adults in migration	4	adult migration loss fraction	25%

that spawn in the Tucannon River. The river rises in the Blue Mountains of Oregon and flows 50 miles toward the Snake River in Eastern Washington. It is estimated that the river originally supported runs of 20 thousand adults. But the number of returning adults has declined substantially due to many changes in the past sixty years. These changes include agricultural development in the Tucannon watershed, hydro-electric development on the Snake and Columbia, and harvesting in the ocean.

Each of the stocks in Fig. 5 correspond to a different phase in the salmon life cycle (see Table 1), with a total life-cycle of 48 months. The parameters represent predevelopment conditions, the conditions prior to agricultural development in the Tucannon watershed and hydro-electric development on the Snake and Columbia. Each of these parameters is fixed regardless of the size of the salmon populations. One of the most important variables is the "juvenile loss fraction depends on density." It can be as low as 50% when there are only a few emergent fry each spring. With higher densities, however, juvenile survival becomes more difficult due to crowding in the cool and safe portions of the river.

Figure 6 shows the model results over a 480 month period with the population parameters in Table 1. The simulation begins with a small number to see if the population will grow to the 20 thousand adults that were thought to have returned to the river in earlier times. The time graph shows a rapid rise to around 20 thousand adults within the first 120 months of the simulation. The remainder of the simulation tests the population response to variability in environmental conditions, as represented by random variations in the smolt migration loss fraction. (This loss tends to be high in years with low runoff and low in years with high runoff.) Figure 6 confirms that the model simulates the major swings in returning adults due to environmental variability. The runs can vary from a low of ten thousand to a high of thirty thousand.

 Stella diagram of the model of the salmon life cycle

System Dynamics Models of Environment, Energy and Climate Change, Figure 6  
 Test of the salmon model with random variations in the smolt migration losses

System Dynamics Models of Environment, Energy and Climate Change, Figure 7  
Key feedback loops in the salmon model

System dynamics models are especially useful when they help us to understand the key feedbacks in the system. Positive feedback loops are essential to our understanding of rapid, exponential growth; negative feedbacks are essential to our understanding of the controllability of the system. Causal loop diagrams are often used to depict the feedback loops at work in the simulated system. Figure 7 shows an example by emphasizing the most important feedback loops in the salmon model.

Most readers will immediately recognize the importance of the outer loop which is highlighted by bold arrows in the diagram. Starting near the top, imagine that there are more spawning adults and more eggs in redds. We would then expect to see more emergent fry, more juveniles, more smolts in migration, more salmon in the ocean, more adults entering the Columbia, and a subsequent increase in the number of spawning adults. This is the positive feedback loop that gives the salmon population the opportunity to grow rapidly under favorable conditions.

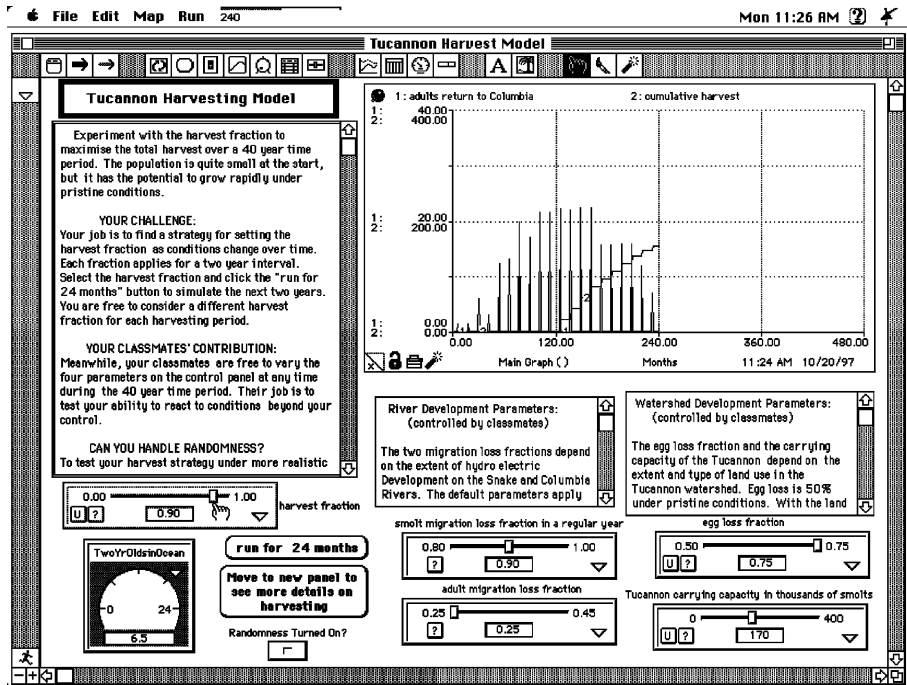

An equally important feedback works its way around the inner loop in the diagram. If we begin at the top with more spawners, we would expect to see more eggs, more fry and a greater juvenile loss fraction as the fry compete for space in the river. With a higher loss fraction, we expect to see fewer juveniles survive to be smolts, fewer smolts in migration, and fewer adults in the ocean. This means

we would see fewer returning adults and less egg deposition. This “density dependent feedback” becomes increasingly strong with larger populations, and it turns out to be crucial to the eventual size of the population. Simulating density dependent feedback is also essential to our understanding of the recovery potential of the salmon population. Suppose, for example, that the salmon experience high losses during the adult migration. This will mean that fewer adults reach the spawning grounds. There will be less egg deposition and fewer emergent fry in the following spring. The new cohort of juveniles will then experience more favorable conditions, and a larger fraction will survive the juvenile stage and migrate to the ocean. The density dependent feedback is crucial to the population’s ability to withstand shocks from external conditions.<sup>2</sup>

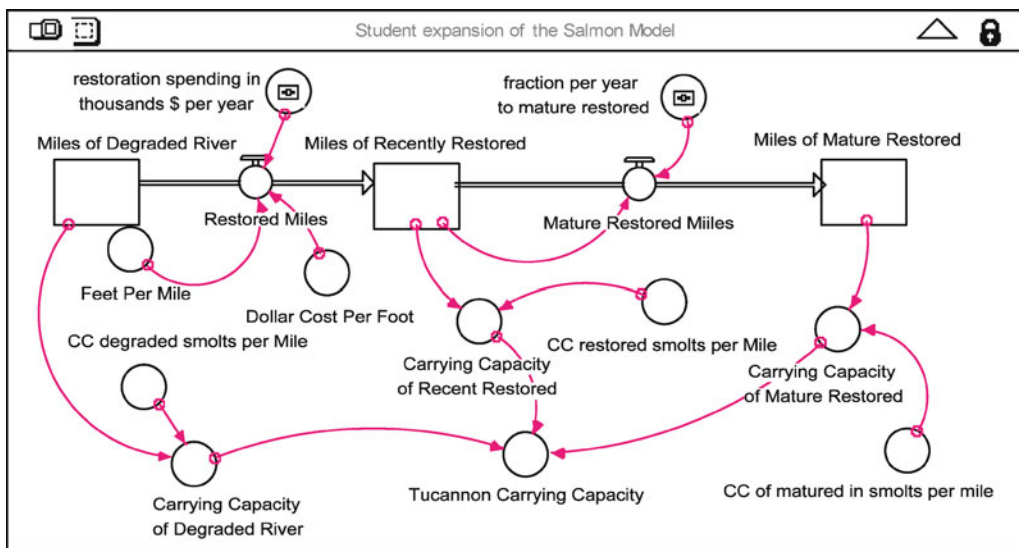

Figure 8 shows a version of the model to encourage student experimentation with harvesting policies. The information fields instruct the students to work in groups of three with one student playing the role of “the harvest manager”. The harvest manager’s goal is to achieve a large, sustainable harvest through control of the harvest fraction. The other students are given control of the parameters that describe conditions on the Snake and Columbia and in the Tucannon watershed. These students are encouraged to make major and unpredictable changes to test the instincts of the harvest manager.

Models designed for highly interactive simulations of this kind are sometimes called “management flight simulators” because they serve the same function as actual flight simulators. With a pilot simulator, the trainee takes the controls of an electro-mechanical model and tests his instincts for managing the simulated airplane under difficult conditions. The Tucannon harvesting model provides a similar opportunity for environmental students. They can learn the challenge of managing open access fisheries that are vulnerable to over harvesting and the tragedy of the commons [12]. In this particular exercise, students learn that they can achieve a sustainable harvest under a wide variety of difficult and unpredictable conditions. The key to sustainability is harvest manager’s freedom to change the harvest fraction in response to recent trends in number of returning adults. This is an important finding for fishery management because it reveals that the population dynamics are not the main obstacle to sustainability. Rather, unsustainable harvesting is more likely to occur

<sup>2</sup>The shocks could take the form of changes in ocean mortalities, changes in harvesting and changes in the migration mortalities. These shocks are external to the boundary of this model, so one is reminded of Coyle’s definition of system dynamics. That is, the model helps us understand how the salmon population could withstand the shocks which fall upon it from the out-side world.

System Dynamics Models of Environment, Energy and Climate Change, Figure 8  
 Salmon harvesting model to encourage student experimentation

System Dynamics Models of Environment, Energy and Climate Change, Figure 9  
 Student addition to simulate river restoration

when the managers find it difficult to change the harvest fraction in response to recent trends. This is the fundamental challenge of an open-access fishery.

The salmon model is a system dynamics version of the type of modeling commonly performed by popula-

tion biologists. System dynamics adds clarity and ease of experimentation compared to these models. It also provides a launching point for model expansions that can go beyond population biology. Figure 9 shows an example. This is a student expansion to change the carrying capac-

ity from a user input to a variable that responds to the user's river restoration strategy. The student was trained in geomorphology and was an expert on restoring degraded rivers in the west. The Tucannon began the simulation with 25 miles of river in degraded condition and the remaining 25 miles in a mature, fully restored river with a much higher carrying capacity. The new model permits one to experiment with the timing of river restoration spending and to learn the impact on the management of the salmon fishery.

The student's model provides another example of interdisciplinary modeling that aids our understanding of environmental systems. In this particular case, the modeling of river restoration is normally the domain of the geomorphologist. The model of the salmon population is the domain of the population biologist. Their work is often conducted separately, and their models are seldom connected. This is unfortunate as the experts working in their separate domains miss out on the insights that arise when two perspectives are combined within a single model. In the student's case, surprising insights emerged when the combined model was used to study the economic value of the harvesting that could be sustained in the decades following the restoration of the river. To the student's surprise, the new harvesting could "pay back" the entire cost of the river restoration in less than a decade.

### Models of Climate Change

Scientists use a variety of models to keep track of the greenhouse gasses and their impact on the climate. Some of the models combine simulations of the atmosphere, soils, biomass and ocean response to anthropogenic emissions. The more developed models include CO<sub>2</sub>, methane, nitrous oxides and other greenhouse gas (GHG) emissions and their changing concentrations in the atmosphere. Claussen [2] classifies climate models as simple, intermediate and comprehensive. The simple models are sometimes called "box models" since they represent the storage in the system by highly aggregated stocks. The parameters are usually selected to match the results from more complicated models. The simple models can be simulated faster on the computer, and the results are easier to interpret. This makes them valuable for sensitivity studies and in scenario analysis [13].

The comprehensive models are maintained by large research centers, such as the Hadley Center in the UK. The term "comprehensive" refers to the goal of capturing all the important processes and simulating them in a highly detailed manner. The models are sometimes called GCMs (general circulation models). They can be used to describe

circulation in the atmosphere or the ocean. Some simulate both the ocean and atmospheric circulation in a simultaneous, interacting fashion. They are said to be coupled general circulation models (CGCMs) and are considered to be the "most comprehensive" of the models available [2]. They are particularly useful when a high spatial resolution is required. However, a disadvantage of the CGCMs is that only a limited number of multi-decadal experiments can be performed even when using the most powerful computers.

Intermediate models help scientists bridge the gap between the simple and the comprehensive models. Claussen [2] describes eleven models of intermediate complexity. These models aim to "preserve the geographic integrity of the Earth system" while still providing the opportunity for multiple simulations to "explore the parameter space with some completeness. Thus, they are more suitable for assessing uncertainty". Figure 10 characterizes the different categories of models based on their relative emphasis on:

- number of processes (right axis)
- detailed treatment of the each process (left axis), and the
- extent of integration among the different processes (top axis).

Regardless of the methodology, climate modeling teams must make some judgments on where to concentrate their attention. No model can achieve maximum performance along all three dimensions. (Figure 10 uses the dashed lines

System Dynamics Models of Environment, Energy and Climate Change, Figure 10

Classification of climate models

to draw our attention to the impossible task of doing every thing within a single model.)

The comprehensive models strive to simulate as many processes as possible with a high degree of detail. This approach provides greater realism, but the models often fail to simulate the key feedback loops the link that atmospheric system with the terrestrial and oceanic systems. (An example is the feedback between CO<sub>2</sub> emissions, temperatures and the decomposition of soil carbon. If higher temperatures lead to accelerated decomposition, the soils could change from a net sink to a net source of carbon [15].) The simple models sacrifice detail and the number of processes in order to focus on the feedback effects between the processes. Using Claussen's terminology, one would say that such models aim for a high degree of "integration". However, the increased integration is achieved by limiting the number of processes and the degree of detail in representing each of the processes.

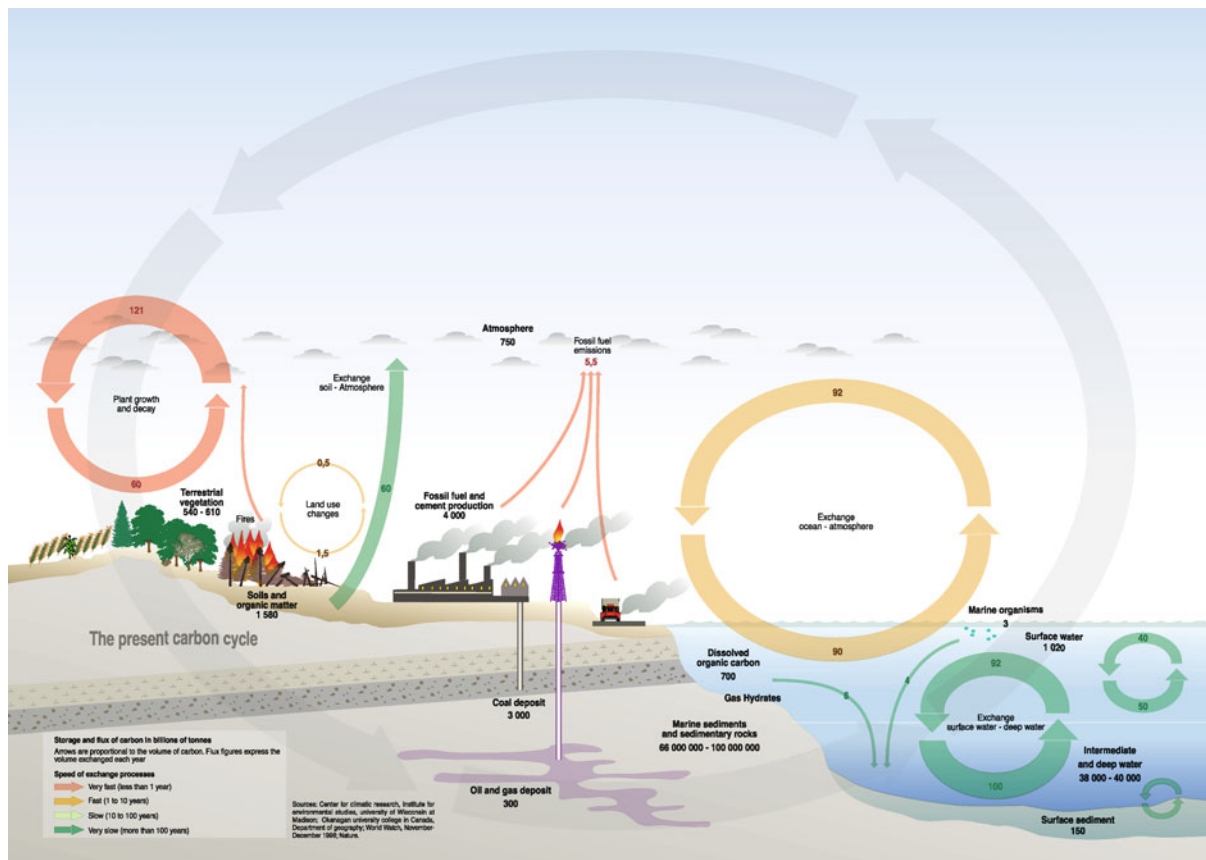

System dynamics has been used in a few applications to climate change. These applications fit in the category of

simple models whose goal is to provide a highly integrated representation of the system. Two examples are described here; both deal with the complexities of the global carbon cycle.

### System Dynamics Models of the Carbon Cycle

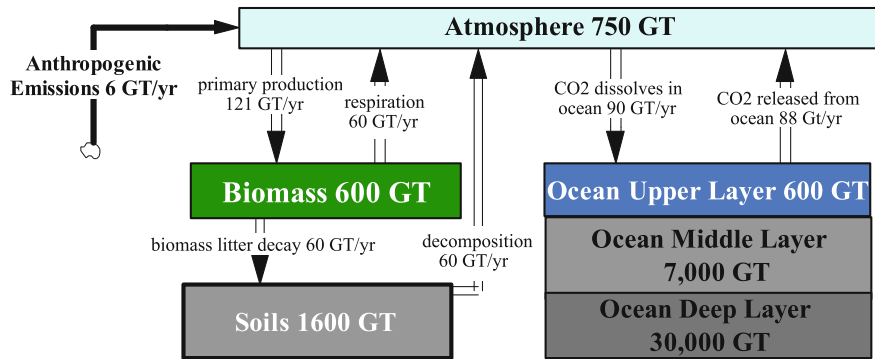

Figures 11 and 12 depict the global carbon cycle. Figure 11 shows the carbon flows in a visual manner. Figure 12 uses the Vensim stock and flow icons to summarize carbon storage and flux in the current system. The storage is measured in GT, gigatons of carbon, (where carbon is the C in CO<sub>2</sub>). The flows are in GT/year of carbon with values rounded off for clarity.

The left side of Fig. 12 shows the flows to the terrestrial system. The primary production removes 121 GT/yr from the atmosphere. This outflow exceeds the return flows by 1 GT/year. This imbalance suggests that around 1 GT of carbon is added to the stocks of biomass and soil each year. So the carbon stored in the terrestrial system would

System Dynamics Models of Environment, Energy and Climate Change, Figure 11

The global carbon cycle. (Source: United Nations Environmental Program (UNEP) <http://www.unep.org/>)

System Dynamics Models of Environment, Energy and Climate Change, Figure 12  
Diagram of the stocks and flows in the carbon cycle

grow over time (perhaps due to extensive reforestation of previously cleared land.) The right side of Fig. 12 shows the flows from the atmosphere to the ocean. The CO<sub>2</sub> dissolved in the ocean each year exceeds the annual release back to the atmosphere by 2 GT. The total, net-flow out of the atmosphere is 3 GT/year which means that natural processes are acting to negate approximately half of the current anthropogenic load.

As the use of fossil fuels grows over time, the anthropogenic load will increase. But scientists do not think that natural processes can continue to negate 50% of an ever increasing anthropogenic load. On the terrestrial side of the system, there are limits on the net flow associated with reforestation of previously cleared land. And there are limits to the carbon sequestration in plants and soils due to nitrogen constraints. On the ocean side of the system, the current absorption of 2 GT/year is already sufficiently high to disrupt the chemistry of the ocean's upper layer. Higher CO<sub>2</sub> can reduce the concentration of carbonate, the ocean's main buffering agent, thus affecting the ocean's ability to absorb CO<sub>2</sub> over long time periods.

Almost of the intermediate and comprehensive climate models may be used to estimate CO<sub>2</sub> accumulation in the atmosphere in the future. For this article, it is useful to draw on the mean estimate published in *Climatic Change* by Webster [23]. He used the climate model developed at the Massachusetts Institute of Technology, one of the eleven models of "intermediate complexity" in the review by Claussen [2]. The model began the simulation in the year 2000 with an atmospheric CO<sub>2</sub> concentration of 350 parts per million (ppm). (This concentration corresponds to around 750 GT of carbon in the atmosphere.) The mean projection assumed that anthropogenic emissions would grow to around 19 GT/year by 2100. The mean projection of atmospheric CO<sub>2</sub> was around 700 ppm

System Dynamics Models of Environment, Energy and Climate Change, Figure 13  
Simple model to understand accumulation of CO<sub>2</sub> in the atmosphere

by 2100. The amount of CO<sub>2</sub> in the atmosphere would be twice as high at the end of the century.

Figure 13 shows the simplest possible model to explain the doubling of atmospheric CO<sub>2</sub>. The stock accumulates the effect of three flows, each of which is specified by the user. Anthropogenic emissions are set to match Webster's assumption. They grow to 19 GT/year by the end of the century. Net removal to oceans is assumed to remain constant at 2 GT/year for the reasons given previously. Net removal to biomass and soils is then subject to experimentation to allow this simple model to match Webster's results. A close match is provided if the net removal increases from 1 to 2 GT/year during the first half of the century and then remains at 2 GT/year for the next fifty years. With these assumptions, the CO<sub>2</sub> in the atmosphere would double from 750 to 1500 GT during the century. This means that the atmospheric concentration would double from 350 to 700 ppm, the same result published by Webster [23].

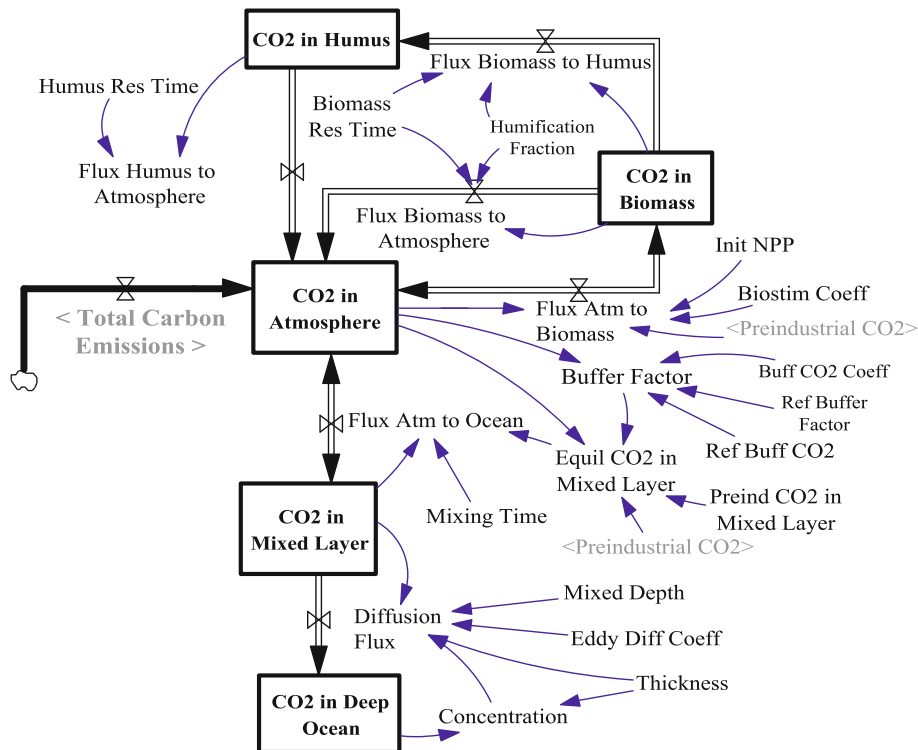

The model in Fig. 13 is no more than an accumulator. This is the simplest of possible models to add insight on the dynamics of CO<sub>2</sub> accumulation in the atmosphere. It includes a single stock and only three flows, with

all of the flows specified by the user. There are no feedback relationships which are normally at the core of system dynamics models. This extreme simplification is intended to make the point that simple models may provide perspective on the dynamics of a system. In this case, a simple accumulator can teach one about the sluggish response of atmospheric CO<sub>2</sub> in the wake of reductions in the anthropogenic emissions. As an example, suppose carbon policies were to succeed in cutting global emissions dramatically in the year 2050. By this year, emissions would have reached 10 GT/yr, so the supposed policy would reduce emissions to 5 GT/yr. What might then happen to CO<sub>2</sub> concentrations in the atmosphere for the remainder of the century? Experiments with highly educated adults [21] suggest that some subjects would answer this question with “pattern matching” reasoning. For example, if emissions are cut in half, it might make sense that CO<sub>2</sub> concentrations would be cut in half as well. But pattern matching leads one astray since the accumulation of CO<sub>2</sub> in the atmosphere responds to the total effect of the flows in Fig. 13. Were anthropogenic emissions to be reduced to 5 GT/year and net removals were to remain at 4 GT/year, the CO<sub>2</sub> concentration would continue to grow, and at-

mospheric CO<sub>2</sub> would reach 470 ppm by the end of the century.

The model in Fig. 13 is an extreme example to make a point about the usefulness of simple models. The next example is by Fiddaman [6]. It was selected as illustrative of the type of model that would emerge after a system dynamics study. Figure 14 shows the view of the carbon cycle, one of 30 views in the model. The model simulates the climate system within a larger system that includes growth in human population, growth in the economy, and changes in the production of energy. The model was organized conceptually as nine interacting sectors with a high degree of coupling between the energy, economic and the climate sectors.

Fiddaman focused on policy making, particularly the best way to put a price on carbon. In the current debate, this question comes down to a choice between a carbon tax and a carbon market. His simulations add support to those who argue that the carbon tax is the preferred method of putting a price on carbon. The simulations also provide another example of the usefulness of system dynamics models that cross disciplinary boundaries. By representing the economy, the energy system and the climate system

System Dynamics Models of Environment, Energy and Climate Change, Figure 14  
Representation of the carbon cycle in the model by Fiddaman [6]

within a single, tightly coupled model, he provides another example of the power of system dynamics to promote interdisciplinary exploration of complex problems.

System dynamics has also been applied to a wide variety of energy problems [1,7]. Indeed, a key word frequency count in 2004 revealed nearly 400 energy entries in the System dynamics bibliography [11]. Many of these applications deal with the electric power industry, and I have selected two electric studies to illustrate the usefulness of the approach. The first involves the regulatory and financial challenges of the investor owned electric utilities in the United States.

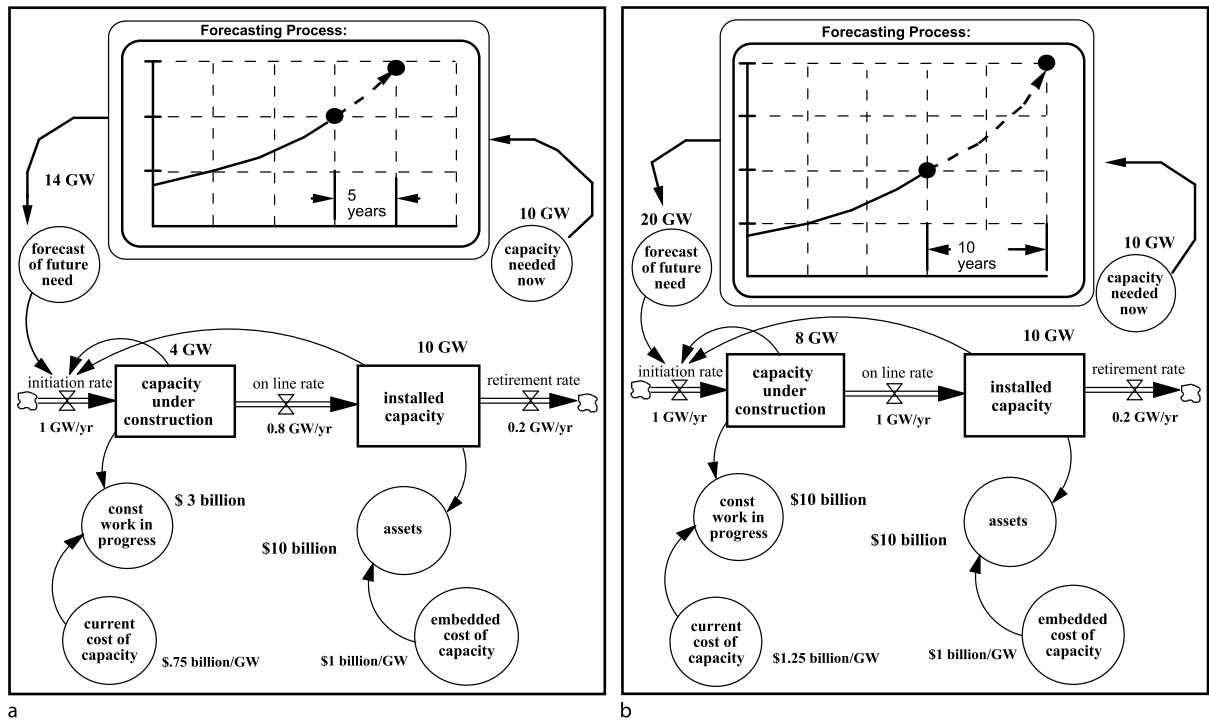

### Lessons from the Regulated Power Industry in the 1970s

The 1970s was a difficult decade for the regulated power companies in the United States. The price of oil and gas was increasing rapidly, and the power companies were frequently calling on their regulators to increase retail rates to cover the growing cost of fuel. The demand for electricity had been growing rapidly during previous decades, often at 7%/year. At this rate, the demand doubled every decade, and the power companies faced the challenge of

doubling the amount of generating capacity to ensure that demand would be satisfied. The power companies dealt with this challenge in previous decades by building ever larger power plants (whose unit construction costs declined due to economies of scale). But the economies of scale were exhausted by the 1970s, and the power companies found themselves with less internal funds and poor financial indicators. Utilities worried that the construction of new power plants would not keep pace with demand, and the newspapers warned of curtailments and blackouts.

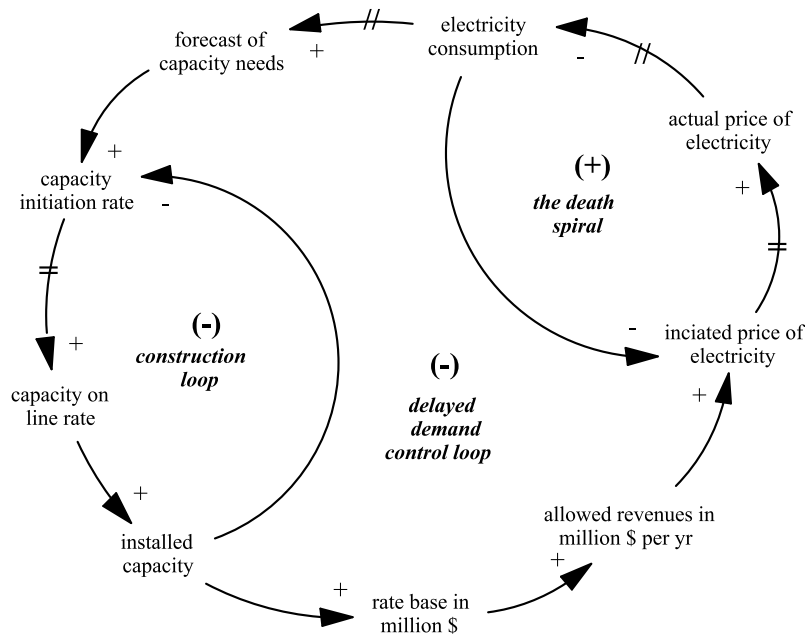

Figure 15 puts the financial problems in perspective by showing the forecasting, planning and construction processes. The side by side charts allows one to compare the difficult conditions of the 1970s with conditions in previous decades. Figure 15a shows the situation in the 1950s and 1960s. Construction lead times were around 5 years, so forecasts would extend 5 years into the future. Given the costs at the time, the power company would need to finance \$3 billion in construction. This was a substantial, but manageable task for a company with \$10 billion in assets.

Figure 15b shows the dramatic change in the 1970s. Construction lead times had grown to around 10 years, and construction costs had increased as well. The power

System Dynamics Models of Environment, Energy and Climate Change, Figure 15

a The electric utility's financial challenge during the 1950s and 1960s. b The electric utility's financial challenge during the 1970s

System Dynamics Models of Environment, Energy and Climate Change, Figure 16  
Key feedbacks and delays faced by power companies in the 1970s

company faced the challenge of financing \$10 billion in construction with an asset base of \$10 billion. The utility executives turned to the regulators for help. They asked for higher electricity rates in order to increase annual revenues and improve their ability to attract external financing. The regulators responded with substantial rate increases, but they began to wonder whether further rate increases would pose a problem with consumer demand. If consumers were to lower electricity consumption, the utility would have less sales and less revenues. The executives might then be forced to request another round of rate increases. Regulators wondered if they were setting loose a “death spiral” of ever increasing rates, declining sales and inadequate financing.

Figure 16 puts the problem in perspective by showing the consumer response to higher electricity rates along side of the other key feedback loops in the system. Higher electricity rates do pose the problem which came to be called “the death spiral”. But the death spiral does not act in isolation. Figure 16 reminds us that higher rates lead to lower consumption and to a subsequent reduction in the demand forecast and in construction. After delays for the new power plants to come on line, the power companies experiences a reduction in its “rate base” and the “allowed revenues”. When the causal relationships are traced around the outer loop, one sees a negative feedback loop that could act to stabilize the situation. The problem, how-

ever, is that the delays around the outer loop are substantially longer than the delay for the death spiral.

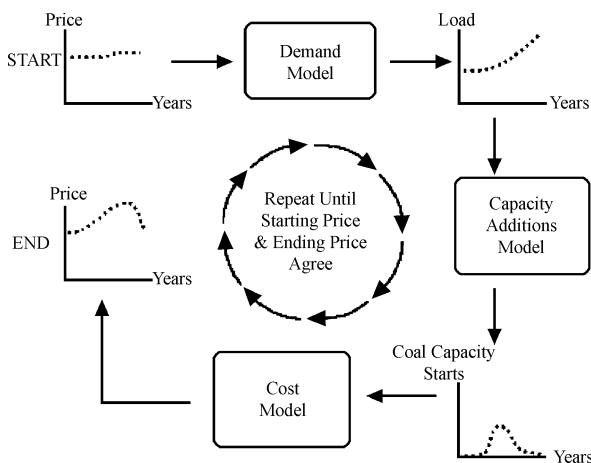

The utility companies financial challenge was the subject of several system dynamics studies in the 1970s and 1980s [7]. The studies revealed that the downward spiral could pose difficult problems, especially if consumers reacted quickly while utilities were stuck with long-lead time, capital intensive power plants under construction. The studies showed that utility executives needed to do more than rely on regulators to grant rate increases; they needed to take steps on their own to soften the impact of the death spiral. The best strategy was to shift the investments to technologies with shorter lead times. (As an example, a power company in coal region would do better to switch from large to smaller coal plants because of the small plants’ shorter lead time.) The studies also revealed that the company’s financial situation would improve markedly with slower growth in demand. By the late 1970s and early 1980s, many power companies began to provide direct financial incentives to their customers to slow the growth in demand. System dynamics studies showed that the company-sponsored efficiency programs would be beneficial to the both the customers (lower electric bills) and to the power companies (improved financial performance).

An essential feature of the utility modeling was the inclusion of power operations along side of consumer be-

havior, company forecasting, power plant construction, regulatory decision making and company financing. This interdisciplinary approach is common within the system dynamics community because practitioners believe that insights will emerge from simulating the key feedback loops. (This belief leads one to follow the cause and effect connections around the key loops regardless of the disciplinary boundaries that are crossed along the way.) This approach contrasts strongly with the customary modeling framework of large power companies who were not familiar with system dynamics. Their approach was to assign models to different departments (i. e., operations, accounting and forecasting) and string the models together to provide a view of the entire corporation over the long-term planning interval.

Figure 17 shows what can happen when models within separate departments are strung together. A large corporation might use 30 models, but this diagram makes the point by describing three models. The analysis would begin with an assumption on future electricity prices over the 20-year interval. These are needed to prepare a forecast of the growth in electricity load. The forecast is then given to the planning department which may run a variety of models to select the number power plants to construct in the future. The construction results are then handed to the accounting and rate making departments to prepare a forecast of electricity prices. When the company finally completes the many calculations, the prices that emerge may not agree with the prices that were assumed at the start. The company must then choose whether to ignore the contradiction or to repeat the entire process with a new es-

System Dynamics Models of Environment, Energy and Climate Change, Figure 17

The iterative approach often used by large power companies in the 1970s

timate of the prices at the top of the diagram. This was not an easy choice. Ignoring the price discrepancy was problematic because it was equivalent to ignoring the “death spiral,” one of the foremost problems of the 1970s. Repeating the analysis was also problematic. The new round of calculations would be time consuming, and there was no guarantee that consistent results would be obtained at the end of the next iteration.

The power companies’ dilemma from the 1970s is described here to make an important point about the usefulness of system dynamics. System dynamics modeling is ideally suited for the analysis of dynamic problems that require a feedback perspective. The method allows one to “close the loop”, as long as one is willing to cross the necessarily disciplinary boundaries. In contrast, other modeling methods are likely to be extremely time consuming or fall short in simulating the key feedbacks that tie the system together.

### Simulating the Power Industry Response to a Carbon Market

The world is getting warmer, both in the atmosphere and in the oceans. The clearest and most emphatic description of global warming was issued by the intergovernmental panel on climate change (IPCC) in February of 2007. Their summary for policymakers (p. 4 in [14]) reported that the “Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice and rising global mean sea level”. The IPCC concluded that “most of the observed increase is very likely due to the observed increase in anthropogenic greenhouse gas concentrations”. As a consequence of the IPCC and other warnings, policymakers around the world are calling for massive reductions in CO<sub>2</sub> and other greenhouse gas (GHG) emissions to reduce the risks of global warming.

Figure 18 summarizes some of the targets for emission reductions that have been adopted or proposed around the world. In many cases, the targets are specified relative to a country’s emissions in the year 1990. So, for ease of comparison, the chart uses 100 to denote emissions in the year 1990. Emissions have been growing at around 1.4%/year. The upward curve shows the future emissions if this trend continues: emissions would reach 200 by 2040 and 400 by 2090. The chart shows the great differences in the stringency of the targets. Some call for holding emissions constant; others call for dramatic reductions over time. Some targets apply to the next two decades; many extend to the year 2050; and some extend to the year 2100. However,

System Dynamics Models of Environment, Energy and Climate Change, Figure 18  
Comparison of goals for emissions (100 on the vertical axis represent emissions in the year 1990)

when compared to the upward trend, all targets require major reductions relative to business as usual.

The targets from the Kyoto treaty are probably the best known of the goals in Fig. 18. The treaty became effective in February of 2005 and called for the Annex I countries to reduce emissions, on average, by 5% below 1990 emissions by the year 2008 and to maintain this limit through 2012. The extension of the Kyoto protocol beyond 2012 is the subject of ongoing discussions. The solid line from 2010 to 2050 represents the “stabilization path” used in the climate modeling by Webster [23]. The limit on emissions was imposed in modeling calculations designed to stabilize atmospheric CO<sub>2</sub> at 550 ppmv or lower. The scenario assumed that the Kyoto emissions caps are adopted by all countries by 2010. The policy assumed that the caps would be extended and then further lowered by 5% every 15 years. By the end of the century, the emissions would be 35% below the value in 1990.

This article concentrates on Senate Bill 139, The Climate Stewardship Act of 2003. Figure 19 shows the S139 targets over the interval from 2010 to 2025. The bill called for an initial cap on emissions from 2010 to 2016. The

System Dynamics Models of Environment, Energy and Climate Change, Figure 19  
Map of the western electricity system

cap would be reduced to a more challenging level in 2016, when the goal was to limit emissions to no more than the emissions from 1990. S139 was introduced by Senators McCain and Lieberman in January of 2003. It did

not pass, but it was the subject of several studies including a highly detailed study by the Energy Information Administration [5]. The EIA used a wide variety of models to search for the carbon market prices that would induce industries to lower emissions to come into compliance with the cap. The carbon prices were estimated at \$22 per metric ton of CO<sub>2</sub> when the market was to open in 2010. They were projected to grow to \$60 by the year 2025.

The EIA study showed that the electric power sector would lead the way in reducing emissions. By the year 2025, power sector emissions would be reduced 75% below the reference case. This reduction was far beyond the reductions to be achieved by other sectors of the economy. This dramatic response was possible given the large use of coal in power generation and the power industry's wide range of choices for cleaner generation.

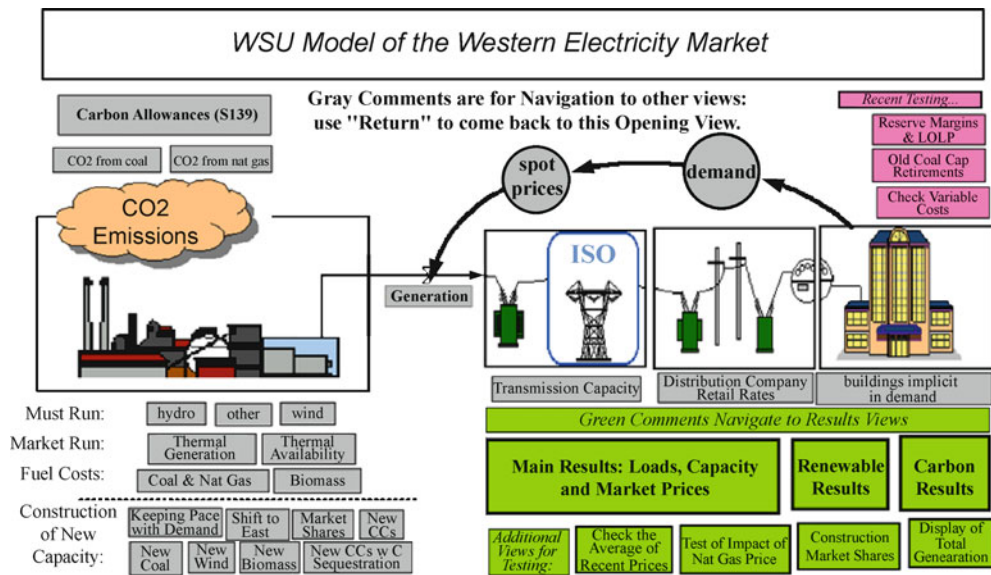

A system dynamics study of S139 was conducted at Washington State University (WSU) to learn if S139 could lead to similar reductions in the west. Electricity generation in the western system is provided in a large, interconnected power system shown in Fig. 19. This region has considerably more hydro resources, and it makes less use of coal-fired generation than the nation as a whole. The goal was to learn if dramatic reductions in CO<sub>2</sub> emissions could be possible in the west and to learn if they could be achieved with generating technologies that are commercially available today.

The opening view of the WSU model is shown in Fig. 20. The model deals with generation, transmission and

distribution to end use customers, with price feedback on the demand for electricity. The model is much larger than the textbook models described earlier in this article. Fifty views are required to show the all the diagrams and the simulation results. The opening view serves as a central hub to connect with all the other views.

The opening view uses Vensim's comment icons to draw attention to the CO<sub>2</sub> emissions in the model. The emissions arise mainly from coal-fired power plants, as shown in Fig. 21. A smaller, but still significant fraction of the emissions is caused by burning natural gas in combined cycle power plants. Total emissions vary with the seasons of the year, with the peak normally appearing in the summer when almost all of the fossil-fueled plants are needed to satisfy peak demand. The base case shows annual emissions growing by over 75% by the year 2025.

A major challenge for the system dynamics model is representing power flows across a transmission grid. Finding the flows on each transmission line and the prices in each area is difficult with the standard tools of system dynamics. It simply doesn't make sense to represent the power flows with a combination of stocks, flows and feedback processes to explain the flows. It makes more sense to calculate the flows and prices using traditional power systems methods, as explained by Dimitrovski [4]. The power flows were estimated using an algebraic approach which power engineers label as a reduced version of a direct-current optimal power flow calculation. The solution to the algebraic constraints were developed with the Matlab soft-

System Dynamics Models of Environment, Energy and Climate Change, Figure 20  
Opening view of the model of the western electricity system

System Dynamics Models of Environment, Energy and Climate Change, Figure 21  
Annual emissions in a base case simulation (annual emissions are in million metric tons of carbon)

ware and then transferred to user-defined functions to operate within the Vensim software. The Vensim simulations were set to run over twenty years with time in months. (A typical simulation required 240 months with changes during a typical day handled by carrying along separate calculations for each of 24 h in a typical day.) These are extensive calculations compared to many system dynamics models, so there was concern that we would lose the rapid simulation speed that helps to promote interactive exploration and model testing. The important methodological accomplishment of this project was the inclusion of network and hourly results within a long-term model without losing the rapid simulation response that encourages users to experiment with the model.

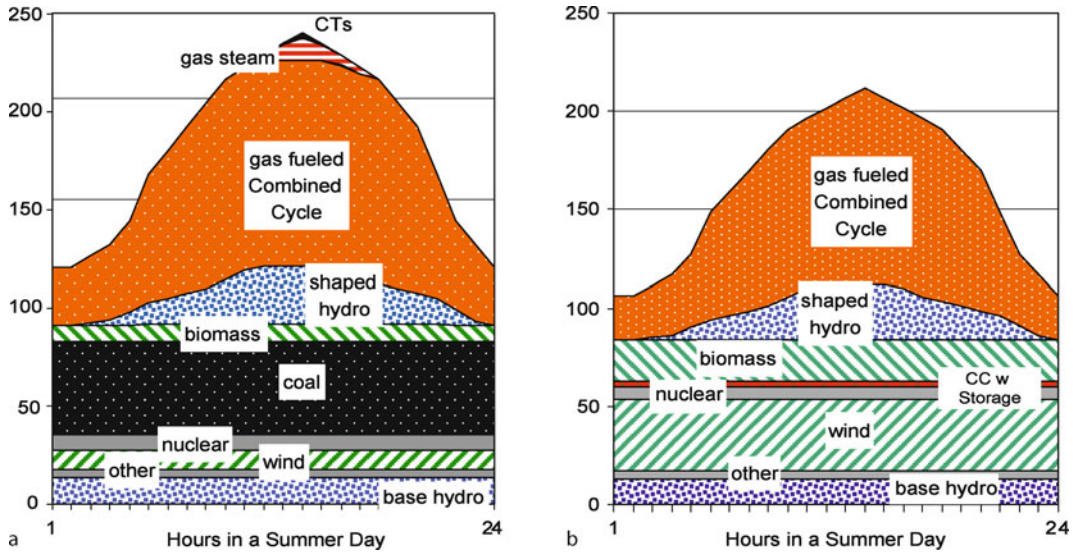

One of the model experiments called for a new simulation with carbon prices set to follow the \$20 to \$60 trajectory projected by the EIA for S139. These prices were specified as a user input, and the model responded with a change in both short-term operations and long-term investments. The important result was a 75% reduction in CO<sub>2</sub> emissions by the end of the simulation. This dramatic reduction corresponds almost exactly to the EIA estimate of CO<sub>2</sub> reduction for the power industry in the entire US.

Figure 22 helps one understand how CO<sub>2</sub> emissions could be reduced by such a large amount. These diagrams

show the operation of generating units across the Western US and Canada for a typical day in the summer of the final year of the simulation. Figure 22a shows the reference case; Figure 22b shows the case with S139. The side by side comparison helps one visualize the change in system operation. A comparison of the peak loads shows that the demand for electricity would be reduced. The reduction is 9%, which is due entirely to the consumers' reaction to higher retail electric prices over time.

Figure 22b shows large contributions from wind and biomass generation. Wind generation is carbon free, and biomass generation is judged to be carbon neutral, so these generating units make an important contribution by the end of the simulation. Both of these generating technologies are competitive with today's fuel prices and tax credits. The model includes combined cycle gas generation equipped with carbon capture and storage, a technology that is not commercially available today. The model assumes that advances in carbon sequestration over the next two decades would allow this technology to capture a small share of investment near the end of the simulation. By the year 2025, the combined cycle plants with sequestration equipment would provide 2% of the generation.

The most important observation from Fig. 22 is the complete elimination of coal-fired generation in the S139 case. Coal-fired units are shown to operate in a base load

System Dynamics Models of Environment, Energy and Climate Change, Figure 22

**a** Projected generation for a peak summer day in 2024 in the reference case. **b** Projected generation for a peak summer day in 2024 in the S139 case

mode in the reference simulation. They provide around 28% of the annual generation, but they account for around two-thirds of the CO<sub>2</sub> emissions in the western system. The carbon prices from S139 make investment in new coal-fired capacity unprofitable at the very start of the simulated market in 2010. As the carbon prices increase, utilities to cut back on coal-fired generation and compensate with increased generation from gas-fired CC capacity. In the simulations reported here, this fuel switching would push the coal units into the difficult position of operating fewer and fewer hours in a day. Eventually this short duration operation is no longer feasible, and coal generation is eliminated completely by the end of the simulation.

The WSU study of the western electric system was selected as the concluding example because of its novel treatment of network flows inside a system dynamics model [4]. The model is also interesting for its treatment of daily price changes within a long-term model. (Such changes are important to the simulation of revenues in the wholesale market.) From a policy perspective, the study confirms previous modeling of the pivotal role of the electric power industry in responding to carbon markets. The study indicated that the western electricity system could achieve dramatic reductions in CO<sub>2</sub> emissions within 15 years after the opening of a carbon market, and it could do so with technologies that are commercially available today [8].

### Conditions for Effective Interdisciplinary Modeling

All of the applications demonstrate the usefulness of system dynamics in promoting interdisciplinary modeling. The article concludes with comments on the level of effort and the conditions needed for effective, interdisciplinary modeling.

The examples in this article differ substantially in the level of effort required, from several weeks for the classroom examples to several years for the energy studies. The textbook examples involved student expansions of models of Mono Lake and the Tucannon salmon. The expansions were completed by undergraduate students in projects lasting two or three weeks. The key was the students' previous education (classes from many different departments) and their receptiveness to an interdisciplinary approach.

Fiddaman's model of the climate and energy system [6] was a more ambitious exercise, requiring several years of effort as part of his doctoral research. Bringing multi-year interdisciplinary modeling projects to a successful conclusion requires one to invest the time to master several disciplines and to maintain a belief that there are potential insights at the end of the effort.

The electric power industry examples were also ambitious projects that required several years of effort. The modeling of the western electricity system was a four-year project with support from the National Science Founda-

tion. The long research period was crucial for it allowed the researchers from power systems engineering, system dynamics and environmental science to take the time to learn from one another. The modeling of the electric company problems in the 1970s was also spread over several years of effort. The success of this modeling was aided by utility planners, managers and modelers who were looking for a systems view of their agency and its problems. They saw system dynamics as a way to tie existing ideas together within an integrated portrayal of their system. Their existing ideas were implemented in models maintained by separate functional areas (i. e., forecasting, accounting, operations). The existing models often provided a foundation for the system dynamics models (i. e., in the same way that the comprehensive climate models in Fig. 11 provide support for the development of the more integrated models). The key to effective, interdisciplinary modeling within such large organizations is support from a client with a strong interest in learning and with managerial responsibility for the larger system.

### Future Directions

This article concludes with future directions for system dynamics applications to climate change. People often talk of mitigation and adaptation. Mitigation refers to the challenge of lowering greenhouse gas emissions to avoid dangerous anthropogenic interference with the climate system. Adaptation refers to the challenge of living in a changing world.

**Mitigation:** The challenge of lowering CO<sub>2</sub> and other GHG emissions is the fundamental challenge of the coming century. The next two decades will probably see various forms of carbon markets, and system dynamics can aid in learning about market design. It is important that we learn how to make these markets work well. And if they don't work well, it's important to speed the transition to a carbon tax policy with better prospects for success. System dynamics can aid in learning about markets, especially if it is coupled with simulating gaming to allow market participants and regulators to "experience" and better understand market dynamics.

**Adaptation:** The world will continue to warm, and sea levels will continue to rise. These trends will dominate the first half of this century even with major reductions in CO<sub>2</sub> emissions. These and other climate changes will bring a wide variety of problems for management of water resource, public health planning, control of invasive species, preservation of endangered species, control of wildfire, and coastal zone management, just to name a few. Our understanding of the adaptation challenges can be improved

through system dynamics modeling. The prospects for insight are best if the models provide an interdisciplinary perspective on adapting to a changing world.

### Definition of the Subject

Seismic tomography refers to a number of techniques designed to investigate the interior of the earth using arrival times and/or waveforms from natural and artificial sources. The most common product of a tomographic study is a velocity model, although other parameters, such as attenuation, are also studied. The importance of seismic tomography stems from two facts. One, it generally has higher resolution than that provided by other geophysical methods. Two, it provides information that (a) can help solve fundamental problems concerning the internal structure of the earth at a global scale, and (b) has been used in tectonic and seismic hazards studies at a local scale. Seismic tomography has also been applied to data collected in boreholes, but because of the high expenses associated with drilling, borehole tomography is relatively little used.

### Introduction

In the most general terms, seismic tomography problems are inverse problems, and before the word “tomography” entered the seismological literature the term inversion was used. This change occurred as a consequence of the revolution in medical imaging caused by computerized (or computed) X-ray tomography (CT) (also known as computer assisted or axial, tomography, CAT), introduced in the 1970s. The importance of CT on seismic tomography was that it provided efficient numerical techniques for the solution of systems of equations with extremely large number of unknowns ( $10^5$  or more), which allowed a great expansion of the seismological inverse problems that could be tackled. In addition, according to [1], chang-

ing the name inversion to tomography enhanced the “believability” of the inverse method.

Seismic tomography covers a wide range of scales, from the very small (e.g., borehole tomography, involving distances of a few kilometers at most) to the very large (i.e., whole earth tomography). Initially, seismic tomography involved body-wave arrival times, but later it was extended to include waveform and surface wave information. Arrival-time tomography is simpler and for this reason it is the most popular. Waveform tomography requires software for the computation of synthetic seismograms for comparison with the observed ones, which makes the whole inversion process more difficult both theoretically and practically. Surface wave tomography involves the determination of phase velocities, which is more complicated than picking arrival times. The three approaches, however, have one thing in common, namely, they all end up requiring the solution of a linear system of equations. This task might sound simple, but in practice it is not because the system generally does not have a unique solution, which means that solving it requires making decisions (either implicitly or explicitly) regarding the nature of the solution. In addition, given the complexity of wave propagation in heterogeneous media (such as the earth), the inverse problems solved by seismologists involve highly simplified models of the earth. These simplifications enter into the linear system to be solved, which adds another layer of uncertainty to the solution. This is in sharp contrast with X-ray tomography, which is comparatively unaffected by this kind of uncertainties. For this reason it might be argued that the name tomography does not do justice to the kind of problems that seismologists solve, and this fact should be born in mind by readers from other disciplines. Other differences between X-ray and seismic tomography, of more practical nature, are given below.

The goal of most of the seismic tomography work is to derive 3-D velocity models of portions of the earth. Currently, most of the research concentrates on two scales, global and local. At the global scale, the tomographic models generally have higher resolution than that provided by other geophysical methods, and for this reason it has the potential to provide constraints on the fate of the subducted slabs, on models of mantle convection, on petrological and geochemical models, on studies of the geomagnetic and gravity fields, on mineral physics, and on the core-mantle boundary, among others (see, e.g., [41,96,129,161]). Local tomography usually involves the simultaneous determination of a 3-D velocity model and the relocation of the seismic events used to determine the model. Traditionally, local velocity models have been used in structural and tectonic interpretations, but more recently

they have become important in seismic hazard studies, as the ground motion caused by earthquakes are amplified by low-velocity materials, which increases the hazard in the case of large events (see, e. g., [160]). As discussed below, the standard practice of locating earthquakes with layered velocity models may lead to significant location errors when the lateral velocity variations are significant. Therefore, the simultaneous velocity-inversion and event relocation has the potential to produce improved event locations, which is also important in the context of seismic hazards studies.

## Fundamentals of X-ray Computerized Tomography

### Historical Overview

Computerized tomography began in the early 1970s with the introduction of the X-ray scanner developed by G. Hounsfield [65,66], who was able to combine data generated using X-ray techniques with computerized data acquisition and processing techniques. This resulted in the first commercially viable CT machine, with clinical applications presented in [6]. The history of the development of CT is extremely interesting and will be summarized here, but to put it into a broader perspective we will review briefly the X-rays acquisition and processing techniques in use before CT was introduced.

Röntgen's discovery of X-rays in 1895 revolutionized the practice of medicine by allowing a view of the interior of the human body. However, an X-ray image is the 2-D projection of a 3-D body, which means that its interpretation is subject to ambiguity. This fact was noticed soon after the radiographic technique was introduced, and a number of researchers began to develop techniques to produce 3-D views (see, e. g., [155]). The goal was to generate X-ray images of thin slices of a patient. This was achieved by moving the film and the X-ray source in such a way that the objects in a particular plane were emphasized while others were blurred by the motion. This process is discussed in, e. g., [138]. Work on this goal began in 1914 in several European countries (Germany, France, Italy, Holland), and was motivated, at least in part, by World War I. Different approaches were tried and different names were assigned to some of them, but only one, tomography, remained. This word comes from the Greek word *tomos*, which means cut or slice, and was introduced by the Berliner physician G. Grossmann, whose tomography was commercially available in 1935 [155,156].

Conventional tomography represented a considerable improvement over the original radiographic techniques, but the advent of computers opened new research avenues based on the digital processing of the X-ray images, or

shadowgrams. A shadowgram is a photographic plate developed after it has been illuminated by X-rays that passed through an object and gives a measure of the absorptivity of the rays by the object, which in many materials is roughly proportional to its density [12]. The availability of computers allowed shadowgrams, as well as other images, to be scanned and digitized for further processing using Fourier transform techniques as well as numerical solution of matrix equations. This work will be referred to below, but it is important to realize that they were in place when CT was introduced, and were major contributors to the improvement of the quality of the early CT results.

One of the earliest papers on medical computerized tomography is by A. Cormack [26], who received the Nobel Prize in Physiology or Medicine in 1979 together with G. Hounsfield for their contributions to the development of the technique, which were carried out independently. Cormack was a South African physicist working at the University of Cape Town. In 1955 the physicist at the Cape Town hospital resigned and Cormack replaced him for six months in 1956. During this time he became interested in the determination of the absorption of X or gamma rays passing through an inhomogeneous medium. His motivation was medical, in the context of radiotherapy, which required a good knowledge of the absorption coefficient of the bones and tissues of a patient. Cormack's approach was to consider a 2-D problem, as a 3-D one can be solved in terms of a succession of 2-D layers. The 2-D problem was well known and can be formulated as follows. A beam of monoenergetic rays of intensity  $I_o$  traverses a finite 2-D domain  $\mathcal{D}$  along a straight line  $L$ , and the intensity of the ray emerging from  $\mathcal{D}$  is  $I$ , given by

$$I = I_o \exp \int_L f(l) dl \quad (1)$$

where  $f$  is the absorption coefficient, which is a function of position within  $\mathcal{D}$ , and  $dl$  denotes a length element along  $L$ . Dividing both sides of Eq. (1) by  $I_o$  and taking the natural logarithm gives

$$g_L \equiv \ln \frac{I}{I_o} = \int_L f(l) dl . \quad (2)$$

The quantity  $g_L$  is known, and the question posed by Cormack was whether  $f$  could be computed using  $g_L$  determined for a number of lines. Cormack solved the problem in terms of a series expansion and demonstrated the feasibility of the method with two simple samples made of aluminum and either wood or Lucite [26,27]. His work, however, went essentially unnoticed until the publication of a paper [28] where the connection between the CT

problem and the Radon transform was discussed. That paper in turn, was stimulated by Hounsfield's work, which became known in 1971 [29]. Cormack moved to Tufts University (United States) in 1957.

The actual implementation of the CT technique as a viable commercial enterprise is due to Hounsfield [65], who was an engineer working at the Central Research Laboratories of Electrical and Musical Industries, the English company that eventually became the well known musical records company EMI. As recounted by Hounsfield [67], after finding that a project he had been working on would not be commercially viable, he was given the opportunity to think about other areas of research that he thought might be more fruitful. This rare opportunity was probably the result of the considerable amount of money that the group *The Beatles* had brought to EMI [107]. One of the projects Hounsfield had been working on was connected with automatic pattern recognition, which in 1967 led to the idea of what eventually became the technique of computerized tomography. To materialize this idea Hounsfield built the CT machine and developed the numerical technique to process the data (see Subsect. "Iterative Solutions"). According to some, the second task may have been the more fundamental of the two [107].

We close this summary with two notes of historical interest. First, B. Korenblyum, S. Tetel'baum, and A. Tyutin worked on tomography at the Kiev Polytechnic Institute and published their results in obscure Russian journals in 1957 and 1958. These authors formulated the tomography problem using line integrals, solved it exactly in terms of the inverse Radon transform, and discussed a recon-

struction algorithm. However, additional references on their work could not be found [11]. Second, W. Oldendorf, a neurologist at the University of California, Los Angeles, developed a scanning instrument, although he did not solve the problem mathematically [106]. Oldendorf patented his instrument in 1963 but was not able to attract companies interested in manufacturing a commercial version of it. Because of this contribution, Oldendorf was considered for the Nobel Prize together with Cormack and Hounsfield, but eventually was excluded. Possible reasons for the decision of the Nobel committee and the politics involved can be found in [19].

### Solving the CT Problem

The computerized tomography problem is to solve Eq. (2) when  $g_L$  has been determined for a large number of lines having different positions and directions. To make this problem more precise, the definition of projection will be introduced. First consider the following line integral of a function  $f(x, y)$

$$p(r, \vartheta) = \int_L f(x, y) dl \quad (3)$$

where the line  $L$  is defined in terms of its angle  $\vartheta$  with the  $y$  axis and its distance  $r$  to the origin (Fig. 1). Alternatively, it can be said that  $L$  passes through point  $P$  with polar coordinates  $(r \cos \vartheta, r \sin \vartheta)$  and is perpendicular to  $\overline{OP}$ . The collection of line integrals along parallel lines is known as a *parallel projection* of  $f(x, y)$ . Because this is the only type of projection considered here, the qualifier

Tomography, Seismic, Figure 1

**Left:** Geometry for the definition of projection.  $L$  is the projection line and  $r$  is the distance from the line to the origin. The axis  $s$  is parallel to  $L$ . **Right:** Geometry for parallel X-ray tomography. The circle bounds an object to be projected. Each line is equivalent to the line  $L$  on the left. There is a source of X-rays on one end of the lines and detectors on the opposite end

parallel will be dropped. In terms of Eq. (3), the projection of  $f$  is obtained by letting  $r$  be a variable while keeping the value of  $\vartheta$  fixed (i. e.,  $\vartheta$  must be considered a parameter). Note that some authors call a particular line integral a projection along that line (see, e. g., [132]).

Equation (3) was solved using two different approaches that broadly speaking can be referred to as analytical and iterative. The analytical approach followed different paths, but in each case the result was a closed-form solution, which had to be solved numerically. This approach is relevant to seismology for at least two reasons. First, it provides the theoretical underpinnings of the concept of backprojection, which has entered the seismic tomography literature. Second, it is directly related to the concepts of slant-stack and Radon transform popular in the reflection seismology literature. The iterative approach was to write the CT problem in matrix form and to solve it iteratively. This approach was widely applied to the solution of seismological inverse problems. Because of their close relation to seismology, the two approaches will be discussed here.

**Analytical Solutions** The most popular solutions are based on the use of the Fourier transform, but before considering them we will briefly mention the work of Radon, the Bohemian mathematician that investigated Eq. (3) in a paper published in 1917. It was written in German, and an English translation (by R. Lohner) can be found in [35].

Radon considered the function

$$\begin{aligned} p(r, \theta) &= p(-r, \theta + \pi) \\ &= \int_{-\infty}^{\infty} f(r \cos \vartheta - s \sin \vartheta, r \sin \vartheta + s \cos \vartheta) ds \end{aligned} \quad (4)$$

(see Eq. (11) below; his symbols were somewhat different), and the mean value of  $p(r, \theta)$  for the lines tangent to a circle with center at a point  $Q = (x, y)$  and radius  $a$

$$\bar{p}_Q(a) = \frac{1}{2\pi} \int_0^{2\pi} p(x \cos \vartheta + y \sin \vartheta + a, \theta) d\theta \quad (5)$$

and proved that

$$f(Q) = -\frac{1}{\pi} \int_0^{\infty} \frac{d\bar{p}_Q(a)}{a} = -\frac{1}{\pi} \int_0^{\infty} \frac{d\bar{p}_Q}{da} \frac{da}{a}, \quad (6)$$

where the last equality is given in [28]. A proof of Radon's result can be found in [62]. Equations (4) (or equivalent expressions) and (6) are known as the Radon and inverse Radon transform, respectively. Although Eq. (6) looks simple, its practical implementation is not [132] and probably for this reason it did not receive as much at-

tention (after Cormack's 1973 paper, [28]) as the other methods developed to solve the problem. As a matter of historical interest we note that Radon's problem arises in a number of scientific fields and had been solved independently more than once in the early part of the twentieth century [30]. Yet, these results were not widely known and had to be derived again.

The analytical approach developed along two different lines and produced results formally different from that of Radon. One was pioneered by Cormack [26,27], but, as noted earlier, it went essentially unnoticed. A second line originated in radio astronomy [17,18], electron microscopy (e. g., [34,36]) and X-ray radiography (e. g., [12,124]), and was based on the use of the Fourier transform. This is the approach that will be taken here and its description will be based mainly on [20,76,88] and [132].

The early development of the CT technique was based on the use of a number of parallel projections determined for different values of  $\vartheta$  in Eq. (3). This is the case that will be analyzed here. To find the equation that represents  $L$  we will use that fact that its slope is equal to  $-1/\tan \vartheta$  and its intercept with the  $y$  axis is  $r/\sin \vartheta$ . Thus

$$y = -\frac{\cos \vartheta}{\sin \vartheta} x + \frac{r}{\sin \vartheta} \quad (7)$$

so that

$$x \cos \vartheta + y \sin \vartheta = r. \quad (8)$$

To tie this definition to the concept of *slant stack* in seismology we note that it is defined using Eq. (3) with  $f$  replaced by a function  $u(x, t)$ , where  $u$ ,  $x$ , and  $t$  represent seismic wave amplitude, distance, and time, respectively,  $y$  is replaced by  $t$ , and  $t$  is written in terms of the intercept and slope of the line  $L$  (generally indicated with  $\tau$  and  $p$ , so that  $t = px + \tau$ ) (see, e. g., [40,127]).

Now we will introduce a new coordinate system  $(r, s)$  obtained by a rotation of angle  $\vartheta$  of the  $(x, y)$  system (Fig. 1). In the  $(r, s)$  system the points on the line  $L$  have constant  $r$  and variable  $s$ . The two systems are related by the following transformations of coordinates

$$\begin{pmatrix} r \\ s \end{pmatrix} = \begin{pmatrix} \cos \vartheta & \sin \vartheta \\ -\sin \vartheta & \cos \vartheta \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} x \cos \vartheta + y \sin \vartheta \\ -x \sin \vartheta + y \cos \vartheta \end{pmatrix} \quad (9)$$

and

$$\begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} \cos \vartheta & -\sin \vartheta \\ \sin \vartheta & \cos \vartheta \end{pmatrix} \begin{pmatrix} r \\ s \end{pmatrix} = \begin{pmatrix} r \cos \vartheta - s \sin \vartheta \\ r \sin \vartheta + s \cos \vartheta \end{pmatrix}. \quad (10)$$

Using Eq. (10), Eq. (3) can be rewritten as

$$\begin{aligned}
 p(r, \theta) &= \int_{-\infty}^{\infty} f(r \cos \vartheta - s \sin \vartheta, r \sin \vartheta + s \cos \vartheta) ds \\
 &\equiv \int_{-\infty}^{\infty} \hat{f}_{\vartheta}(r, s) ds
 \end{aligned}
 \tag{11}$$

where  $\hat{f}_{\vartheta}$  represents the function  $f$  when it is written in terms of  $r$  and  $s$ , and the subscript  $\vartheta$  is used to emphasize that it enters in the computations as a parameter. In Eq. (11)  $r$  is allowed to vary continuously, although in practical applications (such as CT)  $r$  is a discrete variable, as sketched in Fig. 1. Also note that  $r$  is allowed to be negative, which means that  $0 \leq \vartheta < \pi$ , and that although  $|r|$  is allowed to extend to infinity, for functions defined over a finite domain in the  $(x, y)$  plane the projections for lines outside of the domain will be zero.

To proceed further we will work in the wavenumber domain. Let the one-dimensional Fourier transform (or 1-D F.T.) of  $p(r, \theta)$  with respect to  $r$  be

$$P(k, \theta) = \int_{-\infty}^{\infty} p(r, \theta) e^{-i2\pi kr} dr
 \tag{12}$$

where  $k$  indicates wavenumber (equivalent to the frequency in the time domain). Introducing Eq. (11) into this expression and then going back to the  $(x, y)$  coordinate system gives

$$\begin{aligned}
 P(k, \theta) &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \hat{f}_{\vartheta}(r, s) e^{-i2\pi kr} dr ds \\
 &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x, y) e^{-i2\pi k(x \cos \vartheta + y \sin \vartheta)} dx dy \\
 &= F_{\vartheta}(k_x, k_y)
 \end{aligned}
 \tag{13}$$

where  $r$  has been written using Eq. (9), the Jacobian of the coordinates transformation is equal to one,  $F_{\vartheta}$  is the two-dimensional Fourier transform of  $f$  and

$$k_x = k \cos \vartheta; \quad k_y = k \sin \vartheta.
 \tag{14}$$

Note that

$$k^2 = k_x^2 + k_y^2; \quad k_y/k_x = \tan \theta.
 \tag{15}$$

In summary,

$$P(k, \theta) = F_{\vartheta}(k_x, k_y).
 \tag{16}$$

In words, the 1-D F.T. of the projection  $p(r, \theta)$  of  $f(x, y)$  is equal to the 2-D F.T. of  $f(x, y)$ . This relation is known as the Fourier (central) slice theorem. This name comes from the fact that the 2-D F.T. is known in a slice (i. e.,

a line) through the origin in the  $(k_x, k_y)$  space, as Eq. (15) shows. Moreover, the angle of this line with the  $k_x$  axis is  $\vartheta$ , which is equal to the angle between the  $x$  and  $r$  axes. Equation (16) suggests one approach to the determination of  $f(x, y)$ . Find the 1-D F.T. of the projections for discrete values of  $\theta$  between 0 and  $\pi$  and then use the 2-D inverse F.T. to recover  $f(x, y)$  numerically. However, because the values of the 2-D F.T will be defined on a polar coordinates grid, it must be interpolated to a Cartesian grid in the  $(k_x, k_y)$  space.

A different approach is as follows. Let  $F(k_x, k_y)$  be the 2-D F.T. of  $f(x, y)$ . Then,  $f(x, y)$  is given by the inverse F.T.

$$f(x, y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(k_x, k_y) e^{i2\pi(k_x x + k_y y)} dk_x dk_y.
 \tag{17}$$

In this expression  $k_x$  and  $k_y$  are defined on a Cartesian coordinate system, which will be converted to polar coordinates using Eq. (14). This gives

$$f(x, y) = \int_0^{\pi} \int_{-\infty}^{\infty} P(k, \vartheta) e^{i2\pi k(x \cos \vartheta + y \sin \vartheta)} |k| d\vartheta dk
 \tag{18}$$

where Eq. (16) was used and  $|k| d\vartheta dk$  is the Jacobian for the transformation of coordinates. Because the Jacobian relates the elements of area in the two coordinate systems, the absolute value of  $k$  is needed because the area is positive. Two comments are in order here. First,  $\vartheta$  is no longer a parameter; now it is used as a variable. Second, the polar coordinates have been defined using  $0 \leq \theta < \pi$  and  $-\infty < k < \infty$ . This convention is equivalent to the standard one (i. e.,  $0 \leq \theta < 2\pi, 0 \leq k < \infty$ .)

Now Eq. (18) will be rewritten as follows

$$f(x, y) = \int_0^{\pi} p^*(x \cos \vartheta + y \sin \vartheta, \vartheta) d\vartheta
 \tag{19}$$

where

$$p^*(r, \vartheta) = \int_{-\infty}^{\infty} P(k, \vartheta) |k| e^{i2\pi kr} dk.
 \tag{20}$$

The integral in Eq. (20) involves the product of two 1-D F.T.s,  $P(k, \theta)$  and  $|k|$ , so, in principle, one way to solve it would be to use the following property. Given two functions  $g(r)$  and  $h(r)$  with F.T.s  $G(k)$  and  $H(k)$ , then

$$\int_{-\infty}^{\infty} G(k) H(k) e^{i2\pi kr} dk = \int_{-\infty}^{\infty} g(\rho) h(r - \rho) d\rho
 \tag{21}$$

where the integral on the right-hand side is the convolution of  $g$  and  $h$  (see, e. g., [94]). A problem with this formulation is that  $|k|$  does not have an inverse F.T., as can

be seen from the fact that it does not go to zero as  $k$  goes to infinity, which is one of the properties of the F.T. [149]. There are two ways to get around this problem. One is to solve Eq. (21) in terms of distributions. A basic yet rigorous introduction to distributions, which can be considered an extension of the concept of function, can be found in [120]. Let us rewrite Eq. (20) as follows

$$p^*(r, \theta) = \frac{1}{2\pi^2} \int_{-\infty}^{\infty} P(k, \theta) (i2\pi k) (-i\pi \operatorname{sgn} k) e^{i2\pi kr} dk \tag{22}$$

where

$$\operatorname{sgn} k = \begin{cases} 1 & k > 0 \\ -1 & k < 0. \end{cases} \tag{23}$$

Then, using Eq. (21) we can write

$$p^*(r, \theta) = \frac{1}{2\pi^2} \mathcal{F}^{-1} \{ i2\pi k P(k, \theta) \} * \mathcal{F}^{-1} \{ -i\pi \operatorname{sgn} k \} \tag{24}$$

where  $\mathcal{F}^{-1}$  represents the inverse F.T. of the function in braces and the  $*$  stands for convolution. The first inverse is just  $\partial p(r, \theta) / \partial r$  and the second inverse is equal to  $1/r$  [120]. Combining these two results gives

$$p^*(r, \theta) = -\frac{1}{2\pi} \left( -\frac{1}{\pi r} * \frac{\partial p(r, \theta)}{\partial r} \right) \equiv -\frac{1}{2\pi} \mathcal{H} \left\{ \frac{\partial p(r, \theta)}{\partial r} \right\} \tag{25}$$

where  $\mathcal{H}$  stands for the Hilbert transform of the function in braces [120]. The inverse expression for the slant stack can be derived using expressions similar to those presented above [25].

