects of the Look AHEAD study included goal setting (i.e., individualized action plans); participants set goals for overall weight loss, caloric intake, and physical activity. In order to achieve the larger goals of the program, participants established small, measurable, and achievable goals at the beginning of treatment. For example, the physical activity goal during the first month was to walk for 50 min a week with the amount of minutes gradually increasing over time. Additionally, in the Look AHEAD study, it was important to establish differing goals toward a similar outcome in order to lessen the monotony of constantly working toward the same goal. This also allowed participants to choose goals that were most meaningful to them.

Goal setting is necessary as a base for effectively promoting weight loss by reinforcing small changes. Setting small, measurable, and attainable goals also is intended to increase motivation and foster a sense of accomplishment through creating a positive momentum for future change when such goals are achieved. This momentum is important especially as many individuals try multiple times to lose weight and may feel that future attempts are unlikely to be successful. Setting realistic and effective goals is also intended to aid in treatment adherence. Additionally, encouraging changes that can easily be incorporated throughout a "regular" day is of great importance for adherence and promoting sustainability. For example, in the Look AHEAD study, participants were provided with exercises that could be incorporated into their daily routine, such as taking the stairs instead of the elevator, walking to a colleague's office instead of sending an email, and parking at the back of the parking lot instead of in the spot closest to their destination.

Focusing on lifestyle changes incorporated into a daily or weekly ritual may increase awareness of improvements in health and thus lessen the focus on unrealistic goals and increase motivation and treatment adherence. Regarding weight loss efforts, it may be helpful to focus on improvements in health, energy, and fitness that are frequently observed with an initial modest weight loss of 5–10%, which also is a realistic goal to achieve. For example, a weight loss of 5% or 10% is associated with reductions in triglycerides, blood glucose, and hemoglobin A1c (HbA1c, a measure of average blood glucose over the previous 2–3 months) and improvements in one's sense of well-being and self-esteem (Jensen, Ryan, et al., 2014). This may also lead to increasing functional and recreational activities, such as being better able to play with one's children, walking up a flight of stairs without being out of breath, or being able to tie one's shoes with less difficulty.

Contracting Contracting defines expectations and responsibilities as they relate to treatment (Foreyt, 2005). In Look AHEAD, contracts were used in combination with goal setting to enhance motivation to achieve short-term behavioral changes and ultimately successfully adhere to treatment. Contracting involves selecting and writing down realistic behavioral goals to perform between sessions and signing a document to finalize the agreement. In other cultures, this may be viewed differently, but in the USA, contracts emphasize explicit, tangible features that support change. Such goals may include limiting eating out to one less meal a week or walking for 10 extra minutes a day. In order for this strategy to be successful, it is important to understand the responsibilities and explicitly discuss what is required.

Problem Solving As with contracting, problem solving also is important for effective achievement of goals. Once realistic goals have been set, problem solving introduces methods of identifying potential barriers that may hinder achievement of these goals and brainstorming possible solutions to overcome these obstacles. In turn, this may also increase confidence in achieving goals and self-efficacy to effectively face potential problems. Problem solving is a continuous process that involves monitoring toward goals, determining the effectiveness of implemented solutions, and identifying new solutions when appropriate.

Problem solving has been shown to be an integral aspect of weight loss and maintenance efforts (Perri et al., 2001). For example, attrition is a common problem in obesity treatment. Individuals do not return for their next appointment for many different reasons, such as weight gain or not meeting a goal. Thus, it is important to acknowledge early in the intervention that setbacks are a normal part of the treatment process and to develop a plan which can be implemented when setbacks arise.

Stimulus Control Stimulus control, another important component of weight management used to facilitate behavior change, includes techniques of manipulating cues in the environment. Specifically, stimulus control is intended to alter and manage environmental cues that may trigger adaptive or maladaptive patterns of exercise and eating. For example, making unhealthy snacks unavailable may assist in decreasing caloric intake, and making a gym bag readily available may increase the likelihood of engaging in physical activity. Another technique of stimulus control involves controlling the setting in which eating occurs. Eating at the kitchen table only and preparing one's plate before sitting down, as opposed to serving foods placed at the center of the table, are examples of methods used to create a setting that promotes healthier behaviors. Anecdotally, people report fewer thoughts and urges for food as they narrow the cues associated with them. Overall, making healthy lifestyle changes to the immediate environment is a significant aspect of successful weight management.

Complete or partial meal replacements serve as another method of stimulus control by providing exact portions and decreasing exposure to certain foods that may trigger overeating. Meal replacements also have been shown to be a safe and effective strategy for weight loss and long-term weight maintenance (Flechtner-Mors, Boehm, et al., 2010; Flechtner-Mors, Ditschuneit, et al., 2000; Heymsfield, van Mierlo, et al., 2003). The ILI group of the Look AHEAD trial successfully incorporated meal replacements by initially replacing one to two meals per day with portion-controlled, vitamin- and mineral-fortified low-energy meals (Look AHEAD Research Group, Wadden, et al., 2006).

Cognitive Restructuring Another barrier to weight loss is dysfunctional thinking patterns, such as beliefs that losing weight will resolve problems in various aspects of one's life. Cognitive restructuring identifies these patterns and manages thoughts through restructuring them to a more beneficial nature (Fabricatore, 2007; Wadden & Foster, 2000). Cognitive restructuring strategies, such as personal affirmations, are commonly used to deal with setbacks regarding weight loss. Setbacks are common triggers for dysfunctional thinking patterns (Fabricatore, 2007). Dysfunctional thinking patterns may cause one either to view a setback as a reason to abandon efforts or deny the significance of the setback. In either case, these types of thoughts may impede long-term weight loss. To overcome this barrier, cognitive restructuring assists in recognizing thoughts that are rather extreme and helps manage unrealistic expectations about weight loss.

Stress Management For some individuals, successfully engaging in behavior change may be hindered due to stress (Foreyt, 2005). This may be due to negative lifestyle changes adding to their level of stress. Individuals with high levels of stress may need support and psychological resources in order to make meaningful changes in their lives. Since physical activity reduces stress reactivity and aids in weight loss and management, it can be used as a strategy for managing stressful life situations. Additional stress management methods include progressive muscle relaxation and meditation. Progressive relaxation assists in maintaining lower levels of stress during weight loss and maintenance and meditation increases feelings of self-control. Also, meditation may act as an effective goal since it is a relatively easy strategy for patients to incorporate in their daily lives, and like aerobic exercise, meditation appears to be habit-forming for some individuals. Overall, managing stress aids in the transition toward a healthier lifestyle and also increases the likelihood of maintaining these changes.

Social Support Weight loss and long-term weight maintenance efforts can greatly benefit from social support (Foreyt & Pendleton, 2000). Social support provides many benefits including role modeling, assisting with problem solving, and serving as an emotional outlet for issues that may be experienced during weight loss treatments. Individuals can often feel that weight loss changes are daunting; however, the support of other important individuals can make these changes less difficult and demanding. Lack of social support may lead individuals to fall back into old unhealthy habits in the long-term.

In the Look AHEAD study, during the initial phase of the intervention, participants attended weekly sessions, either as a group or individually. The group sessions were designed to increase social support by encouraging participants to create a close bond with other program participants. This also promoted a sense of accountability for reaching weight loss goals. Additionally, techniques such as motivational interviewing were utilized in order to support the relationship between participants and research staff. Participants were also encouraged to seek social support from family members, friends, and any other individuals with similar goals. For example, in order to stay on track with physical activity goals, participants were encouraged to recruit walking partners from their family and social environment.

Maintenance of Weight Loss Despite successful initial weight loss, most individuals receiving behavioral treatment remain overweight, and many regain some or all of their lost weight. This progression of weight regain was shown in Look AHEAD participants (Look AHEAD Research Group, Wing, et al., 2013); however, it was much slower than what is found in other studies. Additionally, participants in the ILI condition demonstrated significant weight loss compared to the DSE condition at every annual assessment including at 9.6 years (6% mean weight loss compared to 3.5%) (Look AHEAD Research Group, Wing, et al., 2013). Overall, Look AHEAD demonstrated that long-term weight loss is achievable with a treatment that has a high enough intensity and appropriate behavioral supports.

Incorporating Behavioral Strategies into Intervention Behavioral change strategies play a prominent role in the treatment of obesity as they are essential in assisting with making lifestyle changes. When written in a way that each behavioral strategy is discussed independently (as done in this chapter), it may seem that they are also used independently; however, behavioral strategies are meant to be used in combination with each other. For example, raising self-awareness regarding caloric intake and physical activity behaviors is essential to weight loss and maintenance efforts, and it should be followed by setting goals for gradual change in order to promote behavior change. Specifically, making gradual changes, such as steadily reducing calories and increasing physical activity, may result in losing weight at a safe rate and relatively easily. Furthermore, social support and scrutiny may support these gradual changes and ultimately long-term weight maintenance as long as individuals believe that they are under scrutiny (Berkel, Poston, et al., 2005; Jeffery, Drewnowski, et al., 2000). Finally, problem solving may be important as individuals regain weight or slowly begin to return to pretreatment behaviors (Foreyt, 2005). Individuals will almost certainly struggle to maintain the behavioral changes they have made. Problem-solving strategies to prevent relapse can include engaging in different ways of dealing with certain situations such as holidays, social interactions, the influence of friends and family members, and one's thoughts.

Key Issues for Success and Dissemination

Individual Differences Several factors can impact treatment outcomes and should be taken into account. For example, individuals with reduced income may be more averse to changing their eating habits if this results in an increased monthly food bill. They also may have less access to safe locations to engage in physical activity. Low-income individuals may be limited in their access to health care and preventative care. The impact and association of the socioeconomic environment of the individual with diabetes and its effects on health and depression have only briefly been addressed (Gary-Webb, Baptiste-Roberts, et al., 2011). Considering the ill health effects and stress that comes with living in lower socioeconomic environments, it is important to determine what these effects have on preexisting conditions such as obesity and diabetes. Look AHEAD participants living in areas of higher poverty, as compared to those living in areas of lower poverty, had significantly lower scores for overall physical and mental health as well as more limitations physically, emotionally, and socially. These findings help further illustrate the negative effects and overall poorer health status that can result from living under lower socioeconomic status (SES) conditions and demonstrate the importance of SES being taken into consideration when designing and evaluating weight management programs. The effect that SES conditions may have on weight management still requires further investigation, but evidence suggest that lower SES may be related to increases in weight (Gary-Webb, Baptiste-Roberts, et al., 2011). Although research is lacking in ways to better reach low-income individuals (Harvey & Ogden, 2014), strategies to address this issue have been developed. For example, telecommunication technology may assist with these individuals by increasing the possibility of dissemination and allowing for significant tailoring to take place (Costa, Fitzgerald, et al., 2009; Griffiths, Blignault, & Yellowlees, 2006; Noh, Cho, et al., 2010). As more and more people have cell phones (Duggan & Smith, 2013), delivering interventions through this method is promising. However, the overall effectiveness of these programs to date is limited (Harvey & Ogden, 2014).

Cultural differences are also important factors that can impact weight loss attempts, and evidence suggests that ethnic minorities are underrepresented in many trials which can affect the interpretability of findings to these groups (Mount, Davis, et al., 2012). For example, in Look AHEAD, African-Americans were found to have higher adverse levels of blood pressure, heart rate, serum creatinine, and other blood markers which excluded them from being enrolled in the study (Mount, Davis, et al., 2012). Based on these findings, it may be important to modify trial eligibility in future studies to ensure greater proportions of often excluded and underrepresented populations (Mount, Davis, et al., 2012).

Genetics The roles of genetic factors in obesity have often been noted (Frayling, Timpson, et al., 2007; Herbert, Gerry, et al., 2006; Loos, Lindgren, et al., 2008; Sabatti, Service, et al., 2009; Scuteri, Sanna, et al., 2007; Speliotes, Willer, et al., 2010; Thorleifsson, Walters, et al., 2009; Willer, Speliotes, et al., 2009), but the mechanisms and processes linking genes and obesity remain unclear. Gene regions associated with higher risks for obesity, as determined from previous gene-wide association studies (GWAS), were compared to dietary intake, as measured through food-frequency questionnaires, from subjects in Look AHEAD. The study found that certain obesity risk genes were associated with various dietary patterns and habits including more eating episodes per day; eating more servings from dairy groups and products; more servings from the meat, eggs, nuts, and beans group; and lower energy use from consumed proteins. These findings suggest a genetic component may affect eating patterns as well as the type of food consumption among overweight patients with type 2 diabetes. These findings provide important information on how genes interact with health behaviors and have implications for providing a more individualized approach to weight loss (McCaffery, Papandonatos, et al., 2012).

Adherence In Look AHEAD, adherence to treatment recommendations predicted weight loss outcomes at 1 year (Wadden, West, et al., 2009). Although adherence to meal replacement recommendations and attendance at treatment sessions were significant predictors of weight loss, adherence to the recommendations for physical activity was the strongest predictor of weight loss at year 1 (Wadden, West, et al., 2009). Participants with the highest levels of self-reported physical activity lost 11.9% of their initial weight compared with 4.4% for those with the lowest physical activity. Although the study design did not allow for conclusions to be made regarding the reasons for weight loss, physical activity appears to play a critical role (Johnston, 2012).

The strongest determinant of achieving significant weight loss at 4 years in Look AHEAD was initial weight loss in year 1 (Wadden, Neiberg, et al., 2011). The oldest participants lost significantly more weight at year 4 than the youngest participants. Likewise, those who were older attended more treatment sessions, had more contacts with treatment staff, and self-reported greater behavioral adherence to the intervention. It was suggested that the older participants (age 65–74 years) may simply have more time to devote to the lifestyle intervention or that motivation to improve health may be higher in this age group. Overall, these findings are encouraging given that older adults are at increased risk in terms of both morbidity and mortality (Johnston, 2012).

Intensity and Duration of Treatment Treatment intensity may provide an effective strategy for weight management through continued contact with the intervention (Foreyt, Goodrick, et al., 1981). In the Look AHEAD trial, the intervention was intensive with participants attending weekly meetings, three group meetings and one individual meeting monthly, for the first 6 months of the intervention (Look AHEAD Research Group, Wadden, et al., 2006). Even though contact was reduced over time, long-term contact with participants also likely played an important role. In many cases, strong relationships were built between participants and study staff creating a supportive environment for long-term behavioral change. Based on these observations, it appears important to find ways to have high levels of intensity at the beginning of treatment and also to include a plan for contact over an extended period of time as this was done in both Look AHEAD and DPP. Engaging social supports may be one way to promote this in a "real-world" setting. For example, peer support has been shown to improve self-management of diabetes in multiple international settings (Fisher, Boothroyd, et al., 2012).

Primary Outcomes

The Look AHEAD intervention ended after 9.6 years due to a lack of significant results and supporting data for the study's primary outcome which was a significant decrease in cardiovascular morbidity and mortality between the ILI and DSE (Look AHEAD Research Group, Wing, et al., 2013). Even though weight loss was significantly greater in the ILI than the DSE group at every annual assessment, the primary outcome of lower rates of cardiovascular morbidity and mortality in the ILI group was unsupported. Specifically, the ILI focusing on weight loss did not significantly reduce the rate of CVD and death in overweight or obese adults with type 2 diabetes. However, many other benefits were experienced in the ILI compared to the DSE group. Most importantly, Look AHEAD demonstrated that long-term weight loss and maintenance is achievable through a lifestyle change intervention. Indeed, Look AHEAD is the largest, most comprehensive, and most successful randomized study of weight loss and maintenance to date (Perri, 2014).

In addition to its impacts on weight loss itself, the ILI intervention led to initial improvements in symptoms of sleep apnea (Foster, Borradaile, et al., 2009), cardiorespiratory fitness (Jakicic, Jaramillo, et al., 2009), physical functioning (Foy, Lewis, et al., 2011), body image (Stewart, Bachand, et al., 2011), and health-related quality of life (HRQOL) (Williamson, Rejeski, et al., 2009). The following is a brief description of some of the additional outcomes associated with the Look AHEAD intervention.

Additional Outcomes

Maintenance of Weight Loss Without follow-up care, obese individuals usually regain much of their initial weight loss within a year following treatment, and a return to baseline weight is often observed within 3–5 years (Perri, 2014). At year 1, participants in the Look AHEAD study who received the ILI achieved greater weight loss, losing 8.6% of their initial body weight compared to 0.7% for participants in the DSE (Wadden, West, et al., 2009).

Over time, participants regained some of their initial weight loss; however, on average, participants who received the behavioral lifestyle intervention maintained 4.7% weight loss at both 4 and 8 years compared to 1.1% and 2.1% for participants in the DSE, respectively (Look AHEAD Research Group, 2014a; Wadden, Neiberg, et al., 2011). Participants in the ILI had a 6.0% weight loss compared to a 3.5% weight loss in the DSE at 9.6 years (Look AHEAD Research Group, Wing, et al., 2013).

Reductions in Cardiovascular Risk Factors Improvements in weight loss were accompanied by reductions in measures of cardiovascular risk factors including fasting glucose and blood pressure as well as a decrease in the number of medicines used to treat their diabetes, blood pressure, and cholesterol compared to participants in the DSE at 1 year

(Look AHEAD Research Group, Pi-Sunyer, et al., 2007). Indicators of cardiovascular health such as cardiovascular fitness (Jakicic, Jaramillo, et al., 2009), resting heart rate (HR), an HR range, HR at 2 min following exercise, and heart rate recovery during exercise were also found to be improved in the ILI group versus the DSE group (Ribisl, Gaussoin, et al., 2012).

Severe Obesity Rates of severe obesity continue to increase, while the prevalence of overweight and mild obesity may have stabilized in recent years (Flegal, Carroll, et al., 2012). This subgroup has primarily been excluded from clinical weight loss trials due to comorbid conditions. Severe obesity is associated with higher mortality rates compared with overweight and moderately obese populations. Severe obesity not only puts individuals at risk for developing diabetes and other cardiovascular diseases, but once an individual develops type 2 diabetes, life expectancy may be significantly shortened. Since extreme categories of obesity comprise the most rapidly growing and high-risk segment of the overweight population (Flegal, Carroll, et al., 2012), effective methods for treatment are needed. Participants in the ILI condition who were severely obese (class III obesity, BMI ≥ 40) were compared to participants in overweight (BMI, 25 to <30), class I obese (BMI, 30 to <35), or class II (BMI, 35 to <40) obese categories. At year 1, severely obese ILI participants showed comparable weight losses in terms of percent weight loss to class I and class II obese participants. All obese participants showed significantly greater weight loss compared to the overweight participants. All BMI groups (i.e., overweight, classes I, II, III obesity) showed improvements in fitness, physical activity, cholesterol, risk factors for cardiovascular disease, and diabetes indicators. Treatment session attendance did not differ among weight categories. That is, far from being "too severe to treat with mere behavioral approaches," the severely obese benefitted in a manner parallel to those with less pronounced overweight. Although bariatric surgery is often recommended for the very severely obese, this treatment option is limited in scope. Although effective, this procedure is performed on less than 1% of the severely obese population each year. The Look AHEAD findings suggest that the behavioral treatment of obesity may be an effective treatment option for some of the severely obese population, a population that is typically presented with limited options for weight loss (Unick, Beavers, et al., 2011).

Nephropathy Overweight and obese individuals with type 2 diabetes are at increased risk for renal dysfunction which also puts these individuals at risk for cardiovascular mortality (Afkarian, Sachs, et al., 2013; Fox, Matsushita, et al., 2012). Renal dysfunction is an example of a microvascular complication resulting from poor control of blood glucose levels (Fowler, 2008). Improvement in glucose control is associated with improvement in microvascular complications resulting from type 2 diabetes. Individuals who participated in the ILI had a 31% lower risk of occurrence of very-high-risk chronic kidney disease (Look AHEAD Research Group, 2014b). Improvements in weight, HbA1c, and blood pressure were found to be associated with the decreased risk of kidney disease in these individuals. Because chronic kidney disease is a risk factor for cardiovascular-related death, reduction in one's risk of chronic kidney disease may ultimately lead to reduced mortality (Afkarian, Sachs, et al., 2013; Fox, Matsushita, et al., 2012). While the ILI was not found to reduce the rate of CVD and death after 10 years, it is possible that the beneficial effects of the ILI will take longer to appear (Look AHEAD Research Group, 2014b).

Markers of CVD Risk Cardiovascular disease is the largest single cause of death in the world (World Health Organization, 2012). Adipose tissue dysfunctions have been found to play a large role in the development of many of the metabolic abnormalities (Xu, Barnes, et al., 2003). Adiponectin is a marker of adipose health and often found in large quantities in circulation; however, adiponectin is often found in decreased amounts in obese individuals. Participants in the ILI condition demonstrated improvements in adiponectin levels by

11.9% and HDL cholesterol levels of 9.7% compared with changes in DSE which were 0.2% and 1.3%, respectively (Belalcazar, Lang, et al., 2012). When adjusting for demographic information and medical history, adiponectin changes were found to remain significantly associated with HDL-C change. Overall, these increased levels of adiponectin suggest that lower instances of cardiovascular events may be expected for individuals in the ILI condition (Belalcazar, Lang, et al., 2012).

Mobility and Bone Health As people age, they begin to experience issues such as joint pain and stiffness and decreased mobility. Obesity in older adults exacerbates these problems (Magliano, 2008). Participation in the Look AHEAD ILI that encouraged physical activity and weight loss resulted in a 48% reduction in mobility-related disability when compared with the DSE group. Improvements in weight and fitness mediated the effect of lifestyle intervention on slowing the loss of mobility (Villareal, Chode, et al., 2011). Improvements in the mobility and physical functioning of individuals with knee pain in the ILI group have also been reported (Foy, Lewis, et al., 2011).

Because decreased bone mineral density is associated with increased risk of fracture which is a common risk for older adults, the impact of weight loss on bone mineral density also was examined (Schwartz, Johnson, et al., 2012). Despite improvements in fitness, the weight loss achieved at year 1 by participants in the ILI condition was associated with greater bone loss at the hip and femoral neck than those in the DSE group. However, changes in bone mineral density at the lumbar spine and the whole body did not differ between the two groups. While there was a modest decrease in bone mineral density in the hipbone of subjects, further research will need to determine if this decrease was associated with increased risk for hip fractures (Schwartz, Johnson, et al., 2012).

Diabetes Remission Diabetes is often considered an irreversible condition; however, results from the Look AHEAD trial suggest that a lifestyle intervention can be effective to help overweight and obese participants achieve partial or complete remission of their type 2 diabetes, defined as meeting criteria of prediabetes or nondiabetic level of glycemia (i.e., fasting plasma glucose <126 mg/dl and HbA1c < 6.5% with no antihyperglycemic medication) and sustain these improvements long-term (Gregg, Chen, et al., 2012). Remission rates were higher among participants who had diabetes for a shorter amount of time, did not require insulin therapy, and had lower levels of blood sugar when they entered the study. In addition, greater weight loss and improvements in physical activity were associated with likelihood of achieving partial or complete remission (Gregg, Chen, et al., 2012).

Quality of Life Health-related quality of life (HRQOL) is a self-reported measure of a person's perceived mental and physical health (Gandek, Sinclair, et al., 2004; McHorney, 1999; Centers for Disease Control and Prevention, 2000; Selim, Rogers, et al., 2009). Participants in the ILI condition demonstrated significant improvements in HRQOL compared to those in the DSE (Williamson, Rejeski, et al., 2009). Additionally, within the ILI group, individuals with the lowest scores for HRQOL at the beginning of the study demonstrated the greatest improvements. Improved physical fitness, weight loss, and reduced physical symptoms partially contributed to the improvements in HRQOL. Much of the research on changes in HRQOL and lifestyle changes related to weight loss has yielded conflicting findings. Look AHEAD addressed some of the shortcomings of previous studies and, therefore, adds clarity to the subject (Williamson, Rejeski, et al., 2009).

Depression Depression and weight management have often been an issue when treating overweight and obese patients. In past studies, some participants suffering from depression have demonstrated further or intensified mood disorders following weight loss (Campos, 2005; Keys, Brozek, & Henschel, 1950; Rubin, Knowler, et al., 2005). The Look AHEAD study sought to further examine these factors and determine if moderate weight loss in depressed subjects led to higher symptoms of depression and thoughts of suicide and whether initial symptoms of depression would limit weight loss after 1 year (Faulconbridge, Wadden, et al., 2012). ILI participants were found to have lost more weight and have lower depression scores compared to DSE participants. Additionally, within the ILI group, there were no significant differences in total weight loss for participants who did and did not demonstrate depressive symptomatology. These findings suggested that intentional weight loss did not worsen mild or moderate symptoms of depression but, in fact, lowered levels of depression in overweight/obese subjects with type 2 diabetes (Faulconbridge, Wadden, et al., 2012).

Extending Related Behavioral Interventions to Global Settings

The Look AHEAD intervention was conducted in the USA. The earlier pioneering work of DPP has been extended globally. DPP has gained significant support from studies focusing on diabetes prevention in Finland, China, Japan, and India with all of these showing a reduction in type 2 diabetes incidence ranging between 42% and 58% (Knowler, Barrett-Connor, et al., 2002; Tuomilehto, Lindstrom, et al., 2001; Kosaka, Noda, & Kuzuya, 2005; Pan, Yang, et al., 1997; Ramachandran, Snehalatha, et al., 2006), with generally good maintenance for up to 20 years (Li, Zhang, et al., 2008). Moreover, in preventing or postponing type 2 diabetes, the behavioral interventions have been shown to be more cost-effective than treatment with drugs such as metformin (Herman, Hoerger, et al., 2005; Ramachandran, Snehalatha, et al., 2007).

After the efficacy studies had demonstrated that lifestyle change was effective in diabetes prevention, the next step was to test whether the findings could be replicated in more "real-world" community settings and in different countries. This has taken place in two phases, starting first with implementation and dissemination studies in high-income countries (HIC) and then, followed more recently by implementation trials in low- and middle-income countries (LMIC).

DPP Translation in High-Income Countries

Both the DPP (Knowler, Barrett-Connor, et al., 2002) and the Finnish Diabetes Prevention Study (Tuomilehto, Lindstrom, et al., 2001) achieved risk reduction of 58% through a program that was intensive and conducted in research settings with special resources. For example, the Finnish study included a median number of 20 individual counseling sessions with a clinical dietitian who had high expertise on type 2 diabetes, offered a free access to gym, had a substantial number of the participants on a very-low-caloric diet, and extended over 6 years, with a median length of 4 years (Lindstrom, Ilanne-Parikka, et al., 2006). Furthermore, all participants in both studies already had impaired glucose tolerance and so were at a high risk for type 2 diabetes. Such interventions are not replicable in real-world community settings, clarifying a need for testing a less intensive and more feasible intervention.

Remarkably, the first wave of implementation studies showed similar outcomes as those of the DPP with more feasible, acceptable, and cost-effective delivery systems (Absetz, Oldenburg, et al., 2009; Ali, Echouffo-Tcheugui, & Williamson, 2012). Here we detail two of these, the GOAL program in Finland (Absetz, Valve, et al., 2007), which tested the real-world implementation of the Finnish Diabetes Prevention Study (Tuomilehto, Lindstrom, et al., 2001), and the Greater Green Triangle Diabetes Prevention Program (GGT DPP) (Laatikainen, Dunbar, et al., 2007), a study that replicated the findings of the GOAL program in Australia. Both programs were successfully scaled up after initial evaluations and are continuing to be refined in their respective countries (Oldenburg, Absetz, et al., 2011).

In contrast to the research settings of the Finnish DPS and DPP, the GOAL and the GGT DPP were designed for the primary health-care setting, where participants could be routinely identified with the FINDRISC screening tool (Lindstrom & Tuomilehto, 2003). Health-care professionals such as dietitians and primary care nurses were identified to deliver the intervention in small groups, with a short, 3-day training for group facilitation. In Finland, the project had formed partnerships with municipal health-care centers, which implemented the program as one of their preventive care practices, while in Australia the GGT DPP project hired allied health professionals to deliver the intervention in GP practices partnering with the project.

Both the GOAL and GGT DPP included five sessions held fortnightly and one booster session at 8 months (Absetz, Valve, et al., 2007; Laatikainen, Dunbar, et al., 2007). The underlying behavior change model adopted was the health action process approach (the HAPA-model, Schwarzer & Fuchs, 1996), and the main behavior change techniques included risk appraisal, self-monitoring, goal setting, action planning and planning of coping with barriers, regular monitoring and evaluation of progress, and feedback directed toward revising individual objectives and plans for action and coping. Each GOAL session was planned to last for 2 h, while in the GGT DPP, session length was reduced to 90 min. Sessions were scheduled for weekdays (Mon–Thu) either late in the afternoon or early in the evening to fit into work schedules of both participants and health-care personnel.

Effectiveness of the GOAL program in Finland and the GGT DPP in Australia was documented in implementation studies involving over 350 participants in Finland and almost 300 in Australia (Absetz, Valve, et al., 2007; Laatikainen, Dunbar, et al., 2007). Both programs were implemented largely as planned with majority of participants and group facilitators satisfied with the programs (Oldenburg, Absetz, et al., 2011). High participant satisfaction was also reflected in the rather high retention rates throughout both programs (Oldenburg, Absetz, et al., 2011). The main source of dissatisfaction by participants as well as facilitators was the relatively short duration of the program and difficulty in handling separate worksheets instead of workbooks, both factors that were raised in the facilitator training and could be effectively dealt with later in the long-term implementation and up-scaling of the program.

The primary objective of both programs was to achieve a reduction in type 2 diabetes risk via attainment of five secondary objectives defined by the Finnish DPS (Tuomilehto, Lindstrom, et al., 2001) and entailing nutrition (total fat ≤30E%, saturated fat ≤10E%, fiber ≥15 g/1000 kcal), physical activity (≥30 min/day moderate), and weight loss (≥5%). By 12 months, 20% of the GOAL participants achieved at least four of these five key outcomes, results that were comparable to the original trial. Physical activity and weight loss goals were achieved significantly less frequently than in the original trial, 65% vs. 86% and 12% vs. 43%, respectively (Absetz, Valve, et al., 2007). Three-year follow-up of the GOAL indicated continued statistically significant risk reduction in weight (−1.0 +/−5.6 kg), BMI (−0.5 +/−2.1 kg/m^2), and serum total cholesterol (−0.4 +/−1.1 mmol/l) (Absetz, Oldenburg, et al., 2009). Twelve-month results of the GGT DPP included reductions in weight of 2.52 kg, waist circumference by 4.17 cm, fasting glucose of 0.14 mmol/l, plasma glucose 2 h after oral glucose challenge by 0.58 mmol/l (0.36–0.79), total cholesterol by 0.29 mmol/l, low-density lipoprotein cholesterol by 0.25 mmol/l, triglycerides by 0.15 mmol/l, and diastolic blood pressure by 2.14 mmHg (Laatikainen, Dunbar, et al., 2007).

For both the GOAL and GGT DPP, analyses on the psychosocial processes of lifestyle change confirmed the general applicability of the behavior change model used in the interventions (Laatikainen, Philpot, et al., 2012; Renner, Hankonen, et al., 2012), as well as its applicability across socioeconomic strata (Hankonen, Absetz, et al., 2009).

Long-Term Implementation and Up-Scaling

For scale-up and maintenance, the GOAL program has undergone some key refinements following the initial real-world implementation trial. Specific modifications have included an inaugural session to give an overview of the program and timetable; one follow-up session to extend support up to 18 months; increased participatory and activating exercises; strengthening facilitators' training program with components on group facilitation; increased user-friendliness of the participant workbook; community-based activities in collaboration with local NGOs, e.g., healthy cooking and physical activity; and a peer support group program that has evolved as a spin-off for participants who have graduated from the GOAL program. Additionally, the training of group leaders has increased: initially, it consisted of 2 days prior to first group session plus 1 day during the program. Currently, 3 days prior to program plus 1 day annually provide adequate opportunity to build skills and self-efficacy in the program delivery and group facilitation and to share experiences with other facilitators.

The GGT DPP was translated and scaled up in the State of Victoria in Australia as the Life! Program (Dunbar, Hernan, et al., 2012; Janus, Best, et al., 2012). Multiple strategies were introduced for reaching the target population such as social marketing and incentives for GP practices and Life! Facilitators. The intervention is now offered either as a face-to-face program with one individual and five group sessions or as a telehealth coaching program with six one-on-one calls. The group sessions are also open to a partner or a friend. Facilitators' training program includes one orientation day, a self-learning period, and a 2-day workshop on session contents and facilitation skills (Reddy, Vaughan, & Dunbar, 2010). Facilitator training program is complemented with online training modules and there is a quality control system in place. Participants also have access to online supports.

DPP Translation in Low- and Middle-Income Countries

Only two of the first-wave efficacy trials were conducted in LMICs, i.e., the Da-Qing study in China (Pan, Yang, et al., 1997) and the Indian Diabetes Prevention Program (IDPP) (Ramachandran, Snehalatha, et al., 2007). The Da-Qing study included a 6-year active intervention with three lifestyle counseling arms targeting either diet or exercise only or both diet and exercise. It was delivered at community facilities in small groups of high-risk individuals identified with IGT. The study is exceptional in showing long-term effects for up to two decades: a 43% lower diabetes incidence 14 years after the 6-year active intervention had ceased. Remarkably, there was little difference in weight change between the intervention and control conditions during the active intervention. Furthermore, the three intervention arms were equally effective in risk reduction both in short- and long-term (Li, Zhang, et al., 2008). As with the other efficacy trials (Knowler, Barrett-Connor, et al., 2002; Tuomilehto, Lindstrom, et al., 2001), the IDPP tested a relatively intensive intervention comprised of individualized advice by a health provider on healthy diet and regular physical activity with monthly telephone calls to maintain motivation. The study was conducted in an urban, mainly middle-class population with persistent IGT. It achieved a 30% reduction in type 2 diabetes incidence. However, the IDPP would be difficult to "scale up" to community or national level as such, it being not feasible to provide one-on-one advice to the >20 million people with IGT in India (International Diabetes Federation, 2013). As over two-thirds of India's population lives in rural areas, strategies that are less dependent on health-care providers and health-care services are needed for broad diabetes prevention.

The limited scalability of the findings from the efficacy trials has been carefully identified in a systematic review of 30 published implementation trials of diabetes prevention programs that have utilized lifestyle interventions derived from either US DPP or Finnish DPS (Aziz, Absetz, et al., 2015). However, none of these were conducted in LMICs. The HICs represented – mainly the USA but also many Western European countries, as well as Australia and Canada – differ from LMICs in terms of their health systems, culture, traditions, and lifestyle behaviors. Further, HICs share many enabling features for disease prevention that developing countries still lack. Thus, extension of the DPP to LMICs requires considerations of the circumstances, health systems, and cultures of those settings.

The Kerala Diabetes Prevention Program (KDPP) (Sathish, Williams, et al., 2013) in India is one of the first studies to test the feasibility and effectiveness of a culturally adapted model for diabetes prevention in a LMIC. We will describe the translation of the KDPP from the GOAL and the GGT DPP as a case example to illustrate key factors in adaptation across cultures and extension into LMICs. Before describing the program in Kerala, the following sections review considerations that guided translation from the HICs to the LMIC setting.

Health on the Public Agenda Although people in the HICs are often said to live in a so-called obesogenic environment, there are also many contextual factors that actually support healthy lifestyle and lifestyle interventions. From the 1980s onwards, health has become an important consideration in many policies, with countries such as Australia, Canada and Finland in the lead (WHO, 1986; 2012). Public and private healthcare organizations and non-governmental organizations support prevention and control of noncommunicable diseases (NCDs). Employers and their organizations increasingly recognize the need for worksite programs and policies to promote occupational health (Sparling, 2010). Furthermore, although people in HICs live in a highly motorized environment, they also often have efficient public transportation, good access to roads that are safe for walking and bicycling, as well as recreational sports facilities.

On the other hand, however, LMICs are increasingly adopting the obesogenic features of modernization, but without the counterbalancing health promoting elements. The main public health emphasis is still largely on communicable diseases, maternal and child health services, and malnutrition, as is reflected, e.g., in the United Nations' Eight Millennium Development Goals for 2015, none of which are directly related to noncommunicable diseases. In LMICs, the informal employment sector is large. Bitran (2014) estimated that in Southern and Southeast Asia, only one-third of the workforce is employed in the formal sector. Hence, with an abundance of cheap, uninsured workforce whose illness costs do not fall on the employers, there are often no incentives for NCD prevention in occupational settings. Furthermore, population awareness of prevention of noncommunicable diseases also tends to be low (Daivadanam, Absetz, et al., 2013).

Research Tradition and Infrastructures for Prevention HICs enjoy a number of resources for prevention not present in LMICs. These include:

- Financial support
- Infrastructure for program implementation and delivery, such as health-care personnel with adequate education
- Research base concerning the factors that influence the development of type 2 diabetes and its prevention

Individualistic Models of Behavior Change Many of the major diabetes prevention programs are based on behavior change models and techniques and a long tradition of behavioral scientific research that has evolved almost exclusively in the Western World. This research tradition has emphasized the individuals' role as an active decision-maker, with psychosocial constructs such as outcome expectations, self-efficacy (Bandura, 2004), and individual goals and self-regulation (Carver, 2004) for lifestyle change identified as primary determinants of behavior change. Strategies for behavior change draw largely from cognitive-behavioral therapeutic tradition such as self-monitoring, goal setting, and creation of specific action plans as some of the most effective behavior change techniques (Lara, Evans, et al., 2014; Michie, Abraham, et al., 2009). As noted earlier in the chapter, for example, the GOAL program and the GGT DPP were each based on the health action process approach (Schwarzer & Fuchs, 1996) with its emphases on risk perception, outcome expectations, self-efficacy, intention to change, and individual actions and coping. However, the relevance of these theories and the applicability and effectiveness of the techniques in more collectivist cultures have not been well tested. Moreover, key contextual factors of a more collective nature such as household decision-making, household efficacy, and perceived household cooperation and response in relation to a change in behavior are not often factored into the intervention process or the program (Daivadanam, Wahlstrom, et al., 2014).

Strategies for Extending Diabetes Prevention to the LMICs Translation and planning of the KDPP intervention were done following the phased approach for designing complex interventions (Campbell, Fitzpatrick, et al., 2000) starting from (1) a comprehensive needs assessment including policy and research reviews and a qualitative interview study, and proceeding through (2) program translation and modeling to (3) exploratory pilot and (4) a definitive RCT, with (5) long-term implementation as the final goal and hence reflected in the entire process. The next sections describe progress to date, through the pilot study and revisions of the program for the RCT that is currently underway.

Needs Assessment: Relevance of the Problem In contrast to the long history of policies, research, and programs in NCD prevention that led to GOAL and GGT DPP, the needs assessment for the KDPP (Daivadanam, Absetz, et al., 2013) showed that, although India currently has the second largest number of people with type 2 diabetes, over 60 million, prevention of the disease still does not emerge high on the national agenda. The history of NCD prevention policy is relatively recent, and the impact still largely unevaluated. It was not until 2010 that recommendations for diet and physical activity were published as part of the National Program for Prevention and Control of Diabetes, Cardiovascular Diseases and Stroke (NPDCS). Epidemiological research revealed a very high prevalence of clinical and anthropometric risk factors for metabolic syndrome and type 2 diabetes. While modernization is increasing these risk factors in the whole of India, Kerala is by far the most advanced in this transition. The changes are largely attributable to diet and sedentary lifestyle. This is most common among women, who also have a higher prevalence of type 2 diabetes. Furthermore, sedentariness related to all aspects of life (work, leisure, and commuting) is not only an urban phenomenon but applies to rural India, too (Daivadanam, Absetz, et al., 2013).

Needs Assessment: Target Behaviors The GOAL and the GGT DPP as well as earlier diabetes prevention studies focused on moderate weight loss, increased intake of fiber, reduced total and saturated fat, and increased in physical activity (Absetz, Valve, et al., 2007; Laatikainen, Dunbar, et al., 2007). In addition to these, reduction in carbohydrates with high glycemic index such as refined rice and sugar containing foods and beverages, as well as improved sleep and reduction of smoking (among males), emerged as important targets.

Research on psychosocial determinants has been very limited in India. Still, the needs assessment review and qualitative research (Daivadanam, Absetz, et al., 2013) pointed at low awareness of personal risk and risk factors as well as low self-efficacy for and outcome expectations of prevention in general and behavior change in particular and hence supported the applicability of the health action process approach, the theoretical model behind the GOAL and the GGT DPP. However, the needs assessment also revealed a high dependence on family and cultural norms in decision-making related to lifestyle in India. Findings from the qualitative research especially suggested that application of the behavior change model would need further adjustment from a purely individualistic into a more collectivist and family-oriented focus. These observations were mirrored in other NCD interventions in India which suggested that risk reduction requires multilevel strategies including awareness raising, community empowerment, and individual and family empowerment (Balagopal, Kamalamma, et al., 2008; Daivadanam, Wahlstrom, et al., 2013, 2014; Krishnan, Ekowati, et al., 2011; Kumar, Sarma, & Thankappan, 2012; Mohan, Shanthirani, et al., 2006; Murukutla, Turk, et al., 2012; Ramachandran, Arun, et al., 2010).

Intervention Aims The KDPP adopted the same risk reduction objectives as earlier studies but without evidence-based benchmark for similarly precise nutritional, physical activity, and weight loss objectives. Additionally, broader secondary objectives for the KDPP included:

1. To increase motivation in type 2 diabetes prevention among participants and their families and communities by
   (a) Raising awareness of type 2 diabetes risk and potential for lifestyle in preventing the disease
   (b) Increasing outcome expectations for and self-efficacy in prevention with lifestyle change
2. To strengthen individual and community skills and capability to healthy lifestyle changes with the support and help of KDPP peer group, families, and community at large
3. To increase opportunities for healthy lifestyle changes with the support and help of KDPP peer group, families, and community at large

Program Translation and Modeling Participants for the KDPP were identified from electoral wards and their diabetes risk tested with home screening using an Indian Diabetes Risk Score. The main mode of program delivery was small group meetings held in a community locality such as reading room, a local school, or participant's home that was accessible to all participants. Although participation was based on risk status, the participants were encouraged to bring family members along to the group meetings. Based on a tradition of peer-led community groups in India and findings from peer-led interventions including the US National Diabetes Prevention Program (Albright & Gregg, 2013), plans included recruiting and training peer leaders specifically for the KDPP.

The KDPP program was designed as a 12-month program to commence with an inaugural small group meeting to introduce the program and nominate peer leaders from within the group, followed by four fortnightly and subsequent monthly small group sessions of 60–90 min each until the end of the program. To meet the participants' needs for information, the program was designed to contain a half-day diabetes education session delivered in larger groups by a specially nominated KDPP expert panel and a possibility for the groups to use the expert panel also later during the program. The decision to extend the program to 1 year was due to several reasons. First, finding a suitable time for sessions was not easy and Sunday appeared to be the only free day of the week. However, there are many festivities, family gatherings, and other events to compete over participants' time so sessions could not be too frequent. Due to time constraints, 90 min was the maximum participants could be expected to spend at the sessions. The program contained a broader range of behaviors than in the GOAL and the GGT DPP. Although the official literacy rate in Kerala is very high, almost 90%, many people have had only a few years of formal education and may not have used their skills for many decades. Hence, many of the exercises in the program were expected to take longer time to complete. Finally, a common point of criticism from participants in the GOAL and GGT DPP had been that those programs should have lasted longer than they did.

Behavior Change Techniques The behavior change techniques of self-monitoring, goal setting, action and coping planning, etc. described earlier in this chapter that were common to Look AHEAD and DPP translations in developed countries also formed the basis of the KDPP behavior change model. Instead of focusing on individual control, the issues related to unhealthy lifestyles and the identification of healthier options were to be addressed collectively. For example, assessing risks and reappraising outcomes were to include consideration of the implications for families. Setting lifestyle goals took place with participants' family members and others living in the same household. By emphasizing collective problem solving and collective ways to pursue healthier lifestyles and to support one another, it was expected that not only individuals' but also families' self-efficacy would be enhanced.

In addition to its emphasis on the family, the KDPP explicitly included community empowerment as a key program objective. Strategies for community empowerment included identification of key community leaders and other influential citizens who act as local resource persons for the KDPP groups and the peer leaders, identification and partnering with key stakeholder organizations in the local communities, and supporting their roles in creating social norms and planning and developing local environments, events, or programs together with the KDPP groups to enable more healthy lifestyles to all the community members.

Flexible Program Content In the GOAL and the GGT DPP, all groups followed the same structured program with predefined exercises. In the KDPP, by contrast, all the groups tackled diet and physical activity, but the specific contents of the group sessions were flexible and depended on the specific needs of each group. Suggested contents for diet covered, e.g., portion size, identifying cooking substitutions to reduce fat, increasing fruit and vegetable consumption, and decreasing sugar intake, while contents for physical activity included, e.g., finding enjoyable activities for individuals and groups, incorporating those activities into daily routines, and avoiding injuries and accidents. Tobacco control and cessation, reducing alcohol consumption, and sleep were to be dealt with based on the participants' needs and interest. The KDPP also included handbook and workbooks for the participants and a manual for the facilitators and peer leaders.

Exploratory Study An exploratory study of the KDPP was conducted with two groups to test (1) participant identification with home screening and mobile clinic testing, (2) delivery of small group sessions from inaugural meeting through session four, (3) delivery and contents of diabetes education session, and (4) peer leader selection process. This pilot highlighted some important challenges. While overall participation was moderate, male participation was a problem not only due to work constraints but also due to the belief that disease prevention activities were more appropriate for women. Although our expectations for illiteracy had been higher than the official 10%, in practice participants frequently were unable to read and write the local language (Malayalam). Many participants were familiar with type 2 diabetes through family members or relatives who already had the disease. However, this led to two things that compromised their motivation in self-care: first, many were fatalistic about getting the disease themselves, and second, they expressed that management of their significant other's disease was their first priority, not prevention of their own disease. Finally, although peer leader identification proved to be unproblematic, a major area of improvement was to find strategies to build the peer leaders' and the group members' confidence in their ability to manage sessions and benefit from them in the absence of the professional KDPP intervention team.

Modification of the KDPP from Exploratory Study Challenges identified in the exploratory pilot study led to development of a staged approach to program rollout and implementation. In the resulting plan, the first 2 months of the intervention focused on recruitment and retention with strategies highlighting the relevance and benefits of the program to participants and their families, as well as to the peer leaders. This initial phase also sought to raise awareness and support for the KDPP objectives from the communities. The community leaders of each electoral ward identified the local resource persons (LRP) to support the peer leaders and the groups. Also, an additional diabetes education session was introduced to address management of type 2 diabetes, as this had been the major concern for the pilot participants, and to link it to prevention of the disease.

The next 3 months focused on building peer leader skills and self-efficacy. The skills were targeted to enable and strengthen peer support among participants, to raise awareness of existing healthy habits and ways to improve them, as well as to build self-efficacy among participants and their families. Peer leader training in phase two included 2 days focusing on further skill building and sharing perceived benefits, positive experiences, and solutions to problems. The KDPP intervention team kept in frequent contact with the peer leaders, providing them with ongoing support both directly and via the LRPs.

The final 6 months of the 12-month program emphasized ways to maintain and expand the changes toward healthier habits with the peer support and help of extracurricular activities such as kitchen gardening, yoga training, walking groups, etc. At this point, the groups sought to disseminate messages into their communities and develop further plans to activate their communities in diabetes prevention and a healthier lifestyle. In a workshop organized by the KDPP, peer leaders and LRPs shared ideas to develop their plans and identify community organizations with which they could partner in putting the ideas into practice.

A randomized controlled evaluation of KDPP with a 2-year follow-up is currently underway (Sathish, Williams, et al., 2013). The findings, so far, indicate that the program has been very successful in engaging those for whom it is intended. This includes recruitment rates of 75% among eligible individuals and a retention rate at the 1-year assessment of over 90%. Additional indicators of successful implementation and engagement include high participation rates – almost half of the participants attended 75% or more of the intervention sessions over 1 year – and very positive feedback from participants as well as local community and health leaders. There are also early indications that many of the activities undertaken by the peer support groups have been further implemented and have "spread" to the broader communities in which the program participants live. These early findings strongly suggest that the Kerala Diabetes Program and delivery model that have been developed for India are well accepted, adopted, and more widely implemented by people with high risk of diabetes and their communities.

Conclusions

A solid foundation for the management of obesity has been laid with behavioral change strategies playing a prominent role. Knowledge about *nutritional* approaches to weight management will continue to evolve, but these *behavioral* strategies will remain the foundation for assisting patients to make lifestyle changes to adopt healthy eating. This has been exemplified through the DPP and Look AHEAD studies. For example, not only is Look AHEAD the largest and longest randomized controlled trial for weight loss (Perri, 2014), it has demonstrated that through intensive intervention, the elusive goal of long-term weight loss is possible. Although the differences in weight loss between the ILI and DSE conditions declined over time and the trial found no significant differences in cardiovascular endpoints (Look AHEAD Research Group, Wing, et al., 2013), significant improvements were initially demonstrated across multiple areas of health including quality of life (Williamson, Rejeski, et al., 2009), mobility (Foy, Lewis, et al., 2011; Schwartz, Johnson, et al., 2012), and sleep apnea (Foster, Borradaile, et al., 2009). Notably a significant proportion of individuals experienced partial remission of their diabetes (Gregg, Chen, et al., 2012).

In the USA, dissemination of these approaches of the DPP – centered on behavior change strategies for lifestyle change – has been vigorous with appreciable successes (Albright & Gregg, 2013). The efforts to extend them globally have shown success in developed countries, through the GOAL program in Finland (Absetz, Valve, et al., 2007) and the Greater Green Triangle Diabetes Prevention Program in Australia (Laatikainen, Dunbar, et al., 2007). The Kerala Diabetes Prevention Program (Sathish, Williams, et al., 2013) has moved the dissemination efforts to low- and middle-income settings. It shows still the general applicability of the basic model and of behavior change but, stimulated by the cultural setting of India, also expands emphases on family and community.

The broad sweep of this work reveals an impressive progression of understanding and application in behavioral medicine. Without requiring change in some highly inferential personality characteristics as had long been assumed, the initial work of Stuart showed that focusing on specific eating behaviors could alter body weight (Stuart, 1967). Throughout the last third of the twentieth century, behavioral medicine researchers refined the set of behavioral change strategies useful in initiating and maintaining weight loss (Foreyt & Pendleton, 2000; Jeffery, Drewnowski, et al., 2000; Stunkard, 1978; Wadden & Foster, 2000; Wing, Tate, et al., 2006). The twenty-first century has brought reports of the remarkable application of these approaches to major public health problems – diabetes prevention and management (Diabetes Prevention Program Research Group, 2002; Look AHEAD Research Group, Wadden, et al., 2006; Look AHEAD Research Group, Pi-Sunyer, et al., 2007; Look AHEAD Research Group, Wing, et al., 2013; Look AHEAD Research Group, 2014a; Tuomilehto, Lindstrom, et al., 2001). Dissemination is in progress in the USA and other upper-income countries (Albright & Gregg, 2013; Absetz, Valve, et al., 2007; Laatikainen, Dunbar, et al., 2007) and, now, with promising results in low- and middle-income settings (Sathish, Williams, et al., 2013).

Among the many lessons from this field, three stand out. First is a model of cultural adaptation. Consider for a moment the extent to which diet and obesity are culturally influenced and, then, how much one might expect key approaches to weight loss to vary tremendously across different groups, cultures, and countries. From that perspective, the general applicability of the basic behavior change strategies for weight management across very different settings – Australia, Finland, the USA, China, and India – is remarkable. To be sure, those principles needed to be tailored to the specific conditions in each of those settings, such as with the increased emphasis on family and community in the Kerala DPP, but still the fabric seems fairly generalizable. This reflects a model of standardization by function rather than by specific protocol or details of interventions (Aro, Smith & Dekker, 2008; Hawe, Shiell & Riley, 2004). In the present case, goal setting is an important feature of weight management programs. How those goals are set, for example, with individuals or, as in India, with families, may vary from setting to setting, but key functions, like goal setting, seem to have quite robust generality.

A second key lesson is the importance of ongoing contact or support. The Da-Qing program continued contact every 3 months throughout its course (Pan, Li, et al., 1997). Look AHEAD provided monthly contact and varied programs throughout the years it was implemented (Look AHEAD Research Group, 2014a). The idea that we can teach individuals skills with which they can autonomously manage their weight for the rest of their lives is not supported by data. Rather, sustained weight loss – like all behaviors – appears to require sustained reinforcement through ongoing contact and support. This appears also to be true of diabetes self-management. In a meta-analysis, duration of intervention was the best predictor of success of self-management programs in improving metabolic control (Norris, Lau, et al., 2002).

The third lesson emerging is the importance of context. Reflecting the importance of ongoing contact to support sustained weight loss, research also points to the importance of families and community contexts for sustained health behaviors. In this regard, the emphasis on these contexts for individuals' diabetes prevention in the Kerala DPP is noteworthy and may provide useful models for other countries in the coming years.

The needs of the 2.1 billion individuals worldwide who are overweight or obese (Ng, Fleming, et al., 2014) remain a daunting challenge. The research reviewed here shows, however, that real benefits are attainable through well-established behavioral change strategies. What is critical appears to be continued innovation in ways to adapt and disseminate those behavior change strategies with different groups, countries, and cultures, along with supportive policies to create food and community environments conducive to long-term healthy diet, physical activity, and body weight (Brownell, Kersh, et al., 2010; Gearhardt, Bragg, et al., 2012).

Preventing Violence and Injury

Jingzhen Yang, Corinne Peek-Asa,
and Trisha L. Welter

Introduction

Traumatic injuries are among the leading threats to global health, causing more than five million deaths annually (World Health Organization [WHO], 2008). Injuries result in more deaths than all other causes combined for people aged 5–44 years and contribute significantly to premature life lost and years lived with disability for all countries, all regions of the world, and all age groups (Peek-Asa & Hyder, 2008). Injury deaths are caused by many factors including unintentional mechanisms such as road traffic crashes, drowning, falls, and fires as well as intentional mechanisms such as homicide and suicide. Injuries disproportionately affect the young, and eight of the 15 leading causes of death for people aged 15–29 are related to injuries (Peden, McGee, & Sharma, 2002), with road traffic crashes, self-inflicted injuries, and interpersonal violence in the top 5 (Krug, Sharma, & Lozano, 2000; Krug, Dahlberg, et al., 2002; Peden, McGee, & Sharma, 2002; Peden, McGee, & Krug, 2002).

Deaths from violence and injury are merely the tip of the iceberg – for each death, thousands of nonfatal injuries require medical treatment, many of which lead to long-term disability. The disability-adjusted life year lost, or DALY, was introduced by the World Bank and World Health Organization as a measure of disease burden (World Bank, 1993). The DALY combines the loss of healthy life from premature mortality and the estimated years of disability from nonfatal disease, thus integrating the burden of mortality and morbidity (Murray, Vos, et al., 2012). Injuries are estimated to account for more than 11% of all DALYs (Murray, Vos, et al., 2012). Road traffic crashes account for 27% of all injury-related disability-adjusted life years lost, followed by self-inflicted injuries, falls, and interpersonal violence (Murray, Vos, et al., 2012).

Injuries place a severe physical, emotional, and financial burden on individual victims, their families, and our society. To prevent injuries and their negative consequences, many intervention strategies have been used to effectively change individual behaviors and/or policies or to improve technologies and the environment. There is strong evidence of the effectiveness of these

preventive interventions, including use of seat belts to prevent traffic injuries, bicycle helmets to prevent bike-related injuries, residential smoke detectors and the implementation of fire safety education programs to improve home safety, home visitation of new parents to prevent mistreatment of children, and tenant-based rental assistance programs to prevent youths from witnessing or becoming victims of crime. Widespread implementation of such interventions could save thousands of lives annually.

When designing interventions, it is essential to take into account the fact that injuries are inextricably linked to behavior at the individual, community, and societal levels. Although injury types and associated risk factors are highly varied, individuals who exhibit risky behavior are likely to be at increased risk for all types of injury, and this link has been identified across many cultures and countries (Begg & Gulliver, 2008; Dong, Peek-Asa, et al., 2011; Yi, Poudel, et al., 2010). Factors associated with communities and larger society, such as safety-related norms and cultural practices, also play a critical role in injury incidence as these factors influence the likelihood that safety-related policies are implemented and enforced and/or the types of environmental approaches that are utilized. Thus, examining multiple levels of influence on behavior is critical in the estimation of the burden of injury and in the design and implementation of effective prevention and intervention programs.

Despite the fact that many intervention strategies have been successfully used in violence and injury prevention and control, injury prevention research continues to remain an understudied area in behavioral medicine, partially due to disproportionate distribution of research funding in the area of violence and injury compared to other health problems. For example, in the United States, injuries account for 31% of years of potential life lost before age 65, more than cancer and heart disease combined (Runyan, Hargarten, et al., 2010). However, federal research support is lower for injury than either of these other research topics. Furthermore, many injury prevention strategies, for example, those to reduce road traffic crashes, occur across multiple governmental sectors and outside of the healthcare field. Because the field is so multidisciplinary, coordinated research and preventive measures require multisectoral collaborations. Despite these challenges, the field of injury and violence prevention has advanced tremendously in the past decade.

This chapter will describe the global burden of injuries, provide a context for multilevel behavioral approaches to violence and injury prevention, and provide four examples that illustrate the intervention programs and strategies utilized to target changes at the individual, family, community, and policy levels to prevent violence and injury. These four examples target increasing seat belt use, smoke detector installation, bicycle helmet use, and preventing intimate partner violence.

Global Distribution of Violence and Injury

According to newly published results from the Global Burden of Disease Study, injury mortality increased to 10.7% from 1990 to 2013 (GBD 2013 Mortality and Causes of Death Collaborators, 2015). During this same period, road injuries increased to 15% and rose from the tenth leading cause of death to the fifth leading cause worldwide. Self-harm, interpersonal violence, and falls all rose in their ranking, while drowning and fire and heat had a lower rank in 2013 than 1990. Globally, injuries are disproportionately distributed in low- and middle-income countries compared with high-income countries. Of the more than five million injury deaths each year, more than 85% occur in low- and middle-income countries (Peden, McGee, & Sharma, 2002). The highest injury mortality rates for men are in Africa, followed by Europe, Southeast Asia, and the Americas, all with an injury mortality rate exceeding 100 per 100,000 population (Peden, McGee, & Krug, 2002). Injury mortality rates for males in the Eastern Mediterranean and Western Pacific are lower, about 87 per 100,000 population. Regional patterns of injury mortality differ somewhat for women. Although African women also have the highest rates, 75.1 per 100,000 population, women in the Americas have the lowest rate, with 29.4 per 100,000 population. Women in the regions of Southeast Asia, Western Pacific, Eastern Mediterranean, and Europe all have rates exceeding 45 per 100,000 population.

These mortality trends illustrate a common pattern found throughout the world: men have higher rates of injury mortality than women. Worldwide, injury mortality rates for men exceed those among women for road traffic crashes, interpersonal violence, self-inflicted violence, drowning, falls, and poisoning. This difference is most marked for road traffic crashes and interpersonal violence, for which men have mortality rates that exceed women's by more than a factor of three. Fire-related deaths are an exception, with women experiencing a slightly higher mortality rate than men. Although a great deal of research has confirmed the gender differential, little research has examined causal reasons. The most frequent reason cited for higher injuries among men and boys is increased risk-taking behavior (Hu & Baker, 2009).

Another uniform trend of injuries globally is the age distribution: injuries disproportionately affect the young. Nearly 50% of the world's injury deaths occur among those aged 15–44, and another 20% occur among those under 15. As with gender, the age trend also has important behavioral implications that present a paradox: compared to the elderly, young people are far more resilient and more likely to survive a traumatic event, yet the majority of injury deaths do not occur among the elderly (although the elderly do have high mortality rates). Thus, the resilience of the young to injury is somehow offset by the frequency or severity of the exposure.

Injury types have different distributions by region. As measured through DALYs, Southeast Asia alone accounts for 34% of the burden of traffic crash injuries. The Western Pacific Rim accounts for another 24%. These regions are characterized with large populations and rapid industrialization (Stevenson, Yu, et al., 2008). However, increases in vehicle production, ownership, and miles traveled have not been accompanied by effective programs to improve safety behavior. Many countries in these regions do not have a sound motor vehicle safety culture that integrates the promotion of individual safety (such as seat belt use and consumer preference for cars with strong safety records), safety-promoting policies (such as enactment and enforcement of drunk driving laws), and coordinated efforts to incorporate safety into road and vehicle design. This paradox of miles traveled vs. road traffic-related DALYs can largely be explained by the effects of safety behaviors implemented at the individual, community, and societal levels (Graham, 1993). Regional road traffic-related DALYs are strongly correlated with income level, with low- and middle-income countries experiencing DALYs lost up to five times greater than high-income countries within the same region, which suggests that availability of resources for infrastructure development is critical (WHO, 2002).

Regional patterns of interpersonal violence and self-inflicted harm show similar correlations by income, with 95% of interpersonal violence and 86% of self-inflicted harm DALYs lost in low- and middle-income countries. More than a third of interpersonal violence DALYs are lost in the Americas and another 23% in Africa. Regional patterns for self-inflicted DALYs are quite different: the Western Pacific Region accounts for only 11% of DALYs lost for interpersonal violence but 38% of self-inflicted harm. Similarly, Southeast Asia accounts for 14% of DALYs lost for interpersonal violence but 26% for suicide (WHO, 2002).

Compared with road traffic crashes, less is known about the larger cultural influences and behaviors that impact violence and self-harm, although these cultural contexts are critical factors in prevention (WHO, 2002). After the World Health Organization released the first global report on violence and health in 2002, attention to violence prevention as a global priority has gained considerable attention (WHO, 2002). The WHO report prioritizes primary prevention and identifies strategies to reduce violence at the individual level, including social development and treatment programs; the relationship level, including family therapy programs; the community level, including coordinated community interventions and public education campaigns; and the societal level, including legislative and policy changes. There is a critical need to grow the evidence base to help identify successful and cost-effective programs and to identify the most effective strategies to translate proven approaches across cultures.

Research to compare global trends of injury mortality rates, DALYs lost, and regional comparisons by age, gender, and injury type has only been available for approximately the last 10 years. Several types of injuries stand out as having distinct regional patterns. Mortality from poisoning was markedly higher in low- and middle-income countries within Europe than any other region or income level. Poisoning-related DALYs lost were high in low- and middle-income countries in Africa as well as in India. DALYs lost from drowning are concentrated in low- and middle-income countries in Africa as well as in India and China. These surveillance efforts, however, represent a very important step in recognizing the burden of injury and, ultimately, in identifying effective prevention and intervention steps. Increased attention to injury research and program development will help identify the causes driving these trends and methods to reduce the injury burden.

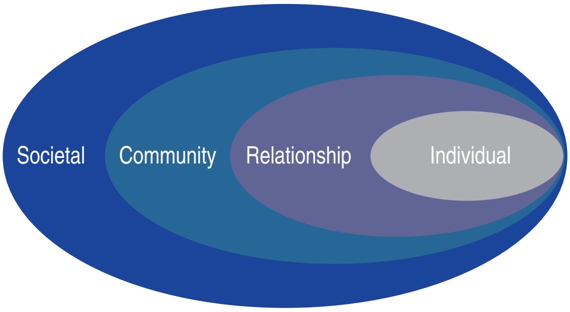
Application of Theory to Violence and Injury Intervention

The Socioecological Model: A Framework for Violence and Injury Prevention

The Socioecological Model is a framework which suggests that there are multiple levels of influence on specific health and health-related behaviors (Centers for Disease Control and Prevention [CDC], 2009). While individuals are responsible for instituting and maintaining specific health behaviors necessary to reduce the risk of violence and injury and improve health, individual behavior is determined to a large extent by the physical and social environment (e.g., road condition, home safety devices, community norms and values, and policies). Efforts to prevent injuries and violence are more likely to be successful when we work within multiple spheres of influence at the same time. The four-level Socioecological Model displayed here includes the interplay between individual, relationship, community, and societal factors that put individuals at risk of injuries and violence (CDC, 2009). The model can assist in better understanding the determinants of behaviors leading to injuries and violence (Dahlberg & Krug, 2002). This knowledge is useful when designing, implementing, and evaluating violence and injury prevention interventions (Fig. 29.1).

Individual Level The first level of the Socioecological Model identifies biological and personal factors that increase or decrease the risk of injuries and/or violence (CDC, 2009). Some of these factors include age, education, income, substance use, history of abuse, and the practice of safety behaviors. Prevention strategies at this level are often designed to promote attitudes, beliefs, and behaviors that will ultimately prevent violence and injury. Interventions for individual-level influences are often designed to target an individual's social and cognitive skills and behavior and include approaches such as counseling, therapy, and educational training sessions.

Fig. 29.1 Socioecological Model



Examples of such programs include an education program for school children to increase their knowledge on bicycle safety and sexual assault prevention programs for college students aimed at increasing awareness and reducing rape supportive attitudes and behaviors (Nagel, Hankenhof, et al., 2003; Vladutiu, Martin, & Macy, 2011).

Relationship Level The second level examines how close relationships with family, friends, partners, and peers increase or decrease the risk of injuries and/or violence. Violence prevention strategies at this level may include mentoring and peer programs designed to reduce conflicts, foster problem-solving skills, and promote healthy relationships. A recent intervention that targeted skill building found that couples who improved their healthy relationship and conflict management skills had reductions in intimate partner violence (Cleary & Gottman, 2012). Injury prevention strategies may include parent-focused programs to increase the supervision of children, peer programs to reduce behaviors that lead to injury (e.g., drinking and driving), and healthcare provider discussions with their patients on injury prevention. A study of children presenting in the emergency department found that 39% of parents who received counseling from a primary care physician reported making at least one positive change in their environment to make it safer for children at a 2-week follow-up (Claudius & Nager, 2005). Several randomized trials that focused on the critical role of parents in the driving experience of their children, including the *Checkpoints Program* and *Steering Teens Safe*, have demonstrated success in improving parent-teen driving safety communication and consequently improved safe driving attitudes and behaviors of the teen drivers (Beck, Hartos, & Simons-Morton, 2006; Hartos, Eitel, & Simons-Morton, 2002; Ramirez, Yang, et al., 2013.; Simons-Morton, Hartos, et al., 2005; Yang, Campo, et al., 2013).

Community Level The third level explores the settings, such as schools, workplaces, and neighborhoods, in which social relationships occur and seek to identify the characteristics of these settings that are associated with injuries and/or violence. Prevention strategies at this level are typically designed to impact the climate, processes, and policies in a given system. For example, establishment of sexual harassment or violence policies in the workplace can send a message that these behaviors are not tolerated, and there are consequences for those who engage in these behaviors (American Academy of Pediatrics Committee on Pediatric Workforce & Pletcher, 2006; Feda, Gerberich, et al., 2010). Another example of a community-level intervention is installing free smoke alarms or offering discounted smoke alarms for resident homes to reduce fire-related injuries and deaths (DiGuiseppi & Higgins, 2001; Yang, Peek-Asa, et al., 2008).

Societal Level The fourth level looks at the broad societal factors that help create a climate in which risk behaviors that lead to injuries and violence are discouraged. These factors include social and cultural norms, including the safety culture. Other large societal factors include the health, economic, educational, and social policies that reduce economic or social inequalities between groups in society (CDC, 2009). One example for societal level influences is to determine societal norms that accept violence and identify strategies for changing those norms. Such interventions often involve collaborations of multiple partners to change laws and policies. Seat belt laws and bicycle helmet laws are two examples of societal level strategies that have been found to increase injury prevention behavior (Karkhaneh, Kalenga, et al., 2006; Nichols, Tippetts, et al., 2014). Further, high visibility enforcement, law upgrades, and higher fine levels have been associated with highest levels of seat belt use (Nichols, Tippetts, et al., 2014).

An example of the application of the Socioecological Model lies in the promotion of smoke alarms in low-income neighborhoods. The socioecological approach can be used to increase the knowledge, skills, and self-efficacy to install and maintain smoke alarms, which can reduce the risk of fire-related injury and death. Door-to-door education about the importance of smoke alarms could be implemented at the individual level. Family-centered programs could be used to teach parents about the importance of smoke alarms and help them set up a fire escape plan with their family. At the community level, smoke alarm giveaway programs through fire departments, and at the societal level, policies that require smoke alarms in all homes will increase the proportion of homes with functioning alarms.

Each of the four levels in the Socioecological Model can be considered a point of influence. Violence and injury prevention interventions should include a continuum of activities that address multiple levels of the Socioecological Model. These activities should be culturally appropriate and specifically tailored to fit the target population's needs. This multifaceted and tailored approach is much more effective at sustaining prevention efforts over time than any intervention that only focuses on a single sphere of influence.

Types of Prevention Interventions

Prevention is a strategy or approach that reduces the likelihood of risk of onset, delays the onset of adverse health problems, or reduces the harm resulting from conditions or behaviors. Violence and injury prevention approaches can be classified into three types based on the time that a violence and injury prevention program occurs: primary, secondary, and tertiary prevention.

Primary prevention is an approach that aims to prevent the injury or violent event from occurring in the first place. Some examples of primary prevention include setting the thermostat on the hot water heater to below 120 F and always testing the water temperature before letting a child get into a bathtub to prevent burns for children; placing a nonskid mat in the bathtub or shower and/or participating in an leg strength exercise program to prevent falls for older adults; and media campaigns in the community to promote nonviolence in relationships. Primary prevention strategies also include educational sessions or mass media campaigns to raise awareness or increase knowledge as well as government and state requirements including those designed to prevent industrial injuries and policies mandating safety features in cars that reduce crash risk or policies that restrict access to workplaces by non-employees.

Secondary prevention is an approach used to reduce the severity of injury during an injury event. For example, secondary prevention strategies for motor vehicle crashes are those that reduce the level of energy in the crash, but do not prevent the crash itself. Some examples of secondary prevention include seat belts, air bags, and helmets. Among secondary strategies are also educational sessions to teach children about the proper use of a bicycle helmet, free residential smoke alarm installing programs to cue evacuation behaviors of residents in the event of a fire, youth sports traumatic brain injury legislation mandating removal from play following actual or suspected concussions and permission to return to play by a licensed healthcare professional, and training of teachers to identify boys who need individualized counseling on conflict management. These activities can either reduce the severity of injury or interrupt the development of subsequent injury or violence.

Tertiary prevention is an approach that takes place after an injury or violent event occurs. The goal is to lessen the long-term effects of the event and optimize full recovery. Tertiary prevention programs aim to improve the quality of life for the injured by limiting complications and disabilities, reducing the severity and progression of injuries, and providing rehabilitation to restore self-sufficiency. Some examples of tertiary prevention include one-on-one counseling for victims of domestic violence, shelter programs for battered women, prescribed physical and cognitive rest for youth with sports-related concussions, and comprehensive trauma systems designed to effectively care for trauma victims. Unlike primary and secondary prevention, tertiary prevention may involve actual treatment for the injuries including medical treatment and rehabilitation after car crashes, fires, and incidents of violence.

Though the distribution varies based on the country and injury or violence topic, a combination of primary, secondary, and tertiary prevention strategies should be used to address incidents of violence and injury. Each type of prevention involves different strategies and, often, different target populations. A growing emphasis has been placed on primary prevention because these strategies have the greatest impact (Krug, Dahlberg, et al., 2002). Interventions can also be divided into groups based on the population that is targeted. They can be classified as being universal, selected, or indicated. *Universal* interventions are designed to favorably shift risk and/or protective factors across a whole population. Examples include mass media campaigns or policies regarding seat belt use, helmet use, and smoke alarm installation and use. *Selected* interventions are those that are aimed at people who have been identified in some way as being at heightened risk for injury and/or violence victimization or perpetration. More specific examples include smoke alarm giveaway programs in low-income areas with high fire mortality rates and intimate partner violence prevention programs for women who live in countries or communities where violence is considered somewhat culturally accepted. *Indicated* intervention approaches are aimed at those who are already experiencing symptoms of a condition. Some examples of indicated interventions include policies restricting gun ownership in individuals who have been convicted of domestic violence and bicycle helmet giveaway programs for children who go to the emergency room after a bicycle accident. In general, universal and selected interventions are more likely to be aligned with primary prevention, while indicated interventions are often forms of secondary or tertiary prevention. Each of these approaches should be considered when determining the best injury or violence prevention design.

Haddon's Matrix

Haddon's Matrix, developed by William Haddon, is a conceptual model that systematically portrays an injury or violence issue in temporal and epidemiological components with the goal of identifying prevention countermeasures (Haddon, 1970; Runyan, 1998). According to this framework, injuries occur with a certain time sequence, and the occurrence of an injury involves the epidemiology triangle (host, agent, and environment) (Fig. 29.2). Thus, the framework combines a temporal dimension similar in some respect to distinctions among types of prevention, with the kind of distinctions among sources of influence of the Socioecological Model. Combining the two axes of the Haddon Matrix framework, one can evaluate the relative importance of different factors and design interventions.

	Personal Factors	**Vector or Agent Factors**	**Physical Environment Factors**	**Social Environment Factors**
Pre-Event	Driver's experience, training or visual acuity	Speed of travel, Vehicle characteristics (lighting, braking, handling)	Road type, quality and markings	Safety-enhancing social norms/ cultural practice
Event	Use of seat belts, Driving impairment (e.g., drunk driving)	Safety devices, Crash protective design	Crash protective roadside objects	Enforced seatbelt and drunk-driving laws
Post-Event	First aid skill, Physical resilience	Ease of access, Fire risk	Rescue facilities, Access to trauma care	Programs of preparedness for EMS responders

Adapted from WHO, 2006.

Fig. 29.2 Example of Haddon's Matrix in crash-related injury prevention (Adapted from WHO, 2006)

There are three steps in using Haddon's Matrix (1970; Runyan, 1998). The first is to use community data to determine the injury problem. Step two is to brainstorm potential ideas for interventions and fill them into the cells of Haddon's Matrix. Within the second step, one should start assessing the contributing factors or characteristics from the perspective of (1) personal factors, (2) the agent of energy, (3) the physical environment, and (4) the social environment. Then, one should examine which factors are related to these time phases: (A) pre-event, (B) event, and (C) post-event.

In the case of a car crash, some examples of personal factors that could be targeted to prevent a crash (pre-event) include the driver's experience, training, and vision. Pre-event agent factors could include speed of travel and vehicle load characteristics. Physical environment factors in the pre-event phase include road type, quality, and markings; social environment factors include safety-enhanced norms or practices. These factors should be identified for each stage in the matrix, until it is completely filled out. It is important to remember that prevention can be focused on any of the cells of the matrix.

Once the matrix is completely filled out, the third and final step in using Haddon's Matrix is to make decisions about the best intervention options. In general, many post-event factors could be target of tertiary prevention, while the pre-event and event factors are more likely to be changed using primary or secondary prevention strategies. When comparing to the Socioecological Model, personal factors are consistent with the individual-level determinants, while the agent and environmental factors are often connected with the community and societal level determinants. For example, interventions can address the host/pre-event cell (e.g., teaching teens about dangers of drinking and driving) or the agent/pre-event cell (e.g., improvements in vehicle safety such as antilock brakes). Interventions can also be implemented to change the physical environment by reducing the risk of injury pre-event or post-event (e.g., building roundabouts or circular intersections to prevent crashes or improving ambulance service systems to reduce paramedic response time). Changes can also be made in the social environment (e.g., changing social norms around driving safety or training responders for emergency preparedness). Many factors should be considered during this step, including evidence on the effectiveness of certain strategies, known characteristics of the culture and population, the setting, and the budget. Nonetheless, the use of the Haddon Matrix and careful consideration of other theoretical approaches will increase the chance of intervention success.

Four Examples Applying Principles and Concepts of Behavioral Medicine to Violence and Injury Prevention

The following sections will describe interventions that were designed to increase seat belt use, smoke detector installation, and bicycle helmet use and reduce intimate partner violence. These four sections highlight injuries that are prevalent, produce immense burden, and have theory-based interventions with evidence of success. These examples will depict the importance of multilevel interventions and illustrate how the behavioral medicine concept can be used to prevent injuries and violence.

Example 1: Seat Belt Use

Road Traffic Deaths and Injuries

Road traffic injuries are among the most rapidly increasing causes of global mortality, estimated to become the third leading cause of death worldwide by the year 2020 (WHO, 2004). Low-income countries account for nearly 85% of this burden, but many high- and middle-income countries also have exceedingly high mortality rates, with motor vehicle crashes representing the largest cause of death among adolescents and young adults (WHO, 2004). An estimated 20–50 million individuals are injured in road crashes each year, accounting for an estimated 38.4 billion, or 2.6%, of all DALYs. The toll of these deaths and injuries, including the physical and psychological burden on individuals, families, and communities as well as medical and quality of life costs, is staggering.

A large proportion of road crash victims in low- and middle-income countries are vulnerable road users such as pedestrians and bicyclists (WHO, 2004). However, increasing industrialization accompanied by increased use of personal vehicles has led to an increase in the proportion of victims who are vehicle occupants. One of the most effective methods of reducing injury during a crash (secondary prevention) is the seat belt.

Studies have overwhelmingly supported the effectiveness of seat belts, which reduce fatalities and severe injuries by more than 50% (Campbell, 1987; Evans & Frick, 1986; Rivara, Koepsell, et al., 2000). The automobile seat belt was first implemented in the early 1950s in both the United States and in Sweden, yet even today, over half a decade later, we have not attained the prevention potential of the seat belt due to low and varied use of seat belts by occupants. Creating a culture of seat belt use has turned out to be a complex interplay of multiple behavioral approaches at the individual, family, social, and political levels.

Efforts to Increase the Wearing of Seat Belts Through Policy

The first step in achieving the potential prevention effect of the seat belt was mandating that they are available in cars, which in Haddon's Matrix is a pre-event agent change that is tantamount to behavioral change at the policy and industry level. In the 1950s, seat belts were first introduced in the United States as an option for consumers, and consumers bore the cost of installation. Strong efforts of medical and advocacy communities that promoted information about the growing toll of motor vehicle crash deaths and the effectiveness of seat belts led to new safety standards, introduced in 1968, that required seat belts to be installed in all occupant positions. Although advocates at that time believed that mandated seat belt availability would lead to a high proportion of use, only about 11% of occupants actually wore their seat belt (Peterson, Tilman, et al., 1999). Other countries have been much slower to regulate seat belt installation in cars. For example, China did not require seat belts to be in the back seat of cars until late 2004 (Routley, Ozanne-Smith, et al., 2008).

In order to increase seat belt use, many countries and localities have implemented policies that require seat belt use. In 1970, the state of Victoria, Australia, passed the first law worldwide making seat belt wearing compulsory for drivers and front-seat passengers (Trinca & Dooley, 1977). The implementation of this law led to an estimated 33% decrease in motor vehicle occupant deaths and injuries. The United States introduced its first seat belt legislation in 1984, when the state of New York required all front-seat and child back seat occupants to be belted (Peterson, Tilman, et al., 1999). Since that time, all 50 states have implemented some type of seat belt use law, but these first laws were "secondary," which allowed ticketing for seat belt non-use only when the vehicle was stopped for a reason not related to the seat belt. These secondary laws in the United States were found to increase seat belt use to about 63%. Currently, 16 states in the United States have only secondary seat belt enforcement laws, and one state has neither a primary or secondary seat belt law for adults (Governors Highway Safety Association [GHSA], 2015).

Implementation of primary laws, which allow police to pull over a car for the sole reason of non-seat belt use, increased seat belt use to approximately 78% (Peterson, Tilman, et al., 1999). Currently, 33 states in the United States have primary seat belt laws for at least the driver and front-seat passengers (GHSA, 2015). In the United Kingdom, front-seat belt usage rose from 37% to 95% after introduction of the seat belt law, which also resulted in the reduction of hospital admissions due to road traffic injuries by 35% (Rutherford, 1985). Primary laws are more effective than secondary laws because they are more easily enforced; one study showed a seat belt use rate of 9 percentage points higher in states with primary laws than those with secondary laws (Nichols, Tippetts, et al., 2014). Enforcement and monetary fine amounts are also essential elements of policy success (Nichols, Tippetts, et al., 2014). However, even with primary laws, the potential prevention effect of the seat belt was far from attained.

Efforts to Increase the Wearing of Seat Belts Through Policy Enforcement

Although policies requiring seat belt use are an essential part of increasing use, policies are largely ineffective without enforcement. Qatar, for example, introduced a front seat passenger seat belt law accompanied with strong enforcement on January 1, 2002, which led to increased safety belt usage among patients hospitalized from a road traffic crash from 8% in 2001 to 67% in 2004. The overall rate of hospital admissions due to road traffic injuries was decreased by 17.7% (Bener, Al Humoud, et al., 2007). Enforcement was identified as a critical element of this law's success.

The absence of enforcement leads to lackluster impact. One study in Russia, for example, found that only 15–20% of the Russian population used seat belts despite a national law requiring their use (Akhmadeeva, Andreeva, et al., 2008). Despite laws in Greece and Italy, seat belt wearing was below 60% (Routley, Ozanne-Smith, et al., 2008). Policies are complicated because they often do not apply to all drivers. In Nigeria, for example, a primary law for drivers led to seat belt use of 31.7%; however, the use among front-seat and rear seat passengers, neither of whom were covered by the law, was 10.3% and 0.4%, respectively (Sangowawa, Alagh, et al., 2010). Pakistan also only requires seat belt use for drivers, with exceptions for some types of vehicles, drivers, and roads. Here too, seat belt use is very low, averaging 20% (Klair & Arfan, 2014). Laws in different countries vary considerably in their requirements, exclusions, enforcement, and penalties (Weiss, Sirin, et al., 2006). In addition, local and state/provincial laws often vary within countries. With the complexities of these policies, it is not surprising that policies alone do not garner the desired level of behavior change.

Research throughout the world demonstrates that policies must be enhanced with larger social efforts to change behavior – a critical step in creating a seat belt culture. In Turkey, seat belt use was observed to be as high as 70% among drivers on inner-city roadways (WHO, 2004), which is attributed to their primary law for drivers. A separate study found that 52.1% of adults were belted, but in the same vehicles only 29.4% of children were belted and the same percentage of children were found sitting on the lap of an adult (Porter, Lajunin, et al., 2010). These findings suggest that occupants are motivated to wear their seat belts in order to obey the law, but the motivation to protect occupants from death or injury if the car crashes seems missing (since the most vulnerable occupants were not protected).

Efforts to Increase the Wearing of Seat Belts Through Educational Campaigns

Evaluations of coordinated approaches to increasing seat belt use have found higher use and more significant decreases in crash fatalities and injuries. A multifaceted intervention in Guanzhou, China, augmented existing legislation with police officer training to increase enforcement and social marketing and health education campaigns to raise public awareness (Stevenson, Yu, et al., 2008). A 12% increase in seat belt use was observed. Social campaigns alone, however, have not shown substantial effects in the absence of enforcement. An intensive campaign to increase seat belt use in Greece, conducted in the absence of increased law enforcement, resulted in gains of less than 6% (Petridou, Trichopoulos, et al., 1999). Studies in the United States have also confirmed that availability, policy, and enforcement, augmented with social marketing campaigns are an effective approach, leading to a strong recommendation in the Guide to Community Preventive Services (Shults, Nichols, et al., 2004).

Finally, studies show that multifaceted efforts must be persistent. China enacted a seat belt law for drivers in 2004, with local and provincial laws following. Seat belt wearing observed in two cities was nearly 50% for drivers, less than 10% for front-seat passengers and less than 1% for rear seat passengers. Only 1 year following the implementation of the laws, seat belt use decreased significantly and continued on this trend for several more years (Routley, Ozanne-Smith, et al., 2008). The authors attributed these declines to reduced efforts for enforcement and public education.

Despite variation in cultures on individual, social, and political behavior, the research available worldwide consistently identifies that a coordinated, multifaceted, and persistent approach is needed to create a seat belt wearing culture. Though much research has shown great impact on societal level changes like seat belt mandates for car manufacturers or laws mandating use, these changes alone do not necessarily lead to individual behavior change. To increase seat belt use, all socioecological levels must be addressed, including the family. Studies have shown that risk behavior, and seat belt use in particular, does have familial patterns (Habib, Hamdan, et al., 2010). Familial patterns, along with cultural differences and norms, should be considered when designing interventions. Although global progress over the last 50 years has included increased seat belt availability, implementation of seat belt legislation and enforcement in many countries, and recognition that public education and social norms campaigns are critical, seat belt use rates throughout the world vary markedly. Great promise in the future lies in our ability to evaluate and translate successful approaches, with the focus of efforts housed in the low- and middle-income countries with the highest motor vehicle occupant fatality and injury rates.