The importance of Eq. (25) is mostly theoretical, and from a practical point of view a different method of solution was found to be more useful. Before proceeding, however, note that Eq. (20) without  $|k|$  on the right-hand side corresponds to the 1-D inverse F.T. of  $P(k, \theta)$ , equal to  $p(r, \theta)$  (see Eq. (12)). Therefore,  $p^*$  is a *filtered projection*, with  $|k|$  the filter response. Clearly, the effect of the filter is to amplify the components of  $p$  corresponding to the higher wavenumbers. The approach used here is also based on the use of Eq. (21), with  $g(r) = p(r, \theta)$  (as before) and  $h(r)$  a function whose F.T. is an approximation to  $|k|$  in the sense that

$$H(k) \approx \begin{cases} |k|; & |k| < K \\ 0; & \text{elsewhere} \end{cases} \tag{26}$$

where  $K$  can be taken as the spatial Nyquist frequency  $k_N$  (equal to  $1/2a$ , where  $a$  is the spacing between projection

lines). To avoid aliasing,  $P(k, \theta)$  must be zero for  $|k| > k_N$ . Clearly, there is some freedom in the selection of  $h(r)$ . For example, in [18] and [124]  $H(k)$  is defined by an expression similar to Eq. (26) with an equal sign in place of the less than sign. This work was followed by the introduction of an improved function [133]. For our purposes, however, what is important is not the particular choice of  $h$  but the fact that we can write the following approximation for  $f(x, y)$

$$f(x, y) \approx \tilde{f}(x, y) \equiv \int_0^\pi \int_{-\infty}^{\infty} p(\rho, \theta) h(x \cos \vartheta + y \sin \vartheta - \rho) d\rho d\theta. \tag{27}$$

Finally, because the projections are determined for discrete and equispaced values of  $r$  and  $\theta$  we can write

$$\tilde{f}(x, y) \approx \frac{\pi a}{N} \sum_{i=1}^N \sum_{j=-J}^J p(ja, \theta_i) h(x \cos \vartheta_i + y \sin \vartheta_i - ja) \tag{28}$$

where  $\theta_i = (i-1)\pi/N$ ,  $N$  is fixed, and  $J$  is a finite limit that takes into account the finite size of the object (after [132]).

To end this discussion of the transform methods of solution we will go back to Eq. (19). The integration there is an example of the operation known as *backprojection*, to be indicated with  $\mathcal{B}$  and defined by

$$\mathcal{B}\{q\}(x, y) = \int_0^\pi q(x \cos \vartheta + y \sin \vartheta, \vartheta) d\theta \tag{29}$$

where  $q$  is an arbitrary function of  $r$  and  $\vartheta$ . An example of this operation is provided in Fig. 2a, which shows two projections of a rectangular object corresponding to  $\vartheta$  equal to 0 and  $\pi/2$ . The two projections, identified by  $p(x, 0)$  and  $p(y, \pi/2)$ , are nonzero for limited ranges of the  $y$  and  $x$  axes. To compute the backprojection let us consider a particular value  $y'$  of  $y$  and assign the value  $p(y', \pi/2)$  to every point in the line defined by the points  $(x, y')$ . The object may be part of a larger body, and for this reason the line will extend beyond the  $x$  values that bound the object. Repeating this operation for all the values  $y'$  and then proceeding in a similar way for the  $p(x, 0)$  projection produces an image such as that shown in Fig. 2b. The two backprojections overlap in the area occupied by the rectangular object, but also contribute values to other areas of the  $(x, y)$  plane, which is clearly not correct. The problem is not related to the use of only two projections; even when a larger number of projections is used, the contributions outside of the object do not disappear. The reason for that is that the determination of  $f(x, y)$  requires  $p^*$ , not  $p$ , as shown by Eq. (19) (see, e. g., [23]).

Tomography, Seismic, Figure 2

Illustration of the concept of back projection. *Left*: projection of a rectangular box using two sets of parallel lines (two representative lines are shown). *Right*: backprojection of the two projections shown on the left. Note the change in the direction of the arrows. For each line, the value of its projection is assigned to all the points along the line and are added to the values that come from all the other projections. See text for details. After [20]

**Iterative Solutions** As was the case with the analytical solutions, the iterative solutions were developed before the advent of CT. The earliest one was the *algebraic reconstruction technique* (ART, [51]) and was developed for the solution of electron microscopy problems as an alternative to analytical solutions based on the Fourier transform. These problems are represented by an equation similar to Eq. (2). The basic idea behind ART was the discretization of a plane object in terms of a square grid of points. The goal was to find the optical density  $\rho_{ij}$  at each point  $(i, j)$  of the grid. A ray of a projection at an angle  $\theta$  was defined as a band of width  $w$  across the plane at the same angle, and corresponds to each of our lines  $L$ . One possible choice for  $w$  is to make it equal to the grid spacing. The basis of ART is to start with an average value of the density (computed from the observations) and to use it to compute the projections for all the rays for all the angles. Then, two updating methods were used, one additive and the other multiplicative. In the original version of the additive method, for each ray the difference between observed and computed projections was used to update the density values in the cells along the ray. If an updated value of density became negative it was set to zero. This was done for all the rays, one ray at a time. This completed one iteration. Then a new one was started with the updated densities used as starting values. Originally, the difference between the observed and computed projections was divided equally among all the cells in the ray, but in later applications each cell received a weight representing its contribution to a given ray. The weight was used when the cell densities were updated (see, e. g., [50]). In the multiplicative version of ART the density value of a cell was updated by multiplying it by the ratio of computed to observed projections. Again, a weighting scheme was introduced later. A technique similar to additive ART was developed inde-

pendently by Hounsfield and applied to his X-ray scanner (see, e. g., [20,133]).

A second technique, simultaneous iterative reconstruction technique (SIRT) was introduced in [48], which was highly critical of the performance of ART. SIRT also has additive and multiplicative versions, and the main difference with the ART counterparts is that at each iteration the density of each cell is updated using all the projections passing through that cell. Subsequent work showed that although ART is computationally more efficient than SIRT, it has the problem that is more affected by errors in the data (see, e. g., [20,39,63]). SIRT, on the other hand, has some undesirable properties, referred to in Subsect. “Regularization Approach”.

### Arrival-Time Seismic Tomography

As noted earlier, this type of tomography is much simpler than surface wave and waveform tomography, and lends itself to a fairly self-contained discussion, to be presented here. The other two types of tomography will not be discussed here because they require a knowledge of seismic theory and data processing beyond the scope of this article.

This section is organized as follows. First, the differences between seismic and X-ray tomography will be discussed. The early applications of CT techniques to seismic problems ignored these differences, and although the results thus obtained opened the way to a new research approach in seismology, they may have been affected by several types of errors, the sources of which will become clear here. Second, tomography using local data will be addressed. In this case both the location of the events as well as the velocity model must be determined. In addition, a distinction between velocity and slowness tomography must be made. As noted earlier, before seismic to-

mography there was velocity inversion. Then, after the introduction of CT techniques the inversion parameter became slowness, not velocity. Therefore, the equations to be solved in the two cases are different, and because some of the velocity inversion programs are still in use, the two parameterizations, and their relationship, will be presented here. In addition, regardless of the parameterization used, it is necessary to decouple (or separate) the location part from the tomographic part of the problem, which requires introducing new analytical tools. Another topic related to local tomography is the computation of travel times, which will be briefly considered here. Finally, the case of tomography using teleseismic arrival times is analyzed.

### Comparison with X-ray Tomography

Seismic tomography differs from X-ray tomography in two fundamental ways because, first, the former is nonlinear, and second, the locations of the seismic sources are generally unknown (i. e., when earthquakes are used). Another major difference is that in X-ray tomography there is control over position and number of sources and receivers, which is not the case for seismic tomography. The first two differences will be considered in more detail.

The expression for travel time,  $t$ , along a ray is given by

$$t = \int_R \frac{1}{v} ds = \int_R u ds \quad (30)$$

where  $R$  denotes the raypath between two fixed points within an elastic medium with velocity  $v(\mathbf{x})$  that depends on position (indicated by the vector  $\mathbf{x}$ ),  $ds$  is a line element along the raypath, and  $u$  is the slowness, equal to the inverse of velocity

$$u(\mathbf{x}) = \frac{1}{v(\mathbf{x})}. \quad (31)$$

An advantage of writing  $t$  in terms of  $u$  instead of  $v$  is that in terms of  $u$ ,  $t$  has an expression similar to Eq. (2), which constitutes the basis of X-ray tomography. This similarity, however, is more apparent than real. To see that we will introduce the concept of linear operation. Given an operation  $\mathcal{O}$ , it is said to be linear if

$$\mathcal{O}(f + h) = \mathcal{O}(f) + \mathcal{O}(h) \quad (32)$$

and

$$\mathcal{O}(\alpha f) = \alpha \mathcal{O}(f) \quad (33)$$

where  $f$  and  $h$  are functions and  $\alpha$  is a scalar. A simple example of linear operation is the integration over a given

interval

$$\int_a^b [f(x) + h(x)] dx = \int_a^b f(x) dx + \int_a^b h(x) dx. \quad (34)$$

In particular, the operation defined by Eq. (2) is linear because  $L$  is always a straight line that does not depend on  $f$ . Therefore, if we let  $f = f_1 + f_2$  we can write

$$\begin{aligned} g_L(f) &= \int_L [f_1(s) + f_2(s)] ds \\ &= \int_L f_1(s) ds + \int_L f_2(s) ds \\ &= g_L(f_1) + g_L(f_2). \end{aligned} \quad (35)$$

Now let us consider the travel time problem. Let  $R(u_1)$  and  $R(u_2)$  denote the raypaths between two fixed points within an elastic medium assuming that it had slownesses  $u_1$  and  $u_2 \neq u_1$  at two different times. This situation is generally not possible in the earth but can be simulated on a computer. The corresponding travel times are given by

$$t_1 = \int_{R(u_1)} u_1(s) ds, \quad t_2 = \int_{R(u_2)} u_2(s) ds. \quad (36)$$

Note that the two raypaths will be different because  $u_1$  and  $u_2$  have been assumed to be different. The trivial case of  $u_1 = ku_2$ , where  $k$  is a constant, is ignored. Therefore, it will not be possible, in general, to write  $t_1 + t_2$  as an integral over a common path involving  $u_1 + u_2$ . Moreover, if the medium has slowness  $u_1 + u_2$  the raypath  $R(u_1 + u_2)$  between the two points will be different from  $R(u_1)$  and  $R(u_2)$  and, in general,

$$t_1 + t_2 \neq \int_{R(u_1+u_2)} [u_1(s) + u_2(s)] ds \quad (37)$$

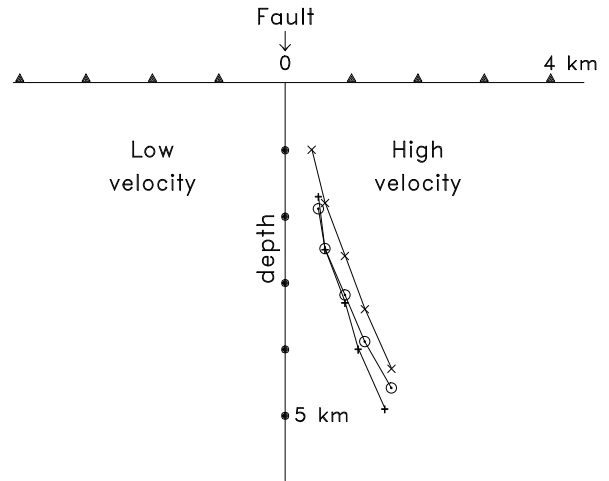

which in turn means that the travel time problem cannot be expressed in terms of a linear operation. Therefore, the seismic tomography problem is nonlinear, and the CT solution techniques cannot be applied directly except when the 3-D velocity variations in the medium are small, a condition that severely limits its application to situations of seismic interest.

Another major difference between seismic tomography and CT is that the locations of the sources (mostly earthquakes) are generally not known. Therefore, the determination of a velocity model requires the simultaneous determination of the source locations. This is particularly important when the events are locally recorded. To see that we will consider a very simple example. Let us assume that a vertical fault separates rocks with low- and high-velocities, denoted  $v_1$  and  $v_2$ , respectively, and that

earthquakes occur along a vertical line within the fault. Let  $v_1 = 3$  km/s and  $v_2 = 4$  km/s. The origin of the coordinate system will be the fault location at the surface and the event depths will be 1, 2, 3, 4, and 5 km. The earthquakes will be assumed to be recorded by a local network of eight stations on the surface. The theoretical arrival times computed for this geometry were used with a single-event location program and two constant velocity models with velocities equal to 3 and 3.5 km/s and with a 1-D model with five layers and velocities between 2.5 and 4 km/s. The locations obtained with these models (Fig. 3) are affected by significant errors, which cannot be inferred by the small root-mean-square errors, which range between 0.02 and 0.09 s, with the larger value corresponding to the deeper event. These results show that the effect of the lateral juxtaposition of high- and low-velocity rocks when the events are located with 1-D velocity models is a mislocation of the events in a direction away from the low-velocity zone. A well-documented example of this situation is provided by the aftershocks of the 1994  $M = 6.7$  Northridge, California, earthquake, which occurred within the sedimentary rocks of the San Fernando basin. These events and the velocity model determined using them are considered in Subsect. “[P Wave Velocity Model for the San Fernando, California, Area](#)”.

This example has a counterpart. What happens when mislocated events are kept at their erroneous locations and are used to determine a 2-D velocity model around the fault? Clearly, such a velocity model will be affected by the location errors and its reliability will be questionable. Examples showing the significant bias that these errors may have in the computed velocities are given in [54,145], and [146] for geometries similar to that in Fig. 3. In [146],  $v_1 = 5$  km/s and  $v_2 = 6$  km/s and there was only one earthquake on the fault. In this case the velocity determined by inversion was 5.44 km/s to the left of the fault and 5.56 km/s to the right of it. This example is clearly an oversimplification, but the result is useful because it shows that ignoring the mislocation introduced by lateral velocity variations will result in a velocity model showing variations smaller than the actual ones. For the case of teleseismic tomography, event mislocation may not be a serious problem except when earthquakes from subducting slabs are used, in which case the effect on the computed velocities may be important (see, e. g., [32,153]).

Another difference between seismic tomography and X-ray tomography is that in the later the position of the sources and the receivers can be chosen so that the computed images have the desired resolution. In contrast, in seismic tomography there is no control over the position of the earthquakes, while the number and position of sta-

Tomography, Seismic, Figure 3

Simple example (2-D) of the effect of lateral velocity variations on earthquake location when those variations are ignored. A fault divides the medium into two quarter spaces with velocities equal to 3 km/s (left) and 4 km/s (right). The triangles and dots represent stations and hypocenters, respectively. Synthetic arrival times computed for these events, stations, and velocity model are used with a single-event location program and three 1-D velocity models. Two models have constant velocities, equal to 3 km/s and 3.5 km/s, and the other has five layers with velocities between 2.5 and 4 km/s. The locations determined using these models are indicated by pluses, crosses and circles

tions is dictated by financial considerations as well as practical constraints imposed by the nature of the terrain. For example, mountains frequently constitute a severe obstacle to station deployments. Even more serious is the presence of oceans, which cover two-thirds of the earth's surface and essentially prevent the routine deployment of permanent seismic networks similar to those on land. As a consequence, seismic tomographic models, particularly at a global scale, are affected to some extent by low-resolution problems.

Finally, we note that soon after X-ray tomography began, several competing methods of solution were proposed (see Subsect. “[Solving the CT Problem](#)”), and to compare their performances synthetic data generated for a model of a cross section of the skull were used [133]. With this approach it was possible to detect artifacts in some of the solutions and to investigate the effect of noise in the data. In contrast, seismic tomography methods were rarely subject to a similar validation analysis in spite of the approximations and simplifying assumptions made. These differences stem, in part, on the complicated nature of wave propagation in the earth, which is difficult to replicate in a computer on account of theoretical difficulties and computational cost. On the other hand, the propaga-

tion of X-rays is relatively simple and easy to simulate on a computer. In addition, medical tomography, in general, is well funded, while seismic tomography is only poorly funded [84].

### Local Velocity Tomography

The simultaneous determination of the locations of a group of earthquakes and a 3-D velocity model can be considered an extension of the standard method of earthquake location. Usually, the velocity structure is modeled in terms of constant-velocity blocks or by velocity values on a grid. The basic ideas were introduced by Aki and Lee [2] and Crosson [33], although the latter only considered layered velocity models. Because this inverse problem is nonlinear in both the earthquake location and the velocity determination, it is solved by linearizing it about initial estimates of the locations and origin times of the events and model velocities. With this approach the original problem is replaced by other in which the unknowns are adjustments to the initial estimates. Then these adjustments are added to the initial estimates, the corresponding values are used as new initial estimates, and the process is repeated iteratively until some stopping criterion is met. This process will be described mathematically in the following.

Let us use subscripts  $i$  and  $j$  to identify the stations and earthquakes used, respectively, and let  $M$  and  $N_j$  be the number of events and the number of stations with arrival times for the  $j$ th event, respectively. The blocks or grid points used to parameterize the velocity structure constitute a 3-D array, but for computational purposes each block or point will be identified with a single subscript, say  $k$ . This requires establishing an ordering scheme that assigns a single index to a triplet of indices. For example, we may use the following scheme:  $(1, 1, 1) \rightarrow 1$ ,  $(2, 1, 1) \rightarrow 2$ ,  $(n, 1, 1) \rightarrow n$ ,  $(n, 2, 1) \rightarrow n + 1$ , and so on. Let  $K$  represent the total number of velocity parameters. The linearized problem can be written as

$$w_{ij}r_{ij} = w_{ij} \left( dT_j + \frac{\partial t}{\partial x} dx_j + \frac{\partial t}{\partial y} dy_j + \frac{\partial t}{\partial z} dz_j + \sum_k \frac{\partial t}{\partial v_k} dv_k \right) \quad (38)$$

$$i = 1, \dots, N_j \quad j = 1, \dots, M$$

where

$$r_{ij} = \mathcal{T}_{ij}^{\text{obs}} - \mathcal{T}_{ij}^{\text{comp}} \equiv \mathcal{T}_{ij}^{\text{obs}} - (T_j + t_{ij}) \quad (39)$$

is the arrival time residual for the  $j$ th earthquake and the  $i$ th station. The subscript  $k$  labels the blocks or grid

points associated with the raypath from the  $j$ th hypocenter to the  $i$ th station. Therefore,  $k$  is a function of  $i$  and  $j$ , but this dependence is left implicit to simplify the notation. Also note that the values of  $k$  associated with a given ray do not have any particular ordering. The meaning of the other variables is as follows:

$dT_j, (dx_j, dy_j, dz_j), dv_k$ : adjustments to origin time, hypocentral coordinates, and velocities, respectively,  
 $\mathcal{T}_{ij}^{\text{obs}}$ : observed arrival time,  
 $\mathcal{T}_{ij}^{\text{comp}}$ : computed arrival time,  
 $T_j$ : origin time,  
 $t_{ij}$ : computed travel time,  
 $t, v$ : travel time and velocity,  
 $w_{ij}$ : quality weight.

In Eqs. (38) and (39) the only unknowns are the adjustments. All the other quantities are computed using initial estimates of the velocities ( $v_k$ ) and the origin time ( $T_j$ ) and hypocentral coordinates ( $x_j, y_j, z_j$ ) of each earthquake. The expressions for the derivatives can be found in [85].

### Local Slowness Tomography

As noted earlier, the travel time problem cannot be expressed in terms of a linear operation on slowness, and for this reason the problem is linearized assuming that the difference between the initial and actual velocity models is small. Let us go back to Eq. (36) with  $u_2 = u_1 + du$ ,  $du \ll u_1$ . Then the difference  $dt$  in travel times is given by

$$dt = t_2 - t_1 = \int_{R(u_1+du)} [u_1(s) + du(s)] ds - \int_{R(u_1)} u_1(s) ds \approx \int_{R(u_1)} du(s) ds. \quad (40)$$

Here we have invoked *Fermat's principle*, which allows replacing  $R(u_1 + du)$  with  $R(u_1)$ . Recall that this principle states that raypaths are paths of stationary travel time (see, e. g., [3,120]), which in turn means that the variation of travel time along a raypath is zero. Two points must be noted here, however. First, the principle applies to small variations in raypaths, which in turn requires a small  $du$ , a condition which may not be valid in reality. This question was tested in the context of the propagation of rays through subducting slabs [31] and it was found that arrival times at teleseismic distances calculated using Fermat's principle were the same or later than those determined using exact ray tracing. The difference between exact and approximate times depended on event depth, with the larger errors corresponding to intermediate-depth events. A consequence of these errors was an underestimation of the

velocity anomaly. Second, Fermat's principle applies to curves with the same end points, but in practice the end point of  $R(u_1)$  corresponding to the event location is not the true location because it has been determined with an incorrect velocity model. Therefore,  $R(u_1)$  is not necessarily close to the true ray path. In practice, however, the approximations involved in the use of Fermat's principle in local tomography improve as the iterations proceed, and can essentially be ignored.

For completeness, the relation between small variations  $dv$  and  $du$  in velocity and slowness will be considered. Because travel time is equal to distance divided by velocity, here we are interested in  $1/(v + dv)$ , with  $dv \ll v$ , which can be approximated as follows

$$\frac{1}{v + dv} = \frac{1}{v} \left(1 + \frac{dv}{v}\right)^{-1} \approx \frac{1}{v} - \frac{1}{v^2} dv \equiv u + du. \quad (41)$$

Therefore, it does not make any theoretical difference whether the inverse problem is formulated in terms of slowness or velocity as long as  $du$  and  $dv$  are such that the approximations introduced are valid.

Now let us go back to the joint hypocentral location and determination of a 3-D slowness model. The only difference with the expression for velocity tomography (Eq. (38)) is in the last term, which is replaced by the right-hand side of Eq. (40). This gives

$$w_{ij}r_{ij} = w_{ij} \left( dT_j + \frac{\partial t}{\partial x} dx_j + \frac{\partial t}{\partial y} dy_j + \frac{\partial t}{\partial z} dz_j + \int_{R_{ij}} du ds \right) \quad (42)$$

$$i = 1, \dots, N_j \quad j = 1, \dots, M$$

where  $R_{ij}$  indicates the raypath between the corresponding station-event pair. To proceed further the integral must be discretized, which can be done using a block model. After that Eq. (42) becomes

$$w_{ij}r_{ij} = w_{ij} \left( dT_j + \frac{\partial t}{\partial x} dx_j + \frac{\partial t}{\partial y} dy_j + \frac{\partial t}{\partial z} dz_j + \sum_k l_{ijk} du_k \right) \quad (43)$$

$$i = 1, \dots, N_j \quad j = 1, \dots, M$$

where  $l_{ijk}$  and  $du_k$  are the length of the ray in the  $k$ th block and the corresponding slowness perturbation.

Note that although the last terms in Eqs. (38) and (43) are different, in principle, the velocity and slowness models derived using the two formulations should satisfy

$u(\mathbf{x}) = 1/v(\mathbf{x})$ . Let us consider this question for the block parameterization. To compute the derivative of travel time with respect to velocity we will use the following approximation

$$\frac{\partial t_{ij}}{\partial v_k} \approx \frac{\partial t_{ijk}}{\partial v_k} \quad (44)$$

[85], where the subscripts in  $t$  are used to identify the rays and blocks involved. The meaning of this relation is that the change in travel time along a ray path due to a change in the velocity of a given block is approximately equal to the change in travel time in that block. Note that

$$t_{ijk} = \frac{l_{ijk}}{v_k} \quad (45)$$

which allows us to write

$$\frac{\partial t_{ij}}{\partial v_k} dv_k \approx l_{ijk} \left( -\frac{1}{v_k^2} dv_k \right) \equiv l_{ijk} du_k. \quad (46)$$

Using this result we see that Eqs. (38) and (43) are identical, which means that the two formulations should give the same results as long as the block structure is the same in the two cases and the approximations introduced are valid. Of course, the numerical implementation of the software corresponding to the two approaches should be the same.

### Decoupling of the Earthquake Location and Tomography Problems

Equation (38) can be written in matrix form as:

$$\mathbf{W}_j \mathbf{A}_j dx_j + \mathbf{W}_j \mathbf{B}_j dv = \mathbf{W}_j \mathbf{r}_j; \quad j = 1, M \quad (47)$$

where  $\mathbf{r}_j$  is the vector of residuals  $r_{ij}$ ,  $\mathbf{A}_j$  is an  $N_j \times 4$  matrix of partial derivatives of time with respect to origin time and hypocentral coordinates,  $dx_j$  is the vector of origin time and hypocenter adjustments,  $\mathbf{W}_j$  is an  $N_j \times N_j$  matrix of weights,  $\mathbf{B}_j$  is an  $N_j \times K$  matrix of partial derivatives of travel time with respect to velocities, and  $dv$  is a vector of  $K$  velocity adjustments. The matrix  $\mathbf{B}_j$  has zero entries for the blocks not traversed by any ray. The matrix  $\mathbf{W}_j$  has only one nonzero entry per row and column and is not necessarily diagonal because the ordering of stations for different earthquakes may not be always the same.

For Eq. (43) the matrix form is

$$\mathbf{W}_j \mathbf{A}_j dx_j + \mathbf{W}_j \mathbf{C}_j du = \mathbf{W}_j \mathbf{r}_j; \quad j = 1, M \quad (48)$$

with  $\mathbf{C}_j$  an  $N_j \times K$  matrix whose entries are raypath lengths in individual blocks and  $du$  is a vector of  $K$  slowness adjustments. All the other quantities are as in Eq. (47).

Clearly, Eqs. (47) and (48) are formally equivalent, which means that for the following discussion on how to solve them it is unnecessary to distinguish between velocity and slowness. For this reason, from now on we will refer exclusively to Eq. (47), with the understanding that the results below apply to Eq. (48) as well.

Equation (47) represents  $M$  systems of equations coupled through the common vector  $dv$ . Therefore, these systems could be combined, in principle, into a single system, but because its size could become computationally unmanageable, it is necessary to decouple the earthquake location part from the inversion part. A very efficient approach to do that is based on the singular value decomposition (SVD) of a matrix [110] and is known as the method of parameter separation. The following presentation is based on [119]. The SVD of an arbitrary  $n \times m$  matrix  $G$  is given by

$$G = U\Lambda V^T \tag{49}$$

(see, e. g., [3,46]) where the superscript T indicates matrix transposition,  $U$  and  $V$  are  $n \times n$  and  $m \times m$  matrices with columns given by the eigenvectors of  $GG^T$  and  $G^TG$ , respectively, and  $\Lambda$  is an  $n \times m$  matrix with diagonal elements equal to the singular values of  $G$  and off-diagonal elements equal to zero. The singular values are positive and equal to the square roots of the eigenvalues of  $GG^T$  and  $G^TG$ . The number of nonzero singular values, say  $p$ , cannot exceed the minimum of  $m$  and  $n$ . Matrices  $U$  and  $V$  are orthogonal, i. e.,

$$UU^T = I_n, \quad VV^T = I_m, \tag{50}$$

where  $I_n$  is the  $n \times n$  identity matrix. Let us assume that the singular values are sorted in nonincreasing order (i. e., largest first). Then, matrices  $U$  and  $V$  can be partitioned as follows:

$$U = (U_p \quad U_0), \quad V = (V_p \quad V_0) \tag{51}$$

where the subscripts  $p$  and  $0$  indicate that the columns of the matrices come from the eigenvectors corresponding to the nonzero and zero singular values, respectively. Partitioned matrices are discussed in, e. g., [103]. Matrix  $A$  can be partitioned in a similar way. Then, writing Eq. (49) in terms of these partitioned matrices gives

$$G = (U_p \quad U_0) \begin{pmatrix} A_p & O \\ O & O \end{pmatrix} \begin{pmatrix} V_p^T \\ V_0^T \end{pmatrix} = U_p A_p V_p^T \tag{52}$$

where  $A_p$  is the  $p \times p$  diagonal matrix having as elements the  $p$  nonzero singular values and  $O$  represents zero matrices of appropriate sizes. Using this result and

$$U_0^T U_p = O \tag{53}$$

which is a consequence of the fact that the columns of  $U$  are orthogonal to each other, we get the following important result

$$U_0^T G = U_0^T U_p A_p V_p^T = O. \tag{54}$$

To apply Eq. (54) to our problem we will use

$$G = W_j A_j = U_j A_j V_j^T \\ = (U_{jp} \quad U_{j0}) A_j (V_{jp} \quad V_{j0})^T = U_{jp} A_{jp} V_{jp}^T. \tag{55}$$

Because  $W_j A_j$  has four columns and at least as many rows,  $p \leq 4$ . If  $p < 4$ , this means that one or more of the columns of the matrix is a linear combination of the others and the location of the corresponding event cannot be determined uniquely. Events with  $p < 4$  should not be used in the inversion. Now multiply Eq. (47) by  $U_{j0}^T$  on the left and use the equivalent of Eq. (54) for the  $j$ th event. This gives

$$U_{j0}^T W_j B_j dv = U_{j0}^T W_j r_j; \quad j = 1, M. \tag{56}$$

Because  $A_j$  does not appear in Eq. (56), we have been able to decouple the velocity parameters from the earthquake parameters. Note, however, that this equation depends on  $A_j$  implicitly via  $U_{j0}$ , which means that location errors will translate into errors in  $U_{j0}$  and, thus, in  $dv$ .

To simplify the following discussion Eq. (56) will be rewritten as

$$\underbrace{B'_j}_{(N_j-4) \times K} \underbrace{dv}_{K \times 1} = \underbrace{r'_j}_{(N_j-4) \times 1}; \quad j = 1, M \tag{57}$$

with obvious expressions for the primed quantities. The sizes of the matrix and vectors involved are also indicated (assuming  $p = 4$ ). Equation (57) represents  $M$  systems of equations with the common unknown vector  $dv$  and can be written in compact form in terms of a partitioned matrix and vector

$$B dv = \rho \tag{58}$$

where

$$B = (B_1^T \ B_2^T \ \dots \ B_M^T)^T \tag{59}$$

and

$$\rho = (r_1^T \ r_2^T \ \dots \ r_M^T)^T. \tag{60}$$

Let  $N$  be the largest of the  $N_j$ . Then, matrix  $B$  has  $K$  columns and up to  $M \times (N - 4)$  rows, which means

that it may become very large. For example, there may be thousands of earthquakes, thousands of velocity parameters, and tens of stations, which means that how to solve Eq. (60) becomes an issue. If the size of the matrix and the computer resources allow it, a solution based on the use of the SVD would be convenient (see Sect. “**Solution of Ill-Posed Linear Problems**”). If this approach is not feasible, one can solve Eq. (60) by least squares, which requires solving

$$\mathbf{B}^T \mathbf{B} \, d\mathbf{v} = \mathbf{B}^T \boldsymbol{\rho} \quad (61)$$

which on account of Eqs. (59) and (60) becomes

$$\left( \sum_{j=1}^M \mathbf{B}'_j{}^T \mathbf{B}'_j \right) d\mathbf{v} = \sum_{j=1}^M \mathbf{B}'_j{}^T \mathbf{r}_j. \quad (62)$$

This approach however, may have two problems. One is that the resulting matrix may still be too large for the computer facilities available and the other is the possibility of numerical loss of precision due to the matrix multiplications. This second problem can be alleviated through the use of double precision, although at the expense of longer computer times. For these reasons, for large tomographic problems the ensuing linear systems are solved using iterative matrix solvers (see Subsect. “**Regularization Approach**”). Also note that Eq. (62) is not the result of the “accumulation” of individual equations  $\mathbf{B}'_j{}^T \mathbf{B}'_j d\mathbf{v} = \mathbf{B}'_j{}^T \mathbf{r}_j$ , as it is sometimes stated.

Once Eq. (58) has been solved, the earthquakes must be relocated. To do that Eq. (47) will be used, but to make the analysis more general it will be assumed that both  $P$  and  $S$  wave arrivals are available. Because the  $P$  wave arrivals are independent of the  $S$  wave velocity, and vice versa, we can write two pairs of equations similar to Eqs. (47) and (56), and to solve for  $d\mathbf{v}^P$  and  $d\mathbf{v}^S$ , where the superscripts identify the type of arrivals. After that is done we can write

$$\mathbf{W}_j^P \mathbf{A}_j^P d\mathbf{x}_j = \mathbf{W}_j^P \mathbf{r}_j^P - \mathbf{W}_j^P \mathbf{B}_j^P d\mathbf{v}^P; \quad j = 1, M \quad (63)$$

and

$$\mathbf{W}_j^S \mathbf{A}_j^S d\mathbf{x}_j = \mathbf{W}_j^S \mathbf{r}_j^S - \mathbf{W}_j^S \mathbf{B}_j^S d\mathbf{v}^S; \quad j = 1, M. \quad (64)$$

These two equations are coupled through the common vector  $d\mathbf{x}_j$  and can be written as a single equation as follows

$$\begin{pmatrix} \mathbf{W}_j^P \mathbf{A}_j^P \\ \mathbf{W}_j^S \mathbf{A}_j^S \end{pmatrix} d\mathbf{x}_j = \begin{pmatrix} \mathbf{W}_j^P \mathbf{r}_j^P - \mathbf{W}_j^P \mathbf{B}_j^P d\mathbf{v}^P \\ \mathbf{W}_j^S \mathbf{r}_j^S - \mathbf{W}_j^S \mathbf{B}_j^S d\mathbf{v}^S \end{pmatrix}; \quad j = 1, M. \quad (65)$$

[122]. The matrix on the left-hand side of this equation is small ( $2N \times 4$  at most) and can be solved using any of the standard methods. Once each  $d\mathbf{x}_j$  has been found, it is used to get new initial estimates of origin time and hypocentral estimates (equal to  $T_j + dT_j$ ,  $x_j + dx_j$  and so on). After updating the velocities (i. e., they become  $v_k + dv_k$ ) a new iteration is started. This iterative process is repeated until some stopping criterion is met. An early criterion [144] was based on the use the statistical  $F$  test. With this test it is possible to determine if the decrease in the sum of arrival time residuals squared from a given iteration to the next is statistically significant ([80] and references therein). A simpler, yet effective approach is to stop when the root-mean square of all the travel-time residuals reaches the expected value of the error in the data.

### Computation of Local Travel Times

The iterative determination of a 3-D velocity model and simultaneous determination of earthquake locations requires the availability of software for the computation of travel times in that type of models. The theoretical solution to this problem using ray theory was well known (see, e. g., [22,44,85,112], and references therein) at the time the seismic tomographic method began to be developed, but because exact ray tracing is a computationally time-consuming task, in most of the earlier tomographic codes approximate ray tracing methods were used. One of them was introduced by Thurber [144], and was based on the use of arcs of circles to approximate the ray paths connecting the source and station. Although the method was fast, its accuracy was questionable. For example, in [42] the weights of arrivals with epicentral distances between 20 and 45 km were decreased and arrivals with distances larger than 45 km were not used. Because this approximate method was popular, the readers of the earlier literature should be aware of the limitations of the method, which can result in errors in the computed velocities and in the locations determined with them.

A significant improvement to Thurber’s [144] method was introduced by Um and Thurber [152], who developed a method based on the perturbation of an initial raypath between the source and the station using a ray-theoretical equation. Ray tracing methods that find the raypath between two points by iterative perturbation of an initial estimate are known as *bending methods* (see, e. g., [75] and references therein). The Um and Thurber method is based on an approximate computation of the perturbations, and for this reason it is commonly referred to as a *pseudo-bending method*. However, one of the disadvantages of this method, noted by the authors, is that it is not appropriate

for use in media with velocity discontinuities and where nearly constant velocities are present. This method is included in a popular tomographic package, and these limitations should be taken into account when considering the results obtained using it. Pseudo-bending solutions that do not have the limitations of the Um and Thurber method exist [99,115], but their applications to seismic tomography appear to be limited. The Um and Thurber's method was used in combination with Snell's law to account for velocity discontinuities at the Conrad and Moho boundaries and the upper boundary of subducting plates [163], but these boundaries must be known from other studies.

An early example of tomography with exact ray tracing can be found in [61]. In this case the ray tracing problem was solved by Runge–Kutta integration of six simultaneous differential equations that can be derived from the eikonal equation. This approach corresponds to the *shooting method*, which requires the specification of the two angles at the source that define a ray. These two angles must be changed until the end point is within a specified distance from the station. This approach does not introduce any approximations (beyond those inherent to ray theory), but, as already noted, is more time consuming than the approximate methods. The software based on this approach was later improved [14] by incorporation of the method of parameter separation described in Subsect. “**Decoupling of the Earthquake Location and Tomography Problems**”. This software was applied to the 1989,  $M = 7.1$ , Loma Prieta, California, mainshock-aftershock sequence [116]. Another example of tomography with exact ray tracing [79] is based on the division of the earth into constant-velocity blocks and ray tracing based on the use of Snell's law.

A different kind of approach to the computation of travel times, which does not require ray tracing, was introduced by Vidale [157,158]. In his method, the velocity model consists of a set of values assigned to points in a regular equispaced 2-D or 3-D grid and travel times are computed using a finite-difference approximation to the partial derivatives of travel times with respect to the spatial coordinates and plane or circular wavefront approximations. It must be noted, however, that the eikonal equation is not solved using the classical finite-difference method, which is not a simple task and is seldomly used [21]. The output of Vidale's method is a series of wavefronts of minimum travel times. This method is more time consuming than the approximate methods referred to above and has some problems when large velocity contrasts are present. Moreover, the approximations involved may not be adequate in the vicinity of the source, where the wavefronts are highly curved [21]. Vidale's method has been imple-

mented in software for earthquake location in media with 3-D variations [102].

Vidale's [157,158] approach motivated a method developed by Podvin and Lecomte [113], who used Huygens's principle for the computation of travel times. The application of the principle is equivalent to the propagation of local wavefronts, which is done as follows. Let us assume that the four vertices of one of the sides of a unit cube in the grid have known arrival times. These points can be combined into four groups of three adjacent points. Each group defines a plane wavefront, which is used to compute the arrival time at each of the other four corners of the same cube. The selection of the appropriate local wavefront follows a set of pre-established rules. In addition, each point within the grid is the common vertex of eight unit cubes around it. These cubes form a larger cube with the grid point at its center and each side contributes sixteen local wavefronts. Therefore, for each grid point within the grid, ninety-six wavefronts must be considered. The advantage of this approach is that it accounts for the existence of transmitted, diffracted, and head waves and performs well even in the presence of large velocity contrasts. The computations can be carried out in parallel in a multiprocessor machine or sequentially when only one processor is used. In the latter case the method becomes computationally very time consuming, but its implementation in a tomographic software package [15] has resulted in highly detailed velocity models. Examples are given in Sect. “**Examples**”. Podvin and Lecomte's software is becoming very popular and for this reason it is worth noting that the software has a minor flaw that results in time differences for rays moving equal distances to the left and right of the source [151]. For example, for a 0.5 km grid size and source-receiver offsets up to 30 km the difference is between about 0.03 and 0.04 s, with the larger values for offsets less than 10 km. Decreasing the grid size reduces the error.

The two wavefront methods referred to above do not compute raypaths directly. However, in seismic tomography they are needed to associate arrival time residuals with specific velocity grid points. In Podvin and Lecomte's software, rays are traced from the receiver to the source following a direction opposite to the time gradient, with the endpoint of the ray at most a distance  $h$  from the source, where  $h$  is the grid spacing. Recall that in isotropic media rays are defined as curves whose tangents are everywhere perpendicular to a wavefront (see, e. g., [69,120]).

There is yet another approach to the computation of travel times, namely, the shortest-path method, which is based on concepts borrowed from network theory. In this approach the velocity model is also based on a grid

of points and connections are established between close points. Each connection is given a weight, equal to the travel time between them. The shortest path between any two points is that along the connections for which the sum of the weights is smallest. This path is an approximation to the seismic raypath. This method was introduced in seismology in [101] and was further developed in [98]. Additional references can be found in, e. g., [9,21], and [147]. Applications to seismic tomography and 3-D earthquake location can be found in [7,8] and [100], respectively.

To end this section we note that the methods considered here assume a Cartesian coordinate system, so that the curvature of the earth is ignored, i. e., the earth is assumed to be flat. This assumption, however, has limitations (see, e. g., [125,134]), which should be taken into account when dealing with epicentral distances that exceed about 150–200 km. This range is provided as guide only. For a given epicentral distance, the error in travel time generally increases with hypocentral depth. For example, for a depth of 200 km and an epicentral distance of 2° the error is about 0.25 s [125]. When the errors introduced by ignoring the earth's curvature become important (e. g., larger than the arrival-time picking errors) it is advisable to introduce a cut-off epicentral distance beyond which the arrival times are either not used or weighted down (see, e. g. [78] and Subsect. “*P and S Wave Velocity Models for Taiwan*”).

### Teleseismic Tomography

The data most commonly used in teleseismic tomographic studies are *P* wave arrivals for the investigation of the mantle and *PcP* and *PKP* arrivals for the investigation of the core-mantle boundary (see, e. g. [96]), although other arrivals have also been used. A major source for the data is the International Seismological Center, which has collected millions of arrivals contributed by hundreds of stations around the world. Although it is possible to perform a simultaneous event location and velocity determination following a formulation similar to that described for local tomography (see, e. g. [137]), the most common approach is to keep the event locations fixed. This is the approach to be describe here.

The use of teleseismic data to determine a 3-D velocity model of the crust and upper mantle underneath a seismic array was introduced by Aki et al. [4]. They divided the portion of the earth being investigated into homogeneous horizontal layers subdivided into blocks, computed the theoretical arrival times for earthquakes having published locations, formed arrival time residuals, and solved for slowness perturbations in each of the blocks with re-

spect to a model with constant slowness in each layer. A simplified version of the arguments presented in [4] follows. Let  $u_k$  and  $u_k^o$  be the actual and reference slowness of block  $k$  and let  $m_k$  be the fractional slowness perturbation, equal to

$$m_k = \frac{u_k - u_k^o}{u_k^o} \equiv \frac{du_k}{u_k^o} \quad (66)$$

where  $du_k$  is equivalent to the  $du$  in Eq. (40) and is assumed to be much smaller than  $u_k$ . Solving for  $u_k$  we get

$$u_k = u_k^o(1 + m_k). \quad (67)$$

Given a particular earthquake-station pair, the actual travel time in the  $k$ th block traveled by the corresponding ray is given by

$$t_k = l_k u_k = l_k u_k^o(1 + m_k) \approx t_k^o + t_k^o m_k \quad (68)$$

where  $l_k$  is the actual length of the ray in the  $k$ th block and the approximate sign arises because the actual path and the path in the reference medium are assumed to be close on account of Fermat's principle. Then, the difference in travel time introduced by the slowness perturbation  $m_k$  is given by

$$dt_k = t_k - t_k^o \approx t_k^o m_k. \quad (69)$$

Introducing the right-hand side of Eq. (66) in this expression gives

$$t_k \approx \frac{t_k^o}{u_k^o} du_k = l_k^o du_k \quad (70)$$

where  $l_k^o$  is the raypath length in the  $k$ th block for the reference model. The right-hand side of this expression is equivalent to  $l_{ijk} du_k$  in Eq. (43).

Let us consider the arrival time residual that arises when using teleseismic data and the earthquake locations used are those determined with the reference slowness model. Using the notation introduced earlier we can write

$$r_{ij} = \delta t_j + \sum_k l_{ijk}^o du_k \quad (71)$$

where the subscripts  $i$  and  $j$  denote station and event, and the sum is over all the blocks. A block not traversed by any ray will have the corresponding  $l_{ijk}^o$  equal to zero. The term  $\delta t_j$  includes the contributions to the residuals not accounted for by the second term. For example,  $\delta t_j$  includes errors in event origin time and location, picking errors, possible errors in the reference slowness model outside of the volume investigated, and possible errors in the model

parameterization. This  $\delta t_j$  is unknown, but because it is assumed to be effectively constant for a given earthquake, it can be eliminated by averaging  $r_{ij}$  over all the stations that recorded the  $j$ th event and subtracting the result from Eq. (71). The average residual is given by

$$\overline{r_{ij}} = \frac{1}{N_j} \sum_{i=1}^{N_j} r_{ij} = \delta t_j + \sum_k \overline{l_{ijk}^o} du_k \quad (72)$$

where the overbar indicates average, as defined by the first equality. Next, subtracting Eq. (72) from Eq. (71) gives the relative residual

$$r'_{ij} = r_{ij} - \overline{r_{ij}} = \sum_k \left( l_{ijk}^o - \overline{l_{ijk}^o} \right) du_k. \quad (73)$$

A similar result can be found in [3]. This equation shows that the slowness perturbations  $du_k$  are obtained by solving a linear system, as expected, and that the main difference with Eq. (43) is the presence of source terms in the latter (aside from a weight factor). Once Eq. (73) is solved, the perturbations are added to the reference slownesses and the tomographic problem is solved. It is important to note however, that the resulting model is not well resolved vertically. In fact, the effect of a uniform perturbation over a layer cannot be distinguished from a change in  $\delta t_j$ . This problem is intrinsic to the method and cannot be removed [3]. Examples showing the capabilities and limitations of the method can be found in [45]. A potentially severe limitation is the effect introduced by the presence of large sedimentary basins, which usually have significantly smaller velocities than the surrounding rocks. These basins may introduce travel time anomalies as large as the upper mantle residuals [93]. Clearly, the tomographic results will be incorrect if the arrival times are not corrected for large crustal effects, which requires information derived independently (see, e. g., [93,131]).

### Solution of Ill-Posed Linear Problems

Regardless of the type of arrivals considered, the tomographic problem reduces to the solution of equations of the form

$$\mathbf{Ax} = \mathbf{b} \quad (74)$$

where  $\mathbf{A}$  is a known  $m \times n$  matrix with information about the model,  $\mathbf{x}$  is an  $n$  vector of unknowns, and  $\mathbf{b}$  is a known  $m$  vector. Solving this problem requires consideration of the question of the existence of a solution, but before proceeding it is convenient to introduce the following definition, due to the French mathematician Hadamard

(see, e. g., [47,53], and references therein). The problem represented by Eq. (74) is said to be *well posed* if it has a solution, it is unique, and depends continuously on  $\mathbf{b}$ . The latest condition means that small changes in  $\mathbf{b}$  cause small changes in  $\mathbf{x}$ . When any of these conditions is not satisfied the problem is said to be *ill posed*. For a unique solution of Eq. (74) to exist a necessary (but not sufficient) condition is that  $m \geq n$ . If  $m > n$ , the system is said to be *overdetermined*. It must be noted, however that this condition (to be assumed here) does not imply that a solution exists, or that it is unique (if it exists). For example, if some of the rows of  $\mathbf{A}$  constitute a linearly dependent set (e. g., some of them are linear combinations of other rows) a solution may exist but it will not be unique. On the other hand, a solution may not exist at all. In this case the system is said to be *inconsistent*, a condition that in seismic tomography arises because of errors in both the data and the model. The magnitude of the data errors depend on arrival type. Teleseismic data generally have larger errors than local data, while local S wave arrivals have larger errors than the corresponding P arrivals because they are more difficult to identify. Model errors arise because the parameterization of the velocity (or slowness) field does not reproduce the actual variations appropriately. Although a more faithful representation of the earth would be advantageous, an obvious problem is that the data may not be adequate to resolve the parameters of a more detailed model. Clearly, if the block size or grid spacing used to parameterize the velocity (or slowness) field are too small with respect to the interstation spacing, and the spatial distribution of the seismic sources is not favorable, then a large number of blocks may not be traversed by any ray, and matrix  $\mathbf{A}$  will be very large with a large number of zero entries (i. e., the matrix is said to be *sparse*). For a given set of arrival times, an increase in the number of unknown parameters results in a relative decrease in the number of constraints, and in the resolution of the solution (see below).

A very powerful tool for the solution of the system (74) is provided by the Moore–Penrose generalized inverse  $\mathbf{A}^\dagger$  of  $\mathbf{A}$ . Let  $\mathbf{A}$  have  $p$  nonzero singular values, sorted by decreasing order. Then, using the SVD (see Eq. (49))

$$\mathbf{A}^\dagger = \mathbf{VA}^\dagger \mathbf{U}^T = \mathbf{V}_p \mathbf{A}_p^{-1} \mathbf{U}_p^T \quad (75)$$

where  $(\mathbf{A}^\dagger)_{ii}$  is equal to  $1/\lambda_i$  if  $\lambda_i \neq 0$  and zero otherwise [3,111]. The second equality follows from the product of partitioned matrices. The generalized inverse solution is given by

$$\mathbf{x}^\dagger = \mathbf{A}^\dagger \mathbf{b} \quad (76)$$

which has the property that is a minimum-length solution (see, e. g., [3]). A more general solution is of the form

$$\mathbf{x} = \mathbf{x}^\dagger + \mathbf{z} \tag{77}$$

where

$$\mathbf{A}\mathbf{z} = \mathbf{0}. \tag{78}$$

The vectors  $\mathbf{z}$  that satisfy Eq. (78) constitute the *null space* of  $\mathbf{A}$ . The column vectors of  $\mathbf{A}$  corresponding to the zero singular value satisfy an equation similar to Eq. (78) and constitute a base for the null space of  $\mathbf{A}$ . Therefore,  $\mathbf{z}$  is a linear combination of the columns of the matrix  $\mathbf{V}_o$ .

The definition of  $\mathbf{A}^\dagger$  is based on a sharp distinction between zero and nonzero singular values. In practice, however, this clear-cut situation does not occur, with some of them nonzero yet much smaller than the largest one. In this case the solution of Eq. (76) may be strongly affected by errors in the data. This question is made more precise when the condition number,  $\kappa$ , of  $\mathbf{A}$  is introduced

$$\kappa = \frac{\lambda_{\text{largest}}}{\lambda_{\text{smallest}}} \geq 1. \tag{79}$$

Then, a perturbation  $d\mathbf{b}$  (such as errors) in the data introduces a perturbation  $d\mathbf{x}$  in the solution that satisfies

$$\frac{|d\mathbf{x}|}{|\mathbf{x} + d\mathbf{x}|} \leq \kappa \frac{|d\mathbf{b}|}{|\mathbf{b} + d\mathbf{b}|} \tag{80}$$

(e. g., [46,49]). Therefore, when  $\kappa$  is large a small change in the data may cause a significant change in the solution. If  $\kappa$  is large the matrix is said to be *ill-conditioned*; otherwise it is said to be *well-conditioned*. Although the terms “large” and “small” are obviously vague, the idea is not. For example, for a given data set and two velocity models leading to matrices  $\mathbf{A}$  having condition numbers that differ by a factor of say 10, the matrix with the larger  $\kappa$  may lead to a solution more affected by the errors in the data.

In the following, ill-conditioned problems will be considered a form of ill-posed problems and the distinction between the two will no longer be made. The question that must be addressed now is how to solve this type of problems. Two approaches are available, one based on the so-called regularization of the problem and the other based on the Bayesian statistics. The two approaches are discussed in detail below.

### Regularization Approach

As noted above, tomographic problems are likely to be ill-posed, and to get a solution it is necessary to recourse to mathematical techniques that turn them well-posed. This process is known as regularization (see,

e. g., [53,55,80,148,164]). The reader must be aware, however, that there is a price to be paid; namely one ends up with a family of solutions and to objectively select the most appropriate among them may not be easy or even possible. For a system with a matrix for which the computation of its singular value decomposition is practically feasible, the generalized inverse solution has several advantages, but for most tomographic problems the size of the matrices involved is so large that this option is not practical and will not be pursued here. Instead, we will discuss techniques that lead to systems that can be solved with computationally efficient methods.

Before proceeding we will introduce the following definitions. A square symmetric matrix  $\mathbf{C}$  is said to be *positive semidefinite* if

$$\mathbf{y}^T \mathbf{C} \mathbf{y} \geq 0; \quad \mathbf{y} \neq \mathbf{0}. \tag{81}$$

The matrix  $\mathbf{C}$  is *positive definite* if the  $\geq$  sign in Eq. (81) is replaced by  $>$ .

Let us summarize some of the properties of these matrices (see, e. g., [121]).

- (1) Let  $\mathbf{v}_i$  be an eigenvector of  $\mathbf{C}$  and  $\lambda_i$  its corresponding eigenvalue. Then

$$\mathbf{v}_i^T \mathbf{C} \mathbf{v}_i = \lambda_i \mathbf{v}_i^T \mathbf{v}_i = \lambda_i |\mathbf{v}_i|^2. \tag{82}$$

Because  $|\mathbf{v}_i| > 0$ ,  $\lambda_i \geq 0$  if  $\mathbf{C}$  is positive semidefinite, and  $\lambda_i > 0$  if  $\mathbf{C}$  is positive definite. In the second case the inverse of  $\mathbf{C}$  exists because  $\mathbf{C} = \mathbf{U}\mathbf{A}\mathbf{U}^T$ , with  $\mathbf{U}$  and  $\mathbf{A}$  similar to those in Eq. (49) and Eq. (50) (see, e. g., [103]), and  $\mathbf{C}^{-1} = \mathbf{U}\mathbf{A}^{-1}\mathbf{U}^T$ .

- (2) Any matrix of the form  $\mathbf{B}^T \mathbf{B}$  is either positive definite or semidefinite. Consider

$$\mathbf{y}^T (\mathbf{B}^T \mathbf{B}) \mathbf{y} = (\mathbf{B} \mathbf{y})^T \mathbf{B} \mathbf{y} = |\mathbf{B} \mathbf{y}|^2 \geq 0; \quad \mathbf{y} \neq \mathbf{0}. \tag{83}$$

Therefore,  $\mathbf{B}^T \mathbf{B}$  is at least positive semidefinite. In addition, if the inverse of this matrix exists, all of its eigenvalues will be positive and  $\mathbf{B}^T \mathbf{B}$  will be positive definite. If the inverse does not exist, the matrix will be positive semidefinite.

- (3) Let  $\mathbf{C}$  be a diagonal matrix with positive diagonal elements. Then  $\mathbf{C}$  is positive definite because

$$\mathbf{y}^T \mathbf{C} \mathbf{y} = \sum_i c_i y_i^2 > 0; \quad \mathbf{y} \neq \mathbf{0}, \quad c_i = (\mathbf{C})_{ii} > 0. \tag{84}$$

- (4) Let matrices  $\mathbf{B}$  and  $\mathbf{P}$  be positive semidefinite and definite, respectively, and let  $\lambda^2$  be a scalar. Then  $\mathbf{B} + \lambda^2 \mathbf{P}$  is positive definite because

$$\mathbf{y}^T (\mathbf{B} + \lambda^2 \mathbf{P}) \mathbf{y} = \mathbf{y}^T \mathbf{B} \mathbf{y} + \lambda^2 \mathbf{y}^T \mathbf{P} \mathbf{y} > 0; \quad \mathbf{y} \neq \mathbf{0}. \tag{85}$$

These results will be used to show that the typical methods of solution of Eq. (74) when  $\mathbf{A}^{-1}$  does not exist or is ill-conditioned are based on the solution of a new well-posed problem.

The simplest regularization approach is to constrain (in some sense) the length of the solution vector  $\mathbf{x}$ . Let us consider the minimization of the function

$$\bar{S}(\mathbf{x}) = w|\mathbf{Ax} - \mathbf{b}|^2 + \mathbf{x}^T \mathbf{D} \mathbf{x} \equiv wS(\mathbf{x}) + Q(\mathbf{x}) \quad (86)$$

with respect to  $\mathbf{x}$ . Here  $w$  is a positive weighting factor,  $\mathbf{D}$  is a symmetric positive definite matrix, and  $S$  and  $Q$  are defined by the identity. This problem was solved by Levenberg [87] and a similar one by Marquardt (who used  $\mathbf{D} = \mathbf{I}$ ) [92] in the context of non-linear problems. The minimization of  $\bar{S}$  leads to the following equation

$$(\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{D}) \mathbf{x} = \mathbf{A}^T \mathbf{b}; \quad \lambda^2 = \frac{1}{w} \quad (87)$$

(see, e.g., [121]). A similar equation was introduced by Tihonov [148], who investigated the regularization of ill-posed linear problems in the context of integral equations. The  $\mathbf{x}$  that solves Eq. (87) is known as the *damped least-squares estimator*. When  $\lambda^2 = 0$ , Eq. (87) corresponds to the *ordinary* least-squares solution.

Note that Eq. (87) is a special case of Eq. (85) with  $\mathbf{B} = \mathbf{A}^T \mathbf{A}$  and  $\mathbf{P} = \mathbf{D}$ , which means that there is a value of  $\lambda^2$  that makes the matrix on the left side of Eq. (87) well conditioned. Therefore, for a given  $\mathbf{D}$ , Eq. (87) will have a family of solutions, which will depend on  $\lambda^2$ . A problem with this equation, however, is that it may be too large for tomographic problems. For this reason, Eq. (87) will be derived by consideration of the following system

$$\begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{D}^{1/2} \end{pmatrix} \mathbf{x} = \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix}. \quad (88)$$

This new system will be solved using ordinary least squares, which requires solving

$$(\mathbf{A}^T \quad \lambda \mathbf{D}^{1/2}) \begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{D}^{1/2} \end{pmatrix} \mathbf{x} = (\mathbf{A}^T \quad \lambda \mathbf{D}^{1/2}) \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix} \quad (89)$$

where  $\mathbf{D}^{1/2}$  is known as the square root of  $\mathbf{D}$  (see, e.g., [121]). After performing the matrix multiplications we obtain Eq. (87), which shows that the minimization of  $\bar{S}(\mathbf{x})$  is equivalent to solving Eq. (74) under the constraint

$$\lambda \mathbf{D}^{1/2} \mathbf{x} = \mathbf{0}. \quad (90)$$

Clearly, the  $\lambda$  in this equation is unnecessary, but it is introduced to indicate that it is a weighting factor. We also note that in many applications  $\mathbf{D} = \mathbf{I}$ .

Let us mention some of the properties of the damped least-squares solution in the context of nonlinear linearized inverse problems. This type of problems require an initial estimate of the solution, say  $\mathbf{x}_0$ . If this estimate is poorly chosen, it may lead to a non-convergent iterative process, and for this reason Levenberg [87] decided to minimize  $\bar{S}$ . Moreover, when dealing with linearized problems,  $S$  is the linearized version of the true residuals. Let  $s$  represent the sum of residuals whose linearization leads to  $S$ . A question investigated by Levenberg [87] regards the relations between  $\bar{S}$ ,  $S$  and  $s$ , and between the damped and ordinary least-squares solutions, indicated by  $\mathbf{x}_\lambda$  and  $\mathbf{x}^{ls}$ , respectively. Some of his results are as follows:

$$S(\mathbf{x}_\lambda) < S(\mathbf{x}_0) \quad (91)$$

$$Q(\mathbf{x}_\lambda) < Q(\mathbf{x}^{ls}) \quad (92)$$

and

$$s(\mathbf{x}_\lambda) < s(\mathbf{x}_0) \quad \text{for some } \lambda^2 \quad (93)$$

as long as  $\mathbf{x}_0$  is not a stationary point of  $s$  [87,121]. Equations (91) and (92) show that it is possible to simultaneously minimize  $S$  and  $Q$  for all  $\lambda^2$ , while Eq. (93) shows that there are values of  $\lambda^2$  that minimize  $s$ , which is the quantity of actual interest to us. Although none of these results is obvious, they are implicitly assumed when solving linearized problems. In addition, if  $\lambda^2$  is large enough, Eq. (87) becomes

$$\mathbf{x} \approx \frac{1}{\lambda^2} \mathbf{D}^{-1} \mathbf{A}^T \mathbf{b} \quad (94)$$

with  $\mathbf{x}$  going to zero as  $\lambda^2$  goes to infinity. Therefore, when solving linearized nonlinear problems  $\lambda^2$  should be relatively large in the early iterations, so that  $\mathbf{x}$  is small enough to assure convergence to a solution. Then, as the iterations proceed the value of  $\lambda^2$  should be decreased gradually until it reaches its regularization value.

Another regularization approach is to limit the ‘‘roughness’’ of the solution by constraining its Laplacian to be equal to zero ([86] and references therein). This constraint can be introduced by writing the Laplacian using a finite-difference approximation

$$6x_{i,j,k} - (x_{i-1,j,k} + x_{i+1,j,k} + x_{i,j-1,k} + x_{i,j+1,k} + x_{i,j,k-1} + x_{i,j,k+1}) = 0 \quad (95)$$

where  $x_{i,j,k}$  is the value of  $\mathbf{x}$  at a grid point (identified by the three indices) and  $x_{i\pm 1,j,k}$ ,  $x_{i,j\pm 1,k}$ , and  $x_{i,j,k\pm 1}$  are the values of  $\mathbf{x}$  at adjacent points. This 3-D constraint is

used in [15]. Equation (95) must be translated into a matrix form, which will depend on the number of grid points in the three dimensions. Let  $\mathbf{L}$  indicate this matrix. Then, the constrained system becomes

$$\begin{pmatrix} \mathbf{A} \\ \lambda \mathbf{L} \end{pmatrix} \mathbf{x} = \begin{pmatrix} \mathbf{b} \\ \mathbf{0} \end{pmatrix}. \quad (96)$$

To solve this new system by ordinary least squares we must write an expression similar to Eq. (89), which in turn gives

$$(\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{L}^T \mathbf{L}) \mathbf{x} = \mathbf{A}^T \mathbf{b}. \quad (97)$$

In general,  $\mathbf{L}$  is positive definite (see, e. g., [5,114]) and so is  $\mathbf{L}^T \mathbf{L}$ , which means that this approach also leads to a well-conditioned system.

In practice, Eqs. (88) and (96) can be solved using methods that compute the solution iteratively, such as the ART, SIRT, and LSQR methods. As noted earlier, ART is affected by noise in the data, while SIRT has the disadvantage that it introduces an unwanted scaling of the problem. This question will not be discussed here, but it should be noted that the term SIRT does not refer to a single technique; rather it refers to a family of iterative methods based on ideas similar to those described in [48]. The earlier application to geophysical problems is described in [39], but the algorithm used there was equivalent to the solution of a problem that was a scaled version of the original one, i. e., an equation similar to Eq. (58) is multiplied by a certain diagonal matrix which is not controlled by the user [73]. A similar problem affects the original SIRT formulation [63]. A general discussion of this question can be found in [154]. The LSQR method [108] was introduced in seismology by Nolet ([104] and references therein), does not have the problems that affect ART and SIRT, and is very well suited for the tomographic method because the matrices involved are highly sparse, which helps speed the computations considerably. For these reasons, the LSQR method is used widely used in seismic tomography (see, e. g., [15,86,163]).

So far we have not discussed how the parameter  $\lambda^2$  should be chosen. This question does not have a definite answer. In their discussion of the damped least-squares method, Lawson and Hanson [83] plotted the norm (i. e. length) of the solution vector versus the norm of the vector of residuals obtained for different values of the damping parameter and noted (for specific examples) that the resulting curve had an approximate L shape. The optimal value of the damping parameter was that corresponding to the corner of the curve at which it goes from nearly vertical to nearly horizontal. The idea here is to minimize both the residual and the length of the solution. This approach

is discussed further in [55] and [56], where the logarithms of the two norms, rather than the norms themselves, are used. A somewhat related approach is based on the plot of the data variance versus the solution variance [42]. A recent example of choice of damping parameter motivated by this latter approach is provided in [78].

We end this section with the definition of *resolution*. Regardless of how Eq. (74) is solved, we can write

$$\hat{\mathbf{x}} = \hat{\mathbf{A}} \mathbf{b} \quad (98)$$

where  $\hat{\mathbf{A}}$  can be considered the inverse, in some sense, of  $\mathbf{A}$ . Now write  $\mathbf{b}$  using Eq. (74). This gives

$$\hat{\mathbf{x}} = \hat{\mathbf{A}} \mathbf{A} \mathbf{x} \equiv \mathbf{R} \mathbf{x} \quad (99)$$

where  $\mathbf{R}$  is known as the resolution matrix (see, e. g., [3]) and is defined by the identity. If  $\mathbf{R} = \mathbf{I}$ ,  $\hat{\mathbf{x}} = \mathbf{x}$ . If  $\mathbf{A}$  were known perfectly well, this result would imply that the solution vector  $\hat{\mathbf{x}}$  is exactly equal to the true solution. In practice, in seismic tomography  $\mathbf{A}$  is only poorly known, and even if  $\mathbf{R} = \mathbf{I}$  there is no reason to say that  $\hat{\mathbf{x}}$  represents the true solution, as sometimes stated. To see that, consider an extreme case. Let us suppose that a velocity model consists of just one block. In this case  $\mathbf{A}$  will have only one column and will be well conditioned, which means that the corresponding Eq. (74) can be solved by least squares. The resulting resolution matrix will be equal to  $\mathbf{I}$ , but it is obvious that the computed solution will not correspond to the true velocity of the earth (except in the unlikely case that the velocity is a constant). If the number of blocks is gradually increased to make the model more realistic, at some point  $\mathbf{A}$  will become ill-posed and a regularized solution must be introduced. In this case from Eq. (87) we get

$$\hat{\mathbf{A}} = (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{D})^{-1} \mathbf{A}^T \quad (100)$$

and

$$\mathbf{R} = (\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{D})^{-1} \mathbf{A}^T \mathbf{A} = \frac{\mathbf{A}^T \mathbf{A}}{\mathbf{A}^T \mathbf{A} + \lambda^2 \mathbf{D}} \neq \mathbf{I} \quad \text{for } \lambda^2 \neq 0. \quad (101)$$

Here  $\mathbf{R}$  was written as a ratio for visual purposes only. Note that  $\mathbf{R}$  is not equal to  $\mathbf{I}$  when  $\lambda^2 = 0$  unless  $(\mathbf{A}^T \mathbf{A})^{-1}$  exists. On the other hand, from Eq. (85) we know that the inverse of the matrix in parentheses always exists because  $\mathbf{D}$  is assumed to be positive definite.

Now consider the implications of a resolution matrix not equal to the identity. Using Eq. (98) we can write the  $i$ th component of the solution vector as

$$\hat{x}_i = \sum_k R_{ik} x_k, \quad (102)$$

so that  $\hat{x}_i$  is equal to a linear combination of some of the components of  $\mathbf{x}$ , not to  $x_i$  (as would be the case if  $\mathbf{R} = \mathbf{I}$ ). This result can be interpreted as follows. As the number of parameters in a velocity model is increased (e. g., the number of blocks is increased), it is expected that it will become a more realistic representation of the actual velocity variations in the earth. However, the available data do not allow the determination of individual values of the parameters; only average values can be computed. We may summarize this situation by saying that in geophysics, as in economics, “there is no such thing as a free lunch”. Note that  $\mathbf{R}$  does not depend on the the data. Rather, it is controlled by the distribution of stations and seismic sources. Seismologists have some control on the former (within financial and logistic limits), but not on the latter, which places a strong constraint on the resolution that can be achieved in any given case. The Bayesian approach discussed below is an attempt to circumvent this intrinsic limit.

The computation of the resolution matrix when the number of velocity parameters is very large is computationally too expensive, and in such cases the resolution is estimated using synthetic arrival times using velocity models with simple patterns. An early approach [52] was based on the use of several high velocity areas extending through the whole model depth embedded in a constant velocity medium. The synthetic data were computed using the data raypaths and inverted as the actual data. Comparison of the model obtained by inversion with the model used to generate the synthetic data gives an idea of the resolving capabilities of the distribution of sources and receivers used. In a similar approach, synthetic data were generated for a checkerboard model with alternating positive and negative velocities in three dimensions [72]. In another variation only two blocks of the model had velocities different from those of the rest of the blocks [70]. The checkerboard approach has become very popular, but in principle, other synthetic data sets can be used (see Sect. “Examples”).

Finally, let us note that in addition to its mathematical definition, the term resolution is generally used (i. e., not only in seismology) to indicate level of detail. For example, given two images of the same physical object acquired using different instruments, the one showing more detail is said to have more resolution. The same idea applies to velocity models, and it is not uncommon to see references in the literature to high- or low-resolution models. These terms are useful in a qualitative way, and may not be directly related to what one would call high or low in a mathematical sense. In fact,  $\mathbf{R}$  can be made closer (and even equal) to  $\mathbf{I}$  by decreasing the number of parameters (see, e. g., [74]), which by itself will decrease the level of detail in

the model. For example, if a number of blocks in a model is replaced by a single block occupying the same volume, the velocity in the larger block will be the average (in some sense) of the velocities in the smaller blocks. As a consequence, if the small-block velocities are significantly different, the model based on the larger blocks would have lost detail and, thus, will have less resolution, although mathematically it may be larger.

### Bayesian Approach

This approach is based on probability considerations, and to discuss it we need a few basic definitions and results, based on [130]. Let  $X$  and  $Y$  be random variables and  $x$  and  $y$  be elements of a discrete set of real values. Also let  $P_X(x)$  be the probability that the event “ $X = x$ ” occurs and  $P_{X,Y}(x, y)$  be the probability that the event “ $X = x$  and  $Y = y$ ” occurs. Then the *conditional probability* that the event “ $Y = y$ ” occurs given that the event “ $X = x$ ” has occurred is given by

$$P_{Y|X}(y|x) = \frac{P_{X,Y}(x, y)}{P_X(x)}. \quad (103)$$

Similarly,

$$P_{X|Y}(x|y) = \frac{P_{X,Y}(x, y)}{P_Y(y)}. \quad (104)$$

These two equations can be combined by elimination of the common factor, giving

$$P_{X|Y}(x|y) = \frac{P_{Y|X}(y|x)P_X(x)}{P_Y(y)}. \quad (105)$$

This result is known as *Bayes’ theorem* (or rule).

When the random variables can take on values defined over a continuous interval, which is the case of interest to us, the following definitions are introduced.

(a) *Probability distribution function*  $F_X(x)$ :

$$F_X(x) = P(-\infty < X \leq x) \quad (106)$$

where  $P$  indicates the probability of the event in parentheses.

(b) *Probability density function*  $p_X(x)$ :

$$p_X(x) = \frac{dF_X(x)}{dx}. \quad (107)$$

From Eq. (107) it follows that

$$F_X(x) = \int_{-\infty}^x p_X(a) da. \quad (108)$$

A well known example of probability density function (or pdf, for short) is the Gaussian pdf, introduced below.

The definitions given above are for a single random function. When dealing with a number of them it is convenient to introduce a vector notation. For the case of  $n$  random variables  $X_1, X_2, \dots, X_n$ , we have the following two definitions

$$p_{\mathbf{X}}(\mathbf{x}) = p_{X_1, X_2, \dots, X_n}(x_1, x_2, \dots, x_n) \quad (109)$$

and

$$F_{\mathbf{X}}(\mathbf{x}) = \int_{-\infty}^{\mathbf{x}} p_{\mathbf{X}}(\mathbf{a}) d\mathbf{a} \quad (110)$$

where the subscript in  $p_{\mathbf{X}}$  and  $F_{\mathbf{X}}$  is the vector  $\mathbf{X} = (X_1 X_2 \dots X_n)^T$ , the integral symbol represents an  $n$ -fold integral, and  $d\mathbf{a} = da_1 da_2 \dots da_n$ . Then

$$p_{\mathbf{X}}(\mathbf{x}) = \frac{\partial^n F_{\mathbf{X}}(\mathbf{x})}{\partial x_1 \partial x_2 \dots \partial x_n} \quad (111)$$

and

$$\begin{aligned} p_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} &= F_{\mathbf{X}}(\mathbf{x} + d\mathbf{x}) - F_{\mathbf{X}}(\mathbf{x}) \\ &= P(\mathbf{x} < \mathbf{X} \leq \mathbf{x} + d\mathbf{x}) \end{aligned} \quad (112)$$

where  $d\mathbf{x}$  is the vector with  $i$ th component given by  $dx_i$ .

For vector random variables Bayes' theorem becomes

$$p_{\mathbf{X}|\mathbf{Y}}(\mathbf{x}|\mathbf{y}) = \frac{p_{\mathbf{Y}|\mathbf{X}}(\mathbf{y}|\mathbf{x}) p_{\mathbf{X}}(\mathbf{x})}{p_{\mathbf{Y}}(\mathbf{y})}. \quad (113)$$

In the following we will adopt the common practice of dropping the subscripts of the probability density functions.

The application of Bayes' theorem to inverse problems is based on the following interpretation of the theorem. Before an experiment is conducted, a random variable  $\mathbf{X}$  has a given a priori pdf  $p(\mathbf{x})$ . During the experiment data  $\mathbf{y}$  are collected, and as a result  $\mathbf{X}$  has an a posteriori pdf given by  $p(\mathbf{x}|\mathbf{y})$  (see, e. g. p. 36 in [10]). The pdf  $p(\mathbf{y}|\mathbf{x})$  represents the probability that an experiment would have produced the result  $\mathbf{y}$  if the value of the variable had been  $\mathbf{x}$ . To apply Bayes' theorem to our problem, we need to rewrite Eq. (74) adding a random error vector  $\mathbf{e}$

$$\mathbf{Ax} = \mathbf{b} + \mathbf{e} \quad (114)$$

and to assume that  $\mathbf{x}$  and  $\mathbf{b}$  are random variables. In this formulation the data are represented by  $\mathbf{b}$  (which plays the role of  $\mathbf{y}$ ), and  $p(\mathbf{b}|\mathbf{x})$  for a given  $\mathbf{x}$  is the probability of the error  $\mathbf{e}$  [71]. The denominator in Eq. (113) does not depend on  $\mathbf{x}$  and can be ignored. The question that remains

is the selection of the form of the probability density functions on the right side of the equation. The standard choice is a *Gaussian* pdf, given, in general, by

$$p(\mathbf{x}) = (2\pi)^{-n/2} |\mathbf{C}_{\mathbf{x}}|^{-1/2} \cdot \exp \left[ -\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}})^T \mathbf{C}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}}) \right] \quad (115)$$

where  $n$  is as in Eq. (109),  $\mathbf{C}_{\mathbf{x}}$  and  $\boldsymbol{\mu}_{\mathbf{x}}$  are the covariance matrix and mean of  $\mathbf{x}$ , respectively, and the vertical bars indicate determinant. Introducing this expression and a similar one for  $p(\mathbf{e})$  in Eq. (113), and then taking logarithms on both sides of the resulting equation gives

$$\ln[p(\mathbf{x}|\mathbf{b})] = -\frac{1}{2} [(m+n) \ln(2\pi) + \ln |\mathbf{C}_{\mathbf{e}}| + \ln |\mathbf{C}_{\mathbf{x}}| + S] - \ln(p(\mathbf{y})) \quad (116)$$

where  $m$  is the number of components of  $\mathbf{b}$  and

$$S = (\mathbf{e} - \boldsymbol{\mu}_{\mathbf{e}})^T \mathbf{C}_{\mathbf{e}}^{-1} (\mathbf{e} - \boldsymbol{\mu}_{\mathbf{e}}) + (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}})^T \mathbf{C}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}}). \quad (117)$$

Now we will make the additional assumption that  $\boldsymbol{\mu}_{\mathbf{e}} = \mathbf{0}$  and will write  $\mathbf{e} = \mathbf{Ax} - \mathbf{b}$  (using Eq. (114)). Under these conditions Eq. (117) becomes

$$S = (\mathbf{Ax} - \mathbf{b})^T \mathbf{C}_{\mathbf{e}}^{-1} (\mathbf{Ax} - \mathbf{b}) + (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}})^T \mathbf{C}_{\mathbf{x}}^{-1} (\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}}). \quad (118)$$

The last step is to find the value of  $\mathbf{x}$  that maximizes  $\ln p(\mathbf{x}|\mathbf{b})$  (and thus,  $p(\mathbf{x}|\mathbf{b})$ ) and, therefore, minimizes  $S$ . Taking the derivative of  $S$  with respect to  $\mathbf{x}$  and setting it equal to zero leads to the *maximum a posteriori estimator*  $\mathbf{x}_{\text{MAP}}$ , given by

$$\mathbf{x}_{\text{MAP}} = \mathbf{P} (\mathbf{A}^T \mathbf{C}_{\mathbf{e}}^{-1} \mathbf{b} + \mathbf{C}_{\mathbf{x}}^{-1} \boldsymbol{\mu}_{\mathbf{x}}) \quad (119)$$

where

$$\mathbf{P} = (\mathbf{A}^T \mathbf{C}_{\mathbf{e}}^{-1} \mathbf{A} + \mathbf{C}_{\mathbf{x}}^{-1})^{-1}. \quad (120)$$

An alternative expression for  $\mathbf{x}_{\text{MAP}}$  is

$$\mathbf{x}_{\text{MAP}} = \boldsymbol{\mu}_{\mathbf{x}} + \mathbf{PA}^T \mathbf{C}_{\mathbf{e}}^{-1} (\mathbf{b} - \mathbf{A}\boldsymbol{\mu}_{\mathbf{x}}). \quad (121)$$

These results are based on [13]. An expression similar to Eq. (119) is given in [130]. The Bayesian approach presented here was introduced in the context of X-ray tomography under the assumption that  $\boldsymbol{\mu}_{\mathbf{x}} = \mathbf{0}$  [71]. An application can be found in [64]. In geophysics a similar approach was introduced in [141] and [142].

Equation (121) is important for two reasons. First,  $\mathbf{x}_{\text{MAP}}$  can be interpreted as the sum of two terms: one corresponding to the prior information about the value of  $\mathbf{x}$

(given by  $\boldsymbol{\mu}_x$ ) and another one that contains the new information provided by the data collected in the experiment. Second, using Eq. (121) and the fact that the mean values of  $\mathbf{x}$  and  $\mathbf{e}$  are  $\boldsymbol{\mu}_x$  and  $\mathbf{0}$ , respectively, it can be shown that the expected value of  $\mathbf{x}_{\text{MAP}}$  is  $\boldsymbol{\mu}_x$ . Therefore, the estimator is *biased* (i. e., its expected value is not  $\mathbf{x}$ ). The significance of this result is that the expected value of the estimator is independent of the data, which is not a desirable feature. Finally, we also note that the covariance matrix of the difference  $\mathbf{x}_{\text{MAP}} - \mathbf{x}$  is equal to the matrix  $\mathbf{P}$  [13].

Now let us consider two special cases. First, no a priori information is used. In this case  $S$  in Eq. (118) is equal to the first term on the right hand side and its minimization leads to the *generalized least-squares estimator*, given by

$$\hat{\mathbf{x}} = (\mathbf{A}^T \mathbf{C}_e^{-1} \mathbf{A})^{-1} \mathbf{A}^T \mathbf{C}_e^{-1} \mathbf{b} \quad (122)$$

(if the inverse exists). The *ordinary least-squares estimator* is obtained from Eq. (122) with  $\mathbf{C}_e = \sigma_e^2 \mathbf{I}$ , where  $\sigma_e$  is a measure of the standard deviation of the errors. The estimator  $\hat{\mathbf{x}}$  has the properties that it is unbiased and minimizes the determinant of its covariance matrix, and does not require a Gaussian pdf (see, e. g., [10]).

Second, let us assume that the a priori information is  $\boldsymbol{\mu}_x = \mathbf{0}$  and  $\mathbf{C}_x \neq \mathbf{O}$ . Then, using Eqs. (119) and (120) we get

$$\begin{aligned} \mathbf{x}_{\text{MAP}} &= (\mathbf{A}^T \mathbf{C}_e^{-1} \mathbf{A} + \mathbf{C}_x^{-1})^{-1} \mathbf{A}^T \mathbf{C}_e^{-1} \mathbf{b} \\ &= \mathbf{C}_x \mathbf{A}^T (\mathbf{A} \mathbf{C}_x \mathbf{A}^T + \mathbf{C}_e)^{-1} \mathbf{b}. \end{aligned} \quad (123)$$

A derivation of the second equality is given in [13]. This result agrees with similar results derived in [47] and [74] using different approaches. An alternative derivation can be found in [3]. If we further simplify the problem by letting  $\mathbf{C}_e = \sigma_e^2 \mathbf{I}$  and  $\mathbf{C}_x = \sigma_x^2 \mathbf{I}$ , the first equality in Eq. (123) gives

$$\begin{aligned} \mathbf{x}_{\text{MAP}} &= \left( \frac{1}{\sigma_e^2} \mathbf{A}^T \mathbf{A} + \frac{1}{\sigma_x^2} \mathbf{I} \right)^{-1} \frac{1}{\sigma_e^2} \mathbf{A}^T \mathbf{b} \\ &= \left( \mathbf{A}^T \mathbf{A} + \frac{\sigma_e^2}{\sigma_x^2} \mathbf{I} \right)^{-1} \mathbf{A}^T \mathbf{b}. \end{aligned} \quad (124)$$

This particular form of  $\mathbf{x}_{\text{MAP}}$  has been referred to as the *stochastic inverse* [2,4]. If we now put  $\lambda = \sigma_e / \sigma_x$  we see that this solution is formally similar to the damped least-squares solution obtained from Eq. (87) with  $\mathbf{D} = \mathbf{I}$ .

Another important result concerning  $\mathbf{x}_{\text{MAP}}$ , as given in Eq. (119), is that it can be obtained by simply treating the prior information as a constraint, i. e.,  $\mathbf{x} = \boldsymbol{\mu}_x$ , which then can be added to Eq. (114) in a way similar to what was done in Eqs. (88) and (96), and then finding the general-

ized least-squares estimator, defined by Eq. (122) [74,136]. When proceeding in this way there is no need to make the Gaussianity assumption, although without it (or some other assumption) it is not possible to derive statistical properties of the estimator.

Finally, we note that although the Bayesian approach seems to be a good way to handle the problem of low resolution that affects many seismic tomography problems, it has some serious drawbacks that should not be overlooked. As noted earlier, the Bayesian solution is biased by the prior information, and if this information is incorrect, the solution will be affected by some amount of error that cannot be quantified objectively. The assumption that the velocity adjustments can be described by a Gaussian pdf (or any other simple pdf) is introduced by mathematical convenience, not because it is likely to represent the actual 3-D variations of the velocity adjustments within the earth. This applies, particularly, to crustal areas within complicated tectonic settings. Finally, the covariance matrix is also needed, but because it is essentially unknowable, it is frequently assumed that it is diagonal. Again, this is an assumption based on convenience, rather than on scientific facts. A critique of the Bayesian approach as applied to geophysical inverse problems can be found in [109]. For a somewhat different perspective see [104]. A good overview of the Bayesian method can be found in [57]. An example of the problems that erroneous prior information may introduce is provided in Subsect. “**Effect of Inaccurate Prior Information on the Location of Aftershocks**”.

## Examples

Here we present two examples of local tomography, one from the San Fernando basin in southern California and one from Taiwan, and also give an example of the problems that can be created when erroneous prior information is used. The tomography software used was written by H. Benz [15] and solves for earthquake locations and slownesses using the formulation described in Subsect. “**Local Slowness Tomography**” – Subsect. “**Decoupling of the Earthquake Location and Tomography Problems**”. The slowness model is parameterized in terms of constant velocity blocks and the computation of arrival times is performed using the software of Podvin and Lecomte [113]. As noted in Subsect. “**Computation of Local Travel Times**”, this software has become popular because of its ability to handle sharp velocity variations accurately. As a consequence, the resulting velocity models show high resolution (i. e. a high level of detail). For the examples presented here, none of the other existing models show such resolution. Additional results derived using

Benz's software can be found in, e. g., [95,105] and [159]. The original software relocated the events with a constant  $v_p/v_s$  ratio but was modified according to Eq. (65). To regularize the solution Eq. (96) is used.

### **P Wave Velocity Model for the San Fernando, California, Area**

The Los Angeles, California, region is one of the most seismically active in the United States, and because of its extremely large population (over ten million), a large earthquake there may be catastrophic in terms of human and/or economic costs. A major source of seismic hazard there is the presence of large sedimentary basins, which have much lower velocity than their host rocks. As a consequence, they can amplify significantly the ground motion caused by earthquakes. For example, a study published in 1989 [160] showed that the ground motion in the San Fernando and Los Angeles basins can be amplified by factors of about three and four with respect to rock sites, and that the 3-D velocity models available were not capable of generating this amplification. To address this and other problems, the Southern California Earthquake Center (SCEC) supported the development of reference of 3-D  $P$  and  $S$  wave velocity models for the major basins of southern California [91]. These models were constructed using depth and age of sediments data compiled as part of oil and water exploration studies and geological studies. Empirical relations between these two types of data were used to estimate  $P$  wave velocities. Additional empirical relations between  $P$  wave velocities, density, and Poisson's ratio were used to calculate  $S$  wave velocity. For depths less than 300 m, the  $P$  and  $S$  wave velocities were constrained using borehole velocity data. Deep borehole information was used for calibration purposes. For the San Fernando basin four boreholes were available, but the deepest one was only one 3.5 km deep. Therefore, below that depth the model does not have hard constraints. For the rocks outside of the basins an existing 3-D tomographic velocity model [58] was used. This model assigns velocities to points on a grid, which has a 15 km x 15 km horizontal spacing at depths of 1, 4, 6, 10, 15, 17, 22, 31 and 33 km.

The  $P$  wave velocities in the SCEC model for the Los Angeles basin were compared to sonic log velocities in [140]. This comparison shows that the standard deviation of the velocity differences is about 440 m/s, which is up to 20% of the model velocities. An underestimation of the velocities near the center of the basin and an overestimation near the border was also observed. An additional comparison [139] produced results that are consistent with those in [140].

The 1994,  $M = 6.7$ , Northridge, California, earthquake occurred on a previously unknown blind thrust fault in the San Fernando valley, to the NW of Los Angeles. This was the costliest earthquake in the United States (about US\$ 20,000 million), although the number of deaths was small (58, [143]), thanks to building code provisions and the fact that the event occurred early in the morning (4:30 AM local time). Because of its importance, this earthquake has been extensively studied, but more than ten years after its occurrence, a number of important questions still remain partially or totally unanswered (see, e. g., [123]). One of them is the exact nature of the 3-D velocity variations in the area, as the existing velocity models (see, e. g., [59,97,118,162]) have low resolution.

The velocity model issue has been addressed in [123]. The Benz's tomography software was applied to events in the Northridge mainshock-aftershock sequence and to aftershocks of the nearby 1971,  $M = 6.6$ , San Fernando earthquake. The data used were 192,421  $P$  wave first arrivals from 12,656 events recorded during 1981–2000 by 81 permanent and temporary stations and 799 aftershocks of the San Fernando earthquake recorded by a portable network of 20 stations (Fig. 4). The velocity model covers a volume with a surface area of 80 km by 80 km and a depth of 24 km and was divided into cubic blocks with sides of 2 km. For the computation of travel times cubic blocks with sides of 1 km were used. The initial locations were computed using a standard 1-D velocity model with three layers having thicknesses of 5.5, 10.5 and 16 km, and corresponding velocities of 5.5, 6.3, and 6.7 km/s. For the inversion the initial velocity model was the 1-D model described in [60] with a small modification (the velocity in the upper 2 km was reduced from 4.8 to 4.5 km/s). A cross section of the model is shown in a subsequent figure. The number of iterations was ten, and the value of  $\lambda$  in Eq. (96) ranged between 64 (first four iterations) and 20 (last two iterations) with intermediate values in between. Because some of the stations are in the mountains, a depth of  $-2$  km was used as a reference depth for the model. The root-mean square residual for all the events was 0.17 s and 0.07 s for the first and last iterations. Representative velocity cross sections (Fig. 5) show that the resulting model has much more detail than any of the other published models. To make sure that this detail was not artificial the initial model was changed and different data subsets were used, with the result that the most important aspects of the model were robust. In addition, realistic synthetic arrival times were generated with the velocity model and event locations from the last iteration. This involved using the stations that had recorded the observed data (for each event) and applying the original weights. Then the synthetic arrivals times were

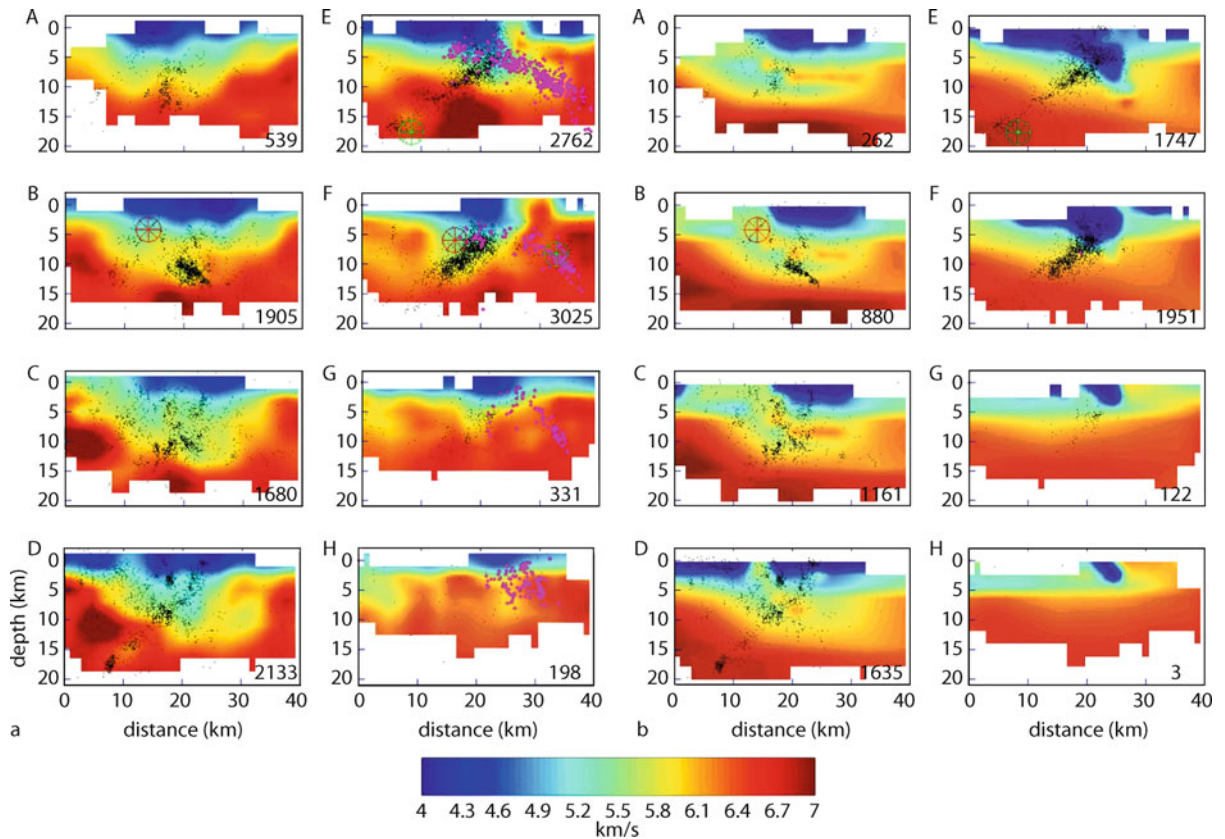

Tomography, Seismic, Figure 4

Area around the San Fernando valley, California, for which a 3-D  $P$  wave velocity model has been determined. *Blue dots* indicate the epicenters of 12,656 seismic events recorded during 1981–2000 (mostly aftershocks of the 1994,  $M = 6.7$ , Northridge earthquake). *Red dots* indicate epicenters of 799 aftershocks of the 1971,  $M = 6.6$ , San Fernando earthquake recorded during February–April 1971. The locations shown here were determined as part of the velocity determination and earthquake relocation. The large *black* and *green circles* indicate the epicenters of the Northridge and San Fernando mainshocks, respectively, the latter provided by the U.S. Geological Survey (U.S.G.S.). *Magenta open* and *crossed circles* indicate the stations that recorded the Northridge and San Fernando events, respectively. The large *red circles* indicate the epicenters of the two largest Northridge aftershocks (the location of the eastern one is from the U.S.G.S. and is poorly constrained). *Black lines* indicate faults. The San Andreas and San Gabriel faults are labeled SAF and SGF. The bold box is the projection of the Northridge earthquake fault plane determined in [68] using geodetic data. The events and velocities in boxes A through H are shown in cross section form in Fig. 5. Most of the San Fernando events are to the east of the *green dashed line* while the Northridge mainshock rupture occurred to the west of that line. The prominent band of Northridge seismicity in a roughly N-S direction (identified by the red arrow in box F) did not occur within the area that ruptured during the main shock. The events and velocity within the box labeled a are shown in cross section form in Fig. 5. From [123]

inverted as the actual data (i. e., the same initial locations and velocity model were used). The corresponding velocity model is very close to the input model (Fig. 6). A few areas have velocity differences of up to  $\pm 0.5$  km/s, but this does not detract from an overall good agreement. Regarding the hypocentral locations, the average difference between the true and computed values is 0.15 km in epicenter and 0.23 km in depth.

The inversion model is also supported by two additional pieces of evidence. One is the SCEC model, which

was sampled at the centers of the blocks in the inversion model. However, because the SCEC model has the surface as zero depth and the elevation in the area ranges between 0 and 1.6 km, a direct depth comparison is not strictly possible and for comparison purposes it was referred to a base elevation of  $-0.6$  km. As Fig. 5 shows, the inversion model has the main features of the SCEC model, and although there are some obvious differences, some of them come from deficiencies in the SCEC model, as discussed next. A second piece of evidence is the ex-

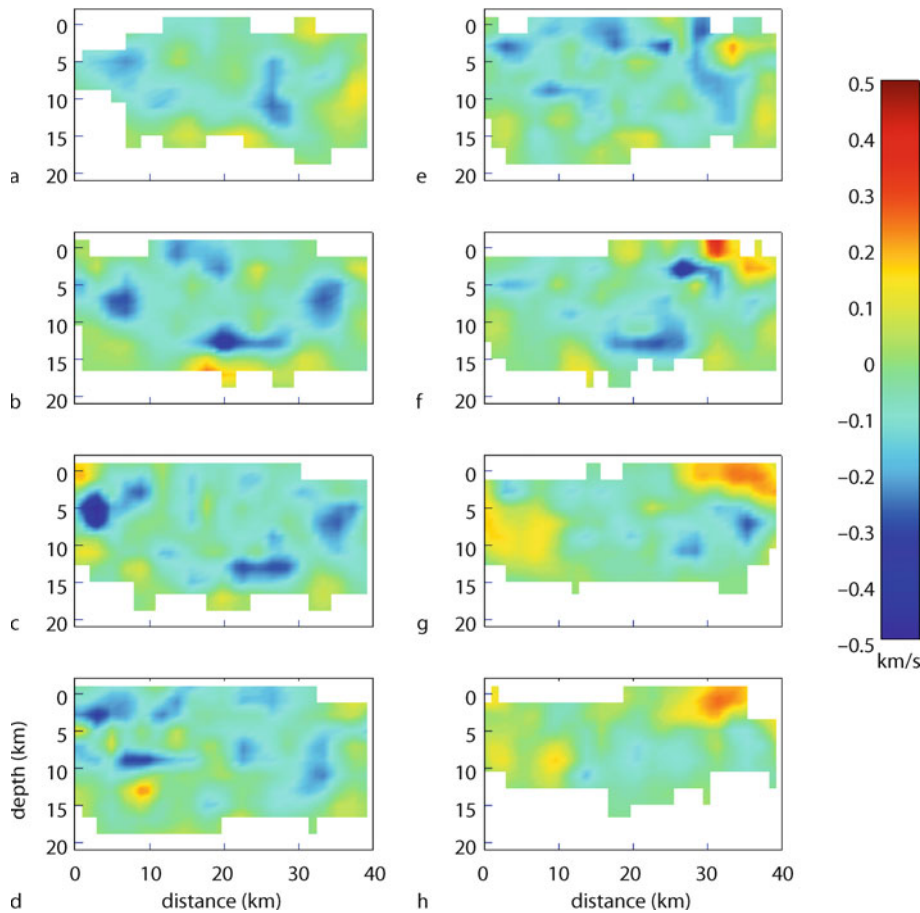

Tomography, Seismic, Figure 5

**a** Depth cross sections for the 3-D  $P$  wave velocity model determined by inversion and the events in the boxes A through H in Fig. 4. The width of the cross sections is 5.3 km. The letters are on the southern ends of the cross sections. The velocities are assigned to the centers of the model blocks and are interpolated along planes passing through the centers of the cross sections. *Black and magenta dots* indicate Northridge and San Fernando aftershocks. The large circled asterisks in cross sections E, B and F indicate the Northridge mainshock, its two largest aftershocks and the San Fernando mainshock (see Fig. 4). The number in the right lower corner of each cross section denotes the number of events. Only the velocity blocks covered by a combined ray length of 0.1 km or more are shown. Note the correlation between seismicity and velocity. The events between about 10 and 20 km in D and E are within high-velocity, basement rocks, and form narrow and well-defined lineations. These events span about 10 km horizontally and basically define the width of the fault that slipped during the main shock. The Northridge aftershocks in F correspond mostly to those indicated by the *red arrow* in Fig. 4. Most of these events are shallower than about 14 km and form a band of seismicity within and near the edge of the basin. The north-dipping events in B below about 10 km probably occurred on the Santa Susana fault. **b** Corresponding cross sections for the SCEC 3-D velocity model [91] and the events that occurred during 1994. From [123]

cellent agreement (Fig. 7) with a roughly 55 km long density model derived from the analysis of gravity data [82]. In particular, the low-velocity areas in the model correlate with the Los Angeles, San Fernando and Soledad basins, while high velocities underlie the Santa Monica and San Gabriel mountains. In contrast, the SCEC model does not match the density model equally well. Figure 7 also shows another tomographic model [59], computed for a grid with a 10 km  $\times$  10 km horizontal spacing at depths of 1, 4, 6, 8, 12, 16 and 20 km. Clearly, this model has a poor resolution and may be affected by significant artifacts, which may be

a direct consequence of the large horizontal dimensions of the blocks. Therefore, for a more direct comparison the inversion with Benz's software was repeated with blocks having horizontal sides of 10 km. As Fig. 8 shows, the corresponding results closely resembles those in Fig. 7b, which seems to indicate that the lack of resolution of the model in Fig. 7d may be due to either the software or the inversion parameters used, or both.

The results of the event relocation are also important. There are two types of differences between the initial and final locations. One is quasi-systematic, with the initial lo-

Tomography, Seismic, Figure 6

**a** Depth cross sections of the difference between the 3-D model shown in Fig. 5a and the 3-D model determined by inversion of synthetic arrival times generated using the model in Fig. 5a and the event locations determined during the inversion. See text for further details. From [123]

cations on average 1.0 km to the east and 0.5 km to the south of the inversion locations, and 1.5 km deeper. These epicentral differences are a consequence of the low velocities within the basin, which bias the event locations as noted earlier (see Fig. 3). These results are in agreement with a similar shift found using the joint hypocentral determination (JHD) technique [118], and have not been reported in other published tomographic inversion papers. A second difference between the initial and final locations is a considerable reduction in the epicentral scatter seen in the single-event locations. On average, there is a 1.5 km difference between the single-event and inversion epicentral locations.

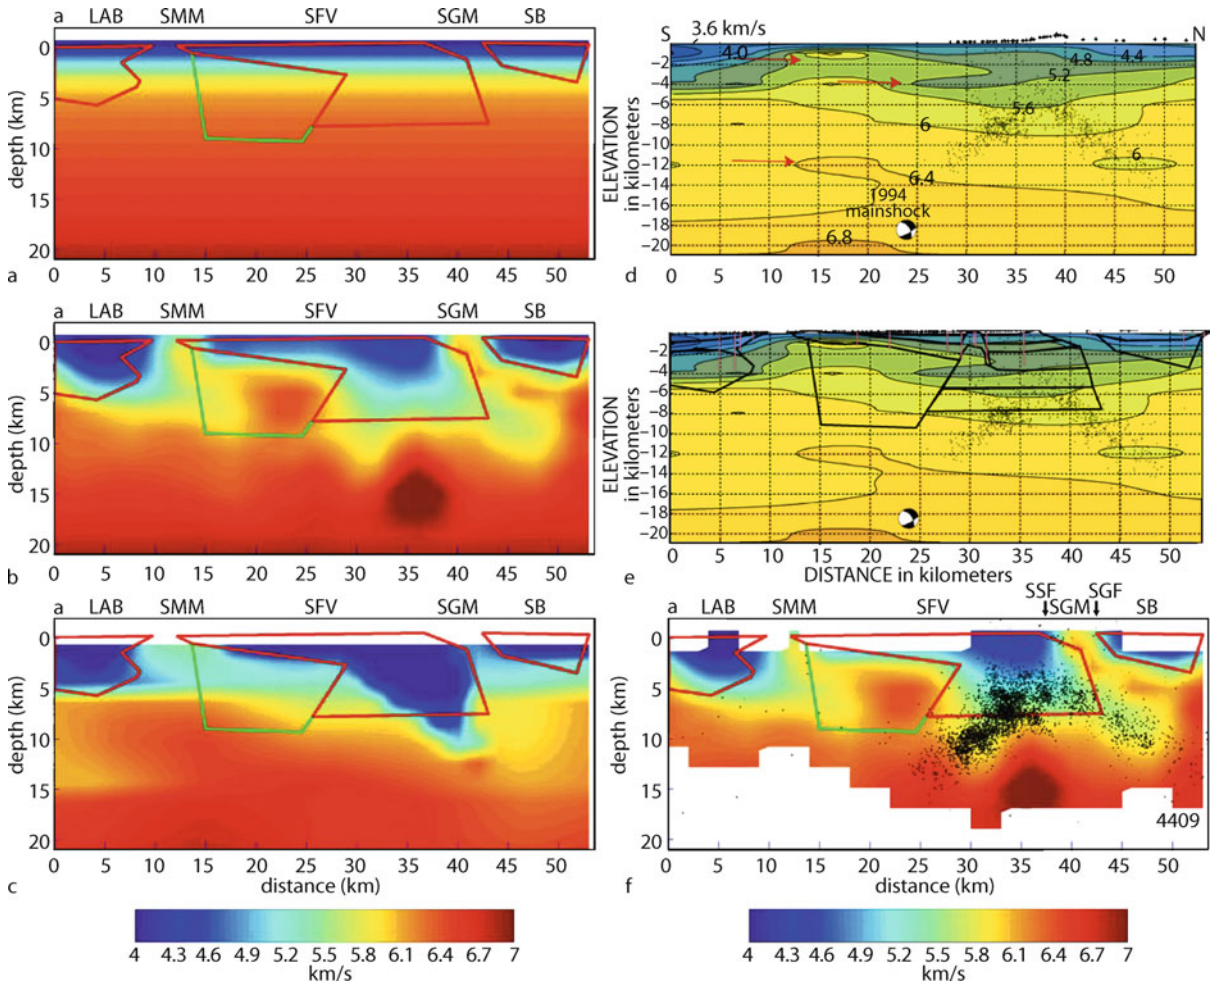

The combination of a high-resolution velocity model and improved event locations has important tectonic implications. For example, Fig. 5a shows that the most of

the seismicity occurred within the sedimentary rocks of the basin. There is little activity within the basement, mostly confined to an area around the fault plane of the Northridge earthquake. The relation between the Northridge earthquake aftershocks to the east of the main shock and San Fernando aftershocks has also been clarified; they occur on the flanks of a common high velocity block (Fig. 7f). Other significant results, not discussed here, can be found in [123].

### P and S Wave Velocity Models for Taiwan

The seismic hazard in Taiwan is also very high and for this reason a large network of seismic stations covers the island (Fig. 9). In addition, the collision and subduction processes involving the Eurasian and Philippine plates in

Tomography, Seismic, Figure 7

Velocity depth cross section along the center of box a in Fig. 5 for several velocity models. **a** Initial model. **b** Inversion model. All the blocks, regardless of the ray coverage, are shown. The polygons represent the bodies (simplified) used in [82] to match a gravity profile. The *red lines* bound materials with densities ranging between 2.00 and 2.55 g/cc. The area bounded by *red and green lines* corresponds to low-density basement (2.65 g/cc). Elsewhere in the figure the density is 2.71 g/cc. Note the excellent agreement between the extent of the low velocities in the Los Angeles (LAB), San Fernando (SFV) and Soledad (SB) basins and the low-density bodies, as well as the presence of high velocities in the areas of the Santa Monica (SMM) and the San Gabriel (SGM) mountains. **c** SCEC 3-D velocity model. This model does not fit the density model as well as the inversion model. **d** and **e** the 3-D velocity model described in [59] and original density model (from [82]). The contour labels in **d** indicate velocities in km/s. The *red arrows* indicate possible artifacts in the model. *Crosses* indicate the locations of gravity stations. **f** Inversion velocity model for blocks having ray coverage of 0.1 km or larger. The fact that the initial model is one-dimensional indicates that the 3-D velocity variations seen in **a** for the blocks not shown here were determined in earlier iterations. Also shown are the events within box a in Fig. 4. The box width is 8 km. Note that the Northridge and San Fernando aftershocks are underlain by a wedge of basement, with the seismicity occurring where rocks with lower velocities are present. The *arrows* labeled SSF and SGF indicate the positions of the Santa Susana and San Gabriel faults. From [123]

the Taiwan region have resulted in very strong ongoing tectonic and orogenic activities. As a consequence, Taiwan is the focus of numerous studies, past and present, aimed at getting a better understanding of the nature of the deformation processes there. Some of those studies involve

the determination of the crustal an upper mantle velocity structure, which has been investigated by a number of researchers (see, e. g., [90,126,128]). However, although the resulting information has been highly valuable, the resolution of the velocity models was relatively low. This situ-

Tomography, Seismic, Figure 8

Similar to Fig. 7f for a velocity model with blocks having the two horizontal sides and the vertical side 10 km and 2 km long respectively. Comparison with Fig. 7b shows that even though the block size is horizontally much larger, the major features of the model are recovered

ation was improved by the work described in [77], which resulted in  $P$  and  $S$  wave velocity models with much higher resolutions. The main results will be described here (see also [78]). As noted above, the inversion was carried out using Benz's software. The block size was 8 km  $\times$  8 km (horizontally) and 2 km in depth for velocity and 2 km  $\times$  2 km  $\times$  2 km for travel time computation. The dataset included 69,758  $P$  wave arrivals and 42,733  $S$  wave arrivals from 6285 events distributed as uniformly as possible recorded by 78 permanent stations as well as 18,502 and 10,789  $P$  and  $S$  wave arrivals, respectively, from 1298 events recorded during two 30-station portable deployments (Fig. 10). The initial and final values of  $\lambda$  in Eq. (96) for the  $P$  and  $S$  wave inversions were 128 and 50 and 128 and 20, respectively. The number of iterations was 20 and the initial and final average root mean square residuals were 0.58 s and 0.15 s and 0.67 s and 0.21 s for the  $P$  and  $S$  waves, respectively. To avoid exceeding the limitations of the flat-earth approximation (see Subject. "Computation of Local Travel Times"), station-event pairs with epicentral distances greater than 140 km were not used in the inversion. The number of events used in the inversion was less than 5% of the total number of events recorded. Once the velocity models were determined, they were used to relocate all the locatable events using a 3-D location program based on the tomographic software [24].

Representative cross-sectional views of the computed 3-D  $P$ - and  $S$ -wave velocity models are shown in Fig. 11. As in the previous example, these models show higher resolution than other published models. The resolution of these

models was investigated with a checkerboard test, which shows that most of the original velocity pattern is well recovered to depths of 25 to 30 km for most blocks (Figs. 12, 13). Below that resolution decreases. Further evidence for the reliability of the velocity models comes from the comparison of observed station corrections and those determined using synthetic data generated with those models. This approach was introduced in [116] and [118]. The station corrections were computed using the JHD technique (see, e. g., [116,119]). The JHD corrections carry information on the lateral velocity under an array and are usually much larger than the corresponding station residuals. For example, in Taiwan they can be up to about  $\pm 1$  s and  $\pm 2$  s for  $P$  and  $S$  waves (Fig. 14), with the positive corrections corresponding to low-velocity areas (such as sedimentary basins) and the negative corrections associated with high-velocity areas. In general, if the observed and synthetic station corrections do not agree well with each other, it can be stated with confidence that the velocity model used to generate the synthetic data cannot be correct. On the other hand, a good agreement indicates that the inversion model is able to reproduce, at least, the actual velocity variations in an average sense along raypaths. For the Taiwan 3-D velocity model the agreement between the actual and synthetic  $P$  and  $S$  wave JHD corrections for two subsets of events is good (see Fig. 14 for an example), which gives confidence to the overall quality of the model.

Additional evidence in support of the  $P$  wave model is provided by the analysis of anomalous  $Pn$  waves recorded by stations along the collision suture zone in eastern Taiwan and generated by shallow eastern Taiwan events [89]. These waves can be observed at stations with epicentral distances as small as 60 km. This critical distances is much smaller than that for stations elsewhere in Taiwan and indicates the presence of an elevated Moho (i. e., a thinner crust) along the suture zone. Figure 15 shows travel times for three eastern earthquakes showing the normal and anomalous  $Pn$  waves and the corresponding Moho depths (having 36–38 km and 22–23 km depth ranges, respectively). In contrast, an earthquake in western Taiwan only shows the normal  $Pn$  waves. The presence of thinner crust along the suture zone agrees well with the 3-D velocity described here [77,78], as Fig. 16 shows. Because this zone is on the edge of the network, the resolution, although still acceptable, is not as good as under the network and the details of the model are not well resolved. However, an inversion of synthetic data similar to that described for the Northridge data showed that the main features of the velocity model on the eastern side are well recovered [77] and confirms that the profiles in Figs. 11 and 16 are representative of the actual velocity variations.

Tomography, Seismic, Figure 9

Tectonic setting of Taiwan and surrounding area. The Philippine Sea plate both subducts beneath, and collides with, the Eurasian plate, while the South China Sea sub-plate subducts beneath the Philippine Sea plate in southern Taiwan. The Longitudinal Valley (LV) is the suture zone corresponding to the collision and separates the Coastal Range (COR, part of the Philippine Sea plate) from the Central Mountain Range (CR). The beach ball symbols numbered 2–4 correspond to earthquakes with abnormal  $P_n$  waves recorded by stations along the eastern coast. Number 1 corresponds to an earthquake that does not show those  $P_n$  waves. See text for details. From [89]

### Effect of Inaccurate Prior Information on the Location of Aftershocks

The relocation of the mainshock and aftershocks of the 1989,  $M = 7.1$ , Loma Prieta, California, earthquake, offers a good example of the pitfalls that inaccurate prior information may introduce. This sequence occurred along the San Andres fault and was located using two 1-D  $P$  wave velocity models, one for stations to the southwest of the fault and one for stations to the northeast of it [37].

This division was based on differences in surface geology across the fault. The velocity of the NE model was up to about 0.1 km/s lower in the upper 1 km, and between 0.2 and 0.5 km/s higher between 1 and 9 km depth, with respect to the SE model. Below that depth the velocity differences did not exceed 0.1 km/s (Fig. 17). The two models were derived using a 1-D velocity inversion program that also included the computation of station corrections. According to [37], these models reflected the presence of elevated basement to the NE of the fault and Tertiary and

Tomography, Seismic, Figure 10

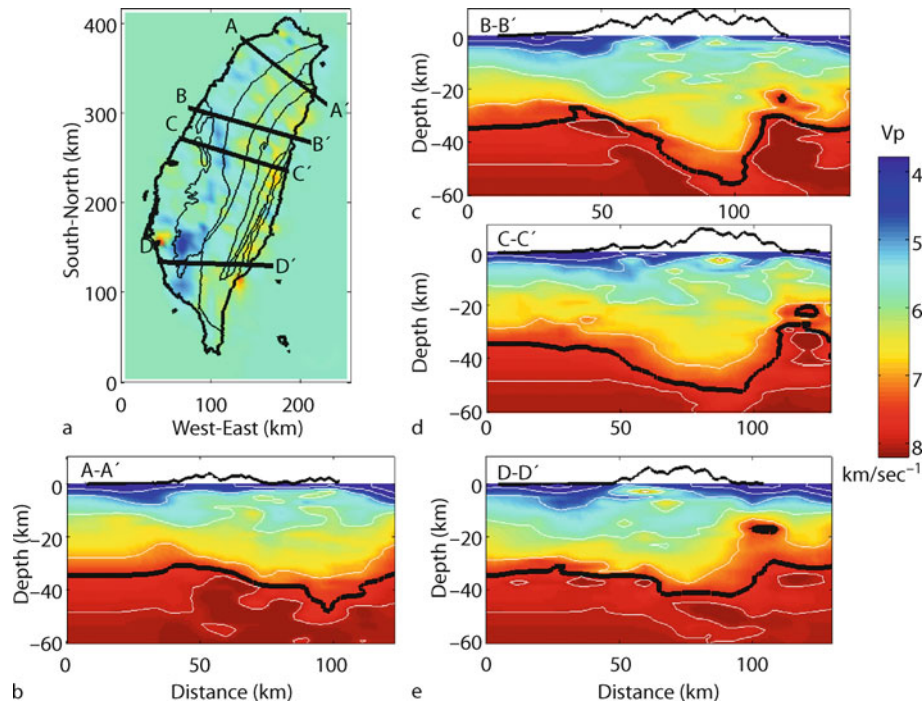

Seismic stations and events used in the 3-D tomographic study of Taiwan. *Solid triangles* indicate stations of the Taiwan Seismic Network (TSN), operated by the Central Weather Bureau (CWB). *Grey and inverted triangles* indicate stations of a portable network (PANDA) deployed in the Hualien and Pingtung areas (*solid rectangles*), respectively. The *small circles* correspond to the epicenters of the events used in the 3-D tomography. The *grey background* corresponds to the epicenters determined by the CWB between 1991 and 2002. The events within the *dashed rectangles* (labeled G1 and G2) were used with the joint hypocentral determination (JHD) technique. The  $8\text{ km} \times 8\text{ km}$  grid of the 3-D velocity is shown by the *dashed lines*. From [78]

younger sediments above 9 km depth to the SW of the fault. Note that although the prior information was not used as a quantitative constraint, it was essential to establish the boundary between the two velocity models and was implicitly used to justify the main features of the models. The seismicity was located with a single-event location program and these two velocity models and the corresponding station corrections. The mainshock fault plane inferred from the seismicity, however, had a considerable discrepancy with the fault plane determined using geodetic data, with the former consistently to the northeast of the latter by as much as 3 km. A possible explanation for

this discrepancy was the presence of lateral variations in the values of the elastic constants in the vicinity of the fault zone, which were not taken into account when the geodetic fault plane was determined [43]. A more likely explanation, however, is that the discrepancy was the result of a systematic mislocation of the events introduced by the use of incorrect velocity models. This problem was identified in [117], where the geodetic fault plane was compared to the event locations computed with the joint hypocentral determination (JHD) technique and a single velocity model, equal to the average of the two models described above [116]. With these new locations, the discrepancy was greatly reduced except in the southern end of the rupture zone, where the difference was about 1.2 m. This residual discrepancy is probably due to a significant lateral velocity contrast there. Subsequently, the analysis described in [37] was repeated with two modified velocity models [38], with the result that the new locations became similar to those in [116]. Interestingly, the new NE and SW velocity models in [38] are significantly different from their earlier counterparts (Fig. 17), with higher velocities to the SW of the San Andreas fault, rather than to the NE. Thus, these new models contradict the geological arguments used as supporting evidence for the earlier models, which in turn means that the prior information was not quite correct. Also worth noting is the fact that the locations determined using a 3-D velocity model also showed the discrepancy with the geodetic fault plane (see, e.g., [43]). Clearly, this result casts doubts on the reliability of the 3-D model used.

### Future Directions

Seismic tomography began about thirty years ago [2,4,33] and since then the field has grown steadily. However, because of the intrinsic difficulties of wave propagation in the earth and its computer simulation, the ill-posedness of the inverse problem that must be solved (particularly at the global scale), and very limited funding, progress has been slow. Fortunately, in spite of these obstacles the point has been reached where it is possible to establish with some certainty which features of the internal composition of the earth are well resolved and which ones are not, and what needs to be done to improve the existing knowledge (see, e.g. [16,41,129,135,150]). It is clear that progress will come from several fronts and will be fueled by the steady decline in the price of computers and their increased power as well as the availability of relatively inexpensive PC clusters. This development will allow the generation of more realistic synthetic seismograms (see, e.g. [81]) and the computation of more accurate inverse

Tomography, Seismic, Figure 11

Cross-sectional views of the Taiwan 3-D  $P$  wave velocity model. The 7.8 km/s contour line (*black line*) marks the depth to the Moho (approximately). The cross section locations are shown in a. The *bold lines* below 0 depth indicate the 7.8 km/s contour line. The *bold lines* above 0 depth indicate elevation (with a vertical exaggeration of 3). From [78]

solutions as well as the computation of resolution and covariance matrices. The integration of tomographic, geodynamic, and mineral physics models will lead, hopefully, to a better understanding of the earth's interior and the processes therein. However, because oceans cover two-thirds of the earth-surface, it will be necessary to make progress in the deployment of ocean-bottom seismographs before these goals can be achieved fully.

### Glossary

**$m_b$**  body wave magnitude, based on the amplitude of the direct P wave, period of the measurement: 1.0–5.0 s. Also see: Seismic Magnitude.

**$M_S$**  surface wave magnitude, based on the amplitude of surface waves, period of the measurement: 20 s. Also see: Seismic Magnitude.

**$M_w$**  moment magnitude, determined from the seismic moment of an earthquake, typical period of the measurement: > 200 s. Also see: Seismic Magnitude.

**Magnitude saturation** due to the shape of the seismic source spectrum, relatively short period measurements of seismic magnitude will produce similar magnitudes for all earthquakes above a certain size. The value of this threshold earthquake size depends on the period of the measurement: magnitude measurements using shorter period waves will saturate at lower values than magnitude measurements using longer period waves.  $M_w$  will not saturate.

**Run-up height** difference between the elevation of maximum tsunami penetration (inundation line) and the sea level at the time of the tsunami.

**Tsunami earthquake** an earthquake that directly causes a regional and/or teleseismic tsunami that is greater in amplitude than would be expected from its seismic moment magnitude.

**Tsunami magnitude** a scale for the relative size of tsunamis generated by different earthquakes,  $M_t$  in particular is calculated from the logarithm of the maximum amplitude of the tsunami wave measured by a tide gauge distant from the tsunami source, corrected

for the distance to the source (also see: Satake, this volume).

**Seismic magnitude** a scale for the relative size of earthquakes. Many different scales have been developed, almost all based on the logarithmic amplitude of a particular seismic wave on a particular type of seismometer, with corrections for the distance between source and receiver. These measurements are made for different wave types at different frequencies, and thus may lead to different values for magnitude for any one earthquake.

**Seismic moment** the product of the fault surface area of the earthquake, the rigidity of the rock surrounding the fault and the average slip on the fault.

### Definition of the Subject

The original definition of “tsunami earthquake” was given by Kanamori [37] as “an earthquake that produces a large size tsunami relative to the value of its surface wave magnitude ( $M_S$ )”. Therefore, the true damage potential that a tsunami earthquake represents may not be recognized by conventional near real-time seismic analysis methods and may only become apparent upon the arrival of the tsunami waves on the local coastline. Although tsunami earthquakes occur relatively infrequently, the effect on the local population can be devastating, as was most recently illustrated by the July 2006 Java tsunami earthquake. This event (moment magnitude  $M_w = 7.8$ ) was quickly followed by tsunami waves two to seven meters high, traveling as far as two kilometers inland and killing at least 668 people ([http://www.searo.who.int/en/Section23/Section1108/Section2077\\_11956.htm](http://www.searo.who.int/en/Section23/Section1108/Section2077_11956.htm)).

It is important to note that the definition of “tsunami earthquake” is distinct from that of “tsunamigenic earthquake”. A tsunamigenic earthquake is any earthquake that excites a tsunami. Tsunami earthquakes are a specific subset of tsunamigenic earthquakes, which we will later in this article more precisely define as earthquakes that directly cause a regional and/or teleseismic tsunami that is greater in amplitude than would be expected from their seismic moment magnitude.

### Introduction

Shallow oceanic earthquakes may excite destructive tsunamis. Truly devastating tsunamis occur only infrequently, but as the natural disaster of the tsunami following the 2004 Sumatra–Andaman Islands earthquake has shown, may cause widespread damage (in this case in the region of the Indian Ocean) and lead to hundreds of thousands of casualties. In general, tsunamis are caused by shal-

low earthquakes beneath the ocean floor displacing large volumes of water. Thus, the magnitude of the earthquake plays an important role in determining its tsunamigenic potential. However, a particular subclass of shallow subduction zone earthquakes: “tsunami earthquakes”, poses a special problem.

For the purpose of this article, we will define the term “tsunami earthquake” as follows: an earthquake that directly causes a regional and/or teleseismic tsunami that is greater in amplitude than would be expected from its seismic moment magnitude. With this definition we specifically exclude seismic events that were followed by tsunamis directly caused by slides or slumps resulting from the original earthquake (as was the case for the 1992 Flores [28,32] and the 1998 Papua New Guinea earthquakes [22,73] for example). We further exclude events that only very locally caused large tsunamis as a result of, for example, focusing effects due to features of the ocean floor bathymetry (e.g. [63]) or directivity effects combined with the shape of the coastline, as was the case for the tsunamis that hit the harbor of Crescent City after the 1964 Aleutian Islands earthquake [12] and the November 15, 2006 Kurile Island event ([http://www.usc.edu/dept/tsunamis/california/Kuril\\_2006/](http://www.usc.edu/dept/tsunamis/california/Kuril_2006/)). Furthermore, this definition compares the size of the tsunami with the moment magnitude of the earthquake and not its surface wave magnitude, slightly modifying the definition given by Kanamori [37], in order to exclude great events for which the surface wave magnitude saturates.

Our primary objective in this article is to describe the characteristics of tsunami earthquakes and the possible factors involved in the anomalously strong excitation of tsunamis by these events. We will also discuss a possible model for these infrequent, but potentially very hazardous, events. The earthquakes listed in Table 1 and plotted in Fig. 1 are considered tsunami earthquakes, according to our modified definition presented in the previous paragraph, by the majority of the community of earthquake and tsunami researchers. However, we note that the interpretation of the 1994 Java and the 1946 Aleutian Islands earthquakes varies with investigators. The 1994 Java earthquake occurred off the southeastern coast of this island, near the east end of the Java Trench in the Indian Ocean, at 1:18 am local time. It generated a devastating tsunami that took the lives of more than 200 East Java coastal residents. Run-up measured along the southeastern Java coast ranged from 1 to 14 m, while run-up measured along the southwestern coast of Bali ranged from 1–5 m [74,82]. Although the anomalously high tsunami excitation of the 1994 event is not in doubt, its earthquake source characteristics have been debated [3,59]. The 1946

Date	Geographical Region	$M_w$	$m_b$	$M_S$	$M_t$	Deaths
1896/06/15	Japan			7.2	8.0	26360
1946/04/01	Aleutian Islands	8.2		7.3	9.3	165
1960/11/20	Peru	7.6	7.0	7.0		66
1963/10/20	Kurile Islands	7.8	7.1	7.2		
1975/06/10	Kurile Islands	7.5	5.6	7.0		
1992/09/02	Nicaragua	7.7	5.4	7.2		179
1994/06/02	Java	7.8	5.7	7.1		250
1996/02/21	Peru	7.5	5.8	6.6		12
2006/07/17	Java	7.7	6.2	7.2		668

Aleutian Islands earthquake off Unimak Island produced one of the largest trans-Pacific tsunamis and had a tsunami magnitude of 9.3 [1], but its moment magnitude is only  $M_w = 8.2$ , making it a tsunami earthquake [36]. Some of the great tsunami heights measured (exceeding 30 m in height on Unimak Island and 16 m in run-up at the Hawaiian islands; [78]) can be attributed to slumping [19]. However, its anomalously high tsunamis are probably primarily due to the seismic source directly [47].

The other, less controversial, tsunami earthquakes listed in our table are: the 1896 Sanriku event near the coast of Japan, two events near the Kurile Islands: one in 1963 and the other in 1975, the 1992 Nicaragua earthquake, the Peru earthquake 4 years later, as well as an earlier event in this region in 1960 and most recently the 2006 Java earthquake. The June 15, 1896 Sanriku earthquake generated devastating tsunamis with a maximum run-up of 25 m and caused the worst tsunami disaster in the history of Japan with over 20,000 deaths, despite its moderate surface wave magnitude ( $M_S = 7.2$ ) and weak seismic intensity [2,26,76]. The November 20, 1960 Peru earthquake excited a tsunami that was anomalously large for an earthquake of moderate magnitude [57], resulting in 66 fatalities (from the tsunami event database of the National Geophysical Data Center, <http://www.ngdc.noaa.gov/nndc/struts/form?t=101650&s=70&d=7>). The October 20, 1963 Kurile earthquake was an aftershock to the great Kurile Islands underthrusting earthquake ( $M_w = 8.5$ ) of October 13, 1963 and produced a maximum run-up height of 10–15 m at Urup Island, much larger than the height of the main shock tsunami of 5 m [2]. The 1975 earthquake occurred south of the Kurile Islands and was weakly felt along the entire southern part of the Kurile Islands. Like the 1963 tsunami earthquake, this event

Tsunami Earthquakes, Figure 1

Map of tsunami earthquakes (listed in Table 1). Location for 1896 earthquake from [2] and for 2006 earthquake from the Global CMT catalog. All other earthquake locations from the Centennial Earthquake Catalog [18]

can be considered an aftershock [21] of a larger event ( $M_S = 7.7$ ) that occurred essentially at the same location on June 17, 1973. The maximum run-up height was 5 m on Shikotan Island, while the main shock had a run-up height measured at 4.5 m. A fairly strong tsunami was also recorded on tide gauges in Alaska and Hawaii (from the tsunami event database of the National Geophysical Data Center <http://www.ngdc.noaa.gov/nndc/struts/form?t=101650&s=70&d=7>). After a time period of almost two decades without a significant tsunami earthquake, the 1992 Nicaragua earthquake was the first tsunami earthquake to be captured by modern broadband seismic networks. This tsunami caused 179 deaths (from the Emergency Disasters Database, <http://www.em-dat.net/disasters/list.php>) and significant damage to the coastal areas of Nicaragua and Costa Rica, reaching heights of up to 8 m. The 1996 Peru earthquake struck at 7:51 am local time, approximately 130 km off the northern coastal region of Peru. Approximately one hour after the main shock, a damaging tsunami reached the Peruvian coast, with run-up heights of 1 to 5 meters along a coastline of 400 km [27], resulting in twelve deaths [11]. Finally, the 2006 Java earthquake was located only about 600 km

west-northwest of the tsunami earthquake that occurred 12 years earlier in the same subduction zone. The Ministry of Health reported that approximately 668 people died and 65 are missing ([http://www.searo.who.int/en/Section23/Section1108/Section2077\\_11956.htm](http://www.searo.who.int/en/Section23/Section1108/Section2077_11956.htm)) due to a tsunami that had a maximum run-up height of 15.7 m along the coast of central Java [45].

Several other earthquakes in the last few years have produced damaging tsunamis and have been mentioned as possible tsunami earthquakes. Seno and Hirata [69] suggest that the great 2004 Sumatra–Andaman earthquake also likely involved a component of tsunami earthquakes, because tsunamis larger than expected from seismic slip occurred, possibly due to slow slip in the shallow subduction boundary. It has also been proposed that the Kurile Islands earthquake of November 15, 2006 [35] may have exhibited some characteristics of tsunami earthquakes and, even more recently, the Solomon Island earthquake of April 1, 2007 excited large tsunamis, at least locally (<http://soundwaves.usgs.gov/2007/04/>). However, the disparity between seismic and tsunami excitation by these events is not nearly as large as for the events in Table 1, and we do not list these events as tsunami earthquakes.

### Characteristics of Tsunami Earthquakes

Fortunately, tsunami earthquakes occur only infrequently. Fewer than ten of these events have occurred in the last three decades since the global installation of seismic broadband instruments and tide gauges and easy availability of their data were established. However, from the detailed investigations of the most recent events and comparisons with the limited data available for the older earthquakes in Table 1, several characteristics of these earthquakes clearly emerge.

#### Slow Character

The slow character of tsunami earthquakes manifests itself in several different, yet related, ways. One well-established

characteristic of tsunami earthquakes is the discrepancy between the determined values of the different seismic magnitude types, calculated from various kinds of seismic waves or waves of different frequency ranges. A typical comparison is that of the body wave magnitude,  $m_b$ , or the surface wave magnitude,  $M_S$ , with the moment magnitude of the earthquake,  $M_w$ . For tsunami earthquakes  $m_b$  is typically much smaller than the other two magnitudes,  $M_S$  and  $M_w$ , and  $M_w$  typically exceeds  $M_S$ . The discrepancy between these different magnitudes is more pronounced than for regular subduction zone earthquakes with similar moment magnitudes. For example: for the 1992 Nicaragua earthquake:  $m_b = 5.4$ ;  $M_S = 7.2$ ,  $M_w = 7.7$  [18]; for the 1994 Java tsunami earthquake:  $m_b = 5.7$ ;  $M_S = 7.1$ ,  $M_w = 7.8$  [59]; for the 2006 Java earthquake:

Tsunami Earthquakes, Figure 2

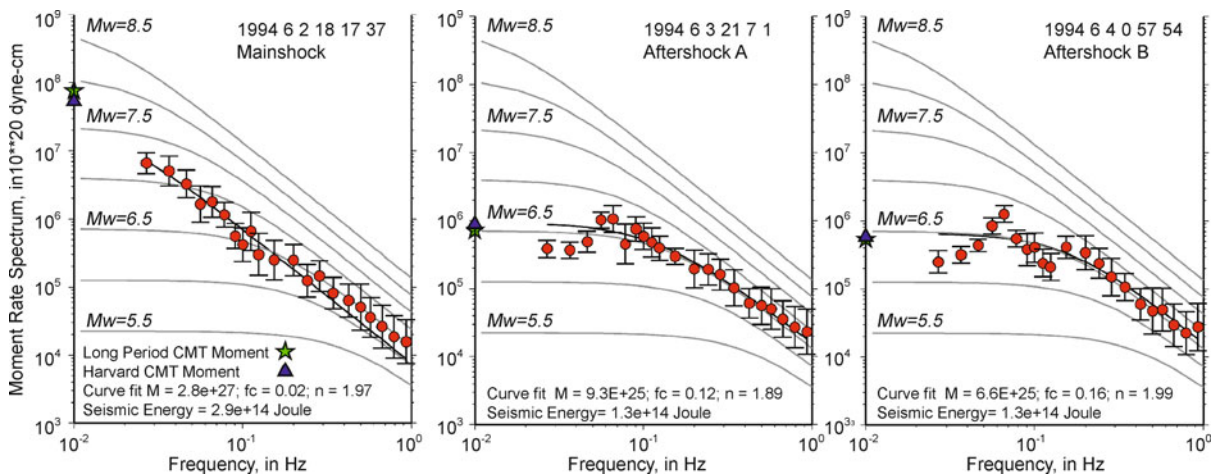

Average of log of moment rate spectrum at four periods (2, 5, 10, 22 s) as a function of the seismic moment as determined by CMT inversion of long-period surface waves. Reference curves were calculated for an  $\omega^2$  model [13]. Values next to the grey curves indicate the stress drop used to calculate the reference curve. Events shown are all shallow subduction zone earthquakes from 1992 to 1996 with moment magnitude 7.0 or greater. Earthquakes followed by anomalously large tsunamis are indicated with open circles. Of these events, only the 1992 Nicaragua, 1994 Java and 1996 Peru earthquakes are slow tsunami earthquakes, as is shown in this figure by their relatively low moment rate spectrum at shorter periods. Adapted from [59]

$m_b = 6.2$ ;  $M_S = 7.2$ ,  $M_w = 7.7$  [5]. Since the body wave magnitude is calculated from short period P-waves, the surface wave magnitude is determined by the amplitude of surface waves with a period of 20 seconds and the moment magnitude is generally based on longer periods for big events, this consistent discrepancy is an indication of the relatively greater seismic energy release at longer periods (or the “slow” character) of these tsunami events. Similarly, investigations of teleseismic P-waves [5,59] have shown that their source spectra are depleted in high frequency energy at periods shorter than 20 seconds as compared to other shallow subduction zone earthquakes (see Fig. 2, from [59]), as well as their own aftershocks (see Fig. 3, adapted from [60]). Modeling of the rupture processes shows that the rupture velocities for tsunami earthquakes are slower than for most other subduction zone earthquakes (for several events: [58] and [33]; for Aleutians 1946: [47]; for Nicaragua 1992: [40] and [30]; for Peru 1996: [31]; for Java 2006: [5]). Correspondingly, the centroid times and source durations or rise times determined for these events are also relatively large with respect to other large subduction zone earthquakes ([59]; for Kurile Islands 1975: [71]; for Peru 1960: [57]; for Java 2006: [5] and [25]), although they may not be anomalous relative to other, smaller, subduction zone earthquakes at very shallow depth [9]. The energy that is radiated by these slow rupture processes is also anomalously low, as is shown by analyses of the radiated energy to moment ratio (for several recent tsunami earthquakes: [51]; for the

1946 Aleutian Islands earthquake: [47]) and radiation efficiency [83].

Unfortunately, the slow character of tsunami earthquakes also means that local residents are not warned by strong ground shaking of the possibility of an impending tsunami. Field surveys and first-person accounts describe the motion of tsunami earthquakes more as a weak “rolling motion” than the usual impulsive character of local events. In the case of the Nicaragua earthquake, some felt a very feeble shock before the tsunami, but most did not feel the earthquake at all [30]. For the 1994 Java event earthquake-induced ground shaking was not noticed by the coastal residents interviewed in Bali and Java [74]. Interviews with local residents carried out for the 2006 Java earthquake [50] also indicate that they felt little or no shaking.

Most designs for tsunami earthquake discriminators and early warning systems make use of a number of the manifestations of the unusually slow character of tsunami earthquakes listed above and many incorporate the use of long period seismic waves for robust estimation of the size of the event. For example, the pulse width of the P-wave, used to calculate moment magnitude  $M_{wp}$ , can give an accurate estimate of source duration time. The combination of  $M_{wp}$  and the source duration can provide an effective tool to issue early tsunami warnings [81]. A slightly later arrival on a seismogram, the W-phase, is a distinct ramp-like long-period (up to 1000 s) phase that begins between P and S waves on displacement seismograms and is particu-

Tsunami Earthquakes, Figure 3

Moment rate spectra for the Java thrust mainshock (left) and two of its largest aftershocks, tensional events in the outer rise (right panels). The stars indicate the Harvard CMT moment, the triangles the moment determined using very long period surface waves. Grey reference curves were calculated for an  $\omega^2$  model [13] with a stress drop of 30 bars and an S-wave velocity of 3.75 km/s. The moment rate for the main shock is similar to that of its much smaller (in terms of  $M_w$ ) aftershocks for periods shorter than 10 seconds. Adapted from [60]

larly pronounced for slow earthquakes; thus it can be used for identification of these types of events [38]. Another method for fast regional tsunami warning uses the ratio of the total seismic energy to the high-frequency energy (between 1 and 5 Hz), computed from the seismograms [70]. Similarly, the detection of deficient values of seismic energy-to-seismic moment ratio can be accomplished in automated, real-time mode [51].

### Location: Close to Trench

The hypocenters of the recent tsunami earthquakes are located relatively close to the trench, as compared to regular subduction zone earthquakes. The Global CMT and other [59] centroid locations for several of these events are located even on the seawards side of the trench (also see Fig. 4). It may be possible that the inversion process mislocates the centroid of the event due to the unusually long duration of the seismic source for its moment and thus its unusually late centroid time. Inversions using seismic and/or tsunami waveforms and other waveform investigations for the 1896 Sanriku event [76], the 1946 Aleutian Islands earthquake [36,78], the 1960 Peru earthquake [58], the 1963 Kurile earthquake [7,58,86], the 1975 Kurile earthquake [58,86], the 2006 Java earthquake [5,20], the Nicaragua earthquake [40,41,62] and the 1996 Peru event [31,64] indicate the presence of concentrated slip in a narrow region near the trench (see Fig. 4). Although in many of these inversions only 1-D Green's functions were used, preliminary research results using a more realistic velocity model for the shallow subduction zone [54] shows a similar picture for the 2006 Java tsunami earthquake.

### Aftershocks

The aftershock sequences of (recent) tsunami earthquakes are unusual in the preponderance of events not located on the interface between overriding and subducting plates [59]. Some of these aftershocks are located in the outer rise according to their Global CMT centroid locations and, in the case of the Java 2006 aftershocks, relocations using a 2.5-D model of the subduction zone [54] confirm this location. Others are located in the overriding plate ([8] for the 2006 Java earthquake), with some deeper within the accretionary prism (for the Java 2006 earthquake: [54]). The low number, or non-existence, of large (greater than magnitude 5.5) interplate earthquakes suggests that the main shock almost completely relieved the stress on the interface or may be related to the frictional properties of the fault. Several explanations have been proposed for the anomalously high number of intraplate earthquakes following tsunami earthquakes. Because

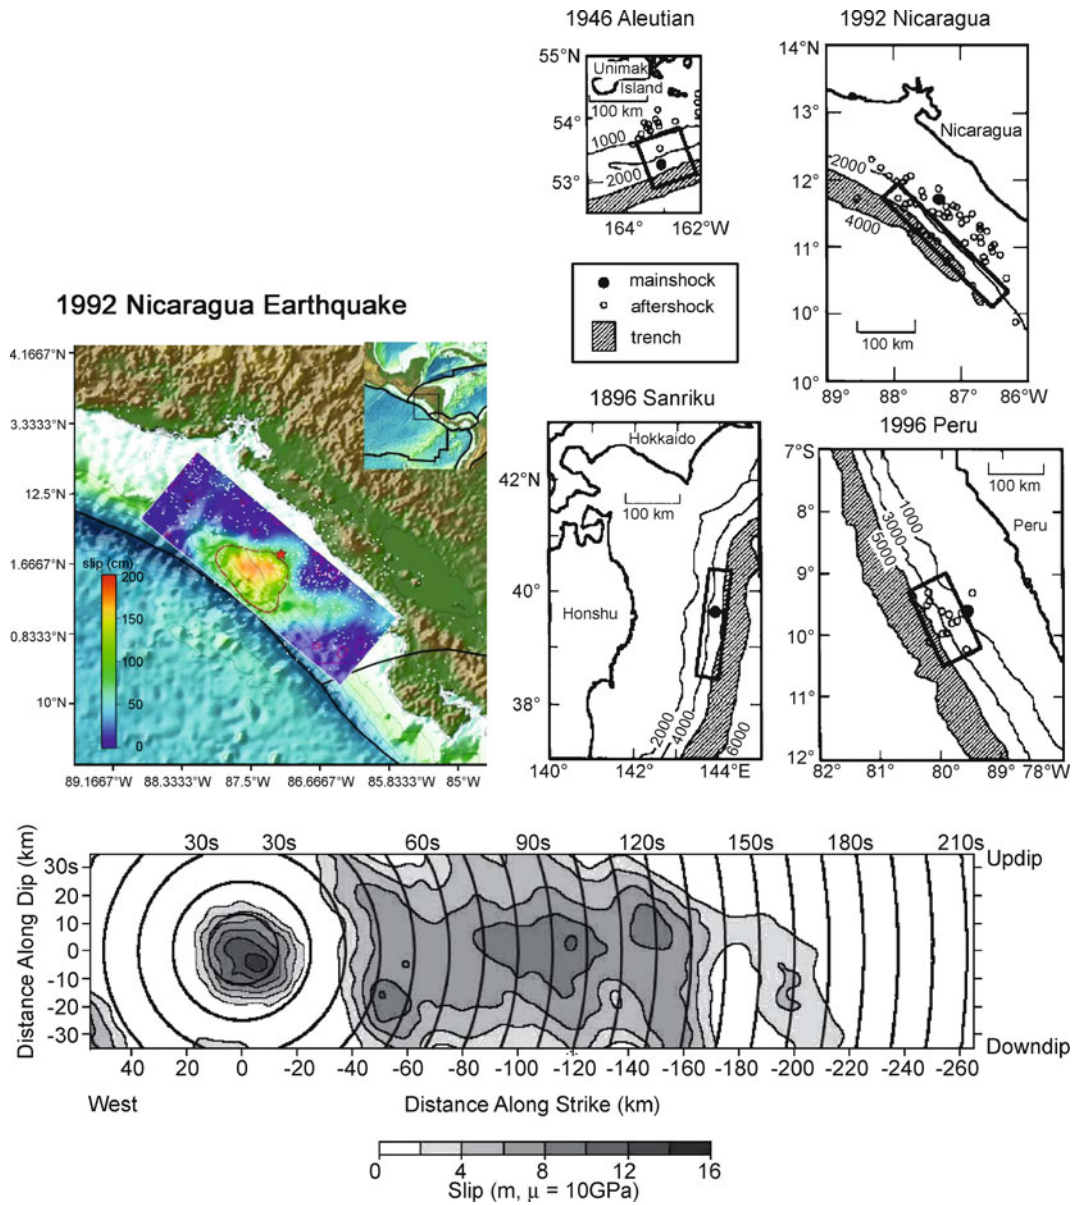

of the proximity of the areas of high slip to the trench, the stress-change in the outer rise and trench area due to a tsunami earthquake are greater than for the "standard" subduction zone earthquake. Several modeling studies of stress alterations caused by large subduction earthquakes suggest that the subduction slip will act to increase the tensional stress and favor normal events in zones towards the ocean from the upper limit of the rupture [16,80]. The subducting plate also seems to have a highly-broken up or rough character in many areas in which tsunami earthquakes have occurred ([49,75]; for Java: [48]; for Peru: [29] and [44]), which suggests the presence of more pervasive pre-existing weak zones, due to, for example, seafloor spreading related fabric. These weak zones may be re-activated in outer rise, or deeper intraplate, earthquakes following a tsunami earthquake.

### Factors Involved in the Seismogenesis and Tsunamigenesis of Tsunami Earthquakes

Based on the consistent characteristics of tsunami earthquakes, as described in the previous section, and observations of their tectonic environments, hypotheses have been developed as to the cause of their extraordinary tsunami excitation and unusual seismic source process. In this section, we will document the factors that have been proposed to affect the seismo- and tsunami-genesis of tsunami earthquakes. Some are associated with the numerical prediction of tsunami wave-heights based on observed seismic waveforms, and others with possible unusual conditions of the tectonic environment in which these events occur; many of these factors are closely or at least somewhat related.

### Slow Character May Lead to Underestimation of Earthquake Size

Prior to the installation of the broadband Global Seismic Network, the magnitudes of earthquakes were often determined from the amplitude of their teleseismic P-waves only. In the case of tsunami earthquakes, using this technique to determine their magnitude would lead to an initial underestimation of their true size, since their source spectra are depleted in the relatively high frequency energy that usually dominates the direct P-wave signals of regular earthquakes [59]. A similar issue would occur, although to a lesser degree, when using surface waves of periods of 20 seconds to determine the surface wave magnitude of these slow events [58]. With the advent of broadband sensors in the past several decades, it has now however become possible to investigate seismic waves to very long periods, hundreds or even thousands of seconds. Using more sophis-

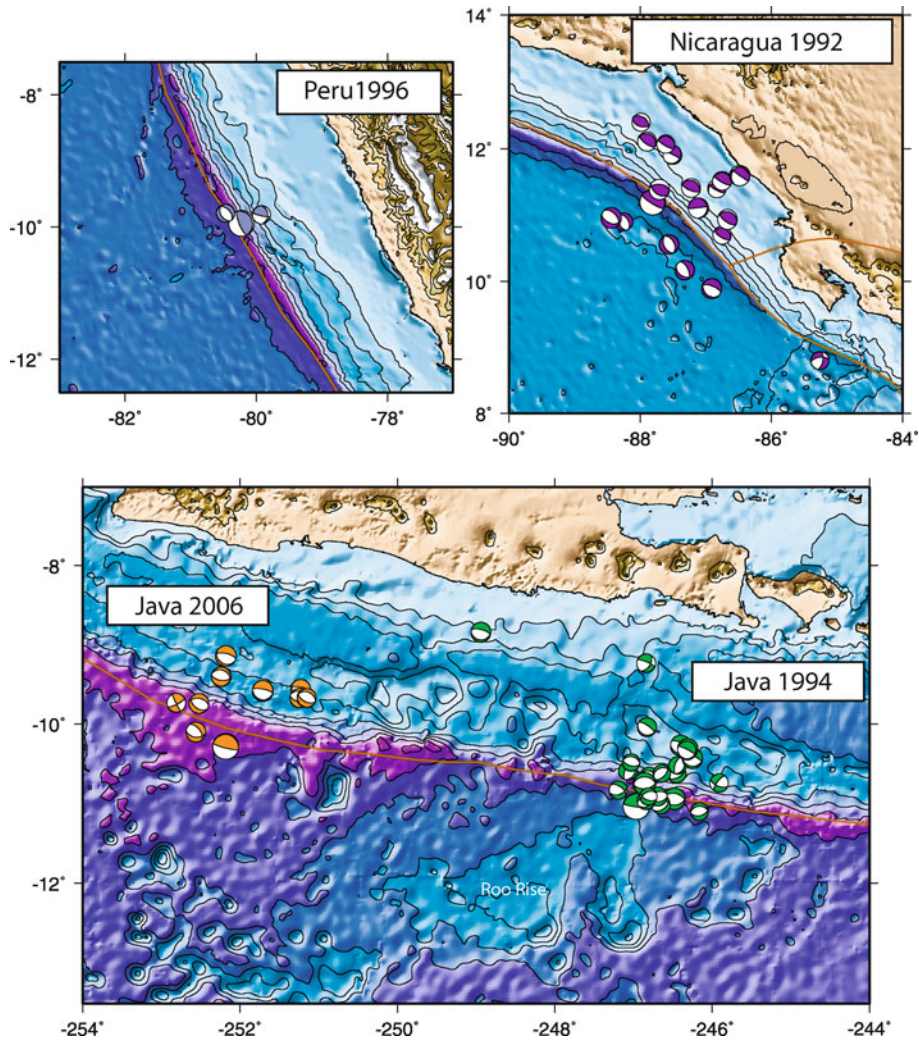

Tsunami Earthquakes, Figure 4  
 Slip or fault models determined for various tsunami earthquakes. The models shown are for: Nicaragua 1992 (top left, from [33]) Java 2006 (bottom, from [5]) and four tsunami earthquakes (top right, from [64]; the main shock and aftershock epicenters are shown and the hatched area indicates the trench). These models all show the presence of substantial slip close to the trench

ticated techniques and the waveforms from technologically advanced sensors, the source spectrum of the recent tsunami earthquakes can now be modeled to these very long periods. Thus, no long period seismic energy that would excite tsunami waves should be “hidden” from the view of seismologists in the computation of moment magnitude or full rupture models using long period surface and body waves. However, for the earthquakes discussed

in this paper, the observed tsunami are still larger than would be expected, even for their moment magnitude.