Example 2: Smoke Detector Installation

Fire-Related Injuries and Deaths

Fires are a leading cause of unintentional injury deaths worldwide. It is estimated that fires cause about 1% of the global burden of disease and 300,000 deaths per year (Murray & Lopez, 1996). In just 1 year's time, residential fires caused 491 deaths and 14,100 nonfatal injuries in the United Kingdom. In the United States, a total of 3240 civilian deaths and 15,925 injuries resulted from fires (Karter, 2014). Fire death rates are far higher in low-income countries. Though deaths and injuries resulting from fires have decreased in the last 25 years, home fires still cause 85% of all fire deaths in the United States (Karter, 2014). Injuries and deaths caused by fires remain a global public health and safety concern today, because of the immense impact on health, the environment, and society as a whole.

Globally, children and adults under the age of 44 account for the highest proportion of deaths from fires. Socioeconomic status is also associated with a disproportionate burden of fire-related consequences; as in many countries, the poorest groups are less likely to practice safety behaviors and more likely to suffer from fire-related injuries and deaths (CDC, 2010; Flynn, 2010; Istre, McCoy, et al., 2001; Mock, Rissa, et al., 2002). Furthermore, low socioeconomic status is also associated with many personal risk behaviors and home characteristics. Some of these include cigarette smoking, alcohol intoxication, nonfunctioning smoke alarms in homes, homes located in rural areas, and older housing (Mallonee, Istre, et al., 1996; Peek-Asa, Allareddy, et al., 2005; Runyan, Johnson, et al., 2005). Each of these behaviors and home characteristics are found to be associated with increased risk of fire-related injuries and deaths in many countries (Leistikow, Martin, & Milano, 2000; Netherlands Institute for Safety Nibra, 2009).

Most fire deaths occur at night while victims are sleeping. The cause of death is likely to be inhalation of smoke and toxic gases rather than burns. This may be partially explained by the fact that vapors from the fire are inhaled before the sleeping occupant is aware of the fire (Ahrens, 2001; Hall, 2001). A working smoke alarm is one of the most effective and least expensive ways to help prevent and reduce fire-related deaths and injuries, because they detect fires before they become dangerous and provide sufficient warning to occupants so that they can escape safely from the building. Smoke alarms ensure a high level of protection and safety in a residence. Results from existing research show that functional smoke alarms minimize property damage, prevent injuries, and reduce the risk of dying in a fire by 50% and the risk of having a reportable fire by 75% (Marshall, Runyan, et al., 1998; Runyan, Bangdiwala, et al., 1992).

Like other injury prevention interventions, resident fire safety can in theory be advanced by educational, engineering, or legislative strategies. Several resident fire safety intervention programs have focused on promoting smoke alarm ownership, improving smoke alarm functionality, or both. Strategies include local ordinances requiring alarms, smoke alarm giveaway programs, counseling by physicians and other health professionals, and reminders to test alarms and replace batteries (DiGuiseppi & Higgins, 2001). These interventions consider the strategies influencing both individual level determinants (e.g., education campaign or counseling) and environmental level factors (e.g., providing or installing free alarms) in the Socioecological Model. Through randomized or nonrandomized trials, these intervention strategies have been shown to increase smoke alarm ownership and function. Among these strategies, installation and maintenance of smoke detectors in households have been shown to be one of the most effective ways to prevent deaths and injuries from fires.

Increasing Smoke Alarm Ownership and Functioning

Two commonly used intervention strategies include programs that provide free smoke alarms and programs that install them within homes, and often these two steps are combined. Results from several smoke alarm giveaway community trials show a modestly greater effect on smoke alarm ownership and functioning alarms than did education alone (DiGuiseppi, Slater, et al., 1999; DiGuiseppi & Higgins, 2001; Mallonee, Istre, et al., 1996). Several large-scale fire safety projects have utilized this strategy. The “Let’s Get Alarmed!” program (DiGuiseppi, Slater, et al., 1999) distributed 20,050 smoke alarms to households in the inner-city London area. Individuals in low-income areas or areas with material deprivation were successfully targeted. Other smoke alarm community trial giveaways have been able to more successfully track smoke alarm outcomes. The “Oklahoma Smoke Alarm Project” in the United States found that during the 6 years following the project, the fire-related injury rate decreased by 81% among the target population, compared to a 7% decrease in the rest of Oklahoma City (Mallonee, 2000). A community-based installation program in Dallas, Texas, found house fire-related deaths and injuries to be reduced 68% in program homes about 5 years after installation, compared to non-program homes (Istre, McCoy, et al., 2014). However, rates declined after the sixth year, probably due to alarms losing their functionality. One randomized controlled trial in the United Kingdom (Ginnelly, Sculpher, et al., 2005) found that over 1 year later, the prevalence of functioning smoke alarms was about the same in the intervention and control groups, suggesting that giving away free smoke alarms may not automatically increase an individual’s awareness of the benefits of having a working alarm, or the skills and knowledge required to install and maintain smoke alarms (DiGuiseppi & Higgins, 2001).

Existing evidence indicates a substantially greater effect on smoke alarm functionality when free alarms were actually installed compared to just providing vouchers for free alarms (DiGuiseppi & Higgins, 2001). An additional analysis showed both types to be cost-effective, but installation programs fared better on a cost-benefit analysis (Liu, Mack, & Diekman, 2012). One program in the United States tested the difference in outcomes by having two separate groups – one that received free direct installation of fire alarms and the other which received free vouchers (Harvey, Aitken, et al., 2004). Upon follow-up, almost 90% of households in the installation group had working alarms, compared to just 65% of the voucher group. One large reason for this is that 47% of households in the voucher group never redeemed their voucher. Similarly, results from a randomized trial involving free smoke alarm installation in rural homes in Iowa in the United States showed that approximately 99% of the study homes had at least one functioning alarm (Yang, Peek-Asa, et al., 2008). While several programs that solely utilize either home or school-based smoke alarm education did not show strong beneficial effects on smoke alarm ownership or alarm functioning, interventions that used multifaceted mass media and community-based injury prevention approaches have demonstrated success in smoke alarm functionality (Ta, Frattaroli, et al., 2006).

For example, one intervention paired smoke alarm installation with in-home education on escape planning. At follow-up, participants had significantly increased their fire safety knowledge and practices, and 97% of homes had functioning alarms on each level of the house (Duchossois, Nance, et al., 2009). Canvassing programs that include free smoke alarm installation demonstrate higher rates of working smoke alarms 1 year later, compared with programs that did not install alarms or only installed for participants who requested it (DiGuiseppi & Higgins, 2001).

Findings and Regulations That Influence Behavioral Interventions

Despite the immense impact of smoke alarms on fire safety, several studies have indicated high rates of nonfunctioning alarms in homes, with estimates ranging from 20% to 50%. Common reasons for alarm nonfunctioning include alarm removal, missing batteries, and the batteries being disconnected. False (nuisance) alarms often lead residents to deliberately disable smoke alarms, often as result of the alarm going off because of cooking fumes or steam and making noise continuously when powered (Netherlands Institute for Safety Nibra, 2009). To ensure smoke alarm functionality, the National Fire Protection Association in the United States has authorized standards and codes on how smoke alarms should be installed in homes. The codes require that a smoke alarm be placed on each level of a house (including the basement). In the USA, smoke alarms have been required in all new buildings since 1998. In rental properties, landlords are responsible for installing working alarms, and tenants are responsible for their upkeep. The codes require that alarms be installed according to the manufacturer's directions and recommend that alarms are not installed near kitchens, bathrooms, garages, or workshops.

Smoke alarms with ionizing sensors are especially prone to false (nuisance) alarms because they are more sensitive than photoelectric alarms at detecting small particles produced by hot and flaming fires, including particles created through cooking (Mueller, Sidman, et al., 2008). Since false (nuisance) alarms are the most common reason that residents disable smoke alarms, such actions can result in a nonfunctioning smoke alarm, which puts a household at an increased risk of fire-related injuries and deaths (Yang, Peek-Asa, et al., 2008). Therefore, photoelectric alarms, which are less likely to have nuisance alarms, have better long-term function near kitchens. Because alarm type and location can have such an impact on the alarm's effectiveness, these considerations should be kept in mind when designing interventions aimed at smoke alarm installation (Rowland, DiGuiseppi, et al., 2002; Yang, Jones, et al., 2011). It is essential to address the long-term maintenance of smoke alarms, so greater emphasis should be given to the continued functionality of alarms (Peek-Asa, Yang, et al., 2010; Peek-Asa, Yang, et al., 2011).

Because many fire deaths occur during sleeping hours, it is essential that alarm warning systems are effective at waking a variety of populations from deep sleep in order to increase the chance of survival. Research has shown that young children and older adults have a more difficult time being awakened by a smoke alarm than do other age groups. It is important to consider the pitch and frequency of the tones that these age groups are awakened by (Manchester, Meklenburg, et al., 2009). Similarly, individuals with hearing problems may need alternative smoke alarms to best receive warning of a fire.

Smoke alarm regulations also have an impact on the scope of behavioral interventions to reduce fire-related injuries and deaths. Denmark, Finland, Japan, Norway, and Sweden have adopted legislation requiring all homes to be equipped with smoke alarms, while many others require all new homes to have smoke alarms (Manchester, Meklenburg, et al., 2009). Other countries including Australia, the United States, and Canada do not have nationwide legislation but rather have provisions that territories/states/provinces can adopt. Even local provisions may be unrealistic in other nations, due to the fact that smoke alarms are unaffordable to the general population (Hendrie, Miller, et al., 2004). In many of these countries, it is essential to identify alternative methods to protect a home and its residents from fire-related injuries and deaths. Several research studies detail the most effective smoke alarm arrangements for residences. However, this "ideal" is not applicable to all countries. Differences in cooking methods, housing style, economic climate, and source of heating are just a few considerations that are important in determining the best fire prevention intervention.

Example 3: Bicycle Helmet Use

Bicycle Injuries

Injuries to bicyclists are a global public health problem with detrimental effects on the health and well-being of individuals both in higher-income countries where the prevalence of recreational bicycling is high and in low- and middle-income countries where bicycling is one of the predominant modes of transport. Furthermore, in recent years, injuries to young bicyclists have emerged as a particular concern in higher-income countries, such as in the United States, (USA) because of the popularity of bicycling as means of recreation and exercise among young people – especially children and the costs associated with these injuries (Hamann, Peek-Asa, et al., 2013). Nearly three-fourths of children aged 5–14 in the United States have ridden a bicycle in the past month (Dellinger & Kresnow, 2010). In the United Kingdom (UK), children aged 11–16 had an average annual cycling mileage that was higher than any other age group (Gill, 2005). Although the age of riders may vary, the risk of injuries remains a threat to all bicyclists.

Head injuries are among the most severe injuries to bicyclists, comprising one-third of emergency department visits and two-thirds of bicycling deaths (Rowe, Rowe, & Bota, 1995; Sacks, Holmgreen, et al., 1991). However, most of these injuries are largely preventable. Bicycle helmets provide physical protection for the face and head by partially absorbing the force of blunt trauma and dissipating energy so that the head alone does not sustain the total force of a blow. Research findings have revealed that helmet use substantially reduces both the likelihood and severity of head injury, with the risk of head injury reduced by 63–88% (Thompson, Rivara, & Thompson, 2000). Bicycle helmets provide nearly equal protection for crashes involving motor vehicles and crashes from all other causes, with a reduced risk of head injury at 69% and 68%, respectively (Thompson, Rivara, & Thompson, 2000).

Despite the vast degree of protective effects afforded by bicycle helmets, relatively few children and young people wear them. Observational studies from high-income countries estimate the proportion of child bicyclists who wear helmets to be relatively low, with examples from Sweden (33%), the United Kingdom (14%), France (22%), and the United States (13–65%) (Dellinger & Kresnow, 2010; Inwood, Whitley, & Sexton, 2005; Nolen, Ekman, & Lindqvist, 2005; Richard, Thélot, & Beck, 2013). In Turkey, a middle-income country, child bicycle helmet use is estimated at 4% (Secginli, Cosansu, & Nahcivan, 2014), and helmet use in other middle- and low-income countries is not likely to exceed this proportion.

To effectively promote bicycle helmet use among children, a number of intervention programs have been designed and implemented that utilize a behavioral approach. These approaches are often informed by social and behavioral theories emphasizing multilevel interventions. The behavioral medicine bike helmet interventions are all event-level factors in the Haddon Matrix, as helmets do not prevent accidents necessarily but can reduce the number and severity of injuries that result. They range from educational programs, promotional campaigns, and community incentives, to state and local laws requiring that bicyclists wear helmets. These interventions have been implemented across many countries, been carried out in different settings, and employed multiple strategies (Royal, Kendrick, & Coleman, 2007). The examples provided below illustrate how intervention strategies may effectively modify the behavior of an individual by incorporating educational campaigns, community incentive programs, and legislative initiatives.

Efforts to Increase the Wearing of Bicycle Helmets Through Legislation

The Socioecological Model posits that mandating bicycle helmet wearing may be an effective societal level approach in increasing the behavior of helmet use because efforts to increase the use of bicycle helmets through legislation affect virtually the entire population, in contrast to interventions that only reach individuals who choose to participate. Many countries, including the USA, have taken this approach to promote bicycle helmet use. In the United States, the first bicycle helmet law was passed in California in 1986 and became effective in 1987. This law was amended in 1994 to cover everyone under age 18. In Australia, the Royal Australian College of Surgeons played a leading role in initiating both a statewide campaign to promote the use of approved safety helmets and also in introducing a compulsory safety helmet law in Victoria, Australia. Following their efforts, bicycle helmets then became mandatory nationwide (Grande, 2007). Since then, many other countries including Canada, the Czech Republic, Finland, Iceland, New Zealand, and Sweden have passed bicycle helmet laws, in at least one jurisdiction, for either minors only or for all riders. Spain requires helmets on interurban routes. To date, in the USA, 21 states and the District of Columbia have statewide mandatory helmet laws, either for children under 18 or for all ages, and 37 states have mandatory helmet laws for varying age groups in some jurisdictions. Surveys from the United States, Canada, and France indicate support for helmet use legislation (Parkin, Degroot, et al., 2014; Richard, Thélot, & Beck, 2013).

Reports demonstrate an increase in bicycle helmet use following enacted helmet laws (Karkhaneh, Kalenga, et al., 2006). One study conducted in the United States found that laws have increased the average helmet use probabilities by 18.4% (Rodgers, 2002). Further, a systematic review of the scientific evidence on the effectiveness of bicycle helmet legislation in various countries suggests that helmet use increased significantly – between 45% and 84% – after passing helmet laws (Gilchrist, Schieber, et al., 2000). The effects of helmet laws have crossed several countries and cultures, as they have been shown to increase helmet use in Australia, New Zealand, and Canada (Hagel, Rizkallah, et al., 2006; Povey, Firth, & Graham, 1999; Vulcan, Cameron, & Watson, 1992). Considering its international success, mandatory helmet legislation is recognized as an effective strategy in increasing bicycle helmet use.

While increased bicycle helmet use is often systematically related to the presence of state helmet laws, there remains a debate on whether helmet laws help reduce head injuries. Some researchers conclude that bicycle helmet legislation appears to be effective in increasing helmet use and decreasing head injury rates among intervention groups (Karkhaneh, Rowe, et al., 2013; Macpherson & Spinks, 2007). However, others have found that although enforced helmet laws increased helmet use by 40% or more, they did not produce an obvious decrease in the percentage of head injuries (Robinson, 2006). Some opponents contend that bicycle helmet laws may not reduce the rate of injuries but rather reduce injuries by reducing overall cycling. Along these lines, data from New Zealand and Western Australia indicate that reductions in numbers of injuries are less than reductions in cycling (Erke & Elvik, 2007).

Promoting Bicycle Helmet Wearing by Children Using Nonlegislative Interventions

Bicycle helmet interventions often include a variety of components. Some of these are education campaigns, distribution of free helmets, and/or a provision of subsidized or discounted helmets, since bicycle helmet wearing is not currently enforced in every country. The theoretical assumptions that underline these nonlegislative, community-based intervention approaches are that a change in an individuals' knowledge of and/or attitudes toward bicycle helmet use and increases in that individuals' perceived benefits and/or reductions in the perceived barriers of bicycle helmet use will increase use. In addition, the provision of free or subsidized helmets may serve as cues to action for bicycle helmet use.

Nonlegislative bicycle helmet interventions have been utilized in many settings and with a variety of program components and have been shown to be an effective prevention strategy for head injuries caused by bicycle crashes or falls. Results from a recently published meta-analysis show that nonlegislative interventions led to more than double the bicycle helmet use among children and young people compared to control groups. The effect was greater in community-based studies and in those providing free helmets, compared to interventions that were in school settings or provided subsidized helmets (Royal, Kendrick, & Coleman, 2007). Several studies on community-wide education campaigns focusing on bicycle helmet use by school-aged children found that helmet use increased significantly, with increases varying from less than 5% to over 10%, after a campaign and/or distribution of educational material. Additional research has found an increase in bicycle helmet use after a program for children admitted to the emergency department for treatment. Children who directly received a free helmet (vs. a voucher or verbal counseling) had greatest chance of helmet use at follow-up (Wu & Oakes, 2005).

Global Implications of Helmet Use as a Behavioral Intervention

Behavioral interventions that focus on increasing bicycle helmet wearing vary across the globe. Because of this, it is important to consider many factors when designing an intervention to increase the use of bicycle helmets. First, it is essential that the specific helmet types used have been shown to be effective in reducing the risk of head injury. There are contrasting results in the literature in relation to the effect of helmets on the rate and severity of head injuries, and through the use of research-based effectiveness criteria, the most successful types of helmets can be identified. Only helmets that have been proven to reduce injury risk should be used in interventions.

Second, many individuals may have little or no access to bicycle helmets because of helmet cost and lack of availability to consumers. In this case, helmets must be provided for free or at a greatly reduced price as an important first step of head injury prevention. Because research has shown that providing helmets is not sufficient to ensure their success in reducing head injuries, additional components that promote fitting a bicycle helmet properly and wearing a bicycle helmet consistently need to be included in the intervention.

Third, it should be recognized that legislation/policy surrounding bicycle helmet use can have a significant impact on injury prevention programs. However, such legislation or policies are not easily enacted or changed. Even if policies do exist, if they are not enforced, bicycle helmets may still not be used regularly. Thus, enacting bicycle helmet laws alone may not be adequate for ensuring their protective effect on head injuries.

Last, it is important to consider the knowledge and attitudes surrounding bicycle helmet use in the context of culture and population. Studies looking at cross-cultural helmet practices have shown that bicycle helmet use varies from 39.2% to 1.9% among all of the countries studied (Klein, Thompson, et al., 2005). Because openness to wearing helmets, as well as resistance to them, will be so different from one culture to another, ideal program components would likely vary based on the country at hand. Considering cultural and population factors in designing an intervention to improve bicycle helmet knowledge, attitudes and behaviors will undoubtedly contribute to the program's success.

Example 4: Preventing Intimate Partner Violence

An Emerging Global Public Health Priority: Preventing Intimate Partner Violence

Worldwide, UNICEF and the WHO report that a quarter to three quarters of women around the world experience some form of violence from an intimate partner over their lifetime (The Commonwealth Fund, 1999; WHO, 2005a, 2005b). Despite this high prevalence, intimate partner violence is heavily underreported, with barriers to reporting that include societal stigma of being a victim, fear of retaliation by the perpetrator, fear of lost income, and fear of isolation from family.

In addition to its high prevalence and global pervasiveness, intimate partner violence is gaining attention as a public health priority because of the deleterious effects on its victims, their families, and society. Over half of women who are victims experience mental health effects, including depression, anxiety disorder, symptoms of post-traumatic stress disorder, and suicide attempts (Coker, Sanderson, & Dong, 2004). In addition to physical trauma from the violence itself, victims are also at risk for physical conditions, such as gastrointestinal disorders, chronic pain syndromes, hypertension, and cardiovascular disease. Intimate partner violence has been linked to alcohol, tobacco, and drug use. It has also been linked to increased exposure to HIV, other STIs, pregnancy complications, and adverse pregnancy outcomes such as premature labor and low infant birth weight (WHO, 2013). Negative effects on families include a high co-occurrence with family and child violence, chaotic and disordered familial relations, and the potential for generational patterns of perpetration and victimization (Fishback & Herbert, 1997). From a societal standpoint, the United Nations recognized in its Millennium Declaration of September 2000 that violence against women is a major threat to social and economic development (WHO, 2005a).

Steps toward preventing IPV first involve change at the social and political levels to develop a strong intolerance for violence and second to make assault against an intimate partner an unacceptable and illegal act. This level of behavior change has taken a long time in many countries, but creating attitudes of intolerance toward violence are being adapted more readily as global attention to family violence increases.

Developing a Strong Intolerance for Violence

The root causes of intimate partner violence are broad and complex, as is the development of effective intervention and prevention programs. Attitudes regarding partner violence are influenced by individual, familial, and societal norms. Social acceptability of violence against women is a complex construct: although many cultures include some level of intimate partner violence as acceptable, every culture has a threshold at which the frequency, intensity, or severity is unacceptable (Go, Johnson, et al., 2003). This diversity in social norms complicates a uniform approach to reducing violence in intimate relationships. Qualitative research in a low-income community in Chennai, India, found that both partners reported that husbands regularly beat wives in most marital relationships. However, violence was intensified by familial financial and work-related stress, societal gender norms, and strict gender role expectations (Go, Johnson, et al., 2003). In sub-Saharan Africa, a survey found that women were more likely to justify IPV than men. Common situations where it was perceived to be more justified included neglecting the children and going out without telling the husband (Uthman, Lawoko, & Moradi, 2009).

Because social definitions of unacceptable violence vary considerably, comparable measures of the frequency of violence against women are difficult to define. The World Health Organization has published a multi-country study on the prevalence and risk factors for IPV (WHO, 2005b). Research to identify the prevalence of IPV is an important first step in changing social norms; before the problem can be reduced, it must first be recognized. Thus, surveys from around the world that rigorously define and measure the prevalence of IPV are critical in helping identify the health burden before intervention strategies are developed to change the notion that violence against women is unacceptable.

Legal strategies to respond to intimate partner violence exist in most countries, but little evidence exists to suggest that these approaches reduce the prevalence or severity of IPV. In most countries, murder of an intimate partner is considered unacceptable, and such acts have severe legal and social penalties. However, most countries also have some situations in which partner homicide is condoned. Dowry deaths or honor murders, although officially illegal, receive lax judicial penalties due to the social acceptability of the act. Many countries also have specific legal penalties for nonfatal domestic violence. For example, the United States usually requires mandatory Batterer Education Programs as part of the sentence of a domestic violence conviction. However, growing evidence suggests that these programs have poor compliance and little effect on recidivism (Babcock, Green, & Robie, 2004; Hilton & Harris, 2009). Individual behavioral strategies that focus on the dynamics of the couple have been more promising in reducing intimate partner violence than those implemented through the court system (O'Leary & Smith Slep, 2011; Woodin & O'Leary, 2010).

Multilevel Behavioral Strategies to Change the Cycle of IPV

Growing evidence suggests that the most effective approach to reducing the burden of intimate partner violence lies with prevention (pre-event factors in Haddon Matrix) rather than treatment (post-event factors). The World Health Organization identified the public health approach as an effective means to reduce intimate partner violence and encouraged efforts to focus on primary prevention (WHO, 2005a). Changing the cycle of IPV will require multilevel behavioral strategies at the societal, community, relationship, and individual levels, with efforts focused on both prevention and intervention.

Prevention will be most effective at the community and societal levels, focused on increasing national commitment and changing social norms regarding IPV (Salazar, Valladares, et al., 2009; Vanderende, Yount, et al., 2012). Two studies of attitudes of acceptance toward IPV, one conducted among European Union countries and one conducted with 17 countries in sub-Saharan Africa, found that accepting attitudes toward IPV, long tied to higher prevalence, were independently influenced by socioeconomic indicators at the individual, neighborhood, and country levels (Gracia & Herrero, 2006; Uthman, Moradi, & Lawoko, 2009). The European Union study also found high levels of victim blaming across participating countries (Gracia & Herrero, 2006).

IPV may be effectively reduced through social programs and infrastructure improvements that have little to do with the violence itself, such as increased access to education, generally increasing levels of income and financial stability, and promotion of gender equality. Individual risk factors that increase the risk of intimate partner violence victimization and perpetration include young age, illiteracy, low educational levels, lack of financial means, lack of social networks, drug and alcohol use, and poor communication skills (WHO, 2005b). Program strategies that address these risk factors may be promising prevention approaches. Long-term gender equality is also seen ecologically as a method to reduce IPV prevalence (WHO, 2005a). One study in Ethiopia focused on gender equitable norms in young men and found self-reported reductions in violence toward their partners (Pulerwitz, Hughes, et al., 2015). Ironically, however, another study found efforts to promote gender equality to be linked to increased prevalence of IPV (Uthman, Lawoko, & Moradi, 2009) possibly because women become empowered and report more incidents. Given the high public health burden of IPV, increased attention from global organizations such as the World Health Organization, World Bank, and UNICEF is highly appropriate. The World Health Organization has outlined country-level goals to address domestic violence, and these call for a coordinated multisector approach that addresses the violence directly and integrates with programs that increase social infrastructure with tangential gains in violence reduction (WHO, 2005a).

Conclusion

Injuries cause significant physical and psychological trauma as well as substantial costs to individuals, families, communities, and societies. Historically, the investment in injury prevention has not been commensurate with its burden (Bonnie, Fulco, & Liverman, 1999; Runyan, Hargarten, et al., 2010), and many countries are just beginning to identify violence and injury prevention as a public health priority. Despite the historic lack of priority, violence and injury prevention is increasingly recognized an important aspect of public health (Krug, Sharma, & Lozano, 2002; Peden, McGee, & Sharma, 2002; WHO, 2002). Thus, the future is likely to bring many new and innovative methods to reduce the burden of injuries. A socioecological approach is a useful framework to work within when designing, implementing, and evaluating violence and injury prevention interventions. Factors that can influence the risk of injuries and violence can be broken down into four spheres: individual, relationship, community, and society. The use of the model can aid in the identification of behavioral determinants leading to injuries and violence (Dahlberg & Krug, 2002). Because the behavior of an individual has a reciprocal impact on the environment at multiple levels, when violence and injury prevention interventions focus on changes within multiple spheres of influence simultaneously, an impact on health outcomes may be larger than that seen by single-level approaches. These interventions may also be more cost-effective because of the greater ability to influence behavior change.

As this chapter noted, a large number of interventions have successfully incorporated environmental changes and targeted influence at the societal level, which seems to have the most impact. Interestingly, legal approaches show strong results in reducing the three unintentional injuries discussed in the prior sections – those from fires, automobile crashes, and bicycle crashes. However, legal approaches have not been shown to have much of an impact on intimate partner violence, an intentional injury. This may be because IPV is deeply ingrained in sex roles and cultural practices and may be more resistant to change without transformation of social norms. The fact that such social roles and cultural factors may be resistant to change does not invalidate the importance of community and societal-level interventions. Indeed, interventions and campaigns at these levels are likely to be of especially great importance in changing cultural practices, social roles, and other broad, foundational determinants of IPV as well as other injury-related behaviors and health behaviors in general.

Environmental strategies may have the most impact alone, but the person-environment interaction must not be ignored. Policies or environmental changes without information, regulation, and enforcement will not necessarily lead to individual behavior change. Furthermore, these strategies require behavior change at the higher levels of the Socioecological Model, such as changes in policy-maker knowledge and attitudes that lead to policy implementation. Thus, it is essential that violence and injury prevention interventions target multiple levels of influence to maximize impact on reduction of injuries.

Applying a socioecological approach to designing a multilevel violence and injury prevention intervention will remain a challenge. First, a Socioecological Model doesn’t necessarily provide information as to which determinants may be the most important nor does it lay out specific constructs that could be addressed in a violence and injury intervention. In order to use a socioecological approach to design an injury prevention program, one also needs to use other social behavioral theories and models to address factors at each level.

Second, when evaluating the effect of multilevel comprehensive interventions, one cannot easily determine which target level activity caused the greatest change in behavior. Because it is difficult to examine the effectiveness of each point of influence, it might require a reliance on the effect as a whole. Nonetheless, because most of these interventions are usually used with populations providing large numbers of observations, it often allows for multilevel, multivariate analyses. Continued research with different intervention components can lend information on the effect of specific intervention components as well as a combination of multilevel influences.

Lastly, multilevel interventions are often very complex and require the cooperation of many groups as well as time and resources. It can be especially difficult to make changes on the policy level. Thus, without strong relationships among a variety of groups and organizations dedicated to a common cause, multilevel interventions are unlikely to reach their full potential.

Injury prevention continues to be a major global public health concern but is still an underappreciated area within behavioral medicine. Due to the variety of problems it encompasses and immense burden on individuals, communities, and society as a whole, there is a great need to expand awareness to health professionals. As the body of research and recognition in the field grows, so too does the need for more sophisticated intervention approaches. By applying the Socioecological Model involving several levels of an individual's environment, behavior change undoubtedly becomes more likely. Without this multilevel approach, interventions aimed at behavior change, as well as a reduction in global violence and injury, may have little impact.

Research and dissemination of proven practices in injury prevention offer strong potential for improved health and well-being, and perhaps one of the most promising elements is increased attention to safety behavior. At the individual level, improved efforts to create safe behavior as a social norm have been very promising in areas such as driving safety and violence prevention. At the societal level, research to better understand how to improve the safety culture – i.e., to ensure that safety is a priority in important decision-making processes, is badly needed. A concerted effort to develop an evidence base on how to implement strong policies, for example, could help standardize and make more effective existing safety policies. The area of injury prevention is an exciting frontier for behavioral medicine.

> Sontag, 1979, p. 3

Introduction

Teaching medical students about medical care for patients with chronic illnesses tends to lead to confusion, bewilderment, and anger in at least a few of them. Most medical students have images of their future professional lives as young physicians, dressed in white coats that flutter while running through empty hallways late at night – heading for the emergency room where they will perform heroic, complex medical miracles, after which the patient will go home the next morning, completely recovered. To many of them, it comes as quite a shock to learn about the "epidemiological transition": the shift from "cure" to "care" and the shift from acute illness to chronic disease (Harper & Armelagos, 2010). These changes in the focus of medical care have many implications for all involved: patients, their partners, physicians, other healthcare professionals, society, and psychologists who teach medical students or provide clinical care for patients with chronic somatic disorders in a behavioral medicine setting.

In this chapter we will outline some of the implications of this epidemiological transition for medical care and for behavioral medicine and specifically review and discuss the following:

- The characterization of "chronic illness" and its implications for the contributions that medical care and behavioral medicine offer to the well-being of patients with those illnesses
- Some theoretical models that are instrumental and important for providing medical and behavioral medicine care to persons with chronic physical illness
- Self-management of chronic illness
- The empirical literature on the ongoing behavioral management of six major chronic somatic illnesses, namely, asthma, COPD, cancer, cardiovascular disorders (in particular, heart failure), diabetes mellitus, and rheumatoid arthritis

The chapter will conclude with some suggestions that may help strengthen research on ongoing behavioral management of patients with chronic illnesses.

Chronic Illness

The word "chronic" comes from the Greek "chronos," meaning "time"; in Greek, "chronikos" means "during a long period of time." The element of time, therefore, is a core concept in most descriptions of chronic illness. There is no generally accepted definition of "chronic illness." Verbrugge and Patrick provide a definition of "chronic conditions" that encompasses the core elements of most other descriptions of the concept:

> long-term diseases, injuries with long sequelae, and enduring structural, sensory, and communication abnormalities. They are physical or mental (cognitive and emotional) in nature, and their onset time ranges from before birth to late in life. Their defining aspect is duration. Once they are past certain symptomatic or diagnostic thresholds, chronic conditions are essentially permanent features for the rest of life. Medical and personal regimens can sometimes control but can rarely cure them. (Verbrugge & Patrick, 1995. p. 173)

"Most people reading this chapter will probably die of a chronic disease" – this is how Burish and Bradley (1983, p. 3) start the introduction to their book on coping with chronic disease. Some 30 years later, this statement is more true than ever. Public health researchers predict that by 2020, the chronic illness conditions of cancer, ischemic heart disease (including cerebrovascular disease), and chronic obstructive pulmonary disease (COPD) will make up the top of the list of diseases causing morbidity (Lopez, Mathers, et al., 2006).

Two myths deserve attention in the context of chronic (somatic) disorders. First, it is too simplistic to assume that medical care has contributed greatly to the increased longevity in industrialized societies. Bunker (2001) debunks this myth by demonstrating how "age-adjusted death rates were reported to be greater in countries with greater numbers of doctors, and presumably with more medical care […] death rates for diseases amenable to treatment were reported to be greatest in areas with the most medical care resources" (p. 1260). Behavioral scientists who claim that behavioral interventions for high-risk health behavior produce meaningful gains in life expectancy create myths as well: "with about a quarter of the population smoking, the population as a whole would gain about one and a half years if every smoker quit" (Bunker, 2001, p. 1262). Rose's "prevention paradox" seems to be valid here as well (John, 2011): "Population strategies which focus on reducing the risk of those already at low or moderate risk will often be more effective than strategies which focus on "high risk" individuals at improving population health" (John, p. 250). Morbidity and mortality are part and parcel of the "condition humaine" (Murray & Lopez, 1997).

Theoretical Models Regarding Behavioral Medicine Interventions in Chronic Illness

Various models have been developed, and tested, regarding medical and behavioral medicine management of people with chronic physical illnesses. Two models in particular stand out as they have been instrumental in the development of theoretical and empirical work: (1) the Common Sense Model, and (2) the Chronic Care Model.

In the *Common Sense Model*, the central tenet pertains to the making sense of physical sensations by people and the consequent steps in this process of sense making (Leventhal, Brissette, & Leventhal, 2003). When a person perceives a physical sensation, the person is assumed to be motivated to minimize the health-related risks and reduce the health threats in a fashion that is consistent with the representations s/he has about an illness. People form representations of an illness based on their knowledge of an illness, its representation in media (TV, Newspapers, Movies etc.), and encounters with the medical system. It is irrelevant whether these representations, or illness perceptions, are medically "correct" (assuming one could define what "correct" is). What *is* relevant is that these perceptions guide the response of patients to illnesses and, thereby, their self-management and outcome (see Fig. 30.1). Systematic reviews and meta-analyses

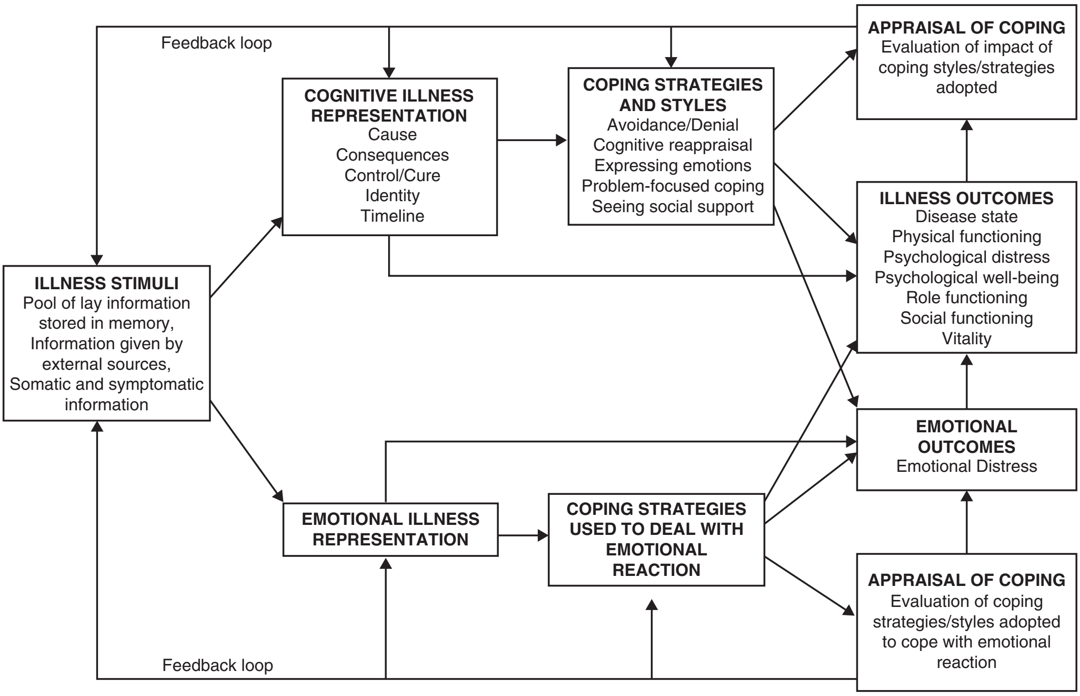

Fig. 30.1 The common sense model (From Hagger & Orbell, 2003)

of empirical work employing the Common Sense Model show how illness perceptions are powerful predictors of outcome in patients with chronic illnesses (Hagger & Orbell, 2003; Kaptein, Scharloo, et al., 2003). At least as important is the evidence about the effectiveness of interventions in the context of the Common Sense Model. If illness perceptions determine outcome, then changing illness perceptions should lead to changes (i.e., improvements) in self-management and, therefore, in outcome. A number of intervention studies do support this statement. For example, Jansen, Heijmans, Rijken, and Kaptein (2011) describe an intervention program and its initial encouraging results in patients with end-stage renal disease and their partners, based on the Common Sense Model. Skinner et al. (2011) report the positive effects of a self-management intervention in patients with diabetes, where the intervention lead to improvements in illness perceptions, which in turn were associated with positive changes in clinical characteristics.

As demonstrated in Fig. 30.1, contextual factors are not explicitly integrated into the Common Sense Model. These issues *are* part of the second model, the *Chronic Care Model* (Fisher, Brownson, et al., 2007; www.improving-chroniccare.org).

Here, self-management – a core concept in the Common Sense Model – is embedded into a social context and characteristics of the health system. The elements “community, resources, and policies” and “health systems, organization of healthcare” pertain to organizational characteristics of care delivery, where “practitioners have relationships to larger health care organizations and community resources that can support and enhance high quality chronic illness care” (Wagner, 2010, p. S637). Primary care (or family medicine, general practice) is conducive in achieving these conditions. Also, these organizational structures have implications for the education of healthcare professionals (e.g., Bodenheimer, Lorig, et al., 2002).

As Wagner and colleagues have noted, self-management interventions “generally emphasize the patient’s crucial role in maintaining health and function and the importance of setting goals, establishing action plans, identifying barriers, and solving problems to overcome barriers” (Wagner, Austin, et al., 2001, p. 74). These authors also importantly point out that “with a few exceptions, the tested interventions do not include long-term support for patient self-management or efforts to engage the primary care team” (Wagner, Austin, et al., 2001, p. 74). Other elements in the Chronic Care Model outlined in Fig. 30.2, such as delivery system designs, decision support, and clinical information systems, are aspects which help achieve productive interactions and improved outcomes.

A systematic literature review of applications of the Chronic Care Model in various chronic physical illnesses leads to modest optimism (Minkman, Ahaus, & Huijsman, 2007): “some evidence has been found that implementing interventions based on the Chronic Care Model improves performance (of the health care system and its professionals)” (p. 96). In their meta-analysis of interventions to improve care for chronic illnesses, Tsai, Morton, Mangione, and Keeler (2005) review 112 studies on asthma, congestive heart failure, depression, and diabetes in the context of the Chronic Care Model. They conclude that “… interventions that contain 1 or more elements of the Chronic Care Model can improve outcomes and processes for several chronic illnesses of interest to managed care organizations” (p. 487). Additional information on theoretical models and their application to the (self-) management of patients with chronic physical illnesses is provided by Newman and colleagues (Newman, Steed, & Mulligan, 2009).

The Common Sense Model and the Chronic Care Model – and related models, cf. Newman, Steed, and Mulligan, (2009) – point at the increasingly central position of the patient in modern medical care for people with chronic illnesses. Figure 30.3 illustrates this evolution.

The concepts of “self-management” and “disease management” at the top right-hand corner of Fig. 30.3 roughly reflect the Common Sense Model and the Chronic Care Model, respectively.

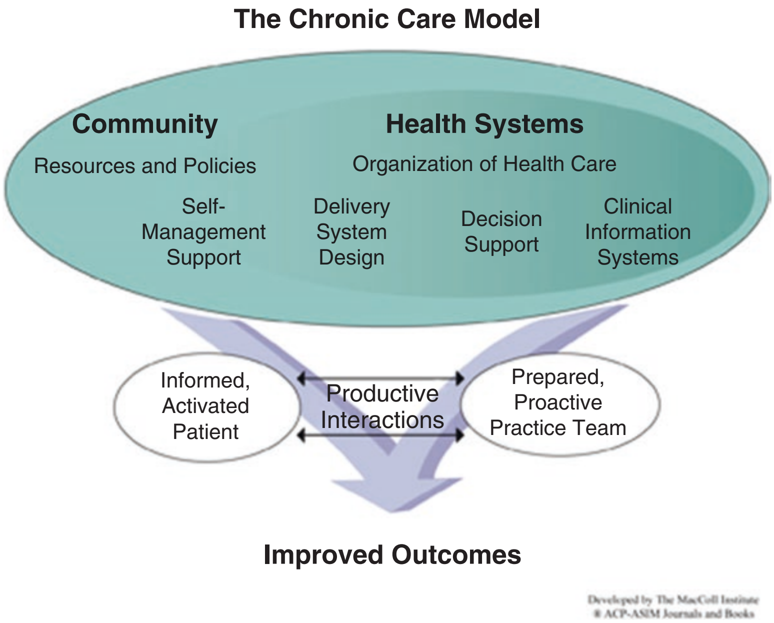

Fig. 30.2 The Chronic Care Model (Fisher, Brownson, et al., 2007)

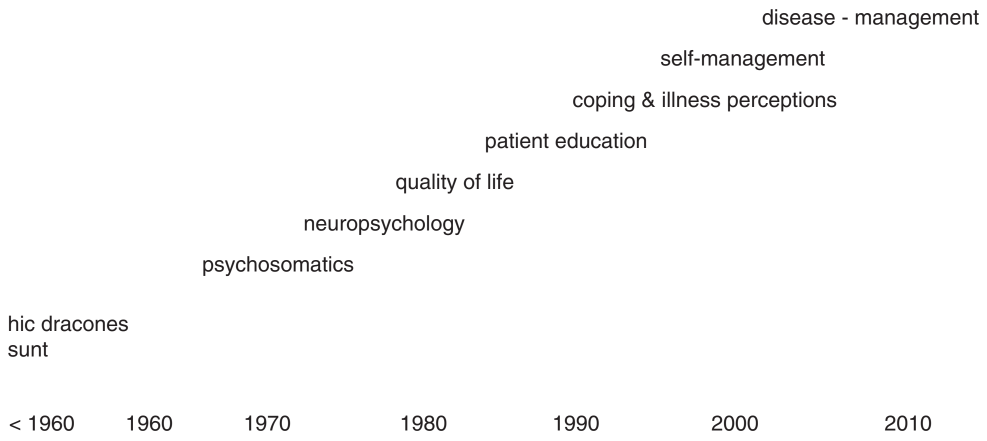

Fig. 30.3 Power to the patient: the increasing involvement of patients in medical care (Kaptein, Scharloo, et al., 2009)

Some 60 years ago, patients were quite often perceived as merely passive recipients of and in medical care. At best, their responses to illness were examined and conceptualized in the context of psychopathology, which it was thought contributed to the somatic disorder. Increasingly, patients have become more active partners in their interactions with healthcare professionals. Disease management is the most recent concept in this evolution. It is defined as “an approach to patient care that emphasizes coordinated, comprehensive care along the continuum of disease and across health care delivery systems – patient counseling and education, coordination, and standardization are key components” (Peytremann – Brideveaux, Staeger, et al., 2008, p. 434).

Self-management is a key component in the management of chronic illness. We might estimate that an “average” patient will have direct face-to-face contact with a health professional in the healthcare system about 1 hour per year, which means that during the other 8759 h of the year, the patient must manage his or her illness without healthcare providers. Self-management is defined by Barlow and colleagues as:

> … the individual’s ability to manage the symptoms, treatment, physical and psychosocial consequences and life style changes inherent in living with a chronic condition. Efficacious self-management encompasses ability to monitor one’s condition and to effect the cognitive, behavioural and emotional responses necessary to maintain a satisfactory quality of life. (Barlow, Wright, et al., 2002, p. 178)

Self-management skills are diverse and include such behaviors as gathering information, managing medication, symptoms and psychological consequences, adjusting lifestyle, mobilizing and drawing on social support, and communicating effectively (Barlow, Wright, et al., 2002).

In this part of the chapter, we have outlined some key theoretical concepts and models that have been employed in the chronic illness field. We now move on to self-management interventions and applications, focusing on ongoing efforts from healthcare providers and patients to continue self-management behavior in the long term.

Behavioral Management of Common Chronic Illnesses

As suggested in Fig. 30.2, self-management and disease management imply that patients with chronic physical illnesses are encouraged and empowered to self-manage their medical condition, in collaboration with people in their social environment, healthcare providers, and society.

Our focus in the current chapter is on *ongoing* behavioral management and its effect on various outcome measures. We will explore this in the context of six specific chronic illnesses, selected due to their high prevalence and the availability of a fairly substantive body of knowledge on the effects of self-management in patients with these illnesses: asthma; chronic obstructive pulmonary disease (COPD); cancer; cardiovascular disease, in particular heart failure; diabetes mellitus; and rheumatoid arthritis. Research was selected for inclusion here based on its empirical and theoretical contributions.

Asthma

Behavioral medicine management for patients with asthma aims at controlling and reducing the effects of the illness in the daily lives of patients. School absenteeism, absence from work, limitations of daily activities, hospitalization, and even death are consequences of asthma. Via managing medication, based on adequate symptom perception, quality medical care, and adjusting one's lifestyle, most patients are able to limit the impact of asthma in their daily lives (Kaptein & Creer, 2004). Cochrane reviews (e.g., Gibson, Powell, et al., 2002; McLean, Chandler, et al., 2010) and systematic reviews (e.g., Bravata, Gienger, et al., 2009) provide empirical support for this statement. The area of self-management in asthma is relatively well developed. Empirical studies on the effects of ongoing support for behavioral management of asthma are discussed below.

The promotion of self-management throughout the illness trajectory is nowadays considered one of the cornerstones of asthma treatment (BTS, 2008; GINA, 2010; NHLBI, 2007). Emphasizing the long-term character of care for patients with asthma, practitioners are advised to review patients' asthma control and to reinforce knowledge and self-management skills at every opportunity (NHLBI, 2007). A Cochrane review showed that for adult patients with asthma, the combination of regular review of asthma control by a healthcare provider with the promotion of self-monitoring of symptoms and/or of peak expiratory volume (PEF) and the use of a personalized written action plan for exacerbations was more beneficial than either of these initiatives alone (Gibson, Powell, et al., 2002). These combined interventions were associated with a reduction in hospitalizations, ER and unscheduled doctor visits, days lost from work due to asthma, episodes of nocturnal asthma, and improvement in quality of life. Although the evidence regarding the effectiveness of these interventions is quite consistent, recent surveys indicate many GPs do not yet appear to incorporate them on a regular basis (Boulet, Devlin, & O'Donnell, 2011).

School-based educational programs for children are an alternative route to provide asthma education. The advantage of these programs is that they provide education to children in a setting in which they are accustomed to receiving instruction and emphasize teaching children how to manage asthma rather than relying on parents to do so (Coffman, Cabana, & Yelin, 2009). Typically these programs are efficacious in improving knowledge, self-efficacy in managing asthma, and self-management behaviors. The effects of these educational programs for children with asthma on health outcomes, however, are mixed (Coffman, Cabana, & Yelin, 2009).

Bruzzese and colleagues (2011) present results from an intensive school-based program, targeting not only urban adolescents but also their medical care providers. Three group educational sessions about asthma were organized. In addition, students received individual coaching sessions once a week for 5 weeks, in which skills for asthma management were taught and reinforced. Students were coached in overcoming barriers to optimal self-management and were encouraged to visit their healthcare provider for evaluation and treatment (health educators offered to accompany students to the medical visit). Students' medical care providers were informed that their patients, participating in the program, would be referred to them and received instructions on how to complete a personalized action plan together with their patient. Participants were followed for 12 months. Every 2 months health outcomes (daily/nocturnal symptoms, school absenteeism, days with activity restrictions, and quality of life) were reviewed. In addition, self-management, medication adherence, use of the written action plan, and urgent healthcare use were assessed at 6 and 12 months. Results after 1 year following the intervention showed that this comprehensive approach had led to an increase in steps taken by the students to prevent asthma symptoms and higher self-efficacy to control asthma. Students in the intervention arm used their personalized action plan more frequently. Nocturnal symptoms, asthma-related school absenteeism, and days with activity restrictions were also consistently lower in the experimental condition. Finally, there was a significant reduction in healthcare use, while the number of acute medical visits, emergency department visits, and hospitalizations were all lower for students in the experimental condition. The authors themselves acknowledge the self-report nature of major outcome measures as a study limitation.

Community health programs have been developed to intervene in the living environment for patients with asthma. Repeated home visits provide the opportunity to tailor the intervention to the specific conditions of each patient and to monitor progress. Usually, the interventions focus on patient education regarding asthma triggers and ways to decrease or avoid triggers. Additionally, patients are often provided with tools or resources to decrease the impact of triggers (e.g., mattress or pillow encasements, vacuums, air filters, rodent traps, or high-quality door mats). A review of the outcomes of community health worker-delivered home-based interventions showed positive effects of these interventions on asthma symptoms, daily activity limitations, and emergency care use (Postma, Karr, & Kieckhefer, 2009). Changes in preventive (asthma trigger reduction) behaviors, hypothesized to mediate the effects of the intervention, were observed although this was largely dependent on the provision of resources as part of the intervention. Combining community health interventions with traditional clinic-based asthma education may yield a long-term added effect on symptoms and trigger prevention actions (such as vacuuming the child's bedroom, washing sheets, and avoiding indoor smoking (Krieger, Takaro, et al., 2009)).

Interventions that offer remote support to patients with asthma have been introduced over the last decade. McLean and coworkers performed an extensive review study on the effects of tele-healthcare for asthma patients (McLean, Chandler, et al., 2010). Tele-healthcare interventions were defined as those programs that enable remote delivery of patient-centered care (e.g., by telephone, text message, video, Internet), facilitate timely access to health advice and medications, prompt self-monitoring and medication compliance, and educate patients on trigger avoidance. Twenty-one randomized controlled studies were identified that compared tele-healthcare interventions with care as usual. The authors concluded that, on average, there were no clinically meaningful differences between the control group and the experimental condition with regard to quality of life and emergency visits over 12 months. However, it appears that for patients with poorly controlled asthma, tele-healthcare interventions reduce the risk of hospitalization and, as a consequence, have a beneficial effect on healthcare costs. Additionally, tele-healthcare interventions enable healthcare providers to review more patients in the same time span than during face-to-face consultations. There was no evidence that the delivery of remote healthcare increased chances of adverse events.

One example of a successful tele-healthcare intervention was performed by van der Meer and colleagues (van der Meer, Bakker, et al., 2009). In this study an Internet-based self-management program for patients with asthma was compared to usual care. In addition to the usual physician care, patients in the experimental condition monitored their asthma symptoms weekly by completing an online questionnaire. Patients received feedback with advice on how to adjust their medication (increase or decrease). This feedback was generated automatically according to a predefined algorithm and treatment plan.

During the study, patients were provided with asthma specific information and had the opportunity to contact a respiratory nurse specialist online. Additionally, patients were provided with two group-based self-management education sessions, aiming to increase knowledge, skills, and self-efficacy. After 1 year, patients in the internet group showed greater improvement in self-reported quality of life and asthma control than patients in the control group. Also, patients in the online group had experienced an increase in symptom-free days and showed a modest improvement in lung function. In sum, weekly online self-monitoring and subsequent treatment adjustment appears to be an efficient long-term intervention to improve asthma control, particularly for patients who report difficulty in controlling their asthma (van der Meer, Bakker, et al., 2009). Similar results were reported by Krishna, Francisco, Balas, König, Graff, and Madsen (2003).

Estes discusses the Chronic Care Model with “asthma as an exemplar” (Estes, 2011) –illustrating the potential relevance of the model for asthma. Fisher et al. (2009) report on the effects of ongoing support of self-management behaviors in a predominantly African American population, where mothers of children with asthma were encouraged to adopt an action plan about self-management by “asthma coaches.” These coaches aimed at providing the mothers with a regular visit to encourage them to adhere to the action plan. Rates of hospitalization were reduced significantly in the children with asthma in this condition of the randomized controlled study.

In summary, empirical evidence suggests there are positive outcomes of ongoing behavioral support to improve self-management in patients with asthma.

Chronic Obstructive Pulmonary Disease (COPD)

Chronic obstructive pulmonary disease (COPD) represents a major chronic illness in western societies, with developing countries picking up rapidly. COPD will be the third leading cause of death in the next decade (Lopez, Mathers, et al., 2006). The irreversible destruction of lung tissue, caused mainly by smoking tobacco, is associated with high levels of restrictions in daily activities, psychological problems (depression, anxiety), social isolation, high rates of use of healthcare services, forced retirement, and increased levels of mortality. Pharmacological treatment is helpful in reducing breathlessness, cough, and fatigue. However, progress in pharmacological management of patients with COPD is underwhelming. Behavioral interventions focus on pulmonary rehabilitation, self-management, smoking cessation and support, and disease management (for systematic review, Cochrane review, and meta-analysis, see Adams, Smith, et al., 2007; Effing, Monninkhof, et al., 2007; Peytremann – Brideveaux, Staeger, et al., 2008). The Cochrane review on self-management education in COPD concludes that “it is likely that self-management education is associated with no indications for detrimental effects in other outcome parameters. This would in itself already be enough reason for recommending self-management education in COPD. However, because of heterogeneity in interventions, study populations, follow-up time, and outcome measures, data are still insufficient to formulate clear recommendations regarding the form and contents of self-management education programmes in COPD.” (Effing, Monninkhof, et al., 2007, p. 2). The systematic review and meta-analysis conclude that “COPD disease-management programs modestly improved exercise capacity, health-related quality of life, and hospital admissions, but not all-cause mortality” (Peytremann – Brideveaux, Staeger, et al., 2008, p. 433).

As is the case in so many studies in so many medical conditions, there is a dearth of studies where *ongoing* interventions of self-management support are part of the experimental design, assessment, and outcome. Two early and two recent studies are worth briefly reviewing here. Güell et al. (2000) examined the short- and long-term effects of an ongoing pulmonary rehabilitation (PR) program in COPD patients. In a controlled design, 30 patients received PR care as usual, while 30 additional patients received PR care plus ongoing self-management support. This support consisted of 3 months with outpatient breathing retraining and physiotherapy, 3 months of daily supervised exercise, and 6 months of weekly supervised breathing exercises which included relaxation techniques and "educational sessions." On outcome measures such as dyspnea perception, fatigue, and emotional functioning, self-reported improvements were observed in the self-management group compared to the control group, even after a 2-year follow-up. Improvements were also found on the 6-min walk test.

Case management comprised the content of ongoing support in a study where a clinical nurse specialist and a social worker were part of an experimental condition in a controlled study design (Poole, Chase, et al., 2001). Both professionals saw the patients in their homes on a regular basis for a year. The patients (n = 16) were encouraged to discuss any problem they had with managing their illness, and they were provided with a problem plan and received education about how to self-manage exacerbations. Family members were encouraged to become involved with the intervention components. Weekly telephone calls and home visits every month were part of the ongoing interventions and support. The control group received care as usual, i.e., without case management. The support intervention led to a reduction in the number of bed days, while in both conditions the number of hospital admissions was reduced.

Adams et al. (2007) reviewed the use of the Chronic Care Model (CCM) in COPD prevention and management and concluded that "… patients with COPD who received interventions with 2 or more CCM components had lower rates of hospitalizations and emergency/unscheduled visits and a shorter length of stay compared with control groups" (p. 551). Two studies published following this review provide further evidence for this conclusion. In a study by Lawlor et al. (2009), long-term follow-up education, telephone support, and rapid future access to respiratory outpatient clinics led to significant reductions in emergency department visits and hospital admissions. In a qualitative Australian study, community nurses who provided ongoing behavioral medicine support to COPD patients reported changes in their views on their contribution to the care for the patients: "… this included a shift from a fatalistic, prescriptive, biomedical approach to a primary health care approach characterized by empathy, consultation, facilitation and a holistic focus" (Robinson, Courtney-Pratt, et al., 2008, p. 371).

In a recent review of behavioral interventions in COPD, we concluded that COPD is no longer an orphan disease with regard to self-management interventions (Fischer, Scharloo, et al., 2007; Kaptein, Scharloo, et al., 2009; Scharloo, Fischer, et al., 2012). Given the increasing amount of research examining the effects of ongoing self-management support in COPD, our cautious optimism seems to be upheld. Yet more rigorous research is required to further identify and elucidate the effective characteristics and aspects of self-management support. In this way we may be able to design more effective interventions to improve quality of life in people with COPD.

Cancer

Given the high incidence and prevalence of cancer, and the relatively long research tradition regarding behavioral interventions in this area (with or without ongoing support and intervention), there exists a relatively substantial body of empirical studies which has examined ongoing support and interventions. McCorkle et al. (2011) recently employed the Chronic Care Model as a guiding principle to review 16 studies on self-management, enabling and empowering patients to live with cancer as a chronic illness. Below we briefly discuss three of these 16 studies, in which the design encompassed ongoing (elements of) self-management interventions.

Bakitas et al. (2009) examined the effects of a nurse-led intervention on quality of life, symptom intensity, mood, and resource use in patients with advanced cancer. In a randomized controlled trial format, advance practice nurses ran four weekly educational sessions with monthly follow-up until death or study completion. The content of the intervention was "*e*ducate, *n*urture, *a*dvise, *b*efore *l*ife *e*nds [ENABLE]," and this led to significant improvements in quality of life and mood compared to the care as usual condition.

Miaskowski et al. (2004) examined the effects of the PRO-SELF Pain Control Program on pain intensity and quality of analgesic prescription in a randomized clinical trial design in patients with bone metastases. Specially trained oncology nurses delivered the intervention: pain was discussed from various perspectives (i.e., knowledge, self-management, medication, communicating with health providers). The nurses contacted patients in the experimental group by phone, and pain and its management were reviewed. Home visits were also part of the program. In the control group, patient received phone calls from the research nurses as well, but not home visits. Results showed significant health gains on self-reported pain levels and adequacy of pain medication prescription in the intervention group compared to the control group.

While the Miaskowski et al. study focused on individual patients in individual sessions, a study by Northouse, Kershaw, Mood, and Schafenacker (2005) had the dyad patient – family caregiver as the unit of intervention. Patients with breast cancer and their family caregiver were randomized in the experimental FOCUS condition or in the care as usual condition. FOCUS is the acronym for the elements of the program: *f*amily involvement, *o*ptimistic attitude, *c*oping effectiveness, *u*ncertainty reduction, and *s*ymptom management. The intervention comprised of three home visits by a trained nurse, spaced 1 month apart, with a booster phase 6 months later, two prearranged follow-up phone calls to both the patient and family caregiver. Results showed improvements in psychological outcomes, in patients and their family caregivers in the FOCUS compared to the control condition, and these positive results remained apparent after 3 months but not 6 months.

A UK review on cancer follow-up (Davies & Batehup, 2011) is also worth mentioning, not because it focuses on self-management per se, but because it adds the perspective of health service research. The review focuses on cancer survivors ("someone who is living with or beyond cancer," p. 143) and follow-up medical care. The authors conclude that their review highlights "… a shift towards patient empowerment via individualized and group education programmes amid an increasing survivors' ability to better manage their condition and the effects of treatment, allowing for self-referral or rapid access to health services when needed. The role of specialist nurses as key facilitators of supportive aftercare is emphasized, as is the move towards technology-based aftercare in the form of telephone or web-based services" (p. 142).

Cardiovascular Disorders: Heart Failure

An exhaustive review of ongoing support and intervention in the area of cardiovascular disease would merit a separate chapter in itself. Therefore, we have selected one diagnostic category within the class of cardiovascular disorders, associated with a major burden of disease and many self-management skills, namely, heart failure.

In a systematic review of randomized controlled studies, Jovicic, Holroyd–Leduc, and Straus (2006) examined six studies on self-management interventions and health outcomes in patients with heart failure. A later review by Yehle and Plake (2010) identified 12 studies, nine of which are randomized controlled trials. Two conclusions can be drawn from these reviews: (1) self-management in patients with heart failure leads to reductions in all-cause hospital readmissions and heart failure readmissions, and (2) self-management in these patients improves self-efficacy, which may be associated with positive outcomes on clinical variables. In intervention studies in which self-efficacy is the central dependent outcome variable, the reviewers found no dose-response effect, even following long-term interventions with ongoing support of self-management.

Jaarsma et al.'s (1999) study involved heart failure patients who received intensive, systematic, and planned education from a study nurse. Visits started in the hospital and continued in the home 3 and 6 months following discharge. Patients also received telephone calls in their homes, and during these calls and the visits self-management behavior was discussed and encouraged. Generic self-care behavior and heart failure-specific self-care behavior improved in the intervention group compared to the care as usual group. Use of healthcare resources was not different across the groups.

Krumholz et al. (2002) employed a similar randomized design of education and support intervention in patients with heart failure. An experienced cardiac nurse provided the patients with educational lessons and material. Telemonitoring was used by the nurse who phoned patients once a week for 4 weeks, then biweekly for 8 weeks, and monthly for the total intervention period of 1 year. Patients in the care as usual condition did not receive the calls. The study found that patients in the intervention group showed improvements in clinical outcomes, such as reductions in healthcare costs and hospital readmission and increased survival.

As with ongoing support for self-management behaviors in other chronic illnesses, internet-based interventions have been applied in patients with heart failure. One such application is System Providing Patients Access to Records Online (SPPARO), which was developed by Ross, Moore, Earnest, Wittevrongel, and Lin (2004). SPPARO is specialized software that consists of a patient-accessible web-based electronic medical record, an educational guide, and a message system for communication between the patient and hospital staff. Access to medical records may educate, engage, empower, and assist patients in the self-management of cardiovascular diseases. The authors conducted a randomized controlled trial in 107 patients with heart failure to assess SPPARO. Patients in the intervention (n = 54) and control group (n = 53) received questionnaires on health status, patient satisfaction, and self-reported compliance at baseline, 6 months, and 12 months. Use of SPPARO was highest during the first 3 months after enrolment and then gradually declined. The intervention group sent more messages to the practice than the control group. There was a trend toward self-efficacy improvement and patient satisfaction with doctor-patient communication in the intervention group. The authors conclude that patient access to medical records may offer modest benefits. However, only a small sample size was used, which limited the power to detect effects of the intervention.

Diabetes Mellitus

As emphasized by Fisher, Thorpe, DeVellis, and DeVellis (2007), living with diabetes mellitus is a lifelong situation patients must face and cope with. At the same time, they may feel somewhat comforted by the fact that support for ongoing self-management of this prevalent chronic physical illness seems to be one of the most developed. The relatively high prevalence of the illness and the major role of the patient him/herself in managing the daily tasks of monitoring and managing blood glucose levels may have contributed to this situation. In addition, patient organizations in the diabetes area were relatively quick in understanding the great importance of helping patients manage their illness themselves. Given this situation, it is not surprising that excellent systematic reviews, meta-analyses, and Cochrane reviews are available to allow conclusions to be drawn about the current state of knowledge regarding ongoing self-management support for people with diabetes.

A 2009 Cochrane review by Deakin and colleagues (2009) of group-based training for self-management in patients with diabetes mellitus type 2 concluded rather spectacularly that “Adults with type 2 diabetes who have participated in group-based training programmes show improved diabetes control (fasting blood glucose and glycated haemoglobin) and knowledge of diabetes in the short (four to six months) and longer-term (12 to 14 months) whilst also having a reduced need for diabetes medication. There is also some evidence that group-based education programmes may reduce blood pressure and body weight, and increase self-empowerment, quality of life, self-management skills and treatment satisfaction” (p. 2).

In her 2008 review of the effects of community-based peer support groups, ongoing home support via telephone, and eHealth, Clark concludes that

"… evidence supports the effectiveness of self-management education in individuals with diabetes, particularly in the short term … however, reviews have demonstrated sharp declines in benefits only a few months after interventions ended … overall, self-management education is most likely to be successful when it is part of a comprehensive and coordinated approach to diabetes care" (Clark, 2008, pp. 118–119).

Davis, O'Toole, Brownson, Llanos, and Fisher (2007) explored the contributions of community health workers (CHWs) on diabetes self-management. The authors collected data from logs completed by CHWs which described mode, place, type, duration, and focus of individual contact between the type 2 diabetes patient and the CHW. Data from semi-structured interviews with patients (n = 47, purposeful sample) were also used in the analysis. The CHWs logged 1859 individual contacts, in which they reported using the telephone 82% of the time, while face-to-face contact was used in 15% of the contacts. Most contacts were initiated by the CHWs (89%), and the median time of the contact was approximately 6 min. CHWs reported providing assistance (38% of the time) and teaching or practicing a skill (29% of the time) as the main focus of these individual contacts. The interviews with patients revealed that community health workers were monitoring the status of the patients and encouraging self-management through ongoing follow-up and support.

The authors conclude that community health workers make important contributions in teaching skills, helping with problem solving, motivation, and ongoing follow-up and support. CHWs were perceived by the patients as more accessible and helpful in explaining how to carry out self-management and more attentive than health professionals, family, and friends.

However, results should be treated cautiously given that the study involved a small and purposeful sample of type 2 diabetes patients, limiting its external validity.

Gambling and Long (2006) explored patients' perceptions of movement through the transtheoretical stages of change model (TTM) within a diabetes tele-care intervention. Case study data (n = 25) were drawn from a wider randomized controlled trial in which the effectiveness of proactive call center-based treatment support for patients with type 2 diabetes was explored. Twenty-five patients participated in in-depth post-trial semi-structured interviews. Patients were categorized in four groups based on their pre- and post-HbA1c results: good controllers that remained good (n = 7), poor controllers who remained poor (n = 6), poor controllers who became good (n = 10), and good controllers who became poor (n = 2). The "good to good" patients were all at the maintenance stage (having changed behavior for over 6 months) and only tweaked their management approach practices. The "poor to poor" group was at the pre-contemplation stage (no intention to take action within the next 6 months) and either did not apply advice provided, did not apply it long enough, or were unsuccessful in their attempts. The "poor to good" group tended to display strong experiential processes in terms of consciousness and dramatic relief. In this group, the tele-care workers became the first or major point of advice and support. The "good to poor" group only consisted of two patients who made some behavioral changes but did not fully understand the implications of poor control and/or did not make changes consistently. It is clear that each group had different processes over time and in different ways.

Qualitative studies may help shed light on patients' views regarding self-management. Danish researchers explored diabetes patients' views about their experiences with managing their illness, following self-management training. The results are important in the context of this chapter: patients said they needed specific support in the daily responsibility of managing diet, exercise, medication, and blood glucose monitoring (Rosenbek Minet, Lønvig, et al., 2011). In a similar vein, a study by van Bastelaar, Pouwer, Cuijpers, Riper, and Snoek (2011) identified symptoms of depression and diabetes-specific distress as barriers to adequate self-management. A web-based cognitive behavioral intervention was developed to address these issues.

Increasingly, nurses and physicians acknowledge the great relevance and importance of (ongoing) self-management in patients with diabetes (Dancer & Courtney, 2010, for nurse practitioners; Yu & Beresford, 2010, for (family) physicians). Both papers underline the point made by Fisher, Brownson, O'Toole, Shetty, Anwuri, and Glasgow (2005), "beyond the self in self-management" (p. 1524): contextual factors are at least as important as patient-related variables in encouraging and maintaining self-management behavior in patients with diabetes (or for any chronic illness, for that matter). This focus on contextual factors also minimizes the likelihood of blaming the patient, as their life worlds are revealed in greater depth.

Rheumatic Illnesses

The benefits of short-term programs promoting exercise, physical activity, and self-management regarding rheumatoid arthritis (RA) outcomes have been consistently demonstrated (Hurkmans, van der Giesen, et al., 2009; Iversen, Hammond, & Betteridge, 2010). However, as in other chronic illnesses, studies on the effectiveness of approaches to provide ongoing follow-up and support for promoting sustained disease management are scarce.

Three main areas have been investigated in the research to date, namely, interactive online environments for peer group support, community-deliverable exercise programs, and consolidation after rehabilitation.

Interactive Online Environments for Peer Group Support

One small qualitative study on the effect of participating in an online support group (van Uden-Kraan, Drossaert, et al., 2008) found positive empowering outcomes experienced by the participants, such as being better informed, feeling confident in their relationship with physicians, treatment and social environment, acceptance of the disease, optimism and control, self-esteem and social well-being, and collective action. Respondents (10 breast cancer, 11 fibromyalgia, and 11 arthritis) were highly active users, mostly female (*n* = 30), relatively young (43 years), with a mean disease duration of 2 years. The study was replicated in a larger sample (*n* = 528, 23% arthritis) with the same results, and no significant differences were observed between the diagnostic groups with regard to empowering outcomes (van Uden – Kraan, Drossaert, et al., 2009). The authors suggest that online support groups are a useful resource for patients and that healthcare providers should thus acquaint their patients with the existence of these groups. However, their studies also revealed that online support groups for arthritis are the least active when compared to the other diagnostic groups.

Community-Deliverable Exercise Programs

Arthritis-appropriate interventions identified by the Centers for Disease Control and Prevention (CDC) for use in public health settings in the USA include three physical activity and three self-management interventions (Brady, Jernick, et al., 2009). Of these the Arthritis Foundation Aquatic Program (AFAP, www.arthritis.org/aquatic-program.php), the Arthritis Foundation Exercise Program (AFEP/PACE, www.arthritis.org/af-exercise-program.php), and the Project Enhance Fitness (www.projectenhance.org) can be offered on an ongoing basis. The Arthritis Foundation offers practical help (training for instructors, implementation guidelines, marketing, connection to other programs, educational resources) for lay people from a community wanting to start a group.

With respect to other countries, ongoing exercise programs for patients with arthritis are generally offered through websites from (local) Arthritis Foundation offices (e.g., the UK, Australia, New Zealand, Germany) or patient alliances (e.g., UK, Netherlands). A recent meta-analysis suggests that (short-term) community deliverable exercise significantly improves pain and physical function in arthritis and other rheumatic diseases (Kelley, Kelley, et al., 2011).

Consolidation After Rehabilitation

Based on the trans-theoretical model of behavioral change, the Community Rehabilitation Network (CRN, Hong Kong) developed a three-phase self-management service which places more emphasis on the process of self-help and support services to assist patients with RA (Siu & Chui, 2004).

In the orientation (pre-contemplation) phase of the program (2–4 weeks duration), patients are provided with disease-related information and information on community resources. Patients are encouraged to (re-)mobilize their peer and social support network and alleviate their sense of helplessness in facing the disease, and readiness for developing effective ways of coping with illness is promoted. In the intervention (contemplation) phase (2–3 months duration), patients are encouraged to participate in three standardized intervention programs, including a stress management group, a self-management course, and a water exercise class. In the consolidation phase (6 months), patients are assisted to habituate self-management behavior and are stimulated to maintain a supportive social network. The services provided in this stage include regular reunion meetings and volunteer training programs to equip participants with further knowledge in disease management and available community resources as well as communication and peer counseling skills training to prepare them to conduct home and hospital visits to peers. In addition to the program elements, informal activities are organized throughout the three phases to help expand social support among participants and provide mutual support. Activities include social and recreational activities such as camping and outings, hospital visit/home visit by groups of two or three volunteers in the company of a staff member, and visits to centers offering consultations, educational talks and seminars, and community resources.

Compared to the control group (patients who declined after the orientation phase of the program), the 29 patients in the treatment group (self-) reported significantly greater improvement at the end of the consolidation phase. They improved significantly in self-efficacy, exercise behavior, and cognitive symptom management and made less use of community services for tangible help and more use of education service/support groups for health problems and of organized exercise programs. Their communication with their physician also improved. However, the study did not find significant differences in change scores for health outcomes such as pain and physical discomfort, energy and fatigue, self-rated health, and healthcare utilization between the intervention and the control groups.

For the treatment group, it was noted that more changes occurred in the consolidation phase, when the CRN adopted a facilitator role rather than an interventionist role, suggesting that the development of social networks plays an important part not only in sustaining the effects from the initial program but also in producing further improvements.

Discussion

There are a number of key themes that arise from the selective review we have presented in this chapter concerning ongoing behavioral intervention and support in patients with six major chronic physical illnesses. Self-management is associated with positive outcomes in patients with chronic physical illness. Self-management impacts on two major categories of outcome: it reduces use of healthcare services in some illnesses, and it improves quality of life in virtually all patients (see Newman, Steed, Mulligan, 2009, and the systematic reviews described in our chapter). In some cases, self-management may be as effective as some medical treatments. Much of the research (but not all) is guided by theoretical models on self-management, behavioral interventions, healthcare services, and medicine. Humanistic motives seem to be important in these scientific efforts, as are issues regarding financial costs of healthcare.

It is surprising that the “acute care model” still dominates not only medical care but self-management research and practice as well. Self-management research tends to employ the classic randomized trial, in which patients are allocated randomly to an intervention or a control condition. The control condition is generally care as usual, while the intervention is generally a 6-week self-management program.

Studies typically assess changes in a number of outcomes in both groups after a relatively short period of time and based on the results conclude that the patients in the intervention groups do better in some of these outcome measures. However, these improvements are not always maintained, nor frequently followed for longer periods of time. Some research indicates that 1 year later, patients are back to baseline levels of outcome measures. We are surprised that researchers (ourselves included) adopt an episodic care model in patients with lifelong illnesses, assessing the effects of intervention efforts after only 3-month "follow-up" (at best). Studies where effects of interventions in self-management behavior are assessed after much longer, and perhaps more relevant, periods are scarce. Researchers understand immediately why this is: research grants usually run for no longer than 3 or 4 years. Within this context, even a 1-year follow-up is difficult in such a limited period of research time. In addition, patients move to other cities, get bored by our ongoing self-management support effort, or die. Additionally, we know surprisingly little about patients' wishes regarding ongoing self-management support (cf., Devitt, Hatton, et al., 2010; Mann, & Gooberman – Hill, 2011; Tiemensma, Kaptein, et al., 2011). Healthcare providers may become annoyed by requests from researchers for filling out questionnaires and selecting and including patients in studies – although there are exceptions (e.g., Khunti, Gray, et al., 2012).

However, the research does suggest that the Chronic Care Model, and other theoretical models about human health and illness behavior, seem to be helpful in designing research about ongoing support in self-management of chronically ill persons. This is valuable for future research. Nurse practitioners, research nurses, and specialized nurses are a group of professionals who are providing much of the self-management training and material. Perhaps surprisingly, physiotherapists are conspicuously absent in studies on delivering self-management guidance and skills. Physicians also do not seem to spend enough time and care regarding discussing self-management with their patients, perhaps due to the time scarcity in healthcare organizations. Ironically, the same might be said for psychologists. Expert patients do not yet appear to represent a major category of trainers. This option deserves further study, in our opinion (cf., the Chronic Disease Self-Management Program, e.g., Ghorob, Vivas, et al., 2011; Ritter, Lee, & Lorig, 2011; Willis, Robinson, et al., 2011). In male veteran patients with diabetes, for instance, a reciprocal peer support program produced positive outcomes on biomedical outcome measures and self-reported diabetes social support (cf., Fisher, Boothroyd, et al., 2012). Web-based interventions are increasingly being employed in self-management interventions, and these are naturally appealing as methods to be used in this context: they can, once developed, be employed easily, cheaply, and at a time and place chosen by and convenient for the patient. Interventions available via the Internet allow patients more autonomy in deciding how to apply these interventions.

Within the field of behavioral medicine, a topic that is receiving increasing attention is "translational behavioral medicine," i.e., the translation and application of evidence-based, effective interventions from the behavioral medicine domain to patients. The Society of Behavioral Medicine launched a journal devoted to this topic recently. As we have seen in this chapter, scientists working in a behavioral medicine setting do achieve quite acceptable successes in motivating patients with chronic somatic illness to use available, effective, ongoing support systems. This use does impact on major outcomes, for most patients, most of the time. However, patients, healthcare providers, (commercial) companies that pay for and/or reimburse health services, and the society at large do not appear to be wholeheartedly convinced about this effectiveness. It cannot be overstated: incorporating self-management and ongoing self-management support should be part and parcel of regular care for patients with chronic illness (cf., Greenhalgh, 2009). However, while researchers may be confident that their research-based interventions lead to positive outcomes, it is another matter to convince clinicians to incorporate these findings as regular components of (medical) care (see for instance the paper by Hack et al. (2011), on facilitating the implementation of empirically valid interventions in psychosocial oncology and supportive care). The area of translational behavioral medicine research clearly deserves great attention in future research and clinical applications. Incorporating standards for self-management education into guidelines used by healthcare providers is another more structural way of trying to improve the quality of medical care (cf., Funnel et al., 2011, for diabetes).

The research we have reviewed in this chapter supports the statement that self-management is a crucial part of quality medical care. Whether self-management interventions are suggested, offered, and assessed soon after the contact between patient and healthcare provider, or 3, 6, 12, or 24 months later, is somewhat irrelevant. Patients with the conditions that were discussed in this chapter – asthma, COPD, cancer, cardiovascular disorders, diabetes mellitus, and (rheumatoid) arthritis – will have to self-manage their condition for the rest of their lives. Self-management and ongoing support for self-management, therefore, should be part and parcel of regular medical care.

Figure 30.4 below (in Fisher et al., *Diabetes Educator* 2007, 33 (Suppl 6), pp. 216S–224S, p. 221S) ties in the Chronic Care Model that we discussed before (p. 8) and the Common Sense Model (p. 886, this chapter) with self-management behaviors. The figure underlines the importance of the connections between the models that are discernable in the figure, and the three levels of variables, indicated in the left-hand side of the figure (cf., Battersby, von Korff, et al., 2010).

The model has implications for medical education as well. We need to educate and teach our physicians-in-training the skills to incorporate self-management techniques in healthcare, enabling them to know how to, for example, support the ongoing self-management of a 76-year old woman with rheumatoid arthritis – and probably more than one comorbid condition. Journals in medical education do pay attention to this issue (e.g., Bowen, Provost, et al., 2010; Holman, 2004). It is important to align medical education with the changes in patterns of morbidity in the next decades.

Disease	Behavioral objectives	Outcomes	Overall objective
Asthma	Symptom perception, symptom control, incorporating asthma in social and psychological life	Reduction of healthcare use, absenteeism from school/work, better QOL	Adapt and self-manage
COPD	Maintain physical activities, maintain social relations	Reductions in depression and anxiety, healthcare use, mortality	Adapt and self-manage
Cancer	Management of cancer treatment and its consequences	Improvement of QOL	Adapt and self-manage
Cardiovascular diseases	Management of physical, psychological, and social consequences of illness and its management	Improved survival, improved QOL	Adapt and self-manage
Diabetes mellitus	Adjust eating behavior, physical activities	Reduction of complications	Adapt and self-manage
Rheumatoid arthritis	Manage consequences of illness in daily life	Reductions in limitations in daily activities	Adapt and self-manage

Schematic representation of behavioral objectives, outcomes, and overall objective in six chronic somatic disorders
QOL quality of life

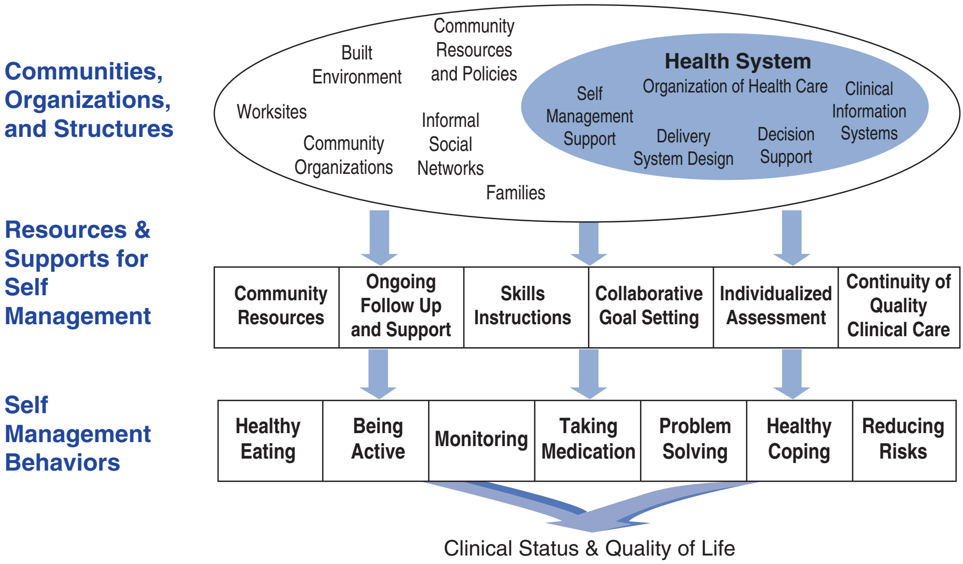

Fig. 30.4 Trilevel model of self-management and chronic care

Wagner, an important contributor to the thinking regarding chronic care management, quite rightly emphasizes the role of academic primary care in this context (Wagner, 2010). In line with our finding about nurses playing a central role in providing ongoing self-management support, Wagner maintains that "increasingly, nurses, medical assistants, or others on a practice team receive training in counseling strategies (e.g., motivational interviewing), and interact regularly with chronically ill patients at visits or by telephone" (p. S637).

Our review of studies on ongoing self-management support is limited – somewhat paradoxically – by the relative success of self-management in people with chronic illness: the number of studies in this area makes it virtually impossible to really adopt a helicopter view of the area. By focusing on review papers, meta-analyses, and Cochrane reviews, we have attempted to deal with this limitation. This research area would be improved with longer follow-up periods, and those providing research funds should also consider the implications of this for grant durations. Patients themselves, and their partners, may beneficially be more fully involved in the design and delivery of self-management intervention studies.

"The only important indicators of health and wellness are behavioral" – this exciting, albeit somewhat provocative, quote summarizes a major paper by Kaplan: "Behavior as the central outcome in health care" (1990). Given our review of self-management in six chronic somatic disorders, it should be evident that self-management has disease-specific elements, in addition to elements that appear to be valid for all chronic somatic disorders. In the table we present a rough sketch of behavioral objectives of self-management for the six illnesses and the associated behavioral outcomes (cf. Kaplan, 1990). A recent position paper in the *British Medical Journal* examined the concept "health." Rather than adopting the 1948 WHO definition, the author group took a bold step. They defined health as "the ability to adapt and to self manage" (p. 236, Huber et al., 2011). We think this author group is absolutely right – our chapter hopes to contribute to this viewpoint on health, illness, and quality of life. Therefore, in the table, the ultimate outcome measure is labeled "the ability to adapt and to self-manage."

The Evolution of HIV Prevention Interventions and Chronic Disease Management

Jamila K. Stockman, Eileen V. Pitpitan,
and Thomas L. Patterson

Introduction

The Joint United Nations Programme on HIV/AIDS estimates that 2.6 million new infections and 1.8 million AIDS deaths occurred in 2009, and almost 33.3 million adults and children worldwide are currently living with HIV or AIDS, with the great majority of them in low- and middle-income countries (UNAIDS, 2010). Fortunately, the advent of antiretroviral therapy in 1996 has led to drastic positive changes to both the state of HIV prevention and the lives of people living with HIV. Since then, the mortality rate from AIDS has decreased, and the infection has transformed from a fatal illness to a chronic, more manageable one. Meanwhile, 30 years into the HIV epidemic, HIV prevention interventions throughout the world have varied tremendously in both the theories that guide them and the contexts in which they are delivered. Our main aims in this chapter are to (1) selectively review approaches to preventing HIV infection and (2) discuss issues surrounding chronic disease management of HIV.

In the development of HIV prevention interventions, an important consideration is the distinction between primary prevention (for uninfected individuals) and secondary prevention (for HIV-infected individuals). Primary prevention aims to help persons avoid contracting HIV. Primary prevention interventions can be undertaken at the individual, couple, community, and social-policy or structural level; it can also involve the promotion of HIV testing and counseling for HIV-negative persons who engage in high-risk behaviors. Secondary prevention aims to reduce adverse consequences for persons living with HIV as well as to reduce transmission to uninfected persons. Within secondary prevention, the most significant advancement has been made with antiretroviral therapy (ART) for HIV infection and associated medication adherence. ART works to suppress replication of the virus resulting in improved immune functioning, health, and reduced viral load for people living with HIV. However, the potential maximum benefits of ART will not be realized if people fail to adhere to their medications.