**Effect of the Presence of Weak Materials with Low Shear Modulus**

Most earthquake source inversions (either for full rupture or Centroid Moment Tensor parameters) implement

Tsunami Earthquakes, Figure 5

Aftershock sequences (seismicity in the region of the main shock within a period of 4 years after its occurrence) for several tsunami earthquakes, from the Global CMT catalog. Relatively few interplate aftershocks occur on the fault plane after a tsunami earthquake occurs, but a preponderance of normal-fault, probably intraplate, aftershocks is apparent

a simple one-dimensional velocity and rigidity model to compute synthetic seismograms and model the recorded waveforms. If tsunami earthquakes are unusually shallow and/or involve sediments of low seismic wave speed, this is probably a poor approximation of the actual structure near the source region [23,64]. Some authors have attempted to rectify this error by using moment or slip distributions determined by seismic inversions in a structural model with significantly reduced shear modulus, more appropriate for the shallow trench region, and forward modeling the tsunami waves (e.g. [23]). This approach, however, is not satisfactory because a seismic inversion for moment or slip using this more appropriate rigidity model would

produce a different distribution of moment or slip. Thus, a simple “correction” for the use of an inappropriate value of rigidity cannot be carried out after the rupture model has already been computed. If available, a correct rigidity model should be part of the seismic inversion process itself. To do this correctly, Green’s functions should be computed for a three-dimensional (or possibly two dimensional, if the velocity structure is relatively uniform in the trench-parallel direction) velocity structure of the shallow subduction zone and incorporated in the modeling of the seismic waveforms. However, such sophisticated models are currently only available for very few subduction zones and the computational power required for these calcula-

tions (for body wave frequencies) is substantial. Unfortunately, whichever approach is chosen to go from recordings of seismic waveforms of tsunami earthquakes to the prediction of tsunami wave heights, a good model of the velocity and elastic properties of the shallow subduction zone is an unavoidable requirement.

Even when the moment distribution or moment magnitude of a tsunami earthquake has been determined using an appropriate model for the velocity and elastic parameters, there exists also the issue of enhanced tsunami excitation in material with weaker elastic properties, such as sedimentary layers. Modeling suggests that an event for which 10% of the moment is in sediments generates a tsunami 10 times larger than its seismic moment would suggest [52] mainly because the slip in this material would be much greater than that for the same seismic moment in a stronger material (moment is the product of slip, area and rigidity after all). Therefore, the moment of a tsunami earthquake, even if determined correctly, may not directly reflect its tsunamigenic potential when low velocity sediments are present in the rupture zone. Since tsunami wave heights are mainly determined by the vertical displacement of the ocean floor, which in turn is primarily controlled by the slip on the fault plane, the slip (distribution) is more directly indicative of tsunamigenic potential. Since variations in shear modulus of a factor of five are not uncommon in shallow subduction zones [23], earthquakes with similar moments can result in substantially different slip models and tsunami excitation.

### Shallow Depth of Slip Causes Relatively Great Displacement of Ocean Floor

Shallower earthquakes produce greater and shorter wavelength vertical displacement of the ocean floor, and thus greater and shorter wavelength tsunami waves right above the source region. However, higher frequency waves travel more slowly than longer period waves and, after a few hundred or thousand kilometers of travel, they drift to the back of the wave train and do not contribute to the maximum amplitude. Beyond about 2000 km distance, any earthquake at a depth less than 30 km appears to be equally efficient in tsunamigenesis ([85] and Fig. 6). Therefore, the exact depth of the slip in a shallow earthquake is not a key factor in determining its teleseismic tsunami wave-heights. Although the teleseismic tsunami wave-heights for a shallow slip event may not be significantly greater in amplitude than those for a somewhat deeper slip event [85], at local and regional distances the depth of the slip is an important factor. Therefore, for tsunami earthquakes, which have anomalously great tsunami height at

**Tsunami Earthquakes, Figure 6**  
Cross sections of an expanding tsunami from a M7.5 thrust earthquake. The fault strikes north south (into the page) and the sections are taken east west. Elapsed time in seconds is given at the left and right sides. Red lines are for a fault that breaks the surface and blue lines for a fault with its top at a depth of 20 km. Deeper earthquakes make smaller and longer wavelength tsunamis at relatively short distances

mainly local and regional distances close to the rupture, the depth of the rupture should be a significant factor in their tsunamigenesis (see Fig. 6). Furthermore, modeling of shallow subduction zone earthquakes using a specific crack model [24] indicate that a rupture intersecting the free surface results in approximately twice the average slip. However, under the assumption of other specific frictional and crack models, the modeling of subduction zone earthquakes by Wang and He [84] produces slip models that have less vertical displacement of the ocean floor when the slip reaches the surface, due to a different slip distribution and the curvature of the subduction interface.

### Shallow Fault Dip May Lead to Underestimation of Slip from Seismic Waves

It is notoriously difficult to resolve moment,  $M_0$ , and dip,  $\delta$ , independently for shallow thrust earthquakes. The excitation functions of Rayleigh waves for shallow thrust earthquakes show that only the product of dip and moment (more precisely  $M_0 \sin(2\delta)$ ) can be resolved [39] when using these surface waves in inversions for a source mechanism. If Love wave data are also included in the inversion, it may be possible to add constraints by concentrating on fitting the amplitudes of those Love waves recorded at azimuths corresponding to the along strike direction [34], however, this approach may be complicated by directivity effects. The polarity of body waves can only be used to constrain the focal mechanism of an earthquake at a limited range of incidence angles and thus also cannot provide any additional constraints on the dip of the shallowly dipping plane, unless assumptions are made about the rake angle. It is thus possible to (severely) underestimate the amount of slip in the earthquake, if the dip of the mechanism is poorly constrained and the inversion leads to a value for dip that is too high. This could be particularly important for very shallow subduction earthquakes, since the dip is expected to be small for these events. Thus, a difference between a dip of 3 or 6 degrees in a CMT solution may not seem significant, but it could lead to a difference in moment (and thus slip) of a factor of two. To illustrate the importance of this issue for very shallowly dipping thrust events, we show in Fig. 7 three different homogeneous slip models (only slip was changed, fault surface area and rigidity were kept constant) that will produce similar surface waves because the product of their slip and dip is identical. However, the vertical deformation of the ocean floor and the tsunami waveforms resulting from these three different earthquakes would be significantly different in amplitude.

### Horizontal Deformation of the Ocean Floor May Lead to Great Displacement of Water, Yet Is Neglected in Tsunami Modeling

Most tsunami modelers only consider a water surface displacement identical to the vertical deformation of the ocean bottom due to faulting when computing the tsunami height resulting from an earthquake and neglect the effect of horizontal deformation. However, when the tsunami source is located close to a steep slope and the horizontal displacement is large relative to the vertical displacement, which is generally the case for tsunami earthquakes due to their mechanism and shallow depth,

**Tsunami Earthquakes, Figure 7**  
Tsunami wave heights as a function of time for three different slip models for a shallow thrust earthquake, which will produce similar surface wave recordings (because the product of dip and moment is held constant). Thus, it is difficult to resolve between these different models using an inversion of surface waves, yet they produce very different vertical displacement of the ocean floor and thus very different tsunamis

the effect of horizontal deformation may become significant [77].

Furthermore, it has been suggested that the lateral collision force of a continental slope into the ocean due to faulting could also play an important part in the tsunami-generation of these events [72]. This type of dynamic excitation of tsunami waves would be particularly important for very shallowly dipping, shallow, thrust events, which would have a large component of horizontal motion. However, this concept has still been debated. This problem will be resolved if tsunami excitation is computed

using the three-dimensional bathymetry in the source region with the displacement of the sea-floor as the initial condition.

### **Subduction of Bathymetric Features May Enable Seismic Slip in Usually Aseismic Region and Be Related to Unusual Aftershock Sequences**

Sandbox experiments show the pervasive influence on the geomorphology of the shallow subduction zone margin when a seamount on the subducting plate is being subducted [17]. Subduction and underplating of relatively undeformed and water-laden sediments beneath the rear part of the margin could, together with the dense fracture network generated by seamount subduction, modify the fluid pressure and introduce significant variations of the effective basal friction and thus the local mechanical plate coupling. More directly, subduction of a seamount may increase the normal stress across the subduction interface and hence enhance seismic coupling [15,67]. Unusual earthquakes have been documented in regions where ridges, seamounts or other bathymetric features are being subducted (e. g. [14,43]) and investigations of rupture characteristics of large underthrusting earthquakes provide evidence that seamounts can be subducted to seismogenic depths and that variations in seafloor bathymetry of the subducting plate may strongly influence the earthquake rupture process [10,61]. In the case of the Java tsunami earthquake of 1994, the bathymetry of the area landwards of the trench suggests that a local high is in the process of being subducted close to the area of maximum slip ([3], Fig. 4). A bathymetric high in the form of the Roo Rise can also be found just seaward of the trench region. In the bathymetry of the area around the 2006 Java event no such pronounced local feature can be found (Fig. 4), but the regional bathymetry south of the Java trench region is distinguished by an overall rough character. Similarly, the Nicaragua subduction zone is characterized by a highly developed horst and graben structure in the subducting plate, but no large-scale features, like a subducting seamount, are obvious. However, in case of the Peru earthquakes, both the 1996 and 1960 tsunami earthquakes occur at the intersection of the trench with major topographic features on the Nazca plate: the Mendaña fracture zone and the Trujillo trough, respectively [53].

Thus, subduction of either pronounced local bathymetric features or more regional seafloor roughness or horst-and-graben structures, which may modify the local coupling between subducting and overriding plates, has been documented in or near the rupture zone of many tsunami earthquakes.

### **Accretionary Prism: Uplift, Slides or Splay Faulting May Displace a Relatively Great Volume of Water**

Tsunami earthquakes may involve seismic slip along the normally aseismic basal decollement of the accretionary prism [58,76]. Sediments near the toe of an inner trench slope may be scraped off by a large horizontal movement over the decollement due to an earthquake and thus cause an additional inelastic uplift, which could have a large effect on tsunami generation (for the 1896 Sanriku earthquake: [79]; for the 1946 Aleutian Islands earthquake: [78]).

The existence of splay faulting, which would be more effective in exciting tsunamis due to their steeper dip, within the accretionary prism itself has been suggested to be a cause of the large tsunami excitation for the 1994 Java earthquake [3], the 2004 Sumatra mega-thrust event [46] and the 1963/1975 Kurile earthquakes [21]. Splay faulting can further promote extensive vertical deformation of the ocean floor, and hence large tsunamis, through partitioning or branching of a rupture upwards from the interface along multiple splay faults leading up to the surface [21,56].

### **Presence of Fluids Influences Seismic Behavior**

In subduction zones, fluids expelled from the subducting plate play an important role in many different subduction related phenomena such as volcanism, metamorphism and seismogenesis. Zones of high pore fluid pressure in the shallow subduction zone would change the effective normal stress significantly, possibly extending the region in which seismic slip is possible to shallower depths and generate slip of a slow nature. The presence of such zones has been suggested to be related to the occurrence of silent slip in the Nankai trough region [42]. In the case of tsunami earthquakes, the presence of large zones of elevated fluid pressure has been proposed to cause fairly rapid seismic slip close to the trench axis, following the breakage of asperities [68].

### **A Model for Tsunami Earthquakes**

Most explanations for the slowness of tsunami earthquakes involve the presence of low velocity, low strength and low rigidity sediments in the accretionary prism and between the overriding and subducting plate in the shallow subduction zone. Rupture through these slow sediments is thought to promote a slow rupture velocity. In Scholz's [65,66] model of the typical subduction zone (see Fig. 8 for an interpretation of this model from [9]), three possible stability regimes exist. In the stable zone, seismic

Tsunami Earthquakes, Figure 8

Cartoon illustrating frictional conditions of the subduction interface between subducting and overriding plate. Individual unstable sliding contact areas (dark gray) can provide the nucleation sites for rupture in the shallow subduction zone environment, which is typically a stable (stippled) or conditionally stable (light gray) frictional region. From [9]

slip cannot be supported and aseismic creep releases all strain. In the unstable zone episodic seismic slip occurs. In the conditionally stable zone, in between these two zones, slip can be abrupt if it experiences loading from a nearby slip patch. This conditionally stable zone may be very heterogeneous due to roughness of the thrust fault [75] creating isolated asperities or due to permeability changes [55] from the subduction of low permeability materials or the presence of fluids [68]. Tsunami earthquakes may represent a rupture of one or several large “unstable” asperities, which then propagates for a significant distance in the conditionally stable sedimentary materials [9,59].

Alternatively, but consistently, we could interpret tsunami earthquakes in the context of fracture mechanics as displaying a lack of radiated energy and a low rupture speed in a high  $G_C$  (fracture energy) environment [5,83]. As stated above, if these ruptures also involve localized patches of relatively strong unstable friction (that would be associated with high rupture speed and low  $G_C$ ) it would allow the rupture to propagate seismically, instead of as a continuous creep process. From this point of view, tsunami earthquakes dissipate a large amount of energy during the fracture process and are left with little energy to radiate. It is possible that the highly faulted trench and deformed sediments result in larger energy dissipation during failure due to an excessive amount of branching and bifurcation of cracks which gives rise to inelastic behavior and hence a large dissipation of energy [6,83], possibly involving the branching of the rupture into multiple splay faults in the accretionary prism.

Tsunami earthquakes therefore would represent slip at unusually shallow depths that would typically be dominated by creep-processes. Their nucleation would be made possible through the existence of localized asperities or

patches of unstable friction in a typically stable or conditionally stable region. The presence of compartments of elevated fluid pressure may aid in the propagation of the seismic slip by creating zones of nearly zero friction surrounding the asperities [68]. These asperities may be created by the subduction of bathymetric features like seamounts or ridges or by the broken up nature of the subducting plate itself, creating a horst-and-graben system, which would act as buckets for sediment subduction [59,75]. The stress-release on these asperities would be near complete, and any additional unloading of stress on the plate interface due to the rupture may occur mostly through creep. This would result in a relatively low number of aftershocks occurring on the interface between overriding and subducting plate. However, the static stress change in the outer rise area would be significant due to the shallow nature of most of the slip and thus normal faulting outer rise earthquakes would be more likely to be triggered [16,29,80]. The subduction of a bathymetric feature would also likely result in fracturization of the margin [17] in the overriding plate, thus further promoting the occurrence of intraplate aftershocks in this area of the shallow subduction zone. If the subducting plate itself is highly broken-up and thus contains pre-existing weak zones, this may facilitate further faulting within the subducting plate, in particular close to the lower edge of the rupture where the stress change due to the main shock is relatively large.

In this model for tsunami earthquakes discussed above, the unusually high effectiveness in the excitation of tsunami waves can be attributed to several factors, with the shallowness of the slip as the main underlying cause. Other important concerns coming into play are the possible failure of seismological techniques to provide an accurate estimate of the slip due to complexities associated with a very

shallowly propagating rupture in a subduction zone, the possible failure of tsunami modeling to determine accurate wave heights due to similar complexities and the possible involvement of splay faulting or uplift of sediments near the trench in the accretionary prism.

### Future Directions

The Sumatra–Andaman earthquake and tsunami of 2004 renewed interest in the development of near real-time methods to estimate the true size of large earthquakes and the tsunamis that might follow them, and the installation of instrumentation that will facilitate these measurements. Because the time between the earthquake and the arrival of the first tsunami waves at the local coastline is short, it is still unclear how effective these types of early warning systems are for saving lives at short distances from the tsunami source, but they will be useful at large distances.

New technologies and surveys will enhance our knowledge of the geomorphology and velocity structure of the shallow subduction zone. Ocean bottom seismometers, tide gauges, buoys and other seafloor monitoring devices will provide high quality data, which will enable us to place better constraints on where exactly the slip in shallow earthquakes occurs and in what tectonic environment. Although tsunami earthquakes occur relatively infrequently and thus may be difficult to capture, comprehensive characterizations of their rupture processes placed in the context of detailed three-dimensional models of the shallow subduction zones they occurred in will be an important next step in understanding their unusual seismic and tsunami-genic processes.

### Glossary

**Tsunami early warning system** It consists of four components, namely, 1) Seismic network, 2) Seismic data processing system, 3) Tsunami forecast system, and 4) Sea level data monitoring system. In a broader sense, warning transmission system (downlink to disaster management organizations and public) is also included.

**Tsunami amplitude** Amplitude is measured from undisturbed sea level to peak or trough of the wave. By definition, it can be positive or negative. Tsunami amplitude can be measured in real-time by instruments like tide gauge, pressure sensor, etc., and can be reproduced by numerical tsunami propagation simulation. One needs not to be confused with the term 'run-up height'. It is the maximum height of inundation on land, and measured in post-tsunami field surveys from traces of tsunami (i. e. damage of constructions, vegetative markers, etc.).

**Simulation point** In this article, it is defined as the surface projection location of the hypothetical earthquake fault center. The vertical component of ocean bottom deformation due to earthquake fault dislocation calculated by elastic theory gives the initial tsunami waveform for the numerical tsunami propagation simulation.

**Forecast point** In this article, it is defined as the location of the offshore point where tsunami amplitude is evaluated by using numerical tsunami propagation simulation.

**Intergovernmental coordination group** The group established under UNESCO/IOC to facilitate interna-

tional cooperation for the tsunami disaster mitigation. There are four ICGs as of now (Pacific Ocean, Indian Ocean, Caribbean Sea, North Eastern Atlantic Ocean and Mediterranean Sea). One of the most important characteristics of tsunami is that it can cause huge disaster even after long distance propagation due to amplification near the coast. Therefore, international cooperation, especially the prompt data and information exchange, is essential for the disaster mitigation.

**Centroid moment tensor solution** One of the representation of seismic source process. It is represented by the moment tensor, which is a combination of six independent equivalent force couples, and is a weighted average of the source process in time and space. Since it represents an overall image of the source process, it is suitable to evaluate tsunamigenic potential of the earthquake.

**Earthquake early warning** Earthquake Early Warning is to enable countermeasures in advance for strong motion disaster by detecting seismic *P* wave at stations near the epicenter, quickly estimate seismic intensity and arrival time of *S* wave, and transmit these estimation before the *S* wave arrival. The Japan Meteorological Agency (JMA) started to provide EEW to the general public in October, 2007. This technique is applicable to quicken tsunami warning dissemination.

### Definition of the Subject

A tsunami is, along with strong motion, one of the two major disasters caused by earthquake. To mitigate tsunami disaster, it is important to integrate software countermeasures like tsunami forecast to enable timely evacuation from area at risk before tsunami strikes the coast, as well as to intensify hardware countermeasures particularly in vulnerable coastal areas like building banks and water-gates. Tsunami disaster mitigation can be achieved effectively by the appropriate combination of the software and hardware countermeasures. Also, improving people's awareness on the tsunami disaster, necessity of spontaneous evacuation when they notice an imminent threat of tsunami on their own (feeling strong shaking near the coast, seeing abnormal sea level change, etc.) and how to respond to a tsunami forecast, and conducting tsunami evacuation drill are very important issues for disaster mitigation.

In this article, a tsunami forecast, as the most typical software countermeasure that a national organization can provide, is mainly described. Recent progress in science has deepened our understanding of the tsunami-generating source mechanisms, tsunami propagation and inundation process and enabled the development of sophis-

ticated numerical simulation programs. But at the same time, complexities of focal process and tsunami behavior, especially near the coast, have also been revealed. Therefore, careful consideration of the complicated nature of tsunami phenomena is essential in order to make tsunami forecast contents and the dissemination of warnings effective for disaster mitigation.

## Introduction

A tsunami is an oceanic gravity wave generated by submarine fault dislocation or other origins such as mud or rock slumps on steep continental margin slopes, marine volcanic eruptions and others. A large tsunami may cause disasters along densely populated or built-up coasts and sometimes also by the inundation of low land areas, up to several km inland. Most tsunamis are generated by large earthquakes occurring in oceanic areas, and it is possible to estimate tsunami generation to a certain extent from seismic wave analysis. By taking advantage of the propagation velocity difference between the much faster seismic and the slower tsunami waves, it is possible to mitigate tsunami disasters by issuing tsunami forecast before the tsunami arrives at the coast, thus enabling evacuation and other countermeasures. For other origins of tsunami, it is still difficult to quantitatively forecast tsunami generation until it is observed actually by the sea level change sensors.

In earlier years, an empirical method had been used to estimate tsunami amplitude via a regression formula that relates tsunami amplitude to the magnitude of the earthquake and its epicentral distance from the coast of interest. Recently, significant progress has been made in the understanding of the tsunami characteristics. This permits numerical simulation of the tsunami propagation once the initial tsunami wave distribution in the source area is correctly known, and bathymetry data are available with sufficient spatial resolution. In Japan, numerical simulation technique has been used in the operational tsunami forecasting procedure in the Japan Meteorological Agency (JMA) since 1999. Efforts have been made also in other countries to incorporate numerical simulation technique in tsunami forecasting. In this article, mainly based on JMA experience, procedures are introduced how to conduct tsunami forecast service by using numerical simulation techniques and giving due consideration to the complexity of this problem.

## Complexity Problem in Tsunami Forecasting

The complexity of tsunami forecasting with numerical methods is twofold and mainly due to the following:

- The uncertainty of the initial tsunami wave distribution in the source area
- The complexity of bathymetry and coastal topography

### Uncertainty of the Initial Tsunami Wave Distribution

For a local tsunami, only limited time is left from the generation of tsunami to its arrival at the coast. In order to assure maximum lead time for evacuation, this necessitates the tsunami forecast to be based on the earliest available data from seismic wave analysis. On the other hand, in the case of a distant tsunami sources, a relatively long lead time is left until the tsunami strikes the coast, and data of sea level change can be recorded in near real-time by tidal stations on the way from the source to the coast. This allows the tsunami forecast to be based on the actual observation of generated tsunami waves and thus to reduce the uncertainty in the initial spatial distribution of the tsunami wave in the source area. Also for local events it is possible to improve the accuracy and reliability of the tsunami forecast in a step-by-step manner, if more detailed data and reliable analysis results become available after the first forecast has been issued. Therefore, the most practical approach in view of the disaster mitigation is to assure the rapid issuance of the first forecast based on the seismic wave analysis, and then to update it with improved data.

There are several uncertainties when the initial tsunami wave distribution is inferred from seismological data analysis alone.

### Uncertainty of the Relative Location of the Hypocenter in the Rupture Area

The hypocenter of an earthquake is merely the location from where the rupture starts. It is calculated from first arriving seismic waves. Depending on the direction of rupture propagation (e.g., unilateral, bilateral, radial) and the complexity/irregularity of the actual fault rupture, the seismologically determined hypocenter may neither lie in the center of the rupture area nor coincide with the area of maximum fault displacement. The bigger the earthquake and thus the larger the spatial extent of the rupture area, the less representative the seismologically derived hypocenter as a parameter for characterizing the earthquake rupture is. To reduce this uncertainty, some methods have been developed, like a rupture process inversion by using teleseismic broadband seismogram [20], or near-field strong motion data [11]. A fault model inversion by using a co-seismic step estimated by real-time GPS data analysis is under development [5,22,25]. And the spatial extent of the tsunami source area can also be constrained by using inverse refraction diagrams from tidal stations [1] or deep ocean wa-

ter pressure sensor (DART (Deep-ocean Assessment and Reporting of Tsunamis))-type stations [6] that recorded tsunami arrivals as well as by satellite sea surface altimetry data taken over the source area [7,10].

In general, the rupture process is complicated, and the slip distribution on the fault is not uniform. Non-uniformity of the slip distribution can make the initial tsunami wave distribution much more complicated, especially in its short wavelength component, and may strongly affect the tsunami behavior on the coast. To estimate the slip distribution, in addition to the seismological and geodetic methods mentioned above, fault slip distribution inversion techniques have been developed which compare actually observed tsunami waveforms with pre-calculated theoretical tsunami waveforms from unit fault dislocation segments as Green functions [26] ► **Tsunamis, Inverse Problem of.**

**Uncertainty of the Magnitude** The maximum amplitude of a seismic body or surface wave group is usually used for estimating the earthquake magnitude (see this volume) as a measure of earthquake size in a certain period range, which is often limited by the bandwidth of the seismometer response. Therefore, the tsunamigenic potential may be underestimated, especially for gigantic earthquakes (such as the Sumatra-Andaman Mw9.3 earthquake of 26 December 2004) and “tsunami earthquakes” that generate bigger tsunami than expected from its shaking potential and magnitude values in the short-period range. To overcome this difficulty, some fast body-wave methods have been developed that consider besides single maximum amplitudes also multiple rupture amplitudes over the rupture duration [2], ► **Earthquake Magnitude**, integrated seismic energy and/or total rupture duration time [8,21], while others use successfully long-period spectral mantle surface-wave amplitudes in real-time applications in the context of tsunami warning [38], and  $W$ -phase for quick estimation of CMT solution for a practical tsunami warning service [17]. Besides these seismological methods for estimating earthquake magnitude, geodetic methods that use the co-seismic step or ultra-long period component observed by crustal deformation sensors [5,13,18] play an increasing role for estimating the size of great earthquakes.

**Uncertainty of the Fault Parameters** It is difficult to estimate fault geometry promptly after the earthquake occurrence. Sea floor deformation due to fault motion is usually assumed to be identical to initial tsunami wave distribution. Accordingly, the latter is significantly affected by the specifics of fault geometry, fault and slip orienta-

Tsunami Forecasting and Warning, Figure 1  
Definitions of fault parameters.  $L$ ,  $W$ ,  $D$  and  $d$  denote the fault length, width, average slip amount and depth of the top margin of the fault respectively. The fault dip  $\delta$  is measured down from horizontal, strike  $\phi$  clockwise round from North and slip (rake)  $\lambda$  anti-clockwise round from strike direction along the fault plane (motion of the hanging wall relative to the footwall)

tion in space as well as rupture complexity. These complexities are usually neglected and the real fault rupture is roughly approximated by a dislocation model that is represent by a rectangular fault that is described by 6 parameters, namely the fault length  $L$ , width  $W$ , average slip amount  $D$ , and the three angles of fault dip  $\delta$ , strike  $\phi$  and slip (rake)  $\lambda$  (Fig. 1).

**Fault Length, Width and Average Slip Amount** Different scaling laws exist between  $L$ ,  $W$  and  $D$  with earthquake magnitude (e. g., [3,4,16,37,39]). They allow us to roughly estimate these values from determined magnitudes. Such scaling relations are based on the assumption of more or less constant stress drop (i. e. High stress drop earthquake has larger  $D$  for the same  $L$  and  $W$  of low stress drop earthquake). But the stress drop is different between inter-plate thrust events and intra-plate events. In general, intra-plate event has higher stress drop than inter-plate event. Such differences may cause significant errors when estimating these fault parameters via scaling relations with magnitudes. Best estimates of these parameters, that characterize the earthquake size, are possible via the determination of the seismic moment  $M_0 = \mu DA$  with  $\mu$  being the rigid-

ity of the crustal/lithosphere material in the rupture area  $A = L \times W$ , and  $L$  and  $W$  estimation by rupture process analysis described in Sect. “Uncertainty of the Relative Location of the Hypocenter in the Rupture Area”.

*Fault Dip, Strike and Slip Angle* Representative values for dip, strike and slip angles can be set based on the analysis of past great earthquakes having occurred in each region. The fault plane of a newly occurred earthquake is likely to be close to either one of the two nodal planes derived from centroid moment tensor (CMT) solutions. But to select from these two candidates the real acting fault plane, precise aftershock location or rupture process analysis as described in Subsect. “Uncertainty of the Relative Location of the Hypocenter in the Rupture Area” are necessary.

### Complexity due to Complicated Bathymetry

If the spatial distribution of the initial tsunami wave is given correctly, the tsunami propagation can be forecast in a deterministic manner by using numerical simulation technique. In a long-wave approximation, which considers only wavelengths of the tsunami that are much larger than the sea depth, the propagation velocity  $v$  of the tsunami is represented by  $v = \sqrt{gd}$ , where  $g = 9.81 \dots \text{m/s}^2$  is the Earth’s gravity acceleration and  $d$  the sea depth in m. This approximation is valid for most tsunami cases. As wavelength is the product of velocity times period, tsunami wavelength is proportional to the square root of sea depth. Accordingly, the wavelength of the tsunami become shorter as it approaches the coast because the sea depth becomes shallower, and the wave becomes much more sensitive to finer bathymetry changes and coastal feature. Therefore, a finer mesh of bathymetry and coastal features is necessary near the coast in order to represent the tsunami behavior correctly. But, even if very fine mesh bathymetry data are available, it is not appropriate to use it in an early stage of tsunami propagation simulation when the initial tsunami wave distribution is still uncertain as mentioned in Subsect. “Uncertainty of the Initial Tsunami Wave Distribution”.

Further, very fine-mesh simulations require a substantially long time for the conduct of simulation. Time constraints are crucial when incorporating numerical simulation techniques in an operational tsunami forecast procedure, except for distant events. Therefore, especially for local events, it is most practical to conduct tsunami simulations for a variety of scenarios in advance, to store these results in a database, and to conduct tsunami forecast by retrieving the most appropriate case for the determined hypocenter. As described later, the JMA has adopted this

way. Even in that case, the mesh size to be used in the simulations must be carefully examined taking into account the required accuracy and spatial resolution in the tsunami forecast for guiding disaster mitigation efforts and the need to complete the simulations for all scenarios in a realistic time span.

When very fine mesh is used, depending on the complexity of the bathymetry and topography near the coast, tsunami amplitude distribution along the coast shows significant scatter, and sometimes, extremely large tsunami amplitude will be estimated very locally. Therefore, it must be clearly defined in advance as to what kind of statistical average value, using a finite number of estimated tsunami amplitudes for the area of interest, should be adopted in the tsunami forecast.

### Components of a Tsunami Early Warning System (TEWS)

In general, a tsunami early warning system consists of the following constituents:

1. Seismic network (seismometers and real-time data transmission link)
2. Real-time seismic data processing system for hypocenter and magnitude determination
3. Tsunami forecast system (including warning criteria, assembling of the text, and dissemination)
4. Sea level data monitoring system (tide gauge/tsunami-meter and real-time/near real-time data transmission link)

Such a composition is adopted in Japan, USA, Russia, Chile, Australia, French Polynesia, New Caledonia and in other countries around the Pacific Ocean. The up-to-date status of the TEWS of these countries can be consulted on the UNESCO/Intergovernmental Oceanographic Commission’s (IOC) website as based on the national reports submitted to the latest meeting of the Intergovernmental Coordination Group/Pacific Tsunami Warning System (ICG/PTWS). Also in Indian Ocean countries, after the tremendous tsunami disaster brought by the Great Sumatra Earthquake in 2004, efforts have been made to establish tsunami early warning systems of the similar composition in different countries (e. g. GITEWS: German Indonesian Tsunami Early Warning System, see <http://www.gitews.org/>). Similar efforts are under way in the Caribbean, North Eastern Atlantic and Mediterranean regions too, inspired by the Sumatra event and taking into account potential tsunami risk assessments for these areas based on historical records.

To accomplish tsunami warning for local events, local seismic networks (see Subsect. “**Seismic Network**”) and real-time seismic data processing systems (see Subsect. “**Real-Time Seismic Data Processing System**”) are indispensable. For a distant event, one can utilize the hypocenter parameters contained in the international tsunami watch information provided by the Pacific Tsunami Warning Center (PTWC), West Coast/Alaska Tsunami Warning Center (WC/ATWC) of US and North West Pacific Tsunami Advisory Center (NWPTAC) of the JMA.

As a typical example, technical details of Japan’s Tsunami Early Warning System, in which all four constituents are fully deployed, is explained in the following section.

As for the item 4 (sea level data monitoring system), the US and also GITEWS are now deploying DART type of buoys [6] system. This is to measure a sea surface vertical displacement by observing the related pressure change at the ocean bottom. DART buoys are placed in far offshore regions where bathymetry is simple, and very simple tsunami waveforms can be observed without the influence of complicated bathymetry near a coast. Such measured data are preferable for a comparison with simulated waveforms. And by placing such buoys with proper spacing at a certain distance from the tsunamigenic zone over the deep ocean basin, tsunami waves, that are sufficiently separated in time from seismic waves, can be observed early enough after the earthquake occurrence to be useful for tsunami EW from distant sources.

The Pacific Marine Environmental Laboratory (PMEL) of the National Oceanic and Atmospheric Administration (NOAA) is developing a tsunami forecasting system named SIFT (Short-term Inundation Forecasting) [33] based on the DART buoy data. Like in the JMA’s tsunami simulation database, described in detail below, tsunami simulations are conducted for many different unit faults located along the tsunamigenic zone, and the calculated tsunami waveforms at DART buoy locations are stored in a database as Green functions, together with simulated waveforms at coastal points. In the case that a tsunami wave is observed by DART buoys, the observed waveforms are represented by a linear combination of several Green functions. Then, tsunami amplitudes at coastal points can be estimated from the linear combination coefficients and the simulated waveforms at coastal points (see web-page of NOAA/PMEL (<http://nctr.pmel.noaa.gov/>) for applications of their method to recent actual tsunami events). This system is planned to be introduced in the actual tsunami forecasting procedures of the US tsunami warning centers.

In Japan, a similar study is in progress at Tohoku-University [35]. They conduct tsunami simulations originat-

ing from unit vertical sea surface displacements in a unit sea area, and the resulting simulated waveforms at offshore tsunami meters are stored as Green functions in a database. They do not adhere to a specific fault model. The procedure for the estimation of tsunami waveform at coastal points is similar to that of SIFT.

### Tsunami Early Warning System in Japan

Before describing the present status of the JMA’s TEWS, a historical review is briefly given.

The JMA started tsunami warning service in 1952. Since then, the JMA has been making an effort to integrate its TEWS, and this is exactly a history of ‘fight against time’.

At the commencement of the tsunami warning service, the JMA had 46 seismometers at meteorological observatories (basically near populated area on a sedimental layer). In case of earthquake occurrence, seismograms were read at observatories, and their results (*P* and *S* arrival times and maximum amplitudes) were transmitted to the headquarters in a telegram format. At the headquarters, hypocenter and magnitude were determined manually, and the tsunami warning grade was determined by using an empirical chart based on the relation between tsunami amplitude, earthquake magnitude and epicentral distance to a coast of the past events. It took about 15 to 20 minutes to disseminate a tsunami warning.

From the late 1960s to early 1980s, telemetry technology to transmit seismic waveform data from observatories to the headquarters and a processing computer were introduced. Detection capability of the earthquake was improved by monitoring collected seismic waveforms at one place, and the *P* and *S* picking precision was also improved by introducing a digitizer. By these, dissemination time was reduced to 12 to 13 minutes.

In 1983, the Mid-Japan-Sea earthquake (Mjma7.7) occurred. The JMA disseminated a tsunami warning in 14 minutes, but in about 7 minutes, the tsunami struck the nearest coast, killing 104 people. After this event, the JMA deployed a more sophisticated computer system for the seismic waveform processing. A graphical man-machine interface was introduced for more accurate and quicker phase reading and hypocenter and magnitude calculation. Still, the empirical method was used for the tsunami amplitude estimation. Dissemination time was reduced to between 7 and 8 minutes.

In 1993, the Southwest off Hokkaido earthquake (Mjma7.8) occurred. The JMA disseminated a tsunami warning in 5 minutes, but the tsunami struck Okushiri-Island in a few minutes, and 230 people were killed or lost by

tsunami. After this event, the JMA totally replaced the seismic network. All seismometers were installed in remote un-manned sites on hard rock, and the total number of the site increased to about 180. Dissemination time was reduced to 3 to 5 minutes.

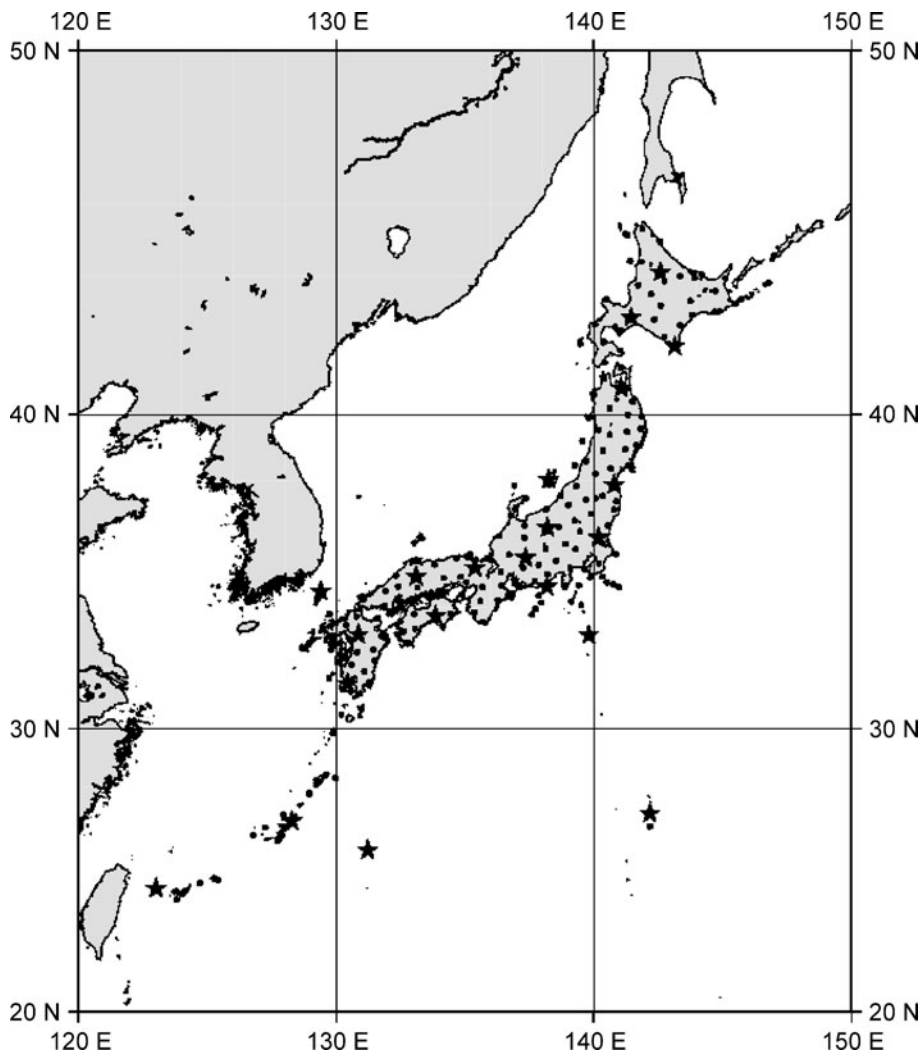

The present status of the JMA's TEWS is as follows.

### Seismic Network

The JMA operates about 180 seismometers installed in Japan (Fig. 2). The seismic waveform data are sent to JMA

continuously on a real-time basis through dedicated telephone lines.

There are two kinds of sensors deployed at each station: A short-period velocity sensor and an accelerometer. The records of the short-period sensor are mainly used for precise picking of the onset times of *P* and *S* phases which are required for an accurate hypocenter determination. Accelerometer records are used for the calculation of magnitude of large earthquakes in the case that the ground motion amplitude exceeds the dynamic range of the short-period sensor.

Tsunami Forecasting and Warning, Figure 2

Seismic network of the JMA used for tsunami forecasting. *Solid circles* and *stars* denote the locations of seismic stations operated by the JMA. The average spacing between the about 180 stations is 50 to 60 km. *Stars* denote the location of stations where STS-2 velocity broadband seismometers have been installed in addition to the Japanese short-period velocity-type seismometers and accelerometers

STS-2 broad-band seismometers have additionally been installed at 20 stations. These broadband velocity seismic records are mainly used for obtaining CMT solutions and moment magnitudes  $M_w$ .

### Real-Time Seismic Data Processing System

The JMA applies the short term average/long term average (STA/LTA) method as trigger criteria. It is most widely adopted in the seismological community and used to limit seismic recordings to relevant seismic event waveforms. When the ratio of STA/LTA exceeds the trigger threshold, it is supposed that a significant signal, possibly an earthquake signal, has been detected by the considered station.

STA/LTA trigger may occur due to some troubles or local noise at one station. To avoid “false trigger”, the JMA also applies other criteria including the group trigger criterion. A group is set to include several neighboring stations. When the STA/LTA trigger turns on at a certain number of stations in one group, the system considers it to be caused by an earthquake.

For the precise picking of the  $P$  onset, an auto regressive (AR) model is applied to represent seismogram time series. Akaike’s information criterion (AIC) is used to search the optimal time to separate the seismogram into two sub-stationary time series (noise part and signal part), which are represented by AR models, respectively, in a certain time window around trigger time [32,40].

The usual least square method is used in the hypocenter calculation. As for the velocity structure, the Japan local standard model JMA2001 [36] is applied. To better locate the hypocenter,  $S$  arrival times are used in addition to  $P$  arrival times. First, a preliminary hypocenter is calculated by using only  $P$  arrival times picked by an automatic picker. Then,  $S$  arrival times are picked automatically by applying the AR model and AIC in a time window centered at the theoretical  $S$  arrival times estimated from the preliminary hypocenter location and origin time. The final hypocenter is then calculated by using both the  $P$  and  $S$  arrival times.

For magnitude calculation, one of the local magnitude definitions in Japan, the JMA magnitude ( $M_{jma}$ ) according to Katsumata [19] is used, in which average amplitude decay characteristic in Japan is taken as a decay correction term of the formula. Maximum amplitude of the horizontal ground displacement is the measured input value in the formula. The displacement waveform is calculated by applying real-time recursive filter that integrates twice the accelerometer data and applies a high-pass filter to avoid computational instability. Due to historical reasons, the long-period cut-off of the high-pass filter is set at

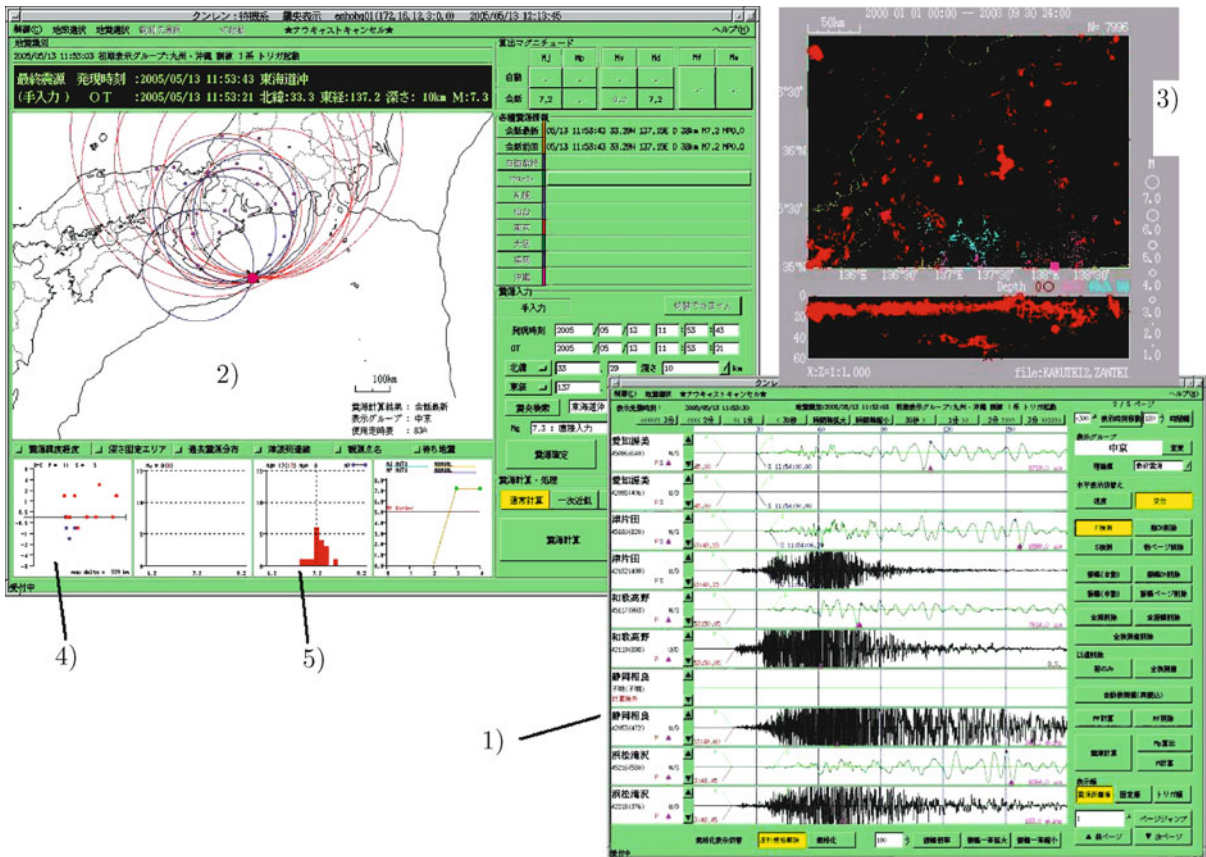

Tsunami Forecasting and Warning, Figure 3  
Relation between  $M_w$  (Global CMT) and  $M_{jma}$ , based on events that occurred after September 2003 in and around Japan. Both magnitudes agree on average well up to around magnitude 8.0

5 seconds. Since unsaturated strong-motion data are used, magnitude calculation can be started promptly after the earthquake occurrence by using data from stations very close to the epicenter. Therefore, such magnitude data are suitable for the tsunami warning purposes of local events.

The comparison between  $M_{jma}$  and the moment magnitude  $M_w$  of the Global CMT Project’s solution is shown in Fig. 3.  $M_{jma}$  values are on average comparable with  $M_w$  for earthquakes with magnitudes between  $M_{6.0}$  and about 8.0.

All procedures mentioned above are run automatically by the computer. Considering the possible impact of a tsunami warning on the potentially affected communities, a human check of the adequacy of the calculated results is indispensable for minimizing false alarms. The following items are checked by the operators, using a man-machine interface:

1. Adequacy of the phase pickings and maximum amplitude readings: The seismic waveforms are plotted together with picked and theoretical arrival times for  $P$  and  $S$ , and the marked position at which the maximum amplitude was measured. This plot also allows them to discriminate noise from seismic signals.
2. Adequacy (mathematical) of the hypocenter location: A hypocenter plot map is used in which the locations of used seismic stations and the circles denoting the calculated epicentral distance from each station are shown. If the circles intersect densely at one point, and if the

Tsunami Forecasting and Warning, Figure 4

Examples of the JMA's man-machine interface screen image in the seismic data processing system. Numbers in the figure are related to the respective numbers of items explained in the main text

- used stations assure a wide azimuthal coverage around the source, then the calculation is judged as fine.
- Adequacy (seismological) of the hypocenter location: The hypocenter plot on the background seismicity map is used together with the vertical cross section. If the hypocenter is located in a region where no background seismicity is found, it should be re-examined carefully.
  - Adequacy of the depth estimation: Travel time residuals are plotted as a function of epicentral distance. If the residuals depend on epicentral distance, the depth estimation should be revised.
  - Adequacy of the magnitude calculation: A histogram of station magnitudes is used. Outliers are checked and excluded in the re-calculation.

Sample images of the man-machine interface are shown in Fig. 4.

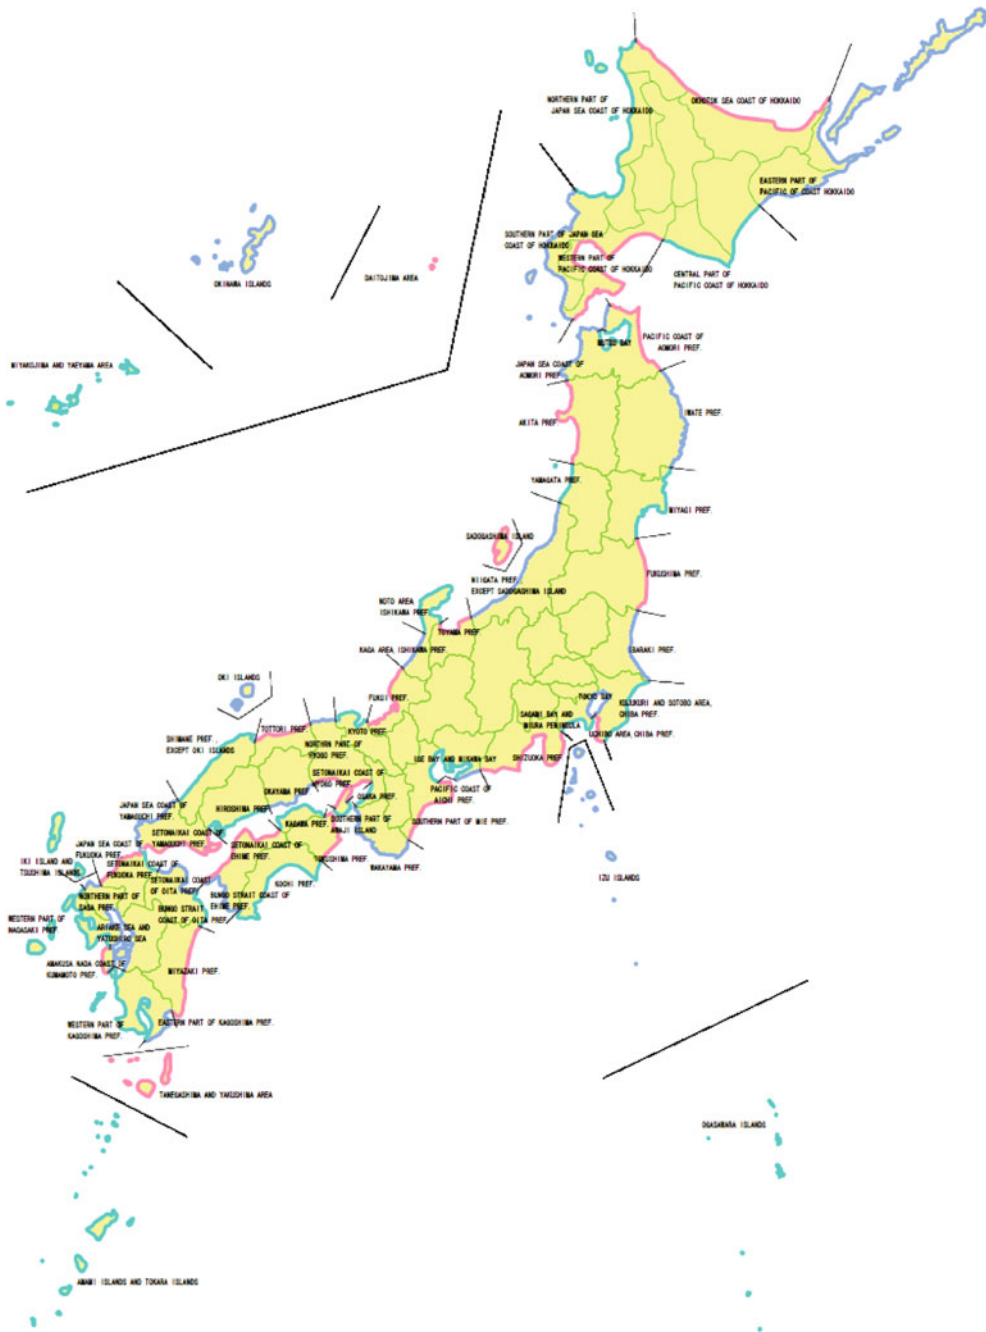

The JMA's man-machine interface is designed so that re-picking and recalculation of hypocenter and magnitude can be done within about 30 seconds.

Calculated hypocenter parameters (latitude, longitude, depth and magnitude) are transferred to the following tsunami forecast system as its input.

### Tsunami Forecast System

**Tsunami Forecast in Japan** For a tsunami forecast to be useful, a mere general description of the tsunamigenic potential estimated from calculated hypocentral parameters is not sufficient. From the issued message, the recipient disaster management organization should be able to clearly grasp the severity of the expected disaster in its own jurisdiction. In Japan, a tsunami forecast is disseminated to each coastal block (the coast line of Japan is separated into certain number of blocks), giving three kinds of grade corresponding to the anticipated severity of the disaster.

**Tsunami Forecast to Coastal Block** The coastal blocks divide the Japanese coasts into 66 regions (Fig. 5). These blocks are defined by taking into account:

Tsunami Forecasting and Warning, Figure 5  
 Coastal block partitioning for tsunami forecast in Japan. *Straight lines* denote the borders between the 66 coastal blocks

- a) The administrative districts of local governments, which are the disaster management units to take actions in emergency situations
- b) The sea areas to which each coast is facing
- c) The uniformity in the behavior of tsunami
- d) The precision of tsunami forecast technique

Basically, one coastal block corresponds to one prefecture, or finer.

Before the introduction of numerical tsunami simulation technique, the total number of coastal blocks was 18, due to a low precision of empirical tsunami amplitude estimation method.

**Tsunami Forecast Criterion and Category** The JMA categorizes tsunami forecast into “Tsunami Warning” and “Tsunami Advisory”. Further, “Tsunami Warning” is divided into two grades, “Tsunami” and “Major Tsunami”.

In Japan, there exist ample number of materials on the relation between tsunami disaster and observed tsunami amplitude along the coast. From the materials, high correlation between these two can be seen. Therefore, estimated maximum tsunami amplitude at the coast is used as a criterion of the tsunami forecast in Japan. The speed of water current in the sea near the coast could be another good index for assessing the tsunami disaster potential. But, up to now, only a few examples of the current observation are available. Therefore, the estimated tsunami amplitude at the coast is still the most appropriate criterion for tsunami forecast.

In Japan, tsunami disaster in the land area occurs when the tsunami amplitude exceeds 1 meter [30], so the warning criterion is set at 1 meter. When tsunami amplitude exceeds 3 meters, the proportion of damaged wooden houses and fishing boats increases remarkably [9,28,29]. Therefore, the JMA issues the highest warning grade “Major Tsunami” when the estimated maximum tsunami amplitude is 3 meters or higher. When the estimated maximum tsunami amplitudes range between 1 meter to 3 meters, the grade name is “Tsunami”. If a “Tsunami Warning” is issued, the head of municipality must order evacuation to the residents in the “Tsunami Evacuation Zone” assigned by each municipality in advance.

Even when the tsunami amplitude is less than 1 meter, it is occasionally the case that bathing people are affected and aquaculture rafts for marine products industry are damaged. Considering safety criteria in sea bathing places (beaches, bays), and the relation between the tsunami amplitude near the coast and damage on aquaculture rafts in the past, the JMA’s criterion for “Tsunami Advisory” is set at 20 centimeters. In the case that a “Tsunami Advisory” is issued, there is no need of evacuation in the land areas, except vulnerable very low-land areas, but people on beaches or swimming should go to higher places.

Table 1 shows the tsunami forecast grades and levels of the estimated maximum tsunami amplitude that are used by the JMA when issuing tsunami information for each coastal block after a tsunami forecast has been made.

When the estimated tsunami amplitude is less than 20 cm, no warnings or advisories are issued, but a message “No threat of tsunami disaster” is promptly provided to the public in order to prevent unnecessary spontaneous evacuations in accordance with the widely spread recommendation in Japan: “When you feel a strong shaking near

Tsunami Forecasting and Warning, Table 1

**Tsunami forecast grades and corresponding levels of expected maximum tsunami amplitudes as used in tsunami information issued by the JMA for each coastal block after a tsunami forecast has been made**

Forecast Grade		Levels of Estimated Tsunami Amplitude
Warning	Major Tsunami	3 m, 4 m, 6 m, 8 m, 10 m or greater
	Tsunami	1 m, 2 m
Advisory		0.5 m

a coast, run to a high place without waiting for tsunami forecasts from the JMA”.

**Tsunami Database Creation** The JMA introduced in 1999 a numerical simulation technique to implement accurate tsunami warning. However, even most-advanced computers require substantial time for the completion of the calculations. Therefore it is impossible to issue prompt tsunami warning based on numerical simulation technique even if the calculations start simultaneously with the occurrence of an earthquake.

Alternatively, the JMA employs a database method to achieve a breakthrough on this issue. Tsunami propagation originating from various locations, fault sizes and likely rupture mechanisms are calculated in advance and the results, namely estimates of maximum tsunami amplitudes and arrival times, are stored in a database together with the associated hypocenter location and magnitude.

If an earthquake occurs, the most appropriate case for the actual hypocenter location and magnitude is retrieved from the database and the tsunami forecast is issued accordingly.

**Hypocentral Location** The first step to create a tsunami database is to set fault models. ‘Simulation points’ are defined as surface projection locations of the center of possible causing faults, and are placed in the areas where tsunamigenic earthquakes are likely to occur. These points are selected on the basis of background seismicity and the records of the past earthquakes that generated tsunami.

Figure 6 shows the locations of simulation points in Japan and surrounding areas.

The total number of scenarios calculated for these points is about 64,000 (lat.  $\times$  lon.  $\times$  dep.  $\times$  mag.). Earthquakes with hypocenter depth of more than 100 km or magnitude less than 6.2 are not considered, because they do not cause disastrous tsunami [23].

**Fault Parameters Setting** Figure 1 shows fault parameters used in the numerical simulation. Length  $L$ , width  $W$ ,

Tsunami Forecasting and Warning, Figure 6

Distribution of simulation points in and around Japan. *Solid triangles* denote locations of simulation points to which likely hypothetical fault models are attributed. *Spacing* between the simulation points is 0.5 degrees in near coastal areas, and 1.0 degree in off-shore areas

and slip amount  $D$  of the fault are represented in terms of empirical formulas as functions of magnitude. The following are common relations used in Japan [37] based on  $M = M_j$ ma:

$$\begin{aligned} \log L &= 0.5M - 1.8 \quad \text{with } L \text{ in km,} \\ W &= L/2 \quad \text{or } \log W = 0.5M - 2.1 \quad \text{with } W \text{ in km,} \\ \log D &= 0.5M - 3.3 \quad \text{with } D \text{ in m.} \end{aligned}$$

These formulas are consistent with the next two formulas, assuming a common rigidity  $\mu = 2.0 \times 10^{10}$  Newton/m<sup>2</sup> of the rock-material in the source area

$$\begin{aligned} M_0 &= \mu \times L \times W \times D \\ \log M_0 &= 1.5M_w + 9.1 \end{aligned}$$

(in international standard units, i. e.,  $M_0$  in Nm = Newton meter).

The dip ( $\delta$ ), strike ( $\phi$ ) and slip ( $\lambda$ ) angles of the fault at each simulation point are based on average values of past earthquakes at or near these locations. But if they are uncertain, they are assumed to be those of a pure reverse fault ( $\lambda = 90$  degrees) whose strike is parallel to the trench or nearby coast, and with a dip angle of 45 degrees, corresponding to an efficient tsunami generation in view of disaster management.

*Initial Value for Numerical Simulation of Tsunami Propagation* The vertical deformation of sea floor due to fault motion is calculated by the elastic theory [24], using fault parameters as set above. The initial deformation of the sea surface is assumed to be identical to the vertical deformation of the sea floor and used as input value for the numerical simulation, because in most cases, rupture propagation

velocity is much higher than the tsunami propagation velocity, and the ocean bottom deformation can be treated to occur instantaneously [14].

*Numerical Simulation of Tsunami Propagation* Non-linear long-wave approximation equation with advection term and ocean-bottom friction term is adopted as the equation of motion, and solved together with the equation of continuity as shown below by finite difference method with staggered leap frog scheme [27].

$$\frac{\partial V_x}{\partial t} + V_x \frac{\partial V_x}{\partial x} + V_y \frac{\partial V_x}{\partial y}$$

$$= -f V_y - g \frac{\partial h}{\partial x} - C_f \frac{V_x \sqrt{V_x^2 + V_y^2}}{d + h}$$

$$\frac{\partial V_y}{\partial t} + V_x \frac{\partial V_y}{\partial x} + V_y \frac{\partial V_y}{\partial y}$$

$$= f V_x - g \frac{\partial h}{\partial y} - C_f \frac{V_y \sqrt{V_x^2 + V_y^2}}{d + h}$$

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x} \{V_x(h + d)\} + \frac{\partial}{\partial y} \{V_y(h + d)\} = 0,$$

where  $V_x$  and  $V_y$  are the  $x$  (east) and  $y$  (south) components of the average water particle motion velocity in the depth direction, and  $h$  and  $d$  are sea surface displacement

Tsunami Forecasting and Warning, Figure 7  
 Computational area for creating the Japanese tsunami simulation database. Bathymetry is given by a color grade scale. One arc minute mesh bathymetry data are used throughout this area for the tsunami simulation

and sea depth, respectively.  $f$  is the Coriolis parameter ( $= 2\Omega \cos \theta$ ,  $\Omega$  is the angular frequency of Earth's self rotation,  $\theta$  is the co-latitude), and  $C_f$  is the sea bottom friction coefficient.

Advection and ocean bottom friction are considered only in sea areas with sea depth less than 100 m. Coriolis force is considered only in the distant tsunami case (see Sect. “**Tsunami Forecast for Distant Event and Northwest Pacific Tsunami Advisory (NWPTA)**”).

Figure 7 shows the computational area. Mesh size is 1 arc minute throughout the computational area. Eight hours of propagation simulation is conducted for all scenarios with a fixed time interval three seconds for the integration. The Coriolis force is not considered for local and regional tsunami simulations. Total reflection boundary condition is used at the land-ocean boundary, and open boundary condition is used outside of the computational area.

To represent the tsunami waveform correctly in a shallow sea area, very fine bathymetry data mesh is necessary (in a strict sense, 20 or more grid points are necessary within one wave-length [31]), and a vast time is required for the completion of such detailed calculations. To overcome this difficulty, the numerical simulation with the long-wave approximation is applied only to points which are a few to a few ten kilometers seaward from the coast (“forecast points”) where sea depth is about 50 m. Then, tsunami amplitude at the coast is calculated by using Green's law described in the next section.

*Derivation of Tsunami Amplitude at Coast* To estimate tsunami amplitude at the coast, Green's law (= energy conservation law) is applied to the estimated amplitude at the forecast points just seaward of the coast. As shown in Fig. 8, Green's law says that the tsunami amplitude at the coast is represented by fourth root of the ratio of sea depth at the forecast point and at the coast:

$$h_0 = \sqrt[4]{\frac{d_1}{d_0}} h_1 .$$

$h$  and  $d$  denote tsunami amplitude and sea depth, and suffix ‘0’ and ‘1’ denotes the value at the coast and forecast point.

As the forecast points are set close enough to the coast, horizontal convergence and divergence of the rays can be ignored, i. e., the wave front is regarded as almost parallel to the coast due to a refraction towards the direction of the largest sea-depth gradient. As for the “ $d_0$ ” value, the sea depth at the coast, 1 m is assumed, but actually measured value would be more appropriate, if available.

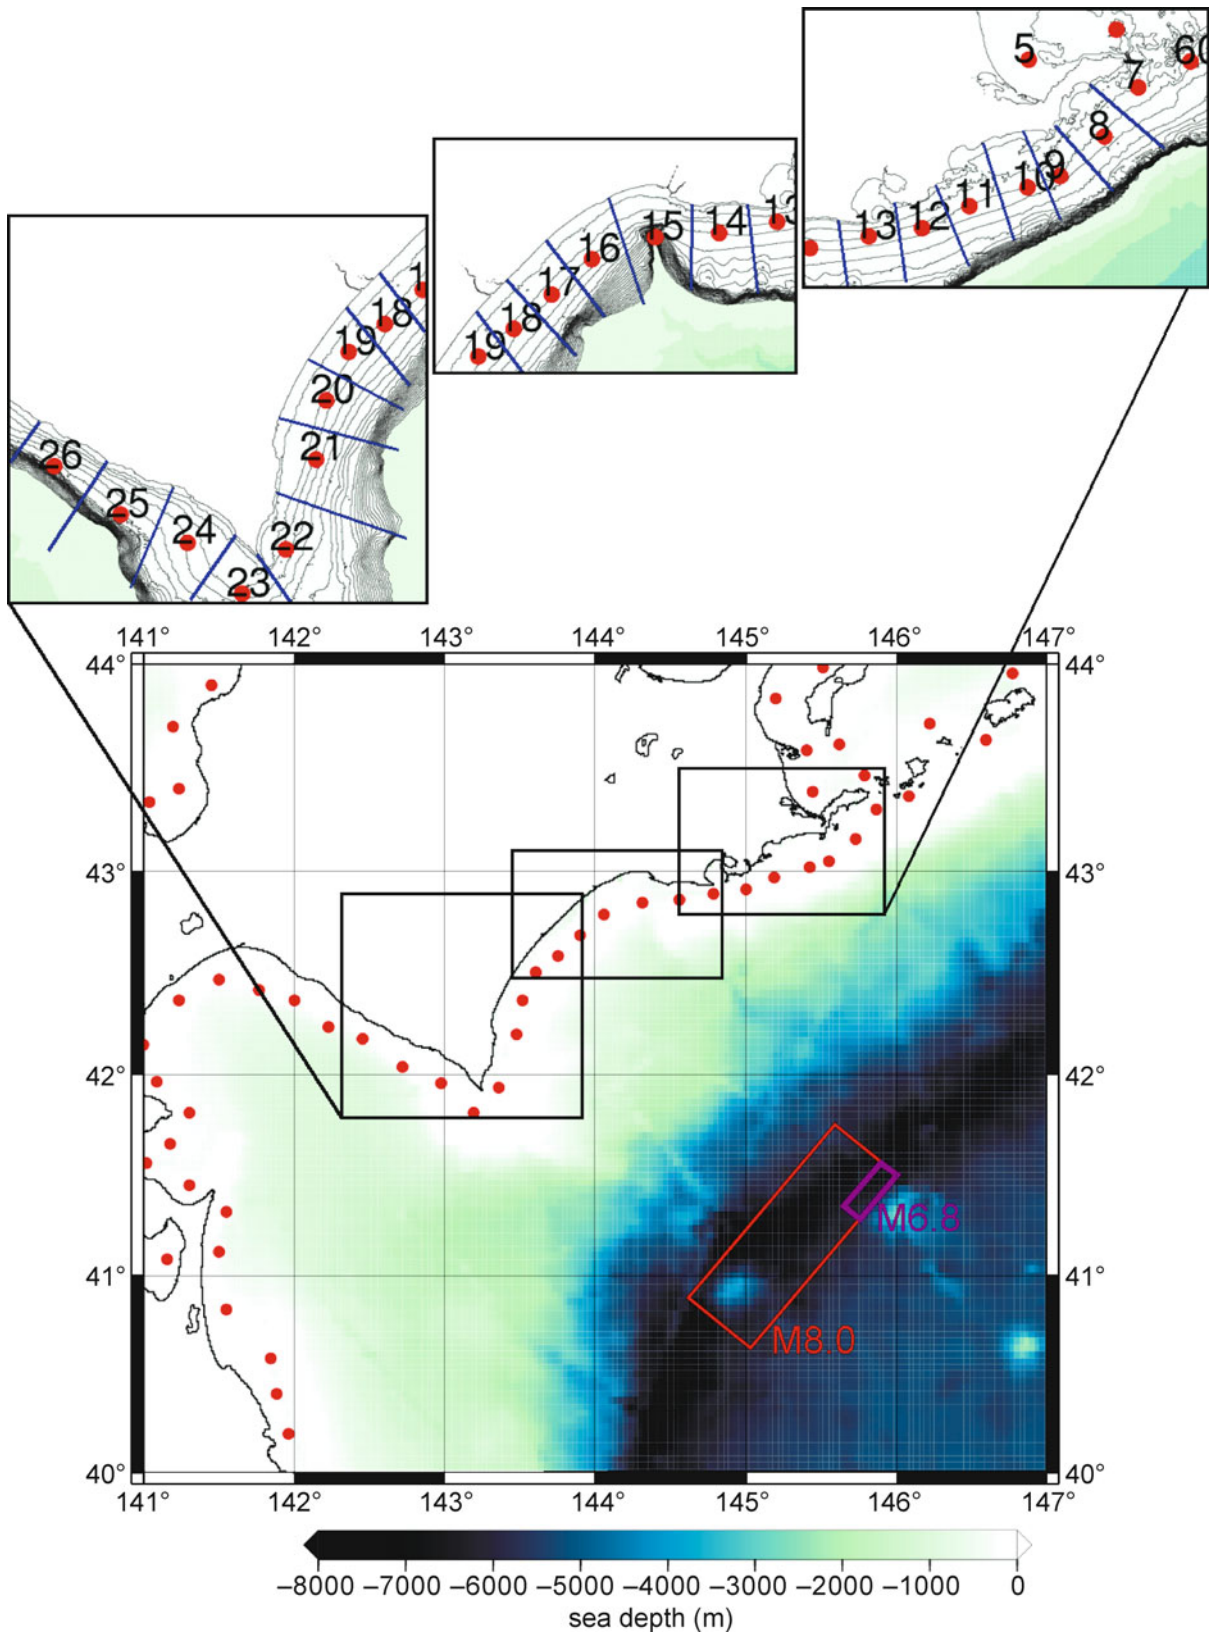

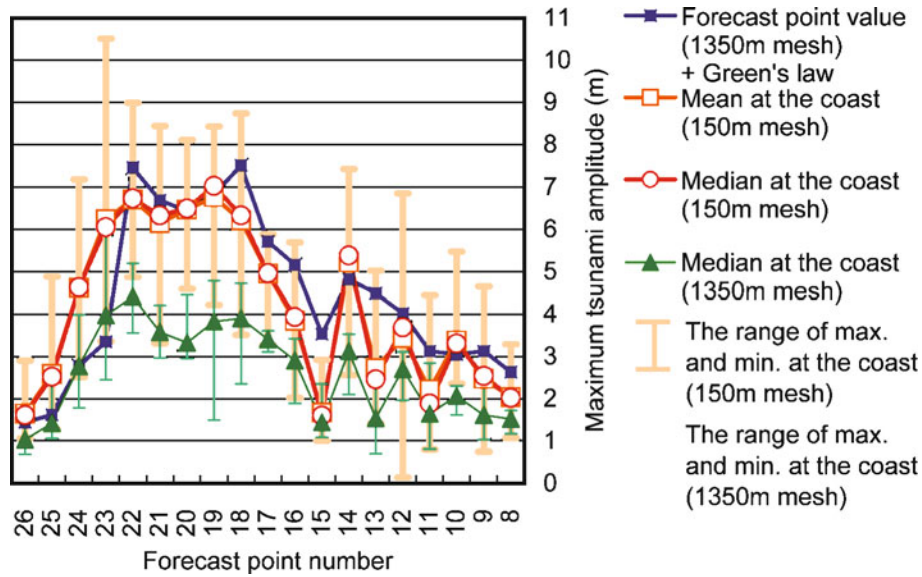

Tsunami Forecasting and Warning, Figure 8  
Schematic sketch to illustrate the application of Green's Law for tsunami amplitude calculation in near coastal areas. Ray convergence and divergence are ignored

*Adequacy of the Green's Law Application* The adequacy of Green's Law application to estimate tsunami amplitude at the coast is examined by using the TSUNAMI-N2 [12] program. It is equivalent to the program used at the JMA [27] to create tsunami simulation database. Up to 150 m mesh at the finest was used by adopting nesting technique, and the tsunami amplitudes estimated at the coastal mesh are considered “true” ones. We compared the case using 1,350 m mesh throughout the computational area (which is equivalent to 1 arc minute mesh) and then estimating the tsunami amplitude at the coast by applying Green's Law to the value at the offshore forecast point, with the expected “true” amplitude at the coastal point using finer mesh. Forecast points actually used for the database creation are shown in Fig. 9. Hypothetical fault models corresponding to two different magnitudes (8.0 and 6.8) have been depicted in this Figure as red and violet rectangles, respectively, south off the Pacific coast of Hokkaido Island. The results are shown in Fig. 10a,b. For

► Tsunami Forecasting and Warning, Figure 9

The map shows the distribution of forecast points (red dots) along the southern and eastern shore of Hokkaido and part of NE Honshu together with the surface projections of two hypothetical faults representing earthquakes with magnitude 8.0 (red rectangle) and 6.8 (violet rectangle), respectively. The depth of the fault top is 1 km from the sea bottom for both cases. Pure reverse fault with dip angle 45 degrees is assumed. In the upper half of the figure the coastal blocks are enlarged, showing the locations of forecast points denoted by numerals and the blue separation lines between sub-sections of the coast. The numbers correspond to the ‘forecast point number’ given on the abscissa of Fig. 10. Also depicted are bathymetry contour lines near the coast at 20 m depth intervals

Tsunami Forecasting and Warning, Figure 10a

The presented diagram illustrates the adequacy of the Green's law application. Shown are the tsunami forecast results for the hypothetical earthquakes of magnitude 8.0 (above) and 6.8 (below). On the abscissa the numbers of the 'forecast points' depicted in Fig. 9 are given. On the ordinate the maximum tsunami amplitudes in meter are given, as they result from the application of different modeling procedures (fine mesh as well as coarse mesh with and without applying Green's law; see legend). Vertical thick bars denote the range between maximum and minimum values of estimated tsunami amplitudes in each sub-section using an up to 150 m mesh. Vertical thin bars denote the range of directly estimated maximum and minimum tsunami amplitudes at the coast in each sub-section using a 1,350 m mesh

both events the estimated tsunami amplitudes at the coast by using a 1,350 m mesh and applying Green's Law to the forecast points (solid squares) agree well with the means (open squares) and medians (open circles) of tsunami amplitudes calculated by using a finer mesh in each coastal subsection. The coastal subsections are separated by middle points between the forecast points (see upper part of Fig. 9). Thus, it was confirmed that the application of Green's Law to tsunami amplitudes at the offshore forecast points yields amplitude estimates at the coast that are comparable with those calculated with much more time consuming fine mesh simulations. Therefore, we consider the former as representative estimates of the tsunami amplitude in the coastal subsection centered at the coastal projection of the forecast point.

It could also be shown that direct estimates of tsunami amplitudes at the coast based on coarse mesh simulations will underestimate values. This trend is even clearer for smaller event with shorter typical tsunami wavelengths (Fig. 10b). Therefore, it is not proper to estimate the tsunami amplitude directly at the coastal mesh when the mesh size is coarse relative to the typical tsunami wavelength.

However, there will be some issues to be considered in future in this method as follows.

- Strictly speaking, the Green's Law should only be applied to a direct wave. Therefore, in case the maximum amplitude is created by the superposition of multiply reflected waves, then this method can give overestimated tsunami amplitude.
- Scatter of estimated tsunami amplitude in one coastal subsection differs from section to section depending on the complexity of the coast line feature. It would be very difficult to precisely represent tsunami amplitudes for individual coastal points even if very fine bathymetry data are used in a simulation, because a short wavelength tsunami is significantly affected by small scale bathymetry and coastal feature or by a small change in an initial tsunami waveform. Therefore, incorporating a standard deviation of estimated tsunami amplitude to represent a degree of scatter in one coastal subsection, as well as a median or mean, in the tsunami warning/advisory grade determination would be effective for disaster management.

Tsunami Forecasting and Warning, Figure 10b  
(continued)

**Retrieval of the most Appropriate Case from the Database** In general, no identical case for actually determined latitude, longitude, hypocenter depth, magnitude exists in the database. Thus, some kind of selection rule is necessary to choose the most appropriate one.

**Hypocenter Depth and Magnitude** The logarithm of the estimated tsunami amplitude changes approximately positively linear with magnitude and negatively linear with hypocenter depth. Therefore, first, one has to calculate the logarithm of the estimated tsunami amplitudes for four cases (i. e., for two different depths and magnitudes each) which include the calculated depth and magnitude in between, then apply a two-dimensional linear interpolation and finally convert the log values back to a tsunami amplitudes.

**Latitude and Longitude** As for the location of the epicenter, either one of the two methods is used depending on the hypocentral area.

**Interpolation method** One selects the nearest four locations of simulation points in the data base which enclose the epicenter determined for the real event and performs a two-dimensional linear interpolation. This method is used far off the coast areas where horizontal shifts of the source location cause relatively smooth changes in the estimated tsunami amplitude at the coast. This is applicable in areas with a simulation point spacing of 1 degree (see Fig. 6).

**Maximum risk method** In the case that the assumed fault locations in the data base differ from the real location, tsunami amplitude estimates near the epicenter may differ substantially from observed ones for events occurring near to the coast. The uncertainty in the relative location of the epicenter on the surface projection of the seismic fault has to be considered at an early stage of the seismic data analysis, and all possible cases should be taken into account. Four cases with the epicenter located on one of the four corners of the fault are the most extreme cases, and the truth lies in between. Therefore, in the case of near coastal sources and with a view to disaster management, cases corresponding to every simulation point inside the rectangular area shown in Fig. 11 (solid circles) have to be considered. This rectangular area is centered at the epicenter (star mark). Its length and width are determined via the empirical formulas given in Subsect. "Fault Parameters Setting". Note, however, that the projected width in Fig. 11 is only  $0.5L \cos \delta$  and depends on the source dip. Also one has to remember that each simulation point is located in the center of the respective scenario fault in the data base. Therefore, the length and width of the rectangle to select all possible 'simulation points' are,  $L$  (not  $2L$ ) and  $0.5L \cos \delta$  respectively, and the strike of the length is that given to the simulation point (denoted by an arrow), which is closest to the determined epicenter. And the worst case is chosen amongst them for each of the forecast points.

Tsunami Forecasting and Warning, Figure 11  
**Maximum Risk Method:** The star denotes the epicenter and the circles the locations of simulation points. The rectangle delimitates the searching area from which the simulation points have to be retrieved. This rectangle is centered at the epicenter, and its length and width are  $L$  and  $0.5L \cos \delta$ , respectively, where  $L$  is given by the scaling law (see Subsect. "Fault Parameters Setting"). The strike of the length is the same as that given to the nearest simulation point to the epicenter. All simulation points inside of the rectangle (solid circles) are selected. Small arrows point into the strike direction assigned to simulation points

When readings of the tsunami arrivals at tidal gauges or tsunami meter become available, improbable simulation points can be excluded by applying inverse refraction diagrams. Thus the uncertainty in the spatial extent of the tsunami source area can be reduced.

If the number of the simulation points inside of the rectangular area is less than 4, the nearest 4 simulation points from the epicenter are retrieved.

**Tsunami Arrival Time Estimation** Forecast points are located not along the coast but offshore. Travel time estimation by adding the travel time from the source area to the forecast point to that from the forecast point to the coastal point may lead to substantial errors, especially when the tsunami source area is close to the coast. Therefore, for the tsunami arrival time estimation at the coastal point, an inverse refraction diagram from the coastal point to the source area is used to reduce such errors. Finite spatial extent of the source area, depending on the calculated magnitude value, is considered, and the earliest arrival time corresponding to the crossing point of the inverse refraction diagram and the outer rim of the source area is used with a view to disaster management.

**Tsunami Forecast Assembling** The tsunami forecast grade for a considered coastal block depends on the maximum of the expected tsunami amplitudes at the forecast points located in that block which are converted to amplitudes at the coast by applying Green's law. Forecast points are placed off-shore parallel to the coast with spacing of about 20 km. The average number of forecast points in one coastal block is 9. As mentioned above, expected tsunami amplitude at a forecast point, including Green's law application when using 1 arc minute bathymetry mesh, agrees reasonably well with expected mean or median tsunami amplitudes on the coast that have been calculated by using very fine bathymetry mesh in a coastal subsection separated in the middle between forecast points. This means that the expected tsunami amplitude at the forecast point can be regarded as being representative for the respective coastal subsection. We think this approach is reasonable with a view to disaster management requirements because the forecast grades for a coastal block are based on the maximum of these representative values in each coastal subsection. This prevents that the forecast grade is affected by abnormally large local maxima as they may re-

sult from very fine-mesh simulations (see Fig. 10). However, the JMA informs in its public information releases that tsunami amplitude might very locally be much higher than in the forecast.

The content of tsunami warning/advisory is very simple, namely, tsunami grades and corresponding coastal block names. This is to enable recipient organizations to understand the most important information easily, namely the necessity of evacuation. Tsunami information that follows just after the warning/advisory provides then more detailed estimates of tsunami amplitudes and arrival times for each coastal block, as well as hypocentral parameters. Examples of tsunami forecast/information are given in Table 2a–f.

**Tsunami Forecast Dissemination** Like other forecast/information disseminated from the JMA, tsunami

forecast/information is transmitted to relevant organizations by fully utilizing existing online facilities. In case of land line failure, forecast/information is also transmitted through satellite link. Loud speaker/sires operated by municipalities/prefectures are used in ‘the last mile’ to reach the public. Police and fire departments have their own robust transmission routes, which are also used. Additionally, the public broadcasting company plays a very important role because of its wide outreach and timeliness.

### Tsunami Monitoring System

Data from more than 100 tidal observation stations (including those operated by other institutes, like the Japan Coast Guard) are collected on-line at the JMA (Fig. 12). Data sampling and transmission rate are every one second.

### Tsunami Forecast for Distant Event and Northwest Pacific Tsunami Advisory (NWPTA)

For a distant event, a similar method to a local event as mentioned above is used, but the seismic waveform data from global network which are available in real-time through the Internet is used for hypocenter and magnitude calculation, instead of those from domestic seismic network. The PTWC's bulletins are also incorporated in the framework of ICG/PTWS. For magnitude estimation, Mwp [34] is used commonly with PTWC and

WC/ATWC. Tsunami simulation database has been created also for distant events, taking the Coriolis force effect into account considering long distance propagation. In case enough time is left until the earliest estimated tsunami arrival time at Japan coast, the JMA monitors sea level data collected via the data collection platform function of geostationary meteorological satellites, and circulated through GTS (global telecommunication network operated by the World Meteorological Organization of UN) circuit in near-real-time. After confirming the generation of tsunami at sea level observation sites near the

<b>Tsunami Warning (Revision)</b>
Issued by the Japan Meteorological Agency (JMA)
Issued at 2330JST 15 Nov 2006
"Tsunami Warning" has been revised into "Tsunami Advisory" for the following coastal blocks.
Eastern Part of Pacific Coast of Hokkaido
Okhotsk Sea Coast of Hokkaido
"Tsunami Advisory" has been in effect for the following coastal blocks.
Eastern Part of Pacific Coast of Hokkaido
Okhotsk Sea Coast of Hokkaido
Central Part of Pacific Coast of Hokkaido
Western Part of Pacific Coast of Hokkaido
Northern Part of Japan Sea Coast of Hokkaido
Pacific Coast of Aomori Pref.
Iwate Pref.
Miyagi Pref.
Fukushima Pref.
Ibaraki Pref.
Kujukuri and Sotobo Area of Chiba Pref.
Uchibo Area of Chiba Pref.
Izu Islands
Sagami Bay and Miura Peninsula
Shizuoka Pref.
Ogasawara Islands

Tsunami Forecasting and Warning, Table 2f  
(continued)

<b>Cancellation of Tsunami Warning</b>
Issued by the Japan Meteorological Agency (JMA)
Issued at 0130JST 16 Nov 2006
Tsunami warning has been all canceled.
"Tsunami Advisory" has been canceled for the following coastal blocks.
Eastern Part of Pacific Coast of Hokkaido
Central Part of Pacific Coast of Hokkaido
Western Part of Pacific Coast of Hokkaido
Pacific Coast of Aomori Pref.
Iwate Pref.
Miyagi Pref.
Fukushima Pref.
Ibaraki Pref.
Kujukuri and Sotobo Area of Chiba Pref.
Uchibo Area of Chiba Pref.
Izu Islands
Sagami Bay and Miura Peninsula
Ogasawara Islands
However, sea level is expected to fluctuate in above coastal areas.
Be careful in sea bathing and fishing.

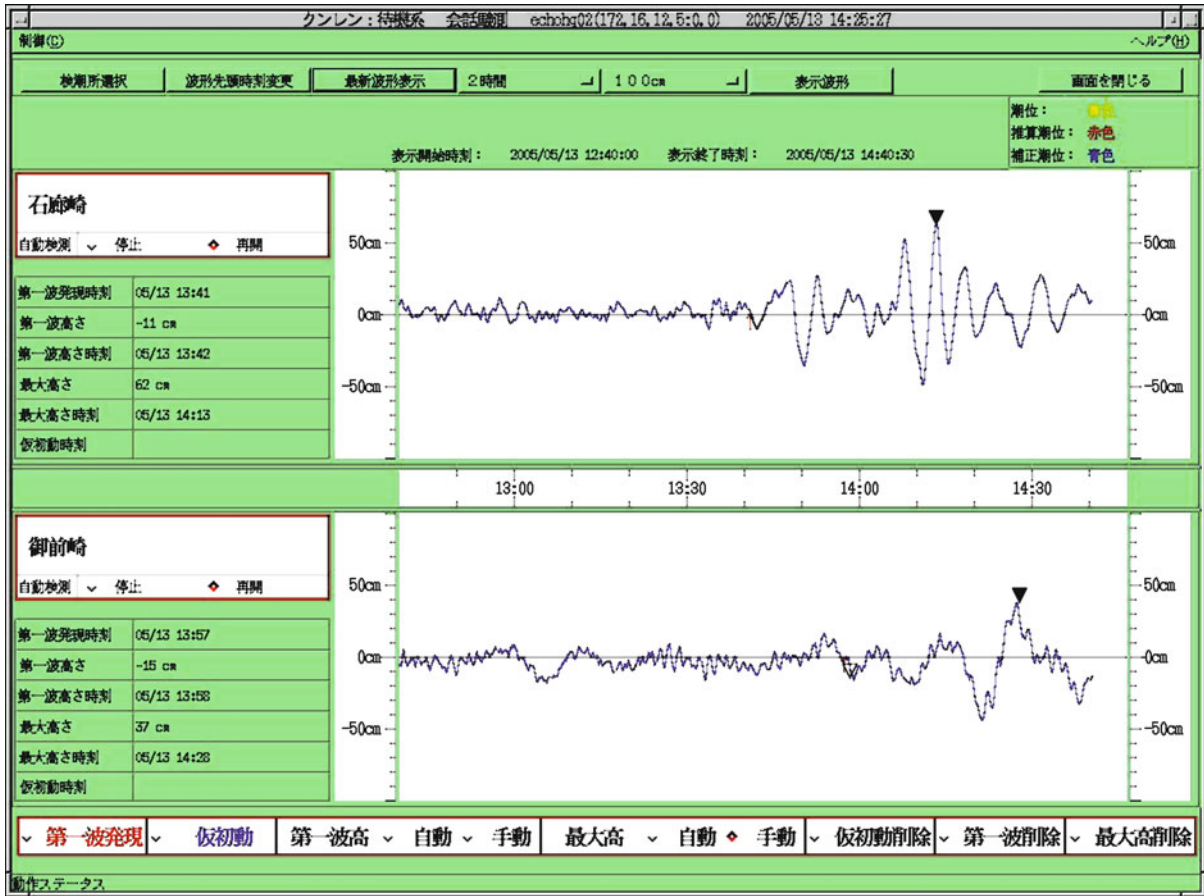

Tsunami Forecasting and Warning, Figure 12  
Tidal stations network used for tsunami monitoring by the JMA. More than 100 tidal stations are monitored in real time. Symbols denote instrumentation type. Circle, star and square denote float-type, acoustic-type and pressure sensor type, respectively

source, tsunami warnings/advisories are disseminated for the same coastal blocks as for local tsunami if necessary. Estimated tsunami amplitudes in the database can be calibrated by the actually observed tsunami amplitudes before the dissemination. Furthermore, if a reliable causing fault model is available, the JMA conducts tsunami propagation simulation for a specific setting of fault location, depth, magnitude and mechanism so that tsunami warnings/advisories can be based on more reliable tsunami estimation.

By using the same method as described above in this section, the JMA, as a regional center of the ICG/PTWS, is providing international tsunami information (NWPTA: Northwest Pacific Tsunami Advisory) to relevant countries when an earthquake with magnitude 6.5 or larger occurs in the northwest Pacific area since March 2005. NWPTA contains estimated tsunami amplitudes and arrival times, as well as estimated hypocenter parameters.

#### Some Lessons Learnt from a Recent Event

At 11:14 (UTC) on Nov. 15, 2006, a large earthquake with Mw8.3 occurred in the Kuril Island Region which gen-

Tsunami Forecasting and Warning, Figure 13

Example of the JMA's man-machine interface screen image in the Sea Level Data Monitoring System. Shown are two sea level recordings by different tidal gauge stations. The ocean tide component has been removed for more precise reading of the relevant tsunami wave parameters. Arrival time, initial wave amplitude, polarity, maximum amplitude and corresponding time are picked. The reversed solid triangles denote the maximum amplitude within the analyzed time window

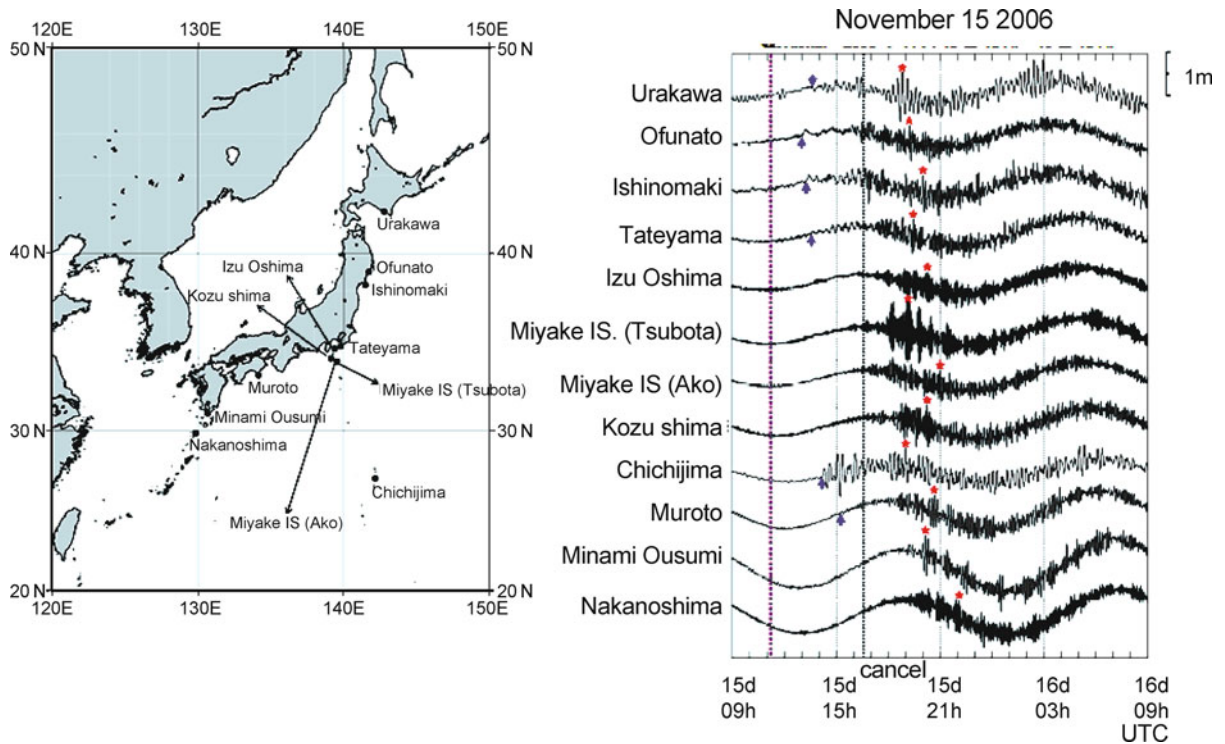

erated a Pacific-wide tsunami. Tsunami records at tidal gauges in Japan are shown in Fig. 14. The JMA disseminated tsunami forecasts at 11:29 (UTC) (corresponding to 20:29 JST in the related case example given in Table 2) based on the estimated tsunami amplitudes in the database. About 4 hours after the first detection of the tsunami on the Japan coast, the JMA cancelled all the forecasts at 16:30 (UTC) judging from the amplitude decay in the sea level record of Chichijima station (cf. Fig. 14) that no higher tsunami will be observed. But, after the cancellation, maximum amplitudes were recorded at many of the tidal gauges along the Pacific coast of Japan up to 5 hours later. The largest tsunami amplitude recorded in Japan for this event was 84 cm at Miyake Is. (Tsubota).

The JMA conducted a close examination of this case and found that these large amplitudes were tsunami waves reflected from the Emperor Sea Mount Chain in the mid-

dle of the Pacific (Fig. 15). Since the computational area for the tsunami simulation database of the JMA was limited around Japan (cf. Fig. 7), such reflected wave could not be represented by the simulation. Therefore, the JMA examines now the scenarios for which the computational area should be expanded.

### Recent Improvements

**Application of Earthquake Early Warning (EEW) Technique to Quicken Tsunami Forecast** In the near-coastal area (i. e., roughly within 100 km from the coast) EEW hypocenter and magnitude estimates [15] are equivalent to those resulting from the common procedures described above. Therefore, EEW results can be used as input data for tsunami forecast. The JMA started this incorporation in October 2006. In the case of the Mjma6.8 Niigataken

Tsunami Forecasting and Warning, Figure 14

Tidal station records of regular ocean tides superimposed by tsunami waves generated by the 15 Nov. 2006 Kuril earthquake ( $M_w = 8.3$ ). *Left*: Locations of tidal gauges whose data are shown in the right figure. *Right*: Tidal records of the stations shown in the left figure. Time is in UTC. The *thick blue dotted line* denotes the origin time of the earthquake and the *blue arrows* denote the arrival time of tsunami at each site. The *thin dotted line* denotes the time of tsunami forecast cancellation. *Red stars* mark the time of maximum amplitude at each site. At all sites maximum amplitudes were recorded about 2 to 5 hours after the forecast had been canceled. The largest tsunami amplitude recorded in Japan for this event was 84 cm at Miyake Is. (Tsubota)

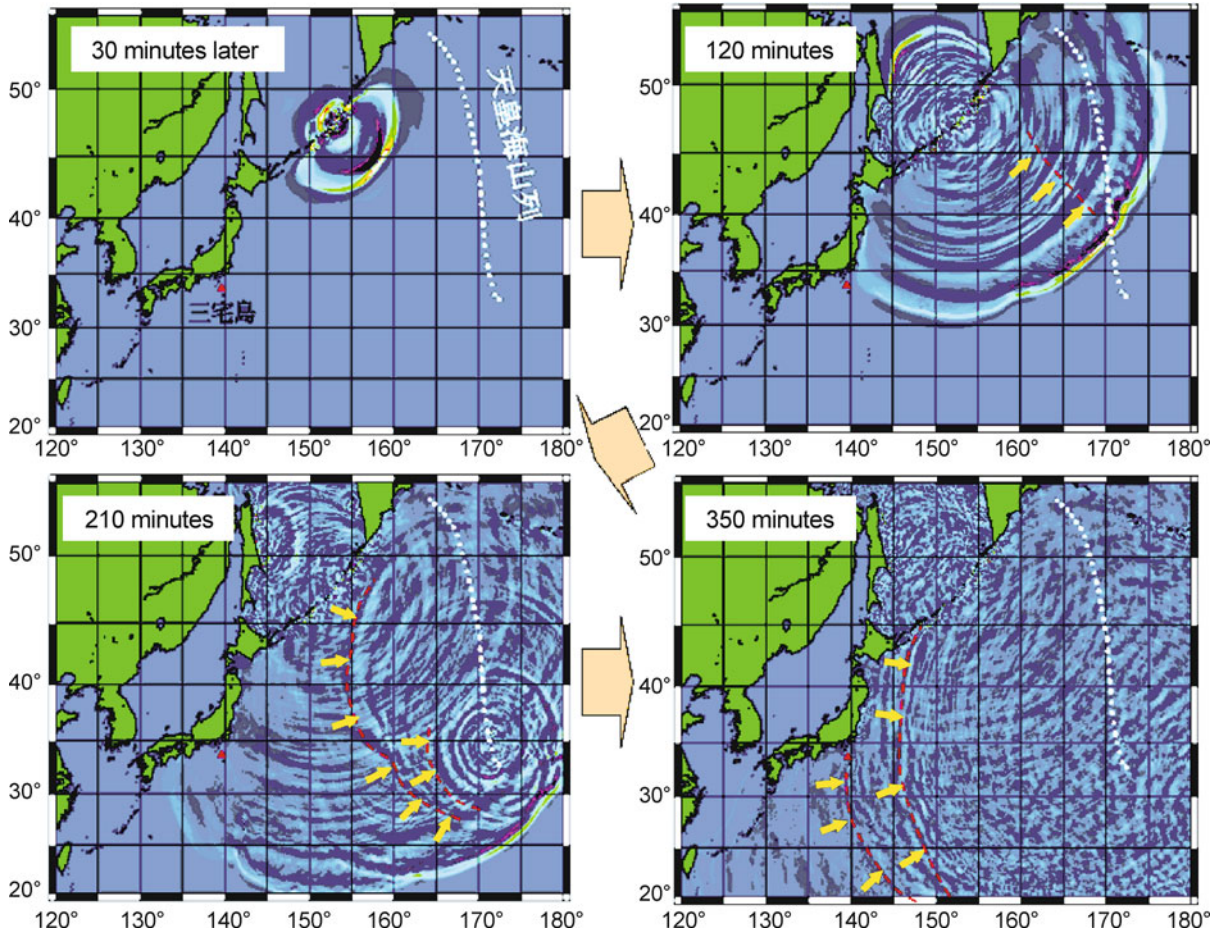

Chuetu-oki earthquake of 16 July 2007, the JMA disseminated tsunami advisory one minute after the first detection of the seismic wave.

**Quicker Revision/Cancellation of Tsunami Forecasts by Utilizing CMT Solutions** In JMA, automatic CMT solutions are available in 10 to 20 minutes after the earthquake occurrence. They yield more realistic magnitudes than Mjma for really great earthquakes ( $M_w > 8$ ) and reliable fault plane solutions. On the other hand, it is not proper to wait for the CMT solution for issuing the first tsunami warning, and it is not realistic neither to prepare the tsunami simulation database for so many different dip, strike and slip angle settings with fine increments and choose the best fitting one, because it requires huge storage and computational time for the conduct of simulations for all parameter settings. Therefore, we use the CMT solution for the revision/cancellation of the first tsunami warning, and we limit the number of different fault parameter set-

tings to 4, namely pure reverse fault with dip angles 10, 45 and 80 degrees and pure strike fault. Normal fault with the opposite slip angle ( $\lambda$ ) direction to the reverse fault with the same values for other fault parameters has almost identical tsunamigenic potential, and the difference is just a polarity of initial tsunami wave. Therefore, normal fault is treated as reverse fault with the same dip angle for this purpose. Strike angles have been fixed to the representative values of the considered regions, or set parallel to the nearby trench axis or coast line. The case with the highest resemblance to the actually calculated CMT solution with respect to its tsunamigenic potential is then retrieved.

The JMA incorporates CMT solutions in the revision/cancellation of tsunami forecast as follows:

- (a) In the case of reverse or normal faults, and if the centroid depth is less than the depth determined by  $P$  and  $S$  arrival times +30 km, and  $M_w$  0.5 or more larger than Mjma, the tsunami forecast is then upgraded in accordance with respective database cases.

Tsunami Forecasting and Warning, Figure 15

Snap shots of numerical tsunami simulation for the 2006 Nov. 15 Kuril event (Mw8.3). Coriolis force has been considered for this case. Four snap shots (30, 120, 210 and 350 minutes after the earthquake occurrence) are shown. The white dotted line marks the position of the Emperor Sea Mount Chain. Broken red curves with arrows denote reflected tsunami waves from the Emperor Sea Mount Chain. The estimated arrival times of the reflected waves at the coast of Japan are consistent with the actual tidal records

(b) In the case of strike faults, taking the database into account, and after confirmation by low or not observed tsunami amplitudes at tide gauges, the tsunami forecast is then downgraded or canceled.

The JMA started this incorporation in July, 2007 for the sea area where additional database creation has been completed.

### Future Outlook

In tsunami forecasting, trade-off exists between promptness and accuracy/reliance. The JMA's tsunami forecasting strategy, especially for local events, is to satisfy both by using state-of-the-art technologies. They assure promptness of the first issuance of tsunami forecast, based on pre-

liminary seismological results including that of EEW, and its subsequent revision, if required, as soon as more accurate and reliable data such as sea level change, and the results of a more detailed complex data analysis have become available. And as for accuracy/reliability there are two ways to be taken. One is quickened the process of reducing the uncertainty of initial tsunami wave distribution assessments. Quick focal process inversion technique, new magnitude definitions applicable for gigantic or tsunami earthquakes and tsunami source inversion techniques using sea level data (also from satellite altimetry) will become effective for this purpose soon. The other way is very detailed numerical simulation, after reduction of uncertainties in the initial tsunami wave distribution, using fine bathymetry mesh data. Along with the development of in-

egrated calculation algorithms, the improvement of the computer performance might solve this problem in future. But even then, due to the stochastic nature of tsunami behavior near the coast, one has carefully to examine on what statistical quantity of simulated results the tsunami forecast criterion has to be based.

### Acknowledgments

We thank Dr. Peter Bormann and Dr. Kenji Satake for reviewing the manuscript, their comments and suggestions greatly improved it.

### Glossary

**Beach profile** A cross-shore, or normal to the beach, survey of the seafloor and dry ground elevation (bathymetry and topography); a series of spatial location and bottom elevation data pairs.

**Bore** A steep hydraulic front which transitions between areas of different water level. Tsunamis can approach land as a turbulent, breaking bore if the incident tsunami is of sufficiently large height.

**Boussinesq equations** An approximate equation model, used for waves with wave length of at least two times the local water depth; a long-wave-based model, but includes some frequency dispersion

**Dispersion, amplitude** The separation of wave components due to a wave-height related difference in wave speed; all else being equal, a wave with a large height will travel faster than one with a small height.

**Dispersion, frequency** The separation of wave components due to a frequency related difference in wave speed; all else being equal, a wave with a longer period will travel faster than one with a short period.

**Navier–Stokes equations** The full equations of fluid motion, including dissipation through the fluid molecular viscosity only. Other models discussed here, namely the Shallow Water Wave and Boussinesq equations, are approximations to these equations.

**Runup, or runup height** The ground elevation (a vertical measure) at the furthest point of landward inundation.

**Shallow water wave equations** An approximate equation model, used for waves with wave length many times

larger than the water depth; a non-dispersive, long-wave model; there is no frequency dispersion in this model.

**Tsunami inundation** The spatial area flooded as a tsunami rushes inland.

### Definition of the Subject

Tsunami inundation is the one of the final stages of tsunami evolution, when the wave encroaches upon and floods dry land. It is during this stage that a tsunami takes the vast majority of its victims. Depending on the properties of the tsunami (e. g. wave height and period) and the beach profile (e. g. beach slope, roughness), the tsunami may approach as a relatively calm, gradual rise of the ocean surface or as an extremely turbulent and powerful bore – a wall of white water. The characteristics of this approach determine the magnitude and type of damage to coastal infrastructure and, more importantly, the actions required of coastal residents to find a safe retreat or shelter.

To gage the nearshore impact of tsunami inundation, engineers and scientists rely primarily on three different methods: 1) Field survey of past events, 2) Physical experimentation in a laboratory, and 3) Numerical modeling. It is the last of these methods – numerical simulation of tsunami inundation – that will be the focus of this article. With numerical simulation, it is possible to predict the consequence of future tsunamis on existing coastal towns and cities. This information allows for the establishment of optimum evacuation routes, identification of high-risk and/or unprepared areas, re-assessment of building codes to withstand wave impact, and placement of tsunami shelters, for example. It is the hope that, through accurate prediction of tsunami effects, in conjunction with policy makers willing to implement recommended changes and a strong public education program, communities will show resiliency to tsunami impact, with minimal loss of life and damage to critical infrastructure.

### Introduction

On December 26, 2004, the boundary between the Indo–Australian and Eurasian plates off the coast of northern Sumatra ruptured in a great (Mw 9.3) earthquake at 00:58:53 universal time (U.T.). Up to 15m of thrust on the plate interface [31] displaced tens of cubic kilometers of seawater and propagated a tsunami across the Indian Ocean. The earthquake was widely felt throughout South Asia and was locally destructive in Sumatra and the Andaman and Nicobar islands, but it was the tsunami that caused widespread damage to densely populated coastal

communities both nearby and thousands of kilometers away.

Due to the extensive damage left behind by large tsunamis such as the Indian Ocean tsunami, it is difficult if not impossible to put together a complete picture of the event with field observations alone. Additionally, for some parts of the world that have not seen a tsunami in recent times, there are no field observations on which to develop safety procedures and protect residences from future tsunamis. It is for these purposes – understanding the detail of tsunami inundation and to estimate tsunami hazard – that we must rely on modeling of tsunamis. There are two primary modeling approaches - physical and numerical. The physical, or experimental, approach uses scaled-down models to look at a particular aspect of a phenomenon. While this approach is integral to the fundamental understanding of waves, because of the huge wavelengths of tsunamis, experiments are limited. For example, a tsunami might have a wavelength of 100 km in a deep ocean depth of 1 km, with a wave height of 1 m. Note that the above values represent approximate order of magnitudes for a large subduction zone tsunami. Now, to scale this down for the laboratory with a wave tank depth of 1 m – the tank would have to be 100 m long and the created lab-tsunami would have a hardly measurable height of 1 mm. Numerical modeling, while not “real” in the sense that modeling is done on a computer chip with approximated equations of motion rather than in the laboratory, does not suffer from this scaling problem, and can generally accommodate any type of arbitrary wave and ocean depth profile.

Numerical simulations of tsunami propagation have been greatly improved in the last 30 years. In the United States, several computational models are being used in the National Tsunami Hazard Mitigation Program, sponsored by the National Oceanic and Atmospheric Administration (NOAA), to produce tsunami inundation maps and predict tsunami runup in real-time for the warning system. In addition, there are numerous other models used by researchers and engineering companies in an attempt to better understand tsunami impact. In this article, an overview of these models, as well as how they are validated and utilized, is provided.

### **Brief Review of Tsunami Generation and Open Ocean Propagation**

Before introducing the physics behind propagating a tsunami across oceans and overland, we must first discuss how a tsunami is created. For earthquake generated mega-tsunamis, such as the Indian Ocean event, a huge

undersea earthquake along a great fault length of a subduction zone must occur. These earthquakes create large vertical motions of the seafloor. This vertical motion of the seafloor pushes the water above it, essentially creating a small displacement of water above the earthquake. This displacement of water will immediately try to spread out and reach a gravitational equilibrium, and it does so as waves propagating away from the earthquake zone – this is the tsunami.

To represent the tsunami in numerical models, we use an initial condition. Simply put, there is placed some irregular ocean surface profile at the instant after the earthquake, when the numerical simulations will start. Then, based on physics – Newton’s Laws written for fluid – the initial condition evolves and transits oceans. As a tsunami travels unhindered across ocean basins, it does so quickly and with little noticeable change. In the deep ocean, even the largest tsunamis have heights only near 1 m and currents of 10 cm/s, and are not likely to be identified by ships or surface buoys in the presence of wind waves.

### **Physics of Nearshore Tsunami Evolution**

A tsunami in the deep ocean is long and travels extremely fast. As the wave reaches shallow water, near the coastline, the tsunami begins the shoaling process. The speed at which long wave such as a tsunami moves, or celerity, is a function of the local water depth. The less the depth, the slower the wave moves. A tsunami, with its very long length, experiences different water depths at any given instant as it travels up a slope; the depth at the front of the wave, the portion of the tsunami closest to the shoreline, will generally be in the shallowest water and thus is moving the slowest. The back of the tsunami, on the other hand, will be in deeper water and will be moving faster than the front. This leads to a situation where the back part of the wave is moving faster than the front, causing the wavelength to shorten. With a shortening tsunami, the wave energy is in essence squeezed into a smaller region, forcing the height to grow. It is for this reason that, despite having a height of only a meter in the deep ocean, the tsunami elevation over land can easily exceed 10 m. With this great increase in wave height comes a more dynamic and complex phenomenon.

Presented in a more technical manner, a tsunami in the open ocean is generally a linear, non-dispersive wave. First, what is meant by a non-dispersive tsunami will be discussed. Also, the discussion here will be in terms of a large earthquake generation tsunami, such as the 2004 Indian Ocean event. Other impulsive waves, such as landslide or asteroid impact generated waves, are more difficult

to generalize and will be introduced separately at the end of this section.

Any wave condition, whether it is a tsunami or a typical wind wave in the ocean, can be mathematically described as a superposition, or summation, of a series of separate sine (or cosine) waves, each with independent amplitude and speed. For example, with the right choice of individual sine waves, it is possible to construct even the idealized tsunami: a single soliton. If a wave is considered a dispersive wave, then the various sine wave components will have different wave speeds, and the wave will disperse as the faster moving components move away from the slower ones. If a wave is non-dispersive, then all the components move at the same speed, and there is no lengthwise dispersal, or spreading, of the tsunami wave energy. It is for this reason that tsunamis can be devastating across such a large spatial region; the tsunami wave energy will not disperse but will remain in a focused pulse.

The dispersion described above is generally what scientists are referring to during a discussion of dispersive vs non-dispersive waves. However, it is more precisely called “frequency dispersion” as it is dominantly dependent on the period of the component. There is another type of dispersion, called “amplitude dispersion.” This second type of dispersion is a function of the nonlinearity of the wave, and is usually discussed under the framework of linear vs nonlinear waves. For tsunamis, the nonlinearity of the waves is given by the ratio of the tsunami height to the water depth. When this ratio is small, such as in the open ocean, the wave is linear; on the other hand, in shallow water the ratio is order unity and thus the wave is no longer linear. The linear/nonlinear nomenclature is not an intuitive physical description of the waves, but comes from the equations describing the tsunami motion, described later in this section. When this nonlinear effect is taken into account, it is found that the wave speed is no longer just a function of the local depth, but of the wave height as well. More specifically, looking at two components of the same period but with different amplitudes, the component with the larger amplitude will have a slightly larger wave speed. Except for the interesting cases of wave fission, discussed later in this section, the nonlinear effect of amplitude dispersion does not spread tsunami energy with an end result of lessening nearshore impact; in fact it will act to focus wave energy at the front, often leading to a powerful breaking bore.

Thus, open ocean propagation of a conventional tsunami is a relatively uncomplicated process which translates wave energy across basins, subject to wave speed changes that are a function of the local depth. As a tsunami enters the nearshore region, roughly characterized by wa-

ter depths of 100m and less, the wave can undergo a major physical transformation. The properties of this transformation depend heavily on the characteristics of the beach profile and the wave itself. In the simplest inundation case, the beach profile is relatively steep (footnote: here “steep” should be thought of in terms of the tsunami wavelength. If the horizontal distance along the slope connecting deep water to the shoreline is small compared to the tsunami wavelength, the beach would be considered steep) and the tsunami wave height is small, then the runup process closely resembles that of a wave hitting a vertical wall, and the runup height will be approximately twice the offshore tsunami height. In these special cases, a breaking bore front would not be expected; in fact horizontal fluid velocities near the shoreline would be very small. Here, the tsunami inundation would closely resemble that of a quickly rising tide with only very minor turbulent, dynamic impacts. However, even in these cases, overland flow constrictions and other features can create localized energetic inundation.

If the beach profile slope is mild, typical of continental margins, and/or the tsunami wave height is large, then the shallow water evolution process becomes highly nonlinear. However, while the nonlinear effect becomes very important, in the large majority of cases, frequency dispersion is still very small and can be neglected. Nearshore nonlinear evolution is characterized by a strong steepening, and possible breaking, of the wave front with associated large horizontal velocities. In these cases, turbulent dissipation can play a major role.

While it may be intuitive to postulate that wave breaking dissipation at the tsunami front plays a significant role in the tsunami inundation, this may not be altogether correct. This breaking dissipation, while extraordinarily intense, is fairly localized at the front which, both spatial and temporal, often represents only a small fraction of the tsunami. So, for tsunamis such as the 2004 Indian Ocean event, the related dissipation likely had only minor impact on leading-importance quantities such as the maximum runup and inland (off-beachfront) flow velocities. However, the properties of breaking are of great importance to other aspects of tsunami inundation. The maximum forces on beachfront infrastructure, such as ports, terminals, piers, boardwalks, and houses, should include the bore impact force as well as the drag force associated with the following quasi-steady flow [54,68]. If one was interested in understanding how bottom sediments are suspended, transported, and deposited by a tsunami, the bore turbulence again may play an important role. Thus, understanding the dynamics of a breaking tsunami front is not of particular importance for near real-time or operational

tsunami forecast models. This information is of great use for engineers and planners, who can utilize it to design tsunami-resistant structures, for example.

A second energy dissipation mechanism, one that does play a major role in determining maximum runup, is bottom friction. On a fundamental level, this dissipation is caused by the flow interaction with the bottom, where bottom irregularities lead to flow separations and the resulting turbulence. All natural bottoms result in some bottom friction; a smooth, sandy beach may generate only minor dissipation, while a coral reef or a mangrove forest can play a huge role in reducing tsunami energy [12]. Such features will be discussed in additional detail in the next section. Other means of energy dissipation will be largely local, and may include enhanced mixing due to sediment or debris entrainment, large shallow-flow vortex generation by headlands or other natural or artificial obstacles and the resulting dissipation, and flow through/around buildings and other infrastructure, sometimes termed macro-roughness and grouped with bottom friction.

Up to this point, we have only discussed the “typical” nearshore tsunami evolution which is portrayed as a wave without frequency dispersion, and may be called a linear or nonlinear tsunami, depending on a number of physical properties. The rest of this section will be devoted to those situations where the above characterization may no longer be adequate. Looking first to the tsunami source, waves that are generated by underwater landslides, underwater explosions, or asteroid impacts will often not behave as non-dispersive waves in the open ocean [44,72]. These source regions tend to be at least an order of magnitude smaller in spatial extent compared to their subduction zone counterparts. Physically, this implies that the generated waves will be of shorter wavelength. As a rule of thumb, if these generated waves have length scales of less than 10 times the local depth, then it should be anticipated that frequency dispersion will play a role [42]. Under this constraint, individual component wave speeds near the dominant period become frequency dependent.

Understanding that an impulsively generated wave can be dispersive has serious implications. Take, for example, a hypothetical landslide located in the Atlantic Ocean which generates a dispersive tsunami (e. g. Ward and Day, 2001). As this tsunami travels across the Atlantic, to either the USA east coast or the European west coast, frequency dispersion effects will spread the wave energy in the direction of propagation. This will convert the initial short-period pulse into a long train of waves. By spreading this energy out, the inundation impact will be greatly reduced. First, by taking a high-density energy pulse and stretching it into a longer, lower-density train, the max-

imum energy flux, and thus intensity, hitting the shoreline will decrease. Second, by increasing the duration of the time series, and creating many individual crests, energy dissipation can play a bigger role. Using simple energy arguments, it can be shown that, comparing a high-density, short-period pulse to a low-density, long-period train, more energy will be removed through bottom friction and breaking. This increase will be related to the ratio of the period of the entire dispersive wave train to the period of the pulse. Numerically studies have shown that for such cases, the individual wave crests are largely dissipated, and runup is dominated by the carrier wave, or in other terms it becomes a time-dependent, wave setup problem [26].

While a topic of current research in the tsunami community, frequency dispersion may occasionally play a non-negligible role in even the long wavelength, subduction zone tsunamis. To date, there have been two categories of argument that dispersion is important for these tsunamis: 1) short-period energy generated at the source is significant and leads to different patterns of runup if included (e. g. [21,28]), and 2) shallow-water nonlinear interactions can generate short-period components which can become decoupled (or un-locked) from the primary wave, and will change the incident tsunami properties [47].

Thinking of an arbitrary and complex initial free surface displacement generated by an undersea earthquake, there does exist the possibility that dispersive wave energy can be initially generated here. This irregular wave condition can be constructed as a continuous wave energy spectrum, and by definition there will be finite (albeit small) energy at all frequencies. The obvious question in this case is: what length scale characteristics of the initial free surface displacement, or the preceding earthquake, will lead to a significant measure of dispersive wave energy? To provide an answer to this question, a simple order-of-magnitude scaling argument is presented here; see Hammack and Segur [19], for example, for a mathematically rigorous attempt at insight. Let us define a characteristic change in vertical free surface elevation,  $\Delta\eta$ , and a horizontal length scale across which this vertical change occurs,  $\Delta L$ . Reducing to the simplest case, a regular wave with wave height equal to  $\Delta\eta$ , then the wavelength would be  $2\Delta L$ . Following this analogy, which will hold in a proportional sense for a Fourier series of wave components, for any  $\Delta\eta$  measured along a tsunami initial condition, there exists a wave component with wave length equal to  $2\Delta L$ . For that component to be significant to the tsunami evolution, the local vertical change,  $\Delta\eta$ , must be some non-negligible fraction of the maximum tsunami height,  $H$ . Note that the  $H$  dis-

cussed here is a global property of the entire initial tsunami wave condition. For the individual wave component, with length  $2\Delta L$ , to be dispersive, its length should be less than roughly 10 times the local water depth,  $h_0$ . Additionally, the difference between dispersive wave propagation and a non-dispersive propagation is cumulative. For example, if the full linear wave theory predicts, or a specific wave component, a wave speed that is 10% less than the long wave speed, then the predicted arrival time difference will grow by 0.1 times the period for each wavelength of propagation. Thus, the impact of dispersion is related to the distance of propagation, and is proportional to  $D/\lambda$ , where  $D$  is the total distance traveled by the wave, and  $\lambda$  is the average wavelength of the wave across  $D$  which can be expected to be proportional to  $2\Delta L$ . Assuming that  $\lambda$  is approximately equal to  $2\Delta L$ , it can be said that in order for frequency dispersion effects to play a role in tsunami evolution,

$$\max \left| \frac{h_0 \Delta \eta}{\Delta L^2} \right| \frac{D}{H} > \delta, \quad (1)$$

where  $\delta$  is some minimum threshold for importance. What this value should be is an open question, although it is likely to be near 0.1. From this term, it is clear the impact of dispersion is a function of a number of the properties of the initial tsunami condition, and should be taken into consideration when creating tsunami initial conditions. For example, use of discontinuous block-type segments (e. g. [30]), with sharp edges (very small  $\Delta L$ ) may lead to the conclusion that frequency dispersion is important, while it could be a direct result of a coarsely approximated initial tsunami condition. Also note that this exercise does not include the effects of radial spreading, which could very likely be important for small-scale irregularities in the initial condition. Wave height decrease by radial spreading is proportional to the horizontal curvature of the initial condition and to  $(\lambda/D)^n$ , and decreases faster for dispersive waves ( $n \sim 1$ ) as compared to non-dispersive waves ( $n = 0.5$ ) (e. g. [72]). Thus, for this case of significant radial spreading, it would be very difficult for source-based dispersion effects to play a meaningful role in the far field.

Under certain conditions, namely a nonlinear tsunami propagating across a wide shallow shelf, a process called fission may occur. Wave fission is a separation process where wave energy, initially part of a primary wave or pulse, attains certain properties, such as higher or lower phase speed, that allow it to disconnect from the primary wave and propagate as an independent wave. In the context of nearshore tsunami evolution, there is a standard mechanism which is the cause of this fission. First, it is nec-

essary to describe what a nonlinear, phase-locked wave is. To do this, we will examine the acceleration terms of the 1D conservation of momentum equation for the velocity component  $u$ :

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = -\frac{\partial p}{\partial x} + \mu \frac{\partial^2 u}{\partial x^2}. \quad (2)$$

Now assume that there is a single wave component, under which the velocity oscillates as

$$\cos(kx - \omega t) = \cos \theta, \quad (3)$$

where  $k$  is the wavenumber,  $\omega$  the frequency, and the speed of the wave is given by  $\omega/k$ . If the wave is nonlinear, which is to say that the convective acceleration term in the above momentum equation is not negligible, the convective term will include the product of

$$\cos \theta * \cos \theta = \cos 2\theta = \cos(2kx - 2\omega t). \quad (4)$$

Thus, through this nonlinear term, a new wave component, with twice the wavenumber and frequency (or half the wavelength and period) has been generated. From linear wave theory, it is expected that this new wave, with a shorter period, will have a different wave speed than the original, primary wave. However, from the phase function of this new wave, there is the speed  $2\omega/2k = \omega/k$ , which is the identical speed of the primary wave. Thus this new wave is *locked* to the *phase* of the original wave. This connection can be rather delicate, and any disruptions to the primary wave, such as a varying seafloor, dissipation, or interactions with other free waves in the train or wave pulse, can cause the new waves to become unlocked. When this occurs, the now free waves retain their frequency  $2\omega$ , but take a wavenumber as given by linear wave theory. Since these freed waves will be of a shorter period than the primary wave, they will travel at a slower speed and generally trail the main wave front.

Long wave fission is most commonly discussed in the literature via a solitary wave propagating over an abrupt change in depth, such as a step (e. g. [17,24,33,37,45,55]). In these cases, there is a deep water segment of the seafloor profile, where a solitary wave initially exists. In this depth, the solitary wave is of permanent form. As the solitary wave passes over the change in depth, into shallower water, the leading wave energy will try to re-discover a balance between nonlinearity and dispersion; the solitary wave. Since this new solitary wave will be a different shape and contain a lower level of mass, by conservation there must be some trailing disturbance to account for the deficient. This trailing disturbance will take the form of a rank-ordered train of solitons. Figure 1 depicts this process. The solitons in the trailing train, while smaller in height than

Tsunami Inundation, Modeling of, Figure 1

Example of experimental data looking at solitary wave fission by propagation onto a shelf from Goring and Raichlen [17]. Note that the flume layout and measurement location is given up in the upper right. The initial solitary wave undergoes the fission process and results in three distinct solitary waves

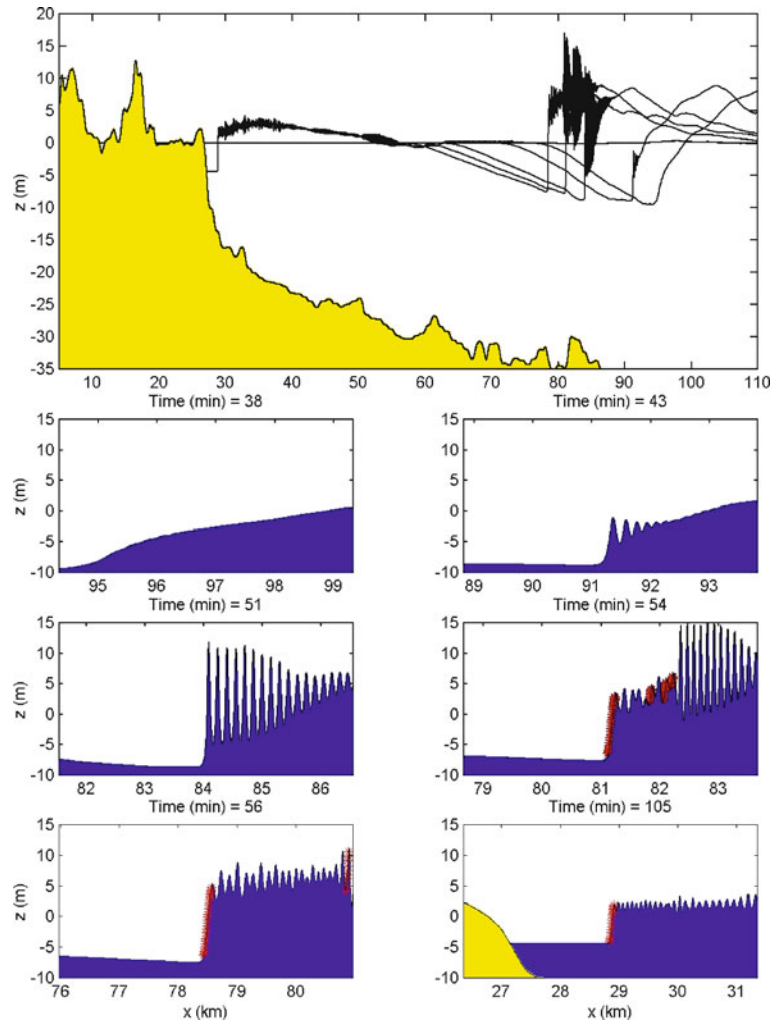

the leading solitary wave, tend to have a similar wavelength; this has been shown both analytically, numerically, and experimentally. Note, however, that discussion of fission in this sense is not particularly relevant to “real” tsunami modeling, where the offshore wave approaching the shelf break rarely resembles a solitary wave solution [62]. However, the offshore wave does not need to specifically be a solitary wave for this process to occur.

In numerous eyewitness accounts and videos recorded of the 2004 Indian Ocean tsunami, there is evidence of the tsunami approaching the coastline as a series of short period (on the order of 1 min and less) breaking fronts, or bores (e.g. [30]). These short period waves may be the result of fission processes of a steep tsunami front propagating across a wide shelf of shallow depth. Along the steep front of a very long period wave, nonlinearity will be very important. There will be a large amount of energy in high-frequency components with wavelengths similar the horizontal length of the tsunami front (on the order of 1 km). As the wave continues to shoal, the high-frequency locked waves may eventually become free waves, and will take the form of very short waves “riding” the main wave pulse. This situation is akin to an undular bore in a moving reference frame. This process is, in fact, identical to that described in the above paragraph, it simply takes place over a much longer distance. The newly freed waves, in the nonlinear and shallow environment, will attempt to reach an equilibrium state, where frequency dispersion and nonlinearity are balanced. Thus, the fission waves will appear

as solitary waves, or more generally, cnoidal waves. This fact provides some guidance as to the wavelength of these fission waves; they can be approximately calculated via solitary wave theory using the tsunami height and depth of the shelf. For example, on a shelf with depth of 30 m and an incident tsunami height of 5 m, fission waves with a wavelength of approximately 240 m and period of 13 s would be generated. In recent work looking at tsunamis along the eastern USA coast, where there exists a wide shallow shelf, this fission process has been investigated [14]. Figure 2 gives a few numerical simulation snapshots, and shows where the fission occurs, and the eventually impact on the waveform. This simulation, run with the dispersive equations, generated fission waves with lengths in the range of 100–200 m, and required a grid size of 5 m to attain numerically convergent results. In this example, the steep fission waves break offshore, and have little impact on the maximum runup. A conclusion of this fission issue is that, if one attempts to simulate tsunami propagation with dispersive equations, and if the grid is not chosen to be fine enough to resolve the short fission waves, the justification to use the dispersive model is greatly degraded.

### Effects of Bathymetric and Topographical Features on Inundation

It is well established that large-scale coastal features, such as small islands, large shoals, canyons, and shelves, can play an important role in tsunami inundation due to con-

Tsunami Inundation, Modeling of, Figure 2

Example of tsunami fission. Simulation results are from Geist et al. [14] for a landslide-generated tsunami off the east coast of the USA. The *top plot* shows the beach profile and six free surface profiles at different times. The *lower subplots* are zoom-in's of those six profiles, with the times given in the individual plot titles. The *red marks* visible in the *lowest plots* indicate regions where the wave is breaking

ventional shallow water effects such as shoaling and refraction (e. g. [4,5,16,36,70]). On the other hand, understanding of the impact of smaller scale features is just now being developed. This work was largely initiated by field observations. Synolakis et al. [60], surveying the coast of Nicaragua for information about the 1992 tsunami in the region, noted that the highest levels of damage along a particular stretch of beach were located directly landward of a reef opening used for boat traffic. It was postulated that the reef gap acted as a lower resistance conduit for tsunami energy, behaving like a funnel and focusing the tsunami. Along neighboring beaches with intact reefs, the

tsunami did not have the intensity to remove even beach umbrellas. Investigating impacts from the same tsunami, Borrero et al. [3], discussed how small scale bathymetry variations affected coastal inundation. One of the conclusions of this work was that bathymetry features with length scales 50 m and less had leading order impact on the runup. Looking to the recent Indian Ocean tsunami, a survey team in Sri Lanka inferred from observations that reef and dune breaks lead to locally increased tsunami impact [38,39]. Also in Sri Lanka, Fernando et al. [12] performed a more thorough survey along the southeastern coastline, and concluded that there was a compelling cor-

relation between coral mining and locally severe tsunami damage. While additional research is needed to quantify the effects of small scale features, the observations hint that defense measures such as seawalls, once thought to be inconsequential to tsunami inundation, may provide some protection.

Onshore, tsunami propagation is effected by the general topography (ground slope), ground roughness, and obstacles (e.g. [41,59,61,67]). The composition of the ground, be it sand, grass, mangroves, or pavement, controls the roughness and the subsequent bottom friction damping. To predict tsunami inundation with high confidence, the ground type must be well mapped and the hydrodynamic interaction with that type must be well understood. If the tsunami approaches the shoreline as a bore, the process of “bore collapse”, or the conversion of potential to kinetic energy, will cause the fluid to rapidly accelerate [56,69]. This fast flow equates to high fluid forces on obstacles such as buildings. Tsunami interaction with these obstacles can lead to a highly variable local flow pattern (e.g. [10,67]). As the flow accelerates around the

corners of a building, for example, the scour potential of that flow increases greatly, and foundation undermining is a concern (e.g. see Fig. 3). As with any fluid flow past an obstacle, the backface of the obstacle is characterized by a low-pressure wake. Combined with the interior flooding of a building, this low pressure wake may lead to an outward “pull” force on the back wall, causing it to fail by falling away from the center of the building. Such failures were observed during field surveys of the 2004 event, as shown in Fig. 4. Increasing the topographical complexity, in built coastal environments, structures are located within close enough proximity to each other such that their disturbances to the flow may interact. This can lead to irregular and unexpected loadings, where for example a 2nd row building experiences a larger force than beach front buildings due to a funneling effect. These types of interactions are very poorly understood, and require additional research.

The *top* photograph shows the front side of the structure, facing the ocean; there is damage but the main structure is intact. The *lower* photo shows the backside of the same building, showing the walls blown out, away from the center of the structure

## Hydrodynamic Modeling of Tsunami Evolution

Numerical simulations of tsunami propagation have made great progress in the last thirty years. Several tsunami computational models are currently used in the National Tsunami Hazard Mitigation Program, sponsored by the National Oceanic and Atmospheric Administration, to produce tsunami inundation and evacuation maps for the states of Alaska, California, Hawaii, Oregon, and Washington. The computational models include MOST (Method Of Splitting Tsunami), developed originally by researchers at the University of Southern California [66]; COMCOT (Cornell Multi-grid Coupled Tsunami Model), developed at Cornell University [35]; and TUNAMI-N2, developed at Tohoku University in Japan [29]. All three models solve the same depth-integrated and 2D horizontal (2DH) nonlinear shallow-water (NSW) equations with different finite-difference algorithms. There are a number of other tsunami models as well, including the finite element model ADCIRC (ADvanced CIRCulation Model For Oceanic, Coastal And Estuarine Waters; e.g., [53]). For a given source region condition, existing models can simulate propagation of a tsunami over a long distance with sufficient accuracy, provided that accurate bathymetry data exist.

The shallow-water equation models commonly lack the capability of simulating dispersive waves, which, however, could well be the dominating features in landslide-generated tsunamis and for the fission processes described previously. Several high-order depth-integrated wave hydrodynamics models (Boussinesq models) are now available for simulating nonlinear and weakly dispersive waves, such as COULWAVE (Cornell University Long and Intermediate Wave Modeling Package; [42]) and FUNWAVE [25]. The major difference between the two is their treatment of moving shoreline boundaries. Lynett et al. [44] applied COULWAVE to the 1998 PNG tsunami with the landslide source; the results agreed with field survey data well. Recently, several finite element models have also been developed based on Boussinesq-type equations (e.g., [73]). Boussinesq models require higher spatial and temporal resolutions, and therefore are more computationally intensive. Moreover, most of model validation work was performed for open-ocean or open-coast problems. In other words, the models have not been carefully tested for wave propagation and oscillations in semi-enclosed regions – such as a harbor or bay – especially under resonant conditions.

Being depth-integrated and horizontally 2D, NSW and Boussinesq models lack the capability of simulating the details of many coastal effects, such as wave overturning

and the interaction between tsunamis and coastal structures, which could be either stationary or movable. At present, stationary coastal structures are parametrized as bottom roughness and contribute to frictional effects in these 2DH models. Although by adjusting the roughness and friction parameter satisfactory results can be achieved for maximum runup and delineation of the inundation zone (e.g., [35]), these models cannot provide adequate information for wave forces acting on coastal structures.

As a tsunami propagates into the nearshore region, the wave front undergoes a nonlinear transformation while it steepens through shoaling. It is in this nearshore region that dissipative effects can be important. Bottom friction can play a major role in the maximum runup and area of inundation (e.g. [67]). In depth-integrated models, bottom friction is typically approximated through a quadratic (drag) friction term, where the friction factor is calculated often through a Manning's coefficient or a Darcy–Wiesbach type friction factor (e.g. [25,35]). The validity of these steady-flow based coefficients has yet to be rigorously validated for use with tsunamis. If the tsunami is large enough, it can break at some offshore depth and approach land as a bore – the white wall of water commonly referenced by survivors of the Indian Ocean tsunami. Wave breaking in traditional NSW tsunami models has not been handled in a satisfactory manner. Numerical dissipation is commonly used to mimic breaking (e.g. [36]), and thus results become grid dependant. In Boussinesq models, this breaking is still handled in an approximate manner due to the fact that the depth-integrated derivation does not allow for an overturning wave; however these breaking schemes have been validated for a wide range of nearshore conditions (e.g. [40]).

Being depth-integrated, NSW and Boussinesq models lack the capability of simulating the vertical details of many coastal effects, such as strong wave breaking/overturning and the interaction between tsunamis and irregularly shaped coastal structures. To address this deficiency, several 2D and 3D computational models based on Navier–Stokes equations have been developed, with varying degrees of success. An example is COBRAS (Cornell Breaking waves and Structures model Lin and Liu 1998a,b, Lin et al. 1999), which is capable of describing the interactions between breaking waves and structures that are either surface piercing or submerged [6,22]. COBRAS adopted the Volume of Fluid (VOF) method to track free surface movement along with a Large Eddy Simulation (LES) turbulence closure model; several other computational models using different free surface tracking methods are also in use, such as the micro surface cell technique developed by Johnson et al. [23]. This 3D Navier–Stokes

Tsunami Inundation, Modeling of, Figure 5

An simulation snapshot taken from a 3D Navier–Stokes solver with an LES turbulence closure. This setup is looking at a bore impacting a column; the wake and vertical splash are clearly visible (Image provided by Philip L.-F. Liu, Cornell University)

equation model has been tested by two tsunami related experiments. The first is 3D landslide experiments [38,39], while the second involves measurements of solitary wave forces on vertical cylinders. Both experiments were conducted in the NEES tsunami basin at Oregon State. An example of a LES numerical solution of a solitary wave impinging on a circular is shown in Fig. 5.

Due to their high computational costs, full 3D models would best be used in conjunction with a depth-integrated 2DH model (i. e., NSW or Boussinesq). While the 2DH model provides incident far-field tsunami information, the 3D model computes local wave-structure interactions. The results from 3D models could also provide a better parametrization of small-scale features (3D), which could then be embedded in a large-scale 2DH model. One-way coupling (e. g. using a NSW-generated time series to drive a 3D model, but not permitting feedback from the 3D model back into the NSW) is fairly straightforward to construct (e. g. [18]). Two-way coupling, however, is difficult and requires consistent matching of physics and numerical schemes across model interfaces. Previous work in this area of two-way coupling of hydrodynamic models is limited. Fujima et al. [13] two-way coupled a NLSW model with a fully 3D model. While the results appear promising, the approach used by Fujima et al. requires ad-hoc and unphysical boundary conditions at the model matching locations, in the form of spatial gradients forced to zero, to ensure numerical stability. Even with these ad-hoc treat-

ments, their hybrid model compares very well with the completely-3D-domain simulation, requiring roughly 1/5 of the total 3D CPU time to achieve similar levels of accuracy. Sittanggang et al. [58] presented work on two-way coupling of a Boussinesq model and 2D Navier–Stokes model. These results indicate that there is large potential for hybrid modeling, in terms of more rapid simulation as well as the ability to approach a new class of problems.

### Moving Shoreline Algorithms

In order to simulate the flooding of dry land by a tsunami, a numerical model must be capable of allowing the shoreline to move in time. Here, the shoreline is defined as the spatial location where the solid bottom transitions from submerged to dry, and is a function of the two horizontal spatial coordinates and time. Numerical models generally require some type of special consideration and treatment to accurately include these moving boundaries; the logic and implementation behind this treatment is called a moving shoreline, or runup, algorithm.

For typical tsunami propagation models, it is possible to divide runup algorithms into two main approaches: those on a fixed grid and those on a Lagrangian or transformed domain. Both approaches have their advantages and disadvantages; currently fixed grid methods are found more commonly in operational-level models (e. g. [66]),

likely due in large part to their conceptual simplicity. A review of these two classes of models will be given in this section, followed by a review of the standard analytical, experimental, and field benchmarks used to validate the runup models. For additional information, the reader is directed to the comprehensive review given in Pedersen [49].

With a fixed grid method, the spatial locations of the numerical grid points or control volumes are determined at the start of a simulation, and do not change shape or location throughout the simulation duration. These methods can be classified into extrapolation, stairstep, auxiliary shoreline point, and permeable beach techniques. The extrapolation method has its roots in Sielecki and Wurtele [57], with extensions by Hibberd and Peregrine [20], Kowalik and Murty [27], and Lynett et al. [43]. The basic idea behind this method is that the shoreline location can be extrapolated using the nearest wet points, such that its position is not required to be locked onto a fixed grid point; it can move freely to any location. Theoretically, the extrapolation can be of any order; however, from stability constraints a linear extrapolation is generally found. Hidden in the extrapolation, the method is roughly equivalent to the use of low-order, diffusive directional differences taken from the last wet point into the fluid domain [43]. Additionally, there are no explicit conservation constraints or physical boundary conditions prescribed at the shoreline, indicating that large local errors may result if the flow in the extrapolated region cannot be approximately as linear in slope. The extrapolation approach can be found in both NLSW and Boussinesq models with finite difference, finite volume, and finite element solution schemes, and has shown to be accurate for a wide range of non-breaking, breaking, two horizontal dimension, and irregular topography problems (e. g. [8,9,26,44,51]).

Stairstep moving shoreline methods, one of the more common approaches found in tsunami models (e. g. [35]), reconstruct the naturally continuous beach profile into a series of constant elevation segments connected through vertical transitions. In essence, across a single cell width, the bottom elevation is taken as the average value. A cell transitions from a dry cell to a wet cell when the water elevation in a neighboring cell exceeds the bottom elevation, and transitions from wet to dry when the local total water depth falls below some small threshold value. These methods are particularly useful in finite volume and *C*-grid [1] type approaches (e. g. [32,36]), but can be difficult to implement in centered difference models, particularly high-order models or those sensitive to fluid discontinuities, where the “shock” of opening and closing entire cells can lead to numerical noise.

Auxiliary shoreline point methods require dynamic re-gridding very near the shoreline, such that the last wet point is always located immediately at the shoreline. Obviously, this method requires a numerical scheme that can readily accommodate non-uniform and changing node locations. There is some relation to the extrapolation methods discussed above; the moving shoreline point must be assigned some velocity, and it is extrapolated from the neighboring wet points. However, it is fundamentally different in that the shoreline point is explicitly included in the fluid domain. Thus, it would be expected that the governing conservation equations near the shoreline are more precisely satisfied here, although still dependent on the appropriateness of the extrapolation. One such method can be found in Titov and Synolakis [65], and has been successfully applied in NLSW equation models.

Another fixed grid treatment of moving boundary problems is employing a slot or permeable-seabed technique [63,64]. Conceptually, this method creates porous slots, or conduits, through the dry beach, such that there is always some fluid in a “dry” beach cell, although it may exist below the dry beach surface. These porous, “dry” nodes use a modified form of the NLSW; it is noted here that although in concept this approach is modeling a porous beach, it is not attempting to simulate the groundwater flow under a real, sandy beach, for example. The equations governing the “dry” domain contain a number of empirical parameters that are tuned to provide reasonable runup agreement with benchmark datasets. The advantage of this approach is that it allows the entire domain; including the fluid and “dry” nodes, to be determined via a somewhat consistent set of governing equations, without requiring a direct search routine to determine the shoreline location. The method has gained some popularity in wind wave models (e. g. [25,46]) when a highly accurate estimate of the shoreline location is not the highest priority. However, the approach has been used with some success in tsunami studies (e. g. [30]) despite the fact that the empirical coefficients that govern the model accuracy cannot be universally determined for a wide range of problems [7].

Alternative to fixed grid methods is the Lagrangian approach. Here, the fluid domain is discretized into particles, or columns of fluid in depth-integrated models, that are transported following the total fluid derivative. There are no fixed spatial grid locations; the columns move freely in space and time and thus these techniques require numerical flexibility, in terms of utilizing constantly changing space and time steps. The Lagrangian approach can be described as both the more physically consistent and mathematical elegant method of describing shoreline mo-

tion. The shoreline “particle” is included in the physical formulation just as any other point in the domain (i. e. no extrapolations are necessary), and thus the shoreline position accuracy will be compromised only by the overarching physical approximation (e. g. long wave approximation) and the numerical solution scheme (e. g. second-order time integration). The cost for this accuracy is a mathematical system that can be more difficult and tedious to solve numerically, typically requiring domain transformations, mappings, and/or re-griddings. Lagrangian methods have been used successfully in finite difference and finite element nonlinear shallow water (NLSW) and Boussinesq equation models (e. g., [2,15,48,50,52,74]).

### Future Directions

Towards a more robust simulation of tsunami inundation, there are two major issues which require additional fundamental investigations: dissipation mechanisms and interaction with infrastructure. Bottom friction, known to play an important role in inundation, needs to be re-examined starting from its basic formulation. Can a steady-flow based Mannings-type expression for bottom friction be used for tsunami? Does the unsteady nature of the tsunami flow make use of these existing formulations invalid? The answer to these questions may be different depending on what part of the wave is investigated (e. g. front). In addition, the hydrodynamic effect of common coastal vegetation, such as mangroves, needs to be quantified. There is current discussion of the use of such natural roughness as a tsunami defense (e. g. [11]); confidence cannot be put in such measures until it is understood how they behave. In addition to bottom friction, which exists at all locations and times under an inundating tsunami, wave breaking can increase the total energy dissipation. While breaking is generally confined to the leading front of a tsunami, the characteristics of this front are important for hydrodynamic loadings on beachfront structures, and may be significant to the net sediment and debris transport of a tsunami. Three-dimensional tsunami breaking is poorly understood and has received little attention.

Wave loadings and interactions with infrastructure are not well understood. To tackle this problem, tsunami hydrodynamic models need to be coupled with structural and geotechnical models. Ideally, these models should all be two-way coupled, such that the displacement of a structure, be it a single collapsed wall, will change the flow pattern, and scour underneath the foundation will change the structure stability. Additionally, impacts of flow-transported debris (e. g. cars) should be included in this frame-

work. If such a modeling capacity existed, engineering design of coastal structures could be undertaken in a very efficient manner.

**Inverse problem** Unlike a forward problem which starts from a tsunami source then computes propagation in the ocean and predicts travel times and/or water heights on coasts, an inverse problem starts from tsunami observations to study the generation process. While forward modeling is useful for tsunami warning or hazard assessments, inverse modeling is a typical approach for geophysical problems.

**Shallow water (long) waves** In hydrodynamics, water waves can be treated as shallow water, or long, waves when the wavelength is much larger than the water depth. In such a case, the entire water mass from water bottom to surface moves horizontally and the wave propagation speed is given as a square root of the product of the gravitational acceleration and the water depth.

**The 2004 Indian Ocean tsunami** On December 26, 2004, a gigantic earthquake, the largest in the last half century in the world, occurred off the west coast of Sumatra Island, Indonesia. With the source extending more than 1,000 km through Nicobar and Andaman Islands, the earthquake generated tsunami which attacked the coasts of Indian Ocean and caused the worst tsunami disaster in history. The total casualties were about 230,000 in many countries as far away as Africa.

**Fault parameters** Earthquake source is modeled as a fault motion, which can be described by nine static parameters. Once these fault parameters are specified, the seafloor deformation due to faulting, or initial condi-

tion of tsunamis, can be calculated by using the elastic dislocation theory.

**Refraction and inverse refraction diagrams (travel time map)** Refraction diagram is a map showing isochrons or lines of equal tsunami travel times calculated from the source toward coasts. Inverse refraction diagram is a map showing arcs calculated backwards from observation points. The tsunami source can be estimated from the arcs corresponding to tsunami travel times.

### Definition of the Subject

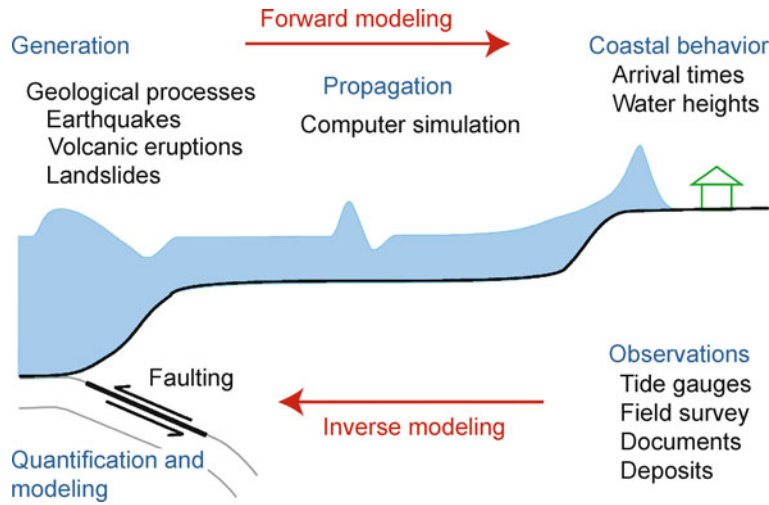

Forward modeling of tsunami starts from given initial condition, computes its propagation in the ocean, and calculates tsunami arrival times and/or water heights on coasts. Once the initial condition is provided, the propagation and coastal behavior can be numerically computed on actual bathymetry (Fig. 1).

Recent technological developments make it possible to carry out tsunami forward modeling with speed and accuracy usable for the early tsunami warning or detailed hazard assessments. However, the initial condition, or the tsunami generation process, is still poorly known, because large tsunamis are rare and the tsunami generation in the ocean is not directly observable. Indirect estimation of tsunami source, mostly on the basis of seismological analyzes, is used as the initial condition of tsunami forward modeling. More direct estimation of tsunami source is essential to better understand the tsunami generation process and to more accurately forecast the tsunami on coasts.

Inverse modeling of tsunami starts from observed tsunami data, to study the tsunami source. The propagation process can be evaluated by using numerical simulation, as in the forward modeling. As the observed tsunami data, tsunami arrival times, heights or waveforms recorded on instruments are used. For historical tsunamis, tsunami heights can be estimated from description of damage on historical documents. For prehistoric tsunamis, geological studies of tsunami deposits can be used to estimate the coastal tsunami heights or flooding areas.