Patient- vs. Disease-Centered Approach

Altogether, with proper adherence to ART, the lives of people living with HIV can potentially be long and productive. Thus, secondary prevention efforts would benefit most when interventions are

not only disease-centered but also patient-centered. That is, prevention for positives must recognize the many and intertwined aspects affecting disease management, including medication adherence, comorbid conditions, quality of life, and HIV stigma. Further, given the fact that these factors operate at multiple levels and multiple domains of an HIV-positive person's risk environment, prevention interventions are most likely to succeed when they shift the focus outside the individual. Interventions that target not only one's individual psychology but also the structural factors in one's environment are those most likely to achieve long-lasting behavior change.

Historically, HIV prevention interventions have been driven by a number of theories of behavior change. Recently, new biomedical models approaches have emerged that can be paired with behavior change models, including "treatment as prevention" (also known as "seek and treat"), pre-exposure prophylaxis, and male circumcision. Additionally, the HIV risk environment has been targeted as a means to achieve optimal HIV risk reduction among populations at risk for HIV.

HIV Prevention Approaches

Interventions based on theory result in greater behavior change (DiClemente & Peterson, 1994). However, standardization of theory-based interventions may not be optimal in achieving reductions in HIV cases given variations in HIV prevalence and incidence worldwide. Risk populations also vary widely by geographic region. Because of this, HIV prevention interventions must be tailored to account for local conditions and needs. The diverse HIV epidemics around the globe may be due to the infectiousness of the virus itself, the stage of the epidemic (generalized vs. concentrated), or the effectiveness of interventions that have been deployed. Different cultures, risk groups, and social drivers suggest that effective interventions may require different theoretical approaches. One way to organize our thinking about HIV prevention intervention that has gained increasing attention is the risk environment model, which asserts that four types of environmental influences – physical, social, economic, and policy – interact at the micro- and macro-levels to explain HIV transmission in at-risk populations. The micro-risk environment focuses on personal decisions and the influence of community-level norms and practices, while the macro-risk environment encompasses structural factors, such as laws, military actions, economic conditions, and wider cultural beliefs (Rhodes & Simic, 2005). Table 31.1 summarizes the HIV risk environment as it applies to HIV prevention interventions. Table 31.1 also lists behavioral theories that have been incorporated into the intervention examples that have addressed various levels of the risk environment. With the HIV epidemic evolving in magnitude and diversity, the development and implementation of interventions that integrate theoretical frameworks, biomedical models, and the risk environment of targeted populations will offer substantial benefits to efforts to reduce HIV transmission worldwide.

Global HIV prevention efforts have focused on various risk populations, including men who have sex with men (MSM), female sex workers (FSW) and their clients, high-risk heterosexual women, injection drug users (IDU), and transgendered individuals. HIV prevention efforts have scored successes and faced challenges, because each geographic region has a different presentation of the HIV epidemic with different populations that are most at risk.

Theories and Models Used in HIV Prevention Interventions

Behavior Change Theories and Models

A number of theoretical models of HIV-related behavior change have been either adapted or used in entirety to reduce sexual- or drug-related risk behaviors (or both) in various high-risk populations. Some of these models and theories are (1) the Health Belief Model; (2) Transtheoretical Model – Stages of Change; (3) Theory of Reasoned Action; (4) Social Cognitive Theory;

Table 31.1 The HIV risk environment model applied to HIV prevention interventions

Risk environment	Micro-environmental			Macro-environmental		
	Content	Theory	Example	Content	Theory	Example
Physical	• Homelessness • Prisons/Incarceration • Sex work locations • Drug use locations	None	**The Iran Prison Organization's** HIV prevention package for IDU prisoners; MMT programs constitute a main component; other services inc. NSPs and HIV education.	• Drug trafficking and distribution routes • Deportation • Geographical shifts in population	None	**The Living with HIV/AIDS project in Portugal** provides home care, treatment, psychosocial, rehab and legal support for migrants living with HIV and their families.
Social	• Relationship and network dynamics • Peer norms • Physical/sexual violence • Community attitudes • Local policing practices • Sexual orientation	Diffusion of Innovation Theory	**NIMH Project Accept in Africa**, designed to change community norms by (1) making VCT more available in community; (2) engaging community through outreach; and (3) providing post-test support.	• Stigma and discrimination • Exposure to war, conflict, or disasters • Ethnic or racial disparities • Gender inequalities • Social and cultural norms	None	**New York State (US) Human Rights Law** Bans discrimination against individuals with HIV/AIDS or those perceived to be infected with HIV; Office of AIDS Discrimination Issues handles complaints of HIV-related discrimination.
Economic	• Cost of condoms, syringes, medication • Few income generation and employment opportunities • Survival sex work • Cost of health care	None	**Intervention with Microfinance for AIDS and Gender Equity (IMAGE)** Group based microfinance and a gender and HIV education curriculum South African women.	• Scarcity of health service revenue and spending • Employment practices • Economic development	None	**CDC Funding ($359 million annually, FY2012-FY2016) for health department funding**: A new approach that better matches prevention dollars to HIV burden in affected areas focusing on high-impact interventions.
Political	Ensuring widespread coverage of: • HIV/STI testing and counseling • Antiretroviral therapy • Housing assistance for drug users, abused women, etc. • Sterile needles and syringes • Drug treatment • Male and female condoms	None	**HIV testing and linkage to care in US** Goal of 2010 National HIV/AIDS Strategy over the next 5 years is to increase percentage of newly diagnosed people linked to care within 3 months from 65% to 85%.	Laws and policies governing: • Protection of human and health rights • Sex work • Possession of drugs • Syringe access and exchange • Free highly active antiretroviral therapy coverage • Drug treatment	None	**100% Condom Use Campaign in Thailand** Condom use-only policy that requires all sex workers to use condoms with every customer; enlisted the aid of health authorities, governors, police, sex workers, and owners and managers of sex establishments.

MMT methadone maintenance treatment, *VCT* voluntary counseling and testing

(5) AIDS Risk Reduction Model; (6) Social Networks, Social Influence, and Peer Norms Theory; (7) Diffusion of Innovation Theory; and (8) Theory of Gender and Power. In the below section, we highlight these theories beginning with those focused more on individual factors followed by those focused on social and environmental factors.

Health Belief Model

The Health Belief Model is used to facilitate behavior change through attitudes and beliefs about the behavior (Rosenstock, Strecher, & Becker, 1994). Based on this model, individuals will change their behavior if (1) they regard themselves as susceptible to the condition, (2) they believe the health condition to have potentially serious consequences, (3) they believe that a course of action available to them would be beneficial in reducing either their susceptibility to or the severity of the condition, and (4) they believe that the anticipated barriers to (or costs of) taking the action are outweighed by its benefits (Rosenstock, Strecher, & Becker, 1994). Additional components of the model are (1) cues to action, a component that has not been systematically examined and refers to physical symptoms of a health condition or environmental factors that motivate individuals to change their behavior; (2) diverse demographic, socio-psychological and structural variables that may affect the individual's perceptions and indirectly influence the behavior; and (3) self-efficacy, introduced by Bandura, referring to the belief that one is able to execute the behavior required to produce the desired outcome (Rosenstock, Strecher, & Becker, 1994). Limitations of the Health Belief Model are that often only selected components are used to guide HIV prevention interventions and it does not incorporate the influence of social norms and peer influences on an individual's decision regarding their behaviors. Nonetheless, the model has been used in primary prevention of HIV through increasing condom use and in secondary prevention through early treatment of HIV.

Transtheoretical Model: Stages of Change

The Transtheoretical Model is organized around five distinctive stages through which individuals go through in making behavior changes: (1) *pre-contemplation*, with no intention to change behavior in the foreseeable future; (2) *contemplation*, giving serious consideration to changing behavior by weighing the pros and cons; (3) *preparation*, when individuals are ready to take action and are seriously planning to change their behavior; (4) *action*, when individuals initiate overt changes in their behavior and their efforts to change are visible to others; and (5) *maintenance*, a time of continued behavior change while preventing potential relapses (Prochaska, Redding, et al., 1994). Applied to HIV prevention in the form of condom use behavior: (1) *pre-contemplation* is not considering using condoms; (2) *contemplation*, recognizing the need to use condoms; (3) *preparation*, thinking about using condoms in the near future; (4) *action*, using condoms consistently for a short period; and (5) *maintenance*, using condoms consistently for a long period.

An important consideration in the application of this model to interventions is the identification of intervention methods linked with each stage. According to the theory, if a given intervention is mismatched to an individual's stage of readiness for change, it is likely to be ineffective (Prochaska, Redding, et al., 1994). Effective HIV prevention interventions are those that have been mapped onto an individual or population's readiness or stage of change. Individuals may pass through all stages but do not necessarily move in a linear manner. For example, in an HIV behavioral intervention for US women at risk for or infected with HIV, stage-tailored intervention print materials based on role model stories were used to model and encourage women's movement from their current stages to the next stage in terms of safe sex practices (Cabral, Cotton, et al., 2004). These stories incorporated a brief narrative about a woman's successful movement from an earlier to a later stage, the processes of change she used that contributed to her successful movement between stages, the stage of change achieved through this process, and her current stage of change related to HIV risk behaviors (Cabral, Cotton, et al., 2004). Most women reached by this intervention were at early stages of change for condom use, and behavior change overall was a gradual process (Cabral, Cotton, et al., 2004). In another HIV/STD prevention program for adolescents, individual counseling sessions were tailored to each participant based on their stage of readiness and influencing factors (i.e., cognitive, emotional, and behavioral activities and processes that people engage in when attempting to change behavior). With regard to disease prevention (i.e., condom use only or postponing sexual activity), those starting in pre-contemplation/contemplation were more likely to move forward to later stages than those in action/maintenance (Hacker, Brown, et al., 2005). Thus, the intervention was more successful at moving teens forward from lower stages of change than helping teens stay in action and maintenance (Hacker, Brown, et al., 2005).

Theory of Reasoned Action

The Theory of Reasoned Action has been applied to HIV prevention interventions targeting a number of at-risk populations including women, FSWs, MSM, and IDUs, frequently focusing on the promotion of condom use. The central premise of the Theory of Reasoned Action is that individuals make behavioral decisions on the basis of a reasoned consideration of the available information. Behavioral intentions reflect the extent to which an individual is motivated to perform the behavior or the individual's willingness to perform it (Fishbein & Ajzen, 2010). An individual's behavioral intentions are influenced by two conceptually distinguishable factors: (1) *attitude*, which reflects how favorably or unfavorably a person feels toward performing the behavior and which is shaped by an individual's beliefs regarding the behavior's outcomes and the evaluation of consequences of potential outcomes, and (2) *subjective norm*, which refers to the extent of perceived social pressure to perform the behavior and which is shaped by an individual's beliefs regarding other people's views of a behavior and the individual's willingness to conform to those views (Terry, Gallois, & McCamish, 1993). A limitation of the Theory of Reasoned Action is its inability, due to its individualistic approach, to consider the role of structural and environmental issues.

Social Cognitive Theory

Social Cognitive Theory asserts that providing information alone will not change behavior; rather, sustained behavior change requires that the person possess the skills needed to engage in the behavior and the ability to use these skills consistently and under difficult circumstances. In a reciprocal causation model, the following elements in Social Cognitive Theory operate as interacting determinants: (1) personal determinants in the form of cognitive, affective, and biological factors, (2) behavior, and (3) environmental influences (Bandura, 1986, 1994). This theory identifies four components for successful implementation: (1) information or knowledge, (2) mastery of self-protective skills and self-efficacy for implementing the skills, (3) social competency skills acquired through rehearsal and practice, and (4) social support for precautionary changes. Social Cognitive Theory is the most frequently used model for HIV behavioral interventions.

AIDS Risk Reduction Model

The AIDS Risk Reduction Model (Catania, Kegeles, & Coates, 1990) incorporates several variables from other behavior change theories, including the Health Belief Model and Social Cognitive Theory to provide a framework for explaining and predicting behavior change efforts of individuals specifically in relationship to the sexual transmission of HIV/AIDS. The AIDS Risk Reduction Model consists of three stages of behavior change: (1) labeling of high-risk behaviors as problematic, (2) making a commitment to changing high-risk behaviors, and (3) seeking and enacting solutions directed at reducing high-risk activities. Movement from stage to stage is expected to be dependent on achieving the goals of prior stages. In addition, several other internal and external motivators may play important roles in maintaining adequate motivation over time. These include (1) knowledge of the risks associated with various sexual practices, (2) perceptions of susceptibility to contracting HIV, (3) perceived costs and benefits associated with reducing high-risk sexual behaviors, (4) self-efficacy beliefs, (5) emotional states, and (6) social factors, including verbal communication skills, reference group norms, help-seeking processes, and social support (Catania, Kegeles, & Coates, 1990). HIV prevention interventions that have been guided by the AIDS Risk Reduction Model often address the reduction of sexual risk behaviors. With minor modifications, the AIDS Risk Reduction Model can be applied to interventions that target reductions in other HIV risk behaviors (e.g., substance abuse, needle sharing) (Catania, Kegeles, & Coates, 1990).

Diffusion of Innovation Theory

Diffusion of Innovation Theory has been used as the rationale for many community-level interventions in the context of HIV prevention. Diffusion of Innovation Theory refers to a process by which an innovation is communicated among members of a social system (Rogers, 2000). An innovation is an idea, practice, or object perceived as new by an individual or other unit of adoption (e.g., an organization). The characteristics of an innovation, as perceived by members of a system, determine the rate at which the innovation is adopted. Five attributes of innovations are (1) *relative advantage*, the degree to which a new idea is perceived as superior to the idea that it replaces; (2) *compatibility*, the degree to which a new idea is perceived as consistent with the existing values, experiences, and needs of potential adopters; (3) *complexity*, defined as the degree to which an innovation is perceived as difficult to understand; (4) *trialability*, the degree to which an innovation may be experimented with on a limited basis; and (5) *observability*, the degree to which the results of an innovation are visible to others (Rogers, 2000).

This model focuses on social networks and utilizes opinion leaders as agents of change. Opinion leaders are trusted, credible, and well-liked people in the community who are recruited and trained to conduct HIV prevention outreach. The Diffusion of Innovation Theory has been applied to HIV interventions in populations at increased risk for HIV through high-risk sexual behaviors. The goal is to diffuse innovative approaches to reducing sexual risk behaviors and increasing use of safer sex strategies. This is accomplished through enlisting a sufficient number of opinion leaders in at-risk communities to support and endorse changes in risk behavior. Although the Diffusion of Innovation Theory provides a framework for conceptualizing how changes in a population's behavior and norms can be achieved by opinion leaders, it does not directly address what opinion leaders should say to influence others to make changes in sexual risk behaviors that are not directly observable (NIMH Collaborative HIV/STD Prevention Trial Group, 2007).

Theory of Gender and Power

The Theory of Gender and Power has been used primarily in prevention interventions that target at-risk women. This theory's conceptual framework incorporates the social influences that compromise disadvantaged women's health and autonomy. The theory distinguishes three primary structures: division of labor, division of power, and the structure of cathexis (Connell, 1987). The sexual division of labor refers to the unequal allocation to women and men of certain occupations, such as "unpaid nurturing work," e.g., child care, housework, and caring for the sick and elderly; this often results in an economic imbalance in which women have to rely on men financially. Applied to HIV prevention, women who are unemployed have a high-demand and low-control work environment, and limited or no health insurance are at increased risk for HIV acquisition (Wingood & DiClemente, 2000). “Division of power” recognizes the power imbalances in heterosexual relationships that contribute to men’s authority, control, and coercion over women. Within this structure, women at increased risk for HIV are those with histories of sexual or physical abuse, low self-assertiveness and self-efficacy, and limited perceived control in their relationships (Wingood & DiClemente, 2000). “Cathexis” refers to society’s approved gender roles and its expectations for appropriate sexual behavior. It has been noted that the Theory of Gender and Power, in isolation, implies an intervention with unstructured discussion among the participants about gender and power issues and about how women cope with these issues in their daily lives (St Lawrence, Wilson, et al., 2001).

Biomedical Interventions

Emerging biomedical approaches include medical interventions to block infection, decrease infectiousness, or reduce the risk for HIV infection. Current interventions under investigation or proven to be efficacious are antiretroviral drugs used to reduce infectiousness in HIV-positive individuals or as pre-exposure prophylaxis, male circumcision, microbicides, and HIV vaccines.

Oral Antiretroviral Prevention

Antiretroviral HIV prophylaxis has been very effective in preventing mother-to-child transmission, with widespread use beginning in the 1990s. The use of short-course zidovudine and, subsequently, single-dose nevirapine for pregnant, HIV-infected women has been proven to reduce mother-to-child transmission in non-breastfeeding populations by two-thirds. Since then, several other regimens have been assessed in non-breastfeeding and breastfeeding populations (Padian, Buve, et al., 2008). Currently, there is great hope that this strategy will prove effective against other routes of transmission (Garcia-Lerma, Paxton, et al., 2010). Antiretroviral therapy has been explored as an HIV prevention measure in three domains: (1) reducing infectiousness among HIV-positive persons, (2) preventing infection in high-risk HIV-seronegative populations through pre-exposure prophylaxis (PrEP), and (3) preventing infection among HIV-negative persons through post-exposure prophylaxis (PEP) after occupational or nonoccupational exposure to HIV-infected blood or fluids (Kelesidis & Landovitz, 2011). PrEP uses ART in anticipation of HIV exposure from known or unknown sources with the aim of preventing HIV acquisition or, at least, altering the natural course of infection to attenuate disease progression, reduce morbidity, and/or decrease infectiousness (Kelesidis & Landovitz, 2011). PrEP is a promising prevention strategy consisting of oral administration of continuous (daily) ARV medication by HIV-negative individuals before potential exposure and throughout periods of risk (Garcia-Lerma, Paxton, et al., 2010).

An advantage of PrEP is that it can be used independently of sexual practices and other risk behaviors (Padian, Buve, et al., 2008). Medical prophylaxis is standard for the prevention of many other infections such as malaria, but it is experimental for HIV. Multiple lines of evidence including animal data, human clinical trials, and mathematical models suggest that PrEP might be effective in preventing HIV among high-risk populations (Abbas, 2011; Garcia-Lerma, Paxton, et al., 2010; Kelesidis & Landovitz, 2011). Candidates for use as an oral PrEP agent have largely been selected from drugs that are currently approved for treatment of HIV infection. The characteristics that make for an effective PrEP drug overlap with those for treatment drugs-good tolerability and safety, low pill burden, once-daily dosing, long half-life, high potency, and a good resistance profile (i.e., the HIV virus does not rapidly develop resistance to the drug or broad cross-resistance with other drugs) (Garcia-Lerma, Paxton, et al., 2010). PrEP has been proven effective among MSM, and the US Centers for Disease Control and Prevention (CDC) have issued interim guidance on its use in this population (Centers for Disease

Control and Prevention, 2011c; Grant, Lama, et al., 2010). Other recent studies have shown PrEP to be effective among heterosexual men and women, although important questions remain about which heterosexuals would benefit most (Centers for Disease Control and Prevention, 2011b). And in 2012, the US Food and Drug Administration approved Truvada for PrEP, a drug originally marketed as treatment for people who were already infected with the virus (US Food and Drug Administration, 2012). Truvada is the first drug approved to reduce the risk of HIV infection in uninfected individuals who are at high risk of HIV infection and who may engage in sexual activity with HIV-infected partners. Truvada, taken daily, is to be used for PrEP in combination with safer sex practices to reduce the risk of sexually-acquired HIV infection in adults at high risk.

Male Circumcision

Male circumcision has been shown to be efficacious in preventing female-to-male transmission of HIV infection (Auvert, Taljaard, et al., 2005; Bailey, Moses, et al., 2007; Templeton, 2010). The mechanisms by which male circumcision reduces HIV infection risk have been explored by researchers. The inner surface of the foreskin has a high concentration of HIV target cells. It is lightly keratinized and susceptible to microscopic tears, is exposed to vaginal secretions during sexual intercourse, and provides a moist environment that might sustain the viability of pathogens. Thus, an intact foreskin may facilitate survival and entry of the HIV virus, so that removing the foreskin reduces the risk of HIV infection (Padian, Buve, et al., 2008). Male circumcision also reduces the risk of genital ulcer disease, which has been shown to increase the risk of HIV infection (Padian, Buve, et al., 2008).

The protection benefit of circumcision for male-to-female transmission (the male partner being already HIV positive) has been debated (de Bruyn, Shiboski, et al., 2011; Padian, McCoy, Karim, et al., 2011). Observational studies have suggested lower male-to-female transmission of HIV from circumcised men who were HIV infected (de Bruyn, Shiboski, et al., 2011); whereas randomized controlled trials have shown either that circumcision had no effect on HIV transmission from HIV-infected men with higher CD4 counts or that circumcision reduced male-to-female transmission by up to 46% (de Bruyn, Shiboski, et al., 2011; Padian, McCoy, Karim, et al., 2011). Nonetheless, after three clinical trials demonstrated a strong effect of male circumcision in reducing HIV acquisition, the World Health Organization (WHO) and UNAIDS held a consultation in March 2007, which recommended that circumcision be recognized as an effective intervention for prevention of heterosexual HIV acquisition in men (Padian, Buve, et al., 2008). It also recommended that countries with generalized heterosexual epidemics and low rates of male circumcision be the focus for scaling up of this intervention, within the context of ensuring universal access to comprehensive HIV prevention, treatment, care, and support (de Bruyn, Shiboski, et al., 2011; Padian, Buve, et al., 2008). Implementation of male circumcision as a biomedical intervention in countries has been variable and confounded by human resource constraints, funding shortfalls, ineffective communication strategies, and lack of support from political and traditional leaders (de Bruyn, Shiboski, et al., 2011; Padian, McCoy, Karim, et al., 2011).

Microbicides

Microbicides are chemical agents in the form of creams, gels, and suppositories, applied topically within the vagina or rectum before sexual intercourse in order to prevent HIV and sexually transmitted infections (STIs) (Weber, Desai, et al., 2005). Microbicides were initially conceived as a female-controlled method (vaginal application) to prevent transmission via heterosexual intercourse; however, safe and effective antimicrobial compounds could also serve as important prevention methods for MSM (rectal application) (Padian, Buve, et al., 2008). The majority of microbicide candidates currently under testing are formulated with ARV drugs. The first vaginal microbicide to be studied was nonoxynol-9, an anionic surfactant initially developed in the 1960s as a contraceptive spermicide with lubricant properties, and latterly used extensively to coat latex condoms (Weber, Desai, et al., 2005). In the 1980s, observational data for nonoxynol-9 gel against HIV/STIs were encouraging. However, in randomized trials in the 1990s, this gel was ineffective in preventing HIV and other STIs (Padian, Buve, et al., 2008). These trials were followed by studies to assess other non-HIV-specific agents, such as vaginal defense enhancers, entry inhibitors, and fusion inhibitors; several of these products have been assessed, with disappointing results (Padian, Buve, et al., 2008). There is hope, however, that better results will be achieved with agents that specifically inhibit HIV and are based on the same ARV drug platforms that have been used successfully for HIV treatment regimens. These ARV drug platforms have shown quite remarkable efficacy in explant tissue and animal infection models.

Unlike their predecessors, these newer-generation products do not have to be applied at the time of sex (Microbicide Trials Network, 2011). Researchers are exploring their daily use as a gel and other formulations, such as a ring, that in theory could be inserted once a month, for example (Microbicide Trials Network, 2011). Tenofovir, a nucleotide analogue reverse transcriptase inhibitor used in HIV/AIDS therapy, represents the most advanced candidate within this category (Hladik & Doncel, 2010). A 1% vaginal gel formulation of tenofovir, delivered into the vaginal vault up to 12 h before and within 12 h after intercourse, reduced HIV acquisition by nearly 40% overall in the recently completed CAPRISA 004 Phase IIb HIV prevention trial, which involved 889 South African women (Hladik & Doncel, 2010; Abdool Karim, et al., 2010).

Tenofovir now represents the first vaginal microbicide proven to be safe and efficacious in the primary prevention of HIV in women. Several other clinical trials are underway investigating anti-HIV microbicides based on non-nucleoside reverse transcriptase inhibitors such as dapivirine. Specifically, the ASPIRE study was recently launched to test the effectiveness and extended safety of a drug-infused vaginal ring for preventing HIV infection in uninfected women in five African countries (Department of Health and Human Services, 2012). Also known as MTN 020, the study aims to determine whether the HIV antiretroviral drug dapivirine can safely and effectively prevent HIV infection when continuously released in the vagina from a silicone ring replaced once every 4 weeks. Significantly, the ASPIRE study is the first effectiveness trial of a vaginal ring for HIV prevention and of a product that contains an antiretroviral other than tenofovir or tenofovir combined with the antiretroviral emtricitabine (Truvada) (Microbicide Trials Network, 2012). Other classes of microbicide candidate involve specific entry inhibitors, including gp120 blockers, gp41 blockers, and CCR5 antagonists, integrase inhibitors, protease inhibitors, and a combination of active ingredients (Hladik & Doncel, 2010; Microbicide Trials Network, 2011). Although the commercial availability of microbicides is likely to be several years away, strategies for regulatory approval and successful product launch should be initiated to address the cultural and educational issues that will be essential to ensure that they be used correctly and in accordance with other prevention strategies (Nuttall, 2010). To date, most microbicide research has focused on vaginal microbicides used for the prevention of HIV in women. Yet receptive anal intercourse is common among MSM, and there is increasing evidence that heterosexual women in both the developed and low- and middle-income countries also practice receptive anal intercourse. Because of the prevalence of this practice, current studies are evaluating the safety of vaginal microbicides when used in the rectum, as well as exploring candidate microbicides formulated specifically for rectal use (Microbicide Trials Network, 2011).

Vaccines

Strategies for vaccine development include innate, cell-mediated, or antibody-mediated resistance to infection, or all three (Padian, McCoy, Karim, et al., 2011). The pursuit of a safe and effective HIV vaccine has met with disappointment over the past three decades, with the termination of studies showing neither protection from HIV nor alteration in viral replication in vaccine recipients (Munier, Andersen, & Kelleher, 2011; Padian, McCoy, Karim, et al., 2011). More recently, there has been renewed optimism about potential HIV vaccines, resulting from the trial of the Thai RV144 (ALVAC and AIDSVAX) vaccine administered to men and women aged 18–30 in Thailand, which revealed a 26.4% efficacy in the intention-to-treat analysis and 31.2% in the modified intention-to-treat analysis. Vaccination with ALVAC and AIDSVAX modestly reduced the risk of HIV infection but did not affect the viral load or CD4 T-cell counts in participants who were subsequently infected with HIV (Munier, Andersen, & Kelleher, 2011; Rerks-Ngarm, Pitisuttithum, et al., 2009). Research is ongoing to elucidate the underlying mechanisms of these modestly successful compounds (Munier, Andersen, & Kelleher, 2011).

A successful HIV vaccine would ideally be safe, affordable, tolerated by recipients, and elicit an effective and long-lasting immune response comprising both neutralizing antibodies (Nabs) and cytotoxic T-lymphocytes (CTL) that recognize diverse strains of the virus and protect at sites of possible infection (Munier, Andersen, & Kelleher, 2011). It is believed that Nabs would function to prevent infection at mucosal surfaces, whereas CTL would control the spread and amplification of any virus that avoids initial neutralization (Munier, Andersen, & Kelleher, 2011). A successful HIV vaccine might thus have two separate effects, one prophylactic and the other therapeutic, slowing or preventing disease progression and reducing viral load and CD4 cell-count decline in those whose infection is not prevented (Munier, Andersen, & Kelleher, 2011). Both effects would reduce transmission and lead to improved control of the HIV epidemic.

Integrating Behavioral and Biomedical Approaches: Treatment as Prevention

Thirty years after the start of the HIV epidemic, scientists are examining the benefits of integrating behavioral and biomedical approaches in HIV prevention. Given that antiretroviral therapy (ART) works in reducing infectiousness of HIV-positive persons, HIV treatment has received attention as a potentially high-impacting prevention strategy. The utility of treatment as prevention in reducing HIV transmission rates has been supported with mathematical modeling and recently with findings from the HIV Treatment for Prevention Trial (HPTN) 052 (Cohen, Chen, et al., 2011). This trial showed a 96% reduction in HIV transmission within discordant couples. In theory, treatment as prevention can be successful in curbing the epidemic when high-risk individuals engage in frequent testing and if found to be HIV-positive, are linked to care and receive early treatment. Further, the “seek and treat” approach argues that a reduction in a community’s viral load may be achieved when masses, ideally every individual, are tested. The effectiveness and feasibility of this approach is currently being tested in the United States in the Test, Link to Care Plus Treat or TLC-plus HPTN 065 study among MSM in Washington, D.C., and New York City (El-Sadr & Branson, 2010).

Individuals infected with HIV must be found, tested, and linked to care in order for seek and treat to achieve maximum outcomes in curbing the epidemic. Therefore, access to hard-to-reach and hidden populations is crucial. There are a number of approaches to finding difficult populations including the use of respondent-driven sampling (RDS) and outreach programs. RDS is a relatively new and arguably most promising sampling approach that involves a mix of snowball sampling and mathematical modeling that weighs the sample to compensate for nonrandomness. The expanded HIV testing component of HPTN 065 involves social mobilization with targeted testing messages, as well as implementation of a universal offer of HIV testing in emergency departments and hospital inpatient admissions. However, even when individuals are adequately found and tested, treatment as prevention will fail when some key factors are not recognized. These include intervention adherence, treatment of sexually transmitted coinfections, and risk compensation.

Intervention Adherence

Issues surrounding adherence are receiving more attention with advances in biomedical technologies for HIV prevention. Findings from studies of HIV-serodiscordant couples suggest near zero HIV transmission when infected partners have undetectable blood plasma viral loads (Quinn, Wawer, et al., 2000). Further, in the absence of co-occurring STI, ART can result in undetectable virus in the genital tract. Thus, with proper adherence, HIV treatment can be an effective prevention tool. Strict adherence is also demanded for the success of other biomedical prevention technologies, including pre-exposure prophylaxis (PrEP) and vaginal gel microbicides.

Different prevention strategies require varying degrees of adherence. For example, male circumcision requires one decision (to obtain the intervention or not), whereas other methods like oral antiretroviral drugs for HIV-negative individuals require daily decisions. Just as with reduced infectiousness among HIV-positive individuals on ART, reduced infectability is only achieved and sustained among HIV-negative individuals on PrEP given optimal adherence. The same is true for microbicidal methods. Whereas HIV transmission was reduced by 39% overall in the CAPRISA 004 trial, a 54% reduction was observed among high adherers (>80%). In sum, adherence is demanded for the success of biomedical prevention methods. Consequently, it has become more important for behavioral and biological scientists who engage in HIV prevention research to use their respective tools and skills to work together toward common goals (Padian, Buve, et al., 2008).

Sexually Transmitted Coinfections

Reduced infectiousness among HIV-positive individuals can only be achieved with proper adherence to antiretroviral medications, as well as the treatment of co-occurring STI. Sexually transmitted coinfection makes HIV-positive people much more infectious than their blood viral load indicates. The inflammatory process involved in STI increases the concentration of CD4 (immune) cells in the genital tract, including concentration of those cells already infected with HIV. STIs like trichomoniasis and bacterial vaginosis can also cause genital bleeding, heightening the risk of sexual transmission and mother-to-child intrapartum transmission. An important question however is whether STI treatment to prevent HIV transmission should target the HIV-negative or HIV-positive individual, as both are potentially rendered more vulnerable to becoming infected and infecting someone else, respectively, when they are dually infected.

Whereas there is strong biological plausibility and different studies and meta-analysis have confirmed the association between STI and HIV infection (Johnson & Lewis, 2008), results from intervention research have not been entirely clear on whether there is a causal association. For example, research among dually infected individuals has shown that suppression therapy of herpes simplex virus (HSV) reduces plasma, seminal, and genital HIV viral load (Baeten, Strick, et al., 2008; Zuckerman, Lucchetti, et al., 2009). However, such findings have not been matched by the results of several randomized control trials. One trial that included women who were HIV negative and HSV positive at baseline who received suppressive treatment with acyclovir did not show evidence of decreased HIV incidence (Watson-Jones, Weiss, et al., 2008). Another trial involving over 3000 HIV-serodiscordant couples where the HIV-infected partner was coinfected with HSV also revealed a similar null finding (Lingappa, Kahle, et al., 2009). Interpreting these trials has been challenging however, as each involves complex issues surrounding adherence, statistical power, population, and/or intervention content and implementation. Treatment of sexually transmitted coinfection is still regarded as an important area for HIV prevention.

Risk Compensation

Risk compensation has been a growing concern with the advent of ART (Baggaley, Powers, & Boily, 2011) and other preventive innovations

(Hagel & Meeuwisse, 2004). Risk compensation related to HIV essentially involves an individual's perception that receiving HIV treatment or another preventive intervention (e.g., male circumcision, PrEP) renders HIV transmission less likely, and therefore the individual "compensates" by engaging in higher-risk behavior. The notion of reduced risk is so powerful that studies have shown that the mere promise of expanded access to treatment or to PrEP is associated with significant increases in risk behavior among MSM (Stolte, Dukers, et al., 2004), IDUs (Tun, Celentano, et al., 2003), and heterosexuals (Grémy & Beltzer, 2004). HIV-positive individuals on ART do not appear to be more likely to engage in unprotected sex than individuals not on ART. There is however consistent meta-analytic evidence that individuals have more unsafe sex than persons if they believe that having an undetectable viral load protects against HIV transmission (Crepaz, Hart, & Marks, 2004). Consequently, perceptions of risk must be addressed in antiretroviral counseling.

Adherence

As important as adherence is across all of prevention and disease management, it takes on particular importance with HIV. Only with strict medication adherence does HIV become a chronic not fatal disease. A window of 85–95% adherence is typically demanded in order to achieve viral suppression and thereby reduced infectiousness, with at least 95% adherence to reduce early mortality (Lima et al., 2009). Strict initial adherence is argued to be especially important, as poor initial adherence can lead to failure of first-line medication regimens and drug resistance. However, attention to the Necessity-Concerns Framework is critical in promoting initial adherence, since patients' views and perceptions of the necessity for ART, even before they begin treatment, may determine whether they maintain adherence over the long term (Horne, Cooper, et al., 2007). In a study that applied the utility of the Necessity-Concerns Framework to patients' perceptions of ART in relation to treatment uptake and adherence, perceived necessity of ART was initially high among those accepting ART (Horne, Cooper, et al., 2007). Variation in perceived necessity of ART at this early stage predicted high adherence 12 months later; however, strong concerns predicted low adherence (Horne, Cooper, et al., 2007). Nonadherence can potentially lead to spread of a drug-resistant virus, resulting in a public health disaster. Some have used this argument to justify withholding treatment to populations at risk for nonadherence, including individuals in sub-Saharan Africa. However, research to date has demonstrated that this concern is largely unfounded. The evidence suggests that sub-Saharan Africans are no more likely to be nonadherent than North Americans and that the reverse may actually be true (Mills, Nachega, et al., 2006). Although different populations and settings may experience different barriers to adherence, many of the important barriers to adherence are consistent across developed and developing nations.

Generally, barriers to adherence can be patient related (e.g., self-efficacy), medication related, (e.g., regimen complexity), schedule related (e.g., a chaotic daily schedule), and social related (e.g., poor social support). A systematic review of the literature showed that consistent barriers across multiple settings include fear of disclosure, concomitant substance use, forgetfulness, suspicions surrounding treatment, a lack of understanding of treatment benefits, complicated regiments, poor quality of life, work, and family responsibilities, and access to medication (Mills, Nachega, et al., 2006). The last is of greatest concern in developing settings.

Chronic Disease Management

As people who are living with HIV are now living longer with proper ART adherence, researchers have focused more attention on chronic disease management among people living with HIV. Research on this issue has shown that approaches to HIV care have shifted from tertiary/specialist care to primary care, which was the approach largely employed at the beginning of the epidemic (Chu & Selwyn, 2011; Northfelt, Hayward, & Shapiro, 1988). Whereas opportunistic infections were of the most significant concern for HIV-positive patients, causes of death have now shifted to end-stage liver and kidney disease, as well as other non-HIV-related malignancies (Hooshyar, Hanson, et al., 2007; Lewden, May, et al., 2008; Palella, Baker, et al., 2006). Thus, HIV care in ambulatory settings has focused on the prevention of common diseases. The HIV-patient population has also evolved since the advent of ART. Aging-related issues have received growing attention in the HIV literature, as most of the people living with HIV are of middle and older age. In fact, 75% of the population living with HIV in the United States are at least 40 years old (CDC, 2007). There is increasing importance to address the needs of aging HIV-positive patients, including financial strain and social isolation (Pitts, Grierson, & Misson, 2005). Living with chronic HIV requires the ability and responsibility of long-term, day-to-day care.

With chronic illness, as opposed to acute illness, the patient is the primary caregiver (Holman & Lorig, 1997). The World Health Organization includes self-management as a best practice to improve clinical care and outcomes for chronic diseases (World Health Organization, 2001). A review of the literature on chronic disease self-management to highlight HIV-specific challenges showed that there are common elements or tasks in chronic disease self-management that fit within the categories of physical health, psychological functioning, and social relationships (Swendeman, Ingram, & Rotheram-Borus, 2009). Self-management programs should include treatment adherence, but this must be nested within a variety of other skillsets, including cognitive techniques for side effect and symptom management, working with healthcare providers, understanding laboratory tests, managing fatigue, and healthy eating and exercise (Gifford & Groessl, 2002). In the section below, we review some of the major factors affecting chronic disease management, including (1) comorbid conditions, (2) quality of life, and (3) stigma.

Quality of Life

As the course of the HIV epidemic has changed with ART, so have the challenges that affect the health-related quality of life of people living with HIV. Health-related quality of life refers to how well one functions and one's perceptions of one's own well-being in physical, mental, and social domains of life (CDC, 2011a). Understanding health-related quality of life among people living with HIV is important as it helps to determine the burden of chronic disease, changes in health over time, and treatment effectiveness.

Research suggests that compared to the general population, people living with HIV have worse health-related quality of life. However, this depends on disease stage and quality of life domain (Imam, Flora, et al., 2012). Individuals who have HIV and are asymptomatic report physical functioning similar to the general population, whereas not surprisingly those who are symptomatic or have AIDS report worse physical functioning (Hays, Cunningham, et al., 2000). In comparison, individuals living with HIV/AIDS regardless of symptoms seem to experience worse emotional functioning or mental health compared to the general population. Further, emotional well-being appears to be worse for people at all stages of HIV than for individuals who have other chronic diseases (e.g., diabetes, multiple sclerosis, end-stage renal disease) but better than individuals with clinical depression (Hays, Cunningham, et al., 2000).

A number of demographic, psychological, and social factors are associated with better health-related quality of life. This includes being employed, higher income, better social support, spirituality/religiousness, engaging in active and positive coping, and physical activity/exercise (Hays, Cunningham, et al., 2000; Remor, Fuster, et al., 2012). From a stress-coping perspective, individuals who utilize adaptive and active coping strategies appear to experience better quality of life than individuals who use maladaptive or passive coping strategies. This body of knowledge has helped lead to the development of interventions aimed to improve quality of life among individuals living with HIV (Brown & Vanable, 2011).

One type of intervention to improve quality of life has focused on exercise. Exercise training improves and maintains health and has been considered an important adjuvant therapy for HIV-positive patients (American College of Sports Medicine, 2006; Stringer, 1999). There has been a focus on improving both physical strength and endurance concurrently. A review of randomized controlled trials testing the efficacy of this concurrent training on health-related quality of life showed that it is safe and may be beneficial for medically stable adults living with HIV (Gomes Neto, Ogalha, et al., 2013). Thus, concurrent training may be an important intervention in the care of people living with HIV.

Other approaches focus on targeting psychological factors and mental or spiritual health (e.g., Brown, Hanson, et al., 2013). One particular intervention that appears to be more comprehensive and efficacious in improving quality of life, as well as HIV outcomes like viral load, uses Cognitive Behavioral Stress Management (CBSM). CBSM interventions directly focus on reducing stress and teaching cognitive coping skills and also indirectly impact perceived environmental control and self-efficacy, thereby also influencing positive social support. CBSM interventions provide relaxation skills training, social skills training, instruction in self-monitoring of environmental stressors, and teaches cognitive restructuring techniques. There is evidence among different populations affected by HIV (e.g., HIV-positive gay men) that CBSM can positively influence a number of outcomes, including reducing sexual risk behavior (Coates, McKusick, et al., 1989), depressed mood (Kelly, Murphy, et al., 1993), and CD4 count (Antoni, Baggett, et al., 1991).

Acknowledging the value of health-related quality of life among people living with HIV means recognizing the significance of mental health. HIV/AIDS is one of the most biologically "strong" diseases with which we deal, yet the roles of emotions and mental health are also substantial. Mental disorders (e.g., depression, bipolar disorder, schizophrenia) make individuals more vulnerable to behaviors that transmit HIV and interfere with HIV treatment adherence (Vlassova, Angelino, & Treisman, 2009). While ART works to improve immune functioning and overall physical health, improving mental well-being should also be a primary goal in prevention for HIV-positive individuals. As others have previously stated, there is "no health without mental health" (Prince, Patel, et al., 2007). Also, improved mental health is associated with other healthy outcomes, including a lower likelihood of substance use, reduced sexual risk behavior, and improved adherence to care and treatment (Sikkema, Watt, et al., 2010). Ultimately then, better mental health among HIV-positive individuals may lead to a reduction in HIV transmission. Secondary prevention efforts must include mental health treatment.

Comorbid Conditions

The most common comorbid conditions with HIV are substance use disorders and depression (Bing, Burnam, et al., 2001). People who receive treatment for substance use are more likely to be HIV-infected than the general population (Woods, Lindan, et al., 2000). Further, data from a large, nationally representative US sample revealed that both substance use and HIV increase the likelihood of having major depression (Hasin, Goodwin, et al., 2005). Depression among people living with HIV is relatively common and may result from multiple stressors including reduced social support, social isolation, and increased exposure to violence (Kokkevi & Stefanis, 1995).

The co-occurrence of HIV and comorbid conditions is associated with reduced self-care, including poor HIV medication adherence and high-risk behavior. For example, in a study of individuals living with HIV who also had an alcohol use disorder, lower self-efficacy was associated with poor medication adherence, which in turn affected viral load (Parsons, Rosof, & Mustanski, 2008). In another study of gay and bisexual men at an outpatient substance abuse treatment, the co-occurrence of HIV and psychiatric diagnoses, including major depressive disorder and social phobia, were associated with an increased likelihood of STIs (Shoptaw, Peck, et al., 2003). A meta-analysis has also shown that depression is related to accelerated immune system decline and mortality in people living with HIV (Herbert & Cohen, 1993), and a study done with HIV-positive persons from a community health center showed that this relationship exists even beyond the effects of ART nonadherence (Safren, Otto, et al., 2001). A body of research has also shown that poor health conditions co-occur and interact synergistically to contribute to higher-risk behavior and ultimately HIV transmission.

Substance abuse, violence, and AIDS have been understood to co-occur in what has been labeled a syndemic or the co-occurrence of two or more epidemics that interact and synergistically contribute to excess burden of disease in a population (Singer, 1996; Singer & Clair, 2003). Since initially proposed and modeled, researchers have used syndemic theory to examine HIV risk in high-risk and vulnerable populations, including urban ethnic minorities, MSM, and women in resource poor settings (González-Guarda, Florom-Smith, & Thomas, 2011; Parsons, Grov, & Golub, 2012; Pitpitan, Kalichman, et al., 2013; Stall, Mills, et al., 2003). This research has shown that individuals who experience multiple comorbid conditions, including but not limited to depression, history of childhood abuse, history of intimate partner violence, and substance use, are more likely to engage in high sexual risk behavior. A consistent finding is that the relationship is linear, such that individuals who report more psychosocial conditions report higher-risk behavior, and in some samples a higher likelihood of being or becoming HIV infected. Indeed, people are less likely to effectively engage in self-care and self-protection when they are dealing with a number of difficult conditions in their lives. This suggests that HIV interventions must be multifaceted to treat the whole person, not solely the disease.

To address this gap in current interventions, a sexual risk and stress reduction intervention was recently developed and tested for HIV-positive African-American MSM with childhood sexual abuse histories (Williams, Glover, et al., 2013). Compared to a general health promotion intervention, the stress-focused intervention was more efficacious in decreasing unprotected anal insertive sex and reducing depression symptoms (Williams, Glover, et al., 2013). This was observed for MSM with histories of both high and low childhood sexual abuse severity. In another culturally specific HIV risk reduction intervention for Hispanic women (SEPA [Salud/Health, Educación/Education, Promoción/Promotion, Autocuidado/Self-care]), there were five sessions covering STI and HIV prevention, communication, condom negotiation and condom use, and violence prevention (Peragallo, Gonzalez-Guarda, et al., 2012). SEPA was efficacious in decreasing STI incidence, improving condom use, decreasing substance abuse and intimate partner violence, and improving communication with partner (Peragallo, Gonzalez-Guarda, et al., 2012). These select interventions demonstrate that addressing comorbidities or syndemic problems can successfully improve multiple health outcomes.

Stigma

Perhaps nothing is more embedded into the multiple facets of the lives of people living with HIV than stigma. The social stigma attached to HIV is the process of being labeled, stereotyped, devalued, and discriminated against as a function of being HIV positive (Goffman, 1963; Link & Phelan, 2001). The underlying processes surrounding stigma are complex as stigma is socially constructed and is tied to concerns for power and dominance (Parker & Aggleton, 2003). Generally speaking, fear of contagion and negative, morally driven, and value-based assumptions about people who have HIV and its transmission helps to account for the severe stigma attached to the disease (Jones & French, 1984). People living with HIV encounter a great deal of prejudice and discrimination at multiple levels and domains of life.

At an institutional level, people living with HIV are affected by their government's laws and policies about or related to HIV. For example, HIV-positive individuals were denied access to care and treatment under the presidency of Thabo

Mbeki, and the United States currently denies federal funding for syringe exchange programs, which have shown to be instrumental in reducing HIV risk among injecting drug users. At an interpersonal level, people living with HIV often experience discrimination from employers and co-workers, are refused access to medication and health facilities, and are isolated by friends and family. Finally, at an individual level, many people living with HIV personally endorse or internalize the negative beliefs and feelings about being HIV positive, which can result in self-isolation from social supports and healthcare. Consequently, HIV stigma is associated with poor mental health, social and physical isolation, reduced access to care and treatment, higher transmission risk behavior, poor medication adherence, and overall poor quality of life. Worsening the situation is the fact that social stigmas are also attached to virtually all of the frequent comborbid conditions with HIV, including drug abuse, violence victimization, and mental health.

Despite its pervasiveness and the negative outcomes associated with HIV stigma, researchers have done relatively little to acknowledge it in HIV treatment and prevention efforts. This neglect has much to do with inconsistent definitions and relatedly an absence of good measurement tools. In an effort to provide direction to HIV researchers, Earnshaw & Chaudoir (2009) put forth an HIV stigma mechanism model that outlined how HIV stigma can operate from the perspective of the target and the perpetrator. That is, from the perspective of the person who is doing the devaluing and discrimination and of the person who is being devalued and discriminated against. Using this approach, HIV-positive individuals can experience stigma in three ways. One is anticipated stigma, or the extent to which an individual expects to be evaluated and treated negatively as a function of their HIV status. The second is enacted stigma, or the extent to which the individual believes they have experienced prejudice and discrimination from others. Third, as previously mentioned, is internalized stigma, or the extent to which the individual herself or himself endorses the negative beliefs, attitudes, and feelings toward people with HIV.

HIV stigma would be ideally tackled with community and political involvement to institute protections for and reduce prejudice and discrimination toward HIV-positive persons. This can include but is not limited to collective action efforts and public education about HIV and its transmission with the aim of reducing or eliminating the social stigma attached to HIV. HIV prevention interventions may also intervene at one or more of these stigma mechanisms. For example, prevention programs might incorporate strategies to reduce anticipated or internalized stigma among people living with HIV. A review of HIV stigma reduction interventions showed that a number of strategies exist for targeting stigma at its multiple levels (Heijnders & Van Der Meij, 2006). At the individual level, different counseling approaches may help to decrease perceived stigma. These include counseling to reduce emotional distress following an HIV test (Simpson, Johnstone, et al., 1998), selective disclosure of HIV status (Kaleeba, Kalibala, et al., 1997), and cognitive therapy to help reduce internalized stigma (Chan, Kong, et al., 2005; Corrigan & Calabrese, 2005). Self-help, advocacy, and support groups also appear to help reduce stigma at the individual level (Lyon & Woodward, 2003). At the interpersonal level, intervention strategies include educating family, community members, and healthcare providers to help eradicate negative attitudes and beliefs among persons potentially providing care to individuals with HIV (Kidd & Clay, 2003). Both the Memory Book Project in Uganda and the Yale Program for HIV-affected children and families are examples of projects aimed at helping individuals come to terms with stigma, secrecy, disclosure, and loss (Gewirtz & Gossart-Walker, 2000). Finally, at the institutional level, programs to reduce stigma target organizations like the workplace. For example, some projects have targeted instances of discrimination, like mandatory testing of applicants (Busza & Schunter, 2001; POLICY Project, 2003). Other strategies include advocacy and protest (Corrigan & Penn, 1999).

Global Review of Risk Environment Integration into HIV Prevention Interventions

The preceding pages have reviewed theoretical, practical, and disease-specific issues in preventing and managing HIV/AIDS. This has included recognition of the frequent connection between these, as in secondary prevention of AIDS among HIV+ individuals, and the importance of treatment of AIDS to prevent HIV transmission. Thus, HIV/AIDS illustrates a continuum from primary prevention through chronic disease management, as opposed to a view of these as distinct categories. This final section reviews global efforts in these areas, illustrating as noted above how theories and general knowledge about the disease, its prevention, and management need to be tailored to the circumstances in different regions and among different populations. In the interest of economy, we have emphasized prevention, but, as will be seen, many of the prevention efforts reviewed carry over and include elements of treatment and management. This review is selective, not comprehensive. Our examples will highlight strategies used in each setting, with an emphasis on how theories may have been appropriately or inappropriately applied. We conclude with guidance for future intervention efforts that utilize combination HIV prevention methods.

The United States

The Centers for Disease Control and Prevention estimate that more than one million people in the United States are living with HIV (Centers for Disease Control and Prevention, 2008). HIV disproportionately affects certain population groups: MSM, African-Americans, and Latinos. MSM account for more than half of all new HIV infections in the United States, and they are the only risk group in which new HIV infections have been increasing steadily since the early 1990s (Centers for Disease Control and Prevention, 2010; Prejean, Song, et al., 2011). During the period 2006–2009, African-Americans and Latinos consistently had rates of new HIV infection that were 7–8 and three times the rate for whites, respectively (Prejean, Song, et al., 2011). Moreover, in 2009, the rate of new infections among African-American and Latina women were 15 and four times that of white women, respectively (Prejean, Song, et al., 2011). The course of the HIV epidemic in the United States has also been fueled by drug use. The National Institute on Drug Abuse estimates that 25% of all infections are drug related (National Institute on Drug Abuse, 2011).

Numerous evidence-based HIV prevention interventions have been rigorously evaluated in these at-risk populations and have shown significant effects in reducing sex- or drug-related risk behaviors, reducing the rate of new HIV/STI infections, or increasing HIV-protective behaviors. For this region, we present select examples of theory-driven risk reduction interventions, most of which are recommended by the CDC as best-evidence interventions and proven to be efficacious in the populations that are most at risk.

Men Who Have Sex with Men

Tailored for black MSM, *Many Men Many Voices (3MV)* is a group-level intervention guided by Social Cognitive Theory (defined in the section on behavioral theories), Behavioral Skills Acquisition Model, and Transtheoretical Model of Behavior Change and the Decisional Balance Model. The Behavioral Skills Acquisition Model emphasizes effective characteristics for risk reduction counseling (e.g., assessing a person's knowledge of risk behaviors and risk reduction strategies; ensuring an individual's accurate perception of personal degree of risk, building confidence; ensuring commitment and intention to change; developing strategies to reinforce change; incorporating positive attitudes and effective listening skills with participants) (Kelly, 1995). The Transtheoretical Model of Behavior Change focuses on emotional, cognitive, and behavioral factors that influence an individual's decision to change behavior. Stages of Change, as described in the Stages of Change Theory section, is a concept central to the Transtheoretical Model of Behavior Change (Prochaska, Redding, et al., 1994). The Decisional Balance Model suggests that cognitive and motivational factors influence a person's perceptions about making decisions. Decisional balance assumes that behavior change occurs when an individual perceives change as a gain rather than a loss (Janis & Mann, 1977).

The *3MV* intervention addresses behavioral determinants and the micro-social environment (e.g., cultural, social, and religious norms, identity of black MSM, degree of connectedness to the black and gay communities, racism, homophobia). A unique component of *3MV* is the development of menus of behavior change options for HIV/STI prevention rather than a singular emphasis on condom use that is common in other HIV prevention interventions for MSM (Wilton, 2009). Some of these behavior change options include helping participants recognize how racism and homophobia are related to sexual and substance use risk behaviors, identifying the power and control dynamics that exist in their relationships, and enhancing participants' intentions to change their own risky behaviors (Wilton, 2009). This intervention was shown to be efficacious among a sample of 338 black MSM of HIV negative or unknown HIV serostatus in New York City. Specifically, participants randomly assigned to the *3MV* intervention reported significantly greater reductions in unprotected anal intercourse with casual male partners and number of male sex partners, consistent condom use during receptive anal intercourse with casual male partners, and increases in HIV testing (Wilton, 2009).

For HIV-positive MSM, the *Seropositive Urban Men's Intervention Trial* (*SUMIT*) used enhanced peer-led intervention to reduce sexual risk behaviors. The *SUMIT* intervention is guided by the Theory of Planned Behavior, Social Cognitive Theory, and Information-Motivation-Behavioral Skills Model without consideration of the risk environment (Wolitski, Parsons, et al., 2005). It is led by HIV-positive gay or bisexual peer facilitators. Structured group activities focus on sexual and romantic relationships, HIV/STI transmission, drug and alcohol use, assumptions about the HIV status of sex partners, disclosure of HIV status, and mental health (Wolitski, Parsons, et al., 2005). Compared with the standard intervention, fewer men assigned to the enhanced intervention reported unprotected receptive anal intercourse with a HIV-negative or serostatus-unknown partner at 3 months; however, there were no other significant differences in transmission risk or serostatus disclosure at 3 or 6 months (Wolitski, Gomez, & Parsons 2005).

Finally, a theory-based, psychosocial intervention for HIV-positive MSM, known as the *EDGE* study, was developed to reduce sexual risk behaviors in the context of ongoing drug use, a unique feature in HIV prevention research. The *EDGE* intervention study used a clinical approach, combining motivational interviewing with elements from Social Cognitive Theory and the Theory of Reasoned Action (Mausbach, Semple, et al., 2007). Motivational interviewing is a client-centered, process-oriented counseling approach that incorporates feedback on current behavior, emphasizes readiness for change and personal responsibility for change, delineates alternative strategies for changing behaviors, and promotes counselor empathy and support. To a certain degree, the macro-social environment (e.g., peer and social norms) was addressed in the course of the intervention sessions. Participants in the EDGE intervention demonstrated a significantly greater percentage of protected sex acts at 12 months post-baseline, as well as a greater increase in self-efficacy for condom use over time (Mausbach, Semple, et al., 2007).

Ethnic Minorities

To address the significant impact of HIV among Latinas, the *Women's Health Promotion (WHP) program* has been used for Spanish-speaking, heterosexual, HIV-negative women (Raj, Amaro, et al., 2001). WHP utilizes tenets of the Social Cognitive Theory, the Theory of Reasoned Action, and the Health Belief Model to reduce risky sexual behavior among a community-based sample of Latinas in Boston. In addition to HIV/STD education, condom practice, and negotiation skills, *WHP* included participant-suggested sessions that addressed aspects of the women's micro-social environment such as intimate partner violence, oppression, social justice, and non-HIV-related partner communication, as well as comprehensive health issues (e.g., mental health, depression, cervical cancer, diabetes, nutrition). Facilitators used psychoeducational strategies through lectures, group discussion, skill-building games, and role playing exercises (Raj, Amaro, et al., 2001). Women in the *WHP* intervention group demonstrated a substantial increase in condom use at the 3-month follow-up evaluation in comparison to women in the control group, who received only HIV prevention material and referrals (Amaro, Raj, et al., 2002). To date, the *WHP* remains the only program on the CDC Best Evidence list that is solely for adult Latinas and is culturally and linguistically tailored to their needs. Although it integrates some components from the micro-social environment, there was lack of evidence of improvements in those components in the 15-month post-intervention follow-up.

The *Eban* HIV/STD risk reduction intervention demonstrates the willingness of couples, specifically African-American HIV-serodiscordant couples, to participate in HIV prevention interventions. *Eban* integrates components of Social Cognitive Theory, such as historical and cultural beliefs about family and community preservation, and an Afrocentric paradigm into a relationship-oriented ecological framework (El-Bassel, Jemmott, et al., 2010). This intervention, facilitated by male and female African-Americans, included four sessions with individual couples and four sessions with groups of couples. Individual couple sessions were designed to address interpersonal factors associated with sexual risk reduction, including communication, problem solving, monogamy, and negotiation skills, while group sessions addressed community-level factors, including (1) increasing positive peer norms for condom use by emphasizing the threat of HIV to African-American communities, (2) reducing the stigma associated with being African-American couples affected by HIV, and (3) increasing social support for HIV risk reduction (El-Bassel, Jemmott, et al., 2010). *Eban* was conducted in four major US cities: Atlanta, Los Angeles, New York, and Philadelphia, and it reported significant reductions in HIV/STD risk behaviors among African-American HIV-serodiscordant couples (El-Bassel, Jemmott, et al., 2010).

Finally, the *SHIELD* program is a peer network-oriented HIV prevention intervention based on Social Identity Theory and peer outreach that was implemented for predominantly African-American HIV-positive and HIV-negative drug users (Latkin, Sherman, & Knowlton, 2003). Participants were asked to make public commitments to increase their own health behaviors and to promote HIV prevention within their social networks and community contacts. The intervention included multiple sessions for training and skill building that involved goal setting, role plays, demonstrations, and group discussions. To present HIV risk within a broader community context, the intervention emphasized the interrelatedness of HIV risk among individuals, their risk partners, and their community. The *SHIELD* intervention showed that by emphasizing pro-social roles and social identity and incorporating peer outreach strategies, interventionists could reduce HIV risk in low-income, drug-using communities (Latkin, Sherman, & Knowlton, 2003).

Western and Central Europe

In Western Europe, MSM were the most commonly diagnosed risk group through 1998. After that year, persons with heterosexual contact have been diagnosed more commonly (Sullivan, Hamouda, et al., 2009). Importantly, however, in Western Europe, MSM remain the group most at risk of acquiring HIV (Sullivan, Hamouda, et al., 2009). In France, for example, MSM accounted in 2009 for more than half the men newly diagnosed with HIV, yet they represented only 1.6% of the country's population (UNAIDS, 2010). In 2007, 3160 new HIV diagnoses were reported among MSM in the United Kingdom, the most ever among that group up to that point (UNAIDS, 2010). Few behavioral HIV prevention interventions have been rigorously evaluated for MSM in Europe; the paucity of studies demonstrates the need for prevention efforts in this area (Berg, 2009).

One of the few interventions designed for MSM with a prior STI diagnosis was conducted in a sexual health clinic in London, England, and drew upon the Transtheoretical Model of Behavioral Change, the Model of Relapse Prevention that focuses on the maintenance phase of the habit change process, and elements from Social Learning Theory (Imrie, Stephenson, et al., 2001). This cognitive behavioral intervention consisted of a one-day cognitive behavioral workshop in addition to a standard, 20-min, one-on-one counseling session through motivational interviewing techniques about sexual risk behaviors. Although this intervention was acceptable to participants and feasible to deliver, it did not succeed in reducing the risk of acquiring a new STI in MSM (Imrie, Stephenson, et al., 2001).

Similar findings were observed for community-based, peer-led interventions modeled after successful opinion leader interventions in the United States (Elford, Sherr, et al., 2002; Flowers, Hart, et al., 2002). For example, *The Gay Men's Task Force* (*GMTF*) intervention was an interagency collaboration in Scotland consisting of three elements, all independently shown elsewhere to be effective in promoting gay men's sexual health but combined here for the first time (Flowers, Hart, et al., 2002). These elements included (1) peer-led sexual health promotion conducted on the commercial gay scene, (2) gay-specific genitourinary medicine services in both hospital and gay community settings, and (3) a free phone "hotline" providing sexual health information and details of local sexual health services (Flowers, Hart, et al., 2002). The *GMTF* intervention did not produce community-wide changes in sexual risk behaviors, but there was higher uptake of hepatitis B vaccination and HIV testing (Flowers, Hart, et al., 2002). The ineffectiveness of the program's intervention for sexual risk behaviors contrasted starkly with the results of North American studies that had shown that peer education was effective for HIV prevention among MSM (Elford, Sherr, et al., 2002; Flowers, Hart, et al., 2002). This suggests that a model of peer education shown to be effective in one country may not be directly transferable to another and may need to be modified according to the risk environment in the target country.

Eastern Europe and Central Asia

In Eastern Europe and Central Asia, the number of people living with HIV has almost tripled since 2000 and reached an estimated 1.4 million in 2009 compared with 760,000 in 2001. The Russian Federation and Ukraine account for almost 90% of newly reported HIV diagnoses (UNAIDS, 2010). Since the early 2000s, there has been a rapid rise in HIV infections among people who inject drugs, causing HIV infection rates in this region to surge. The epidemic is concentrated among IDUs, sex workers and their clients, and, to a much lesser extent, MSM (UNAIDS, 2010). The availability and content of HIV prevention interventions for IDUs have been affected by the region's macro-political environment.

The response in many countries in the region has been heavily influenced by the legacy of the former Soviet Union, with its emphasis on the medical discipline of "narcology" (a subspecialty of psychiatry) to tackle drug dependence and harms. The Russian Federation, the largest country in the region, prohibits the provision of opioid substitution therapy (OST). Similarly, IDUs in Ukraine have traditionally been stigmatized, had no access to treatment, and had little access to prevention. However, in the last few years (and due in part to two large Global Fund grants administered by nongovernmental organizations), Ukraine has made significant improvements in the provision of harm reduction and HIV treatment for IDUs. By mid-2007, 645 needle and syringe programs (NSP) sites had reached more than 120,000 people, and by 2009, Ukraine was one of only seven countries in the world with more than 1000 of these sites (Mathers, Degenhardt, et al., 2010). Additionally, the government recently amended national policies to permit methadone maintenance treatment (MMT).

Although NSPs have been implemented in nearly all countries in the region, overall levels of coverage for the region are low, largely because of low levels of needle-syringe provision in

Russia; although there and in other countries, IDUs can purchase needles in pharmacies. And even though most countries have implemented OST programs, the scale of programs is very limited, with one person receiving OST for every 100 IDUs (Mathers, Degenhardt, et al., 2010). The most significant challenge in the region for IDUs is national policies, particularly in the Russian Federation, that oppose proven, effective, and cost-effective interventions to reduce HIV transmission and acquisition.

South and Southeast Asia

In Asia, an estimated 4.9 million people were living with HIV in 2009, and 360,000 were newly infected (UNAIDS, 2010). However, most national HIV epidemics appear to have stabilized, and no country in the region has a generalized epidemic. Asia's HIV epidemic remains concentrated largely among IDUs and FSWs and their clients (UNAIDS, 2010). HIV prevention interventions for IDUs and FSWs in the region have focused largely on the macro-political risk environment without the guidance of behavioral theories.

In 2008, according to the Reference Group to the United Nations on HIV and Injecting Drug Use, of the estimated 15.9 million (11.0–21.2 million) IDUs globally, 3.9 million (3.5–5.6 million) or 25% live in South, East, and Southeast Asia (Mathers, Degenhardt, et al., 2008). In China, where IDUs account for the largest number of HIV infections, MMT, NSPs, and drug addiction, treatment facilities have been at the forefront of HIV prevention (Chu & Levy, 2005; Li, He, et al., 2009; Qian, Schumacher, et al., 2006). In 2004, a National Task Force comprising the Ministry of Health, Ministry of Public Security, and State Food and Drug Administration was set up in accord with new national guidelines for methadone treatment and NSPs (Chu & Levy, 2005). Methadone treatment for IDUs was initiated as a first-stage pilot program in select provinces. After a 12-month follow-up of IDUs in eight MMT clinics, drug injection rate, drug injection frequency, and needle sharing rate had dramatically declined. By the end of 2007, over 500 officially recorded MMT clinics were available for 40% of heroin abusers, and by 2010, coverage was expected to increase to 70% (Li, He, et al., 2009). NSPs have also produced decreases in needle sharing and HIV infection rates. By the end of 2007, NSPs served at least 30% of officially registered IDUs, and by 2010, coverage was expected to increase to 50% of IDUs (Li, He, et al., 2009). The Chinese government has also actively sought to collaborate with neighboring countries to prevent drug smuggling across borders, discourage new users through anti-drug education campaigns, treat current users through various drug detoxification programs, and encourage community outreach programs to facilitate detoxification, rehabilitation, and harm reduction (Chu & Levy, 2005; Li, He, et al., 2009; Qian, Schumacher, et al., 2006).

For FSWs in the region, the most ambitious and innovative HIV prevention intervention has been the 100% Condom Use Program launched in 1989 in Thailand. The goal of the 100% Condom Use Program was to promote universal use of condoms in commercial sex venues to prevent HIV transmission (Rojanapithayakorn, 2006). Public health officials, brothel owners, local police, and FSWs collaborated at provincial and local levels to implement the program. FSWs were screened for STIs weekly or semi-weekly at government STD clinics, treated, and provided with a box of 100 free condoms. Compliance was checked by tracing male STI patients back to the brothels where they presumably were infected. Health workers could then follow up with visits to the brothels, providing additional information and condoms. The cooperation of law enforcement was also sought; potential sanctions for failing to comply with the program included the threat of closure of the sex establishment (Ainsworth, Beyrer, & Soucat, 2003). The program has increased the use of condoms in sex work from 14% early 1989 to over 90% since 1992, and the number of men presenting to government clinics for STI treatment dropped by 90% from 1989 to 1995 (Ainsworth, Beyrer, & Soucat, 2003; Kilmarx, Palanuvej, et al., 1999). Moreover, the number of FSWs has declined by 25% since 1989 (Kilmarx, Palanuvej, et al., 1999). Thailand is the only country in this region in which HIV prevalence is close to 1%, and its epidemic appears to be stable overall (UNAIDS, 2010). Since its introduction in 1989, this program has also been successfully implemented in Cambodia, the Philippines, Vietnam, China, Myanmar, Mongolia, and Laos, with variations in program components between countries (e.g., formation of FSWs' self-help groups, peer education, issuance of membership cards by local authorities) (Rojanapithayakorn, 2006).

Middle East and North Africa

An estimated 460,000 people were living with HIV in the Middle East and North Africa at the end of 2009, up from 180,000 in 2001 (UNAIDS, 2010). The number of people newly infected has also increased over the last decade; there were 75,000 people newly infected in 2009, more than twice the number in 2001 (UNAIDS, 2010). The general pattern in different countries in the Middle East and North Africa points toward an HIV epidemic heavily concentrated among IDUs and among prisoners who are also IDUs, with heterogeneity between countries dependent on the relative role of each of these high-risk groups (Abu-Raddad, Hilmi, et al., 2010; McFarland, Abu-Raddad, et al., 2010).

Interventions for IDUs and IDU prisoners in the region have centered around the macro-political risk environment but without the use of theories and biomedical models. Although drug use via injection has been identified in every country in the region, only 35% of countries have implemented NSPs and even fewer (13%) have implemented OSTs (Mathers, Degenhardt, et al., 2010). In many African countries, laws prohibiting opioids for treatment of pain have created a barrier to prescribing OST, although some promising changes have recently occurred, for example, in Morocco, where the use of MMT has recently been approved (Mathers, Degenhardt, et al., 2010). Regarding NSPs, evidence has been gathered in Tehran, Iran, that access to an NSP may reduce needle- and syringe-sharing practices among community-based IDUs (Zamani, Farnia, et al., 2010).

For IDU prisoners, the political response toward harm reduction programs has been gradual and limited to Iran, where the largest number of people who inject drugs reside (UNAIDS, 2010). Iran, like many countries, began with a supply reduction policy that criminalized any type of drug use, in any quantity (Razzaghi, Nassirimanesh, et al., 2006). Efforts in the early 1990s resulted in policy changes, and although supply reduction approaches continued, the revised policy allowed the Iran Prison Organization (IPO) to adopt harm reduction policies and implement comprehensive HIV prevention interventions for IDU prisoners in many provinces throughout the country (Farnia, Ebrahimi, et al., 2010). The IPO's main activities include drug treatment and prevention programs that encompass MMT, pilot NSPs, education, and epidemiological surveillance (Eshrati, Asl, et al., 2008; Razzaghi, Nassirimanesh, et al., 2006). Iran is the only country in the Middle East or North Africa that has introduced MMT for opioid-dependent prisoners (Farnia, Ebrahimi, et al., 2010). There are currently 142 clinics across the country's 30 provinces that provide MMT to male and female opioid-using prisoners, and most of the large correctional facilities in the 30 provinces have established MMT programs (Farnia, Ebrahimi, et al., 2010). The Iran Prison Organization's HIV prevention package, with MMT programs constituting a main component, is an exceptional model for other countries in the region (Farnia, Ebrahimi, et al., 2010). It is perceived as effective in reducing illicit drug injection in a prison setting as well as for preventing the transmission of blood-borne infections, including HIV, among prisoners (Farnia, Ebrahimi, et al., 2010).

Sub-Saharan Africa

Sub-Saharan Africa still bears an inordinate share of the global HIV burden. Although the rate of new HIV infections has decreased, the total number of people living with HIV continues to rise, with a 2009 estimate of 22.5 million, 68% of the global total (UNAIDS, 2010). Women represent the majority of those infected and the majority of those dying. Heterosexual sex is the main mode of transmission in the region (Kilmarx, 2009). The key risk factors for heterosexual transmission are transactional or paid sex, concurrent sex partners, high number of lifetime sex partners, coinfection with viral and bacterial STIs, notably herpes simplex virus type 2 (HSV-2), and lack of male circumcision (Chen, Jha, et al., 2007).

Successful HIV prevention interventions have targeted the micro-social, economic, and political environments. Because gender inequalities (i.e., intimate partner violence, relationship power differentials) and lack of economic opportunities for both sexes often contribute to increased rates of HIV infection in women in sub-Saharan Africa, there has been recognition of the need for structural HIV prevention interventions such as microfinance programs. Microfinance programs seek to alleviate poverty by providing access to credit, savings, or business skills (Dworkin & Blankenship, 2009). In addition to providing economic benefits, microfinance may be an effective vehicle for women's empowerment, and newly acquired business skills may be accompanied by improvements in self-esteem and self-confidence, ability to resolve conflicts, household decision-making power, and expanded social networks (Kim, Watts, et al., 2007; Kim, Askew, et al., 2009).

The *Intervention with Microfinance for AIDS and Gender Equity (IMAGE)* study, implemented in South Africa, combined two elements: a poverty-focused microfinance initiative that targeted the poorest women and a two-phase learning and action curriculum of gender and HIV education. The *IMAGE* study's goal was to improve household economic well-being, social capital, and empowerment and thus reduce vulnerability to intimate partner violence and HIV infection. Over a 2-year period, rates of intimate partner violence were reduced by 55% in women enrolled in the intervention group compared to those in the control group; there was also improvement in numerous indicators of empowerment (e.g., challenging gender norms, autonomy in decision-making, communication within the household) (Pronyk, Hargreaves, et al., 2006). Regarding HIV outcomes, young women who took part in the intervention showed significantly higher levels of HIV-related communication, were more likely to have accessed voluntary counseling and testing, and were less likely to have had unprotected sex at last intercourse with a non-spousal partner (Pronyk, Kim, et al., 2008). However, the rate of unprotected sex among youth living in the households of intervention participants did not show a significant reduction (Pronyk, Hargreaves, et al., 2006). This result suggests that the intervention may be more effective for participants directly involved in the program than for those who received the intervention through diffusion (Dworkin & Blankenship, 2009).

Observational evidence has accumulated concerning the effectiveness of male circumcision for reducing HIV infection among men in sub-Saharan Africa. The causal association has been confirmed by three large randomized controlled trials conducted in South Africa, Kenya, and Uganda (Auvert, Taljaard, et al., 2005; Bailey, Moses, et al., 2007; Gray, Kigozi, et al., 2007). Among 3274 uncircumcised men aged 18–24 in South Africa, those randomized to immediate circumcision showed a protection from HIV infection of 61% after accounting for sexual risk behaviors (which increased in the intervention group) (Auvert, Taljaard, et al., 2005). Among 2784 men of similar ages in Kisumu, Kenya, the protection effect of circumcision was also 60% (Bailey, Moses, et al., 2007). Finally, in a trial in Rakai, Uganda, 4996 adult, HIV-negative men aged 18–49 were randomly assigned to either immediate circumcision or circumcision delayed for 24 months. HIV incidence among the circumcised men was significantly reduced compared with the uncircumcised (control) participants. The efficacy of circumcision for preventing incident HIV was 51% in the intention-to-treat analysis; adjustment for enrollment characteristics, behaviors, and symptoms of STIs did not affect this estimate (Gray, Kigozi, et al., 2007). All three trials were halted early by their respective data and safety monitoring boards (Padian, Buve, et al., 2008). The trials also assessed whether male circumcision could lead to sexual disinhibition because men might believe that they were protected against HIV infection after circumcision. In Kenya and Uganda, there was no evidence for an increase in sexual risk behaviors (Bailey, Moses, et al., 2007; Gray, Kigozi, et al., 2007). However, in South Africa, 21 months after the intervention, the circumcised men reported significantly greater numbers of sex partners per month than those in the delayed circumcision group (Auvert, Taljaard, et al., 2005). The success of this biomedical HIV intervention laid the foundation for rapid and intensive scale-up in some countries; however, in other countries, policy makers have been slow to support male circumcision (Padian, McCoy, Karim, et al., 2011).

Latin America and the Caribbean

In Latin America and the Caribbean, an estimated 1.7 million people were HIV positive in 2007, of whom 140,000 were newly infected (UNAIDS, 2010). More than half of Latin Americans living with HIV reside in the region's four largest countries: Brazil, Columbia, Mexico, and Argentina (Avert, 2011). Although MSM account for a significant proportion of HIV infections in Latin America, sex work and injection drug use have also emerged as significant routes of HIV transmission.

Among FSWs in Mexico, recent interventions have been primarily theory based, with an overlapping emphasis on FSWs' injection drug use behavior and on their clients' behaviors. As a result of these interventions, future directions have been identified that incorporate the risk environment. In Tijuana and Ciudad Juarez, FSWs were enrolled in a behavioral intervention to increase condom use under the premises of Social Cognitive Theory (Strathdee, Mausbach, et al., 2009). This intervention integrated motivational interviewing (e.g., key questions, reflective listening, summarization, affirmation, and appropriate use of cultural cues) and principles of behavior change. Improvements in self-efficacy were predictive of significant increases in condom use with clients among FSWs who received the intervention. And among FSW-IDUs, those who improved in HIV knowledge were more likely to increase condom use with clients (Strathdee, Mausbach, et al., 2009). Recognizing the need to integrate a harm reduction component promoting safer injection as well as safer sex negotiation, Strathdee and colleagues expanded the intervention for FSW-IDUs to include an injection risk reduction component (NIHReporter, 2011a). Additionally, clients of FSWs may serve as a bridge population for transmission of HIV from high- to low-prevalence populations (Goldenberg, Strathdee, et al., 2011).

Few behavioral interventions designed to reduce FSWs' risk of contracting HIV have considered the FSWs' clients. To address this lack, one intervention that is based on Social Cognitive Theory targets US and Mexican clients of FSWs in Tijuana. It uses motivational interviewing, active participation, and problem solving to increase clients' use of condoms with FSWs (NIHReporter, 2011b). In the US-Mexico border region, extensive research has identified numerous factors in FSWs' risk environment that can be taken into account for the development of future interventions for FSWs and FSW-IDUs. The factors range from aspects of the microphysical environment (sex work locations, monetary incentives for condom use by FSWs), the social environment (injecting drugs with clients, social norms such as *familismo*, abuse histories, and violence perpetrated by intimate partners and clients), the economic environment (job training opportunities), and the political environment (unjustified policing practices, NEPs, institutional incentives for promoting condom use) (Larios, Lozada, et al., 2009; Ulibarri, Strathdee, et al., 2011; Strathdee, Lozada, et al., 2011).

Successful HIV prevention programs have been implemented for IDUs in select countries such as Brazil, Argentina, and Mexico. A law implemented in the state of Sao Paulo in 1998 paved the way for Brazil to implement an extensive network of harm reduction programs across the country. The Brazilian Ministry of Health has firmly supported an infection control policy related to the use of psychoactive substances. Brazil has been recognized throughout the region for its National AIDS Program, a leading example of an integrated program for HIV/AIDS prevention, care, and treatment in a developing country.

Despite many differences between the epidemics within different countries, all countries in this region have to contend with rigid and restrictive social-cultural norms regarding gender roles and sexuality and contraception. These factors pose barriers to the development of effective HIV prevention interventions (Huedo-Medina, Boynton, et al., 2010). Three cultural beliefs relating to HIV risk that are predominant in this region are (a) *machismo* or "male pride," which is the belief that men should be dominant, have multiple sex partners, and engage in unprotected sex; (b) *simpatía*, which endorses a traditional female role emphasizing sexual submission and women's sexual inexperience; and (c) *familismo*, associated with traditional family values which conflict with less socially acceptable forms of sexual expression, such as condom use and homosexuality (Huedo-Medina, Boynton, et al., 2010). Addressing these social factors will facilitate reductions in HIV infections through promotion of safer sex behaviors in all risk populations.

Implications

Global approaches to HIV prevention have varied by geographic region and risk population. Additionally, appropriate theoretical frameworks and risk environment factors at the micro- and macro-levels have been integrated and targeted in HIV prevention interventions. As the HIV epidemic has evolved, most geographic regions have shifted from interventions that focus solely on the individual level to those that also integrate social networks, peers, communities, and biomedical-based (e.g., male circumcision, microbicides) approaches. There has also been a shift from a narrow focus on prevention to a focus to include treatment of HIV-positive individuals (i.e., treatment as prevention). These different approaches may be preferentially suited to certain populations or for certain periods of an individual's life.

Conclusions

Understanding the complexities of behavioral medicine in HIV/AIDS (i.e., the disease itself and infectious processes that surround it) is critical to the comprehensive development and implementation of comprehensive HIV/AIDS treatment and prevention strategies. Because the life expectancy for people with HIV has increased dramatically, there are challenges that must be faced regarding aging with HIV/AIDS. Comorbid conditions such as substance abuse, trauma, mental illness (e.g., depression, dementia), and incidental factors such as stigma may influence adherence to ART and must be taken into account in HIV treatment regimens. Overall, reduced infectiousness among HIV-positive individuals can be achieved only through proper adherence to ART medications and treatment of co-occurring STI. Treatment as prevention in reducing HIV transmission is a focus of ongoing trials to curb new infections.

When designing and applying HIV prevention interventions, researchers and health officials differ in the ways that they use behavioral theories, biomedical models, and the risk environment approach depending upon the geographic region and with the risk levels of the targeted populations. Risks in high-risk populations also frequently overlap. For example, an epidemic among IDUs may ignite an epidemic among FSWs due to the interaction between injection drug use and sex work, as when men and women who inject drugs also purchase or sell sex. Overall, some interventions, even theory-based ones, could conceivably have been more efficacious if they had taken components of the HIV risk environment into account.

HIV prevention experts agree that no single prevention strategy will be 100% effective nor acceptable and applicable to all populations (Kurth, Celum, et al., 2011). Behavioral interventions will be a necessary, but not solely sufficient, component of a successful prevention program worldwide. A number of biomedical interventions such as male circumcision, microbicides, and PrEP have been shown to have a significant impact on curbing new HIV infections in various at-risk populations. Combination HIV preventions that not only incorporate evidence-based behavioral and biomedical approaches but also take account of the risk environment must be developed to be appropriate, acceptable, and deliverable with high levels of coverage and adherence (Kurth, Celum, et al., 2011; Strathdee, Hallett, et al., 2010). Comprehensive combination HIV interventions will be those that address risk factors at the individual, dyadic, social, economic, and political levels, while accounting for the stage of the HIV epidemic in a particular region.

Geographic regions will vary in their approaches to combination HIV interventions. Some are well positioned to proceed with designing such interventions whereas others need to strengthen their political response to the HIV epidemic in populations most at risk. Combination interventions, particularly when implemented at scale, pose significant evaluation challenges, including how best to determine impact and how and whether to measure the effectiveness of component strategies (Padian, McCoy, Karim, et al., 2011; Padian, McCoy, Manian, et al., 2011). Nonetheless, as an initial step, in 2010, as part of the National HIV/AIDS Strategy in the United States, the CDC implemented a high-impact prevention approach. By using combinations of scientifically proven, cost-effective, and scalable interventions targeted to the right populations in the right geographic areas, this approach promises to greatly increase the impact of HIV prevention efforts (Centers for Disease Control and Prevention, 2011b). Additionally, to mark the third anniversary of the National HIV/AIDS Strategy, a new Federal initiative focused on "the HIV care continuum" (also referred to as the HIV treatment cascade) was launched to increase the proportion of individuals who are aware of their HIV status, are successfully linked to care and remain in care, receive ART, and adhere to their treatment to achieve viral load suppression. If the CDC "high-impact prevention approach" (which has clear and measurable targets to be achieved by 2015) proves successful in the United States, a critical challenge will be how to effectively and efficiently disseminate this approach globally, particularly in countries with limited political will to curtail the HIV pandemic. Ultimately, delivery of effective combination prevention packages could represent a new era for HIV prevention and a turning point for both HIV-positive and at-risk populations (Kurth, Celum, et al., 2011; Warren & Bass, 2013).

Acknowledgments Jamila K. Stockman was supported in part by a grant from the National Institute on Drug Abuse (K01DA031593) and the National Institute on Minority Health and Health Disparities (L60MD003701) of the National Institutes of Health. Psychology, Mental Health, and Quality of Life

32

Frank J. Snoek, Kaitlyn E. Brodar, Gary Cuddeback, Edwin B. Fisher, Carol Golin, and Rebeccah L. Sokol

Behavioral medicine has multiple and varied connections with mental health.[1] Many in behavioral medicine have been trained in clinical psychology, psychiatry, social work, or other professions with a primary focus in the area. For others, interest in mental health emerges from the growing recognition of how a range of psychosocial factors, including mental health problems, contribute to the etiology and complicate disease prevention and management. For all, an integrated view of health problems generally includes psychological, social, and biological dimensions. Problems are best prevented and treated from such an integrative perspective.

Addressing all the issues involved in this area would require several books and, so, is far beyond the reach of this chapter. Here, we set out some of the scope of the problems of mental health worldwide and then of interactions of mental health problems with prevention and care of other health problems, emphasizing maternal health and child development, diabetes, cardiovascular disease, cancer, and HIV/AIDS. We give substantial attention in this chapter to how we think about and conceptualize psychological problems and their roles in physical disease. An important area of progress is the inclusion of treatment for mental health problems in general healthcare systems, in contrast to being relegated to separate agencies, separate funding arrangements, separate treatment facilities, and separate professionals. A benefit of such integrative thinking may be recognition of how concepts previously thought limited to mental health, e.g., the role of early experience, social construction, and stigma, apply as well to other chronic diseases that have clearly biological

---

[1] Throughout this chapter, "mental health" and "mental illness" are used as summary terms for a broad range of phenomena referred to by a variety of terms such as "psychopathology," "abnormal behavior," and "psychiatric disorder." This usage is primarily pragmatic and not intended to convey or privilege any conceptual model as to the nature, causes, or fundamental characteristics of this broad range of phenomena.

bases. At the same time, there are important ways in which schizophrenia, depression, anxiety disorders, personality disorder, and substance use disorder are *not* "just like any other illness." The field is headed toward an integration built on shared themes and approaches, but not an assumption of equivalence of all instances.