### Introduction

Tsunamis are oceanic gravity waves generated by seafloor deformation due to submarine earthquakes or other submarine geological processes such as volcanic eruptions, landslides, or asteroid impacts. While earthquake tsunamis, such as the 2004 Indian Ocean tsunami caused by the Sumatra–Andaman earthquake, are most frequent, large volcanic eruptions such as the 1883 Krakatau eruption off Sumatra Island also cause ocean-wide tsunamis. Landslides, often triggered by earthquakes, cause locally

Tsunamis, Inverse Problem of, Figure 1

Schematic diagram showing tsunami generation, propagation and coastal behavior. Forward modeling starts from tsunami source and forecasts the coastal behavior, while inverse modeling starts from observed data to estimate the tsunami source

large tsunamis, but the effects are usually limited to the area around the source.

Most tsunamigenic geological processes produce seafloor deformation. When horizontal scale, or wavelength, of the seafloor deformation is much larger than the water depth, a similar disturbance appears on the water surface and becomes the source of tsunami. This is called shallow water, or long-wave, approximation. For large earthquakes, wavelength of seafloor deformation is an order of several tens to hundreds of km, while the ocean depth is up to several km, hence the long-wave approximation is valid. For small scale disturbance relative to water depth, such as submarine landslides or volcanic eruptions in deep seas, the shallow water approximation may not be valid.

This paper reviews inverse methods to study tsunami sources from the observations. Section “**Tsunami Generation by Earthquakes**” describes the tsunami generation by earthquakes, with emphasis on the fault parameters and their effects on tsunamis. Section “**Tsunami Propagation**” describes tsunami propagation: shallow water theory and numerical computation. Section “**Tsunami Observations**” summarizes the tsunami observation: instrumental sea-level data, runup height estimates for modern, historical and prehistoric tsunamis. Section “**Estimation of Tsunami Source**” describes methods of modeling and quantifying tsunami source, and of analyzing tsunami travel times, amplitudes and waveforms, including some historical developments. Section “**Estimation of Earthquake Fault Parameters**” focuses on the estimation of earthquake fault

parameters, including the waveform inversion of tsunami data to estimate heterogeneous fault motion and its application for tsunami warning.

### Tsunami Generation by Earthquakes

#### Fault Parameters and Seafloor Deformation

The seafloor deformation due to earthquake faulting can be calculated by using the elastic theory of dislocation. The displacement,  $u_k$ , in an infinite homogeneous medium due to dislocation  $\Delta u_i$  across surface  $\Sigma$  is given by the Volterra’s theorem as [1]

$$u_k = \frac{1}{8\pi\mu} \int_{\Sigma} \Delta u_i \{ \lambda \delta_{ij} u_k^{n,n} + \mu (u_k^{i,j} + u_k^{j,i}) \} v_j dS \quad (1)$$

where  $\lambda$  and  $\mu$  are Lamé constants,  $\delta_{ij}$  is Kronecker’s delta,  $v$  is the unit normal to the surface. The expression  $u_i^j$  denotes the  $i$ th component of the displacement due to the  $j$ th component of a point force at the source whose magnitude is  $8\pi\mu$ , and  $u_i^{j,k}$  indicates its spatial derivative with respect to the  $k$ th coordinate. For a half-space with free surface, a mirror image can be used to cancel the stress components on the free surface. The explicit formulas are given by Mansinha and Smyle [2] or Okada [3].

The fault parameters needed to compute surface deformation are summarized in Fig. 2. They are: fault length ( $L$ ), width ( $W$ ), strike ( $\phi$ ), dip ( $\delta$ ), rake ( $\lambda$ ), slip amount ( $u$ ) and location ( $x, y, z$ ). The slip  $u$  can be decomposed into strike-slip component  $u_s$  and dip-slip component  $u_d$ . The

Tsunamis, Inverse Problem of, Figure 2  
**Fault parameters.** Seafloor deformation can be computed from these static parameters

strike  $\phi$  is measured clockwise from North, dip angle  $\delta$  is downward from horizontal, and rake angle  $\lambda$  is a movement of hanging wall measured counter-clockwise from horizontal (see Fig. 2). Therefore, the fault motion is reverse if  $\lambda > 0^\circ$  and normal if  $\lambda < 0^\circ$ . The fault motion has left-lateral component if  $|\lambda| < 90^\circ$  and right-lateral component if  $|\lambda| > 90^\circ$ .

The physical parameter to quantify the fault motion is the seismic moment,  $M_0$ , defined as

$$M_0 = \mu u S = \mu u L W. \quad (2)$$

More conventional parameter of earthquake size is a magnitude scale, which has been determined from amplitudes of seismograms. To relate the seismic moment and magnitude scales, the moment magnitude scale,  $M_w$ , is defined as [4,5]

$$M_w = \frac{2}{3} \log M_0 - 10.7 \quad (3)$$

where  $M_0$  is given in dyne.cm ( $10^{-7}$  Nm).

Most of the above fault parameters can be estimated from seismic wave analysis. The location and depth of fault ( $x, y, z$ ) correspond to hypocenter, which is estimated from arrival times of seismic waves. The fault geometry ( $\phi, \delta, \lambda$ ) is estimated from the polarity distribution of body wave first motions or azimuthal distribution of surface wave amplitudes. The seismic moment is estimated from waveform modeling of seismic waves. The fault size,  $L$  and  $W$ , are more difficult to estimate; they are usually estimated from aftershock distribution or detailed waveform modeling of seismic body waves. The slip amount,  $u$ , is indirectly estimated, from seismic moment  $M_0$  by assuming  $\mu$  and fault size ( $L$  and  $W$ ). All such estimates assume that the faulting is planar and continuous, which most often is a simplification of real, more complex faulting.

The 2004 Sumatra–Andaman earthquake was the largest earthquake since the 1960 Chilean earthquake ( $M_w$  9.5) or 1964 Alaskan earthquake ( $M_w$  9.2). The seismic moment estimates range  $4\text{--}12 \times 10^{22}$  Nm, and the corresponding moment magnitude  $M_w$  ranges 9.0–9.3 from the seismological analyzes [6,7,8]. The aftershock area extended from off Sumatra through the Nicobar to Andaman Islands with the total fault length of 1,200 to 1,300 km [6]. For such a gigantic earthquake, multiple fault planes with different strike and slip amounts are needed to represent the fault motion, as shown later (Sect. “**Estimation of Earthquake Fault Parameters**”).

### Effect of Fault Parameters on Tsunami Generation

Among the above static fault parameters, the slip amount has the largest effect on the vertical seafloor deformation and the tsunami amplitude. The dip angle and fault depth are also important parameters to control tsunami amplitude [9,10]. Dynamic parameters such as rupture velocity are found to be insignificant for tsunami generation. However, for a gigantic earthquake such as the 2004 Sumatra–Andaman earthquake with the source length over 1,000 km, rupture propagation effect on tsunamis is not negligible [11].

Amplitude of far-field seismic waves, either body waves or surface waves, is controlled by seismic moment, while amplitude of tsunami is controlled by fault slip. Satake and Tanioka [12] found for the 1998 Papua New Guinea tsunami that the far-field tsunami amplitudes are proportional to the volume of displaced water, while the near-field tsunami amplitudes are controlled by the potential energy of the displacement.

Traditionally, only vertical component of seafloor deformation has been considered for tsunami generation (Fig. 3a). If an earthquake occurs on a steep ocean slope such as trench slope, horizontal displacement due to faulting moves the slope and contributes the tsunami generation [13]. The effective vertical movement (positive upward) due to faulting can be written as follows (Fig. 3b),

$$u_z + u_x \frac{\partial H}{\partial x} + u_y \frac{\partial H}{\partial y} \quad (4)$$

where  $u_z$  is vertical component and  $u_x$  and  $u_y$  are horizontal components of seafloor deformation, and  $H$  is water depth (measured positive downward).

Recently, Song et al. [14] proposed that horizontal motion of slope also transfers kinetic energy from seafloor to water. They claimed that the kinetic energy thus transferred was about five times larger than the potential energy

Tsunamis, Inverse Problem of, Figure 3  
**Seafloor deformation and tsunami source. a Vertical seafloor deformation becomes the tsunami source. b When the seafloor is not flat, horizontal displacement of the slope also affects the tsunami generation [13]**

for the 2004 Indian Ocean tsunami, from comparisons of the observed tsunami (sea surface height) data with the computed ones by using an ocean-general-circulation-model.

**Tsunami Propagation**

**Shallow Water Theory**

The equation of motion, or conservation of momentum, for shallow water, or long-wave, theory is given as follows.

$$\frac{\partial \mathbf{V}}{\partial t} + (\mathbf{V} \cdot \nabla) \mathbf{V} = -g \nabla h + C_f \frac{\mathbf{V} |\mathbf{V}|}{d + h} \tag{5}$$

where  $\mathbf{V}$  is the depth-averaged horizontal velocity vector,  $h$  is the water height or tsunami amplitude,  $d$  is the water depth and  $g$  is the gravitational acceleration. On the left-hand side, the first term represents local acceleration and the second term represents nonlinear advection. On the right-hand side, the first term represents pressure gradient, or restoring force due to gravity, and the second term represents nonlinear bottom friction where  $C_f$  is the non-dimensional frictional coefficient.

The equation of continuity, or conservation of mass, can be written as

$$\frac{\partial (d + h)}{\partial t} = -\nabla \cdot \{(d + h) \mathbf{V}\} . \tag{6}$$

These equations can be linearized as

$$\frac{\partial \mathbf{V}}{\partial t} = -g \nabla h \tag{7}$$

$$\frac{\partial h}{\partial t} = -\nabla \cdot (d \mathbf{V}) \tag{8}$$

when the tsunami amplitude  $h$  is small compared to water depth  $d$ , and the bottom friction can be neglected. Such an assumption is valid for deep ocean, or most of the tsunami

propagation path. Near the coasts, nonlinear terms play important roles, hence linearization may not be valid. The major advantage of the linear theory is the superposition principle; the computational results can be easily scaled to estimate with different initial water heights.

From Eqs. (7) and (8), the wave equation with wave velocity (celerity)  $\sqrt{gd}$  can be derived. This indicates that the tsunami speed is controlled by water depth. Once the water depth distribution, or ocean bottom bathymetry, is known, then the tsunami propagation can be computed numerically.

**Numerical Computations**

Equations (5) and (6), or (7) and (8) for linearized case, can be directly solved by numerical methods, once the initial condition is given. The tsunami wave velocity distribution, which is given by the bathymetry, is much better known than the velocity distribution of seismic waves, hence actual values can be used. Finite-difference method with staggered grids is popularly used [15,16], while use of other methods such as finite-element methods have been also proposed [17]. Grid size for finite-difference computations is typically a few km for deep ocean, but grids as fine as several tens to hundreds of meters are used near coasts. The temporal changes in water height at grid points corresponding to the observation points are used as computed tsunami waveforms.

The database of global water depth or bathymetry data such as ETOPO2 (NOAA/NGDC) or GEBCO (British Oceanographic Data Centre) are popularly used. The ETOPO2 database is based on predicted bathymetry from satellite altimetry data [18] with interval of 2 minutes (about 3.5 km), while GEBCO data are digitized from nautical charts with grid interval of 1 minute. Higher resolution bathymetry data near coasts are open to public in some countries such as US (NOAA/NGDC) or Japan (JODC).

## Tsunami Observations

### Instrumental Data

Traditional instrumental data for tsunami observation are tide gauge records. Tide gauges are typically installed on ports or harbors to define datum or to monitor ocean tides. The temporal resolution is usually low with a sampling interval of several minutes or longer. For the tsunami monitoring, higher sampling rate, at least 1 min or shorter interval, is required. While the recorded tsunami waveforms contains coastal effects such as coastal reflections or resonance particularly for the later phase, the initial part of tsunami signals is more dominant by the tsunami source effect hence the source information can be retrieved. Currently, sea level measurement data from many tide gauge stations are transmitted through weather satellite and available in real time. Figure 4 (left) shows some of tide gauge records of the 2004 Indian Ocean tsunami.

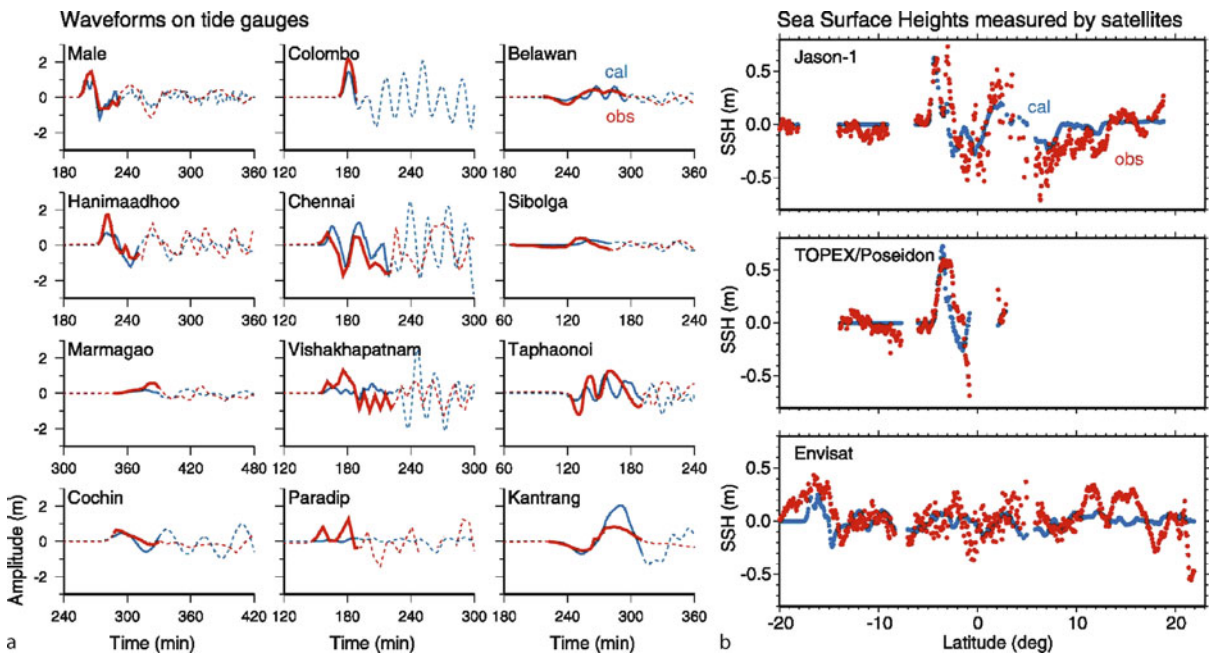

Tsunami waveforms are simpler offshore or in deep ocean, free from nonlinear coastal effects, though the signal is smaller. Offshore and deep ocean tsunami observation facilities have been significantly developed recently. Offshore tsunami gauges such as GPS tsunami gauge have been developed and deployed around Japan [19]. In 2003,

cabled bottom pressure gauges have recorded the tsunami generation process in the source area [20]. The US NOAA deployed dozens of bottom pressure gauges, called Deep-ocean Assessment and Reporting of Tsunamis (DART) or simply Tsunameters [21]. The bottom pressure signals are sent to surface buoys via acoustic telemetry in the ocean, then to land station via satellite. As described later, the DART data are used for real-time data assimilation and tsunami warning purposes [22]. After the 2004 Indian Ocean tsunami, many DART-type bottom pressure gauges have been deployed in the Pacific and Indian Oceans.

Satellite altimeters captured the propagation of the 2004 Indian Ocean tsunami (Fig. 4). Three satellites flew over the Indian Ocean at a few hours after the earthquake and measured the sea surface height (SSH) of about 0.8 m in the middle of Indian Ocean. The tsunami amplitudes in deep ocean are much smaller than the maximum coastal heights of more than 10 m. The SSH data are used to study the tsunami source [11,23].

### Modern, Historical and Prehistoric Tsunami Heights

After damaging tsunamis, tsunami height distribution is often measured by survey teams [24]. Measurements are usually made for flow depth above ground, on the basis of

Tsunamis, Inverse Problem of, Figure 4

The sea level data from the 2004 Indian Ocean tsunami [11]. **a** Tsunami waveforms on tide gauges. *Red curves* indicate observed waveforms and *blue ones* are computed. Data shown in *solid lines* are used for the waveform inversion. **b** Sea surface heights measured by three different satellites (see Fig. 5 for the tracks). *Red* shows the observed data and *blue* is for computed surface heights

various watermarks, then converted to inundation height above sea level [25]. The tsunami inundation heights are usually not constant along a profile from beach, and the height at most inland point is called runup height.

For historical tsunamis, coastal tsunami heights can be estimated from descriptions of tsunami or its damage recorded in historical documents. Such estimates include various assumptions on sea levels and a relationship between tsunami damage and flow depth, but provide important tsunami data for historical tsunamis. For example, date and size of the last gigantic earthquake in the Cascadia subduction zone off North America were estimated as January 26, 1700 and  $M_w \sim 9.0$  from the Japanese tsunami records [26].

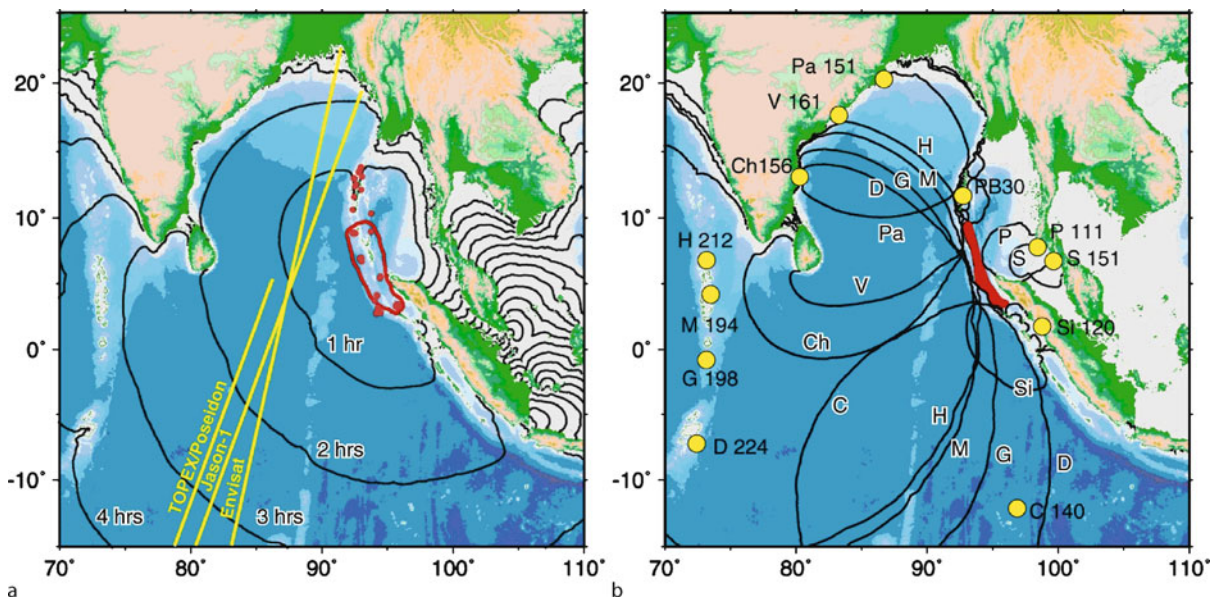

Geological traces such as tsunami deposits can also be used to estimate tsunami heights for prehistoric tsunamis. In the last few decades, many studies of tsunami deposits, combined with numerical computations, have been made to analyze prehistoric tsunamis [27,28]. For example, in Hokkaido, prehistoric tsunami deposits indicate past tsunamis with larger inundation area and longer recurrence interval than those from the recent plate-boundary earthquakes along the southern Kuril trench, which were attributed to multi-segment earthquakes with  $M_w \sim 8.4$  [29].

## Estimation of Tsunami Source

### Refraction Diagram

Tsunami propagation can be computed and described as a refraction diagram. When the tsunami wavelength is smaller than the scale length of velocity heterogeneity, or the water depth variation is smooth, then the geometrical ray theory of optics can be applied. The wavefronts of propagating tsunami can be drawn on the basis of Huygens' principle. Alternatively, propagation of rays, which is orthogonal to wavefronts, can be traced from an assumed source. While refraction diagram do not provide information on water height, the relative amplitudes can be estimated from density of rays [30].

Refraction diagrams can be prepared for major tsunami sources and used for tsunami warning; as soon as the epicenter is known, the tsunami arrival times can be readily calculated. The refraction diagrams are usually drawn from a point source, but it is possible to draw it from an extended source for a great or giant earthquake. Figure 5a shows the refraction diagram from the 2004 Sumatra–Andaman earthquake with wavefronts at each hour. To the east of the assumed source, the tsunami is expected to arrive at the Thai coast in about two hours through Andaman Sea. To the west, through deeper Bay

Tsunamis, Inverse Problem of, Figure 5

**a** Tsunami refraction diagram for the 2004 Sumatra–Andaman earthquake. Red dots indicate aftershocks within 1 day according to USGS. The red curve shows the assumed tsunami source. Tracks of three satellites with altimeters are shown by yellow lines. Black curves indicate tsunami wavefronts at each hour after the earthquake. **b** Tsunami inverse refraction diagram for the same event. Station code and tsunami arrival times (in min) are attached to tide gauge stations (yellow circles) where the tsunami was instrumentally recorded. Black curves are the travel-time arcs computed for each station. Red area indicates inferred tsunami source

of Bengal, the tsunami is expected to arrive at Sri Lanka also in two hours. The predicted tsunami arrival times are similar to the actually observed values [31].

### Inverse Refraction Diagram

Refraction diagram can be drawn backwards from coasts. Such a diagram is called inverse refraction diagram and is used to estimate the tsunami source area. When the tsunami travel time, that is tsunami arrival time minus earthquake origin time, is known, the corresponding wavefront, or travel-time arc, drawn from the tsunami observation point (typically tide gauge stations) would indicate the initial wavefront at the tsunami source. The tsunami inverse refraction diagram was first drawn for the 1933 Sanriku tsunami [32], although the estimated tsunami source was much larger than modern estimates, because both tsunami travel times and the bathymetry were poorly known.

The 2004 Indian Ocean tsunami was observed at many tide gauge stations in the Indian Ocean [33,34]. The tsunami arrival times were read from the tide gauge records and tsunami travel times were calculated from the earthquake origin time. The tsunami propagation was then computed from each tide gauge station, and wavefronts corresponding to the travel time were drawn as travel-time arcs (Fig. 5b). These travel-time arcs surround the tsunami source, and the source area was estimated as about 900 km long [6,35].

### Estimation of Tsunami Source

Tsunami data can be used to study earthquake source processes in a similar way that seismic waves are used. This was first demonstrated for the 1968 Tokachi-oki earthquake ( $M_0 = 2.8 \times 10^{21}$  Nm or  $M_w = 8.3$ ) [36]. The tsunami source area estimated from an inverse refraction diagram agrees well with the aftershock area (Fig. 6a, b). In addition, the initial water surface disturbance was estimated as uplift at the southeastern edge and subsidence at the northwestern edge, from the first motion of recorded tsunami waveforms on tide gauges. This pattern is very similar to the vertical bottom deformation due to the faulting, which was independently estimated from seismological analysis (Fig. 6c).

### Green's Law and Tsunami Heights

The water height in the tsunami source area can be estimated from the observed tsunami heights along the coasts, by using the Green's law. The Green's law is derived from the conservation of potential energy along rays [38],

$$b_0 d_0^{1/2} h_0^2 = b_1 d_1^{1/2} h_1^2 \quad (9)$$

where  $d$  is the water depth,  $b$  is the distance between the neighboring rays,  $h$  is the tsunami amplitude, and the subscripts 0 and 1 indicate two different locations on the same ray. If the tsunami amplitude at location 0 (e. g., on the coast) is known, the tsunami amplitude at location 1 (e. g., at the source) can be estimated as

$$h_1 = \left(\frac{b_0}{b_1}\right)^{1/2} \left(\frac{d_0}{d_1}\right)^{1/4} h_0. \quad (10)$$

The ratio  $b_0/b_1$  represents the spreading of rays, which can be graphically obtained from refraction diagrams. For the Tokachi-oki earthquake, the average tsunami height at the source was estimated as 1.8 m using the Green's law, which is very similar to 1.6 m, the average vertical seafloor displacement computed from the fault model [36].

The Green's law is also used to estimate the shoaling effects. For plane waves approaching the coast, the spreading ratio is unity, hence the amplitude is proportional to a 1/4 power of water depth change. For example, when the water depth becomes a half, the amplitude becomes 1.18 times larger.

### Tsunami Magnitude

Tsunami magnitude scale,  $M_t$ , was introduced to quantify earthquake source that generated tsunamis [39]. The formulas were calibrated with the moment magnitude scale,  $M_w$ , of earthquakes. It is different from other tsunami magnitude or intensity scales that simply quantify the observed tsunamis. The definition of  $M_t$  for a trans-Pacific tsunami is [39]:

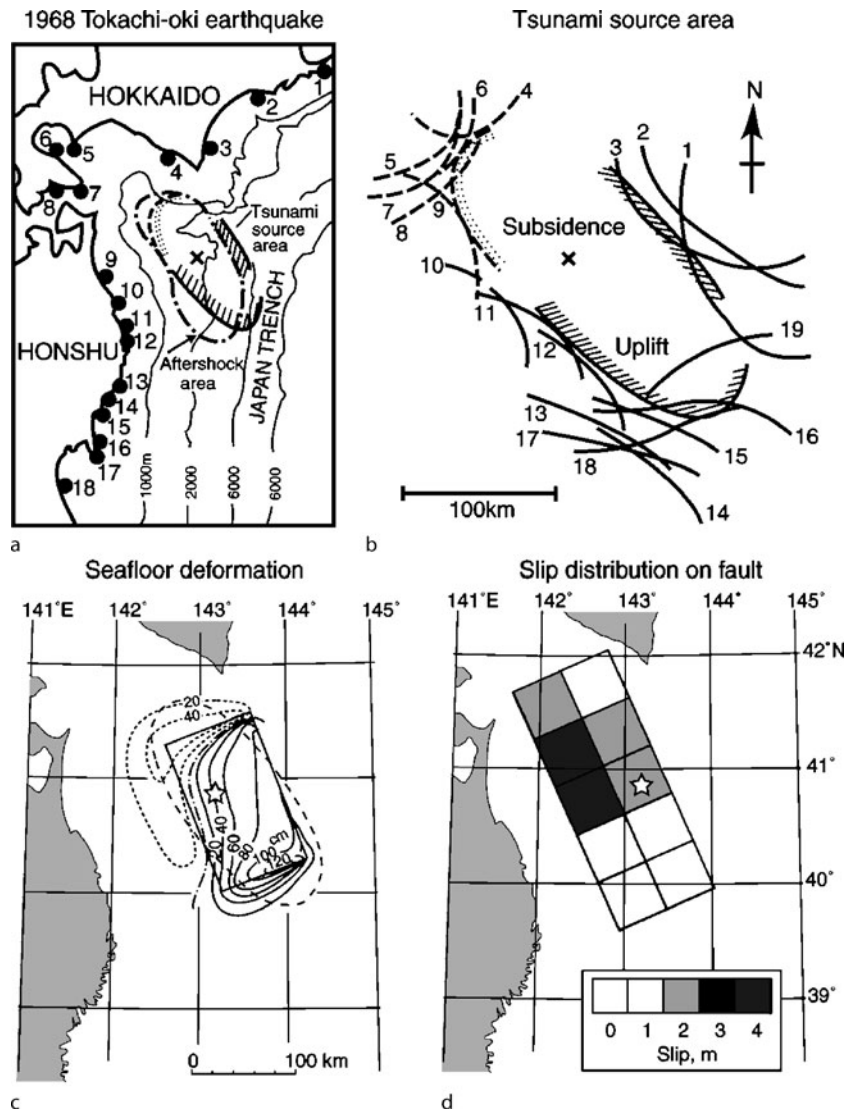

$$M_t = \log H + C + 9.1 \quad (11)$$

and for a regional ( $100 \text{ km} < \Delta < 3500 \text{ km}$ ) tsunami is [40]:

$$M_t = \log H + \log \Delta + 5.8 \quad (12)$$

where  $H$  is a maximum amplitude on tide gauges in meters,  $C$  is a distance factor depending on a combination of the source and the observation points, and  $\Delta$  is the nautical distance in km. The tsunami magnitude  $M_t$  was assigned as  $M_t = 8.2$  for the 1968 Tokachi-oki earthquake and  $M_t = 9.0$  for the 2004 Sumatra-Andaman earthquake.

Because the tsunami magnitude scale  $M_t$  is defined from tsunami amplitudes, it can be used to characterize "tsunami earthquakes" that produce much larger tsunamis than expected from seismic waves (see Polet and

Tsunamis, Inverse Problem of, Figure 6

The tsunami source area and seafloor deformation of the 1968 Tokachi-oki earthquake [36,37]. **a** Estimated tsunami source, aftershock area and distribution of tide gauge stations. **b** Travel-time arcs drawn by inverse refraction diagram. The numbers correspond to tide gauge stations in (a). Solid and dashed curves show uplift and subsidence, respectively. **c** Seafloor deformation computed from a seismological fault model. **d** Slip distribution on fault estimated by an inversion of tsunami waveforms

Kanamori: ► **Tsunami Earthquakes**). Abe [41] defined “tsunami earthquakes” for such events with tsunami magnitude  $M_t$  larger than surface wave magnitude  $M_s$  by more than 0.5. It should not be confused with “tsunamigenic earthquake” which refers to any earthquake that generates tsunami.

### Estimation of Earthquake Fault Parameters

For earthquake tsunamis, the fault parameters can be estimated by inverse modeling of tsunamis. Such attempts

were first made by a trial and error approach. In order to estimate the heterogeneous fault parameters, inversion of tsunami waveforms or runup heights has been introduced.

### Trial and Error Approach

Numerical simulation of tsunami has been carried out for many tsunamigenic earthquakes around Japan [42]. For the 1968 Tokachi-oki earthquake, tsunami waveforms were computed from two models, one based on

seismological analysis (Fig. 6c) and another horizontally shifted by 28 km, and were compared with the observed tsunami waveforms recorded on tide gauges. Comparison of waveforms indicates that the latter model, shifted from that based on seismological analysis, shows better match in terms of tsunami arrival times. The slip amount on the fault was estimated as 4 m.

The best fault models are judged by comparison of the observed and computed tsunami waveforms. A few statistical parameters used to quantify the comparison are geometric mean, logarithmic standard deviation and correlation coefficient. The geometric mean  $K$  of the amplitude ratio  $O_i/C_i$ , where  $O_i$  and  $C_i$  are the observed and computed tsunami amplitudes at station  $i$ , is given as

$$\log K = \frac{1}{n} \sum_i \log \frac{O_i}{C_i} \tag{13}$$

The logarithmic standard deviation  $\kappa$  is defined as

$$\log \kappa = \left[ \frac{1}{n} \sum_i \left( \log \frac{O_i}{C_i} \right)^2 - (\log K)^2 \right]^{1/2} \tag{14}$$

If the logarithmic amplitude ratios obey the normal distribution  $N(\log K, \log \kappa)$ , then parameter  $\kappa$  can be considered as an error factor, because its logarithm shows the standard deviation. The geometric mean  $K$  indicates the relative size of the observed and computed tsunami models. The logarithmic standard deviation  $\kappa$  indicates the goodness of the model; the smaller  $\kappa$  means the better model. The arrival times of observed and computed waveforms are also compared, as indicated in the above example. Another parameter is correlation coefficient of the observed and computed waveforms, which are also used for the comparison of models.

While the above parameters ( $K$  and  $\kappa$ ) were originally defined for maximum amplitudes of waveforms, they are also used for comparison of observed and computed runup heights. For tsunami hazard evaluation of nuclear power plants in Japan, tsunami source models need to satisfy  $0.95 < K < 1.05$  and  $\kappa < 1.45$  for the observed and computed coastal heights [43].

**Heterogeneous Fault Motion**

Seismological studies of large earthquakes have indicated that the slip amount is not uniform but heterogeneous on faults. For the 1968 Tokachi-oki earthquake, inversion of far-field body waves or regional Rayleigh waves showed the slip distributions similar to that estimated from tsunami waves [44,45]. The large slip area, called asperity, produces high-frequency seismic waves thus important for

strong-motion prediction for earthquake hazard assessments. The asperity produces large seafloor deformation, hence it is also important for tsunami generation and its hazard estimation. Lay and Kanamori [46] suggested that characteristic size of asperities differs from one subduction zone to another and is controlled by geological setting. Yamanaka and Kikuchi [47], from studies of recurrent earthquakes off northern Honshu, showed that the same asperity ruptures in repeated earthquakes. Their asperity map can be used for earthquake and tsunami hazard assessment.

**Waveform Inversion**

The asperity distribution can be estimated by an inversion of tsunami waveforms. In this method (Fig. 7), the fault plane is first divided into several subfaults, and the seafloor deformation is computed for each subfault with a unit amount of slip. Using these as the initial conditions, tsunami propagation is numerically computed for actual bathymetry and the waveforms at tide gauge stations, called Green’s functions, are computed. Assuming that the tsunami generation and propagation are linear process, the observed tsunami waveforms are expressed as a linear superposition of Green’s functions as follows,

$$A_{ij}(t) \cdot x_j = b_i(t) \tag{15}$$

Tsunamis, Inverse Problem of, Figure 7  
Schematic illustration of tsunami waveform inversion method

where  $A_{ij}(t)$  is the computed waveform as a function of time  $t$ , or Green's function, at the  $i$ th station from the  $j$ th subfault;  $x_j$  is the amount of slip on the  $j$ th subfault; and  $b_i(t)$  is the observed tsunami waveform at the  $i$ th station. The slip  $x_j$  on each subfault can be estimated by a least-square inversion of the above set of equations, by minimizing the  $l_2$  norm of the residuals  $J$

$$J = \|A \cdot x - b\| \rightarrow \min \quad (16)$$

where  $A$ ,  $x$ , and  $b$  indicate matrix representations of elements in Eq. (15). Figure 6d shows the slip distribution on the fault for the 1968 Tokachi-oki earthquake. The source fault was divided into 10 subfaults, and slip distribution on the subfaults were estimated. The largest slip, about 3.7 m, was estimated on the subfaults to the west of epicenter, but the average slip is 1.2 m, much smaller than that estimated by the trial and error method (4 m) which compared the maximum tsunami amplitudes [37].

The 2004 Indian Ocean tsunami, caused by the Sumatra–Andaman earthquake, was recorded by satellite altimeters, as well as tide gauges. A joint inversion of tsunami waveforms recorded at 12 tide gauge stations and the sea surface heights measured by three satellites indicates that the tsunami source was about 900 km long [11].

Tsunamis, Inverse Problem of, Figure 8  
Slip distribution on 22 subfaults of the 2004 Sumatra–Andaman earthquake estimated from a joint inversion of tsunami waveforms on tide gauges and sea surface heights measured by satellite altimeters [11]

The estimated slip distribution (Fig. 8) indicates that the largest slip, about 13 to 25 m, was located off Sumatra Island and the second largest slip, up to 7 m, near the Nicobar Islands. Inversion of satellite altimeter data alone supports a longer, about 1,400 km long, tsunami source [23], but such a model produces much larger tsunami waveforms than observed at Indian tide gauge stations. Inversion of tide gauge data alone does not support tsunami source beneath Andaman Islands [48]. The slip distribution estimated by the joint inversion is similar to those estimated from seismological analyses. The fault slip was the largest near off the northern Sumatra, followed by off Nicobar Islands [49]. Fault slip around Andaman Islands was estimated to be small from seismological analysis [50].

### Nonlinear Inversion Methods

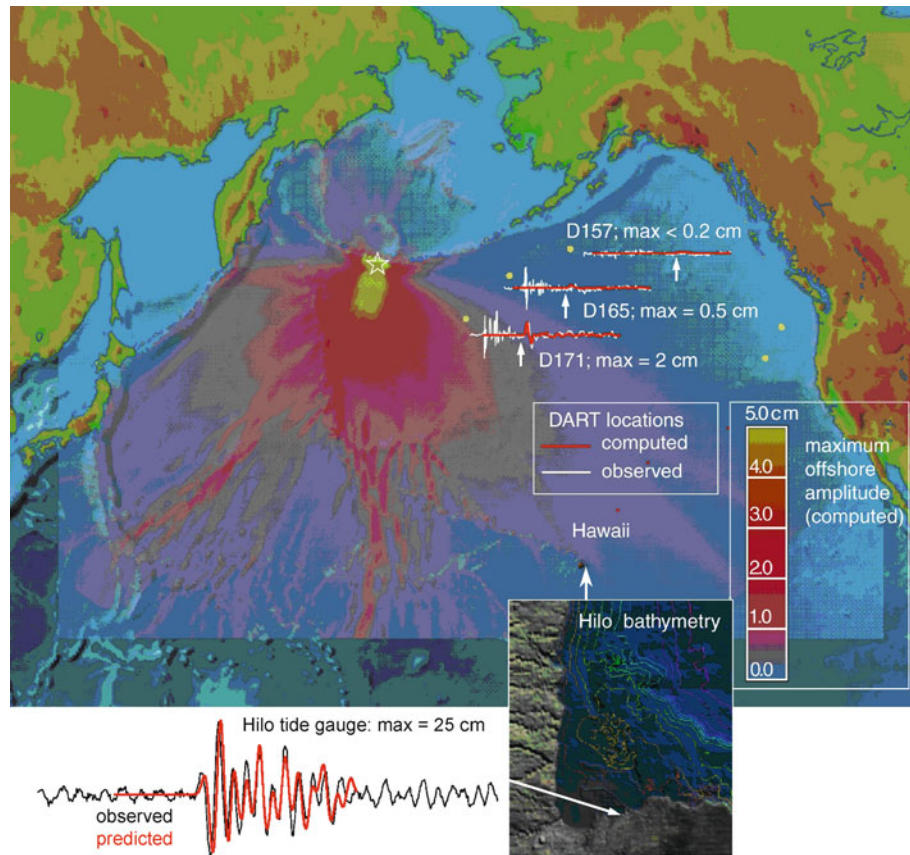

In the above inversion method, both tsunami generation and propagation process are assumed to be linear. Because slip amount  $u$ , among the nine static fault parameters, is linearly related with the seafloor deformation and tsunami amplitudes, and it has the largest effect on tsunamis, other parameters are fixed in the above method. However, the tsunami propagation, particularly near coasts, might be affected by some nonlinear process such as advection or bottom friction.

Nonlinear inversion methods to overcome these limitations have been proposed. Pires and Miranda [51] proposed an adjoint method, which consists of four steps: source area delimitation by backward ray-tracing, the optimization of the initial sea state, nonlinear adjustments of the fault model, and final optimization of fault parameters. The minimum of residual  $J$  is obtained iteratively through gradient descent method using the partial derivative or gradient of  $J$  with respect to parameters to be inverted.

### Inversion of Tsunami Heights

Maximum tsunami heights on coasts, rather than tsunami waveforms, have also been used for tsunami inversion. Distribution of maximum tsunami heights along the coasts is available from field surveys, historical or geological studies, and is valuable to study tsunami source. Pitanesi et al. [52] used coastal tsunami heights of the 1992 Nicaragua “tsunami earthquake” and estimated the slip distribution on the fault, as well as the mean amplification factor of computed coastal heights and measured runup heights.

Annaka et al. [53] proposed a method of joint inversion of tsunami waveforms and runup heights. As a residual to be minimized, they used a weighted sum of difference in waveforms (similar to Eq. 16) and logarithm

Tsunamis, Inverse Problem of, Figure 9

Real-time data assimilation for the November 17, 2003 Rat Island Tsunami [22]. *Star* indicates the epicenter. *Yellow dots* are locations of DART systems. The tsunami waveforms recorded on DART (*white curves*) are compared with computed waveforms (*red*). *Filled colors* on ocean show computed maximum tsunami amplitudes of the updated source. The *bottom plot* shows location of Hilo tide gauge (*right*) and comparison of the predicted tsunami waveforms (*red*) with the recorded tide gauge signal (*black*)

of runup heights. They first tried linear inversion to estimate the initial value, then estimated the perturbation by the nonlinear inversion. Similar nonlinear inversion methods, based on the initial solution estimated by either linear inversion or other data such as geodetic data, have been proposed [54,55].

### Real-Time Data Assimilation

The tsunami waveform inversion can be done in real-time for the purpose of tsunami warning. The real-time data assimilation using the DART records and tsunami forecast have been made by NOAA [22]. They first use seismological information to determine the source location and parameters, then using the database of pre-computed simulation results, invert the DART data to estimate the tsunami source size (slip amounts). The tsunami forecast

is made for farther locations where the tsunami has not arrived. For the 2003 Rat Island (Aleutians) earthquake, they successfully forecasted tsunami waveforms at Hilo, Hawaii, before the tsunami arrivals (Fig. 9).

### Future Directions

Inverse modeling methods of tsunami need to be further developed to better understand the tsunami generation process. Future developments are expected in each field of observation, propagation modeling and application to seismic and nonseismic tsunamis.

The tsunami observation system has been improved recently, particularly after the 2004 Indian Ocean tsunami. Many instrumental data, both coastal and offshore, become available for the studies of tsunami generation process [56]. Maintenance of the systems, particularly for off-

shore systems, is sometimes costly, but essential to record infrequent tsunami. Open and real-time availability of such data is also important for tsunami studies as well as for tsunami warning purposes.

For the past tsunamis, more studies are needed to estimate tsunami heights from historical documents, as well as geological data such as distribution of tsunami deposits. Such historical tsunami database has been developed, e. g., at NOAA/NGDC ([http://www.ngdc.noaa.gov/seg/hazard/tsu\\_db.shtml](http://www.ngdc.noaa.gov/seg/hazard/tsu_db.shtml)).

For modeling tsunamis recorded on coastal tide gauges or runup heights, nonlinear computations with very fine bathymetry data are essential. While computational methods have been developed, fine bathymetry data are not always available. Developments of nonlinear inversion methods are also important.

Finally, inversion of tsunami data can be applied to tsunamis generated from submarine processes other than earthquakes, such as volcanic eruptions or landslides. For such nonseismic tsunamis, parametrization is essential to quantify the geological process and to solve inverse problems.

### Glossary

**Conduit** Subterranean pathways to the surface created and sustained by the flow of volcanic materials are known as volcanic conduits. In the laboratory, tubes are used as scale equivalents. The two terminologies ('conduits' and 'tubes') should be kept distinct to avoid inadvertent acceptance that a laboratory experiment is a direct replica of a volcanic process.

**Magma** When rock melts underground it becomes magma. When magma flows on the surface it is known as lava and when it is projected into the atmosphere it forms pyroclasts. Most magma is silicate-based and comprises a three-phase mixture of solid (crystals, called microlites when small), liquid (melt) and gas (bubbles or vesicles).

**Rheology** When a force is applied to matter it deforms. The rheology of a material describes the relationship between applied force and the material response. Volcanic materials have a wide range of rheological behaviors dependent on the proportions of gas, liquid and solid, temperature, chemical composition, deformation history and rate of deformation.

**Scaling** Explosive volcanic eruptions involve temperatures of order 1000°C, pressures of many MPa and physical sizes from  $\mu\text{m}$  to km. Laboratory study of these processes generally involves observation and measurement of processes operating at lower temperature or pressure, or at smaller physical size. Scaling is the means of making laboratory-scale analogues representative of volcano-scale natural processes.

**Volatiles** Explosive volcanic eruptions are driven by the exsolution of a dissolved gas phase as magma pressure falls. These gaseous species, dominated by water vapor on Earth, are known as volatiles.

### Definition of the Subject

The magnitude of volcanic eruptions may be classified using the Volcanic Explosivity Index (VEI) [95,99]. The lowest VEI index of zero covers non-explosive activity (such as the production of lava flows) and is generally associated with low magma effusion rates or low viscosity magmas, for example, carbonate-based carbonatites [127]. For silicate-based magmas, which are generally more viscous than carbonatites, the boundary between effusive and explosive volcanism is commonly marked by Hawaiian firefountaining activity [96]. Magmas with a high silica content, or a lower temperature (and thus higher viscosity), can erupt either explosively or non-explosively as lava flows or dome-building eruptions [128]. Some eruptions switch between effusive and explosive behavior dependent on prevailing physicochemical conditions (e.g., [54,62]), with magmas tending to become more explosive at higher effusion rates. High VEI eruptions are, therefore, associated with high flow rates, large erupted volumes and substantial eruption plumes.

Such explosive activity comprises a wide range of phenomena, which result from complex non-linear interactions and feedback mechanisms. Processes that initiate in the subsurface plumbing or conduit system determine the nature of following events and control eruption styles. On emerging from the vent, volcanic material enters the atmosphere and the ensuing interactions are key in determining the consequent transport of volcanic debris that defines the impact on the environment and on human lives and infrastructure. On Earth, our capability to mitigate such volcanic hazard relies in large part on forecasting explosive events, a process which requires a high degree of understanding about the physicochemical factors operating during explosive volcanism.

In common with many science disciplines, the approaches taken to gain an understanding of explosive volcanism have relied on a combination of field observations, theoretical models and laboratory models of materials and mechanisms. Field observations form the 'ground truth' for numerical and experimental modeling (and provide vital historical data), but are often very difficult to unambiguously interpret due to their scarcity in both space and time. Numerical modeling complements field observations by providing much greater information density and, hence, the potential to examine processes in great de-

tail. However, the accuracy of the results depends on correctly including all relevant materials properties and system processes in the model and the results can be difficult to verify against often-unobservable field phenomena. Laboratory investigation of the properties of volcanic materials, their modes of interaction and the behaviors of analogous systems provides the third complementary approach; this is the area we focus on here.

## Introduction

In the context of explosive volcanic activity, laboratory experiments cover a wide range of research, the most fundamental of which is to gain an understanding of the properties of the volcanic material involved. Without this to underpin further work, neither accurate computer nor laboratory simulations could be carried out. The materials properties that are relevant to explosive volcanism include the solubility in silicate melts of volatiles (most commonly water and carbon dioxide), melt viscosity as a function of chemical composition, magma rheology as a function of the size, shape and proportion of crystals and bubbles, gas permeability of magma, magma deformation mode (e. g. brittle or ductile) as a function of strain-rate, and volatile diffusivity. Experimental determination of these parameters and their interdependencies results in empirically formulated relationships that can be used in numerical models and compared with the properties of analogue fluids. We first review aspects of the volcanic materials literature in Sect. “[Volcanic Materials](#)”, with the aim of illustrating the nature of molten rock, the complexity of which underpins most explosive volcanic processes.

Experimental modeling of these processes can then build on the materials understanding. Such experiments involve investigation of the behavior of natural volcanic products at laboratory time and length scales, including the response of magma samples to rapid changes in pressure and temperature, the fall behavior of silicate particles in the atmosphere, and the generation and separation of electrostatic charge during explosive eruptions. Here, we encounter the concept of scaling [[11,20](#)], which links the applicability of experimental results using small samples of natural materials to natural scales that are often several orders of magnitude larger. For experiments that replace natural volcanic products with analogue materials (for example, in order to relax the experimental pressure and temperature requirements), scaling arguments are crucial. A scaling approach permits adjustment of experimental durations and sizes, whilst maintaining similitude with much larger and longer events. Consequently, analogue exper-

imentation has allowed investigation of explosive phenomena in the broader context of fluid-dynamic behavior, and is a powerful means of giving ‘insight’ into volcanic processes.

Burgisser et al. [[20](#)] review and discuss scaling criteria for experiments and natural phenomena involving dilute multiphase mixtures in magmatic systems, and conclude “... that, despite numerous experimental studies on processes relevant to magmatic systems, some and perhaps most geologically important parameter ranges still need to be addressed at the laboratory scale”. This emphasizes that small-scale experiments aiming to mimic larger-scale natural processes need to be considered in two contexts. Firstly, laboratory experiments yield valid results in their own right and provide a means of validating numerical models. Secondly, laboratory experiments are not facsimiles of the natural process, but can give perception into how aspects of natural systems behave provided those aspects are scaled; a process normally considered at design stage. Consequently, comparing experimental results with the natural process must always be undertaken with due caution. The analogue experiment literature is reviewed in Sects. “[Volcanic Processes](#)” and “[Analogue Approach](#)”.

In Sect. “[Definition of the Subject](#)”, the combined tactics of field observation, numerical model and experimental model was discussed. In practice, complete overlap of these techniques can be difficult to achieve because the parameters measurable in the field are often incompatible with experimentally accessible variables, which in turn may not coincide with the output from numerical models. Explosive volcanism is also a difficult phenomenon to observe in action, and there are three reasons for this. Firstly, explosions do not happen very often, and the larger the explosion the more infrequent it is, with, for example, repeat timescales of order  $10^3$  years for VEI 6 events like the Krakatau, 1883 eruption. This makes detailed syn-event measurements of large explosive episodes infrequent on the timescale of contemporary volcanology. Secondly, high VEI events tend to destroy near-field observation equipment, making measurements very difficult to obtain even when an event does occur. Thirdly, processes that comprise an explosive event can be difficult to access directly; perhaps a prime example of this is how to obtain data about the nature of flow in the volcanic conduit system during explosive activity. Direct measurements are not possible and our main source of information is the deformation of the conduit wall created by unsteadiness in the flow, which in turn is calculated from the interpretation of ground motion signals detected by seismometers (e. g., [[31](#)]).

These considerations mean that there are many field observations, numerical and experimental models that await comparison with their companion approaches, however, the detailed study of volcanoes with low VEIs is one area where combined tactics are possible. As an example, in Sect. “**Analogue Approach**” we review the contribution that experimental modeling has made to the understanding of fluid flow in the conduit feeding VEI 1–2 explosions at Stromboli Volcano, Italy. Here it has been possible to measure signals from many thousand events, over the period of a few years (e. g., [7]), with a network of seismometers and other instruments, as well as detailed sampling of eruption products (e. g., [72]). Such field data are key to testing both numerical and experimental models of explosive volcanic activity wherever it occurs.

## Volcanic Materials

### Magma Rheology

Rheology describes the way in which materials deform and flow under the influence of an applied stress. Explosive eruptions only occur because considerable stress is applied to magma. The rheology of natural silicate materials was being measured before World War II (e. g., [14]), with empirical models (derived from experimental data) becoming established in the 1960s and 1970s (e. g., [18,92,107] and references therein).

When stress is applied to a solid it deforms or strains elastically, the strain being the macroscopic result of atoms in the solid moving closer together or further apart. These two parameters are related by a constant called a modulus, for example, in solids under tension  $\sigma = E\gamma$ , where  $\sigma$  is tensile stress,  $\gamma$  is tensile strain and  $E$  is Young’s modulus. Similar relationships exist for deformation under shear or by pressure change. These moduli are likely to be a constant for a range of values of applied stress, but could become dependent on strain, or indeed strain rate.

When stress ( $\sigma$ ) is applied to a fluid (the collective term for gas and liquid), viscosity ( $\eta$ ) is the parameter that relates the rate of flow (strain rate,  $d\gamma/dt$ ) to the stress that is being applied to it, giving the relationship  $\sigma = \eta d\gamma/dt$ . The flow of a fluid is the macroscopic result of fluid molecules moving past each other; therefore, changes that influence molecular motion also affect viscosity. The viscosity can be independent of the rate of flow, a case known as Newtonian behavior, and is best exhibited by gases and liquids of low molecular weight. Fluids whose viscosity is a function of strain-rate are described as non-Newtonian, and many foodstuffs, for instance, exhibit this behavior (e. g. tomato ketchup). Viscosity is also a function of temperature, generally decreasing as temperature

increases and molecules move further apart (thermal expansion). An everyday example would be Golden or Maple syrup that becomes easier to pour on heating. The concept of viscosity fails when molecular interactions are rare, for example in gases at low pressure.

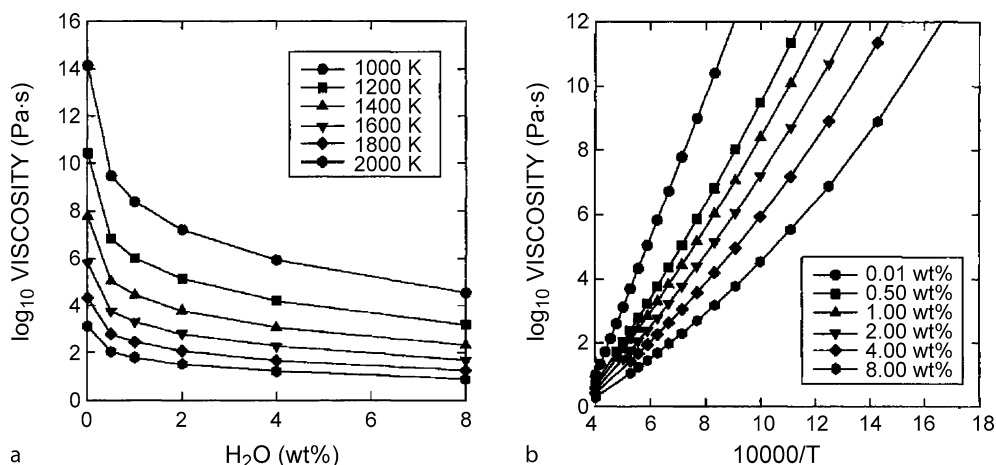

**Newtonian Viscosity** Natural silicates in the liquid state have been assumed to be Newtonian in behavior and demonstrate a strong viscosity dependence on temperature. The relationship was initially represented by an Arrhenius-type equation, such as  $\eta = A \exp[E/RT]$ , where the constants  $A$  and  $E$  are dependent on the chemical composition of the silicate melt (e. g., Murase and McBirney [92]),  $R$  is the gas constant and  $T$  the absolute temperature. With considerable further laboratory effort in measuring the viscosities of a wide compositional range of natural silicate liquids, it became clear that viscosity was not strictly an Arrhenian function of temperature. Hess and Dingwell [49] developed an empirical model to describe laboratory values of viscosity for leucogranitic melts as a function of temperature and water content. The compilation of data used by Hess and Dingwell [49] is shown in Fig. 1, and the empirical equation generated to fit the data is:

$$\log \eta = \frac{[-3.545 + 0.833\ln(w)] + [9601 - 2368\ln(w)]}{\{T - [195.7 + 32.25\ln(w)]\}}$$

where  $w$  is the water % w/w. The constants in this equation will be different for silicate melts of different composition; see Zhang et al. [133] for an updated and modified version of this model. Water is important here because it is a ubiquitous component of explosive volcanism on Earth. The concentration of water has a large and non-linear impact on viscosity (Fig. 1a) because it acts as a network modifier by breaking Si-Si bonds in a silicate melt, thus decreasing the average molecular weight.

The use of laboratory measurement to provide quantitative understanding of the dependence of viscosity on temperature, water content and other parameters has provided a key component in the numerical modeling of the explosive flow behavior of natural silicates, as well as pointing the way to identifying fluids for analogue experiments.

**Non-Newtonian Viscosity** There is laboratory evidence that the viscosity of liquid magmas is not a constant as once assumed, but may be subtly non-Newtonian [110]. The contents of a volcanic conduit are rarely 100% liquid, with crystals present in many silicate melts below 1250°C, considerably higher than most eruption temperatures. The

Volcanic Eruptions, Explosive: Experimental Insights, Figure 1

Model curves, based on experimental measurement, of the dependence of viscosity of metaluminous leucogranitic melts on dissolved water content (a) and temperature (b) from a compilation of data (Hess and Dingwell [49]). Note the logarithmic viscosity scale and non-linear nature of the relationships. Explosive volcanic activity often results in water loss from the melt, and cooling results from expansion and interaction with the atmosphere; melt viscosity increases result. The role this plays on the dynamics of expanding vesiculated flows may be studied by analogue experimental means. Figure reproduced with kind permission of the Mineralogical Society of America

effect of crystallization is to significantly change the relationship between viscosity and temperature [91], especially as crystal content is both temperature and time dependent. The presence of bubbles is also ubiquitous in explosive volcanic materials, and these too alter magma behavior in response to an applied stress. The presence of both yields a rheologically complex 3-phase material.

Combined laboratory and field-measurement of the viscosity of lavas from Mount Etna [98] showed that above 1120°C Newtonian behavior was exhibited. Eruption temperatures ranged from 1084–1125°C; therefore, for much of this range the magma behaved in a non-Newtonian fashion as a consequence of the interaction between crystals suspended within the liquid silicate melt. The Etnean basalt was found to be thixotropic, meaning that the viscosity decreased the longer it was deformed, perhaps indicating that crystals were becoming aligned and could consequently move past each other more readily. The basalt also showed pseudoplastic or shear-thinning behavior, meaning that viscosity decreased as the rate of flow increased, perhaps again, because of the dynamics of crystal alignment. Finally, the basalt showed a small but measurable yield stress of < 78 Pa, below which it behaved more like a solid material. The yield stress is likely to be a consequence of crystals weakly binding together into a mesh-like structure. The small nature of the yield stress means that the viscosity of these magmas could be described by a power law equation (i. e., the yield stress was ignored)

where  $\sigma = \eta (d\gamma/dt)^n$ . Above 1120°C,  $n = 1$  and Newtonian behavior was observed, but as temperature falls to 1084°C,  $n$  decreases to 0.46, meaning that viscosity decreases as strain rate increases. Pinkerton and Norton [98] also noticed that physical motion of the silicate melt could induce crystallization as seen by Kouchi et al. [68]. Similar behavior has been found more recently for laboratory measurements of basalts from Japan [55].

Hoover et al. [51] showed that crystals induce yield strength in magmas at volume fractions as low as 0.2, although this is strongly dependent on crystal shape. These experiments were carried out on natural basaltic samples, as well as using an analogous system of neutrally buoyant particles in corn syrup (Fig. 2). Natural samples do, by definition, provide data directly applicable to the natural system, but analogue experiments are complementary because particles have controlled size, shape and concentration. These experiments provide a good example of the kind of complex interplay of time-dependent processes that can occur in magmatic systems that tend only to be quantified by detailed experimentation.

At eruption temperatures, the non-Newtonian behavior of magmas is due in large part to the presence of crystal networks; however, during flow, bubbles must also move past each other and contribute to fluid rheology. Explosive eruptions only occur because bubbles form and expand; therefore, understanding bubble behavior is central to understanding explosive processes. When both bubble size

Volcanic Eruptions, Explosive: Experimental Insights, Figure 2

Magma has complex rheology partly because of its crystal content. Hoover et al. [51] found that basalt with crystals showed solid-like behavior at low stress. Analogue experiments using near-spherical poppy seeds (a) and highly irregular shavings of kaolin/wax (b) in corn syrup demonstrate the role of particle concentration and shape in giving yield strength to solid-liquid mixtures, the number in each panel being the volume fraction of particles. Yield strength increased rapidly (c) for volume fractions of round poppy seed (filled squares) above about 0.4, allowing extruded material to retain considerable vertical topography (a). The same effect occurs at volume fractions around 0.2 for irregular particles (b) because they interact more strongly with each other than spherical particles. Crystals in magma not only act as nucleation sites for bubbles, but also have a very strong rheological influence in their own right. Reprinted with kind permission from Elsevier

and the fluid flow rate are small, then the surface tension between the silicate liquid and the water vapor in the bubble resists viscous forces and is able to minimize the bubble surface area maintaining spherical bubbles; the bubbles act as if they are solid spheres suspended in the silicate melt. However, if bubbles and flow rate are larger, then surface tension is no longer able to maintain a spherical shape against the viscous drag, and bubbles elongate in the flow field. Under conditions of steady flow, when bubble shape is stable with time, these two behaviors may be distinguished by the capillary number,  $Ca = \lambda \gamma'$  where  $\lambda = a\eta/\sigma$ ,  $a$  being bubble diameter,  $\eta$  viscosity,  $\gamma'$  strain rate and  $\sigma$  surface tension (e.g., Llewellyn and Manga [74]). When  $Ca$  is significantly less than unity, surface tension forces dominate and bubbles remain near spherical. However, when  $Ca$  is significantly greater than unity surface tension is overcome by the combination of liquid shear and viscosity, forcing bubbles to elongate.  $Ca$  provides an example of a parameter that may be used to scale between volcanic behavior and a laboratory exper-

iment. If bubbles preserved in pumice from an eruption were highly elongated, then any experiment simulating this process would need to also produce highly elongated bubbles and not spherical bubbles. The shape-change undergone by bubbles provides an added complexity over the effects of crystals, whose shapes are generally constant.

Bagdassarov and Dingwell [8,9] experimentally measured the rheological behavior of vesicular rhyolite, using oscillatory rheometry, with a liquid viscosity between  $10^9$  and  $10^{12}$  Pa s and gas bubble volume fractions in the region between zero and 0.3. Under these conditions, where  $Ca \gg 1$ , it was shown that vesicular rhyolite decreased in viscosity with increasing gas volume fraction. Such rheological experiments on hot, high-viscosity natural silicate melts are difficult, and the scaling of the small-strain results to larger scales is not straightforward. Using an oscillating viscometer, Llewellyn et al. [75] measured the viscosity of bubbly Golden Syrup, a fluid analogous to molten silicate with water vapor bubbles, but with liquid viscosity between  $10^1$  and  $10^2$  Pa s. The analogue fluid has the ad-

vantage of being liquid at room temperature, thereby placing much less stringent demands on any measurement apparatus. Llewellyn et al. [75] showed the effect of increasing gas volume fraction from zero to 0.5 with small deformations ( $Ca \ll 1$ ) caused viscosity to change by over an order of magnitude. They also discriminated between steady flow (bubbles not changing shape) and unsteady flow (bubbles in the process of changing shape) by proposing the dynamic capillary number  $Cd = \lambda\gamma''/\gamma'$ , where  $\lambda$  represents the timescale over which a deformed bubble can relax. Under steady flow conditions bubbles tended to increase viscosity, but under conditions of rapidly changing strain rate increasing gas volume fraction reduced viscosity; a result consistent with the oscillatory rheometry results of Bagdassarov and Dingwell [9]. This experimental result largely unified the seemingly contradictory literature that preceded it, and the consequences of these two regimes of behavior are discussed lucidly by Llewellyn and Manga [74], where the influence of bubbles is shown to change some model outcomes by factors of two or more. This is an excellent example of the role that analogue experimental measurement can play in helping to understand complex and inaccessible natural phenomena.

**Viscosity or Modulus?** The concept of a relaxation time was encountered above in relation to how long a deformed (non-spherical) bubble takes to approach the relaxed spherical shape. This same approach can also be applied at the molecular level as liquids flow. During viscous flow, molecules move past each other, and this requires them to be able to reorient or deform. If the timescale of molecular deformation is much shorter than the timescale required by the strain rate during flow, then liquid or viscous behavior ensues. However, if the strain rate is such that molecules cannot reorient or deform, then the material behaves, at least in part, like an elastic solid, with strain being accommodated by bond stretching, or fracture, if yield stress is exceeded.

Materials that demonstrate aspects of liquid and solid behavior are known as viscoelastic. Viscoelasticity was first investigated in the nineteenth century using materials like rubber and glass. Viscoelastic behavior in volcanic materials begins with the onset of non-Newtonian liquid behavior at deformation timescales about 100 times longer than the relaxation time of silicate molecules in the melt [39]. The onset of non-Newtonian behavior suggests that there is a range of relaxation timescales for different molecules, and this may be a consequence of silicate melts having a range of molecular weights rather than a single value.

The *timescale* of molecular relaxation is given by the Maxwell relation, *viscosity/modulus*, i. e., the relative

weighting of liquid to solid response when stress is applied. In volcanic materials the modulus is effectively constant as temperature and composition change, but viscosity changes by a factor of about  $10^9$  or more. At low magma viscosities, the relaxation timescale is short and viscous liquid behavior occurs at volcanically plausible strain rates. However, magmas of high viscosity have long relaxation timescales. Here, the onset of non-Newtonian behavior, and ultimately the glass transition to brittle solid behavior, occurs at much lower strain rates. Dingwell [38] discusses the relevance of this to explosive volcanic eruptions, and proposes the onset of brittle failure in high-viscosity magma under significant strain rates as a criterion for magma fragmentation. Zhang [130] showed that magma fragmentation also depends on the number density and size of bubbles within the melt.

### Volatiles Solubility

Volatiles are defined as those compounds that are dissolved within the matrix of a silicate melt at high pressures, but become supersaturated and, consequently, then exsolve in the supercritical or gaseous state as pressure drops towards atmospheric. On Earth,  $H_2O$  is the most common magmatic volatile, with  $CO_2$ ,  $SO_2$ , HCl, and the halogens also present. For water, exsolution occurs into the supercritical state, or gas phase at depths less than about 1 km; therefore, understanding the physicochemical behavior of these compounds at volcanic temperatures and pressures is a key component in the modeling of explosive volcanic eruptions. Water itself has been the subject of extensive laboratory and numerical experiments (with Kalinichev [65] providing a review) because of its anthropogenic usefulness as well as geological importance. The densities of volatile species are less than that of the silicate melt, for instance at the depths of exsolution the density of water is about  $200\text{--}400\text{ kg m}^{-3}$ , a factor of  $\sim 10$  less than magma. The bulk modulus of water (order  $10^7$  Pa) is much less than that of silicate melt (about  $10^{10}$  Pa, Alidibirov et al. [5]). Consequently, as pressure falls, any exsolved volatile phase expands by about three orders of magnitude more than that of the surrounding silicate melt; this is the fundamental driving mechanism of explosive volcanism.

The solubility of volatiles in silicate melts has, and continues to be, the subject of extensive experimentation. Carroll and Holloway [28] review volatiles in magmas, and Liu et al. [73] provide a well-referenced introduction to water and carbon dioxide in rhyolite, and give new experimental data and empirical relationships so important to numerical models of explosive volcanic activity. Empirical  $H_2O$  and  $CO_2$  solubility in rhyolitic melt ( $700\text{--}1200^\circ\text{C}$  and

0–500 MPa) are expressed by Liu et al. [73] as

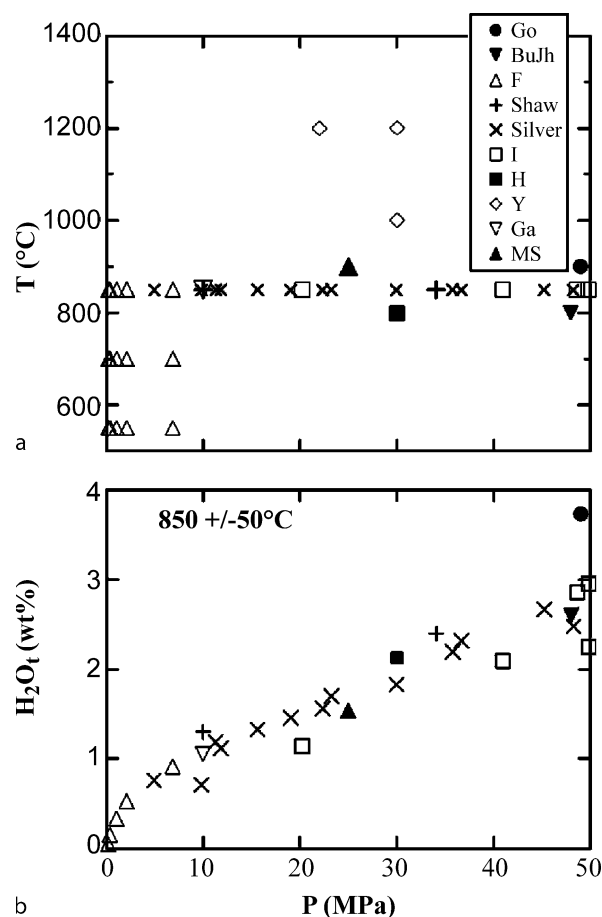

$$\begin{aligned}
 \text{H}_2\text{O}_t &= \frac{(354.94P_w^{0.5} + 9.623P_w - 1.5223P_w^{1.5})}{T} \\
 &+ 0.0012439P_w^{1.5} \\
 &+ P_{\text{CO}_2} (-1.084 \times 10^{-4}P_w^{0.5} - 1.362 \times 10^{-5}P_w), \\
 \text{CO}_2 &= \frac{P_{\text{CO}_2}(5668 - 55.99P_w)}{T} \\
 &+ P_{\text{CO}_2} (0.4133P_w^{0.5} + 2.041 \times 10^{-3}P_w^{1.5}),
 \end{aligned}$$

where  $\text{H}_2\text{O}_t$  is the total dissolved  $\text{H}_2\text{O}$  % w/w,  $\text{CO}_2$  content is in mass-ppm,  $T$  is absolute temperature and  $P$  the partial pressure of water or carbon dioxide.

Figure 3 shows how the solubility of  $\text{H}_2\text{O}$  in rhyolite varies with pressure from a range of experimental work. Experiments focused on explosive volcanism have concentrated on the solubility of water at a temperature of  $850^\circ\text{C}$ , because this is a common eruption temperature for rhyolitic melts. Although water solubility increases as pressure increases, this relationship is not linear, especially at lower pressures, and the nature of the non-linearity is dependent on magma composition (see [86] for review). The root of the complexity of water solubility is that water chemically reacts with the silica glass matrix as a network modifier. This reduction in the average molecular weight is responsible for decreasing the viscosity (Fig. 1), as well as having a range of complex geochemical effects (see [12] for popular review).

### Nucleation and Diffusion

Decreasing the pressure applied to a volatile-saturated magma causes supersaturation of the volatile species. For explosive volcanism to occur, the volatile must make the transition from the dissolved state to a lower-density (and therefore higher volume) exsolved state, i. e., the process of bubble nucleation. Determining the degree of volatile supersaturation required for nucleation to take place has been the subject of significant laboratory effort. Magmas are complex chemical compounds that are rarely free of interfaces. Hurwitz and Navon [52] found experimentally that heterogeneous bubble nucleation dominated, with only small supersaturations of water vapor ( $< 1$  MPa, or  $\sim 50$  m head of magma) being required to nucleate bubbles at the surfaces of Fe-Ti oxide microlites. Other crystal-melt interfaces required supersaturations  $> 10$  MPa for nucleation of water bubbles. Even at supersaturations of  $> 130$  MPa, nucleation was heterogeneous even in apparently crystal-free melts.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 3 **a** shows pressures and temperatures of experiments carried out on rhyolite melts to investigate water solubility as a function of pressure, see Liu et al. [73] for sources. The bulk of the experiments are carried out at  $850^\circ\text{C}$  because this is a common temperature for rhyolitic eruptions. **b** The solubility of water decreases with pressure, becoming increasingly non-linear below 10 MPa (shallower than about 50 m depth for lithostatic pressure). The transition, and consequent expansion, of water going from the dissolved to the vapor (or supercritical) states as pressure decreases is the driving mechanism of explosive volcanic eruptions. Reprinted with kind permission from Elsevier

More recently, Gardner [43] found experimentally that certain crystal interfaces or features acted as nucleation sites, in particular blocky shaped magnetite or the ends of needle-shaped hematite (Fig. 4). Gardner's [43] study, and others cited therein, indicate that bubble nucleation is a complex function of the composition and temperature of the melt, the composition and morphology of crystals, and the degree of supersaturation prevailing. Accurate modeling of bubble nucleation requires detailed knowledge of the melt as it becomes supersaturated. Nucleation could

Volcanic Eruptions, Explosive: Experimental Insights, Figure 4 As pressure decreases, the melt becomes supersaturated in water. During the decompression of small samples of hydrated rhyolite, bubbles of water vapor nucleated then grew at the ends of needle-shaped hematite crystals, but not along their lengths (scale bar = 20  $\mu\text{m}$ , Gardner [43]). Such ‘imperfections’ allow heterogeneous bubble nucleation and prevent large supersaturations developing. Reprinted with kind permission from Elsevier

occur at low supersaturations, with conditions never far from equilibrium. Conversely, in the absence of suitable nucleation sites, volatile supersaturations of the order of 100 MPa could develop as pressure in the melt decreases, and when nucleation does occur, rapid bubble growth can be expected.

Once bubbles of volatile have nucleated, growth is promoted by diffusion of volatiles from the supersaturated melt, and by expansion during pressure decrease. Any decrease in pressure also acts to increase volatile supersaturation (Fig. 3), encouraging either new bubble nucleation or, if bubbles are nearby, the diffusion of volatile into existing bubbles [17]. The diffusivity of volatiles is, therefore, a key parameter in determining the nature of the degassing process and has been reviewed by Watson [124]. Volatile diffusion into a bubble from the local melt surrounding it implies that the bubble will be surrounded by a shell of melt with relatively low volatile content and, thus, with elevated viscosity (Fig. 1a). This viscous melt shell may play an important role in the dynamics of bubble expansion during eruption, further adding to the importance of understanding diffusivity. Zhang and Behrens [131] experimentally investigated the diffusivity of water in rhyolitic melts, which, in combination with previous studies, covers the parameter range 400–1200°C, 0.1–810 MPa, and 0.1–7.7% w/w total  $\text{H}_2\text{O}$  content. The resulting empirical relationship between diffusivity of molecular water ( $D$ ) and pressure ( $P$ ), temperature ( $T$ ) and water concentration ( $X$ )

is given by

$$D_{\text{H}_2\text{O}_m} = \exp \left[ \left( 14.08 - \frac{13128}{T} - \frac{2.796P}{T} \right) + \left( -27.21 + \frac{36892}{T} + \frac{57.23P}{T} \right) X \right].$$

Such experimental determination of water diffusivity then forms key aspects of models of the behavior of silicate melts that undergo decompression, for instance, in how rapidly bubble pressure recovers after a perturbation [32], or in the nature of the resulting explosive activity [84].

### Permeability

Erupting magma usually includes gas bubbles, which can approach and interact with each other due to differences in their rise velocities within the melt and due to expansion. If the residence timescale of magma in the plumbing system is long compared to the time required for bubbles to move through it, then the bubbles can be considered to be separating from the melt. This is often the situation in low VEI eruption styles such as Strombolian activity. Here, gas bubbles can ascend through the low viscosity magma relatively rapidly and are able to collide and concentrate, possibly forming bubble rafts or foam layers. Bubble coalescence may then create fewer, but larger bubbles with significantly increased ascent velocity that, on reaching the surface, result in Strombolian activity.