This chapter closes with a description of some noteworthy approaches to treatment, prevention, and intervention around mental health and psychological aspects of health. The interventions included are a sample of a much larger field but are chosen to illustrate the innovative and integrative approaches emerging in the field. We start, however, with epidemiology.

Global Burden of Mental Health Problems

A 2009 review examined WHO World Mental Health (WMH) surveys in 28 countries. Across these, the inter-quartile range (25th to 75th percentiles) of lifetime prevalence of any of a combination of anxiety disorder, mood disorder, externalizing disorder, and substance use disorders (SUDs) was 18.1–36.1% and that for 12-month prevalence was 9.8–19.1%. "Serious disorders" include non-affective psychosis (including schizophrenia), bipolar disorder, substance dependence with a physiological dependence syndrome, suicide attempts, or substantial functional impairment. With this definition, 12.8–36.8% of those with any disorder were rated as serious (inter-quartile range = 18.5% to 25.7%) (Kessler, Aguilar-Gaxiola, et al., 2009). Table 32.1 presents some of the details of these global estimates, disaggregated by WHO region and individual countries contributing data to the report.

As described in Table 32.1, the lifetime prevalence of anxiety disorders (including agoraphobia, adult separation anxiety disorder, generalized anxiety disorder, panic disorder, post-traumatic stress disorder, social phobia, specific phobia) ranged from 4.8% in the People's Republic of China to 31% in the USA. Similarly, the lifetime prevalence of mood disorders (including bipolar disorder, dysthymia, and major depressive disorder) ranged from 3.6% in the People's Republic of China to 21.4% in the USA. The lifetime prevalence of any disorder ranged from 12.0% in Nigeria to 47.4% in the USA.

Table 32.2 documents the disability-adjusted life years (DALYs) attributable to a variety of mental and neurological disorders (Collins, Patel, et al., 2011). According to the WHO (2016):

> One DALY can be thought of as one lost year of "healthy" life. The sum of these DALYs across the population, or the burden of disease, can be thought of as a measure of the gap between current health status and an ideal health situation where the entire population lives to an advanced age, free of disease and disability. DALYs for a disease or health condition are calculated as the sum of the Years of Life Lost (YLL) due to premature mortality in the population and the Years Lost due to Disability (YLD) for people living with the health condition or its consequences.

That is: $DALY = \text{YLL} + \text{YLD}$

Disaggregating DALYs into years of life lost (YLLs) and years lost to disabilities (YLDs) shows important trends that underscore the importance of mental health. A 2015 study of global trends in mortality and disability (GBD 2013 Dalys, Hale Collaborators, et al., 2015) shows that, over the past decades, life expectancy has increased substantially, largely through improvements in treating communicable diseases. This results in general aging of the population. As the population ages, however, age-adjusted YLDs are not declining – that is, the likelihood of, e.g., an 80-year-old having disability from a health problem has not changed. There are two trends then that need to be understood: generally increasing life expectancy and stable age-adjusted rates of YLDs associated with mental health and substance use disorders as well as musculoskeletal, neurological, and hearing and vision disorders and diabetes. Together these have led to a greater total of YLDs and aggregate disease burden. The authors of the report point out important implications for behavioral medicine:

> We believe that the historical focus of health research funding on causes of YLLs was probably appropriate. However, health progress now means that more research investment is needed for the disorders that debilitate, rather than kill. With each

[a] Anxiety disorders include agoraphobia, adult separation anxiety disorder, generalized anxiety disorder, panic disorder, post-traumatic stress disorder, social phobia, and specific phobia. Mood disorders include bipolar disorders, dysthymia, and major depressive disorder. Impulse control disorders include intermittent explosive disorder and reported persistence in the past 12 months of symptoms of three child-adolescent disorders (attention-deficit hyperactivity disorder, conduct disorder, and oppositional defiant disorder). Substance disorders include alcohol or drug abuse with or without dependence. In the case of substance dependence, respondents who met full criteria at some time in their life and who continue to have any symptoms are considered to have 12-month dependence even if they currently do not meet full criteria for the disorder. Organic exclusions were made as specified in the *Diagnostic and Statistical Manual of Mental Health Disorders*, Fourth Edition

[b] Impulse disorders restricted to age ≤ 39 (China, Ukraine, Nigeria) or to age ≤ 44 (all other countries)

[c] Intermittent explosive disorder was not assessed

[d] Attention-deficit hyperactivity disorder was not assessed

[e] Oppositional defiant disorder was not assessed

[f] Adult separation anxiety disorder was not assessed

[g] Specific phobia was not assessed

[h] Bipolar disorders were not assessed

[i] Conduct disorder was not assessed

[j] Only alcohol abuse with or without dependence was assessed. No assessment was made of other drug abuse with or without dependence

> passing year, the shift towards YLDs as the leading causes of disease burden will be more evident. Action is needed now to develop preventive, curative, and ameliorative strategies for these conditions rather than waiting until this shift is even more obvious. (GBD 2013 Dalys, Hale Collaborators, et al., 2015, p. 2182)

Mental Health and Chronic Disease

Surveys from six low- and middle-income countries (China, Ghana, India, Mexico, Russia, and South Africa) examined the prevalence and

impacts of multimorbidity, defined as two or more of eight common chronic diseases (angina pectoris, arthritis, asthma, chronic lung disease, diabetes mellitus, hypertension, stroke, and vision problems) (Arokiasamy, Uttamacharya, et al., 2015). The prevalence of multimorbidity was 21.9%, ranging from as low as 20.3% in China to as high as 34.7% in Russia. As expected, multimorbidity increased with age and decreased with greater socioeconomic status. Moreover, the number of chronic diseases was associated with greater depression, poorer self-rated health, and more limitations in activities of daily living (ADLs).

Amidst the many forms in which mental health issues complicate health and illness, several stand out: depression, anxiety disorders, substance use disorders, personality disorders, psychological distress, and serious mental illness. We review here the epidemiology of each of these.

Epidemiology of Major Depression Depression is a common mental disorder. WHO estimated that the 12-month prevalence of mood disorders (including different subtypes of depression) in developed countries was between 3.1% (Japan) and 9.6% (USA).

Lifetime prevalence estimates for depression are as high as 21%, with a preponderance in women. Depression affects both an individual's personal life and the society as a whole. The estimated lifetime prevalence of suicide in patients with depression is between 2% (outpatients) and 6% (inpatients). A first episode of depression often occurs early in life; the median age of onset for mood disorders ranges from 25 to 31 years. The natural course of depression varies substantially between patients. Some patients have a full remission after an index episode (20%), many have either residual symptoms (12%) or recurrence after full remission (40%), and chronicity is rather high (28%). Furthermore, interindividual differences in the duration of a depressive episode are large, with a median duration of 3 months. However, the distribution is skewed toward much longer episodes, and nearly 20% of patients do not recover within 24 months. Furthermore, each depressive episode leads to increased damage on psychological, biological, and social levels, which further increases an individual's vulnerability for another depressive episode.

Thus, large heterogeneity exists in the natural course of patients presenting with depression, with a subgroup of patients having persistent or recurrent episodes.

Risk factors for the onset of depression include social factors, such as low education, social defeat, and loneliness; psychological factors, such as a high degree of neuroticism, early life stressors, and minor depressive complaints; and biological factors, such as genetic risk, specific medication and recreational drugs, and physical illness. Epidemiological data suggest that any medical chronic disease carries an additional risk factor for depression. In the USA, Egede (2007) showed that the risk for major depression was increased 2.6 times if a somatic disease was present, with a prevalence of comorbid depression ranging from 7.9% in patients with heart failure to 17% in patients with end-stage renal disease. The WHO World Mental Health Survey reported on depression prevalence based on ICD-10 criteria from 60 countries in all regions of the world and found a significantly higher prevalence of depression in people with at least one comorbid somatic complication (23%) than in people without comorbid somatic complication (3%) (Demyttenaere, Bruffaerts, et al., 2004).

Anxiety Disorders The US National Institute of Mental Health defines anxiety disorder as worry or fear that does not go away and may worsen over time, causing significant impairment to an individual's life (National Institute of Mental Health, 2015). According to the *Diagnostic and Statistical Manual of the American Psychiatric Association*, Fifth Edition (2014), anxiety disorders include separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder, panic disorder, agoraphobia, generalized anxiety disorder, anxiety due to medical conditions or substances, and other/unspecified anxiety disorders (Anxiety and Depression Association of America, 2015). This category is separate from obsessive-compulsive disorders and trauma or stressor-induced disorders (Regier, Kuhl, & Kupfer, 2013). Anxiety, particularly generalized anxiety disorder (GAD), often coincides with major depression (Moscati, Flint, & Kendler, 2016), and the DSM-5 includes a new diagnostic category, "mixed anxiety/depression" (American Psychiatric Association, 2014).

The Global Burden of Disease Study estimates indicate that of the 183.9 million disability-adjusted life years (DALYs) attributed to mental and substance use disorders, 14.6% are attributable to anxiety disorders (Whiteford, Degenhardt, et al., 2013). The estimate of the current global prevalence of anxiety disorders is 7.3%, which corresponds to approximately 1 in 14 people experiencing an anxiety disorder at any given time (Baxter, Scott, et al., 2013). Globally, women are nearly twice as likely to have an anxiety disorder as men. In a sample of adults from the USA ($N = 20{,}013$), women had significantly higher rates of panic disorder (OR = 1.70, $p < 0.05$), agoraphobia (OR = 1.46, $p < 0.05$), generalized anxiety disorder (OR = 1.83, $p < 0.05$), and specific phobia (OR = 1.96, $p < 0.05$) (McLean, Asnaani, et al., 2011). Anxiety disorders are also more prevalent in younger adults (ages 35–54, who later may "grow out" of them), Euro/Anglo cultures, developed countries, and conflict populations (Whiteford, Degenhardt, et al., 2013).

Anxiety disorders are believed to run in families, with twin studies yielding heritability estimates of 30–40% (Rapee, 2012). While there does appear to be a genetic component in anxiety disorders, the influence of genetics does not appear to be as strong as is observed in other disorders, such as substance use disorders and schizophrenia. One consistent and well-documented environmental risk factor is childhood sexual abuse. Other factors related to parent-child interactions, such as overprotectiveness, may also serve as risk factors.

Anxiety disorders pose an enormous burden to both mental and physical health (Comer, Blanco, et al., 2011). In their study of over 43,000 US adults, Comer et al. (2011) found that individuals diagnosed with an anxiety disorder scored significantly lower on multiple dimensions of a health survey when compared to individuals without an anxiety disorder. As a group, individuals with anxiety disorders were significantly more likely to report hypertension, angina, tachycardia, ulcers, gastritis, arthritis, poor social functioning, limitations due to emotional problems, and lower overall well-being. Of all the anxiety disorders, GAD posed the greatest challenges to health. Individuals with GAD reported significantly more medical comorbidities, especially non-cirrhotic liver disease and heart disease other than myocardial infarction.

The relationship between anxiety disorders and cardiovascular illness has been documented in other recent studies. In a study of 1015 adults with coronary heart disease at an outpatient clinic, individuals with GAD experienced a significantly higher rate of cardiovascular events (HR = 1.62, $p < 0.01$) (Martens, de Jonge, et al., 2010). This relationship was maintained even when controlling for health behaviors, disease severity, and biological mediators. Similarly, a meta-analysis of individuals with coronary heart disease found that individuals suffering from anxiety were at a significantly higher risk of cardiac death than non-anxious persons (HR = 1.26, $p < 0.0001$) (Roest, Martens, et al., 2010).

Substance Use Disorders Substance use disorders (SUDs) occur when frequent use of a particular substance results in significant impairment or problems in various areas of life, such as health, work, or relationships (U.S. Department of Health and Human Services, 2015). The DSM-5 combines different categories of abuse and dependence into one disorder, with severity measured on a continuum (American Psychiatric Association, 2014). Common SUDs include alcohol use disorder, tobacco use disorder, cannabis use disorder, stimulant use disorder, hallucinogen use disorder, and opioid use disorder (U.S. Department of Health and Human Services, 2015).

Data from the 2010 Global Burden of Disease, Injuries, and Risk Factors study indicated that mental and substance use disorders were the primary causes of years lost to disability (YLDs), with illicit drug use disorders accounting for 10.9% and alcohol use disorders for 9.6% of all disability-adjusted life years (DALYs) caused by mental and substance use disorders (Whiteford, Degenhardt, et al., 2013). Of the 8.6 million years of life lost (YLLs) to mental and substance use disorders, 81.1% resulted specifically from SUDs. Although the worldwide prevalence of most mental disorders remained fairly stable between 1990 and 2010, SUDs increased significantly during this time. Young adults account for the largest proportion of the global burden, with peak prevalence occurring between ages 20 and 29 (Merikangas & McClair, 2012).

A major risk factor for SUDs is family history; children of substance abusers are two times as likely to develop a substance use disorder as children of non-abusers, and this risk is even higher when the substance involved is alcohol or marijuana (Merikangas & McClair, 2012). Males are significantly more likely to have a substance use disorder than females, and individuals who frequently use or abuse a variety of substances (polysubstance abuse) are more likely to develop SUDs than individuals who only use one substance. Experiencing stressful life events such as losing a job, divorce, terrorism, and natural disasters is associated with increased substance use (Keyes, Hatzenbuehler, & Hasin, 2011). Adverse childhood experiences, particularly childhood maltreatment, consistently predict subsequent development of SUDs across studies (Enoch, 2011; Keyes, Hatzenbuehler, & Hasin, 2011). In young adults, additional risk factors include peer substance use, low academic achievement, moving away from home, and attending college, while protective factors include work, marriage, and graduating from college (Stone, Becker, et al., 2012).

SUDs frequently co-occur with other mental disorders and can severely impact health in a number of ways (U.S. Department of Health and Human Services, 2015). For example, individuals with SUDs are significantly more likely to be infected with HIV than individuals without SUDs (Prince, Walkup, et al., 2012). They are also significantly less likely to adhere to a prescribed medication regimen for type 2 diabetes (Kreyenbuhl, Dixon, et al., 2010) as well as for schizophrenia and bipolar disorder (Jónsdóttir, Opjordsmoen, et al., 2013). Pregnant women who abuse substances are more likely to miscarry and deliver prematurely than non-abusers (Gopman, 2014; Wendell, 2013). Tobacco use during pregnancy is one of the leading causes of preventable infant mortality and morbidity (Wendell, 2013). Alcohol abuse during pregnancy also results in poor birth outcomes, including fetal alcohol syndrome. Preventing the onset and reducing the prevalence of SUDs are therefore a priority for improving both mental and physical health outcomes.

Personality Disorders Individual differences in character, habitual ways of thinking, feelings, and behaviors are part of normal variation. When individual characteristics are manifest in a maladaptive manner, they are clinically identified as personality disorders. Intrinsic to such a definition is the social context within which these behaviors occur, since acceptable behavioral patterns vary across social contexts (Newlin & Weinstein, 2015). For example, highly submissive and deferential behavior may be required in some relationships and cultures but may be dysfunctional and socially unacceptable in other relationships and cultures. Personality disorders are common, estimated to occur among 10% of the general population, and even more common in clinical populations as they coexist often with chronic diseases and health problems (Samuels, 2011).

The DSM-5 currently identifies 10 types of personality disorder: paranoid, schizoid, schizotypal, antisocial, borderline, histrionic, narcissistic, avoidant, dependent, and obsessive-compulsive (American Psychiatric Association, 2014). These are classified into three categories or clusters: cluster A (paranoid, schizoid, schizotypal) characterized by odd, eccentric, aloof, paranoid, or bizarre thinking; cluster B (antisocial, borderline, histrionic, narcissistic) characterized by instability of behavior, mood, and relationships; and cluster C (avoidant, dependent, and obsessive-compulsive) characterized by obsessive, fearful, or anxious thoughts. However, definitions and distinctions among these are difficult, and alternative ways of grouping and characterizing them remain controversial and the object of discussion and research (Gotzsche-Astrup & Moskowitz, 2016; Widiger, 2015).

Personality disorders are associated with poorer outcomes and higher healthcare utilization across a wide range of health problems. One systematic review found personality disorders associated with sleep disturbances, back pain, incontinence, chronic pain, obesity, and varied chronic health conditions including allergic rhinitis, arthritis, asthma, cardiovascular disease, diabetes, gastrointestinal disease, HIV+ status, hypertension, ischemic heart disease, liver disease, stroke, and venereal disease (Dixon-Gordon, Whalen, et al., 2015). In national surveys from the USA including 34,653 adults, a variety of personality disorders were associated with cardiovascular disease, arthritis, diabetes, and gastrointestinal conditions (Quirk, El-Gabalawy, et al., 2015). In a recent systematic review of health service utilization among those with mental disorders in the UK (Twomey, Baldwin, et al., 2015), the presence of a personality disorder, in addition to neurotic symptoms, comorbidity, and several demographic characteristics, were among the variables shown to predict a variety of types of health and behavioral health service utilization, including primary care contacts, medication usage, contacts with psychiatrists, attendance at psychotherapy, inpatient days, accident and emergency admissions, and a total service utilization score.

Interpersonal problems are at the core of personality disorders (Hengartner, von Wyl, et al., 2015) and especially those identified as "borderline personality," characterized by extremely labile relationships and frequent vacillation between all-or-none negative and positive views of self and others. As a result, patients with personality disorders and especially borderline personality presenting in medical settings are often experienced as "difficult" or "high maintenance." This may be related to insecure/avoidant or disorganized attachment styles characterized by fear of abandonment and also fear of closeness (Bowlby, 1980; van Dijke & Ford, 2015). Importantly, individuals with personality disorders are often not aware of the impact of their behavior on others, and working with them requires a willingness to understand their perspective while maintaining appropriate boundaries (Newlin & Weinstein, 2015). As personality disorders often co-occur with other mental health as well as medical diagnoses, treatment involves multiple components.

For borderline personality disorder and cluster B (antisocial, borderline, histrionic, narcissistic), there is evidence that psychological therapies and in particular dialectic behavior therapy are beneficial. A Cochrane review concluded that findings "support a substantial role for psychotherapy in the treatment of people with BPD [Borderline Personality Disorder] but clearly indicate a need for replicatory studies" (Stoffers, Vollm, et al., 2012). Although frequently prescribed, there is little evidence for the effectiveness of psychopharmacological treatment in this patient group (Stoffers & Lieb, 2015) although medication may be helpful for other problems not part of personality disorder per se (Kendall, Pilling, et al., 2009).

Psychological Distress In addition to the specific kinds of disorders detailed in the preceding paragraphs, general psychological distress has emerged as an important consideration in behavioral medicine and especially in chronic disease management. The term distress was introduced in the early 1970s by the Hungarian physiologist Hans Selye to distinguish between stress initiated by negative, unpleasant stressors and positive stress (eustress). Psychological distress is conceptualized as a measure of current state as opposed to a static, personality trait. Thus, it is treated as a continuous variable that can vary in response to different stressful situations and was defined by Ridner as "the unique discomforting, emotional state experienced by an individual in response to a specific stressor or demand that results in harm, either temporary or permanent to the person" (Ridner, 2004). The harm mentioned in this definition refers to negative emotions, such as irritability, fear, nervousness, and sadness, which are burdensome in their own right, associated with low well-being and social functioning, but are not necessarily pathological. Thus, distress is defined as an emotional response toward adverse or unpleasant stressors, whereas the definition of depression is based solely on a count of symptoms, irrespective of cause or context.

Increased psychological distress (or simply distress) is prevalent in medical patients and is often regarded as a normal response to the burden of diagnosis and treatment, discomforting symptoms, and negative social implications. As noted by De Ridder and colleagues (de Ridder, Geenen, et al., 2008), chronic illness challenges patients' habitual coping strategies. Although most eventually reach good psychological adjustment, for about 30% the adjustment phase is long lasting or unsuccessful. In a community-dwelling Japanese population, Nakaya et al. (2014) noted increased nonspecific psychological distress in people with self-reported somatic diseases compared with people claiming to have no somatic disorder. The risk of psychological distress was increased by 20% for hypertension and hyperlipidemia; 30% for diabetes; 50% for cancer; 60% for myocardial infarction, arthritis, and osteoporosis; and 130% for stroke (Nakaya, Kogure, et al., 2014). The differences in prevalence across these different diseases suggest a role for disease characteristics such as prognosis, symptom burden, and specific treatment requirements. Epidemiological studies of depression in different somatic patient populations might offer opportunities for research into causes looking into shared psychological (e.g., coping) and biological (e.g., inflammation, hypothalamic-pituitary-adrenal axis) pathways across different medical disorders.

Serious Mental Illness Serious mental illness is defined by the conjunction of diagnosis, duration, and disability (Goldman, Gattozzi, & Taube, 1981; U.S. Department of Health and Human Services, 2014). More specifically, serious mental illness is defined as (a) a mental, behavioral, or emotional disorder that is currently diagnosable or diagnosable within the previous 12 months, (b) of sufficient duration to meet diagnostic criteria as outlined in current diagnostic and statistical manuals, and (c) resulting in functional impairment which limits one or more major life activities, such as school or work (U.S. Department of Health and Human Services, 2014). Qualifying diagnoses often include especially debilitating disorders such as schizophrenia, bipolar disorder, or major depression. Other disorders such as anxiety disorder, post-traumatic stress disorder (PTSD), and obsessive-compulsive disorder may also be included. Developmental and substance use disorders, however, are not qualifying diagnoses for serious mental illness. Disability can be indicated by *eligibility* for social services such as, in the US Supplemental Security Income (SSI) or Social Security Disability Income (SSDI). (Because the process of enrolling in these programs can take years, eligibility rather than coverage is taken as the criterion for disability.) Duration can be defined in terms of a single episode of psychiatric hospitalization in the previous 5 years of at least 6 months or two or more hospitalizations within a year (Goldman, Gattozzi, & Taube, 1981).

In 2013 in the USA, for example, there were an estimated 10 million adults – or 4.2% of all US adults – aged 18 or older with diagnosed serious mental illness within the previous 12 months (U.S. Department of Health and Human Services, 2014). Best current estimates suggest a lifetime prevalence of bipolar disorder to be approximately 2.6% of all US adults, 9.1% for depressive disorders, and 1% for schizophrenia and other psychotic disorders (U.S. Department of Health and Human Services, 2014). Furthermore, recent prevalence data suggest that nearly 40 million people in the USA (18%) experience an anxiety disorder in any given year, and over 7 million adults in the USA could be diagnosed as having PTSD at any given time (U.S. Department of Health and Human Services, 2014).

Persons with serious mental illness have high rates of co-occurring substance use disorders. Estimates suggest that up to 8.4 million adults in the USA have co-occurring serious mental illness and substance use disorder (U.S. Department of Health and Human Services, 2014). For many persons with serious mental illness, the combination of untreated mental illness and substance use can be associated with a number of poor outcomes, including violence, treatment and medication nonadherence, difficulty accessing much-needed social and medical services, homelessness, and frequent criminal justice contacts (Clark, Ricketts, & McHugo, 1999; Drake & Mueser, 2001; Horsfall, Cleary, et al., 2009; Steadman, 2000; Theriot & Segal, 2005). Moreover, individuals with serious mental illness who are also involved with the justice system have difficulty accessing housing and social services and have high recidivism rates (Cloyes, Wong, et al., 2010; Gagliardi, Lovell, et al., 2004; Lovell, Gagliardi, & Peterson, 2002; Mallik-Kane & Visher, 2008; Skeem & Louden, 2006).

Persons with serious mental illness have higher rates of chronic health conditions and a reduced life expectancy compared to the general population (Chwastiak, Rosenheck, et al., 2006; Colton & Manderscheid, 2006; Daumit, Pratt, et al., 2002; Dickey, Normand, et al., 2002; Hansen, Arnesen, & Jacobsen, 1997; Joukamma, Heliövaara, et al., 2006). Compared to the general population, for example, persons with schizophrenia are at greater risk for colon and breast cancers (Hippisley-Cox, Vinogradova, et al., 2007). Among the persons with serious mental illness, heart disease remains the leading cause of death (Dembling, Chen, & Vachon, 1999; Saha, Chant, & McGrath, 2007). Those diagnosed with schizophrenia also have an increased risk of metabolic syndrome and type 2 diabetes, explained both by lifestyle factors and metabolic effects of antipsychotic medication (Olsson, Westman, et al., 2015; Ward & Druss, 2015).

In addition to the heightened likelihood of disease, the physical health needs of persons with mental illness often go unmet (Colton & Manderscheid, 2006; Druss, Rosenheck, et al., 2002; Salsberry, Chipps, & Kennedy, 2005). There is a speculation that the unmet physical health needs of persons with severe mental illness are due to problems in both primary care and specialty mental healthcare. Primary care providers may view care for persons with serious mental illness as too specialized for primary care (Lester, Tritter, & Sorohan, 2004). On the other hand, mental healthcare providers may lack training and confidence to treat the medical problems of persons with serious mental illness (Unützer, Schoenbaum, et al., 2006). These barriers may be joined by a combination of consumer, provider, and system-level factors (Druss, Rosenheck, et al., 2002), supported by clinical guidelines endorsed by both primary care and mental health professionals (e.g., de Hert, Dekker, et al., 2009).

Key Life Course Phases

There are several areas and points in the lifespan in which mental health issues are especially important in general health and well-being. Here we will highlight three phases: parental health and early child development, adolescence, and adult development and aging.

Parental Health and Child Development

Childhood environment, including parental mental health, parental attachment and parenting styles, and socioeconomic status, impacts child development and subsequent mental and physical health. Mental health problems such as depression or substance use may be linked with parenting characteristics such as neglect that then impact childhood development (Hanington, Ramchandani, & Stein, 2010; Norman, Byambaa, et al., 2012). These parental characteristics can place a child at future risk for a myriad of poor health outcomes, including a range of mental disorders, drug use, and sexually transmitted infections (Hanington, Ramchandani, & Stein, 2010; Norman, Byambaa, et al., 2012). Conversely, a positive childhood environment, characterized by authoritative and attentive parents, can foster healthy psychosocial development and both mental and physical health (Kiuru, Aunola, et al., 2012; Steinberg, Elmen, & Mounts, 1989; Vollmer & Mobley, 2013).

Parental Mental Health Numerous adult health problems are linked to parental characteristics that subsequently have an impact on childhood development. Chief among these health issues is parental depression. Research has demonstrated that maternal mental health problems in pregnancy and/or postpartum place children at risk for poor global, behavioral, cognitive, and socioemotional development (Kingston & Tough, 2014). As recently reviewed by Atif and colleagues, the prevalence of prenatal depression averages 15.6% and postnatal 19.8% and is associated with a number of problems, including preterm birth, low birth weight, and poor infant growth and cognitive development (Atif, Lovell, & Rahman, 2015). Negative impacts are not only associated with maternal depression but paternal depression as well. Parental depression impacts cognitive and socioemotional development in children, both directly and indirectly (Cummings, 1994). Directly, parental depression affects the parent's emotions, thoughts, and behaviors, which in turn influences child development (Cummings, 1994; Hanington, Ramchandani, & Stein, 2010). For example, depressed parents exhibit more unsupportiveness, negativity, and intrusiveness toward their children compared to nondepressed parents (Field, Healy, et al., 1990; National Research Council (US) and Institute of Medicine (US) Committee on Depression, 2009; Zajicek & De

Salis, 1979). Parental depression may enter into relationships with children through criticism, disengagement, lack of responsiveness, coldness, and physical abuse (Panaccione & Wahler, 1986; Webster-Stratton, 1990). A child's prolonged exposure to these, in turn, has been linked to the development of childhood depressive behavior (Cohn, Campbell, et al., 1990; Hanington, Ramchandani, & Stein, 2010). More indirectly, parental depression may affect children by altering patterns of parent-child attachment and interaction (Cummings, 1994), discussed in the next section.

Parental Attachment and Parenting Styles Parental attachment and parenting styles have important impacts on child development and health. Bowlby described how children naturally seek proximity to caregivers in times of need, developing attachment relationships (Bowlby, 1976, 1980). He also noted differences in attachment systems, including secure and insecure attachment. Parental warmth, sensitivity, and responsiveness to bids for support and proximity facilitate secure attachment and build positive mental representations of self and others (Cummings & Cicchetti, 1993; Zeanah & Zeanah, 1989). This formation of secure attachment fosters a child's development and well-being (Mikulincer & Shaver, 2012) However, when a child's caregivers are not reliably available or supportive, insecure attachments result in children viewing others as unreliable and themselves as unworthy (Bretherton, 1985) and lacking self-efficacy (White, 1959). These may in turn lead to childhood depression (Mikulincer & Shaver, 2012) and numerous other disadvantageous patterns of development.

In addition to child-parent attachment, parenting styles have been identified as a way of understanding child development. Psychologist Diana Baumrind identified three major parenting styles – permissive, authoritative, and authoritarian – each with different impacts on child behavior (Baumrind, 1966). Permissive or "laissez faire" parenting is nonpunitive, accepting, and indulgent of children's impulses, desires, and actions. This style creates few expectations for children and, so, may lead to increased aggression and unscrupulous behaviors (Baumrind, 1966). Contrasting sharply with the permissive style, an authoritarian style attempts to control children's behaviors and attitudes with close supervision and high demands. These may foster rebelliousness, passivity and dependence, or low self-assertiveness. In addition to these two styles is authoritative parenting. This directs children's activities in a rational, issue-oriented manner while also encouraging autonomy and self-will (Baumrind, 1966). The warm, firm, and fair parenting characterized by authoritative parentings leads to healthy psychological adjustment (Gray & Steinberg, 1999).

Socioeconomic Status, Parenting, and Child Development As is well known, low socioeconomic status (SES) has a significant influence on mental and physical health. Research has examined how the influence of SES begins in childhood. Children of lower SES have higher rates of many diseases and risk factors for disease (Colhoun, Hemingway, & Poulter, 1998; Hegewald & Crapo, 2007; Wright & Subramanian, 2007). The realities of low SES teach persistent patterns of responding to threatening, negative, or ambiguous stimuli in a manner that leads to more and stronger stress responses compared to children of higher SES (Chen, Langer, et al., 2004). This accentuates stress and can induce significant biological changes in children through increasing allostatic load, which can exert long-term effects on physical and mental health (Danese & McEwen, 2012). Essentially, the allostatic load is a body's cumulative wear and tear; it is the physiological consequence of chronic exposure to stress (McEwen & Stellar, 1993). It serves as the mediator through which the chronic stress many children of low SES face negatively impacts their subsequent physical and mental health.

SES not only has an impact on childhood development through the stress response but also through the early resources that are denied as a result of this status. Proper nutrition during infancy and toddlerhood are essential because these periods are critical for growth and brain development; insufficient energy and nutrients during this time may negatively impact the structural and functional development of the child's brain (Uauy & Dangour, 2006). Research has illustrated that mothers with a lower education level are more likely to have poor infant feeding practices than their more highly educated counterparts, thereby potentially impeding their children's growth and brain development (Emmett & Jones, 2014). Putting these several streams together, low SES may lead to poorer mental and physical health outcomes as a result of both fostering stress and limiting critical resources.

Adolescent Development

Adolescence is an age of both learning and confusion. Because this transitional time allows individuals to explore independence and self-identity, it forces youth to face dilemmas that were previously unknown. Adolescents navigate new issues – sexuality, drugs, alcohol, and socialization – at the same time, they are working to form a clear identity. It follows that emotional distress is an important component of the adolescent experience and adolescent health (Merikangas, He, et al., 2010).

Adolescent behaviors and development have often been framed in terms of the importance of peer influence, social modeling, and observational learning (Carter, Bingham, et al., 2014; Cruwys, Bevelander, & Hermans, 2015; Gerbasi, Richards, et al., 2014; Suleiman & Deardorff, 2015). These factors are significant especially in the roles they play in encouraging or discouraging many risk behaviors in adolescence. We must not ignore, however, the influence of an adolescent's psychological experience and mental health. Here, we explore the emotional aspects of adolescent health and development. Because adolescence is an age of discovery and exploration, it is also an age of increased susceptibility to psychological distress. This distress can have negative impacts on development, physiological health, health behaviors, and overall mental and social well-being. This transitional time is critical to healthy development and the formation of healthy habits that persist into adulthood.

A person's self-concept encompasses beliefs about one's self, such as academic performance, gender identity, sexuality, and ethnicity (Shavelson, Hubner, & Stanton, 1976). These beliefs can significantly change during adolescence due to increased self-consciousness and peer influence (Sebastian, Burnett, & Blakemore, 2008). However, stress may also have a significant impact on self-concept. There are numerous sources of stress and anxiety for adolescents – including academic pressures, bullying, self-esteem issues, and body consciousness – that can manifest as a negative self-concept (Benedict, Vivier, & Gjelsvik, 2015; Rawana & Morgan, 2014; Wenz-Gross, Siperstein, et al., 1997). For instance, high academic stress and low emotional support are related to a low academic self-concept, and high peer stress and low peer companionship are associated with low social self-concept (La Greca & Harrison, 2005; Michie, Glachan, & Bray, 2001; Wenz-Gross, Siperstein, et al., 1997). In addition to its importance in its own right, a negative self-concept damages mental and social well-being. It is associated with a broad range of mental and social disorders including depression, suicidal tendencies, eating disorders, anxiety, violence, and substance abuse (Mann, Hosman, et al., 2004; Rosenberg, 1985).

Unfortunately, such disorders are common. Anxiety disorders are the most common mental disorder in adolescents, with nearly a third of adolescents suffering from them, followed by behavior disorders, mood disorders, and substance use disorders, as per DSM-IV (K. R. Merikangas, He, et al., 2010). Approximately 40% of adolescents with one class of disorder also meet criteria for another class. These disorders can be debilitating – over one in five adolescents with a mental disorder suffer severe impairment and/or distress (Merikangas, He, et al., 2010).

There is a patterned distribution of mental disorders across adolescents. Mood and anxiety disorders are more prevalent among females, whereas males have higher rates of behavior and substance use disorders (Merikangas, He, et al., 2010). With respect to parental characteristics, the prevalence rates of anxiety disorders, substance use disorders, and behavior disorders are higher for adolescents whose parents are divorced or separated compared to married or cohabitating (Merikangas, He, et al., 2010). Lastly, adolescents whose parents are not college graduates have an increased risk for all disorders (Merikangas, He, et al., 2010).

Numerous biological factors both drive and result from adolescent psychological distress. During this life stage, there is an increased responsiveness to sex and stress hormones, and these hormones may influence the risk for mental disorders via their effect on dopamine neurotransmission that is important in feelings of enjoyment and motivation (Sinclair, Purves-Tyson, et al., 2014). With regard to the biological effects that result from psychological distress, the adolescent brain may be particularly sensitive to stress with important consequences on an individual's immediate and long-term health and well-being. There is strong evidence that stress exposure during adolescence can lead to short- and long-term changes in limbic and cortical structure and function, with important behavioral repercussions (Eiland & Romeo, 2013). Beyond its effects on the brain, psychological distress has additional physiological impacts. Even as early as the pre-teenage years, stress increases systolic blood pressure and assists the formation of arterial plaque, placing an individual at higher risk for cardiovascular disease later in life (Roemmich, Lambiase, et al., 2014).

Not only is psychological distress disagreeable in itself and through its direct biological affects, but it can have poor repercussions on adolescents' health behaviors. For instance, stress promotes unhealthy behaviors, including snacking on unhealthy foods and reduced physical activity, which places an individual at risk for obesity (Roemmich, Lambiase, et al., 2014). Furthermore, distress and negative health behaviors such as substance use, risky sexual behaviors, and eating disorders often co-occur (Santos, Richards, & Bleckley, 2007; Waller, Hallfors, et al., 2006). Depression, eating disorder, and substance abuse symptoms tend to increase over time during adolescence, and increases in each of these symptoms are associated with increases in other symptoms (Measelle, Stice, & Hogansen, 2006; Merikangas, He, et al., 2010). In particular, depression has been shown to predict increases in eating disorders and substance abuse symptoms (Measelle, Stice, & Hogansen, 2006; Santos, Richards, & Bleckley, 2007).

The influence of psychological distress on health behaviors is especially important in adolescents facing chronic conditions (Bender, 2006). For this population, depression and risk behaviors may be associated with nonadherence to medications, poor treatment outcomes, and even death (Bender, 2006). In a study of the Pediatric Diabetes Consortium registries, depressive symptoms were found in 13% of adolescents with type 1 and 22% of adolescents with type 2 diabetes (Silverstein, Cheng, et al., 2015). Stress may have negative indirect effects on glycemic control in adolescents with diabetes via stress's impact on diabetes treatment and monitoring, such as nonadherence to meal and exercise plans (Marcovecchio & Chiarelli, 2012). In adolescents with asthma, depression might lead to hopelessness that interferes with adherence and other health-promoting behavior, and depression may even impact asthma directly via altering immune response (Bender, 2006).

Older Adulthood

Setting the stage for psychological development in older adulthood (usually defined as age 55 and above) is a pattern of declining capacity in many domains. Because of an inverted U pattern of development of many cognitive and physical abilities, risks for health problems increase with advanced age. Yet structural factors such as gender, class, and ethnicity also influence health across the lifespan, so that, for example, older adults at high socioeconomic status will tend to be healthier than midlife adults at low socioeconomic status (Connell & Janevic, 2003). Additionally, older adults tend to be more likely to engage in many positive health behaviors. An important demonstration of the capacity of older adults to adopt healthy behaviors was in the Diabetes Prevention Program. The relative advantage of its lifestyle condition (loss of 7%

bodyweight and 150 min of moderate physical activity per week) relative to metformin was greater than among younger participants (minimum age = 25 years, mean across conditions = 50.6) (Diabetes Prevention Program Research Group, 2002).

The declines that accompany aging have psychological effects. Some cognitive abilities (e.g., mechanical or fluid intelligence and pragmatic or crystallized intelligence) decline with age while others, such as "wisdom or knowledge about the meaning and conduct of life" (Connell & Janevic, 2003), may increase with years of experience. Older adults report declines in both perceived and objective control (Bandura, 1997). Again, however, these declines are subject to other influences. On the one hand, increased physical illness and decreased capacities such as with balance may decrease self-efficacy. On the other hand, greater experience with self-management might increase efficacy for things like managing chronic diseases that often emerge in older adulthood. Across several psychological and cognitive dimensions, complex interweaving of changing capacities and factors associated with functioning underscores the importance of recognizing the dynamic interplay among influences in older adulthood (Connell & Janevic, 2003).

Complementing changes in the capacities of the older adult, changes in their social contexts influence psychological status and well-being. Widowhood, illness of spouses and partners, and death of friends may all reduce the support available and individuals with whom to share activities. A classic study (Lowenthal & Haven, 1968) documented the negative impacts on emotional status of level of social interaction. Older adults reporting low levels of social interaction were much more likely to report low levels of morale based on items assessing satisfaction with life, happiness, usefulness, positive mood, and planning, 85% of those low on social interaction versus 42% of those high on interaction (p. 24). Changes in social interaction, however, were substantially moderated by answers to a simple question regarding the availability of a confidant, "Is there anyone in particular you confide in or talk to about yourself or your problems?" Among those whose level of social interaction had decreased, only 44% of those with a confidant reported low morale, but among those without a confidant, that percentage rose to 87% (p. 26). Similarly, among those who had been widowed in the previous 7 years, 45% of those with a confidant reported low morale, but 73% of those without a confidant reported low morale (p. 27). Again, dynamic interweaving of influences characterizes health and well-being among older adults.

Mental health problems are prominent among older adults. In the USA, the Centers for Disease Control and Prevention has estimated that "20% of people age 55 years or older experience some type of mental health concern" including "anxiety, severe cognitive impairment, and mood disorders (such as depression or bipolar disorder)" (Centers for Disease Control and Prevention & National Association of Chronic Disease Directors, 2008). Among these mental health burdens, older men have the highest rate of suicide, "45.23 per 100,000 compared to an overall rate of 11.01 per 100,000 for all ages" (Centers for Disease Control and Prevention & National Association of Chronic Disease Directors, 2008). Nevertheless, the vast majority of older adults do not report serious mental health problems. In national surveys in the USA, only 4.9% of those 65 years old or older reported current depressive symptoms (McGuire, Strine, Allen, et al., 2009) and only 2.7% reported "serious psychological distress," assessed by frequency of feeling "nervous, hopeless, restless or fidgety, so depressed that nothing could cheer you up, that everything was an effort, or worthless" (McGuire, Strine, Vachirasudlekha, et al., 2009). The relationship between age and reported serious psychological distress is complex. In several countries, those 65 years and older report lower levels than those in middle age and younger adulthood (McGuire, Strine, Vachirasudlekha, et al., 2009) although one study reported the highest prevalence among those 80–84 years old (Clarke, Piterman, et al., 2008).

Ways in Which Psychological Problems Are Manifest in Common/Major Diseases

The manifestations of psychological problems and psychopathology in diseases are more varied and numerous than a single chapter can review in detail. Table 32.3 provides key examples of how psychological problems can be risk factors for, can complicate, and can result from physical disease.

Integration of Biological, Psychological, and Socioeconomic Influences

A central challenge is how we conceptualize the interaction of social, economic, psychological, developmental, and biological influences in health, well-being, and disease. Other chapters in this volume detail the social determinants of health (see Siddiqi et al., Sherlaw et al., *infra*), interactions of genetic and behavioral/environmental influences (see Nater, *infra*), as well as cultural influences (see Baumann, *infra*). Here we will focus on the question of how social and psychological influences "get under the skin" to influence biological processes, a question that is central to understanding the complexity of relationships between mental health and chronic disease (e.g., Uchino et al., *infra*, as well as Cohen, Tyrrell, & Smith, 1991; Uchino, 2006; Uchino, Bowen, et al., 2014).

As a model, we will focus here on the ways these processes may interact in diabetes and depression. Depression and stressful life events can lead to the activation of the hypothalamic-pituitary-adrenal (HPA) axis and complex hormonal interactions which might be involved in the pathogenesis of metabolic disorders. These complex hormonal interactions can give rise to a wide range of metabolic and cardiovascular abnormalities which characterize diabetes and are increasingly observed in people with depression, thus creating a vicious cycle of psychological and physical ill health (Axelrod & Reisine, 1984; Ma, Kong, et al., 2007).

Once diagnosed with diabetes or depression, treatment for one may affect the severity or progression of the other. Although requiring considerably more research, there have been reports of metabolic effects of medications used to treat psychological problems as well as reports of effects on mood and behavior of medications that have been used to treat diabetes mellitus and obesity (Boekholdt & Peters, 2010; Burch, McKenna, et al., 2009; Koval, Rames, & Christie, 1994; Lustman, Griffith, et al., 1997; Lustman, Williams, et al., 2007).

Starting with epigenetic effects of early maternal care (Meaney & Szyf, 2005; Strahler, Mueller-Alcazar, & Nater, 2014), there are a variety of ways in which social, psychological, and biological influences may interact in the etiology and course of both depression and diabetes, accelerating the psychological and metabolic abnormalities of each (Golden, Lazo, et al., 2008). As symptoms and complications of diabetes increase, associated psychosocial stress and reduced coping ability may contribute to depression. Additionally, the psychological burdens of diabetes treatments, such as insulin injection or blood glucose self-monitoring, can increase negative emotions and maladaptive behaviors and lead to a loss of interest, low energy, abnormal eating patterns, sleep disturbance, poor treatment compliance, and poor concentration. As diabetes may exacerbate depression, likewise evidence indicates deleterious effects of coexisting depression on clinical status, subsequent complications, mortality, and increased healthcare expenditures (Black, Markides, & Ray, 2003; de Groot, Anderson, et al., 2001; Katon, Rutter, et al., 2005).

What Are We Preventing, Treating, and Managing? Key Definitional and Conceptual Issues

In order to develop comprehensive approaches to the effective prevention and/or management of psychological and physical health, it is necessary to clarify just how the problems and their interrelationships are to be approached. The term

Table 32.3 Manifestation of psychological concerns in common diseases

Linkage 1 – Psychological concerns are risk factors for physical disease
Cancer
• Depression influences immune activation and inflammation, which is associated with increased cancer risk (Currier & Nemeroff, 2014)
• Major depressive disorder is associated with accelerated biological aging, measured by shortened telomere length (Verhoeven, Revesz, et al., 2014)
Cardiovascular disease
• Depression independently elevates risk for various forms of cardiovascular disease (Van der Kooy, van Hout, et al., 2007)
• Major depressive disorder and bipolar disorder are recognized as risk factors for advanced atherosclerosis and early cardiovascular disease in pediatric patients (Goldstein, Carnethon, et al., 2015)
• Women diagnosed with schizophrenia are at a higher risk of acute myocardial infarction (Wu, Chen, et al., 2015)
• Ethnic minorities with severe mental illness are at an elevated risk for cardiovascular disease (Carliner, Collins, et al., 2014)
Chronic Obstructive Pulmonary Disease (Bronchitis, Emphysema)
• Nicotine dependence is a major risk factor for COPD, such that among smokers, the shorter the time to first cigarette after waking, the greater the COPD risk (Guertin, Gu, et al., 2015)
• In Taiwan, COPD is more prevalent in individuals with schizophrenia than the general population (Hsu, Chien, et al., 2013)
Diabetes
• In a meta-analysis of 23 longitudinal studies, depression was highlighted as a major risk factor for incident type 2 diabetes (Rotella & Mannucci, 2013a)
• Individuals reporting high levels of psychological distress were 33% more likely to develop type 2 diabetes than individuals reporting low levels of distress (Mommersteeg, Herr, et al., 2012)
HIV/AIDS
• Among Medicaid beneficiaries, individuals with a substance use disorder were 3.1 times more likely to receive an HIV diagnosis than individuals without a substance use disorder (Prince, Walkup, et al., 2012)
• Among cocaine users, severe psychological distress increases needle sharing behavior, a major risk factor for HIV infection (Lévesque, Bruneau, et al., 2014)
Maternal and child health
• Compared to women without a history of mental illness, mothers with bipolar disorder are more likely to have adverse pregnancy outcomes, specifically, low birth weight, small for gestational age, and preterm birth (Lee & Lin, 2010)
• Children of mothers with comorbid mental disorders are at a higher risk for internalizing disorders (Hser, Lanza, et al., 2015)
Linkage 2 – Psychological concerns complicate physical disease
Cancer
• Depression is related to higher mortality rates among cancer patients (Pinquart & Duberstein, 2010)
• Individuals with mental illness are less likely to undergo routine cancer screenings (Aggarwal, Pandurangi, & Smith, 2013) and more likely to have metastases at diagnosis (Kisely, Crowe, & Lawrence, 2013)
Cardiovascular disease
• Neuroticism is associated with poorer quality of life in patients with chronic heart failure (Samartzis, Dimopoulos, et al., 2014)
• Individuals with coronary heart disease that also have severe anxiety are more likely to experience cardiovascular events than individuals without anxiety symptoms (Martens, de Jonge, et al., 2010; Moser, 2011)
• Among patients with acute coronary syndrome, depression is recognized as a major risk factor for poor medical outcomes (Lichtman, Froelicher, et al., 2014)

(continued)

Table 32.3 (continued)

Chronic Obstructive Pulmonary Disease (Bronchitis, Emphysema)
• Anxiety and depression are known to exacerbate symptoms in COPD (Abrams, Vaughan-Sarrazin, & Vander Weg, 2011; Laurin, Moullec, et al., 2012)
• COPD patients with anxiety tend to have poorer outcomes than those without anxiety; specifically, they have greater difficulty with exercise and report more functional limitations (Eisner, Blanc, et al., 2010)
Diabetes
• Persons with diabetes and severe mental illness are significantly more likely to require re-hospitalization within a month after discharge (Lydia A. Chwastiak, 2014)
• Individuals with substance abuse disorders are less likely to adhere to a type 2 diabetes medication regimen (Kreyenbuhl, Dixon, et al., 2010)
HIV/AIDS
• Depressed individuals with HIV have worse outcomes than nondepressed individuals with HIV, with reduced treatment adherence and quality of life (Nanni, 2015)
• HIV patients with major depressive disorder and psychiatric comorbidity have particular poor outcomes (Gaynes, 2015)
• Depression is thought to increase HIV disease progression to AIDS (Schuster, Bornovalova, & Hunt, 2012)
Maternal and child health
• Mothers who use antidepressants while pregnant are more likely to have preterm births (Einarson, Choi, et al., 2010) and preeclampsia (Palmsten, Setoguchi, et al., 2012)
Linkage 3 – Psychological concerns result from physical disease
Cancer
• Many cancer patients suffer from psychological distress after receiving a diagnosis, and a recent meta-analysis suggests that prevalence rates of clinical depression range from 8 to 24% amongst adult cancer patients (Krebber, Buffart, et al., 2014)
• After receiving a cancer diagnosis, adolescents and young adults are at a significantly elevated risk for suicidal behavior (Lu, Fall, et al., 2013)
Cardiovascular disease
• Myocardial infarctions have been shown to be causal factors of both depression (Meijer, Conradi, et al., 2011) and PTSD (Edmondson & Cohen, 2013; Guler, Schmid, et al., 2009)
Chronic Obstructive Pulmonary Disease (Bronchitis, Emphysema)
• Exacerbations in COPD symptoms lead to a subsequent rise in symptoms of PTSD (Teixeira, Porto, et al., 2015)
• Likewise, patients with COPD have an elevated risk for anxiety (Eisner, Blanc, et al., 2010)
• COPD confers elevated risk of suicide after controlling for psychological status and history. Risk increases with stage of COPD progression (Chung, Han, et al., 2014; Strid, Christiansen, et al., 2014)
Diabetes
• Patients diagnosed with diabetes mellitus are at a significantly elevated risk to develop depressive symptoms (Rotella & Mannucci, 2013b), severe psychological distress (Shin, Chiu, et al., 2013), and anxiety disorders (Smith, Béland, et al., 2013)
• In addition to its relationships with depression and quality of life, diabetes and the burdens and stressors it entails may cause diabetes distress that may also complicate management of the disease (Fisher, Gonzalez, & Polonsky, 2014)
HIV/AIDS
• HIV infection is correlated with a substantially higher risk for major depressive disorder (Bhatia, Hartman, et al., 2011; Ciesla & Roberts, 2001)
• HIV patients may experience emotional distress and suicidal ideation (Kalichman, Heckman, et al., 2000)
Maternal and child health
• Medical difficulties during pregnancy and delivery are associated with a greater risk for maternal postpartum depression (Blom, Jansen, et al., 2010)
• Both infant complications and obstetric emergencies are associated with the development of PTSD symptoms in mothers (Andersen, Melvaer, et al., 2012)

"comorbidity" connotes two well-defined and distinct clinical entities, occurring simultaneously and each tending to occur more frequently in the presence of the other. Viewing comorbid conditions as distinct entities, however, may not capture important relationships and interactions between them. Here we review conceptual approaches to relationships between or among co-occurring conditions, again taking diabetes and depression as a model.

A Dimensional Versus Categorical View of Each of Diabetes and Depression Both depression and diabetes are commonly defined categorically with specific criteria used to classify individuals as having either depression or diabetes. Within each of depression and diabetes, subcategories are increasingly refined based on emerging insights from genomics and phenotyping. These confirm the heterogeneity of the broader categories.

An alternative to categorical definition of depression has been a dimensional characterization of mood or dysphoria, often using standardized instruments such as the popular Beck Depression Inventory which was originally developed and validated as a measure of depressed mood, not of categorical depression (Beck, Ward, et al., 1961; Roy, Lloyd, et al., 2011). As an example of the dimensional perspective in diabetes, the success of preventing incident diabetes in high-risk subjects has led to the identification of a dimension of dysglycemia including varying degrees of insulin resistance and deficiency that underlie manifest abnormalities in glucose metabolism. Supporting the dimensional perspective, "graded relationships" between depression and both myocardial infarction and all-cause mortality suggest that depression "is best viewed as a continuous variable that represents a chronic psychological characteristic rather than a discrete and episodic psychiatric condition" (Barefoot & Schroll, 1996).

With each of depression and diabetes, categorical definitions may be superimposed on the dimensional by defining the diagnostic category according to a convention of some criterion score as in common definitions of hypertension.

Single Problem Versus Group of Problems In addition to the difference between viewing problems as distinct categories and viewing them as dimensions, diabetes and depression may each be categorized as part of a broader class of problems, cardiometabolic abnormalities for diabetes and negative emotions for depression. For example, studies of depression in various groups, such as patients with cancer (Brown & Kroenke, 2009) or asthma (Lavoie, Bacon, et al., 2006), indicate high co-occurrence of depression, anxiety, and other varieties of psychological distress (Hjerl, Andersen, et al., 2002). Similarly, studies in cardiovascular risk indicate the utility of grouping together a set of negative emotions that includes depression, anxiety, hostility, and stress (Williams, Barefoot, & Schneiderman, 2003) for understanding their complex interactions in pathways related to cardiovascular pathogenesis (Brummett, Boyle, et al., 2010). Recent work in diabetes, too, indicates that diabetes distress may be more closely related to metabolic control than measures of depressed mood alone (Fisher, Mullan, et al., 2010). Parallel to the overlap among measures of psychological disorder and distress, hyperlipidemia, central adiposity, and hypertension often co-occur with "prediabetes" or diabetes, leading some to refer to the group as comprising a "metabolic syndrome" (Eckel, Grundy, & Zimmet, 2005).

Whether depression and diabetes are best viewed as distinct or as members of broader categories is controversial. For example, some argue that, however much they may co-occur, one needs to treat the individual cardiovascular and metabolic problems encompassed by the term "metabolic syndrome" with appropriate medications for each of diabetes, hypertension, and hyperlipidemia (Kahn, 2008). Similarly, one may argue that beyond the co-occurrence with anxiety, hostility, and stress, depressed mood alone has a specific and distinctive role with each of diabetes and cardiovascular disease requiring specific treatment rather than a more generalized approach.

Viewing diabetes or depression as distinct entities or as parts of broader syndromes may depend on the lens through which the problems are viewed. For example, Valderas and colleagues (Valderas, Starfield, et al., 2009) noted that the value of different models of comorbidity would vary according to the perspective taken by specialist, primary care, public health, or health services. From the perspective of clinical care of individuals, differentiating among specific problems, depression, anxiety, and hostility on the one hand and diabetes, hypertension, and hyperlipidemia on the other may make great sense. Whether with psychotherapy or psychopharmacology, management of depressed mood generally differs from treatment of hostility or anxiety, just as medication for diabetes differs from that for hypertension or hypercholesterolemia. At the population level, however, co-prevalent problems may share common treatment and prevention targets, such as healthy diet, physical activity, and weight management for diabetes and cardiovascular disease, or, for negative emotions, socioeconomic well-being and communities and families that encourage cooperation and satisfying relationships among neighbors. Thus the broader categories of cardiometabolic abnormalities and negative emotions may help guide population-wide prevention and treatment campaigns. At the same time, the individual components of these broad categories are duly the focus of clinical intervention.

Heterogeneity of Depression and Distress Depression is often discussed as a unitary "thing," when in fact it is quite heterogeneous. A study among Dutch adults examined differences in severity and symptom patterns to identify three subtypes of depression: (1) moderately severe, (2) severe melancholic, and (3) atypical that is "characterized by increased appetite, weight gain, leaden paralysis (e.g., leaden, heavy arms and legs), and to a lesser extent hypersomnia and is associated with female sex, being overweight, and the metabolic syndrome" (Snoek, Bremmer, & Hermanns, 2015). This latter, atypical type may be especially related to diabetes.

In addition to heterogeneity among types of depression, Snoek and his colleagues (Snoek, Bremmer, & Hermanns, 2015) point out varied connections between depression and diabetes distress. Separate from generally depressed mood, diabetes distress is focused on the stressors and demands of diabetes and its management and emotional responses to these. Items from a popular measure of diabetes distress include, e.g., "Feeling overwhelmed with the demands of living with diabetes," "Feeling that I am often failing with my diabetes routine," "Not feeling motivated to keep up my diabetes self-management, " and "Feeling angry, scared, and/or depressed when I think about living with diabetes" (Fisher, Glasgow, et al., 2008). Depression and diabetes distress are related, but not as closely as one might think. L. Fisher and colleagues, for example, have argued that, because it is more closely related to diabetes management and problems with it, distress is more predictive of glycemic control than depression (Fisher, Mullan, et al., 2010).

Snoek and colleagues outline a model of the four combinations of the presence/absence of each of distress and depression and possible treatment strategies for each. Those who are distressed by their diabetes but not depressed, for example, might benefit from "psychoeducation or supportive counseling to help improve their problem solving skills and coping with the daily demands of diabetes self-care" (Snoek, Bremmer, & Hermanns, 2015). This might best be delivered in close coordination or as part of their diabetes care. On the other hand, those who are both depressed and distressed are perhaps "most psychologically vulnerable … [among whom] the interaction between mood and diabetes-related issues deserves special attention … [so that patients] are likely to benefit most from diabetes-specific depression treatment" (Snoek, Bremmer, & Hermanns, 2015).

Separate "Comorbidities" or Depression and Distress as Part of Normal Clinical Picture of Diabetes Snoek and his colleagues conclude their review of depression and distress by arguing for the inclusion of both within our broader understanding of diabetes; "both … deserve to be assessed routinely" among both adults and children with diabetes (Snoek, Bremmer, & Hermanns, 2015). Consider foot ulcers, routinely viewed as an important part of diabetes deserving special attention because of their importance in the development of lower extremity complications and potential for amputations. A 2008 study among older adults with diabetes found an 8% yearly prevalence of foot ulcers (Margolis, Malay, et al., 2011). In contrast, depression affects 10–20% of those with diabetes (Roy & Lloyd, 2012).

Viewing diabetes and depression as part of broader groupings or syndromes may also make sense *across* the categories of mental health and medical illness. Research such as from the Diabetes Prevention Program (Rubin, Knowler, et al., 2005; Rubin, Ma, et al., 2008) raises the possibility that depression is an early sign or precursor of diabetes. Thus, as we think of the comorbidity of diabetes and depression, we might consider whether they are best viewed as distinct clinical entities that occasionally exist together or as components of a broader syndrome encompassing both psychological and physical problems. More generally, the term, "depression" needs to be understood as referring to mood changes that may be combined with a large – probably larger than currently recognized – number of problems and syndromes, rather than as a single entity.

In an integrated approach, the treatment of depression becomes a routine part of diabetes care, just as foot care and yearly retinal checks. So, too, the psychological or medical treatment of depression may be expanded to address its routine metabolic and cardiovascular dimensions. Consider physical activity, often included in diabetes self-management and increasingly recognized as helpful in reducing depression (Penedo & Dahn, 2005; Teychenne, Ball, & Salmon, 2008). When promoting physical activity in diabetes self-management, one should routinely consider reticence to engage in exercise as potentially linked to mood problems. Additionally, one should structure goal setting and monitoring to maximize the possible benefits not only of physical activity itself but also of the mood-elevating effects of achieving a personal goal (Piette, Richardson, et al., 2011). At the same time, promoting physical activity as part of depression treatment may draw added emphasis from the recognition of its value not only in increasing mood but also in reducing cardiovascular risks to which those with depression are prone.

Biosocial Propensity to Chronic Disease and Psychological Distress Bringing together a number of the points developed in this volume, Fig. 32.1 outlines a biosocial complex of determinants of disease, ranging from genetic and epigenetic effects including those of maternal

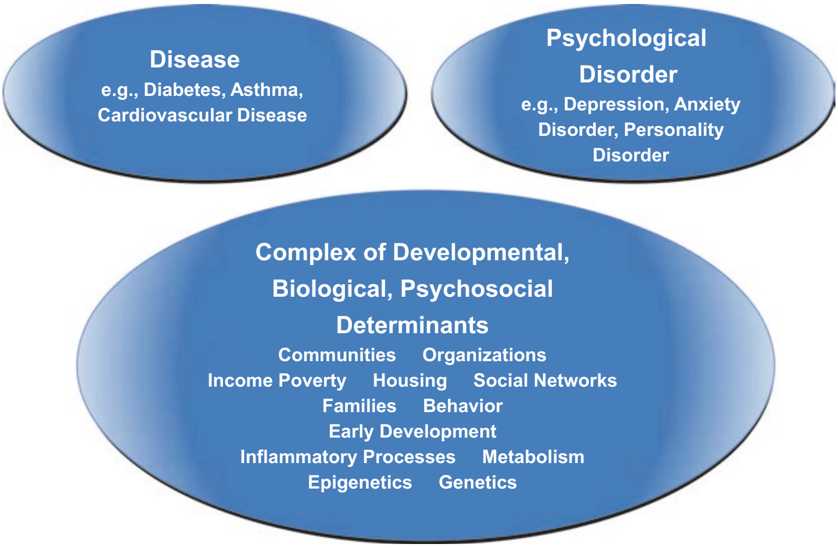

Fig. 32.1 Biosocial complex of determinants of disease and psychological disorder

nurturance during early childhood, to community design. Given sufficient deficiencies in this complex, some kind of disease, whether diabetes, asthma, or others, is very likely as is some variety of appreciable psychological distress or psychopathology. The particular expression of this biosocial complex in one or another disease and one or another type of psychological problem may be hard to predict, but the likelihood of at least one of each – disease and psychological distress – is great. In casual survey of practicing primary care clinicians, the common response is "That's half of my waiting room."

Figure 32.1 raises an important point, "What is fundamental that requires attention?" The fundamental appears to be the biosocial complex of events that makes expression in diabetes and depression or some other varieties of medical and psychological morbidity highly likely. The particular choice of expressions may be almost accidental or perhaps guided by some specific factors such as a particular genotype or type of aggravating experience such as in exposure to trauma and PTSD, but the likelihood of such expressions is almost assured.

Interventions

Peer Support

Among strategies for integrating clinical and preventive, individual and population approaches to treatment of psychological disorders and chronic diseases, peer support (e.g., "community health workers," "lay health advisors," "*Promotores*") may deserve special attention. Peer supporters can assist individuals in adopting and provide encouragement to help sustain the behaviors that comprise psychological and chronic disease management (Fisher, Boothroyd, et al., 2012). They may also provide emotional support and encourage problem-solving to address depression and other emotional distress (Rahman, Malik, et al., 2008). From the perspective of reaching populations, peer supporters can also engage and benefit those who otherwise fail to receive appropriate care (Fisher, Ballesteros, et al., 2015; Fisher, Strunk, et al., 2009; Sokol & Fisher, 2016). All of these can assist in identifying and recruiting into treatment those with psychological disorders and chronic diseases and in helping them take full advantage of resources available.

Both the social isolation or lack of a confidant that often accompany psychopathology and distress (Fisher, Chan, et al., 2012; Lowenthal & Haven, 1968) and the importance of simple social contact and emotional support (Harlow, 1958) suggest that simple, frequent, affirming, and pleasant contact from a supporter may be especially helpful to those with emotional distress.

"Lady Health Workers" and Peer Support in Maternal and Child Health In a striking cluster randomized evaluation in Pakistan, "Lady Health Workers" implemented a cognitive-behavioral, problem-solving intervention (Rahman, 2007) for women who met criteria for major depression during the third trimester of their pregnancies. Relative to controls, the intervention substantially reduced depression 12 months postpartum (OR = 0.23, $p < 0.0001$) (Rahman, Malik, et al., 2008). In India, peer support for depression, anxiety, and other mental health problems included education about psychological problems and ways of coping with them (e.g., deep breathing for anxiety symptoms) as well as interpersonal therapy (de Mello, de Jesus Mari, et al., 2005), all delivered by lay health counselors with backup by primary care and monthly consultations from psychiatrists. Results included a 30% decrease in prevalence of depression and other common mental disorders among those meeting criteria at baseline, 36% reduction in suicide attempts or plans, as well as reductions in days out of work (Patel, Weiss, et al., 2011).

Research with the Lady Health Workers has also considered the roles of socioeconomic determinants in the development of chronic diseases and psychological disorders. If a program reduces the effect of low-income status on some important outcome, for example, then it would be reducing disparity related to low income. In Pakistan, the Lady Health Workers intervention for postpartum depression eliminated the impact of factors such as lack of financial empowerment which, in the absence of intervention, sharply differentiated those becoming depressed (Rahman, Sikander, et al., 2012).

An important consideration among concerns for more effective and affordable care is the relationship between psychological disorders and frequency of hospitalizations among those with chronic diseases. Evidence indicates peer support may have a useful role in this regard. In a randomized study among adults with diabetes in Hong Kong, all received JADE (Chan, So, et al., 2009), a standardized, systematic model of care incorporating quarterly reports to patients providing appraisal of clinical status and self-management recommendations. In addition to JADE, half of the participants were randomized to receive PEARL, telephone-based peer support provided by trained peer supporters. Reflecting patterns familiar to those working in health policy and services, the 20% of patients with elevated levels of depression, anxiety, and/or stress were more likely to be hospitalized (34%) than those without distress (20%). Among this group with heightened distress, the PEARL peer support intervention improved distress scores relative to JADE alone ($p = 0.03$) and reduced overall hospitalizations (relative risk = 0.15, $p < 0.001$), a reduction to the "normal" level of those low on distress measures (Chan, Sui, et al., 2014). That is, among the fifth of patients with the highest scores on distress and who account for greatly disproportionate hospital care, the addition of peer support to standardized, high-quality clinical care substantially reduced distress and lowered associated hospitalization rates to normal levels.

An important impact of psychological distress in chronic disease is its role in complicating efforts to reach and engage patients in recommended care. Peer support may be an especially effective strategy for reaching those who are too often "hardly reached" (Sokol & Fisher, 2016). Asthma coaches pursuing a nondirective, flexible, stage-based approach were able to engage 89.7% of mothers of Medicaid-covered children hospitalized for asthma. The coaches sustained that engagement, averaging 21.1 contacts per parent over a 2-year intervention. Of those randomized to the asthma coach, 36.5% were rehospitalized over the 2 years, relative to 59.1% randomized to usual care ($p < 0.01$) (Fisher, Strunk, et al., 2009).

Other examples illustrate the ability of peer support to reach those too often hardly reached. In a successful peer support intervention for diabetes management among patients of safety net clinics in San Francisco (Thom, Ghorob, et al., 2013), participants were categorized as low, medium, or high medication adherence at baseline. The peer support led to greater reductions in HbA1c than in controls across all groups, but the differential impact of peer support was greatest among those initially in the low adherence group (Moskowitz, Thom, et al., 2013). In a peer support intervention among veterans with diabetes (Heisler, Vijan, et al., 2010), improvements in blood glucose measures were substantially more pronounced among those with low initial levels of diabetes support (p for interaction <0.001) and those with low health literacy (p for interaction <0.05) (Piette, Resnicow, et al., 2013). A systematic review of peer support interventions for hardly reached groups found that 94% reported significant benefits favoring peer support relative to control conditions (Sokol & Fisher, 2016).

Stress Management, Cancer, and HIV

Chronically ill individuals, particularly those with diseases perceived as potentially life-threatening and stigmatizing, such as HIV and cancer, face substantial stressors. These stressors occur as part of people's experiences adjusting to a diagnosis as well as living with and managing a serious, chronic disease. Disease management stressors commonly include undergoing treatments and experiencing side effects, facing one's mortality, feeling stigmatized or isolated from others, and experiencing illness episodes, pain, disability, and strained relationships (Antoni, Lutgendorf, et al., 2006; Brown & Vanable, 2008; Grassi, Caruso, & Costantini, 2015; Scott-Sheldon, Kalichman, et al., 2008). Often individuals with chronic diseases are also exposed to serious life stressors due to psychosocial factors, such as poverty, substance abuse, psychological distress, and childhood trauma (Brown & Vanable, 2008; Scott-Sheldon, Kalichman, et al., 2008).

For diseases like HIV and cancer that are immune mediated, not only is stress more prevalent, but researchers have also found that greater stress, anxiety, and depression, as well as limited skills for coping with these, prospectively worsen disease progression (Antoni, Lutgendorf, et al., 2006; Artherholt & Fann, 2012; Atkinson, Schönnesson, et al., 2008; Balbin, Ironson, & Solomon, 1999; Kalichman, Heckman, et al., 2000; Leserman, 2008). These findings are due, at least partly, to mediating psychoneuroimmunologic effects of stress on disease, through stimulation of the autonomic sympathetic nervous system and the hypothalamic-pituitary-adrenocortical axis, which in turn interact with the immune system (Antoni, 2003; Antoni, Lutgendorf, et al., 2006; Artherholt & Fann, 2012; Balbin, Ironson, & Solomon, 1999; Leserman, 2003, 2008; McGregor, Antoni, et al., 2004; Segerstrom & Miller, 2004). With HIV, for example, psychological distress has been associated with increases in disease progression, including lower CD4 immune cell counts, fewer natural killer cells, and elevated levels of virus in patients' blood (Ironson, Balbin, et al., 2005; Leserman, 2008). Similarly, growing evidence demonstrates that stress and stress-related behavioral factors may contribute to cancer growth and metastasis through their effect on both the hypothalamic-pituitary-adrenocortical axis and the sympathetic nervous system, resulting in the release of glucocorticoids, catecholamines, and other factors that directly or indirectly influence malignancy (Artherholt & Fann, 2012). Affected pathways include the cellular immune response, inflammation, tumor angiogenesis, and tumor cell signaling pathways. Stress is also believed to influence physiological health because it can interfere with individuals' abilities to adhere to medical recommendations (Brown & Vanable, 2008).

In response to evidence that stress is both elevated and worsens the health of HIV and cancer patients, researchers over the last two decades have focused on designing and testing interventions to help patients enhance their capacity to cope with and reduce stressful experiences. These interventions aim to improve both psychological and physiological health outcomes.

The theoretical conceptualization of stress and its effects on clinical outcomes in the setting of chronic illness is based primarily on Lazarus and Folkman's Transactional Model of Stress and Coping (Lazarus & Folkman, 1984, 1987), which builds from Lazarus' book *Psychological Stress and the Coping Process* (Lazarus, 1966). The Transactional Model of Stress and Coping emphasizes the role of cognitive appraisal and the processes ordinary people use to deal with everyday distress. It also emphasizes the relationship between the nature of the stressor and the capacities and skills of the individual. As Lazarus and Folkman defined it in their classic work, *Stress, Appraisal and Coping,* "Psychological stress is a particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being" (Lazarus & Folkman, 1984, p. 19). Simply put, stress occurs as a result of the imbalance between demands and resources. *Coping,* then, is composed of the behaviors and thoughts individuals use to manage the internal and external demands of stressful circumstances. In an effort to capture the complex multidimensional processes humans use to address threats, coping styles are typically categorized as "problem focused" (directly addressing the stressor), "emotion focused" (deregulating negative and enhancing positive emotions), or "appraisal focused" (changing the way one thinks about the stressor) (Folkman & Moskowitz, 2004). Stress management interventions have used this framework to reduce the stress of individuals facing chronic illness by enhancing their coping resources. Researchers at the University of Miami were among the first to design manualized, multi-session, cognitive-behavioral group programs, known as cognitive behavioral stress management (CBSM), to help HIV-infected and cancer patients manage stress (Antoni, 2003; Antoni, Lehman, et al., 2001).

Specifically for patients with HIV, there is now a substantial body of evidence that CBSM and similar approaches offer a promising adjunct to HIV management. For example, two systematic reviews (Brown & Vanable, 2008; Harding, Liu, et al., 2011) and a meta-analysis (Scott-Sheldon, Kalichman, et al., 2008) found generally positive effects of stress-management or coping interventions on physical and psychological health outcomes among people living with HIV. Two additional reviews examined studies of cognitive behavioral interventions to reduce anxiety in people with HIV (Clucas, Sibley, et al., 2011) and comparing the effect of CBSM on outcomes of HIV-infected patients with a history of trauma or post-traumatic stress disorder (PTSD) (Seedat, 2012), respectively.

In Brown and Vanable's (2008) review of 21 randomized, controlled trials of CBSM interventions, all of the interventions utilized cognitive and behavioral stress management strategies designed to facilitate adaptive coping and to decrease the negative impact of stress. Moreover, these interventions highlighted the value of active, problem-focused coping strategies as well as cognitive restructuring, or modifying one's stress appraisal process to match a new coping ability. Emotional regulation strategies and decreasing psychological distress were also often identified as objectives. Three quarters of the interventions included relaxation training and most encouraged strategies to enhance the use of social support networks. Interventions varied in number, length, and timing. All but one of the interventions used a group-based intervention approach. Most used multiple sessions (range 6–20; mode = 10) with a duration of 1–2.5 h (mode = 2). Overall, most studies that assessed the outcome found many improvements in perceived stress, depression, anxiety, global psychological functioning, social support, and quality of life. Effects on the coping and immune function markers, however, were mixed. One study that looked at stress hormone levels found stress effects on norepinephrine and testosterone but not on epinephrine or cortisol levels (Antoni, Cruess, et al., 2000; Cruess, Antoni, et al., 2000). Other assessments found greater naive T cells (Antoni, Cruess, et al., 2002) and higher cytotoxic T cells (Antoni, Cruess, et al., 2000), both cells that facilitate the function of the immune system, respectively, in the intervention groups at follow-up. No studies, however, found any effect on CD4 cell count, which would indicate improved health. Furthermore, most studies did not control for other important factors and most had only brief follow-up periods. Scott-Sheldon et al.'s (2008) meta-analysis of 46 stress management interventions in 35 randomized controlled trials drew similar conclusions (Scott-Sheldon, Kalichman, et al., 2008).

In Harding et al.'s (2011) systematic review of 28 interventions aimed at improving HIV coping strategies, 21 involved psychological interventions (as opposed to others that used medications, diet and exercise, and informational or spiritual approaches), most of which were CBSM (Harding, Liu, et al., 2011). Harding specifically evaluated intervention effects on coping skills. Of all 28 studies, 17 (60%) had a positive effect on coping skills; those that used CBSM, however, were noted to be most promising although comparison across studies was limited by heterogeneity in the measures of coping. Similarly, the reviews of studies specific to HIV-infected patients with anxiety and trauma/PTSD concluded that CBSM was generally most effective at improving psychological distress (Clucas, Sibley, et al., 2011; Seedat, 2012).

All five of the reviews cited above noted the promising nature of CBSM for improving health outcomes in HIV; yet they pointed out the need for further understanding of the mechanism by which the interventions acted and that most studies they had reviewed had been conducted in gay and bisexual white men and called for more targeted interventions of diverse populations. Yet one study, the Stress Management and Relaxation Training/Expressive Supportive Therapy (SMART/EST) Women's Project, was designed specifically to address the unique experiences of minority women living with HIV (Jones, Owens, et al., 2010). While the intervention was generally ineffective, those in the intervention group who increased their self-efficacy also had reduced depression and anxiety. These findings suggest that additional adaptation of CBSM interventions may be required to more fully enhance the cognitive behavioral self-efficacy of women to better address their psychological distress.

More recently, investigators at the University of Miami, as well as others, have sought to adapt and test their 10-week CBSM group intervention for cancer patients, particularly those with prostate cancer (Parker, Pettaway, et al., 2009; Penedo, Dahn, et al., 2004; Penedo, Molton, et al., 2006; Penedo, Traeger, et al., 2007; Traeger, Penedo, et al., 2013) and early stage breast cancer (Carpenter, Stoner, et al., 2014; Groarke, Curtis, & Kerin, 2013; Lechner, Whitehead, et al., 2014; McGregor, Antoni, et al., 2004; Nápoles, Ortíz, et al., 2015; Stagl, Antoni, et al., 2015). Although, to date, no systematic reviews of these trials have been conducted, review of the studies indicate more diverse study sample than those seen in many of the HIV trials.

Among an ethnically diverse group of men who had undergone treatment for localized prostate cancer, CBSM increased men's finding benefits of their cancer experience (Penedo, Molton, et al., 2006), emotional well-being (Traeger, Penedo, et al., 2013), and overall quality of life (which was mediated by stress management skills) (Penedo, Dahn, et al., 2004; Penedo, Molton, et al., 2006), but not in their illness perceptions (Traeger, Penedo, et al., 2013). Women with early stage breast cancer undergoing an adaptation of the same 10-session group CBSM not only increased their "benefit finding," but this increase also mediated their improved immune function 3 months later (McGregor, Antoni, et al., 2004). The intervention also improved sleep quality and reduced fatigue (Vargas, Antoni, et al., 2014) and impressively led to fewer depressive symptoms 5 years after the intervention (Stagl, Antoni, et al., 2015) and better all-cause mortality at 11 years follow-up (Stagl, Antoni, et al., 2015). In another study of the same intervention among underserved African American breast cancer survivors, however, both arms showed significant improvements in mood and perceived stress with no differences between groups (Lechner, Whitehead, et al., 2014). Among monolingual Hispanic men, in addition to overall well-being, physical, emotional, and sexual well-being (often affected by the impact of prostate cancer treatment on urinary and sexual function) were all shown to improve significantly more in the CBSM group (Penedo, Traeger, et al., 2007).

Some studies have assessed whether less intensive CBSM interventions could be effective. One study assessing an individually and presurgically delivered and shorter (two sessions plus two booster sessions) cognitive behavioral stress management program for prostate cancer patients showed immediate benefit on mood and improved physical (but not mental health) quality of life 1 year after surgery (Parker, Pettaway, et al., 2009) suggesting the shorter approach may be a useful adjunct to standard care when longer group sessions are not feasible. Similarly, Groarke et al. (2013) found that a five-session CBSM with breast cancer patients reduced global stress and anxiety while improving benefit-finding, but the effects were also not sustained after a year. Of note, women with greater global stress at baseline responded more to the intervention. More recently, researchers have begun to assess the effectiveness of an online CBSM for breast cancer as an alternative means to facilitate dissemination (Carpenter, Stoner, et al., 2014).

Mindfulness-Based Therapy

Mindfulness meditation has gained popularity as a stress-reduction technique that appears to support general health and well-being (Goyal, Singh, et al., 2014). Mindfulness-based programs are now offered all over the world, in hospitals, schools, workplaces, prisons, and health centers (Kabat-Zinn, 2003). Mindfulness has also been incorporated into a variety of health interventions (Mars & Abbey, 2010). Jon Kabat-Zinn, a leader in introducing mindfulness to Western psychology (Baer, 2003), describes the practice as "the awareness that emerges through paying attention on purpose, in the present moment, and nonjudgmentally to the unfolding of experience moment by moment" (Kabat-Zinn, 2003), p. 145). Mindfulness can be developed through meditation, specifically through the practice of focusing one's attention on thoughts, bodily sensations, and external stimuli, without evaluation or judgment (Baer, 2003).

Mindfulness-based therapy includes several therapeutic approaches that incorporate mindfulness practice (Piet, Wurtzen, & Zachariae, 2012), most notably mindfulness-based stress reduction (MBSR; Kabat-Zinn, 1990). MBSR is an 8-week, group-based program that incorporates formal in-person mindfulness meditation practice with homework assignments for individuals to practice mindfulness throughout the week (Vøllestad, Nielsen, & Nielsen, 2012). MBSR has been shown to be effective in reducing stress and psychological symptoms, improving coping strategies, and enhancing quality of life in both clinical and nonclinical populations (Grossman, Niemann, et al., 2004; Vøllestad, Nielsen, & Nielsen, 2012). A meta-analysis of eight randomized controlled studies highlighted the positive impact of MBSR on the mental health of individuals suffering from chronic diseases, with effect sizes of 0.26, 0.24, and 0.32 on depression, anxiety, and psychological distress, respectively (Bohlmeijer, Prenger, et al., 2010.

Among its positive psychological impacts, mindfulness increases self-efficacy and emotional processing (Grossman, Niemann, et al., 2004) and decreases symptoms of anxiety and depression (Goyal, Singh, et al., 2014; Khoury, Lecomte, et al., 2013; Vøllestad, Nielsen, & Nielsen, 2012). In one randomized controlled trial, individuals in a mindfulness meditation group had greater activation of the left-anterior hemisphere of the brain, which is associated with positive emotions, than a wait-list control group when brain electrical activity was measured (Davidson, Kabat-Zinn, et al., 2003). Carmody and Baer (2008) found that greater time spent practicing mindfulness meditation is associated with increases in various aspects of trait mindfulness, which mediates the relationship between mindfulness meditation practice and psychological well-being (Carmody & Baer, 2008). In another randomized controlled trial of undergraduates ($N = 82$), a mindfulness meditation intervention decreased negative mood, depressive symptoms, fatigue, confusion, and heart rate in comparison to control groups (Zeidan, Johnson, et al., 2010).

Mindfulness has been shown to support general health and well-being in a variety of health interventions (Mars & Abbey, 2010). Recent work indicates that mindfulness can promote healthy eating habits and decrease psychological distress in individuals with binge eating disorder (Dalen, Smith, et al., 2010; Katterman, Kleinman, et al., 2014), improve quality of life in multiple sclerosis patients (Schirda, Nicholas, & Prakash, 2015), and enhance social skills in autistic adolescents (de Bruin, Blom, et al., 2015). Davidson, Kabat-Zinn, et al. (2003) showed that mindfulness improved immune function. In their randomized controlled trial, subjects in both mindfulness meditation and control groups were given a flu shot immediately after the intervention ended. The mindfulness group had significantly greater increases in antibody titers in response to the flu vaccine than the control group ($t = 2.05$, $p < 0.05$).

Mindfulness also appears to help individuals with diabetes. In one randomized controlled trial, participants either participated in a diabetes education program that involved a version of mindfulness training called "Acceptance and Commitment Therapy" (Hayes, Strosahl, & Wilson, 2012) or an education-only program (Gregg, Callaghan, et al., 2007). After 3 months, patients in the Acceptance and Commitment Therapy group had enhanced coping strategies, better diabetes self-management, and were more likely to have glycated hemoglobin (HbA1C) in their target range. Other works support these findings and suggest that increased mindfulness can result in better glycemic control, reduced mean arterial pressure, and fewer depressive symptoms among those with diabetes (Hartmann, Kopf, et al., 2012; Rosenzweig, Reibel, et al., 2007; Tovote, Fleer, et al., 2014).

Cardiovascular health may also be improved by mindfulness. Loucks, Schuman-Olivier, et al. (2015) review the positive effects of mindfulness on known cardiovascular protective factors, such as physical activity, diet, and smoking cessation. They suggest a number of psychological pathways through which mindfulness may act on these factors, including enhanced attentional control, improved emotion regulation, and greater self-awareness. Tacón, McComb, et al. (2003) found that mindfulness practice reduced anxiety and reactive coping styles in women with cardiac diagnoses. In a randomized controlled trial of community-dwelling adults reporting high levels of stress ($N = 88$), individuals who had been assigned to an MBSR condition had greater decreases in both systolic and diastolic blood pressure after being exposed to a stressful task than individuals in the wait list control group (Nyklíček, Mommersteeg, et al., 2013). The MBSR group also had a significantly smaller increase in blood pressure during the task. Similarly, Ditto, Eclache, and Goldman (2006) found that participants in a meditation group had significant increases in respiratory sinus arrhythmia, which measures parasympathetic activity, compared to both control and progressive muscle relaxation groups. They suggest that meditation may be particularly valuable for individuals with hypertension or other cardiac issues. Additionally, results of a meta-analysis of four studies completed by Lawrence and colleagues demonstrated that MBSR was effective at reducing blood pressure and stress levels in patients at high risk for ischemic stroke (Lawrence, Booth, et al., 2013).

Finally, recent work has elucidated the ways in which mindfulness is beneficial for cancer patients. Campbell, Labelle, et al. (2012) found that an MBSR program effectively increased mindful attention and decreased ruminative cognitive patterns in women with cancer. In another study, MBSR significantly improved mood, breast- and endocrine-related quality of life, and well-being in women with breast cancer compared to standard care (Hoffman, Ersser, et al., 2012). In a meta-analysis of 22 studies, mindfulness significantly reduced symptoms of depression and anxiety in cancer patients and survivors (Piet, Wurtzen, & Zachariae, 2012).

Reflecting the broad evidence for mindfulness-based interventions, Merkes (2010) suggested that by incorporating mindfulness practice into primary care, providers may not only improve the health and well-being of their patients but also contain healthcare costs, as mindfulness is a relatively inexpensive therapy to offer.

Assertive Community Treatment (ACT)

ACT is an evidence-based practice for persons with serious mental illnesses (Dixon, 2000; Stein & Test, 1980). ACT is best viewed as a platform for delivering services such as medication management, vocational and housing services, and psychosocial interventions (Stein & Santos, 1998) and is a multidisciplinary, team-based approach with a small (1:10) staff-to-consumer ratio, 24-hour staff availability, and aggressive outreach (Bond, Drake, et al., 2001; Dixon, 2000; Phillips, Burns, et al., 2001; Stein & Test, 1980). ACT team members typically draw from a range of disciplines and are likely to include a psychiatrist, nurse, social worker, psychologist, substance abuse specialist, housing specialist, and vocational rehabilitation specialist. They deliver or arrange comprehensive services including medication management and psychosocial supports in the community. Members of the team might visit the patient in the community at least once or several times a week and might also work with the patient's family or others important in the patient's life. Importantly, these meetings address how the patient can manage difficulties they have and live well in their family or community surroundings, following a model more of chronic disease management than cure.