Conversely, if magma residence timescale is short in comparison to bubble rise velocity, then bubble interactions cannot take place so readily. Under these conditions, the rapid depressurization and expansion of the trapped gas bubbles often results in high VEI events, but not universally. The ability of some such magmas to erupt relatively passively indicates that, as they ascend, they are able to lose gas by some other mechanism. One way for this to happen is for the vesiculated magma to become increasingly able to accommodate gas flow and separation as the volume fraction of bubbles (porosity) increases, allowing gas to move from bubble to bubble to the surface or into the surrounding rock. Such gas escape can be quantified using permeability, which is proportional to the effective pore diameter. Establishing how bubbly magmas become permeable, and the nature of that permeability is, therefore, of key importance to understanding eruption mechanisms.

The permeability of eruption products has only been measured experimentally in recent decades, and by few workers (e. g., [42,67,87,104]). Eichelberger et al. [42] determined the room-temperature gas permeability of rhyolite with between 37% v/v and 74% v/v porosity. Over this

range, permeability increased by over nearly four orders of magnitude from  $10^{-16}$  to  $10^{-12}$  m<sup>2</sup>, precipitating the hypothesis that high permeability can suppress explosive behavior in silicic volcanism, provided gas can escape. Klug and Cashman [67] made laboratory measurements on 73 pumice samples with porosities ranging from 30% v/v to 92% v/v. Permeability ranged from  $10^{-14}$  to  $10^{-12}$  m<sup>2</sup>, with the relationship that  $k \propto \phi^{3.5}$ , where  $k$  is permeability and  $\phi$  is porosity. Permeabilities at high porosity values agree between these two investigations, but disagreement at low porosities suggests greater complexity. Saar and Manga [104] demonstrated that there is not a straightforward relationship between permeability and the volume fraction of bubbles. Samples of basaltic scoria, which expand isotropically then cool rapidly, and therefore contain near-spherical bubbles, are well behaved in their permeability-porosity relationship and may be modeled by established percolation theory. However, many multiphase volcanic products do not have spherical bubbles because anisotropic flow causes high values of the capillary number. The elongate nature of the resulting bubbles causes high permeabilities at low porosities [104]. However, the permeability, like the porosity, is no longer isotropic, and gas escapes in directions determined by the local direction of flow as well as the prevailing pressure gradient. Laboratory measurements of volcanic products have been used to scale and validate theoretical models of magma permeability as a function of porosity. These models have, amongst others, been based on analogy with networks of resistors in electric circuits [16], and combination of classical approaches with fractal pore-space geometry [35]. Such models can then be incorporated into numerical simulations of flow in volcanic conduits that test the importance of permeability on explosive-effusive transitions.

### Consequences

The consequences of the materials properties of magmas responsible for explosive volcanic flows might now be explored. At pressures higher than the total volatile vapor-pressure, magma remains bubble-free. When pressure is reduced sufficiently below that of the volatile vapor pressure, then bubbles of volatile nucleate in the magma. These bubbles grow, and as bubble density is less than that of the magma, the bulk magma density decreases. This may act to increase magma ascent rate, creating a mechanism of positive feedback. Simultaneously, the reducing volatile content of the magma rapidly increases the liquid viscosity, reducing the strain rate required for viscoelastic and brittle behavior. This process occurs at the length-scale of diffusion into bubbles as well as within the liquid as a whole

and, depending on the timescales, crystal growth may also be changing, or indeed driving, the rheological evolution of the system.

These non-linear interactions underpin the complexity of understanding how magma flows, and illustrate the subsurface control on the nature of eruptions. In order to investigate how the properties of volcanic materials interact during the eruption process, experiments of a different nature are required.

### Volcanic Processes

Experiments investigating materials properties are mainly designed to measure parameters under static or steady conditions. However, explosive eruptions are not static and only pseudo-steady at best; therefore, different experiments are needed to explore bulk flow behaviors. Experiments investigating the explosive response of volcanic materials to possible eruption triggers are best conducted using natural silicates that have been well characterized by previous study. These experiments can be designed to minimize the inherent complexity of the overall process by concentrating on specific aspects. Models verified by experiments then contribute to larger models of the whole process.

### Explosive Processes

Magma is a hydrated silicate liquid (normally also containing some solid crystals) that, during the explosive eruption process, is converted into silicate fragments ranging in size from  $10^1$  to  $10^{-6}$  m. The mechanism responsible is fragmentation and understanding fragmentation processes is a major goal of physical volcanology.

Explosive volcanic activity predominantly requires the formation and growth of gas bubbles within magma. Exsolution processes are initiated at pressures generally  $> 10$  MPa, and may extend to pressures of several hundred MPa for water. Such pressures result from overburdens of several kilometers and flow experiments carried out at volcanic temperature and pressure (1100–1500K, up to at least 100 MPa) place severe constraints on containment vessels, measurement transducers and the volume of experimental samples. Another explosive mechanism occurs when volatile species mingle with hot magma at lower pressures resulting in hydrovolcanic activity. This is driven by expansion as liquid turns to gas on heating.

Direct observation of explosive processes is unlikely, but experiments mimicking volcanic conditions give valuable insight. Experimental exploration of explosive processes using natural samples requires that appropriate pro-

portions of gas, liquid and solid are present together with suitable pressures and temperatures.

**Hydrovolcanism** Experiments investigating the response of hot natural silicate melts to explosive ‘molten fuel-coolant interactions’ (MFCIs) with liquid water have been carried out by Wohletz [126] and Zimanowski et al. [134]. MFCIs are not confined to geological processes and are a dangerous industrial hazard, for example, on 4 November 1975, at the Queen Victoria Blast Furnace, Appleby–Frodingham Steelworks, Scunthorpe, UK, up to 90 tons of molten metal were thrown over a wide area after an MFCI explosion involving about 2 tons of water and 180 tons of molten metal. Berthoud [13] reviews MFCIs from the perspective of the nuclear power and other industries, but the physics described also applies to hydrovolcanism.

Volcano-specific research into MFCIs has studied the size and morphology of silicate particles from volcanic eruptions and compared them to those generated experimentally by MFCI processes (Wohletz [126]). The ratio of water to magma was found to be a key parameter in determining the nature of the particles resulting from the explosive process, with particle size reducing as explosivity increases. Such experiments provide insight into hydrovolcanic eruptions where magma may interact explosively with surface water (Surtseyan eruptions) or ground water (phreatomagmatic eruptions). Two processes dominantly produce the explosivity: (1) the rapid ‘flashing’ of liquid water to vapor; and (2) rapid cooling of the silicate melt causing thermal shock. Zimanowski et al. [135] studied how explosive fragmentation of a remelted volcanic rock could be interpreted from the size and shape of expelled silicate fragments. Two methods of fragmentation were used: (1) injection of air at 5 or 10 MPa into the base of the crucible containing the melt (at 1653 K); and (2) initiation of a MFCI using liquid water and a triggering perturbation. With an air injection at 5 MPa pressure, fine particles were uncommon and the particles generally rounded; however, the particle size distribution suggested that two unspecified fragmentation processes had operated. Three unspecified fragmentation modes were implied for the 10 MPa air injections, with finer, but still rounded, particles produced. Interaction with water (MFCI) also had three fragmentation mechanisms, but produced the finest particles, many of which were blocky. The MFCI experiments resulted in a much more complex fragmentation process than the air injection experiments (Zimanowski et al. [135]), with a key difference being the rapid cooling of the silicate melt by interaction with water. The combination of rapid cooling and high strain rates generated by

large pressures is considered to cause brittle failure of the melt and generate the fine, blocky fragments during the MFCI experiment.

Although not hydrovolcanism, the air-injection method of Zimanowski et al. [135] has been used by Taddeucci et al. [117] to experimentally investigate the role of crystal volume fraction during the explosive fragmentation of magma. This is of interest because ascending magmas are thought to have both axial and radial heterogeneity in their crystal contents, both before and during explosive activity. Preliminary results showed a strong correlation between the fragment morphology and the crystal content in both experimental and natural samples, with increasing crystallinity promoting brittle fracture. This suggests a number of interpretations: (1) a higher viscosity liquid phase naturally exists in more crystalline samples; and/or (2) strain-rates in the smaller liquid volume of high crystallinity samples are higher, i.e., there is less liquid to accommodate a similar motion; and/or (3) the macroscopic rheological behavior of the two-phase mixture promotes brittle processes [51].

Comparisons between experimental and natural particles generated by MFCI experiments [22] show that quite subtle surface features can be used to distinguish between events involving either partial or complete water vaporization (Fig. 5). Where vaporization is complete, both experimental and natural particles are blocky and equant in shape, and a brittle fragmentation process is implied from observations of stepped surfaces on the particles, created by mechanical etching. Particles resulting from incomplete vaporization of water show similar features, except that their surfaces host a network of cracks that are considered to be the result of rapid surface cooling (thermal shock), created by interaction with excess liquid water. Büttner et al. [22] comment on the experimental relevance of their research; “In general, the artificial pyroclasts produced in the experiments cover all grain sizes and shape properties of the natural ones, thus illustrating the quality of the experimental scaling in terms of geometry and energy release.” Such phenomenological similarities are a powerful indicator that experimental processes are mimicking the intended natural processes, and this is additional evidence of similarity. However, the experiments did not mimic all the post-explosion fragmentation processes that lead to the final natural product, demonstrating that care must be taken in comparing the outcomes of controlled experiments with the final product of the volcanic process.

Grunewald et al. [48] introduced a chemical aspect to MFCI experiments by using near-saturated NaCl solution as well as pure water, with the intention that the addi-

Magma and water may interact explosively during phreatomagmatic eruptions. Molten fuel-coolant interactions (MFCI) or magma-water interactions (MWI) can be carried out experimentally (Fig. 6). **a** shows a fragment generated by experimental MWI (Büttner et al. [22]) where all water was vaporized. **b** shows a fragment from a natural phreatomagmatic eruption that has not interacted with excess water. **c** shows an experimental fragment that 'erupted' through excess water, and **d** the product of phreatomagmatic activity thought to have interacted with excess water. The phenomenological similarities between **a** and **b**, and **c** and **d** provide powerful evidence that experiments are mimicking the processes that occurred during natural phreatomagmatic eruptions. tion of other species would add complexity. Experimental methods were similar to that of Zimanowski et al. [135] (Fig. 6), with the triggering of a rapid thermal interaction by the injection of hot molten silicate with cool liquid brine. It was found that NaOH and HCl were formed during the heating of the NaCl solution, and that explosion energies were lower than with pure water. The lower explosion energies resulted in more rounded and larger silicate fragments as found by Zimanowski et al. [135]. The reason for the reduced physical energy of fragmentation was attributed to energy coupling into the endothermic chemical process that produced NaOH and HCl, but the heating of brine may well also have introduced a liquid NaCl phase (1074 K–1738 K) that altered the physical MFCI process. These experiments raise the interesting prospect of being able to use the chemistry of volcanic gases and particle surfaces to make inferences about physical processes occurring during hydrovolcanism.

A different experimental approach to studying magma-water interactions (MWI) was used by Trigila et al. [121] in which experiments could be carried out at pressures up to 200 MPa, and temperatures up to 1473 K. In contrast to the method of Zimanowski et al. [135], where water is injected into hot (1650 K), liquid-dominated silicate melt at 0.1 MPa, Trigila et al. [121] 'infused' water into permeable sintered samples of solid-dominated basalt at lower temperature (1100 K), but high pressure (8 MPa). The samples were manufactured by grinding basalt to grain sizes of < 10 µm (powder) or about 0.7 mm (granular). These were heated to experimental temperatures and allowed to sinter for 30 minutes to form a permeable cylinder (about 2 cm in diameter and 6 cm in length) into which water was introduced. Only the more perme-

able granulated samples underwent spontaneous explosive behavior on mixing with water, generating particles similar in size to the original grains. These exploratory experiments indicate the importance of permeability to MFCI processes where groundwater could interact with hot, porous country rock as well as magma. We have already explored the importance of permeability in allowing exsolving volatiles to escape and reduce explosivity; under different circumstances we now we see that permeability can also increase explosivity.

**Exsolution** The nature of geological materials at pressures and temperatures existing within the crust and mantle has been the subject of considerable research by petrologists. Experimental petrology generally studies samples of material in small (millimeter-scale) capsules that are sealed, then pressurized up to tens of GPa and heated up to 2000 K; easily covering volcanically relevant conditions. Adaptation of this experimental technology to volcanic processes by Hurwitz and Navon [52] was used to study the response of hydrated rhyolite to decompressions up to 135 MPa (equivalent to about 5 km silicate overburden) at eruption temperatures (780°C to 850°C). Extended flow processes cannot be simulated with such small samples at these experimentally challenging conditions, but the pseudo-static response of hydrated silicate melt to pressure decreases of varying rate and magnitude provides important dynamic information about the processes of volatile exsolution (bubble nucleation and growth) and diffusion, as well as crystal growth. Hurwitz and Navon [52] revealed that nucleation of water bubbles (as a supercritical fluid or gas) in natural magmas is likely to be dominated by various heterogeneous processes operating over a range of supersaturations.

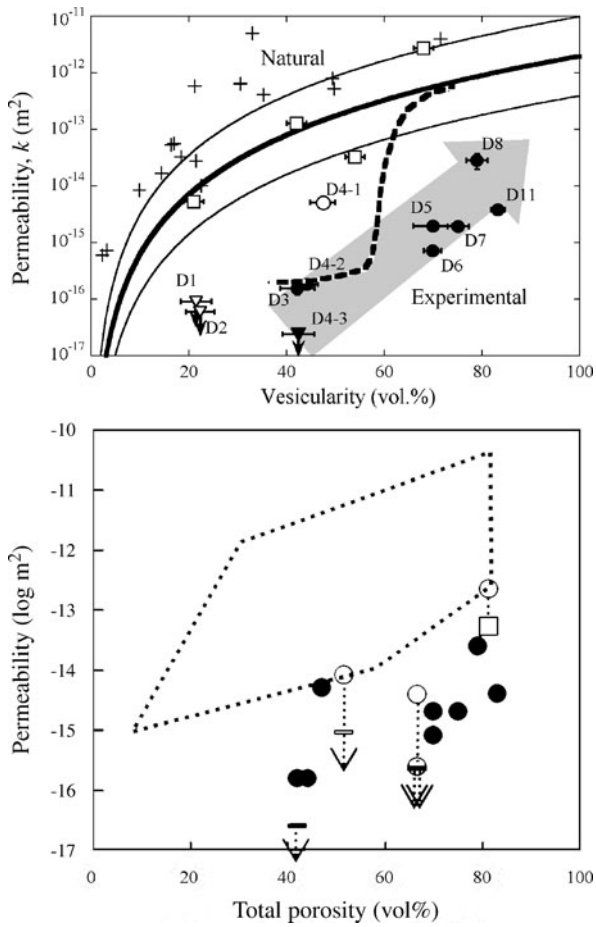

Volcanic Eruptions, Explosive: Experimental Insights, Figure 6 Schematic diagrams and frames from high-speed video illustrate one experimental method of simulating explosive phreatomagmatic eruptions (Grunewald et al. [48]). **a** Pre-experiment conditions with water injection tube in crucible of hot (1300°C) basalt melt. **b** 15 ml of water is injected, with the air expelled from the tube forming a bubble. The bubble was impacted by an air gun pellet to trigger **(c)** the explosive mixing of water and melt. **d** rapid transition of water from liquid to vapor results in pressure rise. The melt is fragmented by the subsequent rapid expansion. Reprinted with kind permission from Elsevier

Lyakhovsky et al. [76] carried out further analysis of the experimental results of Hurwitz and Navon [52] to reveal the controls on bubble growth following nucleation. Numerical modeling of the experimental data showed that diffusion of water from the melt into the bubbles controlled bubble growth at modest supersaturations in hydrated melts (3–6% w/w water, viscosity  $10^4$ – $10^6$  Pa s). The viscosity of the melt played a controlling role only

when bubble surface area was small in the initial stages ( $< 1$  s) of growth. At high supersaturations, the rapidly increasing area of bubble wall physically moves larger volumes of melt closer to the bubble and volatile advection is a significant contributor to bubble growth under certain conditions. As bubbles grow, the water content of the melt declines and the melt viscosity rapidly increases (Fig. 1a). Bubble growth then again becomes influenced by viscosity. These experimental results indicated that at water concentrations  $> 3\%$  w/w in rhyolite, equilibrium degassing was a good approximation. However, as water content declines then equilibrium is not maintained and melt some distance away from a bubble wall, and therefore out of range of significant diffusion, becomes supersaturated in water. Lyakhovsky et al. [76] postulated that these supersaturated melt pockets then encourage additional episodes of bubble nucleation; a process supported by Blower et al. [17] using analogue experimentation and computer modeling. Constrained rapid-decompression experiments provided key insights into the role of continuous nucleation in near-equilibrium degassing of high-viscosity, low-diffusivity melts, with supersaturation limited to that required by heterogeneous nucleation sites.

The role of high viscosities ( $10^7$ – $10^9$  Pa s) on bubble nucleation was studied by Gardner [43], using methods similar to those of Hurwitz and Navon [52]. Heterogeneous and continuous nucleation of water bubbles in a rhyolite with less than 1% v/v microlites of Fe–Ti oxides and plagioclase were again exhibited (Fig. 4). Increasing viscosity and decreasing supersaturation were found to increase bubble nucleation times from a few seconds to greater than 100 s. The controlling parameter for nucleation rate was found not to be temperature, diffusivity or viscosity, but the surface tensions of interfaces between melt, crystal and bubble.

All these experiments were fully sealed, with no opportunity for the exolving volatile phase to escape. This condition was relaxed by Burgisser and Gardner [19] who decompressed 3 mm diameter, 7 mm long cylinders of rhyolite hydrated within gold capsules at 150 MPa and 825°C, with some capsules modified to incorporate a sink for escaping water (pseudo-open conditions). Three bubble growth regimes were identified that depended on balances between diffusivity and viscosity in relation to the rate of sample decompression. The open system experiments showed that, given sufficient time (about 180 s here) water bubbles begin to coalesce once bubble volume fraction exceeds about 43%; note that the permeability of natural samples tends to decline rapidly below about 40% porosity. This is important because bubble coalescence promotes

an increase in permeability as preferential degassing pathways form in the melt. The limited volume of the sample, and its confining capsule, prevents the establishment of the range of flow behaviors that exist in volcanic conduits during explosive eruptions. However, the experiments of Burgisser and Gardner [19] provide useful insight into the role of flow on bubble coalescence for this very reason; features seen in the experimental samples are likely to have been difficult to distinguish in any experiments aimed at flow behavior. This demonstrates the usefulness of experiments for investigating spatially and temporally small (but tractable) aspects of a complex bigger picture. The results of such experiments can be used to verify models of the partial-process, with the facility to eventually combine these into a description of the full process.

The link between porosity and permeability was further explored by Takeuchi et al. [119] who isothermally decompressed 5 mm diameter, 15 mm long samples of Usu dacite in gold tubes from 150 MPa at 900°C, to pressures ranging from 50–10 MPa. Samples were then measured for

◀ Volcanic Eruptions, Explosive: Experimental Insights, Figure 7 As bubble volume fraction (vesicularity) increases, more bubbles coalesce to allow easy gas exchange between them. The result of this is increasing sample permeability with increasing vesicularity. Permeability allows gas to escape from the magma and reduces explosive potential, making permeability an important parameter in understanding the transition from effusive to explosive volcanism. Experiments carried out by Takeuchi et al. [119] (circles and squares with error bars, the solid and open symbols indicate isotropic and deformed vesicular textures of the products, respectively) are compared with measurement of natural samples in the top panel (dashed curve indicates the relationship of Eichelberger et al. [42], the bold solid curve with two fine satellite lines indicates the relationship of Klug and Cashman [67] with the upper and lower limit of the scattered data, the crosses and squares represent permeabilities of Melnik and Sparks [87], and Takeuchi et al. [119] respectively). Permeabilities have been corrected at a later date because of measurement artefact (bottom panel, Takeuchi et al. [118]). The trend of increasing permeability with vesicularity is demonstrated, but experiments generally show lower permeability than natural samples. One explanation for this could be that most of the natural samples have been subject to significant flow, whereas the experimental samples were generally not (open symbols show some evidence of flow). The role that flow plays in the development of permeability remains unclear. Reprinted with kind permission of AGU

permeability along the tube axis and, with their bubble fraction ranging from 22 to 83% v/v, covered the porosity range over which permeability has been measured in natural samples. However, the experimental samples showed significantly lower permeabilities than natural samples, except for the low porosity data of Eichelberger et al. [42], and for experiments where bubbles were elongated along the permeability measurement direction (Fig. 7). This suggests that flow processes act to increase permeability by 1–2 orders of magnitude, and that most of the natural samples measured have undergone significant flow; or as Takeuchi et al. [119] state “The quenched experimental products can be considered as snapshots in vesiculating magma during decompression without deformation of vesicular structure in the late stages of eruption”. Describing experiments as snapshots of a larger, more-complex process is an apt analogy. More recently, Takeuchi et al. [118] have revisited their experimental samples and, after removing the gold tubes, found that the sample permeabilities were further reduced (Fig. 7), especially at low vesicularity. The original measurements had included some gas leakage between the silicate sample and the gold tube and, when operating at the limits of permeability detection, the leakage added a significant systematic error to the measurements. The new results further emphasize the importance of the flow history of vesicular materials in the development of permeability, and illustrate the complex-

ity of interactions in the magmatic degassing process that determine the eruptive behavior.

**Decompression-Driven Flows** At Mt. St. Helens in 1980, a landslide acted to reduce the pressure applied to a body of vesiculated magma. Because the vesicles contained gas, the reduced pressure drove extensive magma expansion. This created the explosive lateral blast that preceded sustained explosive activity on May 18th 1980. Similar behavior may also be exhibited when portions of lava domes collapse. The response of vesiculated magma samples to relatively rapid decompression ( $10^{-3}$ – $10^1$  GPa  $s^{-1}$ ) (Alidibirov and Dingwell [3]) forms a major area of experimental volcanology.

Laboratory apparatus known as a ‘fragmentation bomb’ (Fig. 8) was conceived by Alidibirov and Dingwell [1,2] and has been developed by others since. This shock-tube apparatus rapidly decompresses experimental samples at 850°C from up to 35 MPa to 0.1 MPa (Spieler et al. [112]). The samples, cylinders of approximate dimensions of 2 cm diameter by 20 cm length, are natural volcanic rocks heated to the required temperature in an atmosphere of Ar within a pressure vessel. On reaching the temperature of interest, the sample is further pressurized

with Argon until a system of calibrated rupture discs fail. On failure, the sample rapidly decompresses ( $1$ – $100$  GPa  $s^{-1}$ ) and any explosive products freely expand into the collecting tank for further analysis. The use of Ar for these experiments removes any additional complexities that may arise from the nucleation, diffusion and growth of water bubbles allowing the detailed study of the mechanical response of vesiculated silicates to a rapid pressure drop.

Alidibirov and Dingwell [3] provide a review of the findings of experiments to that date. Samples of Mt. St. Helens Dacite from the May 18th 1980 eruption were decompressed by up to 18.5 MPa at temperatures up to 950°C. Observation of the resulting fragments showed angular material characteristic of brittle failure of the samples. Calculations of the strain rates imposed on the samples indicated that, even at the highest temperatures used, the dacite would behave as a brittle solid. Alidibirov and Dingwell [3] analyze three mechanisms that could explain explosive fragmentation of the sample. The dacite samples had interconnected pores and were, therefore, permeable. Rapid removal of the Ar gas above the sample creates a pressure gradient within the sample. If permeability is very high then the Ar gas can readily escape and pressure gradients will be relatively low. At the other ex-

Schematic diagram and photograph of ‘fragmentation bomb’ shock-tube apparatus (Kueppers et al. [69]). Natural samples are pressurized up to 50 MPa with gas and heated up to 850°C in the autoclave. Samples can be used at room temperature with a transparent experimental section for high-speed imaging (Spieler et al. [111] (Fig. 9); Taddeucci et al. [116] (Fig. 22)). The diaphragms are ruptured to decompress the sample to atmosphere (0.1 MPa) and the resulting flow is collected in the large tank. Pressures, images and fragment morphology then provide information on flow dynamics. Reprinted with kind permission from Elsevier

treme, if bubbles are not interconnected then pressure gradients within the sample will be maximized (note, the experimental samples must have some permeability in order to pressurize them with Ar, but this does not need to be the case volcanically). In reality, the samples have a degree of permeability that allows pressure gradients to develop within the dacite. The pressure gradient was found to be at its highest at the fragmentation front, where the yield strength of the sample was exceeded. The fragmentation front was found to intrude the sample at tens of  $\text{m s}^{-1}$ , much slower than the sound speed and known as the fragmentation wave. In this instance, fragmentation can be described as a pressure-gradient driven change in flow regime from permeable filtration flow where only the gas moves, to two-phase flow where gas and solid are both in motion.

Martel et al. [82] synthesised 2 cm long by 2 cm diameter samples of hydrated haplogranitic glass with water contents ranging from 1.4 to 5.7% w/w. Water bubbles were nucleated and grown within the samples under a range of temperatures and pressures within the fragmentation bomb apparatus (Fig. 8) on timescales of about 1 hour, giving vesicularities ranging from zero to 0.91 v/v. Samples that developed large bubbles and high vesicularities underwent significant expansion and tended to develop elongated, or tube, bubbles during this process. Subsequent rapid depressurizations of between 5 and 18 MPa resulted in explosive fragmentation of the pre-foamed samples purely from expansion of the gas phase within the bubbles; timescales were too short for any significant further diffusion and exsolution of water from the glass. The resulting fragments were collected and analyzed for size, shape and vesicularity. The primary fragmentation process was found to be a sequential brittle spalling of the upper sample surface exposed to the decompression and was imaged by Spieler et al. [111] using Santorini pumice at room temperature in a transparent pressure vessel (reproduced here in Fig. 9). Low vesicularities and small decompressions were found to yield larger fragments than high vesicularities and large decompressions, a result consistent with the amount of energy released during the decompression process. The fragment size distributions may be dominated by the primary fragmentation mechanism (surface spalling), but impacts between fragments, and with the apparatus wall, may increase the proportion of the smallest fragments at the expense of the largest, especially with large decompressions (giving high fragment velocities). Interestingly, the presence of tube bubbles acted to decrease fragment size, demonstrating again that flow history is important in determining the products of explosive events.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 9 The rapid decompression of a sample of Santorini pumice, at room temperature, by at least 9 MPa (3 times higher than at 850°C) in the ‘fragmentation bomb’ (Fig. 8) results in spalling fragmentation (Spieler et al. [111]). The *first frame* shows the 50-mm length by 20-mm diameter sample just prior to decompression. 0.25 ms after diaphragm rupture (*second frame*) the ejection of fine dust from the sample surface indicates that pressure is falling in the *upper reaches* of the sample and gas is starting to escape from the pores. The combined elastic response of the sample and apparatus has detached the sample from the holder, fracturing the sample base. 0.5 ms after decompression (*third frame*), spalling fragmentation propagates through the sample perpendicular to the axis of decompression. Fragmentation results from the build up of a pressure gradient within gas in the upper sample sufficient to exceed the tensile strength of the bubbly solid. After 0.75 ms (*fourth frame*) primary fragmentation is complete and fragments are ejected into the large tank (Fig. 8). The timescale of this transient flow is of order 1 ms, but such visualizations give great insight into possible volcanological fragmentation mechanisms. Reproduced with kind permission from Springer Science and Business Media

In a refinement of these experiments, Martel et al. [83] investigated the effect of adding relatively inert alumina particles to the hydrated haplogranitic samples as an analogue to crystals in a silicate melt. Solid particles influenced the final particle size distribution because they tended to remain intact during the experimental fragmentation process. An increasing proportion of alumina particles acted to increase the fragment size for a given decompression, suggesting that energy release was reducing. This would be consistent with the reduced proportion of gas phase that results from an increasing proportion of solids. This effect may also account for the observed increase in the decompression needed to fragment samples as the proportion of crystals increased, with the limit that a zero-vesicularity sample (100% crystals) would not fragment under decompression. Interestingly, tube bubbles were not formed in these experiments due to enhanced heterogeneous bubble nucleation acting to reduce bubble diameter.

Spieler et al. [112] carried out a systematic investigation of the rapid pressure drop required to cause the brittle spalling fragmentation of natural samples with a wide range of chemistry, porosity, permeability and crystallinity. The major control on fragmentation threshold pressure ( $\Delta P_{\text{frag}}$ ) was found to be the sample porosity ( $\phi$ ). Figure 10 shows the relationship to be approximated by  $\Delta P_{\text{frag}} = 1/\phi$ , with pressure given in MPa. Such a relationship makes qualitative sense because, as vesicularity tends to zero,  $\Delta P_{\text{frag}}$  will tend to a large value because of little or no gas phase to drive the fragmentation. At large vesicularities, there will be little melt to resist the expansion of the volatile and fragmentation will take place with small decompressions. Figure 10 suggests that the rapid removal of order 100 m of overburden from a vesiculated magma with  $\phi > 0.2$  will result in explosive fragmentation caused by pressure-retention in the pores. Such an event could happen by slope failure, for example, at Mt. St. Helens in 1980, or by a dome collapse. At lower vesicularities, the rapid removal of an overburden thickness of order 1000 m is required to initiate explosive fragmentation. However, although smaller overburden removals may not result in immediate spalling fragmentation, slower diffusively driven bubble growth will act to expand the magma and could thus trigger more sustained explosive activity.

Another mechanism of increasing pore pressure in magma is by crystallization of the silicate melt (e.g., Sparks [108]). This occurs because water is not incorporated into the structure of growing crystals and concentrates in the declining proportion of melt. Taddeucci et al. [115] used the ‘fragmentation bomb’ to ascertain the fragmentation threshold of crystal-rich magma from the 2001 basalt erupted at Mt. Etna, as a function of porosity. This was combined with models of pressures generated by crystal growth, and calculations of conduit pressures required to eject magma blocks observed during the explosions. This approach supported an explosion model sourced in the heterogeneous fragmentation of crystallizing magma plugs. The particularly interesting aspect of this model is the introduction of porosity heterogeneity within the magma. Figure 10 demonstrates that as porosity increases, the pressure change required for fragmentation decreases. Therefore, the competence of a body of magma will depend on its weakest link, namely any regions of high porosity. Once these begin to fragment, then the less vesicular regions will be removed as large blocks.

Although volcanically accurate materials were used in fragmentation bomb experiments, the effects of reductions in length and timescale by three orders of magnitude remain unknown. Nevertheless, these important experiments give specific insight into key mechanisms that

Volcanic Eruptions, Explosive: Experimental Insights, Figure 10 Samples of natural volcanic material with a range of vesicularities were heated to 850°C and decompressed in the ‘fragmentation bomb’ (Fig. 8) by Spieler et al. [112]. The pressure drop required to cause explosive brittle fragmentation was inversely related to the sample vesicularity, with the constant of proportionality (here, about 1.07 MPa) being the tensile strength of the solid phase. Intriguingly, this suggests that heterogeneity in vesicularity will result in selective fragmentation of more vesicular regions of magma, particularly at vesicularities below 0.3. Data replotted from Spieler et al. [112]

could operate during the rapid decompression (or internal pressurization) of a vesiculated body of magma, and general insight into the behavior of volcanic materials undergoing explosive eruption.

### Explosion Products

Explosive expansion of magma, driven by the low bulk modulus of gas-phase volatile species, generates a range of consequent phenomena. The primary magma fragmentation (one mechanism is illustrated in Fig. 6, and another in Fig. 9) involves a large increase in surface area within the volcanic system. The mechanism of this increase is the breaking of molecular bonds.

On exiting the volcanic vent, hot silicate fragments and volatile gas (mainly water vapor on Earth) interact with any atmosphere and cool. In the absence of a significant atmosphere, for example on Io, the volcanic ejecta expands, then the silicate fragments follow ballistic trajectories once they have decoupled from any volcanic gases and cool by radiation. Interaction between silicate fragments is

now unlikely and their trajectories end when they impact Io's surface; some may escape Io altogether. On Earth, the presence of an appreciable atmosphere results in different behavior. Explosion products emerge from the vent and interact with the atmosphere. If the silicate fragments are large and the explosive power low then fragment trajectories tend towards ballistic control. Conversely, if eruption power is high and fragments small, then atmospheric interaction may dominate. The mixing of air with hot eruption material and its consequent expansion may result in a thermally buoyant plume that ascends many kilometers into the atmosphere and may circumnavigate the globe by long-range atmospheric transport. If insufficient atmospheric air is entrained in order to develop and maintain buoyancy then some ejecta may fall back to ground to form a pyroclastic flow. On a smaller scale, the presence of electrostatic fields and liquid phases encourages sub-millimeter silicate fragments to aggregate. Many experimental studies have been carried out on the processes that follow explosive volcanic events and we review a selection here.

**Fragment Size Distributions** The fragment size distribution resulting from explosive volcanic eruption has been found to follow a power law distribution,  $N = \lambda r^{-D}$ , where  $N$  is the number of fragments greater or equal in size to  $r$ , and  $\lambda$  is a constant of proportionality. For a single or primary fragmentation event the exponent ( $D$ ) is predicted to be less than 3.0. Experiments carried out by Kaminski and Jaupart [66] impacted a sample of Minoan pumice with a solid piston to give an exponent of 2.7. James et al. [57] impacted two pumices together and found an exponent of 3.5. Pyroclastic flow or fall deposits from explosive volcanic eruptions exhibit an exponent range between 2.9 and 3.9.

Martel et al. [82] rapidly decompressed hot vesiculated rhyolite in a 'fragmentation bomb'. Decompressions of less than 15 MPa produced exponents of less than 3.0 for the resulting fragment size distribution, regardless of initial sample vesicularity. However, decompressions of > 15 MPa, for samples of vesicularity > 0.5, resulted in exponents > 3.0 and ranging up to 4.1 (Fig. 11). These results suggest that secondary fragmentation mechanisms, such as those induced by fragment-wall and fragment-fragment collision, could be occurring within the apparatus after the primary spalling-fragmentation event (Fig. 9). Alternatively, as high exponents were observed at high vesicularities, the highly heterogeneous nature of a foamed silicate could invalidate the assumptions made in suggesting 3.0 as the exponent boundary for primary fragmentation, at least for fragment size ranges smaller than the order of bubble size. Interpretation of fragment size distribu-

Volcanic Eruptions, Explosive: Experimental Insights, Figure 11 Hot samples of bubbly rhyolite glass with a range of vesicularities were decompressed through various pressures in the 'fragmentation bomb' (Fig. 8), and the fragment size distribution (FSD) measured (Martel et al. [82]). The FSD was compared with a power-law distribution given by  $N = \lambda r^{-D}$ , where  $N$  is the number of fragments with radii larger than  $r$ . The power-law exponent,  $D$ , was found to increase with the magnitude of decompression (numbers next to data points in MPa), as well as with higher vesicularity. Compare this to an exponent of 3.5 for colliding pumices in Fig. 12. Theoretically,  $D > 3$  suggests more than one fragmentation process, but these are complex, heterogeneous, multiphase materials and established fragmentation theory based on dense homogeneous materials may not give the full picture. Reprinted with kind permission from Elsevier

tions between experimental and natural systems in terms of fragmentation processes is further complicated by difficulties in obtaining complete natural samples from explosive events. For example, winnowing in the atmosphere separates fragments as a function of fall velocity, which is a function of size and shape; therefore, the products of any individual fragmentation process are subsequently separated.

**Fall Velocity of Silicate Fragments** Understanding the behavior of silicate fragments in the atmosphere requires knowledge of the fall velocities of real volcanic pyroclasts, which rarely conform to an idealized spherical shape. Walker et al. [123] dropped samples of pumice from heights up to 30 m and found that terminal fall velocities were best approximated by the fall equation for cylindri-

cal bodies. Wilson and Huang [125] carried out extensive experiments on silicate crystals and glass fragments in the size range 30 to 500  $\mu\text{m}$ . A fragment shape factor ( $F = (b + c)/2a$ ) was defined in terms of the longest ( $a$ ), intermediate ( $b$ ) and shortest ( $c$ ) principal axes of the fragment, allowing definition of the empirical formula  $Cd = (24/\text{Re})F^{-0.828} + 2(1.07 - F)^{0.5}$ , where the fragment drag coefficient is given by  $Cd$ , as a function of Reynolds number,  $\text{Re}$ , and the shape factor. Suzuki [114] revisited the experimental data and proposed a modified equation,  $Cd = (24/\text{Re})F^{-0.32} + 2(1.07 - F)^{0.5}$ . This empirical, experimentally informed approach allowed calculation of the fall velocity of a fragment in the atmosphere and provided input into numerical models of the dispersal of products from explosive volcanism. Further information can be found in [101,109,120].

**Fragment Electrification** James et al. [56] investigated possible mechanisms by which silicate fragments could become electrically charged during explosive activity. Two natural pumices were collided together resulting in the generation of particles generally smaller than 70  $\mu\text{m}$  in diameter as the silicate foam fragmented in brittle fashion. Fracto-emission generated ions and charged silicate fragments. Ions were found to have one net charge and silicate fragments the opposite net charge. Experiments carried out at atmospheric pressure produced charge densities similar to those found on ash particles resulting from explosive terrestrial volcanism, whilst those carried out at 0.1 Pa sustained at least an order of magnitude more charge. The absolute amount of charge was dependent on the impact energy, (a result comparable to [23] findings of increasing electric field with greater fragmentation energy), with the net charge representing a slight imbalance between positively and negatively charged fragments. The mechanism of producing charged silicate fragments from pumice-pumice collision adequately accounts for the fragment charges and electric fields measured in proximity to explosive volcanic eruptions. This suggests that pumice-pumice collision, i. e., secondary fragmentation, could be a major source mechanism for sub-100  $\mu\text{m}$  silicate fragments.

Experimental hydrovolcanic explosions were found to produce an electrically charged fragment and ion cloud [24]. Interestingly, fragmentation using high-pressure Argon gas produced electrical effects of smaller magnitude than magma-water interaction, even though expansion rates of the ejecta from the experimental crucible were similar. This suggests that the cooling effect of water does produce much more brittle failure resulting in enhanced fracto-emission [37,40], consistent with the production of

smaller blocky fragments from MFCI experiments [135]. It is also possible that polar water molecules dissociated into reactive ions during the MFCI process, a mechanism not so accessible to Argon atoms. Büttner et al. [24] found striking similarities between experimental electric fields and those generated during explosive events at Stromboli volcano.

**Silicate Fragments and Their Aggregation** Accretionary lapilli are widespread in the deposits from explosive volcanic eruptions, and anomalous variation in the deposit thickness and grain size distribution as a function of distance from the explosive vent is commonly observed. Both of these processes are explainable if silicate fragments smaller than about 100  $\mu\text{m}$  clump together, or aggregate, to form a larger entity which has different aerodynamic properties than its constituent particles. Sparks et al. (see Chapter 16 in [109]) provides a review of particle aggregation in volcanic plumes prior to 1997.

Accretionary lapilli are obvious in the geologic record as millimeter to centimeter sized spheroidal aggregates (density range 1200 to 1600  $\text{kg m}^{-3}$ ) of silicate fragments and secondary minerals such as gypsum, and they formed the early focus of study into aggregation in volcanic plumes. Two complementary experimental studies provided insight into the formation mechanisms of accretionary lapilli. Gilbert and Lane [45] focused on formation in atmospheric plumes. A wind tunnel was used to demonstrate experimentally that particles of volcanic ash collide and adhere to the surfaces of objects falling through the atmosphere that are covered with a thin layer of liquid. The liquid layer was found to act as a control on the sizes of silicate fragments that adhere, with high sticking efficiencies at 10  $\mu\text{m}$  diameter, reducing by two orders of magnitude for fragments 100  $\mu\text{m}$  in diameter. A key experimental finding was the importance of hygroscopic chemical species in maintaining thin liquid films. Experimentally this was achieved using NaCl; volcanically, sulphuric acid is the most likely hygroscopic compound that could maintain liquid films at low relative humidity and down to temperatures of  $-70^\circ\text{C}$ . These experiments strongly suggest that accretionary lapilli are diagnostic of a three-phase environment within the volcanic plume in which they formed, supporting earlier hypotheses (e. g., [88]).

Schumacher and Schmincke [105] focused on accretionary lapilli formation in pyroclastic flow processes. Experiments were carried out providing insight into interpreting the structure of accretionary lapilli in terms of their formation mechanisms. Accretionary lapilli were synthesized by a method similar to the industrial production of fertilizer pellets, with mixtures of volcanic ash and

variable proportions of water being rotated in a steel pan. The resulting spheroidal agglomerates varied with the proportion of water present, formation being optimal at between 15 and 25% w/w water, and grain size sorting was found to occur at low water mass fractions. The mechanism of formation, namely capillary binding, is identical to that of Gilbert and Lane [45], but under conditions of much higher fragment number-concentration.

The occurrence of secondary thickness maxima and bimodality of grain size distribution, exemplified by Carey and Sigurdsson [27], implies the mechanism of silicate fragments being transported within aggregates. These aggregates could be accretionary lapilli, but these are often absent from the deposits suggesting that the aggregates are fragile and lose their identities once incorporated into a volcanic deposit. Fragile aggregates have been observed falling from volcanic plumes and one explanation for their formation is the presence of electrostatic charge. During fragmentation, silicate particles become electrostatically charged (see Sect. “Fragment Electrification”), and whilst in the atmosphere these charges have no path to escape to earth unless electric fields exceed the level required for electrostatic discharge in air. This leads to long-lived attractive electrostatic forces between silicate fragments [81], and consequently the formation of aggregates. Once on the ground an electrically conductive path to earth can be established, especially in the presence of moisture, and the aggregates disintegrate.

Schumacher and Schmincke [105] carried out experiments using natural volcanic ash and a stream of ions from an electrostatic paint gun. Silicate fragments smaller than about 180  $\mu\text{m}$  diameter were found to rapidly aggregate into loose fragile clusters demonstrating the viability of the electrostatic aggregation process for fine volcanic particles.

James et al. [57] studied the generation of aggregates resulting from the interaction of ions and charged silicate fragments using the fragment generation and charging mechanism of James et al. [56] with pumice from the May 1980, Mount St. Helens fall deposit. Silicate fragments were allowed to fall and interact over a distance of 0.5 to 1.1 m onto a variety of analysis platforms. Fallout was collected and analyzed for fragment size (Fig. 12) using an agitated dispersion of the particles in a conducting electrolyte to maintain disaggregation. The particle size distribution showed power law behavior with exponent 3.5 (Fig. 12), somewhat above the theoretical maximum of 3.0 for a primary fragmentation event. These experiments indicated that the aggregation process happens shortly after the fragmentation event has generated charged silicate fragments and ions (Fig. 12). The aggregation process significantly changes the size distribution

relevant to aerodynamic behavior (Fig. 12) from the single-fragment form  $N = \lambda r^{-3.5}$  to aggregate form  $N = 15\,089 \exp[-0.011d']$ , where  $d'$  is the aggregate diameter. Experimental measurement of aggregate fall velocities enabled estimation of aggregate densities between 80 and 200  $\text{kg m}^{-3}$ , at least an order of magnitude less than both the fragments that comprise aggregates and accretionary lapilli. The main consequence of electrostatic aggregation for sub-100  $\mu\text{m}$  silicate fragments is to reduce atmospheric residence time because aggregation acts to increase fall velocity above the single fragment value. The size distribution of individual fragments within an aggregate was experimentally examined by James et al. [58], who found empirically that for aggregate diameters less than 140  $\mu\text{m}$ ,  $n = 0.000272d_a^3[\exp(-0.22d_p) + 0.008 \exp y(-0.083d_p)]$ , where  $n$  is the number of fragments larger than diameter  $d_p$  within an aggregate of diameter  $d_a$ . As electrostatic aggregates exceed about 140  $\mu\text{m}$  in diameter the size distribution of their constituent fragments was found to change. This was attributed to the aggregate growth mechanism becoming dominated by aggregate-aggregate interaction rather than aggregate-fragment interaction (Fig. 12), and stabilization of the size distribution of material being incorporated into the aggregate. Electrostatic aggregates can be represented as spheres of density about 200  $\text{kg m}^{-3}$  and an experimentally determined empirical relationship between drag coefficient ( $Cd$ ) and Reynolds number ( $Re$ ) for aggregate diameter range 50 to 500  $\mu\text{m}$  is  $Cd_{\text{agg}} = 23Re^{-0.637}$  (James et al. [58]). Such experimental data can then be used within numerical models of the transport of sub-100  $\mu\text{m}$  volcanic ejecta in the atmosphere, although at the time of writing this has yet to be undertaken.

**Pyroclastic Flows** Pyroclastic flows comprise a hot mixture of silicate particles and gas formed by the collapse of negatively buoyant regions of a volcanic plume or avalanching of material from a growing lava dome. By nature, pyroclastic flows are destructive to infrastructure and almost invariably fatal to plants and animals. Insight into the behavior of pyroclastic flows may be gained by studying their deposits. However, it is difficult to definitively identify fluid dynamic processes operating during a pyroclastic flow from the complex structures within deposits that are revealed once motion has ceased. Here, experiments can help in isolating flow processes and their subsequent effect on deposits. However, scaling between experiment and natural process requires care to ensure behavioral similarity as particles of a range of sizes interact with the gas phase to different degrees.

Dellino et al. [36] designed experiments to investigate the mechanics of pyroclastic flows on a scale com-

Volcanic Eruptions, Explosive: Experimental Insights, Figure 12

Fragmentation during explosive eruptions produces electrically charged fragments and ions by fracto-emission processes (James et al. [57,58]). Electrostatic forces are significant in comparison to gravity for fragments less than about 100  $\mu\text{m}$  in size, resulting in fragment aggregation. Aggregates have different aerodynamic properties than their constituent fragments, thus altering the fallout behavior of sub-100  $\mu\text{m}$  volcanic ash and consequently its atmospheric transport. The top image shows experimental aggregates collected on a plate (scale 1 mm), with the graph showing the size distribution of the aggregates (*curved lines*), as well as that of the constituent fragments (*straight line*). The *bottom panel* (scale 0.5 mm) shows that experimental aggregates of different sizes have different morphologies, and the *right-hand panel* (scale 0.5 mm) shows strobe images of a falling and rotating experimental aggregate. Volcanic Eruptions, Explosive: Experimental Insights, Figure 13

Ejection of natural pyroclastic material by a burst of gas can be used to study both volcanic plumes and pyroclastic flows (Dellino et al. [36]), this also looks enormous fun! a shows an experiment with low specific mechanical energy (SME) generating a collapsing column and (pyro)clastic flow. c shows a high SME experiment generates a plume that, whilst not buoyant, disperses on the prevailing wind, and b shows the transitional case. Such large-scale investigation helps to overcome some of the scaling difficulties imposed by smaller-scale laboratory experiments. Reprinted with kind permission of AGU

parable to the natural process. In order to approach this, the physical scale of the experiments was such that they required an outdoor laboratory. The experimental material was sourced from a natural pyroclastic flow deposit in order to mimic the interaction between fragments and gas as closely as possible. Varying masses of this material were packed into an experimental tube 60 cm in diameter and 2.2 m high. 14 liters of gas at pressures over  $10^7$  Pa was rapidly injected into the base of the tube to eject the experimental material, with experiments triggered and logged under computer control. The experiments were carried out at ambient temperature and were, therefore, not scaled for any thermal effects; this has the benefit of reducing both equipment and process complexity. Ejected material could be sampled for analysis and compared to natural pyroclastic deposits. Preliminary experiments showed two main types of behavior as the specific mechanical energy (SME, given by  $\text{gas pressure} \times \text{gas volume} \div \text{mass of pyroclastic material}$ ) of the system was changed (Fig. 13). At high SME values a dilute particle plume develops with the particles settling out individually. At low SME values the ejected material forms a collapsing column that generates a particle flow similar to a py-

roclastic flow. Intermediate SME values give transitional behavior with aspects of both end-members. These experimental observations have considerable phenomenological similarity to natural explosive eruptions where particle-dilute regions ascend in the atmosphere and more particle-concentrated regions fall under gravity to give pyroclastic flows. Such similarity gives added confidence that mechanisms operating in the natural process also operate in the simulation.

Experiments producing a collapsing-column deposited material at the point of impact of the column with the ground. The resulting deposit was found to be structureless, just as many natural proximal pyroclastic deposits, because grain-sorting processes did not operate in this concentrated particle flow. Other similarities included the formation of a concentrated undercurrent, bed load at the base of the turbulent flow, and continuous atmospheric suspension of small silicate particles; this is very interesting in the absence of thermal processes. These preliminary experiments demonstrate great potential for linking processes in scaled experimental flows with the resulting experimental deposits and, therefore, providing a powerful interpretation tool for natural pyroclastic flows.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 14

The inflation and deflation of a bed of natural pyroclastic material using hot gas shows a range of flow structures (Druitt et al. [41]). During inflation, the bed can be homogeneous or develop gas bubbles or channels, and fine particles can be removed by elutriation. When fluidizing gas velocity exceeds  $U_{mp}$  (left panel), the bed inflates and particles start to segregate on the basis of size and density. Bubbling occurs when gas velocity exceeds  $U_{mb}$  (upper right panel), and the bed expands only weakly with increasing gas velocity (left panel). Agitation of the flow acts to reduce the gas volume fraction. Once the gas supply is closed off then bubble collapse results in rapid deflation ((1) in middle panel). An extended period of hindered settling then generates a layer of settled material at the base of the bed ((2–3) in middle panel). These experiments were used to investigate the gas retention properties of pyroclastic materials as a function of fragment size and temperature. Gas retention was favored by finer fragment sizes, with high temperature having a secondary retention effect. Hot, fine-grained pyroclastic flows are, therefore, predicted to flow further. Reproduced with kind permission from Springer Science and Business Media

Experiments carried out at smaller scale, but which included heating of the volcanic ash [41], have also investigated gas retention in pyroclastic flows. A bed of pyroclastic flow material with a wide fragment size range was fluidized by the drag force of rising hot gas. Both the bed expansion and collapse (degassing) after the gas supply was cut were studied. During expansion, smaller fragment size, lower density and higher temperature all promoted more uniform and easier expansion of the fluidizing bed. Figure 14 illustrates the nature of flow patterns that develop. Collapse experiments were imaged using X-rays and carried out between  $20^{\circ}\text{C}$  and  $550^{\circ}\text{C}$  giving temperatures comparable to those in natural flows. The generic collapse process is illustrated in Fig. 14. Experiments and numerical models identified that an aerated bed loses its gas by permeable flow on a diffusive timescale. A fluidized and uniformly expanded bed was controlled by timescales of hindered settling and diffusive degassing of the resulting sediment layer. The relative magnitudes of these timescales depended on the thickness of the degassing bed, with settling dominating in thin beds and diffusion in thick ones. These experiments indicate that hot pyroclastic flows with small fragment sizes retain gas longer than cool, large fragment flows, with temperature having a secondary effect. The gas retention translates into the distance a flow can travel and these experimental results are consistent with observations of natural pyroclastic flows.

## Analogue Approach

Experiments with volcanic materials can suffer constraints placed by the high temperatures and pressures at which the processes of interest occur. If similar processes can be studied under more amenable environments, then the practical limitations are relaxed and, generally, fluid volumes can be increased and a greater range of transducers are available for measurement. This can be achieved by substituting natural fluids with analogues that can be studied at near room temperatures and pressures. However, one difficulty with this approach is in ensuring the relevance of analogue results to volcanic systems and, perversely, natural volcanic materials are now often characterized more fully than many of the analogue fluids used.

## Explosive Processes

Direct observation of the motion of magma within volcanic conduits would reveal the how and why of volcanic explosive activity. However, direct observation is considered near-impossible and indirect observation open to interpretation. Experiments with natural materials provide constraints on physico-chemical processes within conduits, but extending the experimental parameter space by using analogue materials provides greater insight and enables testing of numerical models.

**High VEI Events** Volcanic eruptions of high VEI involve the transition of a low-velocity, high-density, high-viscosity bubbly magma, for which the liquid phase is considered continuous, to a high-velocity, low-density, low-viscosity ‘dusty gas’ where the gas phase is considered continuous. This fragmentation process represents the point at which the liquid and gas phases start to separate. Studies designed to investigate this process in general, but with volcanic application in mind, form a major part of experimental research using the analogue approach.

As pressure declines, the exsolution and expansion of volatile (specifically water) from magma provides the driving mechanism for most explosive events. In order to study similar behavior in analogue systems the shock tube has been almost universally adopted, as it has for the investigation of fragmentation in natural materials (e. g., [1,2]). Such experiments became of great importance around WW2 when understanding of shock waves and flame fronts from explosions, and supersonic flight, became of interest to the fluid dynamic community; volcanological application of shock tubes emerged from this background. Mader [77] provides a review of early shock tube experimentation relating to flow within volcanic conduits, we briefly summarize these here, but focus on more recent work.

**Post-Fragmentation Flows** The decompression of beds of small, incompressible particles with compressible, gas-filled pore space can give insight into the development of two-phase flows within and above the conduit subsequent to primary fragmentation [6]. The resulting rapidly expanding, but transient flows show development of significant heterogeneity, which declines as expansion reduces particle concentration. The development of heterogeneity within expanding particle-laden gas suggests mechanisms for the formation of pyroclastic flows from high-density sections of eruption columns, whilst lower-density sections become buoyant and form an eruption plume. Using smaller particles, Cagnoli et al. [25] carried out similar experiments to explore the dynamics of short-lived Vulcanian explosions. In similarity (we think, but see Fig. 9) with post-fragmentation volcanic flows, the experimental tube was much larger than the particle size. As in Anilkumar et al. [6], these transient flows demonstrated heterogeneous distribution of particles as the mixture expanded and the gas separated from the particles (Fig. 15). These features include sub-horizontal gas-rich regions that invite comparison with those found by Spieler et al. [111] in decompressed pumice samples; the implication being that the primary fragmentation process may be incidental to the nature of the evolving flow. Heterogeneities also com-

Volcanic Eruptions, Explosive: Experimental Insights, Figure 15 Rapid 20 to 90 kPa decompression of beds of sub-100  $\mu\text{m}$  glass beads generates a particle flow as the gas phase expands in response to the pressure drop (Cagnoli et al. [25]). a shows the decompression of 100 g of beads (with average diameter of 38  $\mu\text{m}$  through 51 kPa) after 28 ms. Note the wispy flow front, indicating escape of gas, and the development of large gas bubbles within the flow (scale shows 1 cm and 0.5 cm gradations). b (150 g of 95  $\mu\text{m}$  beads, 69 kPa decompression, after 23 ms) shows the development of sub-horizontal particle-poor regions, giving some phenomenological similarity to spalling fragmentation (Fig. 9). c shows flow in a narrower tube (100 g of 38  $\mu\text{m}$  beads, 68 kPa decompression, after 20 ms) where large particle-poor regions develop at the flow margin. Reprinted with kind permission from Elsevier

prise gas-rich bubbles, sometimes approaching tube diameter in size, and more elongated towards the flow front. Streamers of particles also emerge from the flow front indicating inhomogeneity in the distribution of gas escaping the particle flow (Fig. 15). As the flow ages and velocities increase, turbulence acts to smear out heterogeneities. The source of the heterogeneities in such transient flows is unclear. They may represent the expansion of gas rich regions in the original packed bed, suggesting that the transient flow reflects heterogeneity in the source material. Variability in permeability, and the dynamics of initial particle acceleration may also act to amplify heterogeneity as the flow expands. These experiments demonstrate the complex nature of even ‘simple’ two-phase flows that are undergoing rapid changes in variables such as pressure and velocity. The volcanic implication is that flow within a volcanic conduit can be highly heterogeneous and that modeling such flows as having smoothly changing density, as a function of time or space, will be far from representing the real

richness of the flow physics. Such modeling may give accurate prediction of time-averaged parameters, but will not reflect variability. However, it could be the variability that ultimately results in hazards like pyroclastic flows.

Chojnicki et al. [29] demonstrated that models of explosive volcanic flows based on pseudogas approximations underestimated the initial shock wave strength and velocity. Pseudogas models, and others based on steady-state experiments, then overestimated the subsequent particle bed expansion rate when applied to laboratory scale experiments. Such discrepancies suggest that one or both of the approaches, numerical and experimental, requires modification to reconcile the differences in order to understand the natural phenomena. In this case, Chojnicki et al. [29] identify processes not accounted for in the numerical approach, but which became apparent from experimental observation. Existing theory was then empirically modified to fit the unsteady experimental flow. Volcanically, these experiments suggest that the pressures present in conduits prior to Vulcanian explosive events were underestimated by a factor of approximately five when calculated using established pseudogas and inviscid shock theories. The pressures calculated from equations based on volcanically relevant experiments are consistent with the overpressures associated with Vulcanian explosions, as well as the rupture strength of volcanic rock. This demonstrates the importance of experimental design to progressing understanding of complex volcanic phenomena, and using the results of these experiments to test, modify and develop the numerical approach.

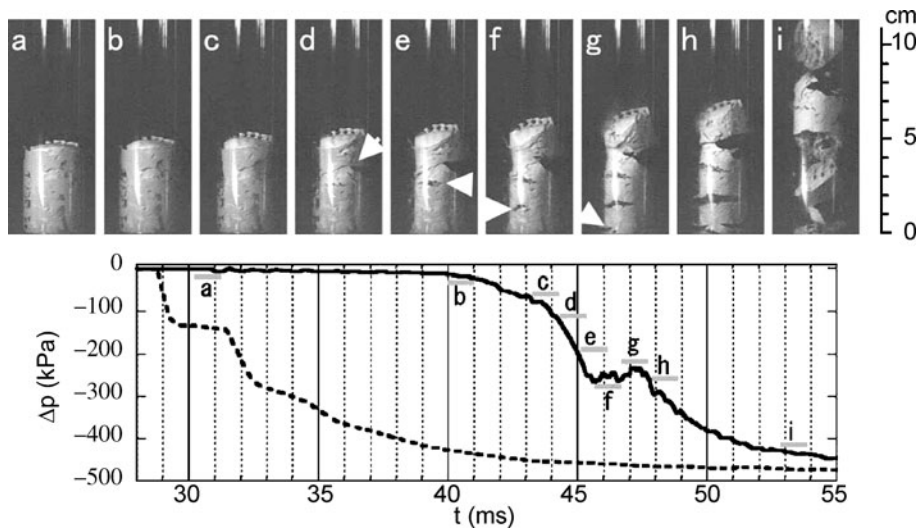

**Decompression-Driven Flows** The rapid decompression of natural vesicular solids causes fragmentation if the pressure drop is large enough for pressure gradients within the sample to exceed the tensile strength (Fig. 9). Such transient experiments have also been carried out on analogue solids in order to further characterize the behavior of this system of flows. Decompression of synthetic organic resin, with about 90% porosity and significant permeability (Alidibirov and Panov [4]), resulted in fragmentation phenomenologically similar to that of natural samples (Figs. 9, 16) undergoing brittle failure. A fragmentation front or wave was observed to propagate through the sample creating spalling-type fragmentation. Fragment size was observed to decrease, and exit velocity increase as the magnitude of decompression increases from 0.1 to 0.8 MPa. The propagation velocity of the observed fragmentation wave was less than sound speed in either the solid resin or the gas in the pores. Combining this observation with the dependence of fragment size on pressure drop suggests that fragmentation occurs as

Volcanic Eruptions, Explosive: Experimental Insights, Figure 16 An 0.8-MPa rapid decompression of vesiculated solid foam (Plastiprin) shows very similar spalling fragmentation behavior to natural vesiculated magma (compare with Fig. 9). This demonstrates the usefulness of analogue experimentation in identifying the universality (or not) of flow behaviors (Alidibirov and Panov [4]). Reproduced with kind permission from Springer Science and Business Media

gas escapes from the decompressed foam surface, creating a pressure gradient within the foam. When this pressure gradient is sufficiently steep, the foam fails revealing the next gas-escape surface. The expanding gas then accelerates the foam fragments. This implies that fragment size will also depend on sample permeability; an impermeable sample fragmenting on a scale comparable with bubble size and at small decompressions, whilst a permeable sample requires large decompressions and fragments on a scale much larger than bubble size. Very permeable materials will not fragment because the gas can escape without applying sufficient tensile force to the foam. Variability in permeability and porosity may well be reflected in fragment size for any decompression event.

Ichihara et al. [53] depressurized a vesiculated silicone compound and studied the expansion of vesicular materials across the viscoelastic transition by varying the decompression rate (Fig. 17). Fragmentation occurred at decompression rates  $> 2.7 \text{ MPa s}^{-1}$ , with only sample expansion occurring at  $< 2.7 \text{ MPa s}^{-1}$ . At high decompression rates, fragmentation occurred before expansion of the fragments. These experiments showed that both the fragmentation threshold and the nature of the fragmentation process depend not on the magnitude of decompression (above a minimum), but on the rate of pressure change. Furthermore, the rate of decompression needed to exceed the critical value for more than about 0.1 s [53], indicating that a pressure change approaching 300 kPa represents

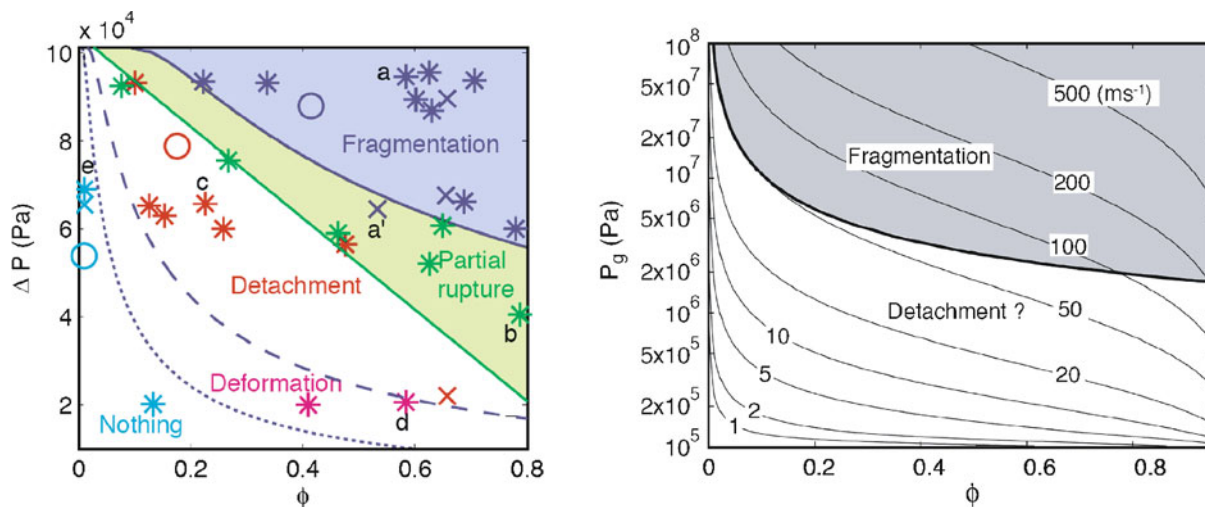

Volcanic Eruptions, Explosive: Experimental Insights, Figure 17

Rapid ( $50 \text{ MPa s}^{-1}$ ) 0.5-MPa decompression of a vesiculated dilatant (*shear-thickening*) silicone compound that acts as a brittle solid at high strain rates ( $> 3\text{s}^{-1}$ ), but a viscous liquid at low strain rates. Pressure above the sample is given by the *dashed line*, whilst that below by the *solid line*. The surface of the sample is decompressing in (a), but pressure beneath the sample remains steady until (b), decreasing more rapidly from (c). Brittle failure of the sample occurs over a  $< 10 \text{ ms}$  time span (d–g) in a spalling-fragmentation manner (Ichihara et al. [53]), about 40 ms after initial decompression. Fractures appear to initiate at the tube wall and then open to expand the flow (h, i). There is little or no expansion of the vesiculated sample or fragments. Reprinted with kind permission of AGU

the minimum pressure drop for fragmentation and also relates to the tensile strength of the experimental material. This fragmentation timescale was similar to the structural relaxation time for the glass transition (about 0.3 s), suggesting that crossing the relaxation timescale results in brittle failure of the sample. Coincidentally, the timescale for viscous control of bubble growth in the experimental material is also in the region of 0.1 s, suggesting that bubble expansion may determine the fragmentation timescale. This coincidence occurs because the rigidity of the silicone fluid is within an order of magnitude of the experimental pressure; in magmas the difference is in the region of three orders of magnitude. The nature of the fracture surfaces (Fig. 17, compare with Figs. 9 and 16), and the observation of minimal expansion before fragmentation suggests, however, that fragmentation occurred because instantaneous strain rate exceeded that required for brittle failure.

Using viscoelastic and shear-thinning solutions of 0.1%, 0.3% and 0.5% w/w polysaccharide (xanthan gum) in water, transient flow experiments exploring a wider parameter range, including variable porosity, were undertaken by Namiki and Manga [93]. Air bubbles were introduced using a hand-mixer, giving gas volume fractions up to 0.79. Samples were rapidly decompressed from atmospheric pressure to pressures ranging from 0.8 to 0.06

of an atmosphere; pressures much lower than this would encounter the saturated vapor pressure of water, causing the flows to be influenced by the production of water vapor. The shock tube was 0.05 m diameter by 0.25 m length, with fluid added to a depth of about 0.05 m. A range of flow patterns was observed (Fig. 18) as system parameters were varied. These include: fragmentation, partial rupture, detachment, deformation, and nothing; only ‘fragmentation’ results in ejection of fluid from the shock tube. Large decompression of highly vesicular samples leads to fragmenting flows (Fig. 18), which initially expand rapidly, then fragment layer by layer (Fig. 19) showing some similarity to spalling fragmentation (Figs. 9, 16, 17). In ‘partial rupture’, large-scale net-like structures develop that allow gas to escape from the fluid, but the liquid phase does not fragment *en masse*. At lower flow energies, the liquid phase detaches and contracts from the tube wall to yield an inverse annular, or ‘detached’ flow. Transient experiments allow the measurement of flow-front position, thus enabling estimation of strain rates within the flow. In these experiments the flow expansion was found to be independent of viscosity, which ranged from about 30 Pa s to 0.01 Pa s and was strain-rate dependent. For all experiments, it was found that shear rates were sufficient for elastic behavior, consistent with the independence from viscosity.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 18

Aqueous xanthan gum solutions are shear thinning and develop brittle solid behavior at strain rates above about 0.1 to 1  $\text{s}^{-1}$ , depending on concentration. The *left panel* shows that rapid decompressions ( $< 0.1$  MPa) of pre-vesiculated xanthan gum solution results in a range of flow patterns (Namiki and Manga [93]). Combining data established from the decompression of natural samples with the analogue xanthan gum experiments allows the calculated fragmentation field for explosive volcanic eruptions (*right panel*) in terms of gas pressure and vesicularity. It was not possible to define the parameter space for other experimental flow patterns applied to magmatic systems. Reprinted with kind permission from Elsevier

Volcanic Eruptions, Explosive: Experimental Insights, Figure 19

Fragmentation of vesiculated xanthan gum solutions occurs if decompression and vesicularity are high enough (Fig. 18). The *first frame* (zero time) shows the sample of vesiculated solution. On decompression, bubbles expand to give an approximately constant-velocity flow front (Namiki and Manga [93]), shown by the *line in frames 4–8* (3 ms between frames). During expansion, bubbles coalesce through film breakage to increase significantly in size, especially in the *upper parts* of the flow. The foam then fragments layer by layer, as shown by the *two lines* following liquid-poor regions. Most of the xanthan gum is ejected from the shock tube during the experiment. Reprinted with kind permission from Elsevier

The changes in flow pattern are attributable to the behavior of the bubble walls. Detachment of the fluid from the tube walls can be explained by the Poisson's ratio of the axially expanding foam, and represents the development of radial heterogeneity within an axial flow. However, if bubble walls rupture, elastic energy is released resulting in radial expansion and, thus, suppression of detachment. This suggests that fragmentation cannot take place from the detached flow pattern. Failure of bubble walls also increases permeability and allows gas to escape. Failure of the thin film, or plateau, between two bubbles, but not of the thicker plateau borders between three or more bubbles, is considered to result in the partial-rupture flow pattern.

The plateau borders form the net-like structure. Wholesale failure of plateau and plateau borders results in fragmentation. Application of experimental processes to volcanic scales (Fig. 18) by utilizing results from studies of transient flows of natural materials, gives indication of the decompressions needed to fragment vesicular magma for a range of vesicularities, but defining other flow patterns at volcanic scale requires further research.

Using a similar technique to Ichihara et al. [53], Namiki and Manga [94] investigated the role of transient decompression rate on aqueous xanthan gum solution. The variables here also included porosity (0.19–0.82 v/v) and absolute decompression (0.41–0.94 atmo-

◀ Volcanic Eruptions, Explosive: Experimental Insights, Figure 20

Images of a 60-kPa decompression of xanthan gum solution of initial vesicularity about 0.6 (Namiki and Manga [94]). In order to study the effect of decompression rate, the top of the shock tube has been choked with an orifice whose radius is a fraction of the tube diameter ( $R_{ori}$ ). Experiments with rapid decompressions have short durations (time in ms on individual frames), and slow decompressions significantly longer durations, with the star indicating the time decompression ended. For  $R_{ori} = 1$ , the flow develops a rough surface suggesting rupturing of bubble walls (ellipse), and the arrow indicates the onset of fragmentation. When  $R_{ori} = 1/2$ , the flow top starts to separate (ellipse), but surfaces are smooth indicating that bubble walls are staying intact. Fragmentation does not occur when  $R_{ori} = 1/4$ , but the flow detaches from the tube wall as it expands. Smaller orifices result in flow expansion that retains wall contact. Different values of vesicularity and absolute decompression yield different patterns of behavior. Reprinted with kind permission of AGU

during high decompression rates, indicating that bubble walls are rupturing; conversely, lower rates of decompression leave flows with smooth upper surfaces. These experiments suggest that decompression rate is an important parameter in determining eruption behavior, in particular the transition between effusive and explosive eruption in low-viscosity vesiculated magmas subjected to decompression. Explosive response (fragmentation) to decompression results from disequilibrium expansion, where pressure in the bubbles is significantly higher than in the surrounding fluid and bubble expansion is limited by the enthalpy change resulting from the decompression. Bubbles cannot physically expand fast enough to maintain the same pressure as the surrounding fluid. Effusive response results from bubble pressure being close to fluid pressure.

Models of equilibrium and disequilibrium expansion were tested against experimental results. At high decompressions, equilibrium expansion would be faster than disequilibrium expansion; experiments follow the slower disequilibrium expansion model. At lower decompressions the disequilibrium model predicts more rapid expansion than the equilibrium model; experiments again follow the slower expansion, this time in equilibrium. Namiki and Manga [94] gave the critical decompression rate for invisible explosive behavior as  $-P'_{Ot} > (2\gamma/\rho_L\phi_i P_{Gi}(1-\phi_i)(\gamma-1))^{0.5}(P_{Ot}^2/h_{Fi})$ , where  $P_{Ot}$  is pressure outside bubble during decompression,  $\gamma$  is isentropic exponent,  $\rho_L$  is liquid density,  $\phi_i$  is initial gas volume fraction,  $P_{Gi}$  is internal bubble pressure and  $h_{Fi}$  the initial height of the bubbly fluid column. This experimentally based threshold decompression rate is consistent with the estimated decompression rate for the explosive/effusive transition in natural basaltic eruptions (Fig. 21), with Hawaiian eruptions sug-

sphere). High decompression rates result in a variety of flow patterns, including fragmentation, depending on porosity and absolute decompression. At low decompression rates only sample deformation or expansion takes place (Fig. 20). Rough upper surfaces develop on flows

Volcanic Eruptions, Explosive: Experimental Insights, Figure 21 Application of experiments from Fig. 20 to the volcanic case give an estimate of the magma velocity required to cause sufficient decompression rate to initiate explosive eruption (*gray region*) as a function of magma vesicularity (Namiki and Manga [94]), where  $P_{Gi}$  is initial bubble gas pressure,  $h_{Fi}$  initial height of bubble column and  $-P'_{Gf}$  the bubble decompression rate. Eruptions that result from the rapid expansion of bubbly magma are likely to plot on the thick line separating equilibrium and disequilibrium fields. Hawaiian eruptions approach the transition and, on this basis, result from the rapid expansion of vesiculated basalt magma. Strombolian eruptions, however, are indicated to result from another mechanism. Reprinted with kind permission of AGU

gested as mainly driven by the sufficiently rapid decompression of bubbly magma.

**Degassing-Driven Flows** The decompression and expansion of materials with pre-existing vesicularity provides valuable insight into volcanic behavior. However, magmas also degas on decompression, potentially adding to the explosivity of eruptions. In contrast to experiments with natural materials, where high temperatures and pressures make spatially and temporally extensive flows difficult to achieve, analogue experiments offer the possibility of studying the evolution of flow processes from single phase liquid to multi-phase fragmented flow using high-speed imaging and other data collection. Decompression of an unvesiculated hydrated magma results in, amongst other effects, the nucleation and growth of bubbles of gas phase or supercritical water, complex changes in the rheology of the liquid phase, increasing permeability and decreasing diffusivity. Incorporating all these interdependent variables into an experimental system adds complexity and makes understanding the first order effects more difficult, even if scaling between experiment and volcano

is possible. Designing experiments to investigate the dominant physics using a canonical approach reduces complexity and eases scaling requirements. The first order physical process occurring during these flows is the phase change of one system component from liquid (or more strictly, dissolved) to gas, with the associated reduction in bulk modulus and response to pressure change. Therefore, the aim of analogue experiments here is primarily to study the effect of degassing on flow.