ACT is one of the most widely studied interventions for persons with mental illness with clear evidence that ACT reduces hospital admissions and days, keeps individuals engaged in services, and increases housing stability compared to standard case management practices (Bond, Drake, et al., 2001; Burns & Santos, 1995; Dixon, 2000; Marshall & Lockwood, 2000). The large literature on ACT also includes a number of qualitative studies that have examined consumers' perceptions of what they like least about ACT (McGrew, Wilson, & Bond, 2002), what is helpful about ACT (McGrew, Wilson, & Bond, 1996), and general experiences with the model (Watts & Priebe, 2002).

ACT adheres to strict criteria with respect to its staffing, organizational structure, and delivery of its services. Until recently, the Dartmouth

Assertive Community Treatment Scale (DACTS) (Teague, Bond, & Drake, 1998) was the standard for assessing the fidelity of ACT teams to its original clinical model, and the DACTS was used to develop evidence in a number of randomized trials that demonstrated that high fidelity is associated with reduced psychiatric hospitalizations (Dieterich, Irving, et al., 2010; McHugo, Drake, et al., 1999). The DACTS was recently replaced by the Tool for Measurement of Assertive Community Treatment, or TMACT, which was developed as a recovery-informed update of the DACTS (Monroe-DeVita, Teague, & Moser, 2011). Similar to the DACTS, there is evidence that TMACT scores are associated with lower psychiatric hospital use (Cuddeback, Morrissey, et al., 2013).

ACT has realized a variety of adaptations and applications over the last 30 years, including urban and rural adaptations (Becker, Meisler, et al., 1999; Calsyn, Morse, et al., 1998; Dixon, Friedman, & Lehman, 1993; Lehman, Dixon, et al., 1997) and adaptations for persons with mental illness and co-occurring substance use disorders (Ackerson, 1995; Drake, McHugo, et al., 1998). Evidence-based practices such as integrated dual-disorder treatment (Ackerson, 1995; Drake, McHugo, et al., 1998), illness self-management (Mueser, Clark, et al., 2004), and supported employment (Gold, Meisler, et al., 2006) have successfully been added to the ACT model and ACT can be adapted to align with contemporary recovery practices (Kidd, George, et al., 2011; Kidd, George, et al., 2010; Salyers & Tsemberis, 2007).

ACT is an ideal setting in which to integrate mental health and physical healthcare. This is especially important given the high rates of chronic physical health issues experienced by persons with serious mental illness (Colton & Manderscheid, 2006). Indeed, integration of services, in general, is recognized as a key attribute of the ACT model (Bond, Drake, et al., 2001), which is promising in light of evidence that integrating primary and behavioral healthcare increases access to preventive health services and cardiovascular healthcare, improves engagement with primary care providers, and improves quality of life for adults with mental illness (Gilbody, Bower, et al., 2006; Katon, Lin, et al., 2010; Rosenthal, 2008; Sheridan, Draeger, et al., 2011). Due to its aggressive, community-based outreach, integrated primary care ACT has the potential to be highly effective at engaging patients and keeping them connected to much-needed primary care services.

Integrative Role of Self-Management and Problem-Solving

Self-management programs in chronic disease may provide important models for approaches to psychopathology and distress in general as well as in the context of physical diseases. Surely the elements of self-management – healthy diet, physical activity, adherence to medication regimens, stress management, problem-solving, and cultivating family and friend support – would all seem equally pertinent to management of mental as well as physical health. Along these lines, a meta-analysis of interventions for depression and diabetes identified diabetes self-management education as contributing to the metabolic benefits associated with cognitive behavioral interventions (van der Feltz-Cornelis, Nuyen, et al., 2010). The "collaborative care" model of Katon and his colleagues (Katon, Von Korff, et al., 2004) stands as an important model of the integration of multiple behavioral objectives in self-management as well as the integration of self-management with clinical care in treating depression and other mental illnesses.

Within self-management, problem-solving may have a special role in integration of care for emotional distress and physical disease. Problem-solving is central to almost all models of self-management in chronic disease (Bodenheimer, Lorig, et al., 2002; Fisher, Brownson, et al., 2005; Funnell, Brown, et al., 2011; Hill-Briggs & Gemmell, 2007; Lorig & Holman, 2003). At the same time, problem solving has emerged as a prominent approach to psychotherapy for depression and other problems (D'Zurilla & Nezu, 1999). Indeed, research indicates that the benefits of cognitive behavior therapy for depression rest largely on the more behavioral, skill-oriented components of problem-solving and "behavioral activation" (Cuijpers, van Straten, & Warmerdam, 2007; Dimidjian, Hollon, et al., 2006; Dobson, Hollon, et al., 2008). In a recent elaboration of peer support interventions, such as those discussed earlier (de Mello, de Jesus Mari, et al., 2005; Patel, Weiss, et al., 2011; Rahman, 2007; Rahman, Malik, et al., 2008), an intervention delivered by lay counselors and focusing on problem-solving, behavioral activation, and activation of social networks showed impressive initial benefits with severe depression (Chowdhary, Anand, et al., 2016). Thus, problem-solving can address the needs of both metabolic control and emotional management. For example, helping individuals to set objectives for increasing physical activity, take steps to accomplish those objectives, and reflect on the pleasure of reaching them may advance both self-management of chronic disease as well as mood and well-being.

Cautions when embracing problem-solving should consider the observation of Detweiler-Bedell and colleagues (Detweiler-Bedell, Friedman, et al., 2008) that self-management objectives for patients with a chronic illness and coexisting psychological or quality of life objectives are not necessarily synergistic or even compatible. With several conditions needing to be managed, "depletion of self-regulatory resources" (p. 1426) may lead to "under-regulation" of one. Also, effectively regulating one condition (e.g., mood repair by increasing pleasurable activities, e.g., dining) can negatively affect self-management of the other (e.g., compromised healthy diet for diabetes management), resulting in what the authors coin "misregulation." What is needed is an integrated model of managing several problems, rather than organizing management of several problems as entailing separate management plans for each.

In addition to its effectiveness in both mental and physical health domains, an emphasis on problem-solving may provide just the integrative, coherent framework to which Detweiler-Bedell and colleagues point. Organizing care of multiple chronic diseases and psychological challenges as problem-solving or self-management to achieve healthy diet, physical activity, adherence to medications, stress management, and maintenance of satisfying social and community engagements may provide patients a coherent framework for accommodating the changes that emerge inevitably in the natural history of chronic disease. It may also avoid concerns about stigma surrounding depression, other forms of emotional distress, or chronic diseases in many cultures.

It is often suggested that emotional distress must be addressed before individuals may be expected to marshal sufficient energy to manage chronic disease or address risks such as smoking cigarettes. There appears however to be little or no evidence to support this tactic. Indeed, the commonalities among the tasks of chronic disease management, prevention, and emotional well-being (e.g., physical activity) and the role of self-management and problem-solving as an integrating theme recommend encouraging patients' healthy *behaviors*, including adherence to appropriate medical treatments, without drawing hard distinctions between emotional and physical health or concentrating on which should be treated first.

Self-management procedures emerged largely out of research on self-control and related processes in psychology, behavior therapy, and health psychology (Mahoney & Thoresen, 1974; Rachlin & Green, 1972; Stuart, 1967). This might lead one to expect great attention to self-management approaches to depression and other mental health problems that psychology has traditionally addressed. This does not, however, appear to be the case. In the diabetes literature, for example, a search of PubMed (12/31/16) for papers with "self-management" and cognates of "diabetes" in their titles yielded 1180 references, while a parallel search for papers with "self-management" and cognates of "depression" in their titles yielded only 84. When expanded to include mention in abstracts, results were 3282 for "self-management" with cognates of "diabetes" and 950 with cognates of "depression." Further, many of those mentioning depression were focused on self-management of other diseases and simply included a measure of depression, not the focus of the self-management program. It should be noted that mental health researchers may use other terms, such as "psychotherapy," "supportive therapy," "bibliotherapy," to refer to similar services as "self-management." Nevertheless, it appears that the *combination* of proactive medical treatment and self-management that constitutes the state of the art in many areas of chronic physical disease (Yarnall, Hayes, et al., 2012) has not been fully recognized in the treatment of mental health problems. This appears to be an area in which behavioral medicine and its strong models of self-management and chronic disease management may make substantial contributions to mental health prevention and care.

Closing Thoughts on Interventions

One hundred years ago, interventions for mental illness in the formal healthcare systems of Europe and North America consisted of hospital confinement, a very few medical and surgical procedures, individual psychotherapy – just emerging in psychoanalysis and limited to a very few recipients – and social service programs. Today, hospital confinement is drastically reduced although not necessarily improved, and medical and psychological interventions have grown enormously in number and in their evidence and differentiated application to specific problems and circumstances. At the same time, approaches addressing the community and social surround of mental health are emerging such as in the attention to community in ACT and in many peer support programs. Because of the limitations of a single chapter such as this, we have omitted important examples in addition to those described here. For example, the Triple P model of parenting and family support addresses a variety of developmental and psychological problems of children and their families. It entails multiple levels of intervention, from broad education of the community regarding the problems it addresses to parent skills training and family behavioral interventions (Guo, Morawska, & Sanders, 2016; Sanders, Mazzucchelli, & Studman, 2004). In Holland, Hogewey is a village designed to meet the needs of those with dementia. Staffed by professionals and volunteers, residents with dementia are able to lived "normally" within the village (Jenkins & Smythe, 2013).

Across all of these and the interventions reviewed in the preceding sections, a crosscutting theme is integration of approaches. Just as state-of-the-art care of diabetes, for example, is not left to "take insulin and stay off sweets," so state-of-the art care of complex mental illness is not just a single psychiatric medication or a single, weekly hour of psychotherapy. Especially pertinent to the integration of care are internet- and mobile phone-based psychological and behavioral (self-help) interventions that offer unique opportunities for expanding reach even to whole populations at low costs (Andersson & Titov, 2014). Online interventions also offer the advantage of anonymity and low risk of stigmatization. Evidence to date suggests that internet-based psychological interventions for mental health problems are effective in a range of psychological and somatic chronic diseases and problems (Andrews, Cuijpers, et al., 2010; Richards & Richardson, 2012; van Bastelaar, Pouwer, et al., 2011; van Beugen, Ferwerda, et al., 2014). An important feature of internet and "eHealth" applications is their ability to integrate information – clinical, behavioral, emotional, as well as environmental and neighborhood data – and integrate individuals and groups, including individuals with others facing similar problems, with families, or with professional and lay health workers.

Future Directions and Implications for Global Mental Health

Across the wide range of topics discussed in this chapter, integration stands out as an important theme, integration across (a) mental and physical disorders, (b) varieties and levels of psychological distress, from daily hassles and disease-specific distress to serious mental illness, (c) types and modes of care – medication, psychotherapy, community based, peer based, internet based, and (d) systems of care – specialty care, primary care, behavioral health, community health. In contrast, many of our health systems and our cognitive models of health reflect still a dualism that, in many respects, has not changed since Descartes. As much as the present authors are proponents of integration, our writing does not always serve our intentions. The astute reader will note that we have several times distinguished between psychological or emotional problems and physical disease or physical illness in the pages that precede this. In addition to needing integrative models, the field needs, perhaps, integrative terminology.

In 1948, the World Health Organization announced an integrative definition of health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (World Health Organization, 1946). This was important in including the realms of "mental and social well-being" as part of health and of moving toward a definition of health as positive and substantive, not just the absence of something – "disease or infirmity." Since then, and with the growing global burden of chronic disease, living well with a chronic condition or challenge has emerged as an important model of well-being but one that surely does not meet the criterion of "complete physical, mental and social well-being."

A "dynamic" model of health has emerged (Huber, Knottnerus, et al., 2011) that not only integrates physical, mental, and social well-being but looks at them within the context of the natural incursions of health problems in the life course. So, health is not being 90 years old with no aches or pains, no problems remembering names, and the energy of a 21-year-old. Rather, health is being 90 with the "ability to adapt and self-manage" amidst the problems that 90 years may have brought. Rather than a "static" definition of health, we should pursue "a more dynamic one based on the resilience or capacity to cope and maintain and restore one's integrity, equilibrium, and sense of wellbeing" (Huber, Knottnerus, et al., 2011; Larson, 1999).

Interestingly, this model of resilience or ability to cope can be considered at the physiological level as in resistance to the virus bringing the yearly flu, at the mental level as in the ability to cope, say, with the decline of favorite abilities with age, or at the social level as in the ability to revise one's social ties following the changes brought about by retirement from work. This dynamic approach that balances the challenges to health on the one hand with the resources of the individual to cope with them also accommodates the "disability paradox" in which individuals with appreciable physical disease may nevertheless rate their health as good, referring apparently to their ability to live well amidst their health challenges, not eliminate them (von Faber, Bootsma-van der Wiel, et al., 2001).

From such a perspective, then, this chapter's examination of the co-occurrence of psychological and emotional problems with biological problems and challenges (we can no longer use "physical disease") reflects both an integrative and dynamic model. Over the life course, biological, psychological, and social challenges are normal and sometimes grow to the extent they may earn the label of "disease" or "pathology," again, biological, psychological, or social. Health and well-being are not the absence of these, but the ability of the biological, psychological, and social resources of the individual to meet or accommodate the challenges faced. The present chapter points then to the wide range of types and degrees of such psychological challenges and the correspondingly wide range of ways to assist individuals in coping with them and achieving wellbeing.

Part VI

Interventions to Enhance Quality of Life

33

Quality of Life and Person-Centered Outcomes: Considerations for Behavioral Medicine

Sarah D. Kowitt, Hairong Nan, and Jane Speight

Introduction

> QoL is such a subjective evaluation and so specific to the individual patient that there is no substitute for asking patients what is important to them, how good these things are in their life and how the elements of their life affect each other and their overall QoL. (Walker & Bradley, 2002, p. 144)

The coining of the modern day term "quality of life" (QoL) has been attributed to a speech made by US President Lyndon Johnson in the 1960s, in which he is reported to have stated that progress on social goals "cannot be measured by the size of our bank balance. They can only be measured by the quality of the lives our people lead" (Cummins, 1997, p. 117). Since that time, a broadening of the scope of medicine has been evident, to encompass a more person-centered approach in which a "life of quality" is sought, alongside optimal biomedical outcomes. QoL is frequently considered an important endpoint, in addition to biomedical outcomes, in clinical trials, and is becoming increasingly commonplace in routine clinical practice. Indeed, according to *PubMed*, since 1959 there have been some 34,000 papers published with "quality of life" in the title, 31,000 of which have been published since 1990. This reflects an increasing interest in the past 25 years in a more holistic approach to health and the evaluation of medical treatments.

The development of QoL as a concept reflects a number of interrelated phenomena: the demise of a purely medical model and rise of the biopsychosocial model (Engel, 1977); the rise of the patient as an active participant or consumer in healthcare (Bury & Taylor, 2008); growing recognition that improvements in medical outcomes entail ever higher financial costs for diminishing returns, thus driving a search for alternative ways to prioritize available treatments and technologies (Murphy & Topel, 2003); and the changing face of global disease burden, whereby the aging population and the inexorable rise of long-term conditions requires that the focus is not so much on "curing" disease but on enabling individuals to live successfully with these conditions. With

few curative treatments available, a focus on managing the condition suggests that maintaining or improving QoL may be among the most realistic of healthcare goals.

In this chapter, we examine QoL – how it is conceptualized, operationalized, and measured in research and practice. Given that life expectancy has increased significantly in the past century, and an increasing number of people living with one or more medical conditions, the effects of chronic care management and collaborative approaches to healthcare delivery are discussed alongside behavioral interventions to improve QoL. With the growing emphasis on QoL in clinical care and recent policy initiatives, considerations for how to integrate QoL into a complex environment will be introduced and explored.

Conceptualizing QoL

Definitions of QoL: Shared Attributes

> There are almost as many quality of life definitions as there are people. (Liu, 1976)

Most people, in the western world at least, are familiar with the term QoL and, intuitively, have some understanding of what it involves, typically emphasizing components of happiness and life satisfaction. It may seem obvious that QoL is a personal evaluation of how good or bad one's life is (McGee, O'Boyle, et al., 1991) but attempts to agree on a universal definition of QoL have met with limited success. Those who have attempted to define QoL generally debate the nature of what is important philosophically for achieving a life of quality. Is it more important to have what one needs or what one wants? Is it more important to function (at a minimal standard) or to enjoy? Compelling arguments exist on both sides of this debate but there is no consensus. Some have argued that human needs (e.g., health, mobility, shelter, food) are the foundations for QoL and that the degree to which those needs are met is what defines QoL (Hörnquist, 1982). We believe this definition to be flawed; however, as it will be clear to most people in the western world that having one's basic needs satisfied does not necessarily lead to contentment. Calman's "expectations model" ('Calman's Gap') suggests that QoL is a measure of the difference between an individual's hopes and/or expectations and the individual's present experience (Calman, 1984) and is concerned with the difference between perceived and attained goals. Calman qualifies his approach by indicating that the goals must be realistic. This definition has inherently more appeal than the needs-based approach because it is concerned with an assessment of what the individual actively wants from his/her life rather than what the individual needs in his/her life. Probably, the truth lies somewhere in between the two approaches.

Although a consensual definition of QoL may not exist, there is agreement as to what attributes reflect its components. First, it is generally accepted that QoL is highly subjective. People will rate their QoL from their unique perspective based upon their own feelings, experiences, and priorities. Thus, while two individuals may experience the same objective health condition, their assessment of QoL may differ according to expectations, prior experiences, traits, etc. Inherent within this argument is that QoL may be best assessed by an individual rather than by proxies, such as clinicians, providers, or family members. This argument will be explored further in section "Source of Report." Second, is the understanding that the QoL is a multidimensional construct (Cella, 1994). If each respondent thinks about different aspects of their life when attempting to evaluate their QoL, this suggests that QoL has several dimensions. However, while there may be agreement that QoL is multidimensional, there is less clarity about what these dimensions may include. At the minimum, there is consensus that physical, psychological, and social dimensions are all important to QoL. However, many definitions of QoL have also included other domains, such as role functioning, spiritual aspects, and environmental considerations (WHOQOL group, 1995). A third characteristic of QoL is that it is "a dynamic construct" (Carr, Gibson, & Robinson, 2001), meaning that assessments of QoL not only differ *between* individuals but will change over time *within* an individual, dependent upon his/her priorities, experiences, and circumstances. This creates an inherent instability in the meaning of QoL, which raises some methodological concerns (examined in section "Response Shift") but also means that QoL may improve or worsen depending on the time, situation, and psychological factors, such as adaptation, coping, expectations, and so on. The final characteristic of QoL is that it includes both positive and negative attributes. This represents a departure from previous deficit-based definitions of health and means that QoL may be inclusive of both negative aspects (e.g., negative emotions, pain, fatigue), as well as positive attributes (e.g., contentment, mobility) (WHOQOL group, 1995).

Reflecting the four characteristics described above, we find the following definition of QoL useful, referring (albeit in general terms) that multidimensional aspects of life are likely to be important for most people in achieving and maintaining a life of quality. QoL is defined as:

> individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns. (The World Health Organization Quality of Life Group, 1995)

Encompassed within the WHO's definition are six broad domains: (1) physical, (2) psychological, (3) level of independence, (4) social relationships, (5) environment, and (6) spirituality, religion, and personal beliefs (WHOQOL group, 1995). Although aspects of this definition may be critiqued on the grounds that it is too broad, the WHO's operationalization of QoL has been extensively validated and referred to in the development of other more widely used QoL measures.

Distinctions and Similarities Between QoL, Health, and Health-Related QoL

> Health is a state of complete physical, mental and social well being, and not merely the absence of disease or infirmity. (World Health Organization, 1948)

Given the breadth of QoL, one may also wonder how QoL differs from health, especially given the WHO's definition of health as "a state of complete physical, mental and social well being, and not merely the absence of disease or infirmity" (World Health Organisation, 1948). This confounding of terms is both understandable in the context of healthcare and medical treatments and logical given the similarity between the definitions. Yet, as will be argued, one may have limited functional or health status and still achieve considerable QoL – and vice versa. Thus, QoL should be viewed as broader and more comprehensive than health status, functional status, and a number of other related terms. In fact, when measured simultaneously, studies have found that while QoL and health status may be correlated, a substantial number of individuals experience discrepancies between the two. For instance, in a study of health status and QoL in a sample of older adults, almost 15% who reported moderate pain also reported very good or excellent QoL (Covinsky, Wu, et al., 1999). Conversely, over 15% who reported the highest physical capacity had fair or poor QoL (Covinsky, Wu, et al., 1999). In a meta-analysis to determine how individuals make determinations of QoL, researchers found that QoL and health status were conceptually distinct constructs, with different path models, estimates, and predictors (Smith, Avis, & Assmann, 1999). Interestingly, when rating QoL, individuals gave greater weight to mental health, and when rating health status, physical functioning was perceived as more important (Smith, Avis, & Assmann, 1999). The authors concluded that if a questionnaire aims to assess only health status, and this assessment is used as the basis for measuring QoL, important domains, mainly regarding mental health, will be missed (Smith, Avis, & Assmann, 1999).

Thus, health status is typically distinguished from QoL by the absence of indicators that are unaffected by health, illness, and treatment. For instance, a QoL measure may include indicators for quality of environment, political freedom, standard of living, education culture, religion, or socioeconomic status, whereas a health status measure will theoretically assess only those indicators most directly related to health (e.g., functionality, pain, mobility, emotional well-being). However, this raises a difficult issue – mainly that while health status refers solely to aspects of QoL that pertain to health, it can often be difficult to differentiate between QoL domains that may affect health and those that do not. For instance, while standard of living may not typically be included within any health status questionnaire – as anyone familiar with public health is surely aware – one's living situation may still affect health and one's health may still affect one's living situation.

Due to general conflation between QoL and health, the term "health-related quality of life" (HRQoL) was coined. HRQoL was intended to narrow the focus of QoL in a medical context onto the effects of health, illness, and treatment (Ferrans, Zerwic, et al., 2005). HRQoL refers to:

> the extent to which one's usual or expected physical, emotional, and social well being are affected by a medical condition or its treatment. (Cella, 1994)

Thus, HRQoL is typically distinguished from the concepts of health/functional status and QoL by referring to the impact of health, illness, or treatment on broad aspects of life that are important for overall QoL, i.e., requiring an attribution to be made regarding how aspects of life are affected by health, illness, or treatment. For instance, while a QoL measure might include an assessment of absolute satisfaction with aspects of life (e.g., working life or family life), and a health status measure might not include these aspects of life at all, a HRQoL measure would ask the respondent to assess the impact of health, illness, or treatment upon those aspects of life (e.g., working life or family life). Unfortunately, the literature is replete with confusions between these concepts and their operationalization. For example, some measures referred to as assessing HRQoL include domains assessing QoL and health status. Thus, differentiation between QoL and HRQoL is often easier to understand in theory than in practice – and the two terms are often used interchangeably.

In one of the earliest conceptual models of HRQoL, Wilson and Clearly theorized that HRQoL would be composed of interactions among biological function, symptoms, functional status, general health perceptions, and how these influence overall QoL (Ferrans, Zerwic, et al., 2005). The takeaway from this model and others is that HRQoL is about the interrelationship between health factors and overall QoL (with the latter being a broader concept, which is influenced also by nonmedical factors). This suggests that when health, HRQoL, and QoL are used, their definition should be specified, their purpose clarified, and their domains identified. Furthermore, while health status, functional status, and symptoms may affect QoL (and be affected by QoL), and represent components of HRQoL and QoL, they should not be thought of as proxies for QoL. In general then, we recommend that QoL be viewed as a broad yet distinct construct with various domains, one of which may be health (Anderson & Burckhardt, 1999).

The Importance of Assessing QoL

> To the lay person, quality of life is of the highest importance and acts as the driving force behind all actions. (Leplège & Hunt, 1997, p. 47)

Now that some clarification of the concept QoL has been considered, we can turn our attention to why QoL assessment is important and why measurement of QoL has proliferated over the past few decades in health research and, increasingly, in clinical practice. As will be demonstrated below, QoL places the individual, rather than his/her condition, medical treatment or other healthcare processes, at center stage. It also adds to the evidence base concerning the overall success of treatment by facilitating an understanding of medical outcomes from the perspective of the individual, which serves a number of purposes discussed below. Lastly, measurement of QoL provides important information to medical providers, patients, and policy makers – all of whom influence the direction of healthcare.

Understanding the Impact of a Medical Condition

Interest in QoL assessment has expanded rapidly in the past 25 years "as a valid indicator of whether or not a medical treatment is beneficial" (Spilker, 1996; Spilker & Revicki, 1996).

Measurement of clinical indicators is integral to healthcare systems. Typically, the focus is on laboratory and clinical tests offering objective markers such as pulse, blood pressure, blood glucose, lipids, and X-rays. More subjective markers are also used, such as pain assessment, strength, and mobility. Why not QoL also? For example, children with mild-to-moderate reduction in kidney function have reduced QoL in comparison with their peers due to impaired growth and reduced stature (Gerson, Wentz, et al., 2010), whereas treatment would not usually be instigated until kidney function was more significantly impaired; early intervention with salt supplementation or growth hormone improves QoL (Gerson, Wentz, et al., 2010). Similarly, people undergoing chemotherapy may experience significant reductions in QoL due to neutropenia (Nirenberg, Parry Bush, et al., 2006). People with diabetes experience significant reductions in QoL due to the impact of dietary restrictions (Bradley & Speight, 2002), which arguably affect their willingness to adopt clinicians' treatment recommendation (Wolpert & Anderson, 2001). QoL screening can be employed to identify those whose QoL is at risk from the negative consequences of their illness or treatment and to guide intervention where appropriate.

Understanding Patients' Priorities and Preferences

Typically, an individual's self-assessment of their condition or medical treatment may differ substantially from the judgments of their healthcare professionals, their caregivers or family members, or the general population. The use of patient-reported outcome (PRO) measures is regarded as a way of ensuring that healthcare is "person-centered" (McGrail, Bryan, & Davis, 2011). Certainly, having an understanding of how a person feels about their illness or treatment, or their level of satisfaction with a given treatment, is considered useful, but it does not provide sufficient information to make decisions about which treatment option would be best suited to the individual. Measures of well-being and satisfaction are used alongside biomedical markers in clinical trials to determine effectiveness without any regard to which of the outcomes are most important to the individual. For example, in arthritis, is a reduction in pain or an improvement in function most important? What degree of pain is acceptable for a given improvement in function, and vice versa? Can a new side effect be tolerated in exchange for improvement in both? Does an outcome that was important at diagnosis remain important several years later? Do trade-offs change over time? Some outcomes of particular importance to people with type 1 diabetes, e.g., dietary freedom, spontaneity, and independence (Bradley & Speight, 2002; Speight, Woodcock, et al., 2010), are rarely afforded prominence as endpoints in controlled clinical trials. Yet, where such endpoints are considered and become the target of new therapeutic efforts, significant long-term benefits may be observed because the treatment has been reframed from the individual's perspective (Wolpert & Anderson, 2001). Equally, the inclusion of such patient-relevant endpoints in real-world evidence trials can give much needed clarity to interpretation of adherence and primary outcome data (Price, Chisholm, et al., 2011).

Evaluation of New Treatments and Technologies

While the primary outcomes of clinical trials focus mostly on biomedical indicators, "explanatory" trials, where the focus lies in understanding the impact of treatment on a disease (e.g., evaluation of new treatments and technologies), can be more effective if consideration is given to the impact on QoL, in addition to change in clinical outcomes (Pocock, 1991). This is particularly true where treatments or technologies entail increased or reduced burden related to pain, lifestyle, psychological health, or self-care. By incorporating QoL assessment into clinical trials as co-primary or secondary endpoints, a more comprehensive evaluation of treatment outcomes can be made, both in respect to individual treatments and for comparisons between treatments. Such evidence is used increasingly by regulatory bodies in evaluating medicines and technologies and by payers and clinicians involved in market access and prescribing decisions (US Food and Drug Administration, 2009; European Medicines Agency Committee for Medicinal Products for Human Use, 2005). QoL may be included as a relevant endpoint in various scenarios:

1. QoL may be the primary endpoint – frequently the case in palliative care, when no cure is possible and QoL considerations may override those of quantity of life
2. QoL may be a co-primary endpoint – increasingly the case when new treatments are expected to non-inferior to the existing treatment option in terms of biomedical efficacy but where the newer treatment may offer QoL benefits
3. QoL may be a secondary or tertiary endpoint – when the treatment of interest confers small benefits in cure rates or improvements in biomedical indicators at the expense of a deterioration in QoL

Allocation of Medical Resources

One reason to assess QoL is to determine or justify allocation of scarce medical resources. Particularly relevant where there is no obvious differentiation in terms of biomedical outcomes, the QoL created, maintained, or unimpaired by a given treatment or care process may well be the critical factor in allocation decisions. Thus, in the case where not everyone in need can be treated, decisions can be made based on who would benefit most in terms of both quantity and quality of their remaining lives. The development of secondary metrics, such as the quality-adjusted or disability-adjusted life year, "QALY" and "DALY" (discussed further in section "QALY: Preference-Based Measures"), has quantified the economic implications of changes in quality of life and formalized this decision-making process (Sassi, 2006). Comparators such as these enable treatment evaluations to be made across and between conditions and reflect the views and preferences of individuals. However, such evaluations are not exempt from the limitations (e.g., lack of validity, sensitivity) inherent in any QoL measure(s) used. Furthermore, while they are employed to balance conflicting resource and economic demands, by their very nature, QALYs and DALYs entail ethical implications that arise when there is a deviation from the principle of equal allocation of healthcare resources (Hirskyj, 2007).

Assistance Toward Autonomous Decision-Making

In the twenty-first century, there is widespread recognition that the patient needs to be an active partner in decisions about medical treatments. This replaces a "paternalistic" approach to decision-making and is associated with both risk and benefit to clinicians and patients (Walsh & Swain, 2011). Much of the emphasis in medical decision-making has revolved around the provision of information to the patient. However, the need for information about treatment options and their impact needs to be framed not only in terms of medical outcomes but also in terms of helping the individual to understand how the specific treatment may impact on his/her life, in ways that are important to the individual, so that he/she can achieve a realistic evaluation of potential benefits or deficits to overall life quality. Use of QoL assessment in routine clinical practice can individualize care by enhancing clinician-patient communication about the ways in which the condition or its treatment impair various aspects of life and serving as the basis for joint decision-making about treatment options.

Measurement of QoL

> The quality of life construct has a complex composition, so it is perhaps not surprising that there is neither an agreed definition nor a standard form of measurement. (Cummins, 1997, p. 6)

Attempts to operationalize the concept of QoL have been as diverse as the definitions employed, and many authors (as discussed above) report using "QoL measures," which may or may not be conceptually valid, methodologically rigorous, or psychometrically sound. Rapley draws comparison with the medical field, asserting that "in an era when medicine is increasingly said to be 'evidence-based', the quality of research on QoL is … at best mixed and at worst unacceptably poor" (p. 29) (Rapley, 2003). Yet nothing could be more important than using a good QoL measure for, if we claim to assess QoL but measures are invalid, unreliable, or psychometrically unsound, then the possibility of Type II error is raised and potentially beneficial interventions may be found inadequate. This has serious ethical implications in terms of wasted funding, participant time, and missed opportunity if a valuable intervention is not demonstrated to be so. For these reasons, appropriate measurement of QoL is of utmost concern.

Development and Validation of QoL Measures: Qualitative Methodologies

Most QoL measures referred to later in this chapter are quantitative, and this is necessarily so because clinical trials, for instance, require the statistical comparison of endpoints over time and between treatment groups. However, qualitative research plays a very important role in both the development and validation of QoL measures. Regarding the former, qualitative research can assist with development of a conceptual framework, identification of appropriate wording for items, responses and recall periods, and clarification of relevant dimensions – all of which are necessary *before* creating QoL measures (Lasch, Marquis, et al., 2010). Regarding the latter, qualitative methodologies are particularly important for evaluating measures, ensuring content validity, respondent comprehension (i.e., of instructions, items, and response options), questionnaire comprehensiveness (i.e., that nothing of importance is missing), and minimal redundancy (i.e., ensuring that the measure does not overrepresent certain issues) (Lasch, Marquis, et al., 2010). Various data collection modes are often used under the umbrella of qualitative research, but two are particularly important to QoL research – "concept elicitation" and "cognitive interviewing."

Concept elicitation is used to identify domains, item content, and areas that individuals consider relevant and important to an overall concept of interest and is particularly important in the development of measures (Patrick, Burke, et al., 2011a). Lasch gives the example of concept elicitation interviews being conducted with people with irritable bowel syndrome to determine what symptoms and/or domains may be relevant to assess (Lasch, Marquis, et al., 2010). Questions could be broad, such as "what is a good day with irritable bowel syndrome (IBS)?" and "what is a bad day with IBS?" in order to determine (without leading) what is relevant to the individual (Lasch, Marquis, et al., 2010). Concept elicitation interviews can also be used to identify language used by the relevant target group and to gather information on frequency, severity, duration, or other issues that may be useful in the design of items.

After initial item development, qualitative research also plays a role in the validation of instruments. A type of validity of particular importance is content validity, which refers to "the extent to which the instrument measures the concept of interest" (US Food and Drug Administration, 2009) or the extent to which a measure is representative of the universe of content of the construct being measured. If the content validity of a measure is unsound, then claims made about the instrument and any outcomes derived from it will also be unsound. In the past decade, the US Food and Drug Administration (FDA) has taken a very active interest in the concept of content validity, due to the increasing number of pharmaceutical companies attempting to make product-labeling claims based upon patient-reported outcomes. The FDA notes in its definitive guidance to industry that "evidence of other types of validity … or reliability … will not overcome problems with content validity" (US Food and Drug Administration, 2009). This statement underpins the importance of solid measurement foundations. Ensuring content validity involves rigorous qualitative research with the target group (e.g., people with the condition or using the medical treatment) and documenting how items were generated.

One approach to ensure content validity is through "cognitive debriefing" interviews (or "think-aloud studies"), which focus on identifying the respondents' thought processes as they answer items on a questionnaire, evaluating the clarity of item measures, and determining if content within the measure is comprehensive (Patrick, Burke, et al., 2011b). Cognitive interviews can be useful in identifying how respondents may interpret items, response options, and prompts. For instance, a cognitive interview questionnaire may include [some of] the following questions:

1. What did [the particular item] mean to you?
2. What were you thinking about when you tried to answer [this particular item]?
3. What did [this specific item or phrase] mean to you?
4. Was [this particular item] easy or difficult to answer? Please explain.
5. Were the response options easy or difficult to understand? Please explain.

It is important that, for each of the above questions, the interviewer probes further to determine why the particular item, word, or response option might be considered problematic. This can help researchers determine if the measure assesses what it claims to assess. Given the importance of qualitative research in QoL measurement, extensive protocols and considerations have been proposed, including a noteworthy article by Lasch et al. (2010).

Source of Report

Patient-Reported Outcomes

Validity of QoL measures does not depend only on how items are developed, also of consideration is the *source* of report. If QoL is a subjective, multidimensional, dynamic construct of the difference between perceived goals and attained goals, then there is a case for adopting the principle that individuals should decide the extent to which their QoL is satisfactory based upon their own criteria for what constitutes good QoL for them personally. If this is accepted, then QoL needs to be defined as "what the patient says it is" (Joyce, 1994, p. 47) rather than what their health professional thinks is relevant or what the researcher decides to measure. While, intuitively, it may make sense that an individual would best understand and be able to evaluate his/her own QoL, the incorporation of PROs into regular healthcare assessment has been a relatively recent phenomenon. A PRO is any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else. Thus, the term PRO has come to be used as a better "umbrella" for assessments based upon the patient perspective, as opposed to QoL, which (as noted above) has a specific and broader meaning.

However, not all PROs assess QoL. There are two explanations for why researchers have been prone to label any and all PROs as QoL. First, in the absence of a universally agreed definition of QoL, the measurement of all psychological outcomes (as opposed to biomedical outcomes) has arguably fit under this broad heading. While all PROs may be important for QoL or related to QoL, as discussed above (section "Distinctions and Similarities Between QoL, Health and Health-Related QoL") they are not QoL per se. Second, the term QoL has become a buzzword in healthcare research, recognized as an important outcome in its own right. Indeed, major clinical trials in recent years have frequently included QoL (or, more usually, a related PRO) as a primary or secondary endpoint in an attempt to ensure holistic evaluation.

In recent years, a host of centers, databases, and quality initiatives have been devoted to PRO use and research (see Table 33.1), testament to the importance now vested in holistic, person-centered outcomes in health research and healthcare.

Proxy Reports

In certain circumstances, people may be unable to report on their own QoL or related outcome, e.g., young children, those with cognitive impairment or communication problems. Even beyond these circumstances, medical providers often make important decisions based on their

perceptions of their patients' QoL. In these situations, we refer to reports coming from proxies, most often caregivers and medical providers. While proxy reports may be *similar* to patients' own assessments, numerous studies have found discrepancies. In a study of adolescents with type 1 diabetes, the Schedule for the Evaluation of Individual Quality of Life (SEIQoL) was used, which assesses QoL from the patients' perspective (McGee, O'Boyle, et al., 1991). Adolescents were asked to nominate five domains important for their overall QoL (Walker & Bradley, 2002). To this list, a sixth domain, "diabetes," was imposed, to determine its relative importance in the adolescents' lives. Surprisingly, the adolescents were unanimous in their nomination of three domains considered to be important for their QoL: "family," "friends," and "school." A further 22 domains were nominated, which could be grouped into ten overall categories, plus the "diabetes" domain. Only 4 of the 15 participants considered diabetes the most important aspect of life for their QoL, with the remainder rating it as fourth or lower on their list. The fact that diabetes was such a low priority for so many of the adolescents is indicative that "treatment strategies that take account of the importance of other aspects of life are more likely to be successful" (Walker & Bradley, 2002). Furthermore, when the diabetes specialist nurses, who had known most of these adolescents since diagnosis of their diabetes, was asked to rate each of the adolescents' QoL, their ratings were more closely related to the adolescents' most recent average blood glucose (HbA_{1c}) results than to the adolescents' own ratings. This indicates that while adolescents are most likely to rate their QoL in terms of family, friends, and school, their health providers are likely to rate it in terms of what they understand of their health outcomes.

Confirming these results, other studies have found that, in general, clinicians underestimate patients' presence and severity of symptoms (Sprangers & Sneeuw, 2000; Pakhomov, Jacobsen, et al., 2008; Basch, Jia, et al., 2009) and overestimate impairments to patients' QoL (Sneeuw, Aaronson, et al., 1998). Of course, this depends on the population, type of proxy, outcome, and setting. Understandably, clinician and patient reports tend to have higher concordance when assessing more observable outcomes (e.g., vomiting, diarrhea) than subjective outcomes (e.g., fatigue) and when evaluating physical functioning over mental or emotional functioning (Sneeuw, Aaronson, et al., 1998; Basch, Iasonos, et al., 2006). Additionally, patient and proxy reports are likely to be more similar to one another when the patient's QoL is either very good or very poor rather than for intermediate levels of QoL (Sneeuw, Aaronson, et al., 1998). Moreover, the length of time proxies spend with the patient, communication between the proxy and the patient, and the level of experience proxies have with medical care and/or the patient all affect the accuracy of proxy ratings (Addington-Hall & Kalra, 2001).

These findings confirm that estimating a individual's QoL is not intuitive and that routine assessment of QoL is needed if the patient's perspective is to be truly considered in treatment decisions. However, that is not to say that providers' assessment of patients' status are without merit. In fact, in one study, longitudinally collected clinician assessments of adverse symptom data better predicted unfavorable clinical events, whereas patient reports better reflected daily health status (Basch, Jia, et al., 2009). As noted by the authors, "patient and clinician perspectives of adverse symptoms appear to be complementary, together providing a more complete picture of the toxic impact of treatments compared with either perspective alone. Clinicians bring professional training and experience to their evaluations, whereas patients are in a better position to communicate their own subjective experiences" (Basch, Jia, et al., 2009). Perhaps then, given its subjective nature, assessment of QoL and many related outcomes may be best ascertained from the individual's perspective, but certain dimensions of QoL may be supplemented usefully by proxy reports, which offer complementary information.

Types of Measure

Generic Versus Condition-Specific

As discussed in section "Distinctions and Similarities Between QoL, Health and Health-Related QoL," measurement of QoL can be generic (i.e., overall QoL) or health-related (HRQoL). Similarly, QoL and related outcomes can be either generic, health-related, or condition specific, the latter referring to the impact of the specific condition (and/or its treatment) on QoL. Health and HRQoL measures fall into the "generic" category, as they can be completed by a person with any (or no) medical condition. Some examples of generic health status measures include the SF-36 (short form 36) (Ware & Sherbourne, 1992), which has domains for physical function, role limitations for physical health, pain, general health, vitality, social functioning, role limitations for emotional health, and emotional well-being and the EQ-5D (Brooks, 1996), which has domains for mobility, self-care, usual activities, pain/discomfort, and anxiety/depression. Generic measures are designed to be relevant to anyone, regardless of disease outcome and as a result can be used to compare the burden of diseases. For instance, in order to understand how health status differs for people with HIV/AIDS compared to those with other chronic conditions and those in the general population, Hays et al. conducted a study using generic HRQoL measures (Hays, Cunningham, et al., 2000). They found that people with HIV/AIDS had worse physical functioning than those with other chronic conditions (i.e., epilepsy, gastroesophageal reflux disease, clinically localized prostate cancer, clinical depression, diabetes) and significantly worse emotional well-being than the general population and those with other chronic conditions, except those with depression (Hays, Cunningham, et al., 2000). By using generic measures, these types of studies may be useful for policy makers who are tasked with allocation of resources, as well as clinicians who must understand the relative burden of disease and provide appropriate treatment (Hays, Cunningham, et al., 2000). One of the disadvantages of generic measures is that they may overlook issues of particular importance in a specific medical condition and focus on other issues of less relevance. For example, among people with diabetes or celiac disease, "food intake is often the most challenging and difficult to manage for individuals and clinicians alike" (Schlundt, Pichert, et al., 1996), yet dietary freedom is rarely included in generic health status measures, while mobility is typically measured but less relevant for these particular conditions.

Condition-specific measures, on the other hand, are targeted to individuals with a particular condition and may include items relevant to only that condition. For instance, the EORTC QLQ-C30 is designed to assess the QoL of people with cancer and includes dimensions for functioning, overall QoL, financial difficulties, and symptoms specific to cancer, such as fatigue, pain, nausea, appetite loss, diarrhea, and insomnia. While condition-specific measures do not allow for comparison with other conditions, they are likely to be more responsive than generic measures. This is because they have usually been informed by qualitative studies involving people living with the condition (see section "Development and Validation of QoL Measures: Qualitative Methodologies").

Both generic and condition-specific instruments have utility in different situations. For instance, generic measures may be more broadly applicable and able to detect unanticipated effects, whereas specific measures may be more acceptable to respondents (as they are perceived as highly relevant) and more responsive (i.e., sensitive to changes in treatment or circumstance) (Patrick & Chiang, 2000). Given the relative advantages and disadvantages of generic and condition-specific measures, clinical trials frequently use both to provide a holistic assessment (Patrick & Deyo, 1989). Such an approach allows for comparability and generalizability while also enabling the responsiveness that condition-specific measures offer (Patrick & Deyo, 1989). Of course, respondent burden can then become an issue, with trials and studies requiring participants to complete multiple (seemingly similar) PRO measures. Suffice to say, as reflected in other parts of this chapter, selection of measures, whether they are generic or condition-specific, will depend on the purpose of measurement, setting, resources, and individuals.

QALY: Preference-Based Measures

Measures can also be differentiated on the basis of whether they are "preference based" or not. With their origins in health econometrics, preference-based measures assign "values" to various health states to enable determination of a single health utility score. "Utilities" as they are known, reflect, in essence, an individual's preference with regard to various possible health outcomes or scenarios (Tolley, 2009). One of the most widely used preference-based measures for cost-utility analyses is the quality-adjusted life year (QALY). For QALYs, the amount of time spent in a health state is weighted by a utility score given to that health state (Phillips & Thompson, 1998). Thus, QALYs take into account not only life expectancy but also the QoL of remaining years. So for instance, if one intervention leads, on average, to individuals experiencing 4 years in a certain health state rated at .75, then three QALYs would be generated by that intervention. If, on the other hand, another intervention leads to 4 years in a health state rated at .5, then two QALYs would be generated. When costs of interventions (e.g., surgical procedures, medications, structured education) are entered into the equation, it is possible to figure out the cost-utility of those interventions.

The EQ-5D is a type of preference-based measure that was derived from the QALY. Within the EQ-5D, individuals are asked to rate the extent to which they (1) are mobile, (2) have pain or discomfort, (3) are able to take care of themselves, (4) have anxiety or depression, and (5) can perform their usual activities. Within each of these five health dimensions, there are three possible ratings: no problem, some problems, and major problems. The combination of these with the conditions "unconscious" and "death" enable description of 245 health states in total. For each of the possible 245 health states, utility scores were constructed from responses within a random sample of 3000 people in the UK, using the time trade-off method (Phillips & Thompson, 1998). This method asks people to consider the amount of time they would be willing (e.g., number of years) to sacrifice to avoid a poorer health state (Tolley, 2009). Other methods to assign health utilities include standard gamble where individuals are given a choice between a health state that is certain and a gamble with a better and worse outcome and rating scales (visual analogue scales, VAS) where respondents are asked to mark a point on a line (with anchors for best and worst possible health states) to indicate their current health state. The EQ-5D (Brooks, 1996) also includes a VAS. Each health state is then assigned a utility, which ranges from best possible health state to worse possible health state. To improve the sensitivity of the instrument and reduce ceiling effects, the latest version of the EQ-5D, the “EQ-5D-5 L,” contains *five* possible severity levels: no problems, slight problems, moderate problems, severe problems, and inability to function (Herdman, Gudex, et al., 2011). Validation and psychometric testing are currently ongoing (Herdman, Gudex, et al., 2011).

Preference-based measures, such as the QALY and EQ-5D may be used to compare the effectiveness of interventions, evaluate cost-utility, and inform allocation of resources; however, they may not be useful in all situations. For instance, QALYs may be less useful for people with medical conditions in which QoL is more important than quantity of life (survival) (Phillips & Thompson, 1998). The limitations of generic measures need to be considered carefully (as discussed in section “Generic Versus Condition-Specific”). QALYs also do not take into consideration age, life context, or impacts on caregivers, thereby making it difficult to compare the health status of different individuals (Phillips & Thompson, 1998). Additionally, there is concern over the complexity involved in obtaining utilities, the representativeness of utilities, and the ethical concerns over assigning dollar figures to QALYs (Patrick & Chiang, 2000). Regarding this last point, there is general consensus that interventions costing 50,000 USD per QALY are “cost-effective,” but what does this mean and how should it be applied? (Eichler, Kong, et al., 2004) Thus, while the benefits of QALYs and other preference-based measures should be acknowledged (e.g., for comparison across conditions, assistance with allocation of resources), their limitations need also to be considered.

Single Item Versus Multi-item

The last way in which measures may differ is whether they are single-item or multi-item measures. Typically, QoL and related measures include a number of items, the responses to which are summed or aggregated to provide a composite “scale” score. Some measures include multiple “sub-scales,” which measure various related dimensions of a particular construct. Conversely, single-item measures attempt to glean an overall assessment of the underlying construct with a single question. For example, a single-item, QoL scale might be worded “Overall, how would you describe your quality of life during the past two weeks?” (Response options can be ordinal (e.g., “excellent, good, fair, poor, terrible”) or a Likert-style rating scale with labeled anchors (e.g., “excellent” to “terrible”)). A single-item health-related or condition-specific QoL scale might be worded “Overall, to what extent has [your health/the condition] affected your quality of life in the past two weeks?” (Similarly, response options can be ordinal or Likert-style, using a unidimensional or a bidirectional scale.)

Single-item measures may impose less respondent burden than multi-item measures. However, the benefits of these single items (often referred to as global or “short-form” measures need to be balanced against their disadvantages. While such general questioning is broadly understood by the majority of respondents and allows each to define the concept in a way that is personally meaningful, responses can be less reliable and more difficult to interpret than the responses to a series of interrelated questions tapping into the underlying, latent, construct. Certainly, studies that have correlated single-item with multi-item scales have found the two to be related but not identical (Bradley, Todd, et al., 1999). Relatedly, despite the inherent appeal of single items (particularly to busy clinicians or wary patients), psychometric theory also favors multi-item scales because they are less prone to random measurement errors (DeVellis, 2011). In sum then, both may generate meaningful but different content that may be useful to researchers and practitioners depending on the situation.

Measurement Issues

Given the complexities discussed above, a number of measurement issues are raised in QoL research. For the sake of brevity, two such issues are discussed below. Further discussion of measurement challenges in QoL research can be found elsewhere (O'Connor, 1993).

Interpretation of QoL Measures

Even after determining which concept measure to use and considering all the issues above (e.g., who should be asked to report? should the measure be generic or condition-specific? should it be preference-based? should it be single- or multi-item?), it may still be difficult to interpret results. While differences between groups or changes over time in QoL scores are typically evaluated for statistical significance, one may be left wondering: will this information be meaningful to clinicians or useful in clinical practice? In other words, how do we tell how important it is to have moved X points on a given scale? Questions such as these have prompted research on the clinical significance of findings, or "minimally important differences," which refers to a change in scores that is "large enough to have an implication for the patient's treatment or care" (Wyrwich, Bullinger, et al., 2005). Without going into the specifics of how to determine clinical significance (which is discussed elsewhere (Cella, Eton, et al., 2002; Norman, Sridhar, et al., 2001)), two methods have been generally applied: anchor-based approaches and distribution-based approaches.

An anchor-based approach maps changes in PRO scores on to clinically relevant and important changes in other measures of treatment outcome. Wyrwich gives the example of a study in which it was determined (based on cross-sectional or longitudinal analyses) that 32% of those who score 40 on the SF-36 physical function can walk a block without difficulty, while 50% of those who score 50 on the same scale can walk a block (Wyrwich, Bullinger, et al., 2005). Given this information, when scores move 10 points from 40 to 50 or 50 to 40, then this would result in an absolute change of 18% of the population (=50−32), a relative increase of 55% (=18/32), and a relative decrease of 35% (=18/50) (Wyrwich, Bullinger, et al., 2005). This can be helpful in determining what changes in PRO scores actually mean in terms of other well-known parameters. While this is relatively straightforward to determine when the PRO measure is focused on a subjective rating of an outcome that can be determined objectively (e.g., mobility), it is less clear-cut for condition-specific QoL scores. For instance, scores on a measure of diabetes-specific QoL may not necessarily be closely related to the measure of average blood glucose (HbA1c), thus clinical significance may be better determined by a distribution-based approach than by an anchor-based approach.

An alternative to anchor-based methods, the distribution-based method for interpretation of QoL relies on measures of variation (e.g., standard deviation, standard error of measurement) to benchmark important changes or differences in the QoL measure. A well-known example of this would be Cohen's effect size, which can be used to classify an effect as small, moderate, or large (Wyrwich, Bullinger, et al., 2005). While both methods are imperfect, they are useful for determining what QoL scores mean, especially in clinical practice, where health professionals will be concerned less with statistical significance and more so with being able to interpret an individual's QoL scores.

Response Shift

Response shift is defined as "changes in the meaning and one's evaluation of quality of life resulting from changes in internal standards, values, or conceptualization" (Sprangers & Schwartz, 1999). According to Sprangers, response shift can result from (1) a change in the respondent's internal standard of measurement (scale recalibration), (2) a change in the respondent's values, and (3) a redefinition of the construct (i.e., reconceptualization) (Sprangers & Schwartz, 1999). Response shift is best illustrated with an example. A woman rates her QoL as relatively high. When evaluating her QoL, she thinks of her working and social life as being fairly important for her overall, and she rates them both highly. After being diagnosed with cancer, she begins to think about the importance of her family and her diminishing independence for her QoL. This woman has reconceptualized her QoL. Over time, the woman adjusts to her diagnosis and treatment, and her score on a QoL measure returns to a point roughly consistent with her score before diagnosis. This woman has now “recalibrated.” While the above is just an example, substantial evidence demonstrating response shift exists. For instance, many people with chronic illness report overall QoL scores that similar to those of healthy individuals or those with milder conditions (Sprangers & Schwartz, 1999), a phenomenon known as the “disability paradox” (Higginson & Carr, 2001). This is yet another example of why condition-specific measures may be more relevant than generic measures – that is, the focus needs to be placed not on understanding generic health or QoL but on the impact of the medical condition (and/or its treatment) on QoL.

If response shift is not accounted for in clinical research, then it will be difficult to assess if or how QoL may have changed (or not) from baseline. Additionally, response shift undermines the psychometric properties of QoL measurements, which thereby makes them difficult to analyze. Various study designs have been proposed to assess response shift, including qualitative in-depth interviews with patients, assessment of patients’ QoL for a previous time concurrently with a present time (which thereby means the same internal standards are used), and statistical methods, such as structural equation modeling or item response theory. Of note, while response shift presents some methodological challenges, it also represents important adaptations to conditions, which should be encouraged and celebrated in QoL research (discussed further in section “Post-traumatic Growth”).

New Methods for Measurement

In measures derived from traditional psychometric methods (i.e., classical test theory, CTT), a QoL score is often aggregated across various dimensions, which inherently assumes that dimensions are equivalent, e.g., physical health and mental health are of equal importance to QoL. However, this might not necessarily be the case (Cella, 1994). In response to the limitations posed by CTT, item response theory (IRT) is being used increasingly in the development, validation, and interpretation of health-related constructs, including QoL (Edelen & Reeve, 2007). IRT refers to “a set of generalized linear models and associated statistical procedures that connect observed survey responses to an examinee’s or a subject’s location on an unmeasured underlying (‘latent’) trait” (Hays, Morales, & Reise, 2000). While IRT is yet to be applied widely in health and QoL research, it offers several advantages for measurement, including the ability to (1) more comprehensively evaluate item characteristics, (2) assess group differences in item and scale differences, (3) evaluate scales containing items with different response formats, (4) improve existing measures, (5) use computerized adaptive testing, (6) model change, and (7) evaluate person fit (Edelen & Reeve, 2007).

One of these benefits, computerized adaptive testing (“CAT”), uses IRT item banks and computer technology to create a more tailored, individualized assessment (Cella, Gershon, et al., 2007). In this mode of administration, item selection is guided by a participant’s response to previous questions (Cella, Gershon, et al., 2007). Because each individual item in IRT measurement is calibrated in relation to the construct being assessed (rather than the entire scale being calibrated in relation to the construct, as is common in CTT), individuals may complete shorter assessments without compromising the precision or validity of results (Cella, Gershon, et al., 2007). In addition to real-time data entry, quick display of results, and ease of scoring, CAT allows for brevity and reduced testing burden for individuals, which may be of substantial value to both clinicians and researchers. Already used in large-scale testing initiatives, such as the “Graduate Record Examination” (GRE) (Cella, Gershon, et al., 2007), when and how to incorporate IRT and CAT into QoL assessment will represent one of the leading questions for the next generation of QoL researchers.

Summary

In summary, the selection of appropriate measures for any given situation will often require a trade-off between seemingly irreconcilable imperatives – sensitivity, specificity, brevity, robustness, reliability, validity, interpretability, burden, and cultural/language adaptations (best practices for cultural adaption of QoL measures are discussed further elsewhere (Guillemin, Bombardier, et al., 1993; Wild, Grove, et al., 2005)). While no single measure will be suitable for every situation, care taken in the development and selection of appropriate measures will be rewarded with achievement of robust data, from which valid and meaningful findings can be derived. That being said, it is important to keep in mind that when evaluating QoL measures, an instrument that works well for one setting, population, or purpose, may not work well in another. Indeed, even when measures are "validated," that does not necessarily mean that they can or should be used in other circumstances.

In the following sections, the term PRO is used as an umbrella term in preference to QoL. While every effort has been made to select studies in which the impact of health-related or condition-specific QoL has been assessed using appropriate instruments, the literature is replete with studies in which a related outcome, e.g., health status, has been assessed and interpreted as QoL. Where we, the authors, consider that such interpretations are reasonable, we have included them among our illustrations of how medical treatments can enhance or damage QoL. However, the reader is urged to consider the literature with a certain level of caution and constructive criticism.

Chronic Conditions and New Models of Healthcare Delivery: Impacts on QoL and Other Patient-Reported Outcomes

> As our society ages and chronic disabling conditions increase in prevalence, the traditional emphasis of our health care system on cure, longevity, and quantity of life has begun to shift to an emphasis on quality of life. (Institute of Medicine Committee on Assessing Rehabilitation & Engineering, 1997)

Challenges for QoL and Other PROs by Chronic Conditions and Their Management

Impacts of Chronic Conditions

The great increase in life expectancy is one of humanity's major achievements; however, population aging has, arguably, contributed to a worldwide epidemic of chronic diseases. With impacts on morbidity and mortality, chronic conditions may substantially affect the QoL for individuals who live with them, as depicted in Fig. 33.1. In addition to physical symptoms, such as pain, mobility, and nausea, which may extend for indefinite periods of time, individuals with chronic conditions are often live with increased stress, healthcare costs, emotional distress, stigma, and decreased social health (Institute of Medicine, 2012).

It is widely accepted that the symptom profile associated with a condition is a fundamental contributor to the QoL experienced (Testa, 2000). However, there are challenges inherent in understanding and interpreting the relationships between symptoms and QoL, particularly where medical interventions are concerned. For instance, various aspects of symptoms (e.g., frequency, severity, duration, and symptom-related distress or bother) contribute to an evaluation of QoL. Thus, the impacts of schizophrenia, which is highly stigmatized and characterized by relapsing symptoms and episodes, may have a very different impact on QoL than asthma, which can cause daily and weekly symptoms that affect physical and role functioning (Institute of Medicine, 2012). In addition to differential signs and symptoms, the medical treatments and management regimens required by chronic conditions also vary, as discussed in the following section.

Impacts of Chronic Disease Management

Traditionally, within healthcare, emphasis has been on biomedical efficacy and outcomes (and, hence, on treatment engagement also), but the growing emphasis on QoL derives from the fact that long-term conditions entail self-management rather than cure and the motivation to achieve better biomedical outcomes balanced with better life quality in terms of personally important aspects of life. Some chronic conditions (e.g., rheumatoid arthritis) need long-term pharmacological treatment and are often characterized by progressive physical disability and pain. Others (e.g., type 2 diabetes) are often asymptomatic, but the lifestyle changes or long-term pharmacological treatment required to optimize blood glucose levels and prevent long-term complications requires significant engagement in self-management regimens, which may impair QoL – in the absence of symptoms (e.g., pain) being reduced, optimal self-management can seem overwhelmingly burdensome in the trade-off for long-term health. Thus, through treatment burden and side effects, effects of the condition, and lifestyle changes, chronic diseases have the potential to induce profound changes in a person's life, leading to negative effects on well-being and QoL, as depicted in Fig. 33.1 (Sprangers, Regt, et al., 2000). It should be noted that various personal, social, and environmental factors can impact on the individual's medical condition and ability to cope, but these are not depicted in the model, as the intent is to focus on the impact of the condition.

As discussed in section "The Importance of Assessing QoL,", QoL is recognized increasingly as an important, valid, and reliable measure of the impact of a chronic condition, especially given the need to assess morbidity and impact of treatment (Rees, O'Boyle, & MacDonagh, 2001). However, there are some challenges to consider when assessing QoL outcomes related to medical conditions and their treatments. For instance, people living with diabetes often feel challenged by their condition and daily self-management routines. These demands can be substantial and can be overwhelming for people with type 2 diabetes, involving countless decisions every day regarding diet, physical activity, and self-monitoring – an often futile effort to achieve within target blood glucose levels. Medications, in particular insulin, can substantially affect QoL, either positively (by reducing symptoms of high blood glucose) (Hajos, Pouwer, et al., 2011) or negatively (by increasing symptoms of low blood

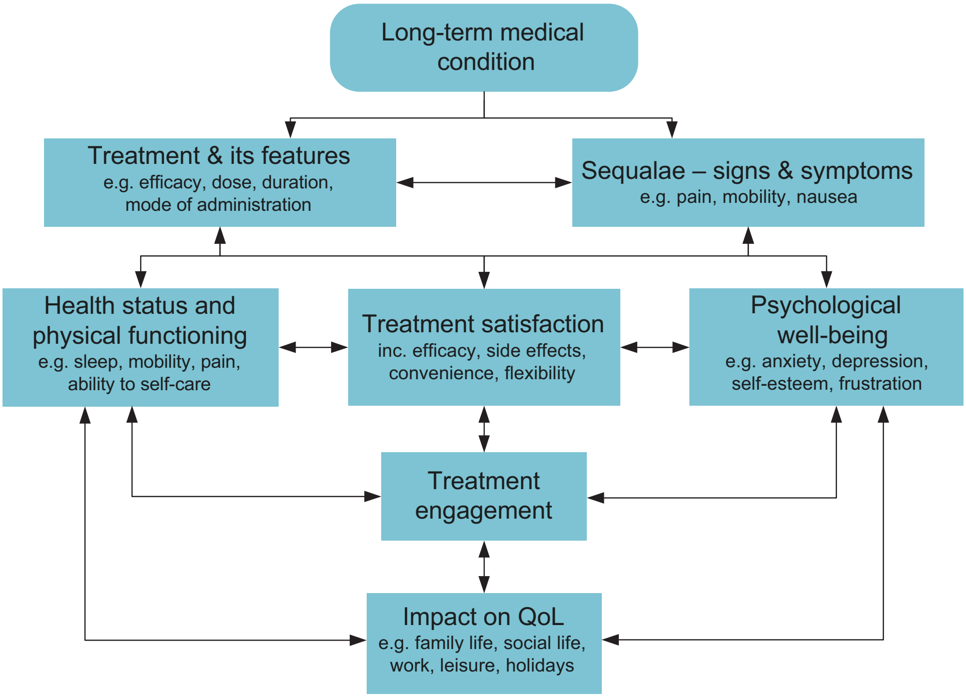

Fig. 33.1 Conceptual model of the impact of a long-term medical condition on QoL

glucose (Marrett, Radican, et al., 2011) and/or imposing restrictions on lifestyle). The problem is that this can be rather difficult to predict. Additionally, the psychosocial toll of living with diabetes is often heavy, and this can, in turn, affect self-care behavior, long-term glycemic control, the risk of developing long-term complications, and ultimately QoL (Rubin & Peyrot, 1999). Moreover, the presence of diabetes-related complications is associated with a more impaired QoL compared to those with no complications (Rubin & Peyrot, 1999).

Despite their potential to be lifesaving, many medical treatments have unpleasant side effects that can compromise QoL. Such side effects span a continuum from universally to infrequently occurring and may have physiological and/or psychological causes. Historically, a focus on "compliance" to medical treatments centered on patients not conforming to the clinician's better judgment, exhibiting apparently inappropriate attitudes and behaviors (Tilson, 2004). However, it is now more widely recognized that medication side effects may impair QoL and well-being (or cause other health concerns), which understandably lead to reduced treatment engagement (as the person makes a trade-off between treatment efficacy, side effects, and convenience/flexibility). Indeed, in more extreme cases, QoL may be compromised so severely that the person may miss treatment appointments or be unwilling/unable to continue treatment, regardless of whether medication is curative, management focused, or palliative (Morrow & Hickik, 1993). In cancer, for example, appetite and weight loss are significant side effects of both chemotherapy and radiotherapy. Clinical malnutrition, though rare, is associated with increased morbidity and mortality, while food aversions are relatively common and can affect daily routines and detract from QoL at a time when quality may outrank quantity of life (Jacobson, 1993). In cancer therapy, a number of solutions have focused on providing sufficient preparatory information (e.g., a tour of the oncology clinic, discussion sessions) to improve coping with treatment (Burish, Snyder, & Jenkins, 1991).

The behavioral aspects of treatment and their impact on QoL are well recognized, e.g., in terms of burden of treatment or self-management. However, unwanted physiological side effects of medically effective treatment regimens may also be detrimental to QoL. A prime example is that of antiretroviral therapy for HIV, which may entail significant adverse sequelae that threaten both QoL and engagement in treatment (Montessori, Press, et al., 2004). Similarly, the success of treatment for tuberculosis has been compromised in part by medication side effects (Forget & Menzies, 2006; Gleissberg, 2001). Such adverse effects are well recognized, but in other circumstances, treatment side effects may be overlooked or dismissed by health professionals. A pertinent example relates to side effects described by patients in the post-licensing period of a new medication and before a body of evidence has accrued regarding its long-term or real-world outcomes. If side effects have not been reported in significant numbers during pre-licensing trials (as might be the case where inclusion criteria are more tightly defined) but are then encountered in larger numbers post licensing, some time may pass before such side effects are widely recognized and acknowledged. Equally, new treatment regimens may also prove to have unwanted consequences.

Impacts on QoL for Partners and Caregivers

Over the past two decades, the prevalence of years lived with chronic disease and/or disability has steadily increased over time without any indication of slowing (Vos, Flaxman, et al., 2012). Improvements in (and rationalization of) healthcare have resulted in shorter hospital stays, while improvements in public health and nutrition have led to population growth and longer life expectancy. In the past, studies focused almost exclusively on the impact of the chronic condition and its management on the individuals' QoL. However, doing so ignores a large proportion of people also affected by the medical condition – the caregivers.

One prime example is Alzheimer's disease. From 2009 to 2013, there was a 17% increase in its prevalence, with the number of people with dementia projected to increase from 115 to 135 million by 2050 (ASD International, 2013). Alzheimer's is characterized by progressive cognitive decline usually beginning with impairments in the ability to form recent memories but inevitably affecting all intellectual functions and leading to complete dependence on others for basic functions of daily life and premature death. The symptoms, which include a broad range of distressing behaviors and psychological reactions, affect the health and QoL of not only the patient but also his or her caregiver (Callahan, Boustani, et al., 2006). Thus, the course of the condition creates many complex caring issues to the point that behavioral and psychological symptoms of dementia become a major challenge affecting an entire family's dynamic and well-being. From a QoL perspective, caregivers who look after people with Alzheimer's disease experience impaired physical, mental, and social well-being from the burden of living with the condition (Callahan, Boustani, et al., 2006).

Similarly, partners of people with cancer are more likely to experience significant severe cancer-related distress, treatment-related worries, and concerns about physical limitations and pain than the person with cancer themselves (Rees, O'Boyle, & MacDonagh, 2001). A number of studies involving people with cancer and their partners have also found that anxiety and depressive symptoms are more common among partners than patients and that many partners attempt to disguise their feelings (Rees, O'Boyle, & MacDonagh, 2001). For instance, among the partners of people with benign prostatic enlargement, despite the benign nature of the disease, 71% of partners were worried that their spouse had cancer and 59% were worried about the possibility of their partner requiring an operation (Sells, Donovan, et al., 2000). Carers of individuals with musculoskeletal disorders, spinal cord injuries, or rheumatoid arthritis have also been shown to have higher levels of depressive symptoms and lower health status scores than do non-carers (Weitzenkamp, Gerhart, et al., 1997; Brouwer, van Exel, et al., 2004). The level of morbidity in carers was only slightly less than that found in individuals with major depression. For carers of children with a mental illness or multiple types of disabilities, subjective well-being may be even lower than for carers of those with physical disability or chronic conditions (Hammond, Weinberg, & Cummins, 2014).

In general, partners who are caregivers face numerous challenges important for QoL, including impaired emotional well-being (fear of the future, hopelessness, depression/anxiety symptoms), deterioration in partner relationship and/or sex life, social isolation (incurred by looking after their spouse or loved one or finding it difficult to attend social functions alone), and struggling with combining their caregiving role with other responsibilities, such as looking after the family or work (Rees, O'Boyle, & MacDonagh, 2001). QoL can also be impaired by the great financial implications of managing chronic conditions and/or caregiving, especially for low-income families, e.g., costly medications, equipment, alterations to the home, or one or both partners needing to give up work to provide care (Rees, O'Boyle, & MacDonagh, 2001).

New Care Models for Chronic Diseases

Given the extensive QoL challenges experienced by people living with chronic conditions and their caregivers or loved ones, new models for organizing healthcare have been proposed. Not only have these models improved the delivery of healthcare and related processes but they also have shown promising benefits for QoL. The following section presents three such models: the chronic care model, the integrated model, and the collaborative care model.

Chronic Care Model

Although evidence exists that a structured, proactive, and person-centered approach helps to improve health outcomes, current delivery of care is often fragmented and event driven (DISMEVAL RC, 2012). To help medical practices improve their quality of care for individuals with chronic conditions, Wagner and colleagues developed the chronic care model (CCM) in the 1990s (http://www.improvingchroniccare.org) (Wagner, Austin, et al., 2001). Nowadays, the CCM has become the most widely referenced model for chronic disease management and prevention activities. The CCM emphasizes that care should be planned, proactive, and person-centered, rather than reactive and focused on acute episodes. Additionally, it is designed to improve care in health systems at the community, organization, practice, and patient levels. The model identifies six key elements as essential to the provision of high-quality care to individuals with chronic illnesses: (1) self-management support, (2) provision of clinical information systems, (3) delivery system redesign, (4) decision support, (5) improved healthcare organization, and (6) the use of community resources. For example, the element “delivery system redesign” focuses on transforming a system that is essentially reactive into one that is proactive, thus ensuring individuals interacting with the system receive structured and planned care, as well as follow-up consultations, as standard procedure (Petersen, Paulitsch, et al., 2014).

Interventions involving one or more elements of the CCM have shown beneficial effects on clinical outcomes and care processes. A comprehensive review of interventions to improve care for chronic illness identified 112 studies for inclusion in a meta-analysis (Tsai, Morton, et al., 2005). The authors concluded that interventions incorporating one or more CCM elements had beneficial effects on clinical outcomes and care processes, and these effects were consistent across a variety of chronic conditions, such as asthma, congestive heart failure, depression, and diabetes. Overall, the authors also found statistically significant effects for improved QoL and PROs, except for those studies involving asthma and diabetes, for which no effects were found. The authors were unable to conclude which elements of CCM were most effective (and it should be noted that CCM has been designed as a “complete package”), but results suggested that delivery system design and self-management support may be particularly promising.

Although the CCM is an evidence-based framework for improving chronic illness care, it is not without its limitations. In particular, some authors have noted that it lacks specificity for meeting the multi-faceted requirements of individuals with multi-morbidity and little is known about the extent to which it has been implemented in routine primary care. Additionally, management of chronic illness depends on both practice-level and individual-level factors that CCM may not be able to overcome. Demonstrating this, Petersen and colleagues collected baseline data from an observational cohort study involving around 160 general practitioners (GP) and over 3000 patients with multi-morbidity in Germany (Petersen, Paulitsch, et al., 2014). The Patient Assessment of Chronic Illness Care (PACIC) questionnaire was employed to assess CCM elements, with higher scores indicating higher levels of care. Multilevel hierarchical modeling was used to identify associations between PACIC (as a dependent variable) and independent variables at the patient level and the practice level. The main findings were that (a) elements of CCM were not fully implemented in primary care practices for individuals with multiple comorbidities, (b) patient-level factors (e.g., higher social support, higher autonomy) and practice-level factors (e.g., solo practices) were associated with higher PACIC scores, and (c) implementation of certain CCM elements (i.e., goal setting and follow-up/coordination) was lacking in comparison to other more developed CCM elements (i.e., system design). In other words, the study found that elements of CCM were only partially in place for people with multiple comorbidities, thereby suggesting a critical area for future translational studies (Petersen, Paulitsch, et al., 2014).

Integrated Care Model for People with Multiple Comorbidities

Given the complex needs of people with challenging chronic conditions or multiple comorbidities, the integrated care model was designed to combine and coordinate care modules to meet the needs of the person rather than the disease(s). A well-accepted definition of the integrated care model's aims comes from Kodner and Spreeuwenberg who stated that the model was designed "to enhance quality of care and quality of life, consumer satisfaction and system efficiency for patients with complex, long-term problems cutting across multiple services, providers and settings" (Kodner & Spreeuwenberg, 2002). Inherent in this definition is the significance given to QoL, which along with functional health, was chosen as the ultimate outcome goal. Indeed, various studies have confirmed the importance of integrated care teams on improvement of QoL. This may occur through two mechanisms. First, integrated care teams can address the varied physical and psychosocial concerns in individuals with chronic conditions (Grumbach, 2003; Provost, Pineault, et al., 2011; Kirby, Chong, et al., 2008). Second, by transcending disease-specific approaches, a multidisciplinary, integrated care team can address the multifaceted nature of symptoms and treatments of people with multiple comorbidities.

The integrated model includes both essential elements of care (that have been widely studied and used in the literature) and novel elements, which are more specific to people with multiple comorbidities and enable both the individual and their healthcare providers to establish health goals and outcomes that are not disease specific (Sampalli, Fox, et al., 2012). The essential elements of the integrated care model identified in the literature include (1) a comprehensive assessment of the multifaceted diagnosis and symptom profile, (2) evidence-based care plans, (3) supporting behaviors to improve engagement with care plans, (4) coordination of care across the integrated care team, and (5) primary care physicians, specialists, hospitals, and community resources. Novel elements include:

1. A medical management scheme that facilitates the care of the patient across the spectrum of diagnoses and symptom profile
2. Multidisciplinary care that includes rehabilitation to improve functional health and quality of life
3. Care coordination appointments integrated into key phases of care delivery to ensure patient engagement and confidence in whole-person care and self-management
4. Education modules that provide skills and coping strategies to help manage the needs of the person
5. Person-relevant and identified self-management and behavior management supports at key phases of care delivery that are specifically designed to motivate and enhance the life skills of individuals to manage their constellation of problems better

The proposed model comprises four key phases, i.e., intake, integrated care, transition, and discharge, which seek to improve functional health and QoL, as shown in Fig. 33.2 (adapted from Sampalli, Fox, et al., 2012). Education modules that impart skills and coping strategies to enhance self-management and facilitate healthy behavior are also an integral aspect of this type of care delivery. Of note, both the CCM and integrated care model emphasize the importance of self-management (discussed further in section "Self-Management Interventions") as an intervention strategy to enhance QoL.

Collaborative Care Models

Collaborative care is the last model of healthcare delivery discussed. Not only has collaborative care shown improvements in physical health for people with chronic physical illnesses but it has also been shown as successful for individuals with mental health disorders. For instance, a 12-month cluster randomized controlled trial was conducted among 581 adults individuals with doctor-diagnosed depression from 51 primary care practices in the UK (Richards, Hill, et al., 2013). Intervention group participants received a collaborative care intervention, which included depression education, medication management, behavioral activation, relapse prevention, and primary care liaison, being delivered by care managers. The control arm participants received usual care from family doctors' standard clinical practice. Compared to those in the control group, those in the intervention group reported statisti-

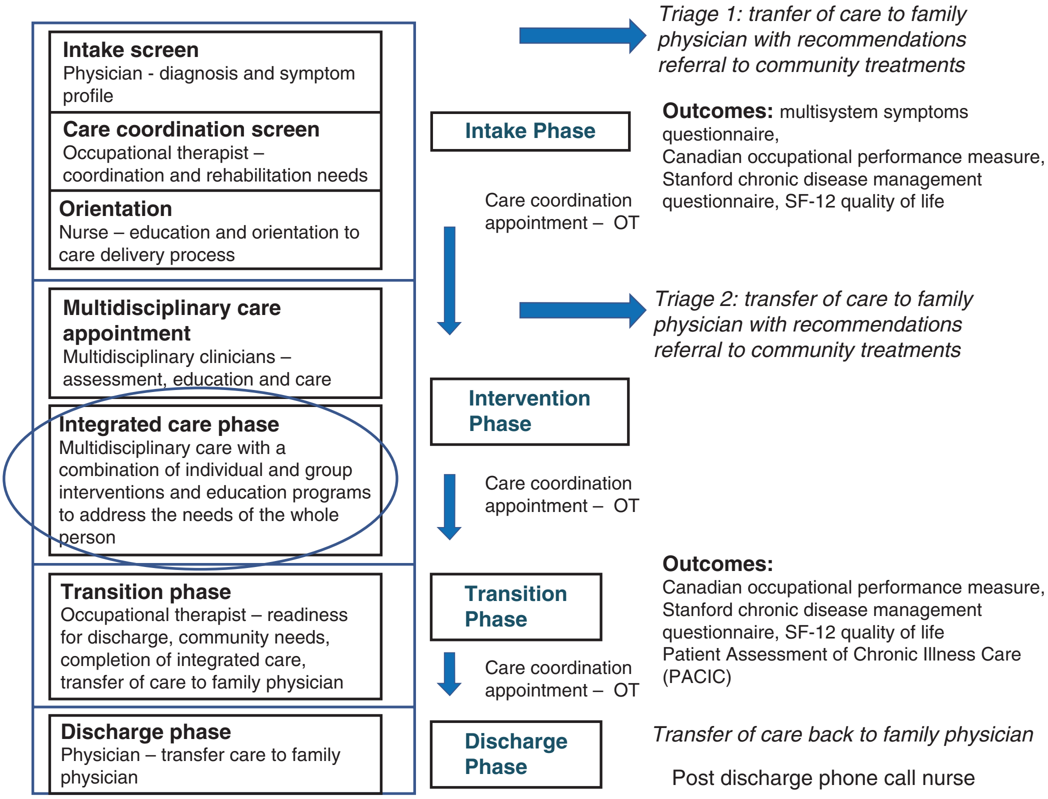

Fig. 33.2 A model of integrated care for people with multiple comorbidities (Adapted from Sampalli, Fox, et al., 2012)

cally significant improvements in depressive symptoms (PHQ-9) and mental health (SF-36) at 4 months. Furthermore, participants receiving collaborative care were significantly more satisfied with their treatment than their counterparts receiving usual care. The authors concluded that "collaborative care has persistent positive effects up to 12 months after initiation of the intervention and is preferred by patients over usual care" (Richards, Hill, et al., 2013).

With regards to the significant prevalence of comorbidities worldwide, these models suggests coordinated, integrated, and collaborative care may be appropriate for many individuals, particularly those with chronic illness, and lead to promising improvements in QoL and QoL-related dimensions, including physical, mental, psychological, and social well-being (Barnett, Mercer, et al., 2012; Bauer, Briss, et al., 2014).

Interventions to Enhance QoL

> "In light of findings that, with the exception of mood, health-related variables exert only indirect effects on quality of life, we must put into perspective any expectations we have of influencing our clients' life quality through health-related interventions." (Anderson & Burckhardt, 1999)

If QoL is conceptualized to include multiple dimensions, including mental and physical health, but also nonmedical factors, such as psychosocial variables, social and role participation, and spiritual well-being among others, then it follows that in order to improve QoL, interventions may need to focus more broadly than improvement of health alone (Anderson & Burckhardt, 1999). Even when interventions are designed to improve health, QoL improvements may result if changes in self-perception, perceived social support, or other psychosocial factors occur (Anderson

& Burckhardt, 1999). For these reasons, in this section, we present examples of how interventions may enhance QoL, not necessarily through improvements in health, but through other processes.

Post-traumatic Growth

Chronic illness affects multiple aspects of an individual's life, no doubt leading to significant impairment of QoL (discussed in section "Challenges for QoL and Other PROs by Chronic Conditions and Their Management"). However, there is also reason to believe that some people find coping (adaptive) strategies to become well-adjusted to their altered life circumstances – "people exposed to even the most traumatic events may perceive at least some good emerging from their struggle" (Tedeschi & Calhoun, 1996). This may be related to the need to "make sense" of or find meaning in adversity – a desire to see illness as part of life, a challenge, rather than to feel dominated by illness (Jacobi & MacLeod, 2011). It may also be related to response-shift (discussed in section "Response Shift"), in which people with chronic or life-threatening conditions may not rate their QoL as significantly poorer than people with milder conditions or those who are healthy (Higginson & Carr, 2001). In the context of behavioral interventions, this phenomenon is called "post-traumatic growth" and defined as positive change or transformation that may occur following a traumatic event (Tedeschi & Calhoun, 1996). Although it may seem counterintuitive, in response to traumatic events, some people report finding a life purpose, enhanced self-assurance, closer family relationships, emotional growth, increased desire to enhance relationships, appreciation for life, and strengthening of religious beliefs (Tedeschi & Calhoun, 1996). While this may not occur for all individuals, research has shown that many people with chronic disease reach a state of psychological adjustment, not merely from the passage of time or absence of distress, but as a separate phenomenon (de Ridder, Geenen, et al., 2008; Antoni, Lehman, et al., 2001).

If people can naturally experience growth after traumatic events, then there is reason to believe that interventions could also foster such growth, thereby improving QoL. Indeed this hypothesis has been confirmed, and interventions have been shown to positively enhance growth and meaning finding, especially among those with cancer (de Ridder, Geenen, et al., 2008). For instance, a cognitive behavioral stress-management intervention for solution-focused coping strategies (e.g., active coping and planning) and emotion-focused coping strategies (e.g., relaxation, emotional support) was implemented with women with breast cancer. Compared to control group participants, those in the intervention group had reduced prevalence of depressive symptoms, reported that having breast cancer made positive contributions to their lives, and increased generalized optimism (Antoni, Lehman, et al., 2001). Effects were strongest for women who were lowest in optimism at baseline, thereby suggesting that the intervention was most effective for women who needed it the most (Antoni, Lehman, et al., 2001). In another study, researchers asked women with early-stage breast cancer to write down their thoughts and feelings regarding breast cancer. Those randomized to the experimental condition experienced fewer visits for cancer-related morbidities at 3 months and decreased somatic symptoms (Stanton, Danoff-Burg, et al., 2002). Again, effects were most pronounced for those with the highest cancer avoidance – in other words, women who had intentionally attempted to avoid thoughts and feelings regarding cancer (Stanton, Danoff-Burg, et al., 2002). Post-traumatic growth interventions are noteworthy for two reasons: (1) they actively take a strength-based approach to improving health and well-being (i.e., focusing on the person's own positive factors and strengths) and (2) in addition to their effects on health, they also improve psychosocial outcomes related to QoL.

Social Support Interventions

Another psychosocial factor of importance for QoL is social support, which has been demonstrated as a clear protective factor for health. In fact, social support is so powerful that researchers have found a 50% reduction in the likelihood of mortality for individuals with strong social relationships, comparable with the benefit for mortality in those who do not smoke (Holt-Lunstad, Smith, & Layton, 2010). In addition to its health benefits, interventions have demonstrated consistently the importance of social support on QoL: "Although health may become an increasingly important determinant of quality of life as health status deteriorates, other influences – particularly interpersonal relationships – remain vital to individual judgments of life quality even in the presence of chronic illness" (Anderson & Burckhardt, 1999). A systematic review of factors affecting QoL in long-term survivors of breast cancer found strong evidence for social support as a significant predictor of decreased emotional distress and increased QoL (Mols, Vingerhoets, et al., 2005). Further evidence of the association between social support and QoL has been demonstrated for those with HIV/AIDS (Friedland, Renwick, & McColl, 1996), diabetes (Tang, Brown, et al., 2008; Fisher, La Greca, et al., 1997; King, Glasgow, et al., 2010; Gallegos-Carrillo, Garcia-Pena, et al., 2009), congestive heart failure (Barutcu & Mert, 2013) among others.

Despite the overall importance of social support in QoL research and practice, important questions remain with regard to translating these findings into practice. For instance, what type and quantity of support are needed? For what type of situation? Who should provide support? Should it come from people within an individual's existing social network or should it come from strangers? What are the relative advantages and disadvantages of both? When should support be provided? At what stage of a health condition? Does it matter what type of support the patient wants? Should we pay more attention to received social support or perceived social support? Can social support be harmful and in what circumstances? Although there may be no clear answers to these questions, considering them in the implementation of QoL interventions will help practitioners (and patients in delivery and receipt of support), especially given the need for translation of social support research into active intervention trials.

Self-Management Interventions

As discussed in section "New Care Models for Chronic Diseases," the importance of self-management has been demonstrated by its inclusion in modern models of healthcare delivery. While self-management may generally improve a person's health status, through promotion of necessary knowledge, skills, and motivation, it also includes benefits for QoL (de Ridder, Geenen, et al., 2008; Cochran & Conn, 2008; Thorpe, Fahey, et al., 2013). A notable example of the positive impact of self-management on QoL comes from the cancer literature. Although cancer has traditionally been viewed as an acute, life-threatening chronic condition, with recent improvements in the early detection, diagnosis, and treatment of cancer, people are living with cancer as a long-term condition and need to become skilled in self-management. Cancer as a chronic condition places new demands on individuals and their families to manage their own care, and it challenges old paradigms that oncology's work is done after treatment (McCorkle, Ercolano, et al., 2011). Over the past two decades, a number of intervention studies have demonstrated significant improvements in patient outcomes at various phases on the cancer care continuum. A systematic review analyzed 16 randomized controlled trials of self-management interventions with cancer patients and families in the treatment, survivorship, and end-of-life phases of the cancer care continuum between 1992 and 2007 (McCorkle, Ercolano, et al., 2011). The self-management interventions positively affected prognoses in terms of symptom distress, uncertainty, problem solving, communication, and general QoL. These interventions, however, depended on the organization of oncology practices (e.g., whether they were designed to help patients and families in self-management efforts), thereby suggesting the importance of self-management as integrated with improved models for healthcare delivery.

Similarly, in people with type 1 diabetes, structured self-management education programs focused on providing participants with the skills to manage insulin flexibly, thereby promoting dietary freedom, have also been shown to improve diabetes-specific QoL (DAFNE Study Group, 2002). Furthermore, such benefits for QoL are maintained in the long-term (demonstrated for up to 4 years) (Speight, Amiel, et al., 2010) and also when such programs are delivered as part of routine care (as opposed to a clinical trial setting) (Cooke, Bond, et al., 2013). Over the past decade, self-management interventions for individuals with diabetes have also incorporated innovative technologies to assist with glucose monitoring and QoL (Thorpe, Fahey, et al., 2013; Fisher, Thorpe, et al., 2007). For instance, fear of hypo- and hyperglycemia, especially at nighttime, is a common concern among individuals with type 1 diabetes (Barnard, Wysocki, et al., 2014). To alleviate these concerns, continuous glucose monitoring can provide real-time feedback, which can then alert individuals' insulin pumps to provide insulin slowly throughout the day and night depending on the individuals' physiological needs. These "closed loop" systems can prevent hypoglycemia, and studies have demonstrated their potentially positive impacts on QoL (Rubin & Peyrot, 2009).

Although benefits of self-management have been demonstrated consistently across various chronic conditions, it should be noted that such interventions do not *always* improve health or QoL; this variance may be tied to the extent that individuals view self-management programs (and self-management itself) as burdensome or not. In a study of 292 adults with diabetes, people who adhered to self-management activities reported more positive health outcomes (Weijman, Ros, et al., 2005). However, among people who viewed these activities as burdensome, poorer health outcomes were observed (Weijman, Ros, et al., 2005). Thus, an important question is raised regarding the utility and direction of self-management interventions designed to improve QoL. How can interventions help those who may be hard to reach? This question is especially pertinent given the often low retention and rates of engagement with self-management routines (de Ridder, Geenen, et al., 2008).

While the organization of this section may lead the reader to believe that interventions to improve QoL (i.e., post-traumatic growth, social support, self-management) may be distinct, research suggests that combining aspects of these interventions can lead to synergistic effects with particularly promising benefits for QoL. For instance, many studies have looked at social support combined with self-management and found significant benefits. Among strategies for improving QoL within interventions, peer support (e.g., "community health workers," "lay health advisors," "*promotores*") deserves special attention. In addition to helping provide encouragement and assistance with daily management of health conditions, peer supporters provide emotional support and encourage problem solving to address emotional distress (Rahman, Malik, et al., 2008). From the perspective of reaching populations, peer supporters can also engage those who otherwise not receive appropriate care (Boothroyd & Fisher, 2010; Fisher, Strunk, et al., 2009). Moreover, not only has peer support been applied to self-management of diabetes and other chronic conditions, e.g., (Fisher, Strunk, et al., 2009; Heisler, Vijan, et al., 2010; Thom, Ghorob, et al., 2013; Fisher, Boothroyd, et al., 2012), it has also been used with self-management for a variety of mental health problems (Rahman, Malik, et al., 2008). Thus, the combination of peer support and self-management regimens have shown promising improvements in not only QoL and components related to QoL but also other factors of importance, including intervention reach and sustainability.

Conclusions and Practice Implications

> Arguably, optimizing HRQOL may be the most substantial impact the health care team will have on the person. (Unruh, Weisbord, et al., 2005, p. 82)

Over the past few decades, a growing body of evidence has demonstrated the value of QoL measurement for various purposes: to identify the holistic impact of chronic medical conditions, to determine ways to improve medical treatments, and to guide the selection (and rationalization) of treatments and regimens. With the introduction and increasing use of brief instruments in clinical research, routine implementation of QoL assessment in clinical practice is closer than it was 10 years ago. However, before the true benefits of QoL assessment are to be realized, substantial barriers to the adoption of QoL measurement in clinical practice need to be overcome. In this section, we present the practice and policy implications needed for integration of QoL.

Practice Implications

While formal assessment of QoL in research settings is relatively straightforward and increasingly commonplace, QoL assessment has yet to be incorporated routinely into clinical practice. In 2002, Levine and Ganz (2002), p. 2216 identified "the challenge for the next decade": "How does the measurement of quality of life in groups of patients and the administration of a quality-of-life questionnaire to an individual patient ultimately improve care?" A decade on, readiness to incorporate QoL assessment into clinical practice is still less than optimal. In a time- and resource-limited clinic environment, formal assessment of the QoL of individuals is a competing procedure – albeit one which offers significant benefits if adopted – and often seen as secondary to the pursuit of biomedical improvements. A number of barriers to routine inclusion of QoL assessment in clinical care remain:

1. On a practical level, appropriate measures, clinic resources, and additional time are required to conduct meaningful and useful QoL assessment.
2. Interpreting outcomes at the individual level is challenging but necessary if truly person-centered care is to be achieved and QoL, medical outcomes, and treatment engagement are to be optimized.
3. Beyond a willingness to engage with QoL assessment in clinical practice, health professionals require training in the conduct and interpretation of results.
4. Health professionals may sometimes be reluctant to use QoL measures if they fear that clinical priorities and QoL preferences are irreconcilable; hence they may choose to focus more tightly on medical outcomes which they more easily understand and/or perceive to be of greater value.
5. Ethical considerations arising from QoL measurement may be challenging. For example, if QoL is to be assessed and measured, but unable to be influenced, then what is the purpose of measuring it? (Higginson & Carr, 2001) Should QoL measurement be the concern of the clinician or does it represent an "over-medicalization" of life and clinical interference in patients' lives? (Higginson & Carr, 2001) What should be done if people face terminal or catastrophic illness/injury and express a wish to discontinue medical treatment which may be life sustaining?

Even where QoL assessment has been adopted into clinical practice, there is a shortfall in the application of results into appropriate clinical care and/or strategies – "from assessment to action" (Katschnig, 2006). Given the difficulty in routinizing QoL measures into clinical practice, a number of authors have presented considerations for review (see Table 33.2) (Higginson & Carr, 2001). For further reference on implementation of QoL measures in clinical care, we also refer readers to the International Society for Quality of Life Research (ISOQOL), which has developed a User's Guide for Implementing Patient-Reported Outcomes Assessment in Clinical Practice (Snyder, Aaronson, et al., 2012) (available at www.isoqol.org).

Linking QoL to Medical Consultations

Despite the many challenges inherent in integration of QoL assessment and routine clinical care, discussing QoL outcomes with individuals is important for two related reasons: (1) it can help inform therapeutic changes based on shared decision-making and linked care pathways and (2) it acknowledges the importance of QoL as an outcome in its own right. Regarding the former, some studies suggest the promise of incorporating QoL assessment into clinical care. For instance, Velikova et al. found that routine, repeated HRQoL measurement with feedback of results

Table 33.2 Considerations when implementing QoL measures into clinical practice (Adapted from Higginson & Carr, 2001)

Phase	Key questions
Planning	What are the goals of the practice and purpose for using the QoL measure? What measures are already used? Which QoL measure should be used? Is the measure valid, feasible to use, interpretable, responsive, and clinically relevant? What should the timing of assessment be? What will be the mode of administration? Will other outcomes also be monitored? How can staff and patients be involved?
Implementation	Who needs to be trained for use of the use of QoL measures? Should a pilot testing of the use of the measure be conducted? Who will the results be reported to? What is the process for reporting results? What strategies can be used to respond to issues?
Assessment	What aids exist to facilitate score interpretation? What is the impact of the measure? How should impact be communicated?
Modification	How should the measure or processes for implementation be modified? What are next steps for continued use of the measure?

led to improvement in HRQoL and emotional well-being compared to those in attention-control and control groups (Velikova, Booth, et al., 2004). Regarding the latter, assessment of QoL by providers underscores the broader context of patients' lives that may not be reflected in conventional medical consultations. To this end, medical providers have begun incorporating QoL into their medical consultations – two examples of which are provided below for reference.

In response to guidelines from the International Society for Pediatric and Adolescent Diabetes calling for routine assessment of QoL, Eilander and colleagues (2016) implemented a QoL monitoring intervention in 11 Dutch pediatric diabetes clinics (Eilander, de Wit, et al., 2016). Prior to implementation, clinical teams were offered 1 day training on how to use and discuss QoL with adolescents. Annually, adolescents completed a web-based measure of diabetes-related QoL prior to periodic consultation with their diabetes providers. During in-person consultations, the clinical team discussed outcomes with their patients. Surveys after implementation showed that most providers believed that discussing QoL contributed to adolescents' health (66.7%) and felt that the tool had additional value to routine care (91.7%) (Eilander, de Wit, et al., 2016). Moreover, the majority of providers found that discussing QoL contributed to the recognition of psychosocial problems (94.4%), that the conversations helped to talk about QoL in more detail (86.1%), and that the conversation differed from their prior expectations (58.3%) (Eilander, de Wit, et al., 2016). Consistent with these findings, most adolescents felt they were "heard" by providers (85.2%), and most parents found the intervention beneficial to their child (78.8%) (Eilander, de Wit, et al., 2016). Despite these benefits and a high level of motivation to incorporate QoL assessment into routine care, clinics struggled with logistics, such as time, manpower, and workflow design (Eilander, de Wit, et al., 2016).

To assess the HRQoL of children with cancer, Engelen and colleagues (2012) asked children to complete an HRQoL assessment with four domains (physical, emotional, social, and cognitive functioning) and then instructed pediatric oncologists to discuss the items identified as a problem (compared to health norm scores or change in items over time) (Engelen, Detmar, et al., 2012). Prior to implementation, extensive formative research and training were conducted with providers and patients. Compared to control group participants in the intervention group, the use of the PRO increased the amount of psychosocial topics discussed in medical consultations (as recorded in audio consultations) (Engelen, Detmar, et al., 2012), increased discussion of emotional and psychosocial functioning (Engelen, Detmar, et al., 2012), and improved HRQoL related to self-esteem, family activities, and psychosocial functioning (Engelen, Detmar, et al., 2012). Importantly, these benefits occurred without lengthening the medical consultation visit (Engelen, Detmar, et al., 2012).

From both of these studies, three important considerations are noted. First, prior to implementation, medical practices were involved in considerable training and engaged in formative research on design, integration, and feedback on the use of QoL assessment. Given the significant barriers regarding implementation of QoL interventions discussed above, further research will be needed to explore organizational factors facilitating integration of QoL assessment. Second, in both studies, the majority of clinical providers discussing QoL with patients were doctors; however, to some extent, both studies also included nurses or nurse practitioners and emphasized the importance of involving different clinical team members, such as social workers, psychologists, nurses, and nurse practitioners. Integrating routine QoL assessment into team-based models of healthcare delivery, discussed in section “New Care Models for Chronic Diseases,” represents an important avenue for future interventions. Lastly, the studies demonstrated considerable QoL-related improvements from both the patients’ and providers’ perspectives, including notably, patient-provider communication, which is important in its own right for patient satisfaction and quality of care.

Despite the benefits that may result from integration of QoL into clinical care, two caveats are noted. First, we caution that assessment and use of QoL in clinical care should not be a substitute for genuine communication with patients, especially given that interpretation and use of QoL results is anything but guaranteed. Second, a question remains regarding the best way that clinicians can improve QoL. In other words, should providers start assessing QoL and incorporating measurement into practice? Or would it be more beneficial to listen to patients and work collaboratively with them (as discussed in section “New Care Models for Chronic Diseases”)? Clearly, integration of QoL measurement into clinical care should not replace communication with patients or other methods for improving QoL. Instead, it may be viewed as a complement to alternative methods, many of which may also improve QoL in more direct or indirect ways.

Policy Implications

“Person-centered care,” “comparative effectiveness research,” “patient-reported outcomes,” and “meaningful use in ‘electronic health records’” are all twenty-first-century buzzwords in health and healthcare. While they have different meanings and are used in different contexts, they all to some extent refer to and incorporate the importance of acknowledging pursuit of QoL – a life of quality. In fact, QoL assessment has reached the national policy agenda in the USA, with two of the four principle goals for *Healthy People 2020* being directly related to QoL: (1) “attain high quality, longer lives free of preventable disease, disability, injury, and premature death” and (2) “promote quality of life, healthy development and healthy behaviors across all life stages.” Given these goals, increased attention is being paid to QoL on local, state, and national levels. Similar initiatives exist in many other countries.

However, several emerging changes in the national landscape are worth mentioning. First, EHRs (also referred to as electronic medical records (EMRs) and personal health records (PHRs)) are gaining widespread acceptance, through which PROs are increasingly being measured. Yet, important questions remain: How can these measures be used by both patients and providers? How can usefulness be optimized? How should QoL and PRO assessment be integrated with other outcomes?, etc. Second, many local and national surveillance systems are incorporating QoL and PRO measures into routine assessment (e.g., PROMIS; Behavioral Risk Factor Surveillance System "BRFSS"). However, it remains unclear which QoL measures should be used, how frequently measures should be collected, how different databases should be integrated, etc. Third, it is still challenging and complex to link the information derived from QoL assessment into policy decision-making (Ahmed, Berzon, et al., 2012). As discussed in previous sections, two of the complexities involved in QoL research are (1) how to interpret QoL assessments and (2) how to make decisions based on results (e.g., what is a QALY worth?). For these reasons, future QoL research will need to focus on how policy makers may derive the benefits of QoL that individuals and medical providers are also beginning to see.

End of Life Issues in Behavioral Medicine

34

Kevin S. Masters, Kristin M. Kilbourn, and Chad E. Barrett

Few topics that fall within the purview of behavioral medicine are as potentially contentious and politically charged as behavioral and medical intervention at the end of life. During the recent debate over universal healthcare in the USA, some activists accused the government of advocating a plan that would ration resources at the end of life and create "death panels" that would presumably make life and death decisions based on rigid bureaucratic algorithms. Earlier, the highly publicized case of Terri Schiavo, a patient in Florida who was kept alive via a feeding tube for approximately 15 years, served to highlight issues regarding advanced health-care directives, what it does and does not mean to be in a vegetative state, indeed, what is consciousness. The public debate surrounding this case lasted from 1998 to 2005. These are high-profile examples but everyday around the world individuals and their families must decide the course that their healthcare should take as they near the end of life.

Much of the current controversy is perhaps the inevitable result of changes that characterize the nature of life's final years in developed countries. Because of advances in medicine and allied fields, humans are now often confronted with information and related decisions regarding their end of life health-care preferences that were not imaginable throughout the overwhelming majority of human history. The case of Carnegie Mellon Professor Randy Pausch is illustrative. Professor Pausch is now well known worldwide for his *Last Lecture*, both an online video and best-selling book that capture a speech he gave at the university only months before his death due to pancreatic cancer. What makes this compelling for our purposes is that at the time of the speech Professor Pausch was keenly aware of his soon death because he had undergone advanced medical diagnostic procedures, but he felt very well. In fact, he performed several physical exercises during the talk to emphasize his high level of energy and good feeling. An individual with Professor Pausch's condition in previous generations would not have known what the future held and, therefore, would not have faced the same end of life issues. In fact, such is still the case in much of the undeveloped world.

Citizens in industrialized countries not only have more information and treatment options, but they also live longer and are much more likely to die slower deaths than in previous generations. Prior to the mid-twentieth century, compared to today, a much higher percentage of deaths were due to infections and accidents (Centers for Disease Control and Prevention, 2011b), and consequently the time from onset of illness to death

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_34

was relatively short. However, improvements in public health (e.g., clean water, vaccinations), the advent of powerful antibiotics, and greatly improved emergency medical services reduced the percentage of deaths that occur quickly. Instead, residents of developed countries are more likely to live with chronic, often debilitating, illnesses for many years prior to their death, and the final years of life are often marked by increasing symptom profiles and a corresponding decline in functionality. Further, the advance of medical technology and the concomitant ability to extend life often leave individuals facing challenging issues and questions regarding the quality, type, and extent of care that they or their loved ones will or should receive as life's end nears. This situation is complicated because many people simply do not want to seriously engage these issues until they are no longer avoidable. Consequently at a time of emotional distress, they are forced to consider, perhaps for the first time, complicated treatment options with probabilistic outcomes sometimes conveyed in a language that is not comfortable or familiar to them.

Common End of Life Experiences

In the context of these quickly changing health-care practices and possibilities, it has become, at least in developed countries, difficult to characterize "normal" dying. Of course some individuals still die quickly with little or no advance indication that their end of life is near, and others die of natural causes in old age with no diagnosable pathology. But many others live with chronic disease for years, and though the degree of precision in predicting time of death varies depending on the particular disease and its physiological progression, the overall course leading toward death is often reasonably well known.

At the end of life, individuals often experience anticipatory grief as they face their mortality. Anticipatory grief refers to the cognitive, affective, social, and culturally appropriate reactions to expected death, over past, present, and anticipated losses (Cheng Lo, Chan, et al., 2010). Importantly, they not only grieve for their anticipated loss of life, but for the loss of their hopes and dreams and their relationships, especially within their families. They also grieve for the significant changes in lifestyle associated with a terminal illness such as increases in symptom and pain severity, decline in functioning, fatigue, loss of independence and mobility, and greater reliance on others for basic needs (Lindemann, 1994). Kubler-Ross (1979) described five stages of grief: denial, anger, bargaining, depression, and acceptance. Though, it is now known that patients do not necessarily progress sequentially through each stage, and may not experience some stages at all, it is common for patients to have at least several of these experiences. However, based on a review of the literature, Telford, Kralik, and Kosh (2006) cautioned that health-care workers who have uncritically accepted the stages of grief model may not listen openly when people tell their own unique stories but may, instead, selectively listen for evidence of denial. This observation is concordant with the current trend toward patient-focused understanding of end of life, i.e., an emphasis on the unique experiences of each patient. Though not necessarily a rebuttal of the work of Kubler-Ross, the current emphasis highlights the fact that individuals providing proper end of life care must be open to unique experiences and interpretations of the dying individual. Later we discuss particular issues and experiences that are both common and problematic at the end of life.

Developmental Issues

Concerns unique to particular developmental stages in the life cycle may differentially impact patients' psychological responses to life-threatening illness. Though end of life concerns are often thought of in the context of older adults, in fact, younger individuals must also sometimes face this difficult reality. Young adults, who are in the midst of establishing their independence, often struggle with ambivalence about having to again depend on their parents. They may view their condition as unfair and struggle with feelings of anger, sadness, and grief about the loss of future experiences. Parents with young children typically worry about the impact of their illness, and death, on their children, maintaining routines and normal lifestyles in order to avoid upsetting their family, and how to discuss their illness with their children. They also typically feel a great deal of sadness and grief about missing their children grow up. Older adults are often concerned with existential issues. Feelings of satisfaction or unhappiness with past achievements can mitigate or exacerbate emotional distress. Older patients, in particular, tend to worry about their surviving spouse. They may also see their illness as unfairly cheating them out of the opportunity to retire and enjoy the fruits of a lifetime of hard work and as a result feel angry, frustrated, disappointed, grieved, and sad. Patients of an advanced age may see the approach of death as a relief. However, this can depend on whether they feel at peace with the life they lived and what kind of attachments, and connections, they have that provide a sense of meaning and vitality (Block, 2006).

Place of Death

Another recent change regarding end of life is where death actually occurs. Throughout history this has been primarily in the home or local village, but in many parts of the world this is less likely the case today. A study (Ahmad & O'Mahony, 2005) covering 20 years (1981–2001) that examined all death certificates in Wales reported a significant shift in location of death from the community to hospitals and care homes. Specifically, deaths in hospital increased from 56.7% to 61.7% and in care homes from 5.7% to 16.2%, whereas deaths in the community decreased from 37.6% to 22.1%. Similarly, Gomes and Higginson (2008) analyzed trends in death from 1974 to 2003 in England and Wales and based on these data made projections to 2030. They noted that home death proportions fell from 31% to 18% overall, and the decline was even steeper for people aged 65 and over. This is noteworthy because it is expected that more people will die at an older age in the next 20 years. If these trends continue, fewer than 10% of the population in the UK will die at home in 2030. Similar trends were noted for Japan and Italy. On the other hand, the USA, Australia, and Canada have seen reductions in the percent of deaths in the hospital. Flory and colleagues (2004) reported that in the USA between 1980 and 1998, there was a 13% decline in inpatient hospital deaths. According to data from the US Centers for Disease Control and Prevention (CDC, 2011a; http://www.cdc.gov/nchs/nvss/mortality/gmwk309.htm), this trend continued between 1999 and 2005 with an additional 3% decline in inpatient hospital deaths. Additionally, in 1999, 22% of deaths occurred at home whereas 24% died at home in 2005. Curiously, in 1999 the CDC worksheets had no category for hospice deaths. In 2005 they report that 1.38% of deaths occurred in hospice facilities.

Where individuals die is the result of an extremely complex chain of events that is influenced by factors that include: (a) presence or absence of advanced medical directives that may include living wills and the interpretation of these directives, do not resuscitate orders, and non-hospital do not resuscitate orders; (b) insurance coverage and policies; (c) cultural norms and values; (d) availability and type of palliative care services; (e) patient and family values; (f) psychological aspects of dying (e.g., fear of being unattended and suffering); (g) availability of information regarding care options; (h) physical condition of the patient; and (i) the availability and capability of the patient's family and social network. Gomes and Higginson (2006) recently reviewed the literature pertaining to home death among terminally ill cancer patients and identified several additional variables that predicted home death including low functional status, intensity of home care, patient preferences, living with relatives, use of home healthcare, extended family support, and caregivers' preferences. Interestingly, geographic areas with greater hospital provision and availability of inpatient beds predicted decreased odds of home death. Nevertheless, in spite of the relatively low numbers of home deaths, well over half of individuals with a progressive illness indicate that they want to die at home (Higginson & Sen-Gupta, 2000) though clearly more research into this area is needed.

Terminology: Palliative Care and Hospice Care

The concept of choice of treatments for individuals with a life-limiting illness implies that there are options. Clearly some patients desire aggressive treatment, i.e., treatment whose goal is to cure the illness or, at least, delay death for as long as possible. This might be characterized as the traditional Western approach. Other patients seek options that are not intended to lengthen life but increase the quality of life as it nears its end. Several terms are used to describe this type of treatment, but they are not always employed consistently in the literature or common usage. Palliative care is a term that is often misused, can be confusing to both patients and providers, and may not have a universally agreed upon definition. The US federal regulations for participation in Medicare as a hospice provider define palliative care this way: "Palliative care means patient and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness involves addressing physical, intellectual, emotional, social, and spiritual needs and to facilitate patient autonomy, access to information, and choice" (§418.3, June 5, 2008). Noticeably absent in this definition is any mention of end of life though the fact that it is stated in federal regulations for hospice care allows that it might be interpreted as an end of life treatment. Both the National Palliative Care Research Center (NPCRC) and the World Health Organization (WHO) similarly define palliative care with an emphasis on relieving suffering, achieving the best possible quality of life, and attending to psychological and spiritual aspects of care. NPCRC, in reference to palliative care, states, "It is **offered simultaneously** with life prolonging and curative therapies for persons living with serious, complex, and eventually terminal illness" (National Palliative Care Research Center, 2011 emphasis in original) (What is palliative care?, para. 1), and the WHO definition similarly notes that palliative care "is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life…" (WHO definition of palliative care, para 1). Thus, although end of life care might include or in some cases entirely consist of palliative care, palliative care is not synonymous with end of life treatment and may, in fact, be administered in cases where death is far from imminent. Palliative care is not intended to either hasten death or extend life but is life affirming and supports the patients' and families' wishes including support for continuing treatments that attempt to cure or prolong life. Thus it is important to distinguish hospice care from palliative care.

Both hospice and palliative care share the goals of reducing suffering and improving quality of life, neither are focused on attempting to cure the illness, and both are typically offered by interdisciplinary treatment teams that include behavioral medicine professionals. But hospice is provided solely for patients for whom death is imminent, whereas palliative care may be provided both in cases of imminent death and in cases where death is not near. In a sense hospice care may be thought of as a subset of palliative care. It is also important to note that hospice care may be delivered in a number of settings, and thus describing care as "hospice" does not necessarily indicate that the individual must be treated in a particular facility. Hospice care may take place at home, in a designated hospice care facility, in a hospital, or in an advanced care treatment facility. In the USA the median length of provision of hospice service in 2009 was 21.1 days, and the mean was 69.0 days (National Hospice and Palliative Care Organization [NHPCO], 2010). Hospice care has been growing in the USA. In 1984 100,000 patients were treated by hospice whereas in 2009 the number was 1,560,000 (NHPCO), or approximately 41.6% of all deaths in the USA were under the care of a hospice program. Hospice has also grown in other countries, but the rates of growth are not uniform and are influenced by many factors including origins and establishment of hospice, connotation of language and symbols, religious considerations, cultural considerations, administration of hospice services, and governmental involvement (Glass, Chen, et al., 2010). Glass and colleagues (2010) provide an interesting review and comparative analysis of the development and acceptance of hospice in Japan, South Korea, and Taiwan. Though there are many similarities across the countries, there are also important differences in, for example, development of a national policy, degree of hospice home care, when hospice was started, and number of trained professionals and multidisciplinary nature of the treatment team.

Roles for Behavioral Medicine Practitioners in End of Life Care

Largely due to these changes in how end of life is often experienced in developed countries, behavioral medicine practitioners are potentially important members of interdisciplinary treatment teams. But it is essential that behavioral medicine providers are clear on their own ability to handle death and dying, and they must be attentive to signs of burnout, depression, or other emotional sequelae that may reduce their professional effectiveness. Not all behavioral medicine practitioners are personally well suited to manage the types of challenges that characterize these patients and this kind of treatment, but for those who are capable, they bring to the treatment team important and possibly unique skills. In many cases the roles for behavioral medicine are straightforward, whereas in others (e.g., spirituality) they may be more complex. The specific skills that capable behavioral medicine practitioners bring with them to end of life care include: (a) utilization of empathic listening and reflection in the context of relationship development; (b) implementation of cognitive-behavioral interventions to alleviate pain, insomnia, anxiety, and depression; (c) intervention with families to improve communication regarding difficult treatment decisions; (d) assisting patients and their families to understand medical terminology and the nature of medical treatments and options; (e) utilization of relaxation and self-control strategies; (f) providing psychotherapy for patients struggling with issues of guilt, regret, and grief as well as anger management; (g) helping patients and caregivers develop appropriate coping skills; and (h) leading group-based interventions for patients as well as their families and caregivers. Particular discussion of patient issues, caregiver concerns, and interventions will be addressed below as will the role of behavioral medicine in spirituality.

Patient-Oriented Issues in End of Life Care

Suffering is a common experience for patients and their families at the end of life. Feelings of sadness, grief, loneliness, despair, fear, anxiety, and anger may be present. The sources of psychological suffering at the end of life are many and include uncertainty about the future, unresolved issues from the past, and concern for loved ones. Physical symptoms, loss of autonomy and functioning, difficulties relating to physicians and health-care systems, and financial strain can also be sources of suffering. Pre-existing psychiatric disorders, difficult family dynamics, poor social support, and existential and spiritual struggles can exacerbate psychological suffering (Block, 2006).

Physical Symptoms in End of Life Care

In addition to changes that occur as part of the natural aging process, patients' experiences at the end of life may involve symptoms specific to terminal illnesses (Waldrop, 2008). Solana, Gomes, and Higginson (2006) conducted a review of 64 studies reporting the prevalence of common symptoms among end-stage patients with cancer, acquired immunodeficiency syndrome (AIDS), heart disease, chronic obstructive pulmonary disease, or renal disease. The following symptoms were commonly reported: pain (34–96%), fatigue (32–90%), breathlessness (10–95%), insomnia (9–74%), nausea (6–69%), constipation (23–70%), diarrhea (3–90%), anorexia (21–92%), confusion (5–93%), depression (3–82%), and anxiety (8–75%). The authors noted that the wide variations in prevalence were likely due, in part, to the range of patients' studied and methodological differences in the studies. The authors identified pain, fatigue, and breathlessness as the three most common symptoms reported. A large number of pharmacological treatments exist to promote symptom management in serious illnesses including analgesics for pain, soporifics for sleep, antiemetics for nausea, and various psychiatric medications for cognitive and emotional dysfunction. Though these medications are often effective, they may also produce iatrogenic problems and uncomfortable side effects, particularly in the elderly. Other methods of symptom management include the use of massage and other physical treatments.

Psychological factors are central to managing symptoms in end of life care, and symptom severity is associated with psychological distress (Kelsen, Portenoy, et al., 1995; Zara & Baine, 2002). Pain severity can increase anxiety, a sense of helplessness and hopelessness, and the risk of depression. Pain also significantly affects quality of life, mobility, physical functioning, and concentration. In addition, psychological factors can moderate patients' perceptions of pain. For example, fear, anxiety, depression, perceived uncontrollability of symptoms, appraisals of pain symptoms, lack of self-efficacy, certain reinforcement contingencies, and lack of sleep are associated with increased perceptions of pain and suffering (Raphael, Ahmedzai, et al., 2010). Patients' thoughts (i.e., their assumptions and expectations) also influence their experiences of pain. For example, engaging in catastrophizing appraisals increases perceptions of pain, pain interference, and anxiety (Bishop & Warr, 2003; Utne, Miaskowski, et al., 2009).

Many psychosocial interventions for pain management at end of life are based on cognitive-behavioral models designed to help patients identify, evaluate, and change maladaptive patterns of thinking and behaving that contribute to physical and mental suffering. The goal is to facilitate more adaptive coping that minimizes distress. Patients are also taught about the physiology of pain and how cognitive appraisals can affect physiological processes and perceptions of pain. Some behavioral medicine interventions also include relaxation training, deep breathing exercises, guided imagery, self-hypnosis, mindfulness meditation, and encouraging distractions such as talking to friends or listening to music (Raphael, Ahmedzai, et al., 2010).

There is evidence to support the use of these behavioral medicine interventions to manage symptoms in serious illnesses. Because specific application of these treatments to end of life has not been as thoroughly studied, we included highlights from the literature that addresses behavioral symptom management in diseases such as cancer or conditions such as chronic pain that are prominent among individuals receiving end of life care. To this end we note that Bolmsjo (2008); Pan, Morrison, Ness, Fugh-Berman, and Leipzig (2000); Raphael et al. (2010); and Waldrop (2008) reviewed studies examining the effectiveness of psychosocial interventions in treating symptoms and concluded that they were effective in reducing symptoms, especially perceptions of pain. Likewise, two meta-analyses (Devine, 2003; Morely, Eccleston, & Williams, 1999) concluded that cognitive-behavioral interventions, particularly relaxation training, were helpful in reducing perceptions of pain in patients with cancer.

Pan et al. (2000) also reviewed studies using psychosocial or alternative medicine interventions to treat symptoms of pain, dyspnea, nausea, and vomiting in end of life patients. Cognitive-behavioral interventions, involving psychotherapy, psychoeducation, relaxation training, guided imagery, and deep breathing training were effective in reducing these symptoms. More alternative medicine interventions such as transcutaneous electrical nerve stimulation, acupuncture, acupressure, massage, music therapy, and hypnosis also effectively reduced symptom severity.

Emotional Experiences of Patients in End of Life Care

Depression

Depression is one of the most common symptoms reported by patients with life-limiting illnesses, frequently ranking as one of the top 10 symptoms (Hotopf, Chidgey, et al., 2002). Prevalence rates for diagnosable depression vary widely from 3% to 58% depending on how depression is defined (Wasteson, Brenne, et al., 2009), the patients' illness, and the severity of their physical symptoms (Solana, Gomes, & Higginson, 2006). Untreated depression can increase the severity of patients' experience of pain and other symptoms, further undermine physical health and quality of life, and increase the probability of morbidity, mortality, and suicide (Irwin & Ferris, 2008). Depression is also associated with decreased treatment adherence, reduced will to live, and prolonged hospital stays (Block, 2006).

Distinguishing depression from grief in end of life care can be challenging, and views relevant to this issue continue to evolve. Currently (April, 2012) there is controversy regarding the diagnosis of depression and whether individuals experiencing bereavement should continue to be excluded from a diagnosis of depression when the next edition of the Diagnostic and Statistical Manual of Mental Disorders is published. It is clear that there is often considerable overlap between symptoms of depression and those of any serious illness. Hopelessness, helplessness, worthlessness, guilt, lack of pleasure, suicidal ideation, social withdrawal, irritability, and anxiety are key symptoms of depression (Block, 2006). In the context of end of life treatment, depression is commonly under recognized by health-care professionals and family members. Patients and their families are also sometimes reluctant to discuss emotional concerns with physicians. Even when recognized, depression is often undertreated. Many health-care professionals assume that depression is an unavoidable part of terminal illness, and they do not adequately address the patients' emotional distress. However, psychotherapy and antidepressant therapy can be effective in treating depression in end of life patients (Irwin & Ferris, 2008). Psychosocial interventions for depression are discussed later in this chapter.

Anxiety

Anxiety is also commonly reported by end of life patients, with some estimates of prevalence as high as 70% (Irwin & Ferris, 2008). Other studies found significant anxiety symptoms in 25% of patients with cancer (Derogatis, Morrow, et al., 1983), with 3% of advanced cancer patients meeting criteria for generalized anxiety disorder and 5% meeting criteria for panic disorder (Kadan-Lottock, Vanderwerker, et al., 2005). Two to 35% of cancer patients show symptoms of post-traumatic stress disorder (PTSD), with lower rates in studies using the Diagnostic and Statistical Manual of Mental Disorders-IV criteria (Block, 2006).

Recognizing anxiety in end of life patients can also be challenging. The symptoms of the illness may overlap with symptoms of anxiety because anxiety frequently presents with somatic symptoms that overshadow psychological and cognitive manifestations (Irwin & Ferris, 2008). These symptoms may include autonomic hyperactivity, hypervigilance, worry, apprehension, insomnia, diarrhea, sweating, palpitations, and dyspnea (Block, 2006). It should be noted that most patients experience worry, fear, and apprehension related to concerns such as death, pain control, disease course, separation from loved ones, interactions with unfamiliar caretakers, loneliness, and isolation. Typically, however, these concerns do not reach the level of an anxiety disorder. The key difference between expected worry or fear and diagnosable anxiety is the severity and pervasiveness of the worry and anxiety. When anxiety interferes with valued relationships, leads to avoidance and distrust of health professionals, causes symptom amplification, or is responsible for patients' delay in seeking treatment or proactive planning for end of life care needs (Block), it crosses the line and is recognized as pathological.

Psychosocial Interventions for Depression and Anxiety

Several literature reviews (Block, 2006; Bolmsjo, 2008; Fawzy & Fawzy, 1998; Waldrop, 2008) and meta-analyses (Himelhoch, Medoff, & Oyeniy, 2007; Meyer & Mark, 1995; O'Neil, Sanderson, et al., 2010; Rehse & Pukrop, 2003; Sheard & Maguire, 1999) conclude that psychosocial interventions can effectively reduce symptoms of depression and anxiety, as well as physical symptoms of serious illness, and improve overall quality of life for patients in end of life care. Group interventions appear to be as effective as individual interventions and are cost effective (Meyer & Mark, 1995; Rehse & Pukrop, 2003; Sheard & Maguire, 1999). Sheard and Maguire concluded that short but intensive treatments were more effective than longer interventions, whereas Rehse and Pukrop concluded that longer interventions were more effective, and recommended interventions last at least 12 weeks. The patient's medical status and prognosis must be considered when choosing an intervention as those of longer duration may not be appropriate for more advanced cases. Psychoeducation groups appeared to be the most effective, but no differences were found between other types of interventions, such as training coping skills, social support groups, and psychotherapy (Rehse & Pukrop, 2003).

We will next provide several prototypic or well-known examples of randomized controlled trials of the types of therapy that have been investigated in the research literature. One early and often cited study (Spiegel, Bloom, & Yalom, 1981) examined the effects of supportive-expressive group therapy for patients with metastatic breast cancer. Patients were randomized to group intervention (*n* = 50) or a no-therapy control group (*n* = 36) that received standard treatment. The intervention group met weekly for 1 year. Therapy sessions involved discussions of death and dying, family problems, communication problems, and living a meaningful life with a terminal illness. Group leaders encouraged patients to share their emotional experiences and emphasized group cohesion and emotional support. At 12 months patients in the treatment group showed significantly less anxiety, depression, confusion, tension, and fatigue than those in the control group. Goodwin et al. (2001) replicated the Spiegel et al. study and found similar improvements in mood and physical symptoms. The intervention was most effective among the most seriously distressed patients.

Linn, Linn, and Harris (1982) provided individual supportive psychotherapy to men with advanced cancer. Patients were randomly assigned to supportive therapy or a non-therapy control group that received usual care. No significant differences were found at 1 month follow-up, but at 3 months patients in the treatment group showed significant improvements in feelings of alienation, self-esteem, and depression. No differences were found in follow-up assessments beyond the 3 months.

Edelman, Bell, and Kidman (1999) provided group cognitive behavior therapy (CBT) to metastatic breast cancer patients who were at various stages in terms of their nearness to death with approximately 13% dying either before or during the intervention. Patients were randomized to either a standard care control group (*n* = 49) or a treatment group that received standard care plus group CBT. Participants attended eight weekly sessions of group CBT, followed by a family night, and three additional monthly sessions. Therapy included instruction in cognitive and behavioral techniques, encouraged expression of feelings, and sought to build group support. Participants were taught basic cognitive skills including how to identify, challenge, and replace maladaptive thoughts and beliefs (e.g., disputation of the thought "what's the point of trying, I'm only going to die anyway") and focus cognitions on active coping (e.g., "just relax, use relaxation skills"). Behavioral techniques were also taught and encouraged, such as deep relaxation/meditation, effective problem-solving, and effective communication strategies. Patients were also encouraged to utilize their available coping resources, including friends and family and pleasurable activities. Patients in the treatment group showed a significant improvement following the end of the program, but no significant differences were found at the 3 or 6 month follow-up assessments.

Typical of these treatments is helping patients develop their coping resources in light of the unique event they are currently experiencing, i.e., end of life. Discussions of death and dying are central to these treatments. As is true generally for depression and anxiety, confrontation of the feared object or event can bring about beneficial change. The treatments go beyond this, however, to guide the patients in development of behavioral (e.g., relaxation training) and cognitive (e.g., restructuring) skills to enhance their quality of life and relationships. Group formats are often used due to their advantages over individual treatments in terms of sharing common concerns and developing empathic relationships with others.

Delirium

Delirium also frequently occurs in end of life care. Up to 80% of patients with cancer or other terminal illnesses experience delirium, and one third of patients experience delirium when they are dying (Irwin & Ferris, 2008). Delirium is often frightening and distressing for patients, families, and caregivers and can impair the recognition and control of other physical and psychological symptoms. However, correctly recognizing and treating delirium can improve symptom management (Cobb, Glantz, et al., 2008; Irwin & Ferris).

Dignity

The advancement of a serious illness can be quite challenging because many patients experience a significant loss of both independence and control which often threaten their sense of dignity. Chochinov and colleagues proposed a model of dignity that consists of three broad categories: illness-related concerns (factors caused by, or associated with, the underlying illness), the social dignity inventory (social or externally mediated factors), and the dignity conserving repertoire (psychological and spiritual considerations) (Chochinov, 2002; Chochinov, Hack, Hassard, et al., 2002). Chochinov et al. (2006) asked patients to identify issues they felt were related to their sense of dignity. Over 80% identified the following experiences as being harmful of their dignity: "Not being treated with respect or understanding," "Feeling like a burden," "Feeling like you do not have control over your life," "Not feeling you made a meaningful or lasting contribution," and "Not being able to independently manage bodily functions." Chochinov and colleagues developed dignity therapy in order to enhance patients' sense of dignity (Chochinov et al., 2005a; Chochinov, Hack, Hassard, et al., 2002; Chochinov, Hack, McClement, et al., 2002; McClement, Chochinov, et al., 2007). In this approach, patients are encouraged to discuss their life histories, accomplishments, and experiences. The discussion is recorded and then transcribed into a manuscript that they can give to loved ones. The goal is to provide an opportunity to create and contribute something meaningful to others in order to decrease patients' psychological suffering and enhance their sense of meaning, purpose, dignity, and quality of life. Dignity therapy has been shown to increase patients' readiness for death, sense of dignity and purpose, and will to live. The families of patients also report that it is comforting for them.

Self-Perceived Burden

The sense that one has become a burden to others has been referred to as self-perceived burden and defined as, "empathic concern engendered from the impact on others of one's illness and care needs, resulting in guilt, distress, feelings of responsibility, and diminished self" (McPherson, Wilson, & Murray, 2007a, p. 425). Self-perceived burden is expressed by many patients nearing the end of life (McPherson, Wilson, & Murray, 2007b); however, patients are often reluctant to discuss their feelings because they worry that such self-disclosure will create further burden to caregivers (Grant, Murray, et al., 2003; Wilson, Curran, & McPherson, 2005). Further, patients with higher levels of self-perceived burden are less likely to seek help (Cousineau, McDowell, et al., 2003).

Seeing oneself as a burden has been associated with psychological distress. Self-perceived burden has been negatively related to quality of life (Cohen & Leis, 2002) and positively related to clinical depression (Wilson, Curran, & McPherson, 2005), a diminished will to live (Chochinov et al., 2005b) and loss of dignity (Chochinov, Hack, Hazzard, et al., 2002). In cancer patients, self-perceived burden was related to increased physical symptoms, depression, anxiety, loss of control, loss of dignity, and hopelessness (Wilson, Curran, & McPherson, 2005), and in patients with amyotrophic lateral sclerosis, self-perceived burden was more highly correlated with depression ($r = 0.64$) than with patents' functional status ($r = 0.35$) (Chio, Gauthier, et al., 2005).

In addition, self-perceived burden seems to influence treatment decisions by patients (Ashby, Op't Hoog, et al., 2005). Studies of hospitalized elderly patients found that not wanting to burden others was one of the top reasons for not wanting life-sustaining treatments (Cohen-Mansfield, Dorge, & Billing, 1992; Zweibel & Cassel, 1989) and for choosing where to receive care at the end of life (institution versus home) (Murray, O'Connor, et al., 2003; Tang, 2009). Self-perceived burden is also associated with the wish for a hastened death (McPherson, Wilson, & Murray, 2007b). Surveys of health professionals and family members suggest that they may underestimate the significance of self-perceived burden for patients. Recognizing and addressing patients' sense of being a burden may help alleviate their distress and influence their treatment decisions and willingness to seek help. Given that patients sometimes conceal symptoms in order to avoid burdening others, their care needs may go unmet (McPherson et al.). Self-perceived burden predicts depression, but research is needed to clarify whether self-perceived burden is a consequence or antecedent of depression (McPherson et al.).

It may seem that the issue of self-perceived burden would be particularly salient in societies where multiple generations of family members often live together, and thus the older population is attended to primarily by family members. For example, in many Asian societies, and communities, cultural norms emphasize the obligation of family members to care for their elders. Cultural norms also emphasize the importance of emotional harmony and the common good (Bowman & Singer, 2001). As a result one might expect patients at end of life to feel they are a burden on family members and thus be reluctant to discuss their symptoms and needs for fear of disrupting emotional harmony and causing further distress. At least four studies exploring attitudes and concerns about end of life care among Chinese (Bowman & Singer), Japanese (Kawa, Kayama, et al., 2003; Morita, Kawa, et al., 2004), and Korean (Kim & Lee, 2003) participants found that becoming a burden to others was a prominent concern. However, as far as we know, there is little to no cross-cultural examinations of self-perceived burden in Asian countries. It is possible that self-perceived burden does not generally differ between Asian and other populations in part because Asian culture often includes an expectation that family members take care of older adults and protect them from distressing experience or information. Thus, this expectation may actually ease feelings of guilt associated with self-perceived burden.

Though individuals at other stages of life may experience emotional distress related to feeling a loss of dignity and perceiving themselves as a burden on others, these concerns are particularly salient during end of life when patients' physical and mental capabilities are often diminished, and they are, in fact, more dependent on others for meeting their basic needs. This is complicated in the case of the dying by the realization that they will not be able to repay the caregiver in kind, and they may perceive themselves as reducing the caregivers' quality of life by requiring attention and care. The reality of lost independence and capacity presents a somewhat unique set of stressful events that for many have negative emotional consequences. As noted above, it is not clear if depression precedes perceived sense of burden or is consequent to it. The complex relations between these and similar mood-based constructs are yet to be fully investigated, but it is clear that the sense of lost dignity and increased burden are particularly important and somewhat unique experiences for those at end of life and as such deserve further investigation.

Coping Style

The experience of terminal illness poses significant challenges and requires patients to make psychological adjustments in order to cope (Block, 2006). Examples of coping styles include: seeking information, keeping busy, redefining options, resigning one's self, examining alternatives, and expressing feelings. In some cases, patients may cope with terminal illness by avoiding its reality. Avoidant coping responses (e.g., denial) can be adaptive if they reduce stress for patients and allow them more time to process and adjust or live in the moment and enjoy their remaining time. They can be maladaptive if they prevent patients from acknowledging the severity of their condition, properly adhering to treatment, or failing to make the proper arrangements for end of life care. Approach or active coping occurs when patients engage the stressful experience and attempt to utilize some method of changing it or their perception of it. They may, for example, seek alternative treatments, gather information, or begin self-management interventions. Obviously a key factor in determining the success of a coping strategy is how well that strategy is matched to the particular stressor that it is responding to. We are reminded of the serenity prayer that suggests that better functioning and quality of life likely lie in changing what can be changed, accepting what cannot be changed but only accepted, and the wisdom to know the difference. In fact, patients typically use a combination of approach and avoidant coping strategies. They often use avoidant coping strategies when they are most distressed, but switch to approach coping strategies when their distress subsides (Block; Weisman, 1984).

There has been interest in determining if coping styles are associated with reductions in recurrence and delayed mortality. This has been particularly discussed in the context of cancer patients where stories in the popular media often note how bravely an individual fought his/her cancer and, if not stated directly, imply that due to the patient's fighting spirit s/he lived longer than would have been the case otherwise. The converse implication in these stories is that if patients feel helpless they will die sooner. In general, studies examining which coping styles are associated with better or worse outcomes vis a vis recurrence and mortality have been equivocal. Specifically, a meta-analysis examining "fighting spirit" and helplessness/hopelessness as predictors of recurrence and mortality in patients with cancer found no evidence for an effect for different coping styles on mortality (Petticrew, Beill, & Hunter, 2002).

Spiritual and Existential Concerns

Spiritual and existential concerns often play prominent roles in patients' end of life experiences (Alcorn, Balboni, et al., 2010; Breitbart, 2001; Trevino, Pargament, et al., 2010). In one study involving hospice patients, 89% of the patients felt that being at peace with God was important to them (Pronk, 2005). In another study involving patients with cancer, symptoms relating to psychological distress and existential concerns were more prevalent than pain and other physical symptoms (Portenoy, Thaler, et al., 1994). Spiritual and existential concerns are strongly related to quality of life and psychological distress in patients with terminal illness (Balboni, Vanderwerker, et al., 2007; Tarakeshwar, Vanderwerker, et al., 2006). It is now widely recognized that quality palliative and end of life care addresses the spiritual and existential needs of patients (Puchalski, Ferrell, et al., 2009). The National Hospice and Palliative Care Organization (NHCPO, 2010) includes spiritual counselors as core members of interdisciplinary treatment teams, and the WHO (2011) definition of palliative care specifically notes the integration of spiritual aspects of care.

Religious coping involves dealing with stress through religious and spiritual means (e.g., prayer or seeking spiritual support) (see Pargament, 1997). A review of the literature on religious coping reported that 30–80% of individuals across various samples used religious coping (Harrison, Koenig, et al., 2001). Generally, religion and spirituality play a positive role in coping with illnesses such as cancer or HIV (Breitbart, 2001; Trevino, Pargament, et al., 2010). A review of the literature examining the relationship between religion and depression suggests that religious coping can reduce the risk of depression (McCullough & Larson, 1999). More recent advances in this area of research have challenged investigators to view religion/spirituality as multidimensional constructs whose various dimensions may differentially predict beneficial and malevolent outcomes. Consequently, though much research on religion/spirituality and health has utilized meta-level constructs (e.g., religious service attendance), the contemporary trend is for investigators to specify what aspect of religiousness or spirituality they are investigating and to avoid broad generalizations about the effects of "religion" or "spirituality." For example, a cross-sectional study of 367 men with prostate cancer found that intrinsic religious motivation ($r = -0.23$) and spirituality

($r = -0.58$) predicted lower levels of depression (Nelson, Jacobson, et al., 2009).

As implied above, religion/spirituality can also be a source of distress and increase the burden of illness (Fitchett, Murphy, et al., 2004; Pargament, Koenig, et al., 2004). Spiritual struggles are common in patients with terminal illnesses. Alcorn et al. (2010) recently explored the religious/spiritual themes in the experiences of 68 patients coping with advanced cancer. Many common themes reflected a sense of spiritual struggle. For example, many felt abandoned by or punished by God, angry at God, and/or doubted their faith as well as God's love and power. However, other themes reflected more positive religious coping responses. For example, more than half of the patients reported a desire to seek a closer connection with God and to find meaning in life and in their suffering. Using both cross-sectional and longitudinal designs, Trevino et al., (2010) investigated the relationships between positive religious coping and spiritual struggle in predicting viral load, CD4 count, quality of life, HIV symptoms, depression, self-esteem, social support, and spiritual well-being in 429 patients with HIV/AIDS. Positive religious coping predicted better outcomes whereas spiritual struggle predicted worse outcomes. Further, high levels of positive religious coping and low levels of spiritual struggle were associated with small but significant improvements over time.

Some writers suggested that religion allows patients to find meaning in the suffering caused by their illness (Breitbart, 2001). A sense of meaning and peace has been shown to mediate the negative relationship between intrinsic religious motivation and depression (Nelson, Jacobson, et al., 2009). Further, patients with a higher sense of meaning report greater satisfaction with their quality of life and show a higher tolerance for pain associated with severe physical symptoms (Brady, Peterman, et al., 1999). Thus, it seems that one of the most important elements of religion and spirituality is that they help patients find meaning. However patients can find meaning in their experiences without religion or spirituality. Interventions intended to enhance patients' sense of meaning have shown improvements in patients' feelings of anxiety and desire for hastened death (Breitbart, Rosenfeld, et al., 2010), as well as levels of self-esteem, optimism, and self-efficacy (Lee, Cohen, et al., 2006).

In order to address patients' needs for spiritual well-being and purpose in life, Brietbart et al., (2010) developed Meaning Centered Group Therapy (MCGP). Patients with advanced cancer ($n = 90$) were randomly assigned to either MCGP or a supportive group therapy, both for eight sessions. The goal of MCGP was to facilitate patients' sense of meaning and purpose through didactics, discussion, and experiential exercises. Patients in the MCGP group showed significantly greater improvement in spiritual well-being and a sense of meaning. These improvements became more substantial at the second follow-up assessment. Significant improvements were also noted in anxiety and reduction in desire for death. Interestingly, patients in the supportive therapy group showed no significant improvements in any of these variables.

The role of behavioral medicine providers in addressing spiritual and religious concerns deserves special comment. First, it is clear that spiritual issues are considered important in end of life care. The WHO, for example, highlights the importance of spiritual care in palliative care and emphasizes the *integration* of psychological and spiritual aspects of patient care (World Health Organization, 2011). Further, Domain 5 (Spiritual, Religious, and Existential Aspects of Care) of the Clinical Practice Guidelines for Quality Palliative Care (National Consensus Project for Quality Palliative Care, 2009) advocates for the integration of this treatment component into palliative care. *Integration* is important because patients prefer spiritual considerations to be integrated with their care, and integrated care is more likely to produce better outcomes than approaches that separate spiritual concerns from the rest of the patients' treatment (Nad, Marcinko, et al., 2008). Further, research indicates that many patients believe that spiritual issues are important to consider in the context of their medical care and treatment. As one of many examples, King and Bushwick (1994) surveyed 203 adult inpatients in Pennsylvania and North

Carolina and found that although 77% of the patients believed that family practice physicians *should* consider their spiritual needs, 68% indicated that their physicians *never* addressed them. (North Carolina is in the part of the USA often referred to as the "Bible Belt"; thus it is fair to speculate that the number of physicians never addressing spiritual issues may be higher in other regions of the USA.) Responding to this need, over 100 of approximately 126 medical schools in the USA now offer courses on spirituality and medicine (Puchalski, 2006).

The integration of spiritual and religious issues into treatment does, however, have its detractors. Prominent among these is Richard Sloan (Sloan & Bagiella, 2002; Sloan, Bagiella, & Powell, 1999). Sloan posits many reasons why religion and spirituality should be kept out of behavioral medicine practice, but principle among these are fears of coercion, violations of privacy, the possibility of doing harm, and discrimination against individuals for whom religion is not important. For a more complete discussion of Sloan's position and the present senior author's opposition, please see Sloan's original writings and Masters (2010). Clearly Sloan highlights important areas that every practitioner must be careful to handle with professionalism and compassion, always operating out of concern for the patient's welfare and respect for the patient's autonomy. It is beyond the space provided for this chapter to enter into a thorough discussion of the relevant issues including the lack of trained professionals who are competent and comfortable in addressing these concerns. But it is, nevertheless, clear that there is a trend for professional organizations to acknowledge the importance and legitimacy of religious and spiritual factors in the treatment context and perhaps nowhere more so than with end of life patients. We return to this issue in our concluding comments at the end of the chapter.

Reflections on Patient-Oriented Issues

Clearly patients face many challenges as they navigate the ends of their lives. Both physical and emotional symptoms may diminish quality of life. Of particular prominence are depression and anxiety and it is therefore important that treatments, including psychological, behavioral, and pharmacological interventions, be thoughtfully considered and implemented when appropriate. The issue of perceiving oneself as a burden on others stands out in this review as a problem that likely does not receive the attention it deserves, and consequently many patients may be left with this concern unaddressed. Understanding the particular phenomenology of individuals with particular life concerns is needed in all areas of behavioral medicine, and the constructs of dignity and burden are important in this regard as pertaining to end of life. Though they certainly overlap with better recognized constructs such as depression, they are also relatively unique psychological events often experienced by the dying. Understanding this nuanced aspect of the psychological phenomenology of end of life as experienced by at least some patients will advance behavioral medicine treatment. Finally, spiritual and existential issues are beginning to receive proper attention from healthcare professionals. Treating the whole patient at the end of life could hardly be deemed complete without adequate consideration of these issues and provision of openings for patients to engage them as they choose.

We next turn our attention to issues of concern for caregivers at the end of life. This group, too, faces many challenges, and though their challenges are similar to those faced by patients, they also differ in important respects. Behavioral medicine practitioners are particularly well suited to intervene with this population.

Caregiver-Oriented Issues in End of Life Care

The Challenges of End of Life Caregiving

In the USA, it is estimated that 25 million people provide an average of 18 hours per week of caregiving to seriously ill family members (Emanuel, Fairclough, & Emanuel, 2000). Not surprisingly, multiple studies document the emotional and physical impact of caregiving for a loved one at the end of life (Aneshensel, Pearlin, et al., 1995; Blanchard, Toseland, & McCallion, 1996; Clark, Reid, et al., 2008; Coristine, Crooks, et al., 2003; McMillian, 1996). Informal caregivers experience an array of stressors that include managing the physical and emotional needs of their loved one, communicating with health-care workers and family, and dealing with practical issues such as finances and insurance while concurrently managing their ongoing work, household, and self-care responsibilities. Caregivers of end of life patients typically encounter increased financial burden, work-related disruptions, negative social consequences, and an interruption of life tasks and goals (Covinsky, Goldman, et al., 1994; Freeborne, Lynn, & Desbiens, 2000; Haley, 2003). The constant demands of caregiving at end of life impact social, leisure, and religious activities resulting in social isolation, loneliness, and decreased life satisfaction (Carr, House, et al., 2001; Davis & Nolen-Hoeksema, 2001; Schulz, Williamson, et al., 1995). Caregiver depression can heighten this impact (Breslin, O'Keeffe, et al., 1995). For example, caregiver depression has been associated with increased likelihood and amount of time missed at work (Gallant & Conell, 1997). As a result of the disruption of their normal routines and activities, caregivers often experience a decrease in social interactions that can result in profound feelings of loneliness (Rokach, Matalon, et al., 2007). The decrease in social support can also impact psychosocial well-being and physical health (Uchino, Cacioppo, & Kiecolt-Glaser, 1996). Older caregivers typically experience additional burdens associated with aging such as the management of their own medical conditions, multiple losses (e.g., loss of function/independence, loss of social support), and financial stressors (Beery, Prigerson, et al., 1997). The strong emotions associated with grief and bereavement can be particularly challenging to caregivers given the high rates of mental, emotional, and physical fatigue associated with the caregiving experience (Burns, Nichols, et al., 2003).

Psychological, Physical, and Behavioral Reactions to End of Life Caregiving

Multiple studies have documented the emotional and physical impact of caregiving for a loved one who is at the end of life (e.g., Fleming, Sheppard, et al., 2006). In terms of psychosocial distress, caregivers show higher rates of depression, anxiety, and anger when compared to non-caregivers (Chentsova-Dutton, Shuchter, et al., 2000; Emanuel, Fairclough, & Emanuel, 2000; Flaskerud, Carter, & Lee, 2000). It is estimated that between 40% and 70% of caregivers of older adults suffer from depressive symptoms, and approximately half meet diagnostic criteria for major depression (Drinka, Smith, & Drinka,1987; Gallagher, Rose, et al., 1989; Redinbaugh, MacCallum, & Kiecolt-Glaser, 1995). An examination of psychiatric problems in caregivers of advanced cancer patients reported that 13% met criteria for a psychiatric disorder and 25% sought treatment for mental health concerns (Vanderwerker, Laff, et al., 2005).

The immense burden of caring for a seriously ill loved one places caregivers at increased risk for a variety of health problems (Schulz & Beach, 1999; Wright, Clipp, & George, 1993) such that caregivers are often referred to as "hidden patients" (Thompson & Doll, 1982). The cumulative stress and physical demands of caregiving are associated with a deterioration of caregiver physical health (Haley, 2003; Schulz, Newsom, et al., 1997; Stroebe, Schut, & Stroebe, 2007) and increased risk of caregiver illness or death (Christakis & Allison, 2006; Kiecolt-Glaser, Dura, et al., 1991). Studies examining biological outcomes in caregiver populations have reported neuroendocrine dysfunction (Mausbach, Mills, et al., 2006), immune decrements (Kiecolt-Glaser, Dura, et al., 1991; Mausbach et al.; Redwine, Mills, et al., 2004; Segerstrom & Miller, 2004; Vedhara, Cox, et al., 1999; Vitaliano, Zhang, & Scanlan, 2003; Von Känel, Dimsdale, et al., 2006), and elevations in inflammatory cytokines (Kiecolt-Glaser, Preacher, et al., 2003; Lutgendorf, Garand, et al., 1999).

The overwhelming physical and emotional demands of caregiving can lead to maladaptive behavioral reactions such as diminished self-care and poor health status (Gallant & Conell, 1997; Gaugler, Edwards, et al., 2000; Robinson-Whelen, Tada, et al., 2001). Caregivers often report significant alterations to their daily health routine, which may include less physical activity, decreased attention to diet and nutrition, and alterations in sleep patterns (Connell, 1994). The diminished quantity and quality of sleep can lead to increased fatigue, elevated distress, and neuroendocrine and immune dysfunction, which can impact long-term health and well-being and health-related quality of life (Persson, Östlund, et al., 2007). In addition, caregivers may become inattentive to their own medical needs, which can lead to exacerbation of chronic conditions or the emergence of new medical problems. There also is a strong association between stressful life events and increased use of alcohol, tobacco, or other drugs in those who tend to use passive coping strategies (Brady & Sonne, 1999; Breslin, O'Keeffe, et al., 1995). This combination of physical and emotional stress and changes in self-care behaviors can eventually result in "caregiver burnout" at which point caregivers may feel that they are unable to continue caring for their loved one and are forced to seek other forms of care (e.g., nursing homes, inpatient hospice care) (Gaugler, Edwards, et al., 2000). This can lead to extreme disappointment and guilt, as most caregivers have a strong desire to keep their loved one in the home as long as possible.

The quality of life for the end of life patient can have an enormous impact on the caregiver's psychosocial adjustment and quality of life (Gill, Kaur, et al., 2003). Steinhauser and colleagues' (2000) cross-sectional survey of end of life patients, families, and physicians found that patients and their families both ranked freedom from pain, coming to peace with God, and presence of family as the top three factors of importance at the end of life. Caregivers who are expending less energy worrying about their loved ones' comfort and care can focus more attention on self-care. This is important given that caregivers' often neglect their own health needs while caring for their loved one. It is crucial that the treatment team explicitly give caregivers permission to attend to their own needs and encourage them to engage in adaptive coping activities.

Grief and Bereavement in End of Life Caregivers

Caregivers of end of life patients typically experience pre-loss grief which is viewed as a normal, adaptive response to the anticipated loss of a loved one (Rando, 2000). Although anticipatory grief may lead to better adjustment following the death of the loved one, research is mixed on whether anticipatory grief ameliorates the bereavement process (Hogan, Morse, & Tason, 1996; Parkes, 1996). Family members who experience prolonged anticipatory grief may begin to feel overwhelmed resulting in emotional detachment or over-involvement with the patient as a means of avoiding their true feelings. It is clear that the time leading up to the death of the patient can have a significant impact on bereavement, and caregivers who use this time as an opportunity to attend to "unfinished business" will be better prepared to manage their post-loss grief (Worden, 2000).

Caregivers experience a wide range of reactions following the death of their loved one, and although grief and bereavement are universal experiences, individuals differ in how they react and adapt to loss. The intensity and magnitude of the emotions experienced following the death of a loved one are associated with a number of factors including: the nature and circumstances surrounding the loss, the relationship between the caregiver and the patient, the caregiver's experience and response to prior loss(es), and the caregivers' personality and availability of psychosocial resources. There are also a variety of social and demographic variables that relate to how the emotional response to the loss is experienced including age, gender, developmental level, social class, culture and religious beliefs and practices, family, and external and internal support (Doka, 1998; Rando, 1984).

In some cases caregivers may experience extreme reactions to the loss of their loved one which is labeled as complicated grief and is considered to be a unique affect distinguishable from depression and anxiety (American Psychiatric Association, 2000; Sanders & Adams, 2005). Complicated grief is characterized by elevated levels of separation distress and typically requires psychosocial or medical intervention (Prigerson, Frank, et al., 1995). Hudson (2006) reported that 7% of caregivers suffered from traumatic or complicated grief following the death of their loved one. Earlier we noted the current controversy regarding the diagnosis of depression and whether bereavement should continue to be excluded from the diagnostic criteria of depression in the next edition of the Diagnostic and Statistical Manual of Mental Disorders. This remains to be decided, but it is clear that for some caregivers, their experience of bereavement is sufficiently troubling to require intervention. Regardless of what is eventually decided regarding diagnostic criteria for depression and bereavement, it remains true that there has been limited research examining complicated pre-loss grief. Variables such as caregiver burden, an insecure attachment style with the patient, being younger, having lower perceived social support, previous episode of depression, lower income levels, higher severity of life events, and pessimistic thinking patterns appear to increase the risk of developing complicated pre-death grief (Beery, Prigerson, et al., 1997; Kelly, Edwards, et al., 1999; Tomarken, Holland, et al., 2008; Van Doorn, Kasl, et al., 1998).

In general, functioning prior to the loss is a good predictor of how well a caregiver or family member will handle loss. Caregivers with a history of psychiatric problems are at increased risk for developing complicated grief reaction. As those currently arguing for inclusion of grief under the diagnostic label of depression note, it is often difficult to distinguish a major depressive episode from complicated grief, particularly among those with a history of depression. Generally it is believed that depression tends to be more global in its impact on thoughts, feeling, and behaviors such that depressed individuals experience distorted cognitions directed at themselves, the world, and the future, whereas those suffering from complicated grief tend to report negative thoughts associated with specific aspects of their loss (Worden, 2002). Table 34.1 presents an overview of the signs and symptoms of complicated grief but clearly this issue is far from settled.

End of Life Caregiver Resources

The stress of caregiving is a multidimensional process that has an impact on almost every aspect of caregiver quality of life (QOL). The Transactional Model of Stress and Coping (TMSC) predicts that those who are able to handle and adapt to the challenges of caregiving will show lower levels of distress and higher QOL (Lazarus & Folkman, 1984). Coping strategies can have a significant impact on one's ability to manage stressful events such that adaptive coping strategies may lead to improved adjustment whereas maladaptive strategies can lead to increased distress and poor health outcomes (for a review see Penley, Tomaka, & Wiebe, 2002). Generally adaptive coping mechanisms such as acceptance, relaxation, or seeking social support were associated with less depressed affect in Alzheimer's patient caregivers (Williamson & Schulz, 1993). Similarly, DeMattei et al. (2008)

Table 34.1 Signs and symptoms of complicated grief in caregivers

1.	Extreme focus on the loss and reminders of the loved one
2.	Intense longing for the deceased
3.	Problems accepting the death
4.	Numbness or detachment
5.	Preoccupation with sorrow
6.	Bitterness about the loss
7.	Inability to enjoy life
8.	Depression or deep sadness
9.	Suicidal thoughts or feelings
10.	Difficulty moving on with one's life
11.	Trouble carrying out normal routines
12.	Withdrawing from social activities
13.	Feeling that life holds no meaning or purpose
14.	Irritability of agitation
15.	Lack of trust in others

found that active coping and problem-focused approaches helped to buffer caregiver-related stress whereas the use of avoidance coping was associated with increased distress. As with patients, caregivers experience a wide range of stressors, so it is particularly important that caregivers are able to distinguish between the controllable and uncontrollable aspects of the various stressors so that they can utilize the appropriate coping mechanisms. For example problem-focused coping strategies (e.g., decision-making, problem-solving) can alleviate controllable stressors, but they are not helpful for uncontrollable stressors which are, by definition, difficult to change but whose impact can be managed through emotion-focused coping strategies (e.g., venting, journaling, exercising, meditation, prayer).

The utilization of social support networks is especially important for caregivers given that they are prone to experiencing loneliness and feelings of social isolation as a result of their caregiving experience (Covinsky, Goldman, et al., 1994; Freeborne, Lynn, & Desbiens, 2000). Social support is an important predictor of adaptive outcomes (Haley, Levin, et al., 1987) and depressive symptomatology (Grant, Elliott, et al., 2006), and interventions that include elements to enhance social support are associated with improved outcomes (McMillan, Small, et al., 2005; Mittelman, Roth, et al., 2007). Additionally, it is important to note that there are different types of social support which may serve different roles in terms of relieving caregiver stress. For example, a study of family caregivers of frail elders found that social support that involved pleasant activities with friends and other family had a greater beneficial impact on caregiver burden when compared to other types of social support (Thompson, Futterman, et al., 1993).

Spiritual and religious coping strategies can help to buffer distress and assist with the process of grief and bereavement (Colgrove, Kim, & Thompson, 2007; Kim, Wellisch, et al., 2007). Family caregivers of hospice patients reported that higher levels of spirituality had significantly greater quality of life (Tang, 2009). Unfortunately, caregivers of end of life patients often report a number of unmet spiritual needs (Buck & McMillan, 2008). Interestingly, a recent review of the literature in the area of religion and spirituality and caregiver well-being noted either no association or mixed association between spirituality/religion and caregiver well-being (Herbert, Weinstein, et al., 2006). The authors speculated that the ambiguous results were a reflection of the difficulties defining and assessing religion/spirituality and the diversity of well-being outcomes.

Many caregivers describe the act of caring for a loved one at the end of life as an existential, potentially life-altering experience. Despite the large body of literature describing the negative consequences of end of life caregiving, it is important to note that a large proportion of family caregivers identify positive benefits. Caregivers often report that caring for their loved one at the end of life led to high rates of satisfaction and gave them a sense of meaning and purpose (Hudson, 2004, 2006). A meta-analysis by Pinquart and Sörensen (2004) examining the association between caregiver subjective well-being, caregiver stressors, and depression found that the positive aspects (e.g., "uplifts") of caregiving were associated with higher well-being and caregiver stressors were related to depression. It has been proposed that the positive elements of caring for a loved one may buffer some of the stressful aspects of caregiving (Hudson, 2004). Caregivers should be encouraged to reflect on how their experience has brought meaning to their life and to consider the challenges of caregiving as opportunities for personal and existential growth.

Psychosocial Interventions for End of Life Caregivers

The NIH "State-of-the-Science Conference Statement: Improving End-of-Life Care" included a recommendation for intervention trials that focus on family caregivers (National Institutes of Health, 2004). This led to a growing body of literature documenting the effectiveness of various psychosocial interventions for a variety of caregivers. The caregiver interventions, which included various combinations of psychoeducation, relaxation training, supportive counseling, cognitive-behavioral counseling, and health promotion, had varied results, ranging from no effect compared to controls to lower depression, decreased caregiver strain and burden, improved quality of life (QOL), caregiver competency, and physical activity (for reviews see Brereton, Carroll, & Barnston, 2007; Eldred & Sykes, 2008; Hudson, Aranda, & Kristjanson, 2010; Selwood, Johnston, et al., 2007; Smits, de Lange, et al., 2007; Sorensen, Pinquart, & Duberstein, 2002).

Although there have been a number of studies specifically examining interventions for caregivers of end of life patients, there are only a few strong evidence-based interventions within this area. Hudson, Aranda, and Kristjanson (2010) recently published a systematic review of psychosocial interventions for caregivers of palliative care patients that examined 14 intervention studies that included five randomized controlled trials (RCTs), two prospective studies that included comparison groups, five studies without comparison groups, and two qualitative studies. Of the identified five RCTs, three received high methodological quality ratings and two were assessed as "good quality." The goals of the RCTs included providing psychoeducation, improving coping skills, training caregivers in symptom management, improving sleep, and promoting family meetings. The outcome measures included caregiver distress, caregiver burden, quality of life, self-efficacy; patient reported symptoms and bereavement-associated depression. As summarized in Table 34.2, these five papers generally found that caregivers in the intervention conditions improved relative to controls in their ability to handle the caregiving role (e.g., more positive perceptions of caregiving, reduced caregiver burden, increased self-efficacy), but there were no differences between groups on many measures suggesting that the literature needs more high-quality, theory-driven, intervention studies.

Despite the small number of strong evidence-based interventions for caregivers of end of life patients, it is likely that evidence-based interventions that have been shown to decrease distress in highly stressed populations (e.g., various medical patients) may also improve adjustment in caregiver populations. Psychosocial interventions that integrate coping skills training with cognitive-behavioral strategies have been shown to improve adaptation to stressful life events (Antoni, Lehman,

Table 34.2 Randomized controlled trials of psychosocial interventions for caregivers of palliative care patients

Study	Caregiver patient sample	Interventions	Outcome
Hudson, Arvanda, and Hayman-White (2005)	Advanced cancer patients	1. Psychoeducation (provided specific caregiver information) 2. Standard services	No differences on most measures; psychoeducation group improved positive perceptions of caregiving role relative to standard service group
McMillan et al. (2005)	Advanced cancer patients	1. Usual hospice care 2. Usual hospice + three supportive visits 3. Usual hospice + three visits to teach coping skills	Coping skills treatment improved caregiver quality of life and reduced caregiver burden compared to other two groups
Walsh et al. (2007)	Specialist palliative care patients	1. Career advisor 2. Control	No difference between groups
Keefe et al. (2005)	Advanced cancer patients	1. Three session partner guided cognitive-behavioral pain management intervention 2. Usual care	No difference in patient specific measures; intervention group increased self-efficacy for helping loved one cope with pain
Haley et al. (2008)	Dementia patients who passed away	1. Enhanced counseling and support condition 2. Usual care	Lower depression scores in intervention condition both before and after patient's death; results maintained more than 1 year

et al., 2001; Marcus, Garrett, et al., 1998). Nevertheless, the interventions that have been used with other stressed populations are not always appropriate for short-term interventions or one-time consultations. Table 34.3 presents an overview of factors that can assist caregivers of end of life patients in their adjustment to the stress of caregiving. The list is designed to assist behavioral medicine practitioners who work with family members who are caring for loved ones at the end of their life.

Table 34.3 Enhancing psychosocial and physical adjustment in caregivers of end of life patients

1.	Be prepared to listen to caregivers and normalize their emotional reactions
2.	Assist caregivers in the identification of personal health risks (e.g., lifting/moving the patient)
3.	Promote self-care activities such as regular exercise, eating a healthy diet, maintaining a regular sleep pattern, and following medical advice (e.g., taking medications, attending regular medical appointments)
4.	Allow caregivers to gain a sense of control and mastery over certain aspects of their caregiving role
5.	Promote the use of problem-focused coping skills for controllable stressors
	Seek out information as needed; set realistic goals; request help when needed
6.	Promote the use of emotion-focused coping skills for uncontrollable stressors
	Use cognitive reappraisal and reframing; utilize humor; find healthy avenues to express emotions (e.g., psychotherapy/counseling, journaling, artistic endeavors, prayer, meditation); accept negative emotions as part of the grief process
7.	Discourage the use of nonadaptive coping techniques that may include denial and avoidance, overconsumption of food, alcohol, tobacco or drugs, holding in feelings, and poor self-care activities
8.	Encourage social connections with others
	Deepening the connection with the patient/loved one, maintaining relationships with friends and coworkers outside the realm of caregiving, and talking with other caregivers or former caregivers
9.	Encourage the caregiver to take frequent respites
10.	Support the caregivers search for meaning
11.	Refer to spiritual and/or psychosocial support services as needed

Reflections on Caregiver-Oriented Issues

Caregivers have been referred to as "hidden patients," and indeed research demonstrates that they are susceptible to disruption of immune system functioning leading to pathological health outcomes, engaging in maladaptive behaviors such as increased use of alcohol or other drugs, isolation and failure to garner social support, fatigue and lack of energy, and psychological difficulties including, prominently, depression. The fact that caregivers experience decreased quality of life seems obvious in light of the stresses that they engage daily. Complicated grief is a particular concern and one that behavioral medicine practitioners should be aware of and vigilantly monitor caregivers for. Fortunately, many caregivers are able to employ adaptive coping strategies, engage social support networks, and utilize their religious and spiritual faith to make meaning out of their experience. In fact, some caregivers find a sense of meaning and purpose in the care that they extend to a loved one. Research into the area of caregiver interventions, i.e., interventions designed to improve the functioning of caregivers, is young, and strong evidence of efficacy and effectiveness is still lacking. Though it is likely that interventions that decrease distress in other highly stressed populations will be effective with caregivers, this awaits empirical verification.

Remaining Issues and Future Directions

Advance Directives

A growing body of literature examines decision-making in the context of life's end from empirical as well as ethical and moral perspectives. Decisions regarding the use of an advance health-care directive, living will, health-care proxy (or medical power of attorney), and addressing medical issues such as do not resuscitate orders require individuals to, in advance, consider how they want their end of life to be managed. For many this is an unpleasant task that is left undone. Though in the USA different states have different requirements and forms for advance health-care directives, in terms of accessing forms, the process has in fact never been easier. A Google search using the term “advance health-care directive” yielded 221,000 web sites, including a combination of federal, state, and private sites that offer standardized forms, information, and procedural detail. Nevertheless, significant barriers remain. A recent examination of legal statutes for all 50 US states and the District of Columbia (Castillo, Williams, et al., 2011) revealed both legal and content-related barriers that discourage implementation of these directives including poor readability, restrictions on surrogates or health-care agents, notarization or witness signatures requirements, and not accepting oral communications. In the USA it is estimated that only 11–22% of patients have some form of advanced health-care directive (Gross, 1998; Kemp, Emmons, & Hayes, 2004; Morrell, Brown, et al., 2008). Jones, Moss, and Harris-Kojetin (2011) studied three long-term care populations and found that 28% of home health-care patients, 65% of nursing home residents, and 88% of discharged hospice patients had at least one advance health-care directive. Differences were found in rates of directives based on race. African American home health patients were half as likely as white patients to have a directive.

Although the completion of an advance medical directive is a positive step in honoring patients’ preferences for end of life treatment, decision-making research indicates that the process is much more complex than most professionals and the public acknowledge. Peter Ditto is a leading investigator in this area and has conducted a series of empirical studies whose results challenge the efficacy of the advance medical directive as currently understood and practiced. An important finding from Ditto’s research is that patient preferences for end of life medical care are somewhat unstable over time and are highly influenced by contextual factors including whether they are currently hospitalized (Ditto, Jacobson, et al., 2006; Ditto, Smucker, et al., 2003). For example, when they are healthy, patients tend to indicate that they want more aggressive medical treatment, whereas during hospitalization this preference declines. However, 3 months subsequent to hospitalization, the preferences for aggressive treatment return to their pre-hospitalization level. The inherent plasticity of choices and preferences is a concerning factor. That measures of patients’ preferences may change from times when they are healthy, to circumstances surrounding diagnosis, through lengthy and often burdensome treatments, up to end of life represents not a failure of measurement but the nature of choices and preferences. Clinicians and policies need to recognize this natural changeability of preferences and develop procedures that best capture and represent the current wishes of patients and their families.

This raises important questions regarding what the patients’ true preferences are and how one would go about ascertaining them. Ditto (Ditto & Hawkins, 2005; Hawkins, Ditto, et al., 2005) also highlights the difficulty that surrogate medical decision-makers have in interpreting patient wishes even when they are relatively specifically detailed in writing. The fact is that the panoply of possible medical circumstances and decisions that can be encountered is large and characterized by varying levels of what is known and unknown, what is probable and improbable. Further it appears that patients largely desire to implement a type of advance directive wherein their values and overall goals are stated but where medical surrogates have liberty to use their best judgment and even, in some circumstances, to overrule the advance directive. But delving into this issue further reveals that beyond the generalization regarding preferences for relatively open directives, patients are highly individual in terms of when they would want a surrogate to have leeway in interpreting a directive, what types of decisions need to be strictly adherent to the directive, and what patients consider to be the most important considerations (Hawkins, Ditto, et al., 2005). Further, most advance directives now in use are designed to specify use of particular medical technologies and therefore do not conform to the type of decision-making process that patients, in fact, desire.

We have only briefly scratched the surface of this important issue, and space does not permit a detailed discussion. We hope that we have alerted readers to the complexities of advance medical directives and thus encouraged greater caution in clinical practice and greater engagement in research on this issue. Behavioral medicine professionals are in a strong position to lead the way in this work.

Communication

Good doctor-patient communication has been shown to promote healthy adjustment in end of life patients and their families (Block, 2006). Physicians need to allow patients the opportunity to voice their fears and concerns while providing support and reassurance. Although negative prognostic information may be initially conveyed by an oncologist or other specialist, the primary care physician typically has the task of providing detailed information to the patient regarding end of life care. It can be difficult to assess the informational needs of each individual, so it is typically best to ask patients what information they would like to know (e.g., all of the details or an overview), how they want to receive this information (alone versus with others, verbally and/or written format), and when they want to receive the information (immediately or later in the process). End of life patients often express anxiety and fear about the future including the fear that they will be abandoned by those near to them including their health-care team. Physicians and behavioral medicine providers can ease these concerns by providing honest and open information to patients and their families with continued reassurance that they are committed to their care, will not abandon them, and will do whatever it takes to alleviate patient pain and suffering.

Future Directions

Patients and caregivers of patients experiencing end of life concerns can both benefit from the kinds of services that practitioners of behavioral medicine provide. Existing research facilitates understanding of the experiences of these individuals, their needs, and how those needs might be met within the health-care system. But much remains to be done. Randomized controlled trials as well as research utilizing other methodologies are needed in this area to provide guidance for how to better intervene to enhance quality of life and reduce suffering. Importantly, this research needs to take an interdisciplinary focus. Physicians are key members of the treatment team, and, obviously, research relevant to physician behaviors and interventions is essential. But also to be included are nursing staff, chaplains and other clergy, as well as psychologists and social workers who are involved with the patients and their families and significant others. Sensitive adaptations of successful coping interventions used with other populations provide a good starting point, but the unique aspects of dealing with end of life concerns as well as adaptation following death of a loved one must be prominently considered.

Religious and spiritual issues are uniquely salient when dealing with the end of life. Unfortunately, many in the helping professions including psychologists and physicians have meager training in or understanding of these issues and are, statistically, less likely than the general population to embrace religious or spiritual beliefs (Curlin, Lantos, et al., 2005; Curlin, Chin, et al., 2006). Frankly, our personal experience over the years suggests that some are even fearful of these issues. Earlier we noted ethical concerns that are raised at the prospect of involving health-care professionals in spiritual concerns. Clearly we are not advocating any kind of proselytizing or aggressive introduction of religious and spiritual perspectives into patients' and caregivers' lives. But it is also clear that patients and caregivers often value discussion of these issues with their health-care providers and not just with clergy. If practitioners are going to communicate respect and value for the whole person, this will, of necessity, in many cases include consideration of religious and spiritual concerns. There is no reason to believe that health-care professionals are incapable of providing proper support around these issues and engaging patients and caregivers in ways that are sensitive and enhance their functioning and quality of life. Organizations that have recently called for increased sensitivity and better training of clinicians concerning management of religious and spiritual issues in assessment and treatment include the following: the American Psychiatric Association, American Psychological Association, Accreditation Council for Graduate Medical Education, Council on Social Work Education, Joint Commission on the Accreditation of Healthcare Organizations, American Academy of Family Physicians, American College of Physicians, and Association of American Medical Colleges (Larimore, Parker, & Crowther, 2002). The American Psychological Association, within the context of recognition of cultural diversity and the call for cultural competence, specifically indicates that psychologists must be competent regarding religious and spiritual issues in therapy. To their credit, medical schools have also begun paying at least some attention to religious and spiritual issues (Brokaw, Tunnicliff, et al., 2002), and in 2004 approximately 67% of US medical schools included something about it in the curriculum (Fortin & Barnett, 2004). Clinical psychology graduate programs housed in secular universities (as opposed to those housed in religiously based universities), on the other hand, are essentially silent on the issue or address it only in passing as it might come up during class discussions or, more likely, is initiated by a patient in therapy (Russell & Yarhouse, 2006; Schafer, Handal, et al., 2011). Clearly if providers are to adequately address these concerns in appropriate and sensitive ways, training in their advanced degree or postdoctoral setting is necessary.

Finally, health-care providers may feel uncomfortable working with patients in situations where the end of life is imminent. Finding ways to influence the prevailing culture to better understand death as a natural and integral part of the life cycle and attending to the personal needs of behavioral medicine specialists who work with patients and caregivers facing a limited life seem promising in terms of destigmatizing the end of life experience. Opening doors to greater discussion, collaboration, and understanding around the experiences of these patients, their families and significant others, and those entrusted with their care will improve the treatment experience for all involved individuals. The recent US health-care debate demonstrated clearly that misinformation and highly charged emotions around end of life care are easily disseminated but not likely to lead to improved care and more compassionate interventions. We hope that the behavioral medicine community will lead the way in research and practice that leads to greater understanding and acceptance of the important issues surrounding end of life and, ultimately, improves the quality of life and quality of death for all.

Part VII

The Contexts of Behavioral Medicine Science and Practice

35

Values in Behavioral Medicine

Gerald C. Davison and Michelle C. Feng

It has been said that a fish doesn't know it is swimming in water. And yet being in water is an essential part of being a fish. So it is with values and ethics.

Often, the most important and influential forces in our immediate world are those that we think little about in our day-to-day life. If we are fish, our values are the water that surrounds us. They guide our thoughts, our questions, and our behaviors. They inform us if we are doing something "right" or "wrong" and can sway us in different directions, like the waves of an ocean. While this guidance, of which we are usually unaware, can be good in many ways, our values feel so natural to us – to the extent that we even think of them – that they can sometimes be mistaken for absolute truths.

We – both scientists and nonscientists – take certain values for granted, not even considering them an issue. For example, we can safely assume that most individuals would not tolerate a child banging her head against the wall. In fact, in certain situations such as working with children diagnosed with autism, health professionals have gone to great lengths, including heavy sedation and/or physical restraints, to prevent this behavior. Why? Well, it has to be because we as a society value keeping the human brain as undamaged as possible. But why do we value this? The reason has to be that we place a high value on children benefitting from life experiences that require as undamaged a brain as possible. These value choices result in our being prepared to take drastic measures to protect human brains. As social scientists and human beings, we certainly agree with this position, but it is a value-laden position, not an empirical one.

In the field of behavioral medicine, value judgments are made all the time regardless of whether the decision-makers are health practitioners, academic researchers, or administrators. It is our purpose in this chapter to examine some of these values and how they affect the way professionals construe problems and design interventions. We would not presume to propose specific solutions, especially in an international handbook. Instead we hope to shine a light on the influences of our values and discuss how they can affect the way we assess and treat patients, especially when there may be little explicit awareness of these values among professionals who influence others.

When referring to "values" in this chapter, we mean the goals and purposes that guide one's activities. Values embody what a person or group of persons deem desirable or even mandatory, the "shoulds" that impose proscriptions and prescriptions for behavior. Do we value collectivism, for

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_35

example, or do we consider individualism more important to pursue? Do we think that being honest with loved ones is always more important than sparing their feelings if complete honesty would offend or hurt? Valuing one of these over the other inherently affects the way we behave, how we see ourselves, and how we see others.

People make value judgments all the time, as just indicated, but those whose expertise in health matters is sought out and paid for by people in pain or other states of unhappiness have especially to consider values, the good and the bad, and they have to be aware of the influence that these values can have over people who consult with them. (Note that the authors have just made a value judgment!)

We begin this chapter by arguing that science and practice within behavioral medicine (but not exclusively to this field) are never free from bias but instead are guided by underlying values, whether they are explicit or implicit. We then discuss in detail some specific values-laden topics that influence the field of behavioral medicine. We pay special attention to longevity, quality of life, suicide, euthanasia, and global and cross-cultural issues in research and practice. We believe these topics and values to be continually present in behavioral medicine and often shape what is viewed as valuable and ethical within the field on an international level.

To be clear, we wrote this chapter from the perspective of behavioral scientists who work in the United States. It goes without saying, though we want to say it explicitly, that values and ethics vary across countries and, in a heterogeneous country like the United States, across subgroups within a country. In addition, the very fact that this handbook contains a chapter like this one in itself is a values statement. That is, the editors and we value discussions about values! We will do our best to acknowledge such variations where appropriate but wish to concede at the outset a degree of ethnocentrism, if you will, that we believe is unavoidable when discussing values.

At the end of this chapter, we present a case study that will, we hope, illustrate many of the themes we are about to set forth. We are the kind of fish that should – a values statement in itself! – be aware of the water it swims in.

Nonobjective Features of Science and Practice

The fields of science, medicine, and other applied health disciplines are often thought of as being objective and ethically neutral**.** "Just give us the facts, ma'am," as the Joe Friday character would say on the old Dragnet series. However, we believe that it is not that simple.

In a landmark book published in 1962, *The Structure of Scientific Revolutions*, the physicist and philosopher Thomas Kuhn articulated a perspective on scientific discovery and theorizing that was underappreciated at the time and has since become normative when people reflect on the role of nonempirical factors in scientific inquiry (Kuhn, 1962).

Central to any application of scientific principles, in Kuhn's view, is the notion of a paradigm, a conceptual framework, or an approach within which a scientist works.[1] A paradigm, according to Kuhn, is a set of basic assumptions that outline the particular universe of scientific inquiry, specifying the kinds of concepts that will be regarded as legitimate as well as the methods that may be used to collect and interpret data.

A paradigm has profound implications for how scientists operate in any given time and place, for "[people] whose research is based on shared paradigms are committed to the same rules and standards for scientific practice" (Kuhn, 1962, p. 11). Paradigms specify what problems scientists will investigate and how they will go about the investigation. Paradigms are an intrinsic part of science, serving the vital function of indicating the rules to be followed. In perceptual terms, a paradigm may be likened to a general perspective or set, a tendency to see certain factors and not to see others.

In addition to injecting inevitable biases into the definition and collection of data, a paradigm affects the interpretation of facts. In other words, the meaning or import given to data depends to a considerable extent on a paradigm.

Let us provide an example. In space exploration, highly sophisticated satellites and robotic

---

[1] This section on paradigms and outer space exploration is adapted from Davison and Neale (1974, Chap. 1).

explorers have been sent aloft to make observations. It is possible, however, that certain phenomena are missed because our instruments do not have sensing devices capable of detecting them. Consider what we regard as a classic discussion surrounding an announcement made on August 7, 1996, by the National Aeronautics and Space Administration (NASA). NASA reported that signs that life once existed on Mars may have been found in a piece of Martian rock. The rock, it is believed, was catapulted into space by an asteroid about 16 million years ago and was drawn into Earth's gravity about 13,000 years ago. Found in Antarctica in 1984, this rock was the subject of study and speculation by chemists and space scientists. Did it contain signs of Martian microbes from 3.6 million years ago? Some scientists believed it did, whereas others disagreed.

The general question was – and remains in all subsequent efforts – how one can decide whether there are indeed signs that life once existed on the now-barren planet. To even begin to address this question, sophisticated scientists have to ask how we can be certain that our own understanding of what is alive matches what may have once lived on Mars? Said a NASA astrophysicist at the time, "Everything we know about life we learned from Earth" (cited in Cole, 1996, p. A1). Another scientist put it this way: "We're working with a sample of one: life on Earth. That's like trying to learn about fruit by studying only apples. We have to look at a lot of apples and oranges" (cited in Cole, 1996, p. A29).

The simple yet profound fact is that we can look for life on another planet or heavenly body only with the instruments we have available, and the design of these instruments is determined not just by technology but by our preconceptions of what life is. Tests that are conducted on material from another part of the solar system rest on earthbound assumptions about the nature of living matter that may not match what might have evolved elsewhere.

This discussion of space exploration is one way of pointing out that scientific observation is a human endeavor that reflects not only the strengths of human ingenuity and scholarship but also our intrinsic inability to know fully what the nature of our universe is. Scientists are able to design instruments to make only the kinds of observations about which they have some initial idea. Thoughtful scientists realize that certain observations are not being made because their knowledge about the nature of the universe is limited.

Science, then, is bound by the limitations imposed on scientific inquiry by the current state of knowledge. It is also bound by the scientist's own limitations. Science is not a completely objective and certain enterprise. Rather, as suggested by Kuhn (1962), subjective factors as well as limitations in our perspective on the universe enter into the conduct of scientific inquiry.

Our position is that paradigms in both scientific inquiry and science-based application are, in Kuhnian terms, manifested as well when it comes to values and ethics. Neutrality does not exist. Science and practice are fundamentally guided by strong values at varying levels of influence. For example, treating the psychological effects from receiving a cancer diagnosis, helping individuals to stop smoking, and formulating techniques for reducing pain, these are all topics of focus in research and practice in behavioral medicine. But let's step back and ask why these questions and interventions are being pursued in the first place. Why do we care to study why people smoke and then help them stop smoking? It seems to us that these decisions derive from the value we place on longevity or quality of life. Is it because we believe that smokers will ultimately regret their actions when they are older and are potentially suffering from chronic health problems related to their smoking? Is it because we believe that regret is inherently a bad feeling that should be avoided? Does the individual's high-risk behavior become a societal concern because of the increased health costs to non-smokers? All of these value-laden questions are related to what we believe is good and helpful and important to us as human beings. Therefore, these judgments and interventions are not bias-free; in fact they are rooted in values that run deeper than we often spend the time to think about.

The shift from a biomedical model to the biopsychosocial framework can also be considered, in Kuhn's terms, a paradigm shift. The biomedical model, which takes a reductionistic approach to disease, also assumes a dualistic split between mind and body. Because of these Cartesian assumptions, the causes of disease within this model are seldom sought in psychosocial factors (Engel, 1977). In other words, measurable biological variables are the focus within a biomedical model. Research and practice conducted within this model have brought great advances in our understanding of pathogens and acute diseases; however, because of its restricted views on what is important in treating illness, knowledge gained within this framework can focus only on part of the picture.

The introduction of the biopsychosocial model allowed for a broader, more integrated view of health and disease which includes psychological, social, and environmental influences. This shift has encouraged new and exciting areas of interdisciplinary research and practice. Moreover, and of relevance to this chapter, the inclusion of psychological and societal factors opened the door to an increased role for value considerations in analyzing, preventing, and treating illness. Smoking addiction, for example, is often comprised of a combination of biological, psychological, and social factors. Interventions based solely on the biomedical model may not take advantage of the potential benefits that behavioral interventions and psychotherapy offer to promote smoking cessation and to alleviate urges to smoke.

Behavioral medicine as a field is based largely on the integration of various levels of healthcare to promote health and treat disease. As reviewed in other chapters of this handbook, this expanded, interdisciplinary focus has led to a wealth of research conducted toward understanding the social and environmental determinants of health-related behaviors, the influence of stress and negative emotions on the immune system, the effects of various types of social support on quality of life and general health, and the development of behavioral/psycho-social interventions for managing chronic illnesses. This field, therefore, appreciates the roles of both internal and external factors.

Longevity and Quality of Life

Perhaps two of the most valued outcomes in behavioral medicine are longevity and quality of life. Let us first consider why we value longevity at all. The urge to keep people alive as long as possible appears to be centrally guided by the high value that we place on our time on earth. This is why, we believe, machines such as the ventilator were invented. While such advancements seem like common sense, they are in fact value-laden. If our value were placed instead on natural selection and living in a world where we valued as little intervention as possible into the "natural" course of evolution, perhaps we may not have committed our time and efforts to inventing the ventilator. Instead, we may have viewed death more as a part of life than something to ward off. Perhaps our focus would be more on fate than on control.

Along with longevity, the quality of one's life is also valued by both practitioners and patients and therefore is a common outcome measure in behavioral medicine (e.g., Taylor-Ford, Meyerowitz et al., 2013). While longevity and quality of life are by no means mutually exclusive, there are points in time where choices need to be made that highlight the relative importance of these two factors, with the definition of quality of life often taking on several different meanings. Multiple self-report questionnaires have been created to capture what is viewed as an important factor in health-related issues (e.g., Cella, Tulsky et al., 1993). Generally, these questionnaires measure subjective feelings of well-being, quality of important relationships, components related to socialization and connectedness, as well as subjective ratings of health. Specific health-related quality-of-life measures have also been created for different illnesses such as prostate cancer in order to hone in on what researchers believe are particularly important for men and their families dealing with this illness (e.g., Cella, Bonomi et al., 1995; Esper, Mo et al., 1997). However, these measures do not specifically address who decides what is valued in life and what makes a person's existence meaningful at a given place and time. In other words, how does one define "quality" without making value judgments?

Consider hospice versus continued hospital care for individuals nearing the end of life. Hospice and palliative care facilities focus on the quality of the time left to terminally ill patients. Hospice also emphasizes emotional and/or spiritual personhood. This model is very different from the continued medical care model, which focuses on sustaining life more than on the quality of that existence. A host of procedures varying in invasiveness are made readily available to terminally ill patients seeking continued medical care, including antibiotic administration, medical respirators, feeding tubes, and resuscitation attempts.

In fact, in the medical field, the default option for physicians is to provide patients with whatever technologies are available that will keep the patient alive. These procedures can be painful and expensive. Or to alleviate pain, heavy sedation is used, which in itself can interfere with the patient's ability to engage his or her social environment. Opting out of all or some of these life-extending procedures requires individuals to think through difficult scenarios. Often the choices fall to those who have assumed decision-making responsibility for the patient deemed not competent to make their own decisions.

In addition, knowingly discontinuing life support or further treatment for a terminal illness can be extremely anxiety-producing because it is ultimately a conscious choice of valuing present quality of life over the hope of a potentially extended future. In the United States as well as most other Western societies, patients, physicians, and family members tend not to do a good job of confronting the possibility of death even when death is near and inevitable. Having said this, there are often other things that we value in addition to basic survival, and these values can become more and more important at different stages in our lives. The difficulty of these competing values and areas of focus is illustrated in a *New Yorker* piece written by Atul Gawande:

> People have concerns besides simply prolonging their lives. Surveys of patients with terminal illness find that their top priorities include, in addition to avoiding suffering, being with family, having the touch of others, being mentally aware, and not becoming a burden to others. Our system of technological medical care has utterly failed to meet these needs, and the cost of this failure is measured in far more than dollars. The hard question we face, then, is not how we can afford this system's expense. It is how we can build a health-care system that will actually help dying patients achieve what's most important to them at the end of their lives. (Gawande, 2010)

While we are not suggesting that obsessing over our remaining days is productive or even necessary, we want to highlight the significance of our values on survival and on quality of life as well as other meaningful priorities that can shift over the lifetime and especially at the end of life.

Indeed, our relative value on quality of life and length of life is dynamic and is often reactive to changes in life situations. Making medical treatment decisions can be affected by our shifting values over the life span. For example, as both healthcare providers and consumers, we often take into account whether a treatment is "worth it" – that is, whether the benefits of treatment outweigh the potential costs. However, the benefits and costs of certain interventions may be weighted differently depending on where that person is in the course of their life and what they view as important. When treating a life-threatening disease, one of the main goals is to extend life as long as possible. For a patient in their 20s, the focus may be on choosing treatments that offer the best chance of long-term survival. However, treatments for both acute and chronic illnesses can have negative health consequences and unpleasant side effects that appear years down the line. Other things being equal, younger patients are likely to live longer than older patients. In such circumstances, therefore, physicians may want to be especially careful of the long-term side effects of treatments.

Consider a 30-year-old and an 80-year-old individual with the same kind of cancer. Treatment options that are seriously considered may be the same or they may be different depending on the values of the physician and the patient. In other words, the costs and benefits of certain types of treatment may be weighted differently depending on how much longevity is valued compared to quality of life and/or eradication of the disease. Eradicating as many cancer cells as possible may be important to the patient, but in an 80-year-old, concerns of recurrence 20 years down the line may be less important than they would be to a 30-year-old.

Another way to view the relative importance of values such as longevity and quality of life over time is within the course of an individual's life. A decision made at, say, age 30 may well not fit with that person's wishes or values at age 70 or if that person becomes gravely ill at age 40. For example, a DNR (do not resuscitate) document signed when one is in good health in early adulthood, when one's timeline stretches out to the horizon, may look very different when that choice has to be made about life support when that person is terminal and in an intensive care unit at age 70. An old adage about religiosity holds that there are no atheists in foxholes.

The relative value of longevity and quality of life is pertinent also when discussing the push and pull factors surrounding chronic health issues such as obesity. Setting aside for purposes of discussion here biological factors in obesity, it is very challenging for overweight people to lose weight and to maintain weight loss. Any dieter knows that cutting back on calories and on certain foods, especially those that are high in sugar and carbohydrates, entails a level of self-denial that lowers their quality of life vis-a-vis sheer hedonic pleasure. Eating badly tastes good! Short-term reinforcement from the ingestion of unhealthful – in the long run – food and drink has to be set against longer-term benefits in terms of reducing the chances of cardiovascular disease, cancer, and longevity. (Note: for those with diabetes, the negative consequences of eating badly are more immediate.) The formidable challenge for anyone trying to lose weight and maintain weight loss is to deal with the short-term "pain" of eating better (and limiting unhealthy food) in service of benefits that are many years into the future.

But the picture is even more complicated than this. Especially if one is looking for a romantic partner and/or if one works and lives in settings where being overweight presents a short-term disadvantage, the hedonic payoff matrix shifts. Furthermore, the positive correlation of ingesting unhealthy foods and becoming more and more obese is far from one to one and is certainly affected by a host of potential known and unknown variables. For example, and partially bringing biological factors into the mix, many individuals have poor eating habits but are not obese. Additionally, while eating chocolate cake every day will most likely lead to weight gain (assuming all other variables are constant), anticipating the negative health effects of eating one piece of cake is difficult and its negative implications are abstract, especially when compared to the near certainty of the deliciousness of the cake. In this case, while an individual's value on longevity may be high, the negative correlation of longevity to a slice of cake is much weaker than the positive correlation of quality of life to cake.

Suicide and Euthanasia

Another uncomfortable example related to our value on longevity is suicide. We in the United States adopt sometimes extreme measures to prevent suicide, including incarceration, heavy psychoactive medication, and physical restraints, although strong tranquilizers have reduced our reliance on restraints. But why do we go to great lengths to keep people from killing themselves? Indeed, why do we make it legally mandatory in most jurisdictions that health professionals take steps to keep people from fatally harming themselves? The reason is that we value the continuation of human life even if the person states repeatedly that they wish to end their life. At least we do so in most Western cultures. There are, however, many belief systems, some of them religion-based, in which suicide under certain conditions is not only not prevented but even actively encouraged.

While fictional, the 1973 film "Soylent Green" provides an instructive example of a postapocalyptic world in which older adults are encouraged to commit suicide in order to create more room and sustenance for the younger generation. In this fictitious world, one would not see therapists or physicians having as their treatment goal the prevention of suicide among seniors. Instead, based on the values of the Soylent Green society, health providers would actually encourage older adults to act on their suicidal thoughts, regarding them as noble and realistic for a society whose resources are so stretched that the survival of younger generations relies upon converting into food the bodies of those who have died.

Physician-Assisted Suicide[2] Physician-assisted suicide has for a number of years been a highly charged issue. In the United States, it came to the fore in the early 1990s when a Michigan physician, Jack Kevorkian, helped a 54-year-old woman in the early stages of Alzheimer's disease to commit suicide. Not yet seriously disabled, she was helped by Kevorkian to press a button on a machine designed by him to inject a drug that induced unconsciousness and a lethal dose of potassium chloride that stopped her heart (Egan, 1990). Death was painless.

Kevorkian believed that it was ethically incumbent on physicians to ease patients' terminal suffering, and if that included helping them die, it was the right thing to do. For almost 10 years, Kevorkian played an active role in assisting more than 100 terminally ill people to take their lives, one such suicide even being videotaped and shown on CBS's "60 min" on November 22, 1998. At the same time, with steadfast intent, he provoked a searching and emotional discussion about the conditions under which a physician might ethically take the life of a dying patient – an issue made all the more heated by widespread knowledge that health professionals every day pull the plug on patients who are brain dead but who are being kept physically alive by sophisticated medical apparatus. Kevorkian was brought to trial several times but was not convicted of murder or professional misconduct until the spring of 1999, when he was found guilty of second-degree murder and sentenced to 10–25 years in prison. He was released on parole on June 1, 2007, on condition he would not offer suicide assistance advice to any other person. He died in 2011.

Right-to-life advocates have claimed that especially in this era of managed healthcare, patients will be pressured, albeit subtly, to ask to have their suffering lives terminated in order to spare their families the high costs of medical care. There is also the fear that physicians will lean in this direction, perhaps pressured by insurance companies that want to save money on expensive terminal medical care and will influence the patient and his or her family to end the person's life. Among the many criticisms leveled against Kevorkian is that he allegedly did not conscientiously enough assess the person's actual desire to commit suicide. Among powerful groups opposing assisted suicide have been the American Medical Association and the Catholic Church. In contrast, Kevorkian's supporters and others, such as the American Civil Liberties Union, believe that terminally ill people should have the right to end their suffering. Many of these supporters have for years objected to the intrusion of the state on what they regard as a person's inalienable right to make such life or death decisions.

Oregon is the US state in which the woman whom Kevokian first assisted in suicide lived. In 1997, it became the first state to have a law – the Death with Dignity Act, originally approved by voters in 1994 and reaffirmed by an even greater margin in 1997 – that made physician-assisted suicide legal. Washington and Montana followed. Similar laws exist in the Netherlands, Belgium, and a growing number of countries. The Oregon law permits a patient diagnosed by two physicians as having less than 6 months to live to seek a doctor's prescription for a lethal dose of barbiturates. But the law also requires that the prescribing physician determine that the patient is not suffering from depression or another mental illness and that there be a waiting period of 15 days before the prescription can be filled.

Decisions not to resuscitate terminally ill patients are made every day in hospitals. One informal estimate is that more than half the deaths in US hospitals follow a decision to limit or withhold access to the kinds of life-sustaining

---

[2] Some of the discussion on physician-assisted suicide and suicide prevention is adapted from Davison and Neale (2001, Chap. 10).

equipment currently available. Furthermore, a report published in the *New England Journal of Medicine* in 1998 indicated that, over the course of their careers, close to 20% of physicians in the United States had been asked by terminally ill patients to help them die, and of this number, about 15% wrote at least one prescription to hasten death and about 5% administered at least one lethal injection. Such euthanasia, whether legal or not, occurs with some frequency (Meier, Emmons et al., 1998). Many people do not consider this practice euthanasia or suicide, however. Rather than ending life, “It is, rather, a desire to end dying, to pass gently into the night without tubes running down the nose and a ventilator insistently inflating lungs that have grown weary from the insult” (Begley, 1991, p. 44). Major legal, religious, and ethical issues whirl around decisions about ending dying among the terminally ill.

Suicide Prevention In bold and controversial publications on coercive suicide prevention, Thomas Szasz (1986, 1999) argued that it is both impractical and immoral to prevent a person from committing suicide. It is impractical because we cannot really force people to live if they are intent on committing suicide unless – and this is when morality especially becomes an issue – we are prepared not only to commit them but to enslave them via heavy medication or even physical restraints. Even then, hospitalized patients do manage to take their own lives. Szasz asserted further that mental health professionals, in their understandable desire to help their patients, open themselves up to legal liability because, by taking it upon themselves to try to prevent suicide, they assume responsibility for something for which they cannot be responsible. In effect, they are promising more than they can deliver.

Further, Szasz argued that health professionals should not assume such responsibility – even if it were practical to do so – because people, including those seriously disturbed, should be accorded freedom to make choices. He allows one exception for what he calls impulsive suicide, when people are temporarily agitated, perhaps truly deranged, and need to be protected for a short while from their uncontrollable impulses.[3] He draws an analogy with patients coming out of general anesthesia, when it is common medical practice to strap them down lest their flailing about involuntarily leads to unintended and preventable harm. But there are limits here as well, including, in our own view, how we can know when we are dealing with an impulsive act rather than an act that the person has been thinking about and planning for a period of time. Often, these decisions are guided by the relative values we place on the autonomy of an individual versus the responsibility we feel we have toward keeping them “safe.”

Szasz was not against advising a person not to commit suicide or otherwise treating problems, such as depression, that might have a good deal to do with self-destructive thinking. It is forcible prevention against which he railed. Indeed, he believed that if professionals excluded coercive suicide prevention from their intervention options, they would be able to be more empathic with their patients and perhaps more helpful. He also suggested a psychiatric will, in which a patient, when not feeling suicidal, agrees ahead of time about how to be treated if later on he or she wishes to commit suicide. If the patient opts for coercive prevention in this will, then it would be all right. This strategy brings to mind the instructions Ulysses gave to his sailors before they were to pass by the coast of the Sirens, sea nymphs whose song compelled hapless mariners to commit suicide by throwing themselves into the sea.

> He filled the ears of his people with wax, and suffered them to bind him with cords firmly to the mast. As they approached the Sirens’ island, the sea was calm, and over the waters came the notes of music so ravishing and attractive that Ulysses struggled to get loose, and by cries and signs to his

---

[3] Presumably he would have broadened this protective stance in the case of children and adolescents, whose problem-solving abilities are not as well developed as those of adults and who therefore need extra social and professional support to protect themselves from impulsive acts. Another exception might be for adults whose problem-solving capacity is compromised by the reduced brain oxygen that can arise from a variety of medical problems, for example, congestive heart failure.

> people begged to be released; but they, obedient to his previous orders, sprang forward and bound him still faster. They held on their course, and the music grew fainter till it ceased to be heard, when with joy Ulysses gave his companions the signal to unseal their ears, and they relieved him from his bonds. (Bulfinch's Mythology, 1979, p. 243)

On the other hand, recall what we wrote earlier about it being very natural that people's values shift over time. It is disingenuous to assert that a person's preferences at Time A may not change years later and under other circumstances. The Ulysses story makes a serious point, but it must be borne in mind that it is just a story, a mythical tale composed by Homer to make a dramatic statement.

Global Research and Ethics

Our world, in a sense, has gotten smaller in the past few decades. We are able to travel around the globe faster, conduct business and research more easily between countries, and have greater access to global resources than ever before. With this increased global connectedness, enhanced in revolutionary ways by the Internet and other advances in communication, comes an opportunity – and in our view, an ethical obligation – to consider how values compare across countries and the different ethical issues that arise when dealing with health and illness on a global level.

Global Clinical Research The fact that clinical trials can be conducted more cheaply in certain countries has benefitted the bottom line of pharmaceutical and medical device companies. The cost of recruiting participants in countries such as China and India is usually lower than in Western countries, and regulations for conducting research in wealthier countries are often more complex and burdensome to investigators. But while there may be clear economic benefits to conducting clinical research in certain countries more than in others, these benefits also bring about challenging questions about ensuring that research subjects enjoy the same protections of their safety and integrity as those who participate in studies conducted in the countries from where the research emanates. While the problem is particularly acute in medical research, the issues apply as well to behavioral medicine and other domains of science and practice involving human beings.

Glickman and colleagues (2009) highlight several ethical issues that arise from the globalization of clinical research. They begin with the overarching question "to what extent should people in developing countries be enrolled in clinical trials [at all]?" (p. 819). To break this question down, we distinguish three specific issues.

First, is there an ethical obligation for treatments being tested in third world countries to be available and accessible to those countries? For example, if a potentially useful antihypertensive medication is being tested by a US drug company in a less developed country, should positive outcomes from the study benefit that country by taking steps to make it available there? Should it be made available at a cost that is generally affordable in that country, very likely at lower cost than would be the case in the United States? In other words, is care taken to maximize the translational value of a given study so that positive results can benefit the people in whose country that study is taking place?

Second, to what extent should the problem being addressed be directly related to something of real importance to the country in which the study is being conducted? It is likely that many of the trials conducted in low-income countries are not geared toward the most prominent medical and social issues concerning their populations. Rather, it is more likely that the trials concern problems of importance to the more economically advanced countries, the ones doing the research.

Third, to what extent are the findings from studies in third world countries applicable to first world countries? While the third question can be examined empirically by conducting multinational trials with representative populations, Glickman et al. (2009) found that fewer than 5% of multinational studies included in their published reports the number or percentage of participants recruited by country, making it difficult to assess the generalizability of each study.

These several questions highlight some ethical challenges that global research presents. On a practical level, understanding these challenges and the way that global research is designed and implemented is important because it plays a role in the way we interpret research findings and, ultimately, how we discuss options and treatment plans with patients.

Ethical Imperialism Versus Ethical Relativism Another important ethical and value-laden topic, particularly when adopting a global perspective, is the issue of ethical imperialism versus ethical relativism. Ethical imperialism refers to the extension of a set of ethical standards and beliefs of one group of people to other groups of people and cultures. To what extent do we believe that there is a set list of universal rules determining what is ethical and unethical? Consider the widespread assumption in the West that human suffering should be kept to a minimum, especially when health professionals are in the picture. But what if the suffering has a chance of resulting in a longer life, such as with cancer treatments or in recovering from surgery? Or in the case of behavioral medicine, dieting and exercise regimens seldom bring pleasure to overweight people, but this kind of suffering is presented to them as less important than the long-term benefits that can follow. Clearly, these “shoulds” are not clear cut.

In contrast to the ideals of ethical imperialism is the principle of ethical relativism, which is based on the awareness of individual cultures having their own set of values, all of which should be equally respected. A case in point, disturbing to most people in the West, is female circumcision and other forms of genital cutting in young women. A recent UNICEF report indicated, for example, that over 90% of women in Egypt have undergone this procedure (UNICEF, 2013). And gender equality, so highly valued for several decades in many parts of the United States, is far from valued in many parts of the world.

Cross-Cultural Perspectives on Self-Efficacy Emotional issues are of great relevance in behavioral medicine. Depression, for example, has been associated with a variety of medical problems, such as cardiovascular disorders, diabetes, and other chronic diseases (Glassman & Shapiro, 1998). Learned helplessness has been explored for many years as a cause of depression. Attributions – the ways people explain to themselves the causes of their behavior – have been invoked as linked to learned helplessness and depression (Abramson, Seligman, & Teasdale, 1978).

Not adequately appreciated, in our view, are the cultural biases inherent in this school of thought. In Western psychological research, self-attributions are often viewed as sources of either positive or negative emotions – positive if an event is defined as desirable, negative if an event is defined as undesirable. Thus, if something good happens, the tendency is to credit one’s own efforts or characteristics and to feel good about it. But if something bad happens, taking responsibility leads to negative emotions. This is part and parcel of an individualistic society that values independence and minimal reliance on others. More collectivistic societies as one finds in American Indian or many Asian cultures, however, place a higher value on support from others and, often, on the needs of the family, tribe, or group over those of the individual.

In the United States, we measure IADLs, *independent* activities of daily living, to determine how capable patients are in performing everyday tasks on their own. While these can be good measures of a patient’s physical health status, they also highlight our value on self-reliance and independence. That is to say, the very development of measures of independent living and their use as a measure of good outcome derives from a high value placed on not depending on others.

In a related fashion, personal control over events in our lives is assumed in Western psychology to be necessary for normal functioning. Even laboratory rats have been shown to be stressed more by electric shocks over which they have some control as compared to the same levels over which they have no control (Mowrer & Viek, 1948). And in a later study, the importance of perceived rather than actual control was demonstrated in humans (Geer, Davison, & Gatchel, 1970). Would such experiments have even been carried out by investigators in a societal milieu that did not value individual control over events?

Albert Bandura's concept of self-efficacy originally focused on the individual's belief in her or his ability to engage in a certain behavior. In contrast to beliefs about the effectiveness of some behavior on a desired outcome (e.g., how foregoing that chocolate cake might influence body weight), self-efficacy is the individual's confidence in her or his own ability to enact the specified behavior, in this instance, foregoing the chocolate cake. An impressive amount of research confirms the importance of self-efficacy in understanding whether a person will engage in a particular behavior at a given place and time (Bandura, 1997). This characteristically Western approach emphasizing individual control has been expanded by Bandura to consider perspectives of more collectivist cultures and has led to parallel considerations of collective agency (Bandura, 2000).

Case Example: Homosexuality

As a case study of the role of values in health matters, we examine a position that one of us took over 40 years ago in how mental health practitioners and scientists should address homosexuality (Davison, 1974, 1976, 2001). While the example here concerns psychotherapy, the issues apply to behavioral medicine and health psychology as well.

Until the end of the 1970s, psychotherapists from all theoretical orientations believed that when a homosexual individual asked for change – and even if they did not – the only acceptable course of action was to work toward a shift toward heterosexuality. At that point in time, homosexuality was still considered a diagnosable psychological disorder. All psychotherapists but perhaps behavior therapists in particular (including Davison) worked assiduously and creatively to design change regimens that would reduce homosexual attraction and behavior and increase heterosexual interests and behavior.

Things have changed a great deal in many countries since the 1970s – e.g., the US Supreme Court ruling in June 2013 that the federal anti-gay rights Defense of Marriage Act is unconstitutional or recent state decisions banning the use of "conversion therapy" for homosexuals (*New York Times*, August 19 and 29, 2013) – but the issues of values in societal and individual attitudes toward homosexuality remain the same. In addition, in most parts of the world, homosexuality continues to be viewed as sick, sinful, and/or illegal. In more than a few countries, homosexuality is even punishable by death, and the still widespread derogation of homosexuality has impeded AIDS prevention in Africa, China, and other areas. Whatever one's point of view, approaches to research and application are influenced by one's values, as we illustrate here with respect to therapy with homosexuals.[4]

We only want to help.
API (Apocryphal Press International, September 30, 1974). The governor recently signed into law a bill prohibiting discrimination in housing and job opportunities on the basis of membership in a Protestant Church. This new law is the result of efforts by militant Protestants, who have lobbied extensively during the past 10 years for relief from institutionalized discrimination. In an unusual statement accompanying the signing of the bill, the governor expressed the hope that this legislation would contribute to greater social acceptance of Protestantism as a legitimate, albeit unconventional, religion.
At the same time, the governor authorized funding in the amount of 20 million dollars for the upcoming fiscal year to be used to set up within existing mental health centers special units devoted to research into the causes of people's adoption of Protestantism as their religion and into the most humane and effective procedures for helping Protestants convert to Catholicism or Judaism. The governor was quick to point out, however, that these efforts, and the therapy services that will derive from and accompany them, are not to be imposed on Protestants, rather are only to be made available to those who express the voluntary wish to change. "We are not in the business of forcing anything on these people. We only want to help," he said.

---

[4] The discussion of values issues in sexual reorientation for gays is adapted from Davison (1974, 1976, 1978, 2001).

The Myth of Therapeutic Neutrality The basic position of this chapter and in Davison's writings on the treatment of homosexuality is that therapists never make ethically or politically neutral decisions. In his important book, "The Politics of Therapy," Seymour Halleck wrote about these issues from the perspective of psychiatry. As he put it, "Any type of psychiatric intervention, even when treating a voluntary patient, will have an impact upon the distribution of power within the various social systems in which the patient moves. The radical therapists are absolutely right when they insist that psychiatric neutrality is a myth" (Halleck, 1971, p. 13).

Halleck's thesis played a major role in Davison's argument against therapists trying to change the sexual orientation of gays in a heterosexual direction. Most of the time, the very naturalness of and familiarity with our therapeutic practices – cf. the abovementioned metaphor of fish not knowing that they are swimming in water – blind us to the nonempirical biases that affect how we construe the patient's problems and the goals we regard as acceptable to work toward. It is better to be aware of and own up to our biases than to pretend that we have none.

Differences Do Not Imply Pathogens Sometimes those who argued in favor of sexual conversion therapies for gays and lesbians sought to justify their position by asserting that homosexuality is pathological and that there is a general and pervasive professional duty and right to set things straight (pun intended). One form that the argument has taken is that homosexuals differ from heterosexuals in a particular way, for example, in how they were raised, and that this difference ipso facto indicates something pathogenic. The classic study in this vein was by Bieber et al. (1962). Overlooking its serious methodological shortcomings, the logic of the findings took the following form: The parents of male homosexuals as compared to the parents of male heterosexuals more often reflect a pattern of a "close-binding intimate mother" and a cold and detached father. Ergo, homosexuality is a mental illness.

So ingrained and unexamined was the ethical bias against homosexuality that the inherent logical fallacy of the argument was not appreciated. Simply put, what is wrong with such child-rearing unless one has decided before the fact that homosexuality is an illness, which in this case is code for undesirable and worse?

No Cure Without a Disease It is fair to say that researchers and clinicians devote effort to developing and analyzing therapeutic procedures only if they are concerned about a problem. Until the 1980s therapists spent virtually all their time and effort trying to reduce homosexual attraction and increase heterosexual attraction in homosexuals (and for the most part, the target population was men only). Again, little if any time – and none at all when Davison made the argument in 1974 – was spent by mainstream therapists encouraging health professionals to change their biases against homosexuality and foster gay-affirmative attitudes and behavior in patients who happened to be homosexual. The question could be framed as follows: How can therapists honestly speak of nonprejudice when they participate in or tacitly support therapy regimens that by their very existence and regardless of their effectiveness condone the societal prejudice and perhaps also impede social change? As Begelman pointed out many years ago (1975), sexual reorientation therapies:

> …. *by their very existence constitute a significant causal element in reinforcing the social doctrine that homosexuality is bad.* Indeed, the point of the activist protest is that behavior therapists [and other therapists] contribute significantly to preventing the exercise of any *real* option in decision making about sexual identity by further strengthening the prejudice that homosexuality is a "problem behavior" since treatment may be offered for it…. homosexuals tend to seek treatment *for being homosexuals*…. contrary to the disclaimer that behavioral therapy is "not a system of ethics" (Bandura, 1969, p. 87), the very act of providing therapeutic services for homosexual "problems" indicates otherwise. (p. 180, emphasis in original)

Moreover, as Davison argued, the availability of a technique encourages its use. For example, Wolpe's (1958) systematic desensitization treatment for fears and phobias ushered in a revolutionary period in psychotherapy research and practice in which behavior therapists looked vigorously for problems that could be conceptualized in terms of anxiety and then treated with this approach. Thus, a problem like social isolation might be viewed at least in part as a consequence of unnecessary anxiety that could be desensitized. The assessment and problem-solving efforts of clinicians are channeled in ways conducive to the application of therapeutic techniques that are available and are believed to be effective. This is not a bad thing! But it does skew what the therapist sees and finds out about a patient, a topic we turn to next.

Clinical Problems as Clinicians' Constructions As argued elsewhere (e.g., Davison, 2001; Davison & Lazarus, 1995), clients seldom come to mental health clinicians with problems as clearly delineated and independently verifiable as what patients often bring to a physician. A client usually goes to a therapist or counselor in the way described by Halleck (1971):

> At first glance, a model of psychiatric practice based on the contention that people should just be helped to learn to do the things they want to do seems uncomplicated and desirable. But it is an unobtainable model. Unlike a technician, a psychiatrist cannot avoid communicating and at times imposing his own values upon his patients. The patient usually has considerable difficulty in finding the way in which he would wish to change his behavior, but as he talks to the psychiatrist, his wants and needs become clearer. In the very process of defining his needs in the presence of a figure who is viewed as wise and authoritarian, the patient is profoundly influenced. He ends up wanting some of the things the psychiatrist thinks he should want. (1971, p. 19)

That is, the person is unhappy; life is going badly; nothing is meaningful; sadness and despair are out of proportion to life circumstances; the mind wanders and unwanted thoughts intrude, etc. The constructivist argument is that the clinician *transforms* these often vague and complex complaints into a diagnosis or functional analysis, a set of ideas of what is wrong, what the controlling variables are, and what might be done to alleviate the suffering and maladaptation. The argument, then, is that psychological problems are for the most part *constructions* of the clinician. Clients come to us in pain, and they leave with a more clearly defined problem or set of problems that we *assign* to them. The same argument can be made for medical problems like "metabolic syndrome" (Fisher, Chan et al., 2012).

Davison's argument has been that when a homosexual went to a therapist, whatever psychological woes they had were generally construed as caused entirely or primarily by their sexual orientation. This happened because (a) their sexual orientation was usually the most salient part of their personhood, to the clinician and usually to the clients themselves because the negative salience homosexuality had been accorded by society and (b) it was regarded as abnormal, regardless of the avowedly **"**liberal**"** stance the clinician might take overtly. The clinician's perceptions and problem-solving were skewed in a direction that implicated homosexuality – no matter what the actual presenting problems were (cf. Davison & Friedman, 1981) – and, most importantly, implied the desirability of a change in sexual orientation.

None of this was intended to gainsay that being homosexual in our society has been easy psychologically and that it can create considerable distress – particularly two generations ago but even now – given the disproportionate exposure to hate crimes and simple everyday prejudice that homosexuals are still subject to in many parts of society and in the world at large. The moral point that Davison began making in 1974 is that health professionals have a responsibility at least to consider carefully the societal pressures that, sometimes subtly, channel our clinical problem-solving and decision-making into narrowly defined domains that result in a maintenance of a status quo that, in official pronouncements, we say we do not support.

As mentioned earlier, anti-gay attitudes have diminished in recent years both in North America and Western Europe, with some jurisdictions even sanctioning civil unions and marriage between same-sexed individuals. But at the time (1974) Davison formulated his position against sexual reorientation therapy, attitudes were negative, often strong, and sometimes virulent, with many people believing that homosexuals were sick and their behavior disgusting (Herek, 1994).

These negative attitudes took the form of open heterosexism – as when people directly insulted a gay person with epithets like *faggot* or *dyke* – or a more subtle, indirect kind of anti-homosexual stance – as when people told jokes that derided homosexuality without knowing (or caring) if a gay person was present. This prejudice created – and, in most parts of the world, maintains – what has been termed "minority stress," a source of pressure and tension that is a special burden of those in despised or feared minorities (Meyer, 1995) and no doubt was the major factor in gay and lesbian people suffering particularly high levels of depression (Herek, Gillis, et al., 1996).

In light of all this, it was not surprising that gays sometimes sought out sexual reorientation treatment. Being subjected to verbal and physical assault for being gay was not likely to enhance one's sense of comfort with and acceptance of one's sexual orientation. Davison's argument, therefore, has been that the expression of a desire to change sexual preference was not truly voluntary. And it fell to the clinician to take into account the societal conditions that were likely influencing homosexual individuals to seek a change in the direction of heterosexuality.

A Proposal Regarding Sexual Reorientation Therapy These several considerations led Davison in 1974 to make a proposal that had been present for a few years in the some of the gay activist literature (see especially Silverstein, 1977): *Therapists should stop engaging in change-of-orientation programs, whether the client makes the request or if someone else does*. The social pressures, discrimination, and in some cases violent hatred directed to people with homosexual inclinations made it highly doubtful that client requests for conversion therapy could be reasonably viewed as voluntary.

Long ago Perry London (1969) warned of an unappreciated danger in behavior control technology, namely, clinicians' increasing ability to engineer what we have tended to regard as free will on the part of our patients. In his view, therapists are capable of influencing patients to want what is available and what they believe their patients *should* want. Moreover, even if therapists assert that they do not work against the will of their patients, this does not free them from the responsibility of examining those factors that determine what is considered free expression of intent and desire on the part of our patients.

Psychotherapy, Politics, and Morality To conclude this discussion of the ethics of sexual reorientation intervention, it may be useful to place the issue within a broader social context. This perspective has traditionally been seen as the defining characteristic of community psychology. In Rappaport's (1977) terms, the argument is at an institutional level, whereby human problems are examined within a macrolevel frame of values and ideologies that shape the decision-making of a society. In behavioral medicine and health psychology, this perspective is referred to as the socio-ecological model (e.g., McLeroy, Bibeau, & Steckler, 1988; Stokols, Grzywacz et al., 2003). In contrast, most therapists and other interventionists operate at the individual level, where the assumption is that society is basically benign and that psychological and physiological suffering can best be alleviated by helping the patient adjust to prevailing values and conditions. Davison's argument was and is that issues surrounding therapy for homosexuality should be addressed at an institutional level and that greater societal acceptance of homosexuality as a normal variation of human sexuality rather than as a problem that needs to be fixed will, in fact, redound to the benefit of the individual by reducing the discrimination and oppression described earlier that, we believe, accounted for the distress that can be associated with homosexuality and ultimately the desire of some homosexual individuals to seek sexual reorientation.

Do therapists have some kind of abstract responsibility to satisfy a patient's expressed desires and wishes, as asserted by some (e.g., Sturgis & Adams, 1978)? No. Therapists constrain themselves in many ways when patients ask for assistance, and under some circumstances, therapists are legally required to break the confidentiality that is inherent in the relationship. In any event, requests alone have never been a sufficient justification for providing a particular service to a patient (Davison, 1978).

Concluding Comments

This case study on ethical issues in sexual reorientation for gays and lesbians highlights the important role played by values in our very conceptions of what it means to have a "disease" and in our decisions on whether and how to intervene to make changes. We believe that the themes raised are relevant to many behavioral medicine and population health issues discussed in this chapter, for example, obesity. In Western cultures, obese individuals are often stigmatized and blamed for physical and/or psychological ailments that are attributed, rightly or wrongly, to their weight. Societal judgments of health and beauty define body types as desirable or undesirable. Has anyone, for example, ever been stigmatized for having hair that is too shiny and teeth that are too white? This is not to say that obesity has no long-term negative effects, rather that the negative appraisals of people deemed overweight go beyond demonstrable negative effects on health.

Our relative values on autonomy and safety are related to the question of whose responsibility or right it is to change and to treat. What is the "best treatment" for each individual, what are the best prevention and health goals for populations, and who should be the ones to make these determinations? The patient, the healthcare provider, or the government?

In this chapter we have presented some ideas about values issues that permeate behavioral medicine and allied health-related fields in ways that are not always fully acknowledged but that nonetheless influence what we study, how we conceptualize the world, and how we intervene into the lives of others. The domains we have examined in some detail – longevity, quality of life, suicide, euthanasia, and global and cross-cultural issues in research and practice – are but a few of the issues that we believe should be considered when professionals presume or are asked to help people make changes.

Acknowledgment We wish to thank Edwin B. Fisher for many helpful suggestions and comments.

Behavioral Medicine and the Benefits of Healthcare: A Critical Appraisal and the Need for Exnovation

Robert M. Kaplan, David A. Chambers,
and Russell E. Glasgow

The goal of healthcare is to enhance health, lengthen life, and reduce illness and disability. In order to work toward these objectives, it is necessary to understand the factors associated with longer life and reduced illness and disability. It is typically assumed that the mechanism for increasing life expectancy and reducing the burden of illness and disability is investment in medical care. However, a variety of different analyses using several different research methodologies have shown that medical care accounts for only a small portion of the variation in health outcomes (Murray, Vos, et al., 2012; Schroeder, 2007).

The traditional biomedical model is limited in its ability to foster health and well-being, in part because the biomedical model often focuses exclusively on measures of biological process rather than the more global goal of helping people live longer, higher quality lives. Understanding how to improve overall health and well-being thus requires perspectives beyond those of fundamental biology and clinical medicine.

Healthcare in the United States is the biggest sector in the biggest economy in the history of the world. In 2015, the United States will spend approximately 18% of its gross domestic product (GDP) on healthcare. This expenditure far exceeds the cost of healthcare in any other country. Unlike other industries, healthcare has not been held accountable for what it produces. Among 34 developed economies, we rank 30th in infant mortality, 25th in maternal mortality, and 26th in life expectancy (data from the Organization for Economic Cooperation and Development, OECD).

Because healthcare systems are very much creations of the countries in which they exist and because the authors have focused much of their work on the US system, the chapter is focused on that system and trends in it.

The Problem: Healthcare ≠ Health

One way of examining the relationship between healthcare and health is in terms of expenditures on care. Figure 36.1 uses OECD data to graph

---

The views expressed in this chapter are those of the authors, and no official endorsement by the Agency for Healthcare Research and Quality, the National Cancer Institute, the US Department of Health and Human Services, or the US federal government is intended or should be inferred.

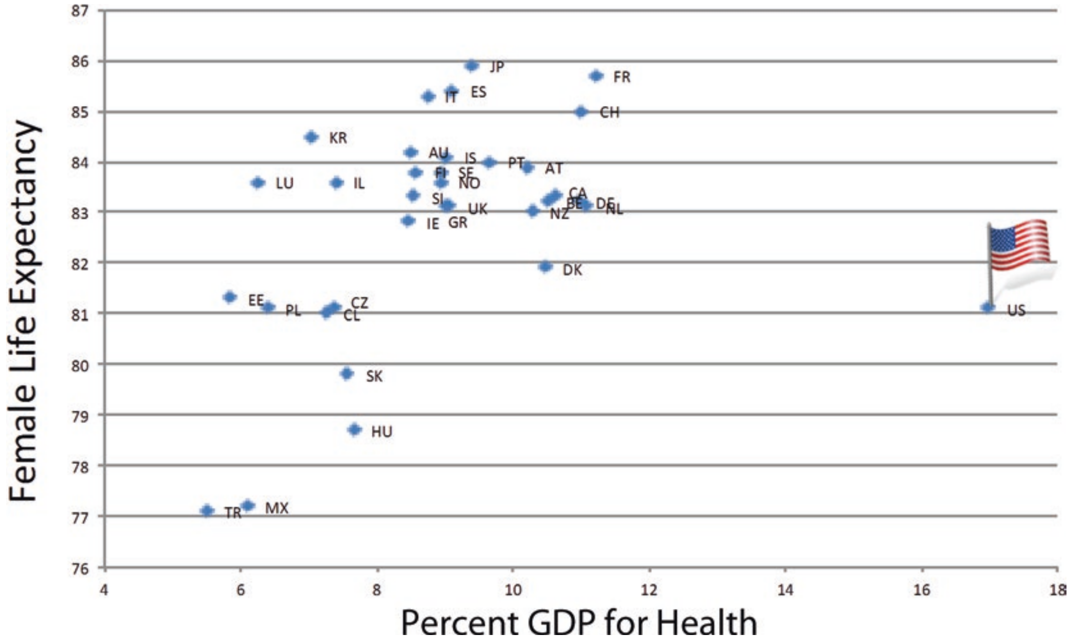

Fig. 36.1 Relationship between percent of GDP spent on healthcare and female life expectancy in OECD countries (Data from OECD, 2011. When missing life expectancy data estimates were imputed from prior year)

total healthcare expenditures for various countries (x-axis) against life expectancy (y-axis). The United States is an extreme outlier in terms of expenditures. We spend more than 18% of our gross domestic product on healthcare, while most of our economic competitors spend about 10%. The United Kingdom, for example, spends only about $0.40 per capita for each dollar spent in the United States, and more or less the same story holds in other developed countries: Belgium and Denmark spend only about $0.50 for each dollar spent in the United States, and Spain spends only about $0.33 (Reinhardt, Hussey, & Anderson, 2004). Nevertheless, US life expectancy is less than in many countries, several of which spend less than half of what the United States spends in terms of percent GDP. If the United States reduced its expenditures to the level of most European countries, we would save over $1 trillion per year—about equal to the total publically held debt of the US federal government.

Further, in spite of spending considerably more, studies tend to show that the increase in life expectancy of US citizens is not keeping up with other wealthy countries. One study from the National Research Council considered current life expectancy for 50-year-old women between the years 1955 and 2010 (Crimmins, Preston, & Cohen, 2011). Current life expectancy is the number of years of life on average remaining once a milestone age has been reached. So, current life expectancy for 50-year-old women is the median number of years of life remaining following the 50th birthday. In 1955 the United States was about 12th in the world on this indicator. By 2006, it had slipped to about 26th, just below South Korea and Malta. In a life expectancy comparison of ten wealthy countries, US women were third out of ten in 1955, but ninth out of ten in 2006. Among the many countries with more rapid increases in life expectancy were Japan, France, and Spain. Japan, for example, was considerably below the United States in 1955 and now is many years ahead.

In response to these findings, the US Office of Behavioral and Social Sciences Research along with the National Institute on Aging sponsored a study that compared life expectancy in the United States against 17 peer countries (Woolf & Aron, 2013). These comparison countries were primarily in Western Europe, but also included Australia, Japan, and Canada. The results of the comparison are quite revealing. Among the 17 countries, the United States had the second highest mortality rate from noncommunicable diseases. Mortality from communicable diseases, on the other hand, was fourth lowest for the United States. Arguably, this reflects sanitation and the availability of antibiotics in the United States, key for preventing communicable diseases, as opposed to risk factors critical for noncommunicable diseases: diet, physical activity, obesity, and tobacco and alcohol use. However, the AIDS incidence in the United States was 122 per million, third highest exceeded only by Brazil and South Africa and about nine times the average of countries in the OECD.

Although US life expectancies are increasing, the rate of increase is much slower than it has been in other wealthy countries. This trend has been developing over the course of several decades. Perhaps the most surprising finding in the NRC study concerned years of life lost prior to age 50 (Woolf & Aron, 2013). The committee considered international differences in the probability of celebrating a 50th birthday. On this indicator, the United States was last among the 17 comparison countries for both men and women. United States losses in life expectancy prior to age 50 are about double the rate observed in Sweden. Perhaps most disturbing is that this problem profoundly affects women. Figure 36.2 shows the trend in years of life lost in 21 high-income countries between the years 1980 and 2006. For men, the United States started at the low end of the distribution and worked its way to the bottom. For women, the United States started near the bottom and now has gone off the scale in relation to the comparison countries.

In addition to differences with other countries' costs and performance of healthcare, there is substantial regional variation in healthcare expenditures within the United States (Wennberg, 1990; Wennberg, Fisher, et al., 2005, 2008). For example, during the last phases of life, Medicare spends $1.80 in Los Angeles for each dollar that it spends in San Diego. The two cities are demographically very similar. The climate is the same, the nature of the industries is similar, and in many other ways, the communities are very much alike. What differs is the way healthcare is delivered. At the end of life, for example, residents of Los Angeles are significantly more likely to be hospitalized, placed in an intensive care unit, and to receive heroic interventions. Yet, there is no evidence that health outcomes for residents of Los Angeles are any better, and some evidence suggests that the quality of care and patient satisfaction is higher in San Diego (Kaplan, 2011). Patients in Los Angeles are receiving many procedures and tests that do not result in health benefit.

In spite of findings such as these, many Americans assume that the United States leads the world in quality of medical research and quality of healthcare. Clearly, there is much cause for concern about both healthcare research and healthcare quality.

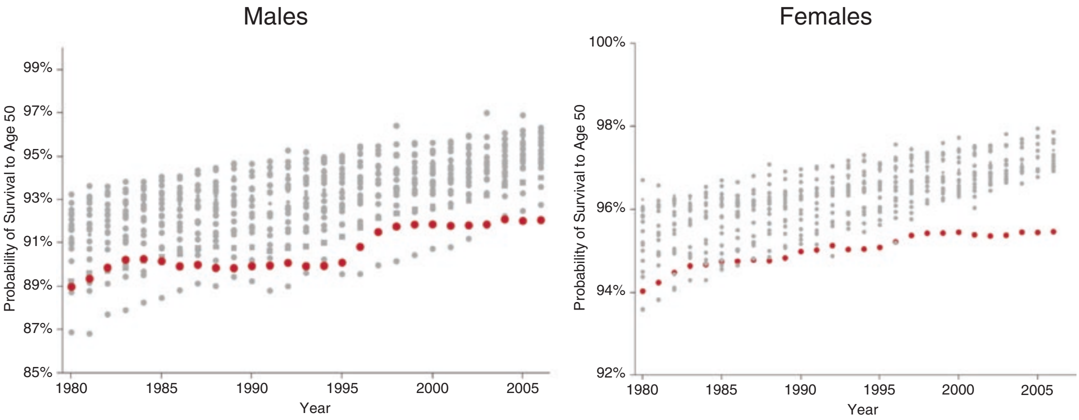

Fig. 36.2 Probability of survival to age 50 in 21 high-income countries, 1980–2006 (From National Research Council: explaining divergent levels of longevity in high-income countries, 2010)

Determinants of Health Outside the Health System

This chapter emphasizes the healthcare system and how it needs to change to do a better and more efficient job of promoting health and lives of quality. As a context of this focus on healthcare, it is important to note that most of the variability in health outcomes is attributable to factors outside of the healthcare system. A variety of different analyses estimate the proportion of health outcome attributable to factors within the healthcare system as opposed to factors outside of healthcare. (See chapters by Siddiqi and colleagues and by Sherlaw and colleagues, *infra*.) Schroeder suggested that medical care accounts for about 10% of the variation in health outcome (Schroeder, 2007). Behavioral and social factors, according to this analysis, account for about 55%. Although the exact number varies, most analyses suggest that behavioral and social factors account for at least half of the variation in health outcomes. One interesting example is provided in a report by Marmot and colleagues from the United Kingdom. An expert panel reviewed a variety of factors associated with life expectancy which demonstrated a systematic relationship between living in economically deprived neighborhoods and life expectancies (Marmot, Allen, et al., 2010).

A growing body of evidence reinforces the observation that social factors have a profound impact on life expectancy. For example, the Los Angeles County Public Health Department reports on life expectancy by gender and racial/ethnic background. The difference in life expectancy between Asian women with an average life expectancy of nearly 89 years and African-American men with a life expectancy of about 70 years is a full 19 years! There have been significant improvements in the life expectancy of Black males in recent years, but on average, White women still live about 9 years longer than Black men (Hoyert & Xu, 2012). To place this in perspective, the difference in life expectancy between a 35-year-old man with normal LDL cholesterol and a man with elevated LDL cholesterol is about 6 months. In contrast, the difference in life expectancy between young adults with less than a high school education and those with a graduate degree is at least 10 years.

Behavior, Systems, Populations, and Persons

If you are stuck in a hole, the solution is probably not to dig. Yet, in many ways, US healthcare resembles trying to dig one's way out of a hole. In spite of the trends of worsening care noted in the previous section, financial strategies in US healthcare have emphasized the continued search for fundamental science breakthroughs and ever more specialized care, arguably strategies that have caused us to neglect the ways out of the hole (Starfield, 2000). The US Patient Protection and Affordable Care Act includes a number of strategies to change this, placing greater emphasis on primary care, prevention, and patient education; services for support of patients with chronic diseases and disabilities; and initiatives to reduce rehospitalization for diseases like heart failure, coronary heart disease, and pneumonia (Cheng, Wise, & Halfon, 2014; Halfon, Long, et al., 2014). These provide opportunities for new directions.

Behavioral medicine along with public health and health services research offers perspectives that complement those of clinical medicine and may help lead us out of the hole. From public health, we learn to think about populations, how prevention and healthcare change the patterns of disease among all individuals affected, not just the individual patient in the examining room or the panel of several hundreds or even several thousands participating in a study of some specific intervention. From health services, we learn to think about how interventions and innovations work within the systems in which they are implemented and how characteristics of those systems influence the care they provide and the health of those they serve. And from behavioral medicine, we learn to examine the effects of interventions not only on the specific disease characteristics or risk factors they may target but on overall health and well-being as perceived and valued by the individual (Glasgow, Kaplan, et al., 2012). Combining the public health, health services, and behavioral medicine perspectives yields analytic frameworks to examine the performance of the healthcare system and identify directions for improving it.

Advances in Treatment ≠ Advances in Outcomes

If it were true that the United States has the very best medical care in the world, we might expect advances in medical therapies to have solved many of our healthcare problems. Recent clinical trials however do not show the level of benefit that the public expects from medical therapies. In fact, most recent large randomized clinical trials have failed to show expected benefits of medical and surgical therapies (Gordon, Taddei-Peters, et al., 2013).

More care is not necessarily better care. For example, one RCT randomly assigned patients with metastatic non-small cell lung cancer to palliative care or to standard cancer therapy. Those in the palliative care condition had higher quality of life and longer survival (Temel, Greer, et al., 2010). In systematic reviews of all of the trials supported by the National Cancer Institute over the last 50 years, the new treatment was found to be superior to standard care or placebo in only about a quarter of the studies (Djulbegovic, Kumar, et al., 2008).

Whose Perspective? Determining whether a treatment works and whether it works efficiently is not a simple task. Different people have different perspectives on what defines an effective treatment. A purely physiological perspective might focus on biochemical or anatomical changes that result from a treatment. A clinical perspective might focus on disease-specific criteria, such as blood pressure or, in diabetes, glucose control. A behavioral approach, on the other hand, leads to consideration of how the individual is living and enjoying life, not just how a particular organ is functioning (Glasgow, Kaplan, et al., 2012). It turns out that treatment decisions, or even the decision to continue to offer a particular service, may be different depending on whether they are guided by the perspective of the whole individual or that of a particular organ or disease state. For example, a treatment might be effective in lowering blood pressure and could be regarded as effective from the perspective of the doctor who prescribed the medication. However, the same treatment may increase cholesterol or make the patient sleepy and would be considered less effective from the perspective of a generalist physician—or the patient.

There are many examples of treatments that show benefit on some measures and lack of benefit or even harm on others. Trials considering intensive therapy for anemia suggest that agents that increase red blood cells do their job and bring hemoglobin counts toward normal. From a traditional perspective evaluating interventions in terms of surrogate endpoints, these trials achieved their goals. Yet patients in these conditions had a higher probability of renal failure requiring dialysis and other adverse outcomes (Drueke, Locatelli, et al., 2006). Large studies on hormone replacement therapy usually show that estrogen levels are raised toward normal premenopausal levels. Yet the consequences for patients, from an outcomes research perspective, are usually poorer rather than better (Chlebowski, Hendrix, et al., 2003).

Examples of Interventions Producing Minimal Benefit

ACCORD Aggressive therapy for the treatment of non-insulin-dependent diabetes mellitus was the focus of the ACCORD trial (Action to Control Cardiovascular Risk in Diabetes Study Group, Gerstein, Miller, et al., 2008). Patients were randomly assigned to standard therapy or to an intensive therapy. The intensive therapy significantly changed biological outcomes in the expected direction. Specifically, those assigned to intensive therapy had significantly lower levels of glycosylated hemoglobin. From a traditional perspective, the treatment had achieved its goal. However, long-term follow-up considered total mortality and deaths from cardiovascular disease. Considering all-cause mortality, those assigned to intensive therapy had a higher probability of death in comparison to the standard therapy condition.

Prostate Cancer Another example is provided by the Prostate Cancer Prevention Trial (PCPT) (Thompson, Goodman, et al., 2013). In this long-term study, 18,882 men at risk for prostate cancer were randomly assigned to the drug finasteride or to a placebo. All of the men were followed prospectively for at least 15 years using the National Death Index. Initially it appeared that the drug had worked successfully. Just over 10% of the men who took finasteride showed evidence of prostate cancer in comparison to nearly 15% in the placebo group. However, the percentage of men surviving for 15 years in the two groups was virtually identical: 78.0% versus 78.2%. The drug reduced the number of men with clinical prostate cancer, but the purpose for taking the drug in the first place was to reduce deaths. The analysis suggested that there was little progress toward that ultimate goal. Further, those men who took the active drug had significantly higher rates of complicating side effects.

Coronary Heart Disease The causes of heart disease are well understood. There is an initial injury to the endothelial wall of the coronary artery. Plaque builds up and narrows the artery and this results in restricted blood flow. Often, a fibrous cap on the lesion ruptures and a blood clot forms, totally occluding the flow of blood to the heart muscle. One solution for this problem is to perform angioplasty by placing a stent in the narrowed artery. The stent holds the artery open so that nourishing blood flow can continue.

It seems obvious that this procedure should reduce deaths associated with myocardial infarctions. Yet systematic studies do not always support this hypothesis. One of the most important studies was the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial (Boden, O'Rourke, et al., 2009). In this evaluation, 2287 patients who had objective evidence of narrowing of their coronary arteries were randomly assigned to undergo either angioplasty using a stent or to optimal medical therapy. The patients were followed for an average of 4.6 years, and the primary outcome was death from any cause or a nonfatal myocardial infarction. Over the course of follow-up, 19% of the patients in the stent group died or had a nonfatal heart attack. In comparison, 18.5% of the patients in the medical therapy group died or had a heart attack (Boden, O'Rourke, et al., 2009).

Schizophrenia Modern pharmaceutical approaches to the management of schizophrenia have been remarkably successful in the realm of severe mental illness. The most effective medicines are in the category of "atypical neuroleptics." These drugs include clozapine, olanzapine, quetiapine, and risperidone. The most important advantage of these medicines is that, in comparison to traditional neuroleptics such as Haldol (haloperidol), they control serious symptoms of schizophrenia but have fewer extrapyramidal side effects, including tremors, slurred speech, restless legs, anxiety, and a host of other psychological symptoms. Using registries from Veterans Administration Medical Centers, one study considered 38,632 patients with schizophrenia. Among these, 15,984 (41.4%) used typical neuroleptics and 22,648 (58.6%) were treated using any one of the atypical neuroleptics. The results suggest that schizophrenic patients treated with atypical neuroleptic medications have a 9% greater chance of developing diabetes in comparison to those taking the traditional medications (Sernyak, Leslie, et al., 2002). This result has been replicated in a variety of different settings (Vidarsdottir, de Leeuw van Weenen, et al., 2010). With respect only to schizophrenia measures or measures of neuropsychiatric side effects, the atypical neuroleptic medications perform well. However, considering total health, the picture is less clear (Rosenheck, Leslie, et al., 2008).

Aggregate Results Point to Diminished Returns

It is surely troubling that the number of recent null or negative clinical trials significantly exceeds the number of trials supporting the use of the interventions they propose (Gordon, Taddei-Peters, et al., 2013). We have placed such a high premium on innovative research, that we may have failed to invest sufficient resources to determine whether the research is replicable. Most medical innovations are introduced with great promise. However, the reported efficacy of many interventions declines over the course of time. Early trials showed stronger effect sizes for statin medications, but as time goes on, the effect size declined (Gehr, Weiss, & Porzsolt, 2006). This "decline effect" occurs in many different sciences (Schooler, 2011).

A growing number of papers acknowledge that clinical and experimental studies often cannot be replicated (Landis, Amara, et al., 2012; Pashler, Coburn, & Harris, 2012). One explanation is the "voltage drop" phenomena in which early trials are carefully controlled with high internal validity, while later studies involve more representative populations and evaluate interventions under circumstances closer to which they are applied in clinical practice (Chambers, 2011). When interventions are evaluated in the "real world" they produce less dramatic results. Some of this occurs when the characteristics of the population in which the intervention is applied differ from the study population in earlier trials. However, there are other problems. For example, publication bias favors the reporting of significant results. A study that offers a significant finding may have been an anomaly, and it is hard to determine this without systematic attempts to replicate.

In larger trials that have strong external validity, null or negative results are not uncommon. For example, a recent review of all major randomized clinical trials from the US National Heart, Lung, and Blood Institute shows that remarkably few are able to demonstrate that treatments resulted in the predicted improvements in patient outcomes. Among large NHLBI trials, defined as having budgets greater than $500,000/year, it has been 15 years since any trial demonstrated a reduction in all-cause mortality, and only two trials published in the last 15 years showed a significant benefit on the primary outcome variable (Kaplan & Irvin, 2015). In short, it has been common for large, well-controlled studies to challenge evidence supporting the use of common medical tests and procedures.

In summary, the effects of clinical medicine can be different when viewed from the patient's perspective. Randomized clinical trials in medicine often show benefits when the outcome is a measure of specific disease indicators or biological process, such as blood sugar or hemoglobin. But, when patient-centered clinical outcomes, such as survival and quality of life, are considered, the same trials often show null or negative results. Certainly, we need continually to evaluate promising new therapies. However, we also need to devote more attention to identifying and promoting those interventions that make real differences in length and quality of life.

Two Paths: Identifying What Works—And What Does Not

The previous sections make clear that we need better methods for deciding what works and to what we allocate the effort and resources of the healthcare system, the time, attention and efforts of individuals, and the dollars available. But as the previous examples also show, practices sometimes persist in spite of minimal evidence to support them. Thus, we also need methods to cull from the enormous healthcare enterprise those practices that contribute appreciable cost but little or no benefit. These two decisions what to include and what to exclude are discussed in the next sections. Patient-centered evaluations and comparative effectiveness research offer important improvements in identifying what to include. *Exnovation*, as will be discussed, provides pathways to identifying what deserves to be eliminated.

The Patient's Perspective and Comparative Effectiveness Research

In determining whether treatments work, perspective is important. As the previous section has shown, there are many circumstances in which treatments are regarded as effective from the perspective of treating a particular disease but not from the perspective of overall mortality or health. Evaluating treatments from the patient's perspective requires a whole set of new research methodologies.

The field of study that concentrates on the evaluation of the benefits and risks of healthcare from the patient's perspective is known as comparative effectiveness research (CER). Although the conceptual underpinnings of this line of scientific inquiry have been discussed for decades, CER did not exist as a formal field of study until 2009. In the early years of the Obama administration, there was extensive discussion among advisers about the costs, risks, and benefits of healthcare. During extensive debates about healthcare reform, the US Congress approved legislation to develop the infrastructure for comparing the effectiveness of healthcare interventions. The discussion was contentious at times. However, what emerged from the discussion was the basis for developing an important new infrastructure for comparing treatments and analyzing which interventions are most effective for patients.

US National Academy of Medicine (NAM) of the National Academies of Science defines comparative effectiveness as "the comparison of one diagnostic or treatment option to one or more others." The methods that are compared are designed to "prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care." According to the NAM, the beneficiaries of CER include consumers, clinicians, purchasers, and policymakers. The NAM suggests that, ultimately, CER will help these groups "make informed decisions that will improve healthcare at both the individual and the population levels." The definition of treatments is very broad and includes traditional medical care as well as alternative approaches to improving health. The key to understanding CER is that it compares the benefits and harms of two or more alternatives.

By definition, CER encompasses more than traditional research methods and study designs such as cohort investigations, population studies, and randomized clinical trials. Beyond these, CER also includes systematic reviews of the literature and comparisons between medical services or different delivery systems.

In terms of identifying what works, the key feature of comparative effectiveness research is that it evaluates not how an intervention compares to placebo or minimal treatment but examines how it *adds to the benefits already available from common practices*. Put simply, it asks whether an intervention helps us do better than we are already doing. For example, one of the most interesting analyses concerns the frequency with which women should have Pap smears. It used to be common practice for women during their reproductive years to have this cancer screening test every year. Analyses have shown that women who are screened every third year have an increase in life expectancy on average of 70 days. If women get a Pap smear every other year as opposed to every third year, the number of expected added days of life increases from 70 to 71. If they get the test every year, the benefit is 71 days and 8 h. In other words, the advantage of getting a yearly Pap smear as opposed to a Pap smear every third year extends average life expectancy by about 32 h. Given the amount of time most women spend going to the appointments for these yearly tests, the added life span may be almost negligible. However, frequent tests also add costs. The cost of being screened every year is three times the cost of being screened every third year. An analysis of the incremental cost in relation to the incremental benefit is quite telling. For women screened every third year, the cost is about $2600 per life year gained. For women screened every single year, the cost is $83,000 per life year gained (Hagen, Garber, et al., 2001).

What Are Indicators of Effectiveness?

Quality of Life The recognition of quality of life as an important outcome was first stimulated by Paul Ellwood's 1988 Shattuck lecture (Ellwood, 1988). Ellwood advocated for what he referred to as "a technology of patient experience". In contrast to management of symptoms, Ellwood emphasized the importance of managing patient outcomes. He advocated that medical care should emphasize four techniques: (1) standards and guidelines that match treatments with patient desires, (2) measurement of patient well-being and functioning, (3) use of normative data to interpret patient outcomes within the context of other people, and (4) dissemination of information in ways that could affect decision makers.

This approach puts the patient at the center of healthcare and uses patient-centered reports to offer guidance and perspective for clinical care. More recently, the use of these technologies has come to be known as patient-centered outcomes research (PCOR). The use of PCOR is well represented in the Affordable Care Act and in the Patient-Centered Outcomes Research Institute (PCORI). At the center of PCOR is the measurement of outcomes from the patient perspective. Most of these measures emphasize health-related quality of life.

Cost of Care One key indicator is the cost of healthcare. Briefly, many healthcare analysts believe that healthcare policies should not consider cost. No one wants cost to be a factor in decisions about who lives and who dies. But costs of healthcare are a very important concern, and it is necessary to consider whether and how costs should be part of the healthcare decision process. Several countries have grappled with this issue, and some have decided that cost is necessarily part of the equation.

A Note on Evidence One of the provisions of the ACA was the required coverage of preventive health services, without co-payment. Services that will qualify for this coverage include those with an A or B rating by the US Preventive Services Task Force. There has been some controversy about how services obtain these ratings. For example, it is difficult to obtain A or B ratings without multiple randomized clinical trials (RCTs) that adhere to specific methodological criteria. The RCT is deservedly highly respected in assessing the value of medications and other interventions which can be rigorously isolated from their surroundings (see chapter by Freedland and colleagues, *infra*). Its value in assessing broader interventions such as in communities or in changes of health systems is questionable. Thus, the reliance on RCTs in grading interventions may be especially a challenge for many behavioral medicine interventions. Alternatives are discussed in the chapter by Allegrante et al., *infra*.

On the other hand, some services that obtain these ratings have relatively low population reach or have inconsistent results when different outcome measures are considered. For example, daily low-dose aspirin to prevent heart disease and colorectal cancer received a B rating, and only for those adults ages 50–59 years who have a 10% or greater 10-year CVD risk are not at increased risk for bleeding, have a life expectancy of at least 10 years, and are willing to take low-dose aspirin daily for at least 10 years. It received a C rating for adults 60–69 years of age and an insufficient evidence rating for adults younger than 50 and older than 70. Aspirin may prevent death from cardiovascular disease, but some studies show it has only a tiny health benefit from the perspective of total mortality (Sanmuganathan, Ghahramani, et al., 2001). European reviewers, who have considered the same evidence, do not advocate daily aspirin use on a population basis (Perk, De Backer, et al., 2012). The USPSTF review suggests some benefits, but encourages a balancing of these benefits with risks for bleeding (Guirguis-Blake, Evans, et al., 2016).

Exnovation

That an appreciable proportion of healthcare provides no or very little benefit raises an important question: *How do we recognize that something doesn't work and that we should stop doing it?* Innovation is defined as the action or process of introducing new methods, ideas, or products. There is no question that innovation is a core ingredient of science and a key to advancing healthcare. On the other hand, medicine and healthcare are plagued by innovations that have not lived up to their promise. In addition, many non-evidence-based practices have been widely adopted. Continuing to use suboptimal innovations uses resources and crowds out the opportunity to apply other approaches that may have a more beneficial impact. In this paper, we consider the need for exnovation—the science of identifying and reducing the application of methods, ideas, or products that do little good, unnecessarily use resources, and may produce harm.

Why Do We Need Exnovation? Although interventions are often identified as innovations, we argue that all care must be carefully evaluated to determine whether or not it actually provides health benefit. Those services that do not provide sufficient benefit should not be supported. We simply cannot have it all. Overtreatment can be dangerous—not just wasteful and inefficient.

We often hear that patients get the evidence-based treatment only about 50% of the time (McGlynn, Asch, et al., 2003). But, we seldom concentrate on the half or more of the services they receive that are not supported by evidence (Smith, Halvorson, & Kaplan, 2012). In addition to increasing the use of evidence-supported services, we also need to exnovate—to reduce the use of services that are not evidence-based or those that provide no incremental benefit beyond less expensive alternatives.

Despite the kind of evidence reviewed earlier, exnovation is difficult to achieve. Prasad and Ioannidis (Prasad & Ioannidis, 2014) suggested that entrenched practices and biases are resistant to new evidence on low effectiveness. Montini and Graham (Montini & Graham, 2015) offered the example of radical mastectomy to document how historical, economic, professional, and social forces help support an ineffective practice. Although systematic evidence played some role in exnovating radical mastectomy, forces outside science had a very powerful influence.

Examples of Services that Need Exnovation There are a wide variety of health services that use resources yet do not necessarily offer patient benefit (Fisher, Wennberg, et al., 2003; Kaplan, 2009). The use of cancer screening tests among populations of varied ages is a good example (Welch, 2004). There has been a long-standing controversy as to whether or not screening mammography for women under 50 produces the probability of breast cancer death and increases the life expectancy (Baum, Thornton, et al., 2010). A small number of randomized clinical trials have evaluated this question. The Cochrane Collaboration in Norway has systematically analyzed the trials and adjusted for methodological quality. They find no evidence that screening mammography increases life expectancy (Gotzsche & Nielsen, 2011). Some trials suggest that screening mammography results in small reductions in deaths from breast cancer, but there are compensatory increases in deaths from other causes. Recently, a series of quasi-experiments was also analyzed (Irvin & Kaplan, 2014). These studies, which have greater external validity than the randomized trials, similarly fail to support the use of screening mammography for women under age 50. At best, screening mammography may save the life of one woman among each of the 2000 screened. However, among the screened women, at least 10% will have false positives and may go through unnecessary evaluations, risky procedures, and anxiety. Some analyses suggest that as many as one third of women who are treated for breast cancer received unnecessary intervention (Bleyer & Welch, 2012).This is important because breast cancer treatment is not benign. It may have serious long-term adverse effects of the central nervous system (Deprez, Amant, et al., 2012) and the cardiovascular system (Ganz & Stanton, 2012). The best evidence suggests that screening mammography in this age group does not result in women living longer, even though it leads to the identification of more cases.

The mammography example may not be unusual for screening tests. Saquib, Saquib, and Ioannidis (Saquib, Saquib, & Ioannidis, 2015) reviewed the effects of a wide range of screening tests on disease-specific and all-cause mortality. They underscore that the goal of these tests is to identify disease early in order to help people live longer lives. Using meta-analysis for 39 different screening tests for 19 diseases, they considered 48 RCTs and 9 previous meta-analyses. They found only small reductions in disease-specific mortality and almost no evidence that screening tests resulted in reductions in all-cause mortality.

There are abundant examples of expensive interventions that appear to have little to no benefit from the patient's perspective. For example, each year, nearly 2.2 million adults receive epidural injections of glucocorticoids for the treatment of back pain resulting from lumbar spinal stenosis. A large systematic randomized clinical trial showed that glucocorticoids plus lidocaine provided no more benefit than lidocaine alone at 6 weeks (Friedly, Comstock, et al., 2014). Recent systematic reviews suggest that in

Table 36.1 Categories requiring exnovation and actions required

Category	Potential actions needed
Use of non-evidence-based procedure	Public disclosure Require patient consent Quality metrics that penalize non-EB interventions
Over-use or over-aggressive treatment	More research on side effects and unintended consequences Relate approvals and guidelines to dose-response data Require EHR checkoff that understand patient has comorbid conditions that may increase risk
Use of overly expensive procedures	Promote use of "MINC"[a] More emphasis on cost, cost-effectiveness, cost benefit More use of stepped care
Assumption that "more, and more frequent is always better"	Publicize what is known about frequency of testing Narratives and simulations on unintended consequences

[a] *MINC* minimal intervention needed for change

well-controlled studies, the failure to confirm the value of commonly prescribed treatment is common in many areas of medicine (Cummings, Morstorf, & Zhong, 2014).

Another important issue is incremental or *marginal* benefit. We usually compare a new treatment in relation to current practice. It is rare that we would do nothing for people with serious illness. Instead, we often need to know how much benefit accrues when we do something that is different from ordinary practice or if we do something that is expensive but provides little or no benefit over a simpler and less expensive approach. The example of Pap smears every year versus every 3 years is a good one. The yearly test relative to the triennial adds 32 h to expected life span (71 days, 8 h, versus 70 days) at a cost of $83,000 versus $2600 per life year gained for the test given every third year (Hagen, Garber, et al., 2001).

The Consequences of Failure to Exnovate Failure to discontinue an ineffective innovation has consequences. One of the most important concerns is that there are opportunity costs for continuing to use ineffective treatments. There are at least three different types of opportunity costs. First, there are financial opportunity costs. Expenditure on programs such as mammography or PSA screening uses resources that could have been applied to more effective treatments.

The second concern is the time opportunity cost. Patients have only a limited number of exposures to the healthcare system and healthcare providers. In primary care, providers are required to do more and more in less and less time. There are many different services that can be provided during this limited time. Continuing to use services that provide little benefit uses valuable time resources that could have been applied for more productive purposes.

The third concern, and perhaps most crucial, is the health opportunity cost. If patients are receiving suboptimal or even detrimental care instead of a more beneficial treatment, their health will be negatively impacted. Even a noneffective treatment or procedure may allow for the patient's condition to worsen, substantially affecting short and even long-term health outcomes. Categories requiring exnovation and strategies to achieve reduction in effective services are summarized in Table 36.1.

Pathways to Exnovation

Several years ago a provocative editorial in the *New England Journal of Medicine* was entitled "Waste, We Know You Are Out There" (Aaron, 2008). It has been estimated that at least 750 billion dollars a year is being spent on services that provide little value. Yet identifying and eliminating these services remains an important challenge (Smith, Halvorson, & Kaplan, 2012). Is it realistic that we can do something about it?

There are at least four pathways to identifying and eliminating the use of unnecessary services. These approaches involve control by payers, change of practices by providers, increased engagement in decision making by patients, and efforts to use research data to inform exnovation. We will consider each of these approaches.

Payer Control One way to exnovate is through the policy changes that allow those who pay for health services to restructure their policies and emphasize payments for services that provide value to patients. Under the Affordable Care Act, significant progress is being made. The Center for Medicare and Medicaid Services (CMS) innovation center (known as CMMI) was created to improve all aspects of patient care, including safety, effectiveness, patient centeredness, timeliness, efficiency, and equity. Ultimately, the center hopes to stimulate better health for the population by encouraging healthier lifestyles, promoting the avoidance of risky behaviors, and encouraging better use of primary and preventive care. They believe that promoting preventive medicine and improved coordination of healthcare will result in lower healthcare costs. A major part of this effort is in finding more efficient ways to reimburse healthcare providers. For example, bundled payments change the way providers are reimbursed. The old system rewarded a high volume of healthcare services. For example, when a patient received surgery, several different healthcare providers billed for their services and the hospital and supportive providers each were reinforced for adding components for this service. Under bundled payments, a single fee is generated for the entire surgery and the providers and hospitals must decide how to divide up the payment. Instead of rewarding inefficient volume, the strategy encourages efficiency and value for the recipient of care. The US Department of Health and Human Services recently announced plans to reward value over volume in payments made to providers in their Medicare programs (Burwell, 2015).

The innovation center also encourages greater use of primary care. A large literature suggests that overuse of medical specialists creates greater expense without improving patient benefit. CMMI is experimenting with programs that offer bonus payments to primary care doctors who achieve better coordination of care for their patients.

Provider-Based Exnovation Some organizations are beginning formal exnovation exercises. For example, the American College of Physicians (ACP) identified 37 screening tests that should be used less often (Qaseem, Alguire, et al., 2012). The ACP suggested that excessive and unnecessary testing costs $200 to $250 billion dollars per year. Some of the most commonly overused tests include imaging studies, CT scans for benign disease, and the overuse of electrocardiograms in patients without symptoms. The ACP considered both the value and the cost of tests. The exnovation exercise is not simply an attempt to cut high-cost tests. Some high-cost tests and treatments also provide high value to patients. For example, antiretroviral therapy for patients with HIV disease not only prolongs life but also reduces the probability of transmission to uninfected partners. These drugs, although very expensive, also provide exceptional benefit and are considered high cost plus high value (Fauci & Folkers, 2012). Conversely, some tests are inexpensive but also provide essentially no value. As stated previously, one example is the annual Pap smear for a low-risk woman. Although screening every third year provides substantial benefit, the incremental benefit of annual screening is remarkably small (Hagen, Garber, et al., 2001). Similarly, chest x-rays prior to surgery for healthy adults provide very little information. Although costs are relatively low, value is also low (Archer, Levy, & McGregor, 1993).

The ACP brought expert clinicians together to consider which tests needed exnovation. They created a working group and each member was asked to identify five screening or diagnostic tests that resulted in little value for patients. Tests that received unanimous consensuses among the groups were retained. If the test was identified as a candidate by at least two thirds of the group, it got further discussion and was only retained if the group ultimately reached consensus. Through this process, 37 commonly used tests were identified.

The group identified two basic principles for exnovation of tests. First, they suggested the tests should not be used routinely if the results would not alter their clinical practice. The second principle was that tests should not be used if the likelihood of a false positive exceeds the likelihood of a true positive. This can happen when the initial probability of a condition is very low. For example, for young men without any symptoms of cardiovascular disease, the likelihood of significant coronary artery disease is low. On the other hand, the probability of a positive exercise stress test is about 50% for women 40–59 years of age who did not have coronary disease and 66% for healthy women over age 60 (Cumming, Dufresne, et al., 1973). Those who have a positive test are then likely to get other diagnostic testing which might result in both psychological distress and, in some cases, physical harm. Costs of the unnecessary test go beyond testing costs. There might be additional time lost from work and costs associated with additional tests to rule out concerns raised by the false positive evaluation.

The "Choosing Wisely" initiative was developed by the ABIM Foundation and quickly spread to many specialty organizations. By 2013, at least 40 groups had created lists of five things providers should question. Although there is much to applaud about Choosing Wisely, important questions have also been raised. In particular, tests and procedures that are used much more frequently in some geographic areas often raise concerns, particularly when regional variation is unassociated with patient outcomes. Yet, there was considerable inconsistency in the listing of these high variation tests and procedures by some groups. The American Academy of Orthopaedic Surgeons questioned low-cost and perhaps harmless over-the-counter supplements and relatively low-cost durable equipment items but did not include several controversial high-revenue-generating procedures as items to question. Specialty groups often questioned activities provided by competing medical specialties, but were less likely to list tests and other medical services that generated significant revenue for their own specialty (Morden, Colla, et al., 2014). Although Choosing Wisely has enormous potential, we await evidence that it affects practice, particularly in relation to the reduction in the use of high-cost unnecessary services.

Consumer-Based Exnovation A major problem in healthcare is the imbalance between the knowledge and power of patients and providers. Often, physicians choose treatments on behalf of their patients. The problem is that physicians have substantial incentives to provide expensive and often unnecessary services. Because there is an imbalance in knowledge about the value of services, patients are at a disadvantage. Shared medical decision making is a process by which patients and providers choose among multiple, clinically appropriate interventions or strategies, taking into account the patients' values and preferences. In some cases, shared decision making simply gives patients more information about the choices they will encounter. In other circumstances, shared decision making involves assessment of patient preferences and values. For example, the value of aggressive surgical treatment for prostate cancer is uncertain (Andriole, Crawford, et al., 2009). However, aggressive treatment is likely to result in serious consequences including impotence. For some older men who are not sexually active, impotence is not a major concern. For others fear of impotence may play an important role in decision making. The shared decision making paradigm involves measuring preference for outcomes and integrating them into the decision process (Frosch & Kaplan, 1999). A variety of studies suggest that engagement in shared decision making is associated with more conservative patient decision making, lower costs, and greater patient satisfaction (Frosch, Kaplan, & Felitti, 2001, 2003).

When presented with the full picture of information about the risks and benefits of treatments, patients often make conservative choices (Kaplan, 2009). One example concerns surgery for back pain. The United States has a significantly higher rate of back surgery than any other developed country (Deyo, Mirza, & Martin, 2006). However, these surgeries are not always necessary, and in most cases, the surgery is elective and there is reason to believe that medication alone may produce equivalent results (Deyo & Ching, 2012).

A clinical trial compared surgery with prolonged conservative treatment for adults with radiologist confirming herniated disks. The surgery patients received surgical treatment within 2 weeks while the other group got physical therapy and medical support. Some of these patients eventually chose to have surgery. Although the surgery patients got better sooner, after 1 year, the outcomes for the two groups were equivalent.

Deyo reviewed a series of surgical trials and considered the question, "who needs back surgery?". He concluded that surgery may be necessary for those who have major motor deficits because of disk problems and those who have had trauma to the spine. Most people with herniated disks or spinal stenosis, according to Deyo, do not need surgery. Surgery may offer pain relief, but that comes with some risks. For most patients, shared decision making is the recommended method for finding the best pathway (Deyo & Ching, 2012).

Deyo and his colleagues conducted a systematic clinical trial to evaluate the effects of shared decision making. Three hundred ninety-three patients who were candidates for elective back surgery were randomly assigned to an interactive video explaining the risks and benefits of back surgery or to a control group. (Both groups got a booklet describing back surgery.) The study demonstrated that exposure to balanced information reduces the number of back surgeries without any adverse consequences on health outcome (Deyo, Cherkin, et al., 2000). The reduction was most likely in the clinical group that was least likely to benefit from surgery.

Research-Based Exnovation In addition to the use of payer, provider, and consumer efforts to reduce use of ineffective practices, a fourth pathway is through research. We see the value of the research field in enhancing all stakeholders' ability to identify and support exnovation. Research into the ongoing comparative effectiveness of different treatment and preventive interventions, for example, may show that even evidence-based practices are less effective than alternatives and should be withdrawn. This same research may be able to identify *for whom* a given intervention works and permit partial exnovation of a practice for those who do not benefit from it.

Research can also identify key strategies, at a given level (i.e., patient, provider, system) or across multiple levels to successfully exnovate a specific practice or set of practices. In the same way that researchers are actively testing strategies to promote adoption, implementation, and sustainability of effective innovations, they can also test strategies to reduce unnecessary use. With the evidence base for any specific intervention constantly evolving, we should expect that the next great innovation may someday be the target of rational exnovation efforts. Health systems, with research evidence, may be able to plan for future exnovation of practices, as well as substitution of an improved practice for that which is currently in use.

The Dividend for Exnovation

Conservative estimates suggest that about US$750 billion are spent on services that provide essentially no health benefit (Berwick & Hackbarth 2012). Others have suggested that the excess may cost as much as 1.2 trillion (Berwick & Hackbarth 2012).

Identifying and cutting these expenses will harm few people, although it will reduce the income of healthcare providers and hospitals. The flip side is that there will be substantial benefits because funds can be put to better use. We sometimes react to concerns for costs as the insertion of the values of business or "the bean counters" in places where only human outcomes should matter. "It doesn't matter how much it costs if it saves one life…." Consider, however, the concept espoused by Martin Luther King that "budgets are moral documents." They express the values of groups as they allocate resources to one or another purpose. For example, the component of the US global competitive index that reflects health and primary education investment, once among the highest in the world, has slipped to 42nd. Further, excessive spending on healthcare contributes to the federal deficit because nearly half of all health services are federally funded. In 2011, for example, the state component of the Medicaid programs used nearly a quarter of the average state budget (McCullough, Zimmerman, et al., 2012). Reducing payments for health services that provide essentially no health benefit would produce a windfall in revenues that could be used for infrastructure development, such as the development of safer communities, better education and nutrition programs, and improved transportation. It might also lead to greater fiscal stability and debt reduction and provide opportunities to support disease-preventing programs such as anti-tobacco campaigns, services for pregnant smokers, or drug use prevention.

Summary

Healthcare is the largest sector in the US economy. Despite spending significantly more on healthcare than any other country, health outcomes for Americans are not exceptional. Life expectancies for Americans are increasing, but the rate of increase is not keeping pace with other wealthy countries. From a consumer perspective, we are paying more, but getting less value.

Part of the problem with American healthcare is that we may be overpurchasing services that have little to no effect on health outcomes, while underpurchasing evidence-based services that have the potential to improve health. In addition, decisions about use of healthcare are often based on surrogate markers, such as blood glucose, rather than on patient-centered health outcomes. Sometimes changes in the surrogate measure are unrelated to improvements in outcomes that are meaningful to patients, including life expectancy and health-related quality of life. In order to address these problems, we need new approaches to health resource allocation that improve the dissemination and implementation of evidence-based services and decrease the use of unnecessary and ineffective services.

Innovation is at the core of medical research and the advance of healthcare practice. Innovative practices have greatly improved the care of patients. On the other hand, not all innovations result in better care and improved outcomes. A growing literature suggests that many expensive interventions provide essentially no benefit. At the same time, some interventions expose patients to unnecessary risk. In addition to the physical harms, overexpenditure has other consequences because of lost opportunities to use resources for services that benefit populations.

Exnovation is a process by which services that are not clearly supported by evidence are extracted from practice and replaced by other services for which there is a stronger evidence base. Although difficult, exnovation might be achieved through modification of payment to providers, through reform efforts initiated within healthcare practice groups, by greater activation of patients in the decision process, and by research on exnovation strategies. Successful exnovation might have broader societal benefits including reductions in the federal deficit, support for nonmedical social services that enhance population health, and greater patient participation in medical decision making processes.

Competing Interests The authors declare that they have no competing interests.

Authors' Contributions All three authors contributed to the conceptualization and writing of the paper. RMK took responsibility for drafting the manuscript and for overseeing the revisions. DAC and REG contributed extensive editing and examples. All authors approved the final version of the manuscript.

Acknowledgment This work was completed while all authors were employed by the National Institutes of Health. The authors did not receive support from any other agency in order to complete this work.

Impacts of Emerging Fundamental Science on Health, Behavior, and Their Interaction

Bradford W. Hesse

Biomedical Discovery in the Twentieth Century

In the first part of the twentieth century, major advances in world health came about primarily through insights garnered from studying populations of individuals and the environment in which they lived. Epidemiologic studies of the patterns of disease throughout a population coupled with fundamental research in microbiology and toxicology led to the revelatory knowledge that paying close attention to a community's water supply, sanitary conditions, and food sources could prevent some diseases altogether. Large public work projects were launched to improve the living conditions of communities and to combat the spread of bacterial or viral infections. Social scientists became engaged in the task of improving communication between public health officials and the general public, as mass media campaigns were initiated to raise awareness on how to improve living conditions and how to engage in self-protective, hygienic behavior. Social scientists were also heavily involved in offering evaluations of health programs in an effort to identify the techniques that were most successful in moving the needle on public health objectives (Colgrove, Markowitz, & Rosner, 2008).

At the midcourse of the twentieth century, in the era of prosperity following the Second World War, industrial nations around the world began investing in a framework of fundamental science and engineering that would soon lead to a "golden age" in clinical medicine. Advances in fundamental knowledge about biochemical processes, for example, would lead to the so-called miracle cures of the twentieth century. In 1952 the first randomized controlled trial was published (Daniels & Hill, 1952), ushering in an era of evidence-based medicine and establishing a pipeline for the industrial age pharmaceutical treatments emerging from the rapidly evolving knowledge base in biochemistry. Likewise, advances in physics would soon lead to a revolution in the ways in which physicians could diagnose disease or injury through radiographic imaging techniques and to the use of radiation to target and eradicate cancer cells (Mukherjee, 2011). Fundamental discoveries in biomechanics would soon lead to life-saving procedures for extending heart life, repairing aneurysms, filtering blood toxins, preventing long-lasting injury, and restoring function from broken or missing appendages. Behavioral scientists were called upon to enhance compliance with complicated therapeutic demands and to provide coping skills for living with the sequelae of invasive procedures.

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_37

As a result of these fundamental discoveries and their interactions with public health and behavioral medicine, great strides were made globally. For example, in 1910 the life expectancy for a Chilean female was 33 years; by 2010 that life expectancy rose to 82 years, a remarkable gain of almost 50 years over one century (World Health Organization, 2010, 2012). In the United States, average life expectancy rose from 48 in 1900 to 74 in 2000 for men and from 51 in 1900 to 80 in 2000 for women (National Center for Health Statistics, 2010). Because of these strides, the World Health Organization has predicted that by 2050 the absolute number of older people aged 60 years and over is expected to increase from 606 million to 2 billion people. The repercussions of these fundamental discoveries will continue to be felt as families and policy makers seek to protect quality of living and promote independence among those benefitting from life-saving science (Fishman, 2010; World Health Organization, 2012). In the wake of these changes, practitioners of behavioral medicine have been called upon to contribute an understanding of the neurological effects of aging (Buscemi, Steglitz, & Spring, 2012), to support caregivers and community systems (Buman, Winter, et al., 2012), and to inform practice through data (Toobert, Glasgow, et al., 2012).

Funding for behavioral medicine began to flourish in the second part of the twentieth century as epidemiological observations of atherosclerotic cardiovasculature conditions uncovered the implications of lifestyle choice in the etiology of heart disease. Behavioral researchers and practitioners were brought in to help cardiac patients change their lifestyle choices, to lose weight, to select healthier diets, to exercise, and to stay adherent to prescribed regimens of preventative medical treatments. A more comprehensive biomedical understanding of the toxic relationship between tobacco smoke and lung disease was revealed in the 1964 Surgeon General's report on smoking and health (US Department of Health, 1964). It took decades of unrelenting behavioral research along with mission-focused public health practice to turn the tide against nicotine addiction at a population level. The first downward spiral of mortality rates from lung and bronchus cancer in the early 1990s in the United States marked a watershed victory in behavioral medicine (Hiatt & Rimer, 1999). Full utilization of those findings in the global arena has taken longer, with efforts from an international cadre of behavioral scientists needed to adapt findings to local, political, and cultural contexts (Eriksen, Mackay, & Ross, 2012).

Fundamental Discovery in the Twenty-First Century

To be sure, the medical victories of the twentieth century were substantive, as the director of the US National Institutes of Health (NIH) explained to members of the US Congress in 2004, but they fall short in meeting the challenges of the next century (Cullington, 2006). "Medicine in the 20th Century was reactive," he explained; it waited until the disease had fully occurred before intervening with ameliorative treatment. By that time, substantial tissue damage may have had already occurred, and care providers would be left trying to prolong life with expensive and invasive treatments. Life expectancy would go up, but quality of life – especially during the waning years – would remain poor. Medicine in the twentieth century was a legacy of the industrial age. Treatments were mass-produced to reach the widest swath of patients with a one-size-fits-all approach, an approach that was successful at extending reach globally and internationally but that often resulted in excessive waste or mismatched therapies at the personal level (Cullington, 2006).

Fundamental discovery in medicine is moving beyond the limitations of the previous century, the NIH director explained. Completion of the Human Genome Project in 2003 (an extraordinary international effort to document the 3 billion + base pairs of the human genetic code) ushered in an age of molecular medicine in which an understanding of the preclinical, cellular events leading to disease would eventually allow healthcare practitioners to identify early warning signs of risk before disease occurs

(Cullington, 2006). The future will be an era of "four P's" medicine; it will be *P*redictive, *P*reemptive, *P*ersonalized, and *P*articipative. It will be *predictive* in the sense that an improved understanding of molecular pathways leading to disease will allow practitioners to identify the predisposing conditions leading up to a deleterious health condition early in its genesis, well before visible symptoms occur and tissue damage begins. It would then be a relatively easy task to intervene in the disease process in a *preemptive*, rather than an ameliorative, way. These profiles of risk, detectable at a subcellular level, will differ from person to person. New fundamental discovery in microchip technology should make it possible to keep track of these changing risk profiles over time and to tailor treatments adaptively to the personal characteristics of each individual patient. In this sense, treatments in the twenty-first century will increasingly be more individualized, yielding results that are "orders of magnitude more effective" (Cullington, 2006) than industrial age approaches. Those movements from an industrial model to a *personalized* model will pragmatically and ethically require that care be given in an increasingly *participative* way. Patients will need to become part of the care team to minimize error, preserve quality of life, and optimize outcomes (Cayton, 2006; Cullington, 2006).

This overarching trend – turning medicine from an industrial, one-size-fits-all approach to one that is predictive, preemptive, personalized, and participative – is a central, organizing principle within this chapter. As new fundamental discoveries exert a "disruptive" influence on medicine (Topol, 2012), it will be incumbent on behavioral scientists and health system researchers to gather the evidence needed to serve the interests of the "whole patient," including the patient's psychosocial needs (Adler & Page, 2008). Practitioners of behavioral medicine will be needed to serve as the "linking pins" (Davis, McGregor, & Likert, 1989) between biomedical science and the platforms that will serve to empower patients, the general public, and the professionals who care for both. As medical technology becomes more advanced, the need to integrate an accompanying understanding of human behavior increases (Goetz, 2011).

Anticipating the Future

What will a new age of fundamental discovery mean for researchers and practitioners of behavioral medicine in the twenty-first century? To answer that question, it is useful to go beyond fundamental biologic discovery to examine predictions for how health and healthcare may be altered by innovations emerging across multiple scientific fields. Scientists at the Massachusetts Institute of Technology refer to this as an era of "convergence" between the life sciences, the physical sciences, and engineering (Massachusetts Institute of Technology, 2011). It will account for some of the fundamental discoveries that are sure to influence healthcare and wellness over the next century, from the predictive information that comes from increasingly fine-grained bioimaging and modeling technologies to the highly personalized treatment modalities made available through molecular medicine and nanotechnology-based delivery systems. Most of these new discoveries will be enabled by, or made available through, the context of highly networked, ubiquitous, and computationally sophisticated information systems (Hesse, 2008b; Nielsen, 2012; Topol, 2012).

A good source for predictions about the influence of these discoveries can be found in the reports generated by the *Institute for the Future* in Palo Alto, California. The institute was founded by a former group of RAND Corporation researchers in 1968 to take leading-edge research methodologies into the public and private sectors. The organization uses multiple techniques including the use of surveys, interviews, archival documents, statistical modeling, and comparative forecasting to do trend analysis for a variety of clients (Johansen, 2007). In 2009, the institute released a report from its Health Horizon's Program anticipating trends up until the year 2020 (Adler, Dunagan, et al., 2009). The report was organized around six mega-trends resulting from their analysis of changes in the scientific and organizational milieu surrounding health and healthcare. The megatrends provide a framework from which to view the continued pipeline of scientific development within the healthcare sector, and they offer a lens through which the interaction between fundamental discovery and behavioral medicine can be viewed. Each will be discussed below, with a predictive analysis for what each of these new fundamental changes might imply for behavioral medicine in the years to come.

Combinatorial Innovation in Health Information Technologies

The Trend

Fundamental advances in engineering have produced an age of ubiquitous computing in which microprocessors are finding their way increasingly into an interconnected network of smart mobile devices, sensors, advanced imaging devices, laptops, and desktops. Information architects have been working on the standard technological and semantic protocols necessary to interlink data from these independent devices into a seamless web of services available to users at any time and in any place through "cloud architectures" (i.e., configurable networks of servers, storage devices, applications, and services available to users remotely through the Internet). Moreover, because these networks span borders, they may provide access to medical knowledge and personalized service universally, regardless of geography or even language. Understanding how these technologies may change healthcare, though, means understanding how interconnected services change business practice.

A presage for the global changes to emerge within the health sector may be glimpsed from the transformations already wrought in international finance and world air travel (Friedman, 2007). The financial industry has morphed (for better or for worse) from a loose collection of parochially limited financial institutions to a broad consortium of globally facing financial networks, all interconnected through wide area networks running highly advanced translational algorithms to move large sums of money across currencies and across economies instantaneously. On the positive side, savvy consumers can find themselves in a world in which they have immediate access to their money, and information about their money, 24 h a day, 7 days a week through an international network of automated teller machines, online banking tools, interactive voice response systems, and mobile device "apps." On the negative side, the unanticipated consequences of an international investment system based on highly sophisticated, but increasingly obfuscated, computer algorithms were blamed with triggering many of the poor financial decisions leading to the global economic crash of 2008–2009 (Salmon, 2009).

Unanticipated effects notwithstanding, these sector-wide transformations based on networking and information technology have helped many sectors in the global economy realize productivity gains while reducing costs. Up until now, however, these benefits from information technology have been slow to stimulate cost savings in the healthcare sectors (Cutler, 2007, 2009). That was the trend that the US Congress attempted to change when it passed the Health Information Technology for Economic and Clinical Health (HITECH) Act of 2009 (Title XIII of the American Recovery and Reinvestment Act). In anticipation of broader healthcare reform efforts in the USA, the Act was intended to spur economic savings and to improve population health by encouraging the "meaningful use" of health information technology (HIT) in the service of patient-centered care.

In translating the HITECH Act into practicable terms, the Office of the National Coordinator for Health Information Technology (ONC) in the USA is encouraging market-driven innovation based around an evolving set of standards for health information exchange (Williams, Mostashari, et al., 2012). The goal is (a) to invest in the standards and technologies needed to ensure protected data flow of health information and then (b) to allow the market to combine distinct elements from an emerging *health* *information technology* (HIT) marketplace into novel products and services that will ultimately improve personal and clinical health. This is the essence of "combinatorial innovation," to nurture an emerging ecosystem of health information technologies based on novel combinations of evidence-based innovations as depicted in Fig. 37.1.

Implications for Behavioral Medicine

For researchers and practitioners of behavioral medicine, this change in the philosophy of health services innovation should help drive a newfound relevancy for the theories, foci, and empirical methods of behavioral research. As the authors of a US-based National Research Council report on "Computational Technology for Effective Healthcare" explained, the target for innovation in health services research should no longer be on the development of new and more expensive technologies, but on the behaviors and context that will drive improved patient outcomes. Funding agencies should "rebalance" their portfolios away from pure technology development to emphasize the behavioral targets associated with providing better "cognitive support" for physicians, patients, and their caregivers (Stead & Lin, 2009).

As the market gears up to innovate on the myriad ways in which new technologies can be combined to support personal health, the work of behavioral scientists will be needed to help shape the technologies' designs in accordance with evolving theories of human health behavior (Riley, Rivera, et al., 2011). Failure to include the perspectives of behavioral scientists in the development and evaluation of these new health-related applications will simply lead to recursive failures in the marketplace in the most benign scenario (Mandl & Kohane, 2008, 2009), or to squandered opportunities for saving lives in the worst case scenario (Abroms, Padmanabhan, et al., 2011; Ahern, Woods, et al., 2011). By the same token, a failure to update the theories and methods of behavioral medicine to take full advantage of the enhanced capacity and real-time testing environments available within these new ecosystems will unnecessarily slow down development (Collins, Murphy, & Strecher, 2007) or could leave behavioral medicine behind as an irrelevant science (Riley, Rivera, et al., 2011).

When contemplating the role of these new emerging technologies, behavioral scientists will be the first to recognize that the new HIT ecosystem cannot – and should not – replace crucial person-to-person communications (Epstein & Street, 2007). Rather, the new ecosystem should serve to augment human capacity (Zuboff, 1988)

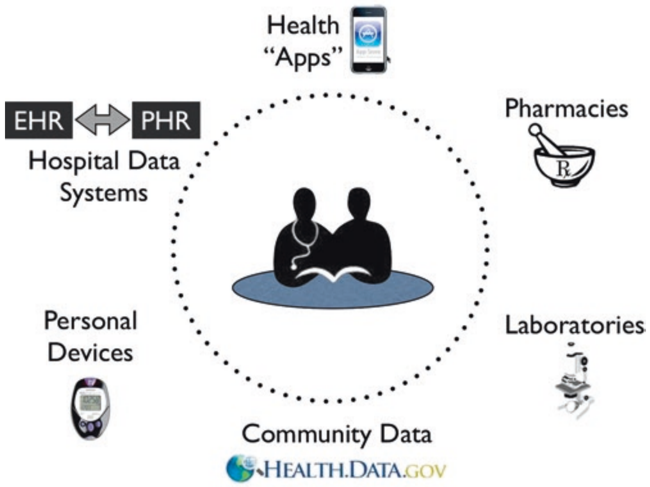

Fig. 37.1 The evolving health information technology (HIT) ecosystem

within the broader systems in which productive and essential conversations occur (Hesse & Shneiderman, 2007). In this sense, it is useful to bear in mind the basic precepts of a sociotechnical design perspective (Coiera, 2004; Pava, 1983): (a) that technical systems have social consequences; (b) that social systems have technical consequences; (c) that we don't design technology, we design sociotechnical systems; and (d) that the key for behavioral science in the future will be to understand how people and technologies interact. The work of communication scientists will be needed to improve the fidelity of signals passed between the patient and the healthcare system, between the patient and their associated networks of social support, and between components of the healthcare system (Hesse, Hanna, et al., 2010; Taplin, Mylks, et al., 2010; Taplin & Rodgers, 2010). Issues of intrinsic motivation will come to bear as system designers find ways to preserve a sense of patient autonomy in decision-making, while enhancing a sense of self-efficacy in mastering health-relevant behaviors and preserving or expanding the patient's sense of connectedness to important others (Hesse, 2008a; Williams, Lynch, & Glasgow, 2007).

From a sociotechnical perspective, there will also be a need for behavioral scientists to monitor the evolution of an HIT ecosystem from the population level (Abernethy, 2011; Forman, Greene, et al., 2010; Hesse, 2007). The work of sociologists and epidemiologists can contribute to our collective understanding of how well the individual components of the rapidly evolving system are working together to influence population health. Are some developments caustic, resulting perhaps not in improved health for all but in reduced health outcomes for some disadvantaged populations (Neter & Brainin, 2012)? If so, what are the policies needed to control for deleterious consequences or to promote alternative solutions? Are innovations lacking reach or diffusion, leaving pockets of the population unnecessarily at risk (Dearing & Kreuter, 2010)? If so, then what processes can be put in place to improve the diffusion potential of efficacious applications (Dearing & Kreuter, 2010; Kreuter & Bernhardt, 2009)? Behavioral medicine at a systems level can be applied to improve system-wide performance of a targeted innovation by monitoring inputs and outputs and by offering empirically based recommendations for improving reach, efficacy, adoption, implementation, and maintenance (Glasgow, McKay, et al., 2001).

The Health Data Marketplace

The Trend

Documenting the human genome introduced a new era of quantified medicine, one in which the molecular profile of individuals could be funneled through the increased processing power of high-throughput computing systems to enhance discovery at both the molecular and population levels (Collins, 2010a; Hesse, Croyle, & Buetow, 2011). It was the harbinger of what some have called "the fourth paradigm" in science (Hey, Tansley, & Tolle, 2009), that is, a succession of scientific capability from basic observation (first paradigm) to the evolution of theory (second paradigm) to hypothesis testing using statistical analysis (third paradigm) and now to the use of data-intensive computing (fourth paradigm).

Genomics pioneer Craig Venter projected that in this new paradigm, "genomic data will soon become a commodity" (Venter, 2010). As he explained it, the challenge of linking genetic variation with physiology and disease will be just as daunting, if not more so, than the original challenge of documenting the human genome. Individuals themselves will find ways of contributing data on their own biologic selves to the combined efforts of scientists in order to achieve progress in combating complex diseases. Setting the pace for a new era of personal data sharing, Venter himself became the first volunteer to make data on his own personal DNA inventory publicly available to researchers in 2007 (Levy, Sutton, et al., 2007).

Around the same time that Venter was making his personal genome fully available to researchers, the start-up company "23andMe" (named after the 23 chromosomes in a human cell) opened its virtual doors for business. The company was one of several efforts to take personal genomics technologies straight to consumers (Lee & Crawley, 2009). Its stated purpose was to "empower individuals" with information from their own genetic risk profiles, while "accelerating science" with data that could be accumulated and mined for new associations between genetic profiles and disease (see https://www.23andme.com/).

This latter point was a transformative concept. It pointed to a way in which citizens, connected directly to each other and to the scientific enterprise, could work together to advance the science and to make progress against diseases. To make the new concept tangible, the company in partnership with Google® enticed members of the 23andMe community to make their genetic information along with inquiries about their personal health and lifestyles available to researchers. With massive amounts of personal genomic information at hand, Google engineers sought to replicate the findings of an NIH study exploring links between a mutation of the beta-glucocerebrosidase gene (GBA, linked to clinical manifestations of Gaucher's disease) and risk for Parkinson's disease. Whereas the NIH study took 6 years to complete, the data-intensive parallelism of the 23andMe study took only 8 months to complete (Do, Tung, et al., 2011; Eriksson, Macpherson, et al., 2010; Lee & Crawley, 2009; Prainsack & Wolinsky, 2010).

"Citizen science" (Kremen, Ullman, & Thorp, 2011) is not a concept lost on governments, either. By investing in a program of "participatory sensing," the US National Science Foundation illustrated how citizens could volunteer to record and share air quality, noise level, geographic position, and even personal biologic data through sensors attached to their smart phones (Estrin & Sim, 2010; Mills & Curtis, 2008). In a similar vein, the European Grid Infrastructure project demonstrated how a high-throughput computing environment could be established to ease data sharing among participating countries within the European Union (Diomidous & Zikos, 2012). The public-facing "PatientsLikeMe.com" Web site extended the concept of citizen science to the multinational pharmaceutical sector by offering access to patient-contributed physiological and self-report data in exchange for an opportunity to accelerate progress toward reliable treatments (Wicks, Massagli, et al., 2010).

What each of these new developments illustrates is the emergence of a new data-intensive marketplace for discovery and innovation resulting from the proliferation of data-generating technologies in biomedicine. The genome sequencing devices on the market in 2011, for example, operate at a rate 50,000 times more quickly than the devices used to complete the first two copies of the human genome in 2003. Costs associated with data collection, storage, and processing have also gone down. In 2007, the asking price for a direct-to-consumer personal genomic risk assessment through 23andMe was $999. In 2011, that price had fallen to an introductory offer of just $99 with a small commitment of $9 per month for a 1-year subscription to the company's "personal genome service."

Implications for Behavioral Medicine

The implications of this new data-intensive ecosystem for behavioral research are themselves daunting. We know from human factors studies that *too much data* presented in the wrong way and at the wrong time can create confusion and paralysis (Nelson, Hesse, & Croyle, 2009; Shenk, 1997). On the other hand, a user interface that is designed to optimize the flow of information in ways that are compatible with human sensory and memory limitations can provide depth and clarity to decision-making (Albers, 2005; Shneiderman & Plaisant, 2010). Consider the simple, clean interface of the Google® Web site. The engineering work at the back end to funnel the right information onto the screen at the right time in accordance with a consumer-focused understanding of user needs has driven the value of the company to the top of its sector. In health, we know that "Dr. Google" often replaces visitation with a real doctor as the first source of contact with biomedical information (Hesse, Moser, & Rutten, 2010; Rochman, 2010). It is simple to use and easy to access (even by mobile telephones) and provides an immediate gateway to the exabytes of data on the open Web. Or consider the engineering accomplishment of channeling real-time satellite telemetry data on top of terabytes of geographical information system data to guide automobile drivers safely on the road aided by their own geographical positioning system (GPS). Engineers worked closely with cognitive scientists for over a decade of focused research to ensure that the data presented through the system did not overload the capacity of a potentially distractible driver.

In an October 2010 conference of the "Health 2.0" innovators' collaborative, computer publisher Tim O'Reilly explained that the ubiquity of health data access would be one of the most significant drivers of health system redesign in the coming decade. Data will become the new "Intel inside," he had been quoted as saying, for a health system striving to increase the personal engagement of individuals and families in preemptive strategies that are evidence-based and participative. What the health system needs, he explained, is an information nervous system; a system that provides all participants in clinical and public health with the right information, presented to the right people, at the right time based on credible data flows. Who would be better than researchers and practitioners in behavioral medicine to help health system engineers understand what the afferent and efferent qualities of a health information nervous system should be?

In the upcoming decades, it will be important for professionals in behavioral medicine to participate directly within these emerging health data markets and not to shy away from them. An exemplary vanguard in this sense is the CYCORE (standing for *Cy*berinfrastructure for *Co*mparative Effectiveness *Re*search) project funded as a collaborative effort between the MD Anderson cancer center in Houston, Texas, and the Supercomputer Center at the University of California at San Diego (UCSD) in La Jolla, California. The precipitating stimulus for the project was the recognition that "learning healthcare systems" must be able to take advantage of internal data flows in order to conduct the comparative effectiveness research needed to improve quality of outcomes while reducing costs (Institute of Medicine, 2011). In many of the discussions surrounding comparative effectiveness research, however, the data are often not available for testing behavioral interventions. The CYCORE project is tackling that problem directly by demonstrating how behaviorally relevant information can be included in the acquisition, storage, visualization, analysis, and sharing of data in a comparative effectiveness context (Patrick, Wolszon, et al., 2011).

Similarly, experts in medical decision-making will be needed to ensure that the presentation of data within a data-infused clinical context will conform to best practices in decision support (Tait, Voepel-Lewis, et al., 2010; Ubel, Smith, et al., 2010). It has been well documented that clinical professionals often underutilize base rate information, that they anchor on first impressions, that they are prey to decisional heuristics, and that they are prematurely dismissive of uncertainty (Montgomery, 2006). Decision scientists have been able to reverse these effects with decision aides that make the right information salient while reducing the burden of high cognitive overhead (Galesic, Garcia-Retamero, & Gigerenzer, 2009; Galesic, Gigerenzer, & Straubinger, 2009; Wegwarth, Gaissmaier, & Gigerenzer, 2009). These effective decision aides can reduce errors within systems while freeing up the clinician's time for more important judgments, such as assessing a patient's emotional and social needs rather than calculating Bayesian probabilities. In a data-intensive healthcare system, every interface to the system is a potential decision aide (Zheng, Padman, et al., 2009). It will be as important to engineer those interfaces to ensure optimal functioning in medical decision-making as it was to craft the geographic positioning systems to support safe driving.

In a truly participative environment, though, data should not simply be the provenance of medical professionals. Patients should be given the chance to review their laboratory findings outside of the office visit as well as in consultation with an appropriately trained medical professional. In this sense, it will be even more important for cognitive and decision scientists to assist in crafting the environment in which these data are presented to lay audiences. Lay audiences, of course, are subject to many of the same decisional heuristics as professionals (Nelson, Hesse, & Croyle, 2009; Schwartz, Woloshin, & Welch, 2007; Woloshin, Schwartz, & Welch, 2007), but without the medical or scientific background to interpret even basic statistical concepts such as probability (Nelson, Hesse, & Croyle, 2009; Reyna, 2008; Reyna, Nelson, et al., 2009; Schwartz, Woloshin, & Welch, 2007; Woloshin, Schwartz, & Welch, 2007). Communication research has demonstrated that it is possible to convey such otherwise complicated concepts as Bayesian conditionalities in formats that are more broadly understood by lay (and professional) audiences (Galesic, Gigerenzer, & Straubinger, 2009; Zhu & Gigerenzer, 2006). More work will be needed to ensure that patients are deriving maximal benefit from an environment that is moving toward evidence as a concrete basis for decision-making.

Reengineering Healthcare

The Trend

Needless to say, the movement from an industrial approach in medicine to one that is predictive, preemptive, personalized, and participative will require an organizational redesign of medical practice. Enervating the health system with actionable and reliable data is only the first stage. From there the challenge will be to create a new workflow in which patients are oriented toward best decisions for healthy living and preemptive vigilance early in their lives and then follow through with the supportive assistance of an interconnected healthcare "system" to add quality and longevity to their lives in proactive ways. In short, the system will need to move away from its current orientation as a provider of sick care to a more idealized and cost-effective provider of healthcare.

One of the most concise, and pointed, set of blueprints for how to redesign healthcare can be found within the set of documents produced by the Institute of Medicine related to their 2001 *Crossing the Quality Chasm* report (Institute of Medicine, 2001). That series of reports pointed to six goals for the redesign of healthcare. The first was to create a system that was *safe*, addressing the often-cited statistic of some 98,000 deaths occurring per year due to some preventable error within the medical system. The second was to create a system that was *effective*, capturing the ideal of moving toward a uniform system of care best on evidence-based guidelines for best practice. The third was to orient systems away from quality as measured by institutional parameters to move toward quality as measured by patients, that is, to move toward a system that was truly patient-centered in its orientation. The fourth and fifth goals had to do with improving the *efficiency* and *timeliness* of care, addressing the escalating costs within the healthcare sector that can be reduced by improving the efficiency through which information flows and actions propagate throughout the system. The sixth goal pointed to a need for *equity*, wherein all types of care – preventative and ameliorative – are offered equally to all populations served by the medical practice (Berwick, 2002; Institute of Medicine, 2001).

All of these goals are reflective of a movement toward creating a system that reliably delivers the best evidence-based treatment possible to every patient, regardless of who the patient sees or the locale in which the patient resides. The challenging nature of delivering high quality care reliably within the complexities of medical practice was revealed by a RAND study in which the study's authors proclaimed that American medicine "gets it right" – in terms of applying consensually approved guidelines for best care – only 54% of the time (McGlynn, Asch, et al., 2003). The remainder represents variation within practices and between practices, a remnant of the days when medicine was considered an individually practiced art form rather than a finely engineered technical system. A data-infused health system could at least help keep track of performance at a system level and, through principles of quality improvement, use that data to track and reduce error (Kohn, Corrigan, & Donaldson, 2000).

Accommodating new knowledge from fundamental discovery within redesigns for healthcare will remain one of the more challenging questions to answer for improving the systemic quality of healthcare. For example, in order to deliver on the promise of "personalized medicine" clinicians will effectively have to take into account information on a patient's individual genetic risk profile, an individual's molecular traces of cellular function or dysfunction, self-reports of risky lifestyle choices, as well as histories of exposure to environmental stressors (McClellan, McGinnis, et al., 2008). As the Institute of Medicine so aptly summarized in the chart depicted in Fig. 37.2, such a task will have long exceeded the cognitive capacities of individuals within the care team. Strategies will be needed to reduce the cognitive load on actors within the healthcare system by reengineering procedures to accommodate the benefits of these new fundamental discoveries without fatally disrupting workflow or exceeding human tolerances (Stead & Lin, 2009).

Implications for Behavioral Medicine

Redesigning the healthcare system to "get it right" reliably, across systems, may imply "rebooting the system" (Hesse, 2010) to include behaviorally oriented therapies as a matter of best practice. For example, results from an NIH study suggested that patients' adherence to a regimen of diet and exercise with a goal of losing just 5–7% of personal weight could successfully prevent or delay the onset of type 2 diabetes (Cullington, 2006). With the impending impact of a widely recognized "obesity epidemic," the amount of money saved and quality of life preserved by including routine support for patients' weight control objectives would save a considerable amount of money at the back end of care. The same goes for the highly preventable instances of tobacco-related illnesses that could be eliminated if the health system were reengineered to deliver substance dependency services reliably as a standard part of preemptive care.

At a broader level, behavioral scientists can offer a contextual understanding of how a redesigned system of care can help nudge desirable

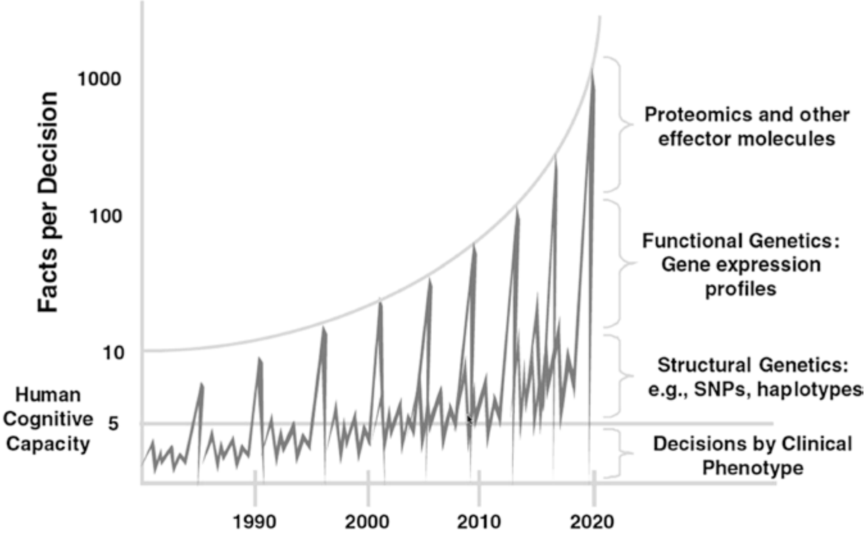

Fig. 37.2 Chart depicting the increased number of "facts" needed for personalized decision-making given explosive growth in fundamental science (Source: Institute of Medicine, "Evidence-Based Medicine and the Changing Nature of Healthcare," Meeting Summary, 2008)

health outcomes (Ahern, Woods, et al., 2011; Hesse, Ahern, & Woods, 2011). For example, electronic health record systems that have been used to offer routine reminders to patients and physicians for age-appropriate screening tests have excelled as an organizational intervention over other types of health system intervention (Klabunde, Lanier, et al., 2009; Nease, Ruffin, et al., 2008; Sequist, Zaslavsky, et al., 2009). Improved communication systems between patients and their care teams have been shown to improve adherence to self-administered treatments, prevent error, and save money in unnecessary office visits (Chen, Garrido, et al., 2009). In a meta-analysis of studies related to health information technology, investigators concluded that although most results of HIT implementation were positive, it was the "human element [that] is critical to health IT implementation" (Buntin, Burke, et al., 2011). Expertise in human system integration, implementation science, behavioral economics, and organizational theory will be needed to assist in the scale-up of effective systematic interventions.

Another challenge of system redesign will be to understand how to bring patients more actively into the process of their own care (Cayton, 2006). To illustrate, the demands of enhanced diabetes management will require patients to keep close tabs on their blood glucose level, to self-medicate as appropriate, and to monitor progress jointly with health professionals. Advances in telecommunications will likely automate the shared monitoring process by sending signals from remote sensors to a centralized gathering place for analysis. A host of implementation questions should then emerge regarding the appropriate frequency of measurements and reports, the format of data for actionable self-management, the creation of warning systems between patients and their providers, and the calibration of equipment to produce optimal signal against the backdrop of real-world noise. As the adoption of personal sensors spreads to international markets, behavioral scientists can use the RE-AIM (extending reach, effectiveness, adoption, implementation, and maintenance) model to adapt the technologies and protocols to be consistent with the mores, norms, and linguistic exigencies of local cultures (Glasgow, Dickinson, et al., 2011; Oldenburg & Absetz, 2011).

Providing support for patients' self-management of conditions takes on special significance within aging populations. Issues of health literacy, impaired memory, or cognitive disorientation can lead to deadly lapses in treatment adherence and self-management (Wolf, Curtis, et al., 2012). With the aging of some of the largest demographic cohorts in world history (World Health Organization, 2012), health system designers will need to consider ways of honoring seniors' wishes to remain at home with a sense of personal independence, rather than follow an automatic path into assisted living or communal care facilities. Honoring these wishes, while at the same time protecting the system from unsustainable economic costs, will likely become an area of acute focus across many nations in the years to come (Fishman, 2010).

Reengineering healthcare should benefit greatly from international comparisons and cooperation (Glasgow & Sanchez, 2011). Most countries differ in the degree to which healthcare is fragmented or centralized, to which preventive care is emphasized over ameliorative approaches, and to which paraprofessionals or teams of professionals engage in care. These naturally occurring experiments present an opportunity for implementation scientists to gather data for the benefit of health service researchers worldwide (Bezruchka, 2012). Comparisons between contexts can offer early evidence for which types of services produce higher quality care in the most cost-effective ways. Behavioral scientists can inform the conversation by orienting analysts toward the appropriate targets for cross-system comparisons and can enrich the discussion with data (Collins, 2010a).

As countries embrace World Health Organization guidelines for data reporting (World Health Organization, 2008), it may also become possible to expand the reach of traditional surveillance systems to achieve regional or global efficiencies. Imagine the power of a "learning healthcare system" that could monitor and report early instances of an avian flu virus in remote regions of the South Pacific, stimulate production of an antivirus in northern France, and then adjust supply chains to prevent or treat disease as needed worldwide. Understanding the complexity of building such a responsive, knowledge integration network could fall within the purview of many "team science" (Stokols, Misra, et al., 2008) experts who could help bridge differences in medical culture while strengthening ties within international consortia (Falk-Krzesinski, Borner, et al., 2010).

A Neurocentric View of Health

The Trend

One of the more intriguing and cautionary predictions from the Institute for the Future's report is the observation that a proliferation of sophisticated, affordable, and pervasive brain scanning technologies is "thrusting the brain into the center of the healthcare ecosystem." Real-time and delayed time images collected through functional magnetic resonance imaging (fMRI), positron emission tomography (PET scans), and fluorescent probes are illuminating the circuitry of the brain in ways that appear to make the inaccessible now accessible. At the very least, the techniques are capturing the imagination of funders and the public as neuroscientists seek to understand the precursors to organic brain dysfunction and as they investigate links between neural processes and converging evidence of parallel cognitive activity.

The power of these new imaging techniques accompanied by a growing understanding of the biochemistry of the brain is beginning to yield substantive leaps forward in our scientific knowledge about neural functioning. Through the use of *neuroinformatic* techniques – a combination of in silico modeling and networked data linking capacities – psychophysiologists are working to combine their knowledge about diverse aspects of neural functioning into a global anatomical map, much in the same ways in which pioneers in human genetics combined their knowledge into a working model of the human genome (Phillips, Nuechterlein, et al., 2011; Toga, Thompson, et al., 1996). The US-based National Institutes of Health has committed some $30 million in its strategic blueprint for neuroscience research to assemble converging evidence on how the 100 billion neurons and 100 trillion connections in the human brain may be implicated with specific sensory, muscular, and cognitive tasks.

The results should be a better understanding, collected through noninvasive techniques, of how the brain functions under both ordinary conditions and under the influence of pathology. Some scientists have begun to patent techniques for observing specific neural signals in relation to pain, a state-based condition that has been notoriously dependent on self-report previously (Goldeen, 2009). With this type of very specific, medical measurement in place, biomedical researchers can begin to work with pharmaceutical companies to create more effective intervention strategies for chronic pain. With the pinpoint accuracy of expanded prediction models, physicians should be able to prescribe more localized and specific types of analgesia. Surgeons may be able to focus their ameliorative procedures on relieving pressure on very specific points of the pain-inducing pathways. By observing the differential functioning of regions within the map over time, neuroscientists should be able to add greater specificity to their predictive models for Alzheimer's, Parkinson's, and other debilitating diseases as well.

Furthermore, these imaging techniques are expanding neuroscience's grasp of basic brain functioning. New knowledge is being gained on how sensory perceptions may vary over individuals or on how conflicting stimuli may serve to short circuit fundamental memory formation processes. Computer simulations of information processing patterns are providing important cues in how the parallel wiring structures of the brain can learn from changes in the contextual environment, while distilling information for higher order processing. New models are being introduced and refined based on this new incoming knowledge for how the brain formulates memories, how it connects disparate memories to derive insight, and how it filters out unwanted information to provide focus in thought. Modeling the consequences of disruption in processing can give new insight to the pathological processes associated with schizophrenia and other mental disorders (Cannon, 2011; Wizemann, Pankevich, et al., 2011).

The wide availability of these neurological imaging techniques has also given new analytic power to professionals working in unusual places. Advertising specialists working to sell consumer products have begun doing their own comparative studies with fMRIs in order to understand how gustatory memories can be triggered by visual stimuli and how "message sensation value" (i.e., the arousal-producing effects of quick-paced videographic techniques) might interfere with message retention (Langleben, Loughead, et al., 2009). That work can have serious public health impact if used to market tobacco products to vulnerable populations or to increase appetites for sugar-sweetened beverages or fat-laden foods (McClure, Li, et al., 2004). Computer software engineers have begun applying the concepts of parallel processing into a particular style of machine learning modeled on brain anatomy referred to as "neural network programming." Although these software programs are a long way off from achieving truly artificial intelligence, they have been applied to the task of delivering superior information selections directly to users and improving the "intelligence" of consumer electronics (Modha, Ananthanarayanan, et al., 2011).

Implications for Behavioral Medicine

Perhaps the rise of a neurocentric view of health, more than any other trend identified by the Health Horizons report, speaks to the importance of behavioral medicine as a guide to the future. Certainly, as the world's population ages through life-extending medical discoveries, the need to predict and preemptively intervene to prevent cognitive decay will be crucial. Population modeling suggests that morbidity from Alzheimer's disease could be reduced by as much as 50% if the onset of the disease could be delayed by only 5 years (Breitner, 1991). Understanding that preemptive therapies might have an influence on delaying onset of the disease, whether that be through the introduction of chemopreventive agents to prevent neural plaque buildup or through intellectual exercises to help keep neural circuitry activated, will be the key to preserving mental functioning in older ages. Researchers and practitioners in behavioral medicine will be needed to provide guidance on diagnosis, prevention, and treatment of this and other neurological conditions.

Outside of the strictly neurological diseases, evidence is emerging to explicate the influence of environmental stressors on neurological functioning and its concomitant influence on other disease processes (McDonald, Antoni, et al., 2005). It has long been understood that stimulation of the adrenergic pathways will influence heart functioning and cardiovascular dynamics, with an activated "flight-or-fight" response stimulating the heart muscles and raising blood pressure. Cardiovascular therapies have therefore included the use of ß-blocker and other adrenergic agonists to control the influence of additional stress when heart function is impaired. Investigations are underway to understand what influence activation of other neurological pathways, such as the dopaminergic and serotonergic pathways, might have on tumor growth and metastasis, on glucose metabolism, and other disease precursors. Specialists in behavioral medicine can contribute to a richer understanding of how psychopharmacological treatments may be needed to accompany traditional treatments for non-neurological disease, either to improve the action of the original treatment or to prevent undesirable side effects (e.g., so-called chemo brain for cancer patients on chemotherapy).

Another contribution from behavioral medicine in the area of neurological functioning is to help explicate the nuanced links between genetic predisposition and health behaviors (Willcutt, Pennington, et al., 2010). As an example, individual genetic differences have been detected in gustatory preferences, metabolic processes, structural bone morphologies, and in other aspects of basic physiology that may predispose some patients to a higher risk for obesity. In a new era of genomic medicine, behavioral practitioners can work with patients to tailor a regimen of food consumption and exercise to mesh with these inherited nutrigenomic tendencies (Kenny, 2011). Likewise, specialists in behavioral aspects of addiction can work to ensure that fundamental improvements in psychopharmacologic treatments are translated into lasting, and personalized, behavior change (Maze & Nestler, 2011).

A Cautionary Note

The report from the Institute of the Future included a cautionary note about the rise of a neurocentric view of health. The field must strive to build on its momentum and expand on its knowledge base; but at the same time, it must strive to avoid the seduction of premature prediction or overselling. Fortunately, the neuropsychologists and psychiatrists operating in the field of behavioral medicine have long understood the dangers of "over-medicalizing" certain behavioral conditions, such as shyness, while taking full advantage of the therapeutic advantages of psychopharmacologic agents for more serious mental health conditions, such as bipolar depression or schizophrenia. Psychophysiological researchers within behavioral medicine have been able to make painstaking leaps forward in going beyond general stress models to identify the specific neural pathways underlying the influence of neural processes on disease. Researchers and practitioners specializing in the aging processes understand fully the risk factors that have already been documented for organic brain dysfunctions and are cautious in prescribing preventions that do not have at least some evidentiary basis.

Personal Health Forecasts

The Trend

As data are generated from multiple quarters to accelerate understanding of biomedical processes, and more sophisticated models are derived to deal with the high dimensionality of those data, the healthcare sector will begin to benefit more routinely from the algorithms biostatisticians create to predict health outcomes. Gradually, the benefit of these actuarial forecasts will begin to enter into the decision support processes used by clinical teams. New data will inform the predictive value of parameters within those models, and new visualization techniques will be constructed to steer decision-making around informative "what if" scenarios. The result will be a set of data-based predictive forecasting techniques that can be used universally to minimize future risk and maximize life goals.

Biotechnology firms are focusing much of their fundamental research and development programs around creating techniques for forecasting future biologic events based on an assessment of personal history and molecular processes. Innovations in the assessment of genomic predispositions, improvements in the ability to predict cellular dysfunction early based on biomarkers in the blood, and the ability to update forecasts based on incoming data from routine medical encounters should all help in making the kinds of early warning health decisions that will help avoid serious illness and extend life (Collins, 2010b). For many, this is the essence of personalized medicine: to create a highly personalized health forecast that will serve to guide health decisions for patients and their care teams over the course of their lives.

As medicine moves more toward preventive strategies, these personalized forecasts should help guide a patient's basic preemptive health choices throughout their life spans. A recorded prevention plan, for example, could trigger individually tailored recommendations for precautionary screenings updated to reflect best evidence for efficacy within risk groups. The plan could offer personalized recommendations for diet and exercise, based on best evidence for how genetic predisposition may influence individual metabolism, and it can offer recommendations for chemoprevention when changes in diet are insufficient. The difference will be to move the decision points earlier in life when a patient can do more with their health decisions, than later in life when repair is more difficult.

The perennial difficulty faced by medical preventionists is in figuring out how to make the consequences of early life decisions apparent to individuals early. Some cutting-edge computer laboratories are tackling this problem by using graphical imaging techniques to illustrate what the consequences of early health choices might be later in life. Using avatars, or three-dimensional representations of persons, these researchers can illustrate what may happen when overexposure to the sun ages skin prematurely or raises the risk for melanoma. The effects of caloric intake and sedentary life style can be modeled on the avatar by showing what a trend toward obesity might look like over a decade or two of unmodified weight gain. Early reports suggest that these types of very engaging illustrations might do a lot in reorienting individuals to think about their future selves and not just focus on present desires.

Implications for Behavioral Medicine

Motivational psychologists have long understood the role that short-term and long-term goals may play in guiding behavior change (Chan & Cameron, 2011). Weight watchers, a dieting strategy cited by researchers as being one of the most effective plans for helping individuals to maintain weight goals, focuses its members on (a) setting goals for ideal weight, (b) sharing those goals with supportive others, and then (c) monitoring nutritional intake en route to achieving those goals often (though not necessarily) in an open, social, manner (Dansinger, Gleason, et al., 2005). Sports psychologists focus heavily on goals as well, helping athletes orient practice toward specific visualizations of desired performance goals and then setting short-term, proximal, goals to achieve the longer-term objective (Maxwell, Hilden, et al., 2011).

The problem with many health behaviors, though, is that communications have been offered at a very broad, diffuse level. People may generally know that it is important to “stay healthy,” without having a clear concept of what they can do in their lives to reduce their own personal risks (Cameron & Leventhal, 2003; Cameron, Marteau, et al., 2011). Personal health forecasting may help in this regard. By offering tailored feedback on how to cope with personalized risk – as has been done with patients experiencing abnormally high levels of hyperlipidemia – it may be possible to offer a more compelling strategy psychologically for organizing behaviors to help stay healthy. Greater specificity in statistical modeling may help physicians and their patients reach superior decisions for alternative treatments when illnesses do occur. Patients can look at alternative “what if” scenarios for their decisions and then can watch how comparative risks may rise or fall when compared to similarly situated patients.

Simulations might even help at a community or organizational level. By modeling the consequences of passing or not passing a smoke-free business law, public health advocates may be able to inform the debate based on data-driven hypotheses rather than loose or hyperbolic conjectures. Resource allocators could use simulation tools to model the long-term benefits of investing in certain types of preventive interventions. Localized forecasts for the health of communities might help stimulate civic and personal action much in the same way that personal forecasts might stimulate goal-driven personal health behaviors.

An understanding of how personalized risk profiles influence behavior from the perspective of behavioral medicine is largely incomplete at this stage, however. In a 2009 article in the journal of Health Psychology, Smerecnik and colleagues found that respondents who were unaware of a genetic predisposition to salt sensitivity, and who were then exposed to a news story about such a predisposition, were less likely to endorse engagement in preventive behavior (i.e., reduce their salt intake) than those who were already aware that such a genetic predisposition existed. For these respondents, the news story seemed to convey a false sense of safety (I don’t think I’m genetically predisposed, so I must be safe) – at least under the conditions of the airport intercept study. The authors concluded that “we are in dire need of more empirical research on this matter before informing the general public about the existence of genetic risk factors" (Smerecnik, Mesters, et al., 2009).

The problem is that with such rapidly escalating progress in biotechnology it is not feasible to wait "until more empirical research" is conducted on the matter before exposing the public to genetic risk factors. Access to personal genetic information from direct-to-consumer genomics companies is fully permissible in at least 23 states in the USA. The good news is that the release of personally relevant genomic data directly to individuals has not caused the uproar, misuse of services, or paralysis once anticipated. Many healthcare providers tend to treat that moment in which the patient arrives at the office with preordered genetic data as a teachable moment. Exposure to raw data on the Internet has created an opportunity for patients and providers to work together in deciphering the otherwise perplexing world of probabilities, rare occurrence, and comparative science (Hesse, Moser, & Rutten, 2010). Studies evaluating exposure of multiple risk messages from genetic tests to patients presented that education and counseling can typically remove the patina of confusion of those confronting the information for the first time (Kaphingst, McBride, et al., 2010).

What is needed, then, is a better understanding of how to shape these personal health forecasts to be optimally useful to individuals and communities striving to use the information to achieve health-related goals.

The Rise of the Therapeutic City

The Trend

In the world of public health, cities have long been centers of both crisis and innovation. John Snow's mapping of the 1854 cholera epidemic, tracked to contaminated well water in London, was a seminal example of public health in action to solve the problems of many people living in close proximity. Knowledge generated by that early public health investigation set the stage for better environmental planning both within the London cityscape and around the world. Throughout the industrial revolution, cities were constantly under siege from conditions of poor air quality, crowding, noise pollution, and the irresponsible dumping of toxic waste materials. Urban planners have spent the better part of the past century considering ways of minimizing the damaging effects of urban blight, while finding ways of improving community living. Innovations in mass transit, architecture, and protected green spaces have all helped to revitalize many spaces within urban settings.

New developments may move even further toward creating cities that are experiments in healthy living. Investments from national health agencies have helped create stellar research hospitals within cities. These academic medical centers will be large enough and have enough resources to put some of the best and most varied care resources in a region available within short proximity for city dwellers. Allied specialty care will generally not be too far away from these academic centers, with skilled primary care physicians and patient navigators serving to steer patients proactively toward the collection of closely located services as they are needed. Health system administrators can easily experiment with load-balancing techniques in urban environments to reduce the wait time for emergency and routine visits across facilities and teams of providers. Grants for translational research will give the academic centers incentives for pushing their knowledge out of the laboratory and into the community. In this way, other surrounding hospitals may begin to benefit from the infusion of funding into successful research institutions.

Apart from healthcare, urban planners are experimenting more broadly with new technological frameworks for enhancing services. Municipalities within the USA have been experimenting for a time with provisions for broad public access to wireless computer networks connectable through laptops and mobile devices. New, emerging, frameworks include support for GPS technologies to help citizens and visitors locate services on a digital map or through "augmented reality" (i.e., location-sensitive labels placed contiguous to a landmark when viewed through an "app" on a smart phone). Some utility companies are experimenting with "smart grid" frameworks in which consumers can monitor and control their energy consumption remotely, or they can preprogram household appliances to optimize efficiencies either singly or in concert with each other. All around the world, cities are pursuing aggressive plans to offer pervasive computing infrastructures in a bid to attract world-class businesses. Following its "U-City" (for ubiquitous computing) concept, the Korean municipality of Incheon-Songdo defines itself as an "information friendly, intelligent city where anyone can get information services through any device on any network at any time" (Leem & Kim, 2013).

Implications for Behavioral Medicine

Taken in concert, these trends for urban design should allow specialists in behavioral medicine to consider the new "therapeutic cities" as living laboratories for a new generation of more effective, preventive, and therapeutic interventions (Stokols, Grzywacz, et al., 2003). Being successful in this regard will mean working across disciplines and seeking to influence the design of real city environments for the betterment of the urban community (King, Stokols, et al., 2002). Environmental psychologists and socioecologists should be able to offer their perspective into the mix as city planners think through best ways of encouraging natural exercise through bike lanes, walking paths, and dedicated green spaces (Stokols, Grzywacz, et al., 2003). So, too, nutritionists and population analysts should be able to work directly with chambers of commerce and city planners to make healthy food options a proximal choice for all neighborhoods, effectively diminishing the deleterious influence of "food deserts" (Beaulac, Kristjansson, & Cummins, 2009; Shinkle, 2010). Tobacco control specialists have already had substantive influences in such cities as San Francisco and New York, where smoke-free laws are cleaning up the environment for nonsmokers and making it easier for ex-smokers to avoid relapse (Frieden, 2010).

As large, urban medical centers continue to attract funding for cutting-edge research, there will be a positive pressure to move fundamental discovery from the laboratory into practice (Westfall, Mold, & Fagnan, 2007). The medical centers will then become hubs of innovation as the barriers between the laboratory and the clinic become blurred. Likewise, the ability to connect sensors and devices to an urban infrastructure of smart, ubiquitous computing will allow accountable care organizations to extend innovative models for care delivery into homes and communities. Behavioral informaticians can contribute within this new environment by evaluating user needs and helping to design the channels, interfaces, and applications to extend the benefits of therapeutic care beyond the walls of the hospital (Ahern, Woods, et al., 2011). Undoubtedly, their goal will be to begin with a firm theoretical notion of how best to empower patients and their families. They can then work within a network of supportive care services, perhaps based around a coordinating "medical home" model, to be sure that there are no weak links in the seamless connections of support available from within the therapeutic community (Glasgow, Dickinson, et al., 2011).

Behavioral economists can fulfill a role as they consider the ways in which the environment influences everyday decision-making. In the days of industrial blight, that influence on behavior was often unhealthy or exploitative. In redesigning the therapeutic city, behavioral economists can offer specific design and policy recommendations centered on principles of improved support for everyday, healthy living. This means understanding:

(a) *incentives*, or what motivates city dwellers to connect and thrive in their environments
(b) *mental models* – that is, the cognitive maps brought with them to interpret the world around them
(c) *defaults,* in order to make healthy behavior – such as walks in the park or buying fresh

produce – the easy path to choose in thriving daily

(d) *feedback* mechanisms to provide individuals and communities the data they need to improve performance relative to explicit goals

(e) tolerances for *error*, thus making it easy within the therapeutic city to reschedule appointments or get back on the wagon after a relapse into unhealthy behaviors

(f) *structures for decision-making*, making the safety paths for reducing risk explicit and easy to follow (Thaler & Sunstein, 2009)

Conclusions

Fundamental scientific discovery is changing the milieu in which world health is produced from an approach that was anchored on industrial age, reactive principles to an approach that is *predictive*, *personalized*, *preemptive*, and *participatory*. Such a movement will be necessary to continue progress against the more serious chronic disease epidemics of the twenty-first century, from the seemingly irrevocable onslaught of the multiple diseases associated with the "obesity epidemic" to the debilitating effects of Alzheimer's disease and cancer in an aging world population. What's more, this movement is occurring not solely because of strategic investments from the biomedical research community, but as a result of converging forces outside of the world of medicine.

Unlike the era of public health advances at the beginning of the twentieth century or the era of miracle medicine in the second half of the twentieth century, this movement is both personal and global. Patients are flocking onto government and academic Web sites looking first hand for information on how to deal with the "vital decisions" of health for themselves and their families (Fox & Rainie, 2002). Virtual communities are springing up to self-regulate based on data, who are taking the matter of accelerating biomedical science into their own hands (Olsen, Saunders, & McGinnis, 2011). The 17-year travail from discovery to implementation is no longer considered tolerable at a broader social level (Topol, 2012). Patients are demanding to be given personal access to medical data so that they can be brought into the conversation about their own healthcare first hand (Walker, Leveille, et al., 2011). Confronted with this onslaught of demand, some bioethicists and biostatisticians are beginning to conclude that having access to personal data may not just be a patient's fanciful desire, but an inherent "civil right" in the information age.

In the context of these changes, specialists in behavioral medicine must increasingly assume the role of linking pin between fundamental scientific discovery and patient well-being. This is an important, albeit subtle, change in the context in which behavioral medicine must thrive in the next century. Behavioral researchers can no longer afford to be isolated in focusing on only one aspect of patient care, say on mental disorders or substance abuse and addiction. To be sure, those areas of practice will continue to be important within the next century, but professionals in behavioral medicine must also be brought into the transdisciplinary teams that will solve translational issues across the spectrum of care.

As fundamental discovery yields new knowledge, the systems we have for interpreting and implementing that knowledge will begin to break. Left unattended, the costs of administering inefficient care based on a diminishing understanding of evidentiary trends will consume an unsustainable proportion of countries' economies. Medical errors – the costs of an inefficient system stretched beyond capacity with new, and more invasive procedures – will continue to proliferate, eclipsing other epidemics in reach and societal impact. With behavioral scientists in collaboration, however, it might just be possible to bend the curve on the most challenging and consuming health issues of the next century.

Behavioral Medicine of the Future: From Disease to Health and Well Being, from the Individual to the Community and the Global, from Causes to Complexity

38

Edwin B. Fisher, Linda D. Cameron,
Alan J. Christensen, Ulrike Ehlert, Yan Guo,
Brian Oldenburg, and Frank J. Snoek

Behavioral medicine is a broad and diverse field. As illustrated by the chapters in this book, it's conceptual bases range from genetics to health policy. Its concerns include all areas of prevention, health, illness, injury prevention, treatment, and disease management as well as related issues such as quality of life and wellbeing. Its application and programs include those implemented with individuals in clinical settings, programs applied to families or through worksites and communities, and those intended for entire populations. The very diverse range of perspectives and approaches underpinning the field of behavioral medicine makes any comprehensive summary of the field very challenging and difficult. Indeed, a summary runs the risk of distorting that breadth and diversity.

Instead of attempting to summarize the previous chapters in this one, we shall discuss future directions for behavioral medicine and its many roles. We discuss these future directions according to three broad themes, (1) understanding the individual and the relationships between behavior and health, (2) the global spread of the field of behavioral medicine. Perhaps most important is (3) developments within the epistemology that undergirds behavioral medicine and how these developments will change our research, scholarship, and conceptualizations of behavior and behavioral medicine within the broader domains of health, health care and prevention. A recurrent

E. B. Fisher (ed.), *Principles and Concepts of Behavioral Medicine*,
https://doi.org/10.1007/978-0-387-93826-4_38

theme is behavioral medicine's breadth, diversity, and transdisciplinarity and how they will influence health, health care and prevention in the next decade and beyond. Reciprocally, we shall also examine ways in which developments in health will stimulate growth of behavioral medicine in the coming years.

Understanding the Individual and the Relationships Between Behavior and Health

1. *Interactionism and Complex Systems*. Those trained in behavioral science and medicine in the twentieth century learned to carry out research designed mostly to detect main effects, the drug that cures a disease regardless of differences among those taking it, or the intervention that brings about smoking cessation or weight loss without being limited by differences among users. Indeed, in the middle of the twentieth century, most investigations were limited by statistical computing capacity that could not easily extend beyond a two-way interaction. Recent decades, however, have seen the development of statistical methods accommodating integrated analyses of multiple influences, the availability of larger, population based data sets and, more recently, "big data." With these tools and growing concern for inequities among countries and among populations within them, attention has turned to studying the relations among influences on health and ways in which individual influences are contingent on their contexts.

   The main effect remains pleasing in its clarity. It is increasingly recognized, however, as an abstraction of an object of analysis but not as a complete, accurate, or representative portrayal of problems as they exist and need to be addressed.

   As the distinguished psychometrician and theorist, Jane Loevinger (Loevinger, 1948, 1976) noted in discussion following her receipt of an award from the American Psychological Association, "The world is not orthogonal." This simple observation, pointing to the ubiquity of interactions among influences is important for our understanding of health and the application of behavioral medicine. With the exception of relatively few problems, such as phenylketonuria, the *general model for health problems* needs to be the interactive influence of genes, epigenetics, environment, development, behavior, and psychology, along with social, cultural, economic and policy influences. This book has sought to reflect this breadth of influence, although the very structure of a book of individual chapters may fail still to capture the importance of the interactions among the many topics the chapters have covered. Clearly, however, the reader works in an environment that is increasingly cognizant of these interactions.

   That health – and healthcare – rest upon such a wide variety of interactive determinants provides opportunity for behavioral medicine based on it's broad conceptual perspectives and accomplishments addressing a variety of influences. Indeed, with its broad perspectives and accomplishments, behavioral medicine has already led in examination of the fundamentally interactive and dynamic processes shaping health and health care. With increasing opportunities afforded by advances in statistical and empirical methods, behavioral medicine is poised to accelerate our understanding of these dynamics.

2. *Broadening "Personalized Medicine" to "Personalized Care."* Recent years have seen exciting developments in genomics and in its application to medical treatment such as in tailoring medications according to individual genotypes rather than what now appear to be relatively superficial symptoms and clinical patterns. This "Personalized Medicine" is an important and exciting development. But the emphasis on personalization is not limited to biological markers or clinical interventions. Growing knowledge of behavioral influences across the lifespan as well as the broad range of influences on behavior and health leads to tailoring also of behavioral, social, community, communications, and even policy inter-

ventions according to the nuances of those groups or settings to which they are applied.

In this context we will also see a significant increase in precision of the measurement of cognitions, emotions and behavior, such as by ecological momentary assessment (EMA) using mobile phone technology and "sensors" or fit applications. More precise measurement will help to tailor psychological and behavioral interventions to individual needs and circumstances.

The availability of digital technologies and wearable devices that facilitate individuals' monitoring their own behavior and health indicators is bringing about a "quantified me" that also leads to greater emancipation and participation of patients in their own care and decisions regarding it. Experiential learning, patient-generated data, and patient preferences will be the basis for shared decision making as the norm for medical consultation and care.

3. *Lifespan Approach*. Understanding of early development has also increased greatly in recent years. This includes epigenetic studies of the influence of the prenatal environment and early childhood, influences through which individuals may become psychologically as well as biologically programmed toward health or illness. This research has greatly increased our understanding of the development of our bodies, our psychology, and our lives. At the same time, research has articulated the evolution of adult lives and aging. Clearly, behavior and health change and continue to change throughout the lifespan, posing important challenges for interventions as well as policies. Behavioral medicine will become more nuanced as it addresses not only differences among people and their settings but differences within and throughout lives as well.
4. With the aging of populations and the epidemiologic transition (discussed below) in which disability-adjusted life years are increasing, this incorporation of a lifespan approach will pay increasing attention to aging, palliative care, and care towards the end of life (e.g., Masters et al. *infra*).
5. *Positive and Protective Factors: Adaptation and Resilience*. With more attention to the breadth of individuals' concerns and interests, not just their disease states, will also come more attention to positive and protective factors, adaptation, coping, and resilience. This emphasis will also be encouraged by a lifespan perspective that incorporates the inevitability of disease and illness, complementing prevention with attention to how individuals cope with the health problems they do not prevent. Beyond coping, increasing emphasis will be placed not on reducing or "managing" illness so much as on "flourishing" and leading good, satisfying lives with the health problems that individuals do face.

Dissemination and Spread of Behavioral Medicine

1. *Population Health.* Across the globe, there is great and growing concern for population health. Disparities and inequities contribute to this concern. So, too, does the size of health care systems and health care budgets amidst countries' economies. To be affordable, health care will have to become more efficient and more focused on ways of improving and investing in health at a societal level relative to the availability of funding. Responding to these concerns requires that planning consider the distribution of prevention, health care, and health status across populations and the identification of where improvements can be made. Leaving choices of health care to the services that provider groups choose to offer and to individuals' decisions to access them has been shown to lead to care that fails to reach all it should and to unnecessary and ineffective care that many resource-constrained nations cannot afford.
2. *Scalability and Dissemination*. If they are to reach populations, behavioral medicine interventions need to be conceptualized, planned, developed and evaluated in terms of their potential to be "scaled up" and to reach large numbers of those they may benefit. This

includes interventions delivered to individuals that are sufficiently efficient to be affordably implemented with large numbers. Within the health care system, interventions that are feasible within primary care may reach the large proportions of populations that visit a primary care provider at least yearly. Reaching populations also includes approaches that may be integrated within existing, low-cost channels so that unit cost is minimal, such as through web-based or mass media approaches. Who provides health care and prevention may also expand as in the growing global utilization of peers support provided by community health workers, *Promotores de salud,* and others (Buttorff, Hock, et al., 2012; Fisher, Ballesteros, et al., 2015; Perry, Zulliger, & Rogers, 2014; Rahman, Malik, et al., 2008) (See Fisher et al. chapter on Peer Support, *infra*.) Community approaches and policy approaches may reach whole populations without any individual being the focus of intervention.

3. *Global Disparities***.** As much as life expectancy is increasing worldwide, nevertheless disparities remain a prominent feature of global health. These are the focus of important behavioral medicine activities such as in community health promotion and policy approaches to promoting disease prevention as well as access to and use of preventive services and chronic disease care. These programs have been shown to be effective as is evident in the chapters describing community health promotion approaches (Ramanadhan & Viswanath, *infra*), as well as approaches to obesity and cigarette smoking (Johnston et al., *infra*; Borland & Yong, *infra*). However, sustaining these programs and their benefits is a challenge that requires policies that will fund and support them, still lacking in many health systems.

   In New Zealand and the US, anticipated impacts on health disparities are being considered in research funding decisions. For example, ethical issues have been raised concerning allocation of government research funds to study expensive tests that are not covered by health care financing plans and, so, may serve to increase disparities rather than reduce them. Increasing recognition of the costs associated with disparities and the ability of preventive and population approaches to reduce those costs should prompt more enlightened policies creating greater opportunities and demand for behavioral medicine in these areas.

4. *Differences and Variability Among Countries and Populations*. Although health is a global concern and fundamental behavioral and biological processes affect all humans, there is great differentiation of need, capacity, and challenges across countries. In addition to economic and system constraints, cultural and social differences have great impacts, especially on prevention and disease management initiatives that need to engage behavior in social and organizational contexts. Metformin may remain metformin and may act similarly wherever it is taken, but a family, group, or community initiative to prevent diabetes through dietary changes will be shaped by the families, groups, or communities through which it evolves. Merely packaging and shipping medicines to those who need them serves very poorly as a model for disseminating *behavioral* medicine. (Indeed, the behaviors needed to obtain a prescription, recognize its value, fill the prescription, and adhere to the instructions for its use will all vary according to cultural and social dynamics. Consequently, simply "packaging and shipping medicines to those who need them" is a poor model even for dissemination of medicines.) Future dissemination research and practice will succeed by considering and finding ways to address how "knowledge management" needs to be a creative, organic synthesis of innovations as well as the characteristics, needs, and strengths of the groups and settings in which they are to be implemented.
5. *Epidemiologic Transition*. The global burden of disease is inexorablly moving from acute disease to chronic disease. Along with this, the more important outcome of health care is moving from mortality to years of life lived with disability, YLD. Life expectancy is increasing worldwide. As much as this is a good thing, it also has the effect of providing people more years in which to develop chronic diseases. With those chronic diseases, especially mental health, substance-use, musculoskeletal, and

neurological disorders, diabetes, and hearing and vision loss come disabilities and complications with which people may live for many years. Thus, total YLDs are increasing as lifespan is increasing (GBD 2013 Dalys, Hale Collaborators, et al. 2015). This creates many needs and opportunities for behavioral medicine interventions to improve management and coping with chronic disease, as well as community and policy interventions to support living well with chronic diseases and including "Health in All Policies." As the authors of a key paper on these issues have noted:

> We believe that the historical focus of health research funding on causes of YLLs [years of life lost/mortality] was probably appropriate. However, health progress now means that more research investment is needed for the disorders that debilitate, rather than kill. With each passing year, the shift towards YLDs as the leading causes of disease burden will be more evident. Action is needed now to develop preventive, curative, and ameliorative strategies for these conditions rather than waiting until this shift is even more obvious. (GBD 2013 Dalys, Hale Collaborators, et al., 2015, p. 2182)

6. *National and International Policies that Influence Behavior and Health Behavior such as "Health in All Policies."* As discussed in several chapters in this book (especially Sherlaw et al. and Siddiqi et al. *infra*), policies in diverse areas including housing, transportation, education, labor and welfare are all important determinants of health, well-being and quality of life. Clearly, the understanding and practice of behavioral medicine is important for all of these. Although international policies and agreements such as the United Nations *Sustainable Development Goals: 17 Goals to Transform our World* (United Nations, 2015) promise improvements that can significantly benefit health globally, their endorsement and implementation are usually sporadic and modest.
7. *New Problems that Affect Life and Health.* Health in All policies expands our understanding of the ways in which health, illness, and quality-of-life are influenced by a variety of factors we may sometimes view as unrelated to health and healthcare. Clearly, global warming, water quality, violence (including gun violence, violence toward women, and violence toward stigmatized groups), inadequate housing, and a variety of other factors affect health either directly or indirectly such as in the influence of domestic violence and violence against women on the spread of HIV and care of HIV/AIDS (Maman, Mbwambo, et al., 2002).

The Zika virus illustrated the confluence of nature-driven and culture-driven phenomena through which new diseases, epidemics, and other problems emerge. In addition to the Zika virus posing unprecedented risks to the fetuses of pregnant women, natural evolutionary processes are leading to "superbugs," and cultural movements in some regions are promoting anti-vaccination beliefs that, in turn, are lowering vaccination rates. Because of its foundation in behavioral science, behavioral medicine includes approaches that can address these issues ranging from individual or family interventions for reducing violence to broad policy, community, and communications initiatives to raise awareness of problems and promote approaches to reducing them.

An interesting dialectic emerges in the interplay between influences that are conventionally seen as part of health and health care, and those that are conventionally seen as separate from them. On the one hand, we may promote behavioral and public health perspectives for considering challenges often not seen as in the realm of public health. In the U.S., for example, advocates for greater regulation of access to guns cite policies mandating automobile seat belts that have greatly reduced the incidence of closed head injuries and fatalities. In the other direction, behavioral medicine and public health may benefit by importing policy and conceptual approaches from areas that are considered unrelated to health. Consumer economics has been translated through behavioral economics to be applied to health in a number of areas. Additionally, models such as those from successful educational or labor policies may be applied to enabling groups and individuals to develop patterns of living that prevent disease and enhance quality of life.

General Themes, How We Study Behavior and Health, *Weltanschauungen*

1. *From Bench and Clinic to Community*. The recognition of diverse influences on health and well-being will continue to drive attention to interventions outside of individual biology and the clinical setting, engaging the families, neighborhoods, and communities in which people live. "Citizen Science" approaches to health behavior research are important models for such growth and expansion of what we mean by health, prevention and care, and knowledge of these (King, Hekler, et al., 2016). Evaluation of these kinds of interventions will pay more attention to lives as they are lived in their diverse contexts, not limited to markers of clinical status or illness.
2. *Big Data*. It is now possible to predict flu outbreaks by monitoring Google queries about symptoms. The applications of big data however reach far beyond epidemiology. Consider, for example, how analyses of millions of individuals' emails over a number of years might identify patterns indicative of risk for dementia. As Google queries may project flu outbreaks better then reports of cases from primary care, might these kinds of analyses of massive amounts of data across large numbers of individuals lead to better indicators of risk and disease progression then clinical markers?

   With big data comes also sharing of data among those who provide it. As discussed in the chapter by Ramanadhan & Viswanath (*infra*) how might big data analyses of community trends encourage greater cooperation and effective action within communities to address challenges they face? Parallel to the empowering influence of individually generated data and the "quantified me," above, how might community generated data empower communities?
3. *Analyzing Complexity***.** Interestingly, genetics may provide helpful models for understanding the non-orthogonal complexity of multiple determinants of behavior. Genetics too entails impacts that are complexly dependent on multiple interacting influences. Figure 38.1, for example, portrays genetic 'signatures' with poor and good prognosis for survival of breast cancer (van

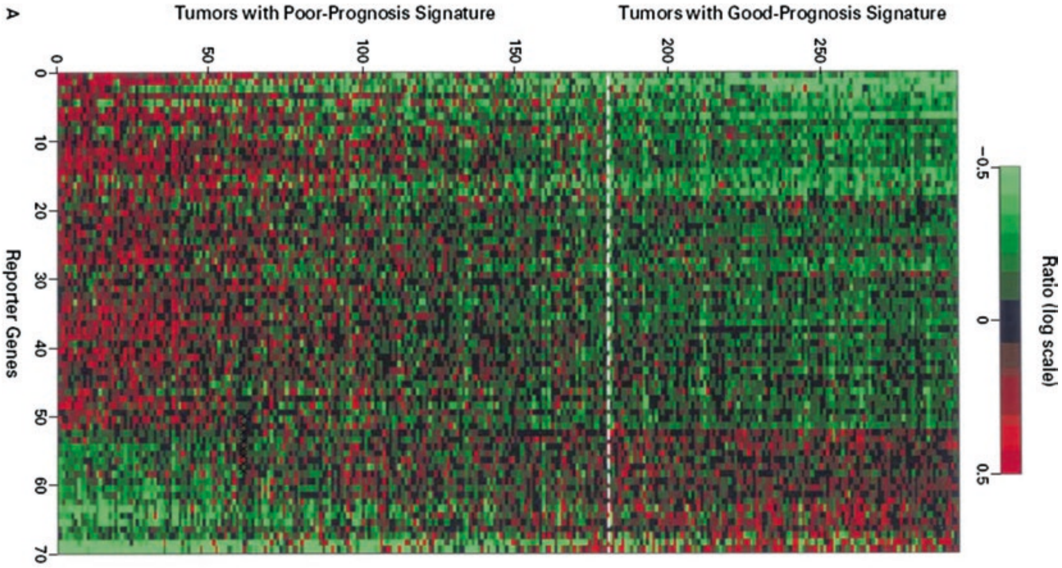

Fig. 38.1 Gene arrays among women with poor or good prognosis signatures for subsequent metastasis following incident breast cancer (van de Vijver 2002)

de Vijver, 2002). It is clear that no element of either signature is necessary or sufficient for survival or death. Rather, complex arrays of elements alter the probability of survival. Similarly, current research on the role of gut microbiota in obesity and diabetes examines interactions among genetics, diet, and the "community structure" of "microbial communities," again examining complex, multivariate influences on and among members of those communities (Ussar, Griffin, et al., 2015). Such analyses from highly respected areas of life sciences may provide useful models for examining the complex, interacting influences – no one necessary, no one sufficient – that surround behavior, health, and disease. Similar to gene arrays' associations with varying likelihood of disease, complex arrays of elements and features of communities and the settings of individuals' lives alter the likelihood of healthy or unhealthy behaviors. Studying those elements in their complexity, instead of trying to isolate them by randomization, may be a valuable strategy. Agent based modeling approaches (Maglio & Mabry, 2011), for example may be an approach for studying not only interactions among varied entities within a system but also the effects of those interactions on the system as a whole.

4. *Ethics and Values*. Recognition of the diversity of influences on our lives changes our understanding of the role of the individual. Autonomy and individual choice are no longer natural givens for which individuals are responsible, but become objectives to be enhanced through humane policies and practices. The community and its policies become responsible for enabling individuals to lead good lives and to make healthy choices in those lives. Indeed, research shows that individualism and collectivism are not opposite ends of a spectrum but tend to be positively correlated (Coon & Kemmelmeier, 2001).

   There can arise a tension among the values that might be used to guide health care and prevention. Should these be the assumed aspirations of people? Should they reflect the goals of the individual? Collectivistic values such as familism might be more recognized and valued for their strengths and potential benefits, as well as promoted in health behavior research and interventions.

   Individualism often entails an assumption that the government and community can "stay out of our lives." However, the fundamental research and conceptual perspectives on which behavioral medicine is based (see Rachlin et al., *infra*) makes clear that the community cannot merely be neutral, leaving things to the individual. Whether by what it does or by what it fails to do, the community *will* influence the lives of those within it. Morality is then not leaving people alone to make their own choices, but enabling their having choices and being able to pursue them. The cornerstone of ethics becomes choice, the availability of alternatives and the opportunities and means to pursue them.[1]

5. *The Place of Behavior and Quality of Life***.** A general model that has characterized much of behavioral medicine and public health has construed behavior as an input that influences disease and illness which, in turn, influence quality of life.

$$\text{Behavior} \rightarrow \text{Disease} \rightarrow \text{Quality of Life}$$

However, the change in focus from avoiding acute disease to living well amidst periodic and chronic disease brings greater attention then toward behavior and quality of life as the outcomes of greatest concern, with diseases as important determinants of them. Instead of preventing or minimizing disease and assuming that quality of life will then be

---

[1] This emphasis on choice and the availability of choices as a central criterion in judging the ethical quality of interventions was suggested to EF as a student by Leonard Krasner around 1970. At the time, Krasner was a central figure in controversy about the ethical qualities of behavioral control and behavioral influence in behavior modification and behavior therapy.

automatically achieved, we will see greater focus on approaches that seek directly to enhance quality of life. After all, if longer lives lead to more years in which health problems may occur (GBD 2013 Dalys, Hale Collaborators, et al., 2015), the challenge is not so much avoiding all disease, but promoting productive, satisfying and relatively healthy lives amidst the likelihood of some disease as lives go forward. Avoiding or minimizing risk and managing disease and disability surely have a place in this, but rather than being the primary outcomes with benefits in quality of life assumed, they are objectives among others which, in their aggregate, may promote good lives. Healthy diet, physical activity, supportive social relationships, strong families and social networks, work that provides a sense of purpose as well as income, and communities and policies that support all of these improve our lives directly while also reducing the intrusions of disease in those lives.

Table 38.1 Transitions in *Weltanschauungen,* world views

Illness as micro, discreet, individual	Health as macro, complex, behavioral, social
Illness – Focus on clinical indicators and outcomes	Patterns of living – Focus on behaviors and quality of life
Micro effects	Molar effects and patterns
Key relationship: Doctor/ Provider-Patient	Key relationship: Community-people
Technical Challenges	Adaptive challenges
Data on individual events, e.g., Blood pressure, disease stage	Mass data • Many events within individuals over time • Many events across many individuals
Individual as isolated locus of disease and change	Individuals as social, situated; "It takes a village"
Greatest scientific status accorded main effects, dominant effects of individual agents	Greatest scientific status accorded illumination of complexity, interactions among influences; "The world is not orthogonal"
Energy from the individual	Energy emerges from the community

6. *Weltanschauungen.* The aggregate of these trends may be summarized as a change in *Weltanschauung,* in the view of the world from health as micro, discrete, and individualistic to health as macro, complex, behavioral and social. Some features of such a change in world view are outlined in Table 38.1 (Fisher, 2016). To explain a few of these, the model on the left sees illness as a micro, discreet event at the level of the individual. In contrast, the model on the right sees health as a macro, complex and social set of events. Accordingly, the two models go from illness and the focus on clinical indicators to patterns of living in the focus on quality of life in a community or population. In community and people-powered movements to enhance health (as championed by the Nesta Health Lab in London, Khan, 2016), we go from data on individual events like a blood pressure reading to mass data – either a mass of data points across an individual's experience or across many individuals. We go from looking at the individual as the site of disease and as the locus of change to the individual as socially situated; as in Hillary Clinton's book title, "It takes a village." In going from micro to molar effects, we are not so interested in what the individual with diabetes eats today but in what she or he eats over 30 or 40 years of living with diabetes. Instead of looking for a unique and dominant effect of a single intervention, we recognize that interactions among influences are the rule and seek to understand the complexity of those interactions. From a statistical perspective and as Loevinger noted, the world is not orthogonal. Finally, we go from seeing motivation and energy as based in the individual to seeing energy as emergent among individuals and from communities. More generally, instead of putting responsibility – and too often blame – on the individual to guide her or his own health, we seek to under-

stand how communities enable individuals to lead healthy lives and look for ways to help communities do that better.