The decompression of a liquid below its saturated vapor pressure results in boiling of that liquid as it becomes superheated. Experiments carried out by Hill and Sturtevant [50] used a shock tube to rapidly decompress a refrigerant. The refrigerant was Newtonian in rheology and of low viscosity, which, whilst dissimilar to the physical properties of magma, reduces the experiments to the first order process. Boiling produced a flow of vapor with entrained liquid drops. The superheating of the experimental liquid can be likened to the supersaturation of water in magma, and the liquid boiling to the exsolution of water from magma. The emerging gas phase expands, entrains liquid droplets and rapidly accelerates the flow. These experiments showed the development of a sharply defined plane at which explosive boiling occurred.

The addition of inert particles to a volatile liquid [113] reduces the proportion of volatile phase and maintains particles in the post-fragmentation flow. Decompression, combined with the imposition of a steep pressure gradient within a centrifuge, results in a well-defined fragmentation front when decompressions are large. However, the mass of inert material acts to reduce post-fragmentation acceleration thus maintaining pressure and suppressing heterogeneous bubble growth below the fragmentation front. Small decompressions result in bubble nucleation on the inert particles throughout the mixture, illustrating that system behavior depends on the rates at which processes respond to imposed changes. Although these experiments probably represent end-member behavior, they provided a tantalizing glimpse of possible explosive fragmentation mechanisms that may operate in volcanic conduits given suitable conditions.

Volcanically, only a few weight percent of the magma degasses to drive the flow, whilst boiling experiments represent an extreme expression of degassing flows where all the liquid can change phase to gas. Experiments that retain low liquid viscosity and Newtonian rheology, but degas only a fraction of their mass, extend our knowledge of degassing flows and are likely to behave in a different, possibly more volcanic fashion. Mader et al. [78,79] rapidly generated bubbles of  $\text{CO}_2$  in water, and throughout the fluid rather than just at the top interface. In volcanic systems,

if bubbles nucleate and grow on timescales over which they can rise and escape then significant fluid expansion does not occur. However, if the  $\text{CO}_2$  can be experimentally generated with sufficient supersaturation to drive bubble growth on timescales much shorter than those needed for bubble rise, then the two-phase mixture rapidly expands and fragments in a ductile fashion, producing liquid and foam drops suspended in gas, as the gas volume fraction increases. Two methods were used to achieve  $\text{CO}_2$  supersaturation up to 455 times ambient. Water was saturated in  $\text{CO}_2$  and decompressed in a shock tube developing high supersaturations. An alternative approach used rapid chemical reaction between  $\text{K}_2\text{CO}_3$  and  $\text{HCl}$  to generate a supersaturated  $\text{CO}_2$  solution. An intriguing positive feedback mechanism was observed whereby agitation of the liquid by the growing gas bubbles enhanced the release of gas thus increasing the violence of the flow. It was found that considerable expansion and acceleration took place before the major change in flow pattern induced by fragmentation. This contrasts with brittle systems that tend to fragment then expand [53]. Accelerations approached  $180\text{ g}$  and were proportional to volatile supersaturation; velocities peaked at  $15\text{ m s}^{-1}$ , and strain rates were in the region of  $30\text{ s}^{-1}$ . These are considered to be in the same range to those experienced volcanically and indicate a degree of similarity between laboratory and natural systems, with strain rates suggesting that high-viscosity magmas will be fragmenting in brittle fashion.

Injection apparatus in the chemical mixing experiments introduces discontinuities in the tube geometry and this appears to play a role in the behavior of the flow. Mader et al. [80] carried out relatively sustained explosive experiments, lasting about  $1.5\text{ s}$ , where a considerable volume of carbonated water was decompressed. The vessel used was a round-bottomed flask. The discharge rate of water was found to fluctuate because of flow instabilities at the base of the flask neck, probably accompanied by pressure fluctuations. The flask neck was also found to pin the point of fragmentation as the flow evolved, with similar results being found by Zhang [129]. These experiments demonstrated the importance of sustained flows in allowing quasi-steady behavior to emerge, as well as demonstrating that conduit geometry influences flow patterns.

Although water- $\text{CO}_2$  experiments illuminate the behavior of explosively degassing systems, water is many orders of magnitude less viscous than magma. Zhang et al. [132] investigated the role of viscosity by adding polymers to the water, increasing liquid viscosity by between 1 and 3 orders of magnitude. Degassing styles ranged between passive degassing with little or no expan-

sion for low supersaturation decompressions, through to rapidly expanding and fragmenting flows when pressure reduces by a factor of 50 or more on decompression. Bubbles were found to appear uniformly throughout the liquid on decompression, and were considered to be the result of heterogeneous bubble nucleation on minute particles in the liquid. This differs from boiling liquid flows and is more consistent with heterogeneous bubble nucleation on crystals in magmas. Initial acceleration of the liquid was found to be constant if ambient pressure was constant, with bubbles growing as  $time^{2/3}$ . Viscosity was found to be less important than the dissolved gas content in determining explosive capability, indicating that the low solubility of  $\text{CO}_2$  in magmas made explosive eruptions driven solely by  $\text{CO}_2$  unlikely. Experimental bubble growth was found to match well with models formulated for bubbles in magma, adding to confidence that the experimental system was, at least in part, similar to the natural phenomena.

Taddeucci et al. [116] increased complexity by carrying out degassing experiments with a viscoelastic analogue material, i. e., one that can change from viscous liquid to brittle solid behavior as strain rate increases. The silicate analogue was polydimethyl siloxane, with various additives, sold commercially as ‘Silly Putty’. Silly Putty is a dilatant material with yield strength, and is viscoelastic [26]. The volatile analogue was the inert gas Argon, which had minimal effect on the rheology of the Silly Putty. Pressures up to  $10\text{ MPa}$  were also found to have minor effect on rheology. The apparatus used was similar to the ‘Fragmentation Bomb’ (Fig. 8) used for decompression of non-degassing samples; however, because the Silly Putty experiments were carried out at room temperature, a visibly transparent shock tube could be used to facilitate high-speed imaging. Samples were loaded into the base of the shock tube, then exposed to Ar gas at pressures varying between  $4$  and  $13\text{ MPa}$ , for times between  $5$  and  $340$  hours, then rapidly decompressed to  $0.1\text{ MPa}$ .

Figure 22 shows the flow response on a depressurization of  $11\text{ MPa}$  after  $5.7$  hours of exposure to Ar gas. On decompression, a small upward bulging of the sample surface was followed by detachment of the upper part of the sample from the tube walls. This is indicated by the change in wall refraction between Figs. 22c and 22d as the Silly Putty ‘unsticks’ from ‘wetting’ the tube wall and allows a thin film of gas to change the refractive index structure of the interface. The detachment possibly represents a solid-like radial contraction to axial extension (Poisson’s ratio) caused by elastic expansion of the bubble-free sample on decompression. Alternatively, the momentary appearance of doming of the sample surface suggests a significant degree of friction with the tube wall and the

Volcanic Eruptions, Explosive: Experimental Insights, Figure 22

An 11-MPa rapid decompression of viscoelastic 'Silly Putty', saturated with Ar gas (Taddeucci et al. [116]), resulted in an expanding degassing flow. The domed flow top indicates the presence of significant wall friction, despite optical indication that the "Silly Putty" did not wet the tube wall during expansion (compare images c and d). Constant velocity expansion then occurred (e to h) with a circumferential fracture forming near the flow front at g. Flow front oscillation is apparent between g and h, but no concurrent pressure data are reported. From h, the flow front velocity increases dramatically as pervasive brittle fractures appear in the flow margin (i and j) where strain rates are highest. Fragmentation did not occur because the fractures did not propagate through the flow center where strain rates were low and viscous behavior persisted. The fractures could then close and heal due to viscous flow once strain rate declined. These experiments give valuable insight into the process of margin fracture, which could provide an efficient means for gas escape, thus suppressing explosive behavior. They also demonstrate a mechanism of generating fluctuations in magma effusion rate. At volcanic scale, margin fracture may be expected to generate a seismic response, and field evidence of such processes exists (Tuffen and Dingwell [122]). Reprinted with kind permission from Elsevier

generation of high strain rate; the Silly Putty wetting of the tube wall breaks down, but wall friction remains significant. Bubbles nucleate and start to expand. The sample surface domes up, suggesting that despite detachment, wall friction is still appreciable (compare with Fig. 20). The sample then expands and develops fractures at the tube wall. Sharp fractures near the flow head were defined as 'rim fractures', with other more numerous and widespread fractures called 'pervasive fractures'. These fractures represent a solid-like response to the high strain rate imposed at the flow margin and give experimental support for a theoretical process proposed by Gonnermann and Manga [47] who postulated that fragmentation was occurring due to

viscous shear along flow edges. The fracturing process may also create seismic signals [122] and act as a trigger for seismically detectable resonant phenomena. The fractures only propagate as far as strain rates maintain brittle behavior, which acts to confine fractures within the outer section of the flow. Fragmentation will occur if the strain rate is sufficient for brittle behavior to persist right to the center of the flow. The fractures were also observed to close and heal because, once formed, lower strain rates caused reversion to viscous behavior. The development of such fracture networks has significant implication for mechanisms of magma degassing. The continual formation and healing of margin fractures gives rapid access to the conduit mar-

gin for gas deeper in the flow. This has consequences for transitions between effusive and explosive behavior.

Only a few Silly Putty experiments underwent explosive fragmentation. All these were triggered at a sudden tube widening, emphasizing the importance of conduit geometry on flow behavior in volcanic systems. In comparison, similar decompressions of pre-vesiculated samples [53] resulted in much more extensive fragmentation. This demonstrates that, although there may be more gas dissolved in an unvesiculated sample than contained in the pores of another non-degassing sample, the pre-vesiculated material is more explosive. The process of bubble nucleation and diffusive growth provides a regulating mechanism on the effective maximum rate of decompression and reduces initial explosive activity. However, the continued supply of volatile into bubbles means that degassing flows are likely to expand more given sufficient time, but in the absence of geometric structures, will they fragment in a brittle solid manner?

The viscosity of the liquid phase in magma increases by several orders of magnitude (Fig. 1) as water degasses, also decreasing the strain-rates over which viscous flow turns to brittle solid behavior. Water and melt interact to change the lengths of silicate molecules and ‘lubricate’ differential molecular motion, hence changing viscosity. As an analogue material, gum rosin derives from removing volatile compounds from tree sap, leaving 3-ring aromatic hydrocarbons typified by abietic acid ( $C_{19}H_{29}COOH$ ). It is a glassy organic solid at room temperature, but melts in the region of 80°C, and becomes increasingly less viscous as temperature rises. Warm gum rosin behaves in a viscoelastic fashion (Bagdassarov and Pinkerton [10]), being brittle when deformed rapidly but viscous under more gentle treatment. Such behavior is phenomenologically similar to a silicate melt. Phillips et al. [97] found that certain oxygen-bearing organic solvents, such as acetone, dissolved in gum rosin to yield a liquid at room temperature. At concentrations below about 20% w/w solvent these appear to be true solutions [71], with a partial pressure of acetone below that of the pure liquid suggesting some chemical interaction; another phenomenological similarity to hydrated magma. The viscosity of this liquid was found to be a non-linear function of the acetone content of the solution, again similar to a hydrated silicate melt (Fig. 23). Decompression of gum rosin-acetone solution below the saturated vapor pressure of acetone (about 20 kPa at room temperature) was found to result in volatile degassing and consequent increase in liquid viscosity. Slow decompression resulted in the establishment of a degassing interface that consumed the liquid solution. No measures were taken to remove nucleation sites from

Volcanic Eruptions, Explosive: Experimental Insights, Figure 23 The viscosity of hydrated silicate melts changes non-linearly with water content (Fig. 1). One experimental system uses gum rosin as an analogy for silicate melt, and organic solvents such as acetone and diethyl ether instead of water. The degassing of gum rosin acetone (GRA) results in increasing liquid viscosity (lower scale), in similarity with the degassing of hydrated magma (upper scale) (Mourtada-Bonnefoi and Mader [90]). The volatile content between natural and analogue systems can be compared by quantifying in terms of moles of volatile per unit volume of liquid; 4% water w/w in magma equates to about 20% w/w acetone in gum rosin. The scales here are not matched on this basis. Reprinted with kind permission from Elsevier

the liquid, suggesting that nucleation was sensitive to pressure and was confined to a surface layer in the liquid. This is similar behavior to boiling experiments [50,113], where the reaction force from expansion of degassing volatile and accompanying liquid was considered to elevate pressure in the underlying liquid and suppress bubble nucleation and growth, therefore acting to confine rapid degassing to a thin interface. This process may not be as prevalent in  $H_2O-CO_2$  and Silly Putty systems because absolute pressures were larger, in relation to hydrostatic, than in gum rosin-acetone or boiling refrigerant experiments.

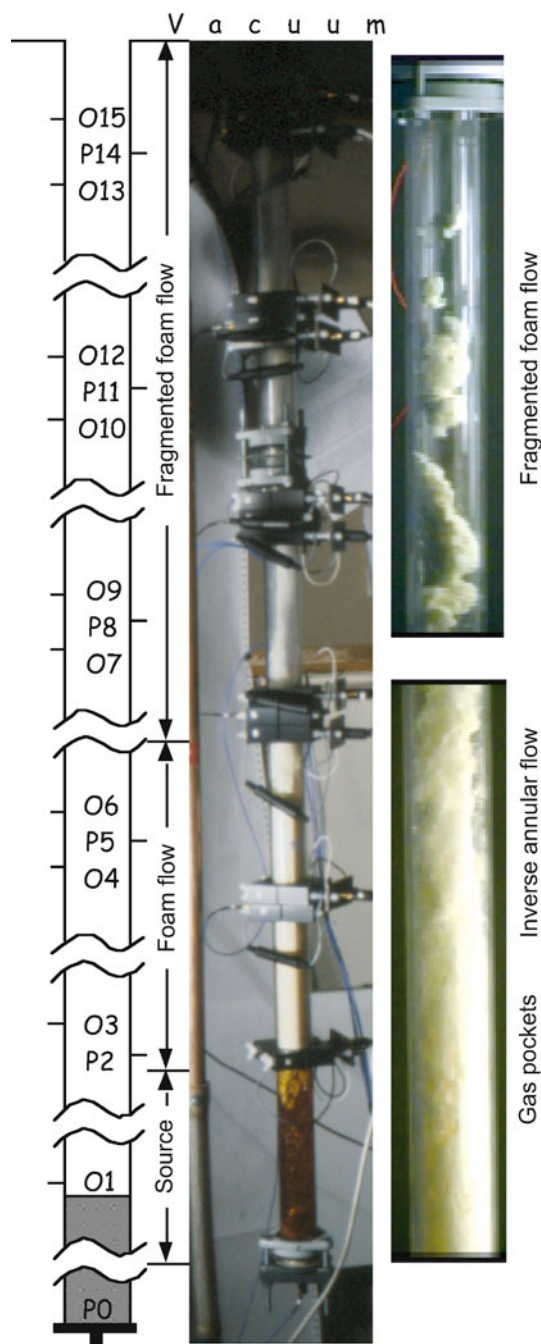

Rapid decompressions of gum rosin-acetone resulted in expanding foam growing from the liquid surface [97]. Flow-front acceleration was generally constant, except for large supersaturations with high acetone content where accelerations increased with time. These were reinterpreted by Mourtada-Bonnefoi and Mader [89] in the light of additional experiments that found bubble growth prior to fragmentation is diffusion-driven, but limited by the high-viscosity skins that develop around growing bubbles because of the reducing volatile concentration. This infers

that diffusion-limited degassing is unlikely before fragmentation removes viscous control as a physical mechanism. Accelerations and velocities using gum rosin-acetone were an order of magnitude less than those produced by CO<sub>2</sub>-H<sub>2</sub>O experiments, but this is consistent with the order of magnitude lower driving pressures. Experiments carried out with high supersaturations allowed extensive acetone degassing to take place. This resulted in the production of solid gum rosin foam with elongated bubbles, phenomenologically similar to woody or tube pumice.

The experiments of Phillips et al. [97] were carried out using small volumes of solution in un-instrumented and relatively short tubes that did not allow sufficient time or length for flow patterns to develop and stabilize. Lane et al. [70] carried out similar experiments using longer tubes, larger volumes of gum rosin-acetone and gum rosin-diethyl ether solutions, and high-speed pressure measurement. Instantaneous decompression from 10<sup>5</sup> to 10<sup>2</sup> Pa resulted in rapid degassing from the liquid surface. Flow became pseudo-steady after about 0.2 s, with foam expanding from the liquid interface, and continued explosive behavior for about 1.5 s. Pockets of gas developed at the tube wall, eventually merging to allow the expanding foam to detach from the wall. Removal of wall drag allowed the foam core to accelerate as an inverse annular, or detached flow, and break up into foam fragments that were ejected from the top of the shock tube (Fig. 24). The fragmentation of the foam core was precluded during expansion of a non-degassing system [93], suggesting that degassing systems have different flow patterns to those driven by gas expansion alone. The reason for this difference may lie with the smaller overpressure in bubbles of pseudo-steady degassing systems compared with those in transient expanding flows. The lower bubble pressures prevent bubble wall breakage and stabilize detached flow until fragmentation commences [93]. This suggests that flow behavior preceding fragmentation may differ between explosive volcanism triggered by rapid decompression of vesiculated magma, for example the May 18, 1980 Mt. St. Helens lateral blast triggered by a landslide, and sustained explosive volcanism such as the Plinian eruption which followed the blast. The fragmentation mechanism may also be different, with brittle spalling fragmentation before expansion (Figs. 9, 16 and 17) suggested for the lateral blast and fluid expansion before ‘plastic’ fragmentation (Figs. 19, 20 and 24) for the Plinian eruption.

The size of fragments of gum rosin foam was initially significantly smaller than tube diameter, but increased to near tube diameter and elongated with time, suggesting a declining flow energy. Interestingly, some of the flow features found by Cagnoli et al. [25] in expanding parti-

Volcanic Eruptions, Explosive: Experimental Insights, Figure 24 An 0.1-MPa rapid decompression of a solution of gum rosin 19% w/w diethyl ether generates a degassing flow (Lane et al. [70]). Bubble growth occurs predominantly at the upper liquid surface. The expanding flow develops gas pockets at the wall, which merge and allow a central foam core to detach from the tube wall giving inverse annular flow. The detached foam core is no longer constrained by wall drag and expands until it breaks up to give a fragmented flow. The fragments of gum rosin foam are ejected from the shock tube. Reprinted with kind permission of AGU

cle beds appear similar to those in expanding gum rosin foams, with bubbles appearing at the margins of both flows and being stretched out (Fig. 15). The sequence of flow pattern changes in the gum rosin flows was found to result in the generation of characteristic pressure fluctuations. Pressure fluctuations may be inherent in the unsteady nature of flows undergoing changes in behavior and such phenomena could be detectable by seismic means during volcanic flow.

Magma can fragment in the presence of pre-existing bubbles alone without any degassing (e. g., Fig. 9), and the presence of crystals increases the number density of nucleation sites (e. g., Fig. 4), and hence the surface area over which degassing can occur. Magmas are decompressed with crystals and bubbles often present, an aspect investigated analogously by Mourtada-Bonnefoi and Mader [90] using gum rosin-acetone mixtures and a variety of particles and existing bubbles. It was found that fragmentation occurred at lower volatile contents and lower decompressions in the presence of particles and bubbles. It was also found that flow behavior depends on the distribution of particles in the liquid, with more rapid degassing where particle concentrations were high. This suggests that heterogeneity in the distribution of crystals and pre-existing bubbles will develop into sizable features within a degassing flow, at least before fragmentation. This raises the possibility that flow heterogeneity over a range of size scales may then play a role in the fragmentation process.

**Low VEI Events** High VEI events do not occur very frequently compared to anthropogenic timescales, and do not lend themselves readily to detailed field investigation of subterranean flow processes. Conversely, low VEI events, typified by Strombolian activity, occur on anthropogenically short timescales and form relatively safe natural laboratories to study magma flow in the volcanic conduit. Low VEI eruptions commonly occur at volcanoes where magma viscosity is low and degassing water is able to separate relatively easily from the magma; indeed, this separation is required to produce low VEI events. Analogue experiments of separating flows may, therefore, be compared with relatively well-studied natural processes in ways that high-VEI events cannot. Experimental conditions are also simplified in relation to those applied to high-VEI processes, with the assumptions that liquid rheology and temperature remain constant being easier to justify. Low-VEI processes may also be studied without shock tube or high-pressure apparatus, making observation and measurement more straightforward.

Strombolian eruptions are characterized by short-lived explosive events that erupt significantly higher water to sil-

icate mass ratio than that of the bulk magma [15,30]. These events are separated by longer periods of relative quiescence, suggesting the presence of a gas separation process that produces gas-rich regions that rise up the conduit between intervals of relatively gas-depleted magma. In two-phase flow terminology, one such regime is that of slug flow, where large ascending gas slugs can form from the coalescence of many much smaller bubbles. However, evidence from extensive research on water-gas systems indicates that for such a flow pattern to be stable in the conduit the overall gas volume fraction would probably need to exceed about 0.25 [34], and the time intervals between explosions would be similar to, or less than explosion duration. It is also very questionable that slug flow would form from numerous small bubbles in a relatively high viscosity liquid like basalt magma. This suggests that other mechanisms operate to promote formation of gas slugs. Jaupart and Vergnolle [63,64] were among the first to recognize that volcanic conduits are not straight vertical tubes, but exhibit significant geometrical heterogeneity that may play a major role in eruptive behavior. Experiments were carried out to examine the effect of a flat roof in trapping the numerous small bubbles rising through the magma (Fig. 25). Small air bubbles were injected at variable rate into the base of a tank containing liquids of various viscosities. The bubbles rose to the roof of the tank, which had a vertical small diameter outlet tube. Three modes of system behavior were observed. At lower liquid viscosity, a raft of bubbles formed at the roof. At some critical thickness the bubble raft collapsed on the scale of the tank roof and flowed up the outlet tube as a large gas bubble. This behavior was considered analogous to Hawaiian eruptions. At higher liquid viscosities, the bubble raft collapsed on a scale smaller than the tank roof and a series of bubbles that are much larger than those injected, but smaller than the low viscosity case, emerge up the outlet pipe. This gives insight into Strombolian eruptive activity. The final mode of behavior was the development of a relatively stable bubble raft and the escape of small bubbles up the outlet pipe to give bubbly flow at the surface.

The ascent of large gas bubbles, or slugs, up a tube can be controlled by surface tension, liquid viscosity or liquid inertia. In basaltic systems surface tension has negligible control, and inertia dominates with some component of viscous influence [106]. Conveniently, this allows the use of water and air at laboratory scale to give inertia-controlled slug flow. Seyfried and Freundt [106] carried out experiments applying the flow patterns that develop with increasing air flux through a column of water to basaltic volcanism. Single gas slug ascent was found to only occur through sudden incidents of limited volume

Volcanic Eruptions, Explosive: Experimental Insights, Figure 25 Numerous small nitrogen bubbles rising in a silicone oil of viscosity  $1 \text{ Pa s}$  (Jaupart and Vergnolle [63]) encounter a structural discontinuity in the form of the horizontal roof of the experimental tank. Bubbles trapped under the roof collide and coalesce to emerge up the narrow exit pipe as much larger bubbles. Such a mechanism can be envisaged for the production of large bubbles some  $1\text{--}3 \text{ km}$  beneath the vent at Stromboli volcano (Burton et al. [21]); however, the experimental geometry canonically demonstrates the process rather than simulating conduit structure. Large bubbles emerging from the trap then expand and become overpressured on approach to the surface (James et al. [61]). Reproduced with kind permission of Cambridge University Press

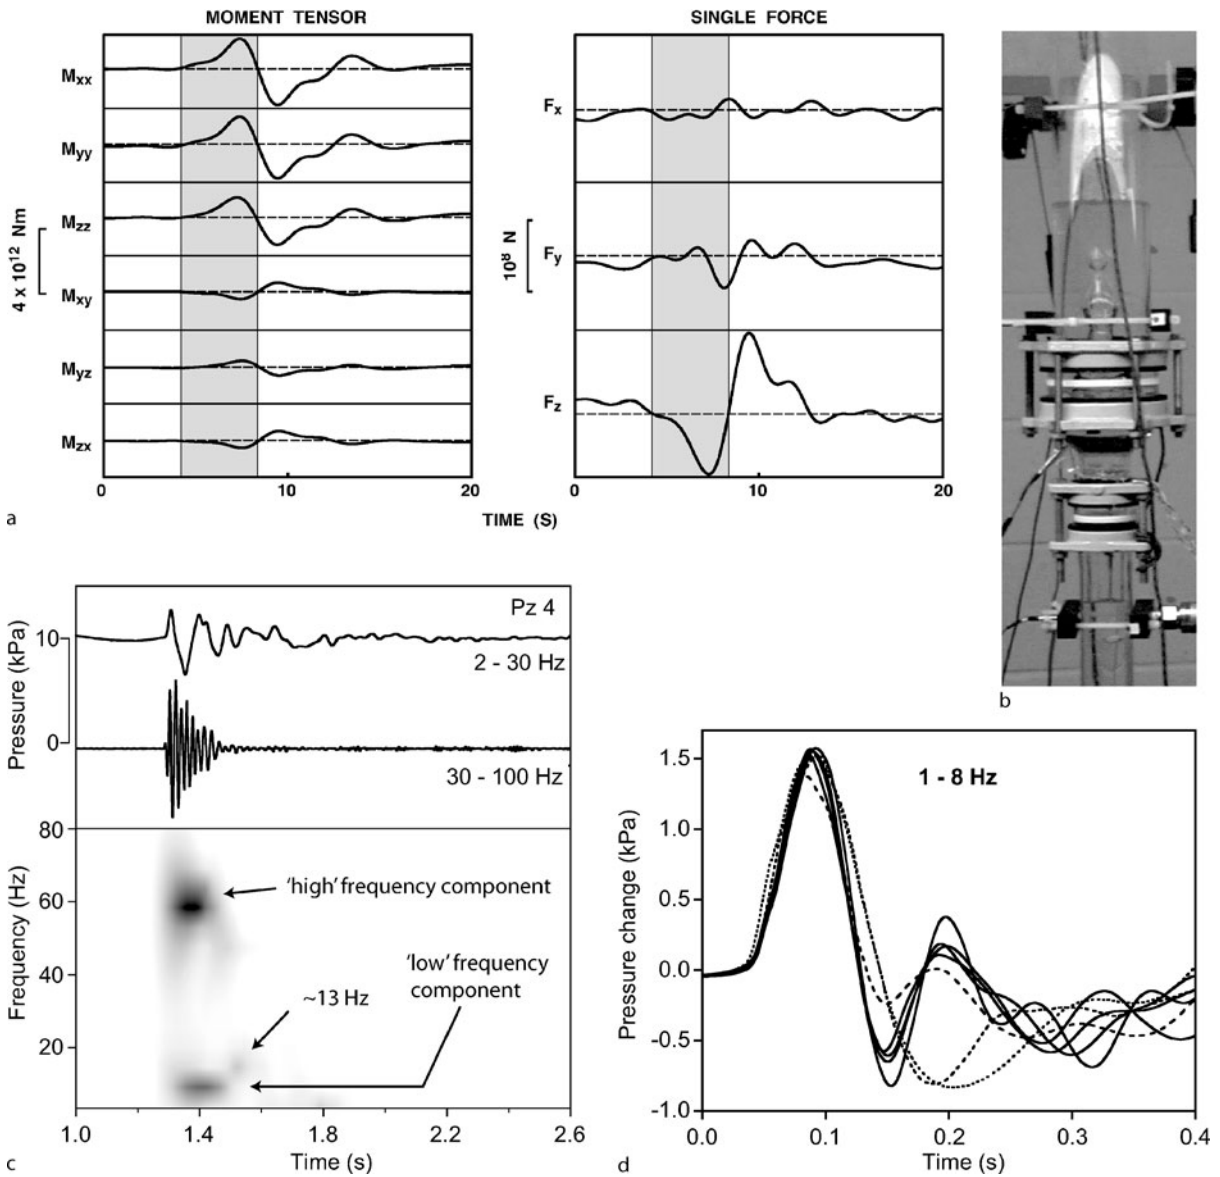

gas release, with one mechanism being that of foam collapse from a trap [63,64]. It was observed that slug burst in the tube was a gentle process, but that if the liquid level was in the reservoir atop the tube (akin to a lava lake) then burst was more vigorous and could be likened to Strombolian activity; another example of the impact of conduit geometry on flow. Experiments with gas traps in the water column found that the coalescence of trapped gas pockets resulted in significant pressure oscillations that were a potential source mechanism for volcanic tremor; linking

volcano-seismic signals to fluid flow could be a powerful method of experimental scaling inaccessible in high VEI events.

Seismic signals may result from the collapse of a foam layer trapped at a roof. Measurements made within apparatus similar to that of Jaupart and Vergnolle [63,64] reveal pressure fluctuations both within the fluid and in the air above the fluid surface in the outlet tube [102]. These could be linked to seismic and acoustic signals measured at Stromboli volcano and give insight into the role of fluid-flow on the generation of seismo-acoustic waves during explosive volcanism. During the build up of the foam layer, no pressure changes were detected. Collapse of the foam layer and motion of the gas slug up the outlet pipe produced pressure changes in the liquid tank of a few-hundred Pa, and of a few-tenths Pa in the air above the liquid level. Collapse of the foam layer generates upward gas flow in the outlet pipe thereby producing downward motion of the dense liquid phase in the outlet pipe, reducing pressure. Oscillation of liquid on the gas spring of the slug produces pressure oscillations within and above the liquid. Slug burst results in a sudden increase in oscillation frequency above the liquid, and a small pressure pulse in the liquid due to decay of liquid flow around the slug nose [59]. Ripepe et al. [102] postulate that seismic signals measured at Stromboli are generated during rapid gas expansion during foam collapse, and estimated that the slug be about  $4.5 \text{ m}$  long and induce a pressure drop of  $0.1 \text{ MPa}$  in the magma.

Inversion of highly repeatable seismic waveforms measured at Stromboli Volcano, Italy [31,33] has enabled imaging of the conduit as well as revealing the forces and pressures being created by magma flow during Strombolian eruptions. In summary, Stromboli's plumbing system appears to comprise a dyke dipping about  $72^\circ$  that runs from the vent system to an intersection with a dyke dipping about  $45^\circ$  and  $900 \text{ m}$  below the vent system. Stable and repeatable seismic sources are inferred at a depth of about  $220 \text{ m}$  below the vent system, and have the characteristics of a dyke segment intersecting the main conduit. Another, weaker, seismic source is located at the intersection of the two main dykes about  $900 \text{ m}$  below the vents. The dominant seismic source at  $220 \text{ m}$  below vent generates a downward vertical force of about  $10^8 \text{ N}$  followed by an upward force of similar magnitude (Fig. 26a). The source volume increases during the downward force and decreases with the upward force. These measurements provided a means of testing laboratory models of Strombolian eruptions.

James et al. [59] studied pressure oscillations resulting from the ascent of single gas slugs in a vertical tube.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 26  
 The geometry of experimental tubes has been observed to change flow behavior in a number of instances. James et al. [60] investigated the dynamics of a gas slug ascending through a tube widening. Inversion of seismic data measured at Stromboli volcano (a, Chouet et al. [31]) indicated an initial downward force of about  $10^8$  N, accompanied by pressure increase expanding the conduit. This was followed by upward force and conduit contraction with a period of about 10 s. The experimental ascent of a gas slug through a tube widening (b) caused breakup of the slug and production of a transient gas jet. Spectral analysis of pressure (c) showed three resonant components. The low frequency component (d, about 6 Hz) showed one to two cycles of pressure increase followed by decrease, qualitatively consistent with pressure change in the conduit at Stromboli during explosive eruption. Measurement of apparatus displacement indicated a peak downward force of 30 N, which when naively scaled by  $100^3$  for physical dimension and 2.5 for density difference gives a force of  $7.5 \times 10^7$  N, encouragingly close to that estimated from seismic inversion. Reprinted with kind permission of AGU

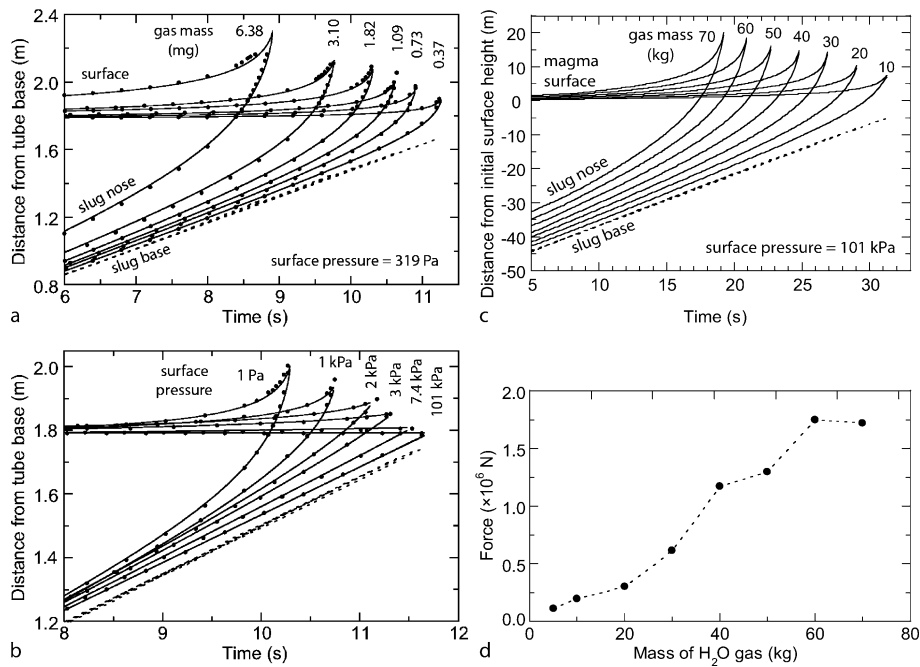

Volcanic Eruptions, Explosive: Experimental Insights, Figure 27

Strombolian eruptions are short-lived, periodic and have high volatile content. For these reasons they are associated with the formation, ascent and bursting of large bubbles of water vapor (often known as slugs), rather than the expansion of a vesicular magma (Fig. 21). The ascent of air slugs in water during small-scale experiments caused pressure oscillations (James et al. [59]). A spectrogram (gray shading) of band-passed (upper trace) pressure data (lower trace) was found to match well with calculations of the oscillation frequency (white trace) of the water above the gas slug bouncing resonantly on the gas slug. This oscillatory mechanism could not be used to account for the seismic signals used to image the conduit at Stromboli (Chouet et al. [31]). Reprinted with kind permission from Elsevier

The oscillations observed at the top of the liquid column (Fig. 27) showed an increasing amplitude and decreasing period as the slug ascended, with oscillations ceasing as the slug reached the surface. Burst of the meniscus produced further pressure fluctuation. Modeling of the oscillations revealed the source mechanism as bouncing of the liquid mass above the slug on the spring of gas within the slug. The observed pressure oscillations were not similar to the change in volume of the VLP seismic source at Stromboli (Fig. 26a), nor were oscillation amplitudes sufficient to account for forces of  $10^8$  N at volcanic scale. Bubble bursting was also quiescent rather than explosive.

Such experiments on Strombolian processes were not scaled for expansion of the gas slug as it rises, and gas chemistry suggests that slug source depths could be in the range 900–2700 m (Burton et al. [21]). A slug ascending from 1000 m in magma will expand about 200 times to reach atmospheric pressure, but in the experiments expansions were in the region of 1.2. In order to investigate more appropriate values, James et al. [61] used low vapor-pressure vacuum pump oil as an analogue liquid and varied the ambient pressure above the liquid surface between  $10^5$  and 10 Pa. The reduction in ambient pressure provided a proxy for slug ascent from depth and allowed potential

gas expansions of factors up to  $10^4$ . The positions of the slug base, slug nose and liquid surface for ascending slugs of various gas masses and ambient pressures are shown in Fig. 28. Regardless of ambient pressure and slug mass, the ascent velocity of the slug base remained essentially constant. However, the slug nose accelerated rapidly on approach to the surface when ambient pressure was low, and burst with a pressure higher than ambient. Gas slugs that underwent little expansion burst at near ambient pressure. Scaling to the volcanic case was undertaken using experimentally verified CFD modeling. This showed that slug burst pressure is a function of conduit radius and slug mass, with large slugs in narrow conduits producing gas overpressures in the region of 1 MPa at burst. This overpressure will fragment the upward-moving (tens of  $\text{m s}^{-1}$ ) meniscus of liquid existing just prior to burst. The effect of such decompression on the vesiculated basalt magma flowing down the conduit walls and slug base could be explosive fragmentation (Namiki and Manga [94]). This would eject pyroclasts, adding greatly to the pyroclast volume from the meniscus and explaining how explosive slug burst results in the ejection of significant masses of pyroclasts. There is also the possibility that the gas slug is not a single bubble, but more accurately described as a foam

Volcanic Eruptions, Explosive: Experimental Insights, Figure 28

Experiments on slug flow are numerous in the engineering literature, but volcanic flows operate under conditions not investigated for anthropogenic purposes. One of these conditions is the large pressure change a gas bubble will experience in rising from some depth. James et al. [61] investigated the dynamics of rapid gas slug expansion as a result of this decompression using an air bubble and vacuum pump oil as analogue fluids. Using surface pressures below atmospheric allows the air bubble to undergo considerable decompression under laboratory conditions. The degree of slug expansion, and hence explosivity on burst, was found to depend on (a) the mass of gas in the slug as well as (b) the applied surface pressure. Computational fluid dynamic modeling was used to apply the experimental findings at volcanic scale (c). The process of slug expansion generated significant pressure change and vertical force (d), but the amplitudes are two orders of magnitude less than those calculated at Stromboli (Chouet et al. [31,33]). Reproduced with kind permission of the Geological Society of London

raft, although such a structure may not survive the degrees of expansion undergone in ascent from 1000 m depth with its bubble walls intact. The rapid 1 MPa decompression of a foam raft would also produce pyroclasts as the foam fragments.

Rapid slug expansion, which generates the explosivity of Strombolian eruptions, is a process operating within the top few tens of meters of the magma column (Fig. 28c). This, and the fact that the forces generated are of order  $10^6$  N upward, means that slug expansion is not the fluid dynamic source process responsible for the VLP seismic signals inverted by Chouet et al. [31]. Slug expansion probably plays little role in this particular seismic signal because the magma head is probably too large for the slug to be expanding at any appreciable rate. The stable position of the seismic source suggests geometric control of a flow process, a phenomena we have seen a number of times before. James et al. [60] measured pressure and force as a gas slug ascended from a narrow tube through a flare into

a wider tube. The gas slug segmented on passing through the flare and liquid flow during this process generated pressure oscillations (Fig. 29). Analysis of these oscillations (Fig. 26) revealed three components centered on 60, 13 and 6 Hz, with the low frequency component showing increasing pressure followed by a decrease, resembling the expansion-contraction waveform from inversion of VLP seismic data (Fig. 26a [31]). The vertical force generated during the experimental pressure increase was 30 N downward. Applying a simplistic scaling based on density and volume differences between laboratory and volcano gives a force in the region of  $10^8$  N, of similar magnitude to that emerging from inversion of VLP seismic data. It was, therefore, suggested that the source mechanism for VLP seismic signals measured at Stromboli by Chouet et al. [31] was the ascent of slugs sourced at depth [21] through a geometric widening of the feeder dyke inclined at  $72^\circ$ . The upward widening disrupts the downward flow of liquid around the ascending slug, allowing significant thicken-

Volcanic Eruptions, Explosive: Experimental Insights, Figure 29

The source mechanism suggested by laboratory experiment (Fig. 26) for seismic signals measured by Chouet et al. [31] at Stromboli Volcano, Italy is the creation and rapid deceleration of a downward-moving liquid piston, formed as a gas slug breaks up in a conduit widening (James et al. [60]). The liquid piston 'bounces' on the lower portion of the slug for a cycle or two before being consumed by the ascending remains of the original slug. The cartoon superimposed on the pressure trace correlates the position of gas bubbles with pressure measurement and spectral analysis of pressure fluctuations. The dramatic velocity increase of the slug nose does not appear to play an obvious role as a source mechanism and may be associated with the highly unstable bubble in the tube widening. Reprinted with kind permission of AGU

ing of the falling film. As this thickening falls through the downward narrowing, it pinches closed and segments the slug. The resulting liquid piston continues to descend because of its inertia, and increases pressure below it. The piston then oscillates for a cycle or two before being disrupted by the buoyancy of the gas beneath. Experimental insight suggests that the source mechanism for the VLP seismic signal is the deceleration of the liquid piston.

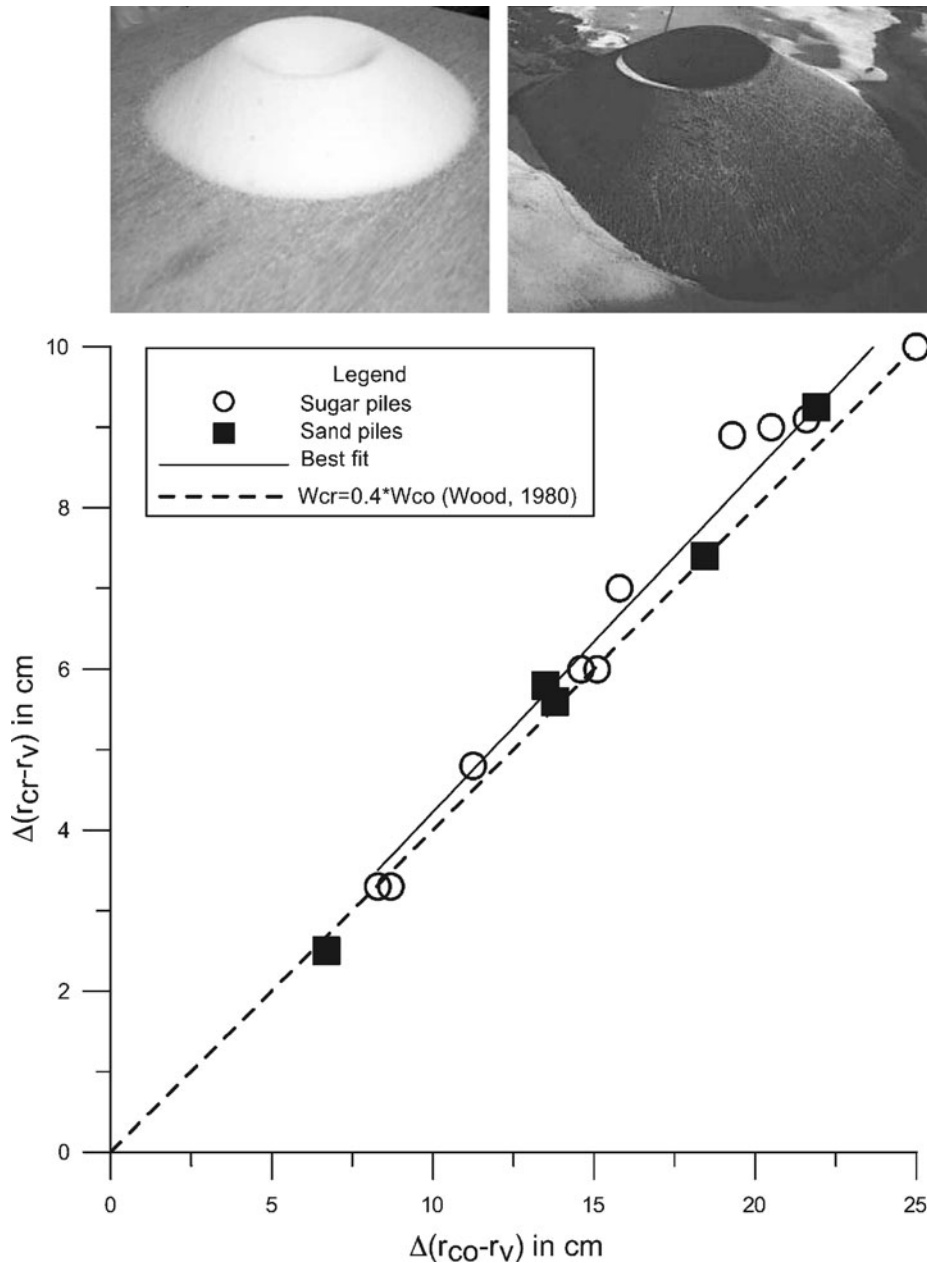

### Explosion Consequences

Various consequences of explosive degassing of magma have been studied by analogue means, and many of these are reviewed in Sparks et al. [109]. Here, we review a sample of more recent literature.

**Cinder Cones** Explosive volcanic eruptions produce pyroclastic constructs, the most common form being known as cinder or scoria cones. The basis for understanding

cinder cone growth was given by McGetchin et al. [85]. These structures, which are piles of generally unconsolidated magma fragments, are prone to gravitational collapse and rapid erosion. To test the hypothesis that cinder cone geometry is controlled by the behavior of unconsolidated fragments, Riedel et al. [100] carried out small-scale analogue experiments using grains of sugar and sand. These were built into cones, drained in the center to represent the crater. These grain piles showed similar geometry to natural cinder cones (Fig. 30). Quantification of the geometry showed that analogue and natural cones were identical in shape to within 5%. This demonstrates that the angles of repose exert fundamental control on cinder cone geometry, with surface grain flow maintaining angle of repose during cone growth. The angle of repose nature of cinder cones emphasizes their vulnerability to erosion and collapse.

**Pyroclastic Flows** Pyroclastic flows 'hug' the ground because their density is greater than that of the atmosphere.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 30

Cinder cones are the proximal expression of fallout from explosive volcanic eruptions. Riedel et al. [100] found that small piles of sugar (left image) or sand look similar in shape to much large piles of cinder (right image). Comparison of characteristic dimensions of laboratory cones ( $r_{cr}$  is distance from central hole to crater rim,  $r_{co}$  is distance from central hole to pile extremity and  $r_v$  is vent radius) with established measurements of natural cinder cones confirms the similarity. These experiments showed that cinder cones grow by the surface transport of grains under gravity to leave the slopes at angle of repose. Reprinted with kind permission from Elsevier

Gravity then drives the pyroclastic material in a lateral fashion; hence pyroclastic flows are part of the family of gravity currents, and the sub-family of particle-driven flows that includes turbidity currents. The flow behav-

ior of pyroclastic flows, which result from explosive volcanism or dome collapse, has been investigated at laboratory scales using analogue materials for a number of years [109]. Gladstone et al. [46] experimentally examined

Volcanic Eruptions, Explosive: Experimental Insights, Figure 31

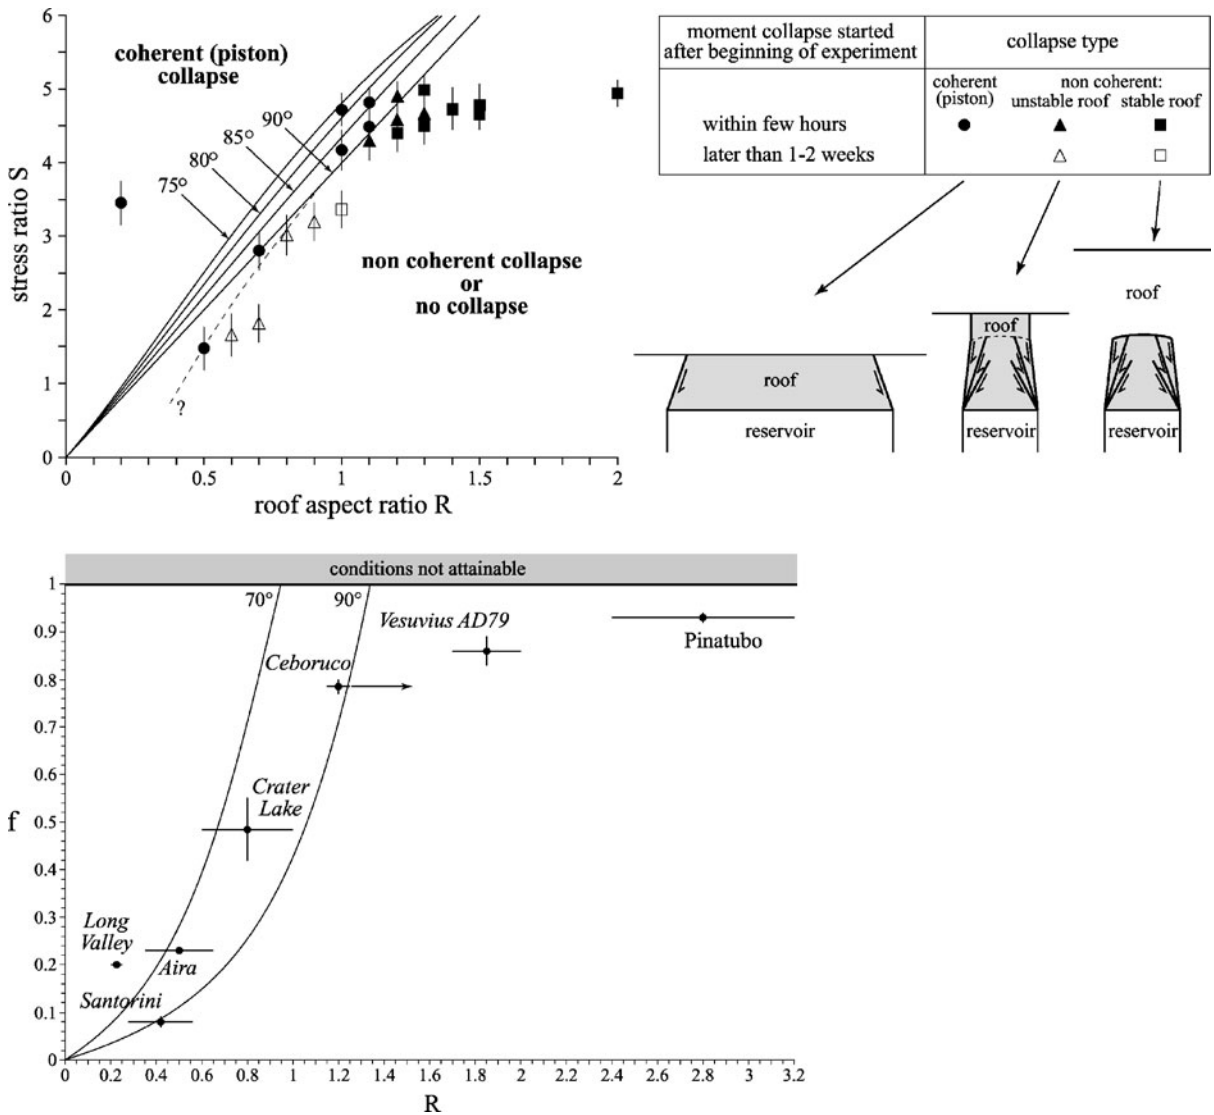

The first order behavior of gravity currents, which include pyroclastic flows, can be studied by analogue experiment using dyed brine solutions of different density propagating in a water-filled flume tank (Gladstone et al. [46]). Density stratification in the flow source material may be preserved under certain conditions of buoyancy and density (*left panel*). Pyroclastic deposits from such flows are likely to show vertical and horizontal stratification. Under other buoyancy and density conditions (*right panel*) the initial stratification is removed by turbulent mixing and resultant pyroclastic flow deposits are expected to be unstratified. Experiments that reduce complexity, as here by not including suspended particles, often give greater insight into primary controlling parameters. Complexity can then be added to understand the smaller scale processes that lead to diagnostic features identifiable in volcanic deposits. Reprinted with kind permission from Blackwell Publishing Ltd

the dynamics of gravity currents that were initially stratified in density using a 3 m long flume. A range of brine solutions of different density were layered into a lock at one end of the flume and released into tap water. The solutions were used singly, in two or three layers to investigate how stratification can develop or be homogenized in pyroclastic flows and turbidity currents. Flows were visualized by coloring the solutions allowing detection of mixing and stratification.

Flow behavior was found to depend on two dimensionless parameters. Firstly, the relative values of buoyancy between brine solutions,  $B^*$ , where most salt is in the lower layer for  $0 < B^* < 0.5$ , and in the upper layer for  $0.5 < B^* < 1$ . Secondly, the density ratio of the solutions,  $\rho^*$ , which is small for strong stratification, approaches 1 for weak stratification and equals 1 for unstratified conditions. When the lower layer has a greater proportion of the driving buoyancy ( $B^* < 0.5$ ), it can run ahead leading to flow stratification ( $\rho^*$  approaches 0, Fig. 31), or the layers can mix to produce a homogeneous current ( $\rho^*$  approaches 1, Fig. 31). If the upper layer is more buoyant ( $B^* > 0.5$ ), it travels to the nose of the current by mixing to produce a homogeneous flow ( $\rho^*$  approaches 1) or overtaking, leading to flow stratification ( $\rho^*$  approaches 0). This suggests that buoyancy-contrast controls separation, whilst density-contrast controls mixing. These observations give insights into the origin of stratification and grain size contrast in pyroclastic flow deposits and allow constraint of flow conditions from field observation.

**Caldera Collapse** The highest VEI eruptions result from the ejection of large volumes of magma. As magma emerges, country rocks overlying the magma storage area subside, resulting in the formation of a caldera. The caldera roof may fail in a number of modes. Roche and Druitt [103] carried out a force balance calculation for a caldera roof to fail as a coherent single piston, predicting that  $\Delta P/\tau_c \geq 4R$ , where  $\Delta P$  is the pressure below lithostatic at which failure occurs,  $\tau_c$  is the rupture shear stress and  $R$  is the ratio of roof thickness to diameter. Experiments were carried out using sand or a slightly cohesive sand-flour mixture as an analogue to country rock, and a draining reservoir of silicone fluid to simulate removal of magma. Comparison of experiment and theory (Fig. 32) shows that coherent roof collapse did occur in line with theoretical prediction. The experiments also showed two other more complex modes of collapse that occur at roof aspect ratios larger than the coherent collapse field, and that these collapse mechanisms may take considerable time to complete. Comparison of the experimental data with known parameters for seven calderas suggested that four had collapsed as coherent pistons, with the other collapses being non-coherent.

Experiments have helped to constrain possible volumes of caldera forming eruptions from pre-caldera conditions [44], showing a potentially powerful route of predicting the time and size of caldera-forming eruptions. Experiments were carried out using a bed of quartz sand as a rock analogue and a deflating water-filled latex bal-

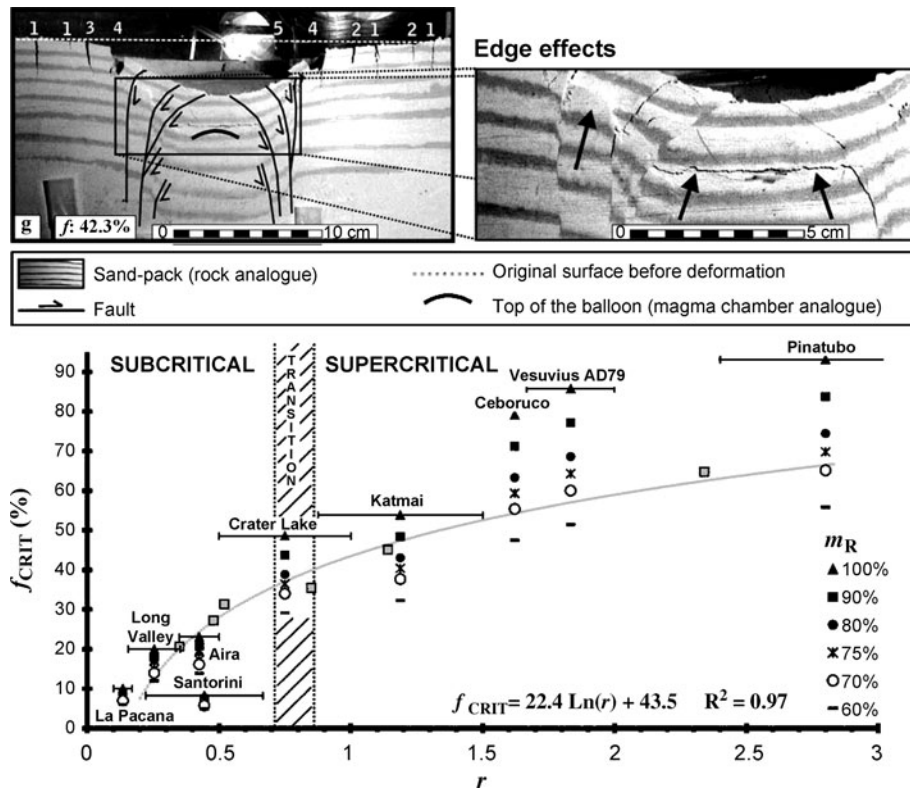

Volcanic Eruptions, Explosive: Experimental Insights, Figure 32

Large VEI eruptions may develop into caldera collapse as the country rock overlying the magma body subsides with pressure drop in the magma. Roche and Druitt [103] experimentally verified a model of coherent, piston-like formation of a caldera (upper left panel). Different modes of collapse were also found experimentally, some of which required significant time to elapse (upper right panel). This suggests that the roof of a deep, narrow magma body may not collapse simultaneously with eruption, but some time afterwards. Comparison of experimentally verified theory and estimates for proportion of magma erupted ( $f$ ) and roof aspect ratio ( $R$ ) in natural caldera collapses (bottom panel) indicate that coherent collapse does occur. Reprinted with kind permission from Elsevier

loon to represent the magma body. Extensive arguments are presented to justify application of the experimental results at volcanic scales. Coherent piston collapse was observed at low roof aspect ratios (roof thickness/diameter), becoming more non-coherent as aspect ratio increased. These experiments showed different fault structures and demonstrated the complex 3D nature of the faults that result from caldera collapse (Fig. 33). Fault development

was monitored as the balloon was drained to establish the sequence of events prior to, and during, caldera collapse. The relationship between the proportion of water drained from the balloon to make collapse inevitable ( $f_{crit}$ ) and the aspect ratio of the roof ( $r$ ) is empirically given as  $f_{crit} = 22.4 \ln(r) + 43.5$  (Fig. 33). Data from caldera-forming eruptions were compared to the experimental trend and found to be in reasonable agreement.

Volcanic Eruptions, Explosive: Experimental Insights, Figure 33

Geyer et al. [44] experimentally ascertained (*top panel*) the critical proportion of a magma chamber that must be erupted for caldera collapse to occur ( $f_{CRIT}$ ). This was related to the aspect ratio of the roof ( $r$ ) by an empirical equation. Experimental data (*gray squares*) were compared with values estimated for caldera-forming eruptions (*bottom panel*) for both subcritical (coherent or piston) collapse and supercritical (non-coherent) collapse. The estimated  $f_{CRIT}$  values are a function of the percentage of magma actually removable ( $m_R$ ). This work raises the possibility of being able to forecast the timing and volume of caldera collapse on the basis of previous eruption history and estimates of chamber depth and volume. Reprinted with kind permission from Elsevier

This suggests that the small-scale experiments mimic the first-order behavior of much larger-scale caldera collapse, but that there are issues of field measurement and second order process that require further investigation. Nevertheless, this work demonstrates the potential of being able to predict the onset and volume of caldera collapse from combining field observation and laboratory experiment.

### Future Directions

Experiments investigating processes that could occur both during, and as a consequence of, explosive volcanic eruptions are many and varied. All the experiments provide insight into volcanic processes because they are all analogous in certain aspects, whether in size in the case of experiments with natural materials, or with analogue materials as well. Curiosity into the fluid dynamics of degassing and

expanding multi-phase flows with non-Newtonian and viscoelastic materials will continue to expand knowledge over a wide parameter range of which volcanic processes form a small but motivating part. Experiments will form a key part of such research and will continue to inspire numerical models that can provide a data density unavailable experimentally. One future direction could be the development of experiments that use much greater volumes of fluid and run for longer time periods. This would be especially attractive using natural materials, but the apparatus and instrumentation challenge is considerable.

The richness of phenomena that emerge from this complex system suggests that volcanoes are individuals in their eruptive behavior, an observation common to field measurement of volcanoes. Eruption models will increasingly be tested by their ability to account for observed eruption phenomena, and linking of detailed field measurement, volcano-specific experimentation and a unified

modeling approach is one of the major current drivers of experimental volcanism. Highly instrumented volcanoes where measurement, in time and space, of such parameters as wide-spectrum ground and atmosphere motion, thermal outputs, chemistry and physics of magma components, electrical effects, flow rates and flow features are required to drive the understanding and forecasting of volcanic events; a task that, in general, becomes more challenging as VEI increases.

The role of experimental models is in providing a real system that can be repeated and measured in some detail. Computer modeling, verified by many experiments, may then be applied at volcanic scale. Quantitative comparison to field observation then tests the model system. Such combined tactics are likely to play a major role in the advancement of volcanology, and it is possible to envisage near real-time interpretation of field measurement in terms of fluid-dynamic, elasto-dynamic, atmospheric and chemical models built on the results of field, numerical and experimental volcanism. Such an autonomous system would be a major tool in quantifying fluid behavior in volcanic conduits and provide rapid assessment of changes taking place.

### Glossary

**Andesite** Magma or volcanic rock is characterized by intermediate SiO<sub>2</sub> concentration. Andesite magmas have rheological properties that are intermediate between basalt and rhyolite magmas. Silica content in andesites ranges from approximately 52 to 66 weight percent. Common minerals in andesite include plagioclase, amphibole and pyroxene. Andesite is typically erupted at temperatures between 800 to 1000°C. Andesite is particularly common in subduction zones, where tectonic plates converge and water is introduced into the mantle.

**Basalt** Magma or volcanic rock contains not more than about 52% SiO<sub>2</sub> by weight. Basaltic magmas have a low viscosity. Volcanic gases can escape easily without generating high eruption columns. Basalt is typically erupted at temperatures between 1100 to 1250°C. Basalt flows cover about 70% of the Earth's surface and huge areas of the terrestrial planets and so are the most important of all crustal igneous rocks.

**Bingham liquid** is a fluid that does not flow in response to an applied stress until a critical yield stress is reached. Above the critical yield stress, strain rate is proportional to the applied stress, as in a Newtonian fluid.

**Bubbly flow** A multi-phase flow regime, in which the gas phase appears as bubbles suspended in a continuous liquid phase.

**Conduit** A channel, through which magma flows towards the Earth's surface. Volcanic conduits can commonly be approximately cylindrical and typically a few 10's meters across or bounded by near parallel sides in a magma-filled fracture. Conduits can be vertical or inclined.

**Crystallization** Conversion, partial or total, of a silicate melt into crystals during solidification of magma.

**Degassing n. (degas v.)** The process by which volatiles that are dissolved in silicate melts come out of solution in the form of bubbles. Open- and closed-system degassing can be distinguished. In the former, volatiles can be lost or gained by the system. In the latter, the total amount of volatiles in the bubbles and in solution in the magma is conserved.

**Differentiation** The process of changing the chemical composition of magma by processes of crystallization accompanied by separation melts from crystals.

**Dome** A steep-sided, commonly bulbous extrusion of lava or shallow intrusion (cryptodome). Domes are commonly, but not exclusively, composed of SiO<sub>2</sub>-rich magmas. In dome-forming eruptions the erupted magma is so viscous, or the discharge rate so slow, that lava accumulates very close to the vent region, rather than flowing away. Pyroclastic flows can be generated by collapse of lava domes. Recent eruptions producing lava domes include the 1995–2006 eruption of the Soufrière Hills volcano, Montserrat, and the 2004–2006 eruption of Mount St. Helens, USA.

**Dyke** A sheet-like igneous intrusion, commonly vertical or near vertical, that cuts across pre-existing, older, geological structures. During magmatism, dykes transport magma toward the surface or laterally in fracture-like conduits. In the geologic record, dykes are preserved as sheet-like bodies of igneous rocks.

**Explosive eruption** A volcanic eruption in which gas expansion tears the magma into numerous fragments with a wide range of sizes. The mixture of gas and entrained fragments flows upward and outward from volcanic vents at high speed into the atmosphere. Depending on the volume of erupted material, eruption intensity and sustainability, explosive eruptions are classified as Strombolian, Vulcanian, sub-Plinian, Plinian or Mega-Plinian; this order is approximately in the order of increasing intensity. Strombolian and Vulcanian eruptions involve very short-lived explosions.

**Extrusive flow or eruption** A non-explosive (non-pyro-

clastic) magma flow from a volcanic conduit during a lava dome-building eruption or lava flow.

**Mafic** Magma, lava, or tephra with silica concentrations of approximately  $\text{SiO}_2 < 55\%$ .

**Magma** Molten rock that consists of up three components: liquid silicate melt, suspended crystalline solids, and gas bubbles. It is the raw material of all volcanic processes. Silicate magmas are the most common magma type and consist of long, polymeric chains and rings of Si–O tetrahedra, between which are located cations (e. g.  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Fe}^{2+}$ , and  $\text{Na}^+$ ). Anions (e. g.  $\text{OH}^-$ ,  $\text{F}^-$ ,  $\text{Cl}^-$ , and  $\text{S}^-$ ) can substitute for the oxygen in the silicate framework. The greater the silica ( $\text{SiO}_2$ ) content of the magma, the more chains and rings of silicate tetrahedra there are to impede each other and hence the viscosity of the magma increases. The pressure regime and composition of the magma control the minerals that nucleate and crystallize from a magma when it cools or degasses.

**Magma chamber** A subsurface volume within which magma accumulates, differentiates and crystallizes. Igneous intrusions can constrain the form and size of some magma chambers, but in general the shape and volume of magma chambers beneath active volcanoes are poorly known. Magma reservoir is an equivalent term.

**Melt** Liquid part of magma. Melts (usually silicate) contain variable amounts of dissolved volatiles. The primary volatiles are usually water and carbon dioxide.

**Newtonian liquid** A liquid for which the strain rate is proportional to the applied stress. The proportionality coefficient is called the viscosity.

**Microlite** Crystal with dimensions less than 100  $\mu\text{m}$ . Usually microlites crystallize at shallow levels of magmatic system.

**Phenocryst** Crystal with dimensions larger than 100  $\mu\text{m}$ . Usually phenocrysts grow in magmatic reservoirs prior to an eruption and or are entrained by magma in the chamber.

**Pyroclastic flow or surge** A gas-particle flow of pyroclasts suspended in a mixture of hot air, magmatic gas, and fine ash. The flow originates by the gravitational collapse of a dense, turbulent explosive eruption column at the source vent, or by dome collapse, and moves down-slope as a coherent flow. Pyroclastic flows and surges are distinguished by particle concentration in the flow, surges being more dilute. Variations in particle concentration result in differences in the deposits left by flows and surges.

**Silicic** Magma, lava, or tephra with silica concentrations of approximately  $\text{SiO}_2 > 55\%$ . The magmas are com-

monly rich in Al, Na- and K- bearing minerals. Silicic magmas are typically very viscous and can have high volatile contents. Rhyolite is an example of a silicic magma.

**Volatile** A component in a magmatic melt which can be partitioned in the gas phase in significant amounts during some stage of magma history. The most common volatile in magmas is water vapor  $\text{H}_2\text{O}$ , but there are commonly also significant quantities of  $\text{CO}_2$ ,  $\text{SO}_2$  and halogens.

### Definition of the Subject

We consider the process of slow extrusion of very viscous magma that forms lava domes. Dome-building eruptions are commonly associated with hazardous phenomena, including pyroclastic flows generated by dome collapses, explosive eruptions and volcanic blasts. These eruptions commonly display fairly regular alternations between periods of high and low or no activity with time scales from hours to years. Usually hazardous phenomena are associated with periods of high magma discharge rate, thus, understanding the causes of pulsatory activity during extrusive eruptions is an important step towards forecasting volcanic behavior, especially the transition to explosive activity when magma discharge rate increases by a few orders of magnitude. In recent years the risks have increased because the population density in the vicinity of many active volcanoes has increased.

### Introduction

Many volcanic eruptions involve the formation of lava domes, which are extrusions of very viscous, degassed magmas. The magma is so viscous that it accumulates close to the vent. Extrusion of lava domes is a slow and long-lived process, and can continue for many years or even decades [71,83,85]. Typical horizontal dimensions of lava domes are several hundred meters, heights are of an order of tens to several hundred meters, and volumes several million to hundreds of million cubic meters. Typical magma discharge rates (measured as the increase of dome volume with time in dense rock equivalent (DRE)) can reach up to 20–40  $\text{m}^3/\text{s}$ , but are usually below 10  $\text{m}^3/\text{s}$  [83].

Dome-building eruptions are commonly associated with hazardous phenomena, including pyroclastic flows and tsunamis generated by dome collapses, explosive eruptions and volcanic blasts. Dome-building eruptions can also contribute to edifice instability and sector collapse, as occurred on Montserrat on 26 December 1997 [87]. Lava dome activity can sometimes precede or follow major explosive eruptions; the eruption of Pinatu-

bo, Philippines (1991) is an example of the former [37], and the eruption of Mount St. Helens, USA (1980–1986) is an example of the latter [89].

Several lava dome eruptions have been documented in detail and show quite complex behaviors. Substantial fluctuations in magma discharge rate have been documented. In some cases these fluctuations can be quite regular (nearly periodic), as in the extrusion of lava in 1980–1982 on Mount St. Helens [89] and in the 1922–2002 activity of the Santiaguito lava dome, Guatemala [35]. In these cases, periods of high magma discharge rate alternate with longer periods of low magma discharge rate or no extrusion. In some volcanoes, such as Shiveluch, Kamchatka, the intervals of no extrusion are so long compared with the periods of dome growth that the episodes of dome growth have been described as separate eruptions of the volcano rather than episodes of the same eruption. Other dome-building activity can be nearly continuous and relatively steady, as observed at Mount St. Helens in 1983 [89] and at the Soufrière Hills Volcano, Montserrat between November 1999 and July 2003. In yet other cases the behavior can be more complex with quite sudden changes in magma discharge rate, which cannot be related to any well-defined regularity or pattern (e.g. Lascar volcano, Chile, [57]).

Pauses during lava dome-building eruptions are quite common. For example, at Mount St. Helens there were 9 pulses of dome growth with a period of  $\sim 74$  days, a duration of 1–7 days and no growth in between [89]. The Soufrière Hills Volcano Montserrat experienced a long (20 months) pause in extrusion after the first episode of growth [72]. On Shiveluch volcano in Kamchatka episodes of dome growth occurred in 1980, 1993 and 2000, following a major explosion in 1964 [28]. Each episode of dome growth began with magma discharge rate increasing over the first few weeks to a peak of 8–15 m<sup>3</sup>/s, with a gradual decline in magma discharge rate over the following year. In between the episodes very minimal activity was recorded.

Fluctuations in magma discharge rate have been documented on a variety of time-scales from both qualitative and quantitative observations. Several lava dome eruptions are characterized by extrusion of multiple lobes and flow units [68,94]. In the case of the Soufrière Hills Volcano, extrusion of shear lobes can be related to spurts in discharge rate and is associated with other geophysical changes, such as onset of seismic swarms and marked changes in temporal patterns of ground tilt [90,91,94]. These spurts in discharge rate have been fairly regular for substantial periods, occurring every 6 to 7 weeks over a 7 month period in 1997 [21,87,91]. These spurts are com-

monly associated with large dome collapses and pyroclastic flows and, in some cases, with the onset of periods of repetitive Vulcanian explosions [14,26]. Consequently the recognition of this pattern has become significant for forecasting activity for hazard assessment purposes. In the Soufrière Hills Volcano and Mount Pinatubo much shorter fluctuations in magma discharge rate have been recognized from cyclic variations in seismicity, ground tilt, gas fluxes and rock-fall activity [23,91,93]. This cyclic activity has typical periods in the range of 4 to 36 hours. Cyclic activity has been attributed to cycles of gas pressurization and depressurization with surges in dome growth related to degassing, rheological stiffening and stick-slip behavior [23,49,61,91,98].

Dome eruptions can show transitions to explosive activity, which sometimes can be linked to spurts in magma discharge rate. For example, in 1980, periodic episodes of lava dome extrusion on Mount St. Helens were initiated by explosive eruptions, which partly destroyed the dome that had been extruded in each previous extrusion episode [89]. At Unzen Volcano, Japan a single Vulcanian explosive eruption occurred in June 1991 when the magma discharge rate was at its highest [68]. At the Soufrière Hills Volcano, repetitive series of Vulcanian explosions have occurred following large dome collapses in periods when magma discharge rates were the highest of the eruption [26,88]. In the case of Lascar Volcano, Chile, an intense Plinian explosive eruption occurred on 18 and 19 April, 1993, after nine years of dome extrusion and occasional short-lived Vulcanian explosions [57].

Lava dome eruptions require magma with special physical properties. In order to produce a lava dome rather than a lava flow, the viscosity of the magma must be extremely high so that the lava cannot flow easily from the vent. High viscosity is a consequence of factors such as relatively low temperature (typically 750–900°C), melt compositions rich in network-forming components (principally Si and Al) efficient gas loss during magma decompression, and crystallization as a response to cooling and degassing. Viscosities of silica-rich magmas, such as rhyolites and some andesites, are increased by several orders of magnitude by the loss of dissolved water during decompression. Many, but not all, domes also have high crystal content (up to 60 to 95 vol%), with crystallization being triggered mostly by degassing [10,86]. In order to avoid fragmentation that leads to an explosive eruption, magma must have lost gas during ascent. Consider, for example, a magma at 150 MPa containing 5wt% of dissolved water decompressed to atmospheric pressure. Without gas loss the volume fraction of bubbles, will be more than 99%. Typical dome rock contains less than 20 vol% of bub-

bles, although there is evidence that magma at depth can be more bubble-rich (e. g., [13,74]). On the other hand, very commonly there is no change in temperature or bulk magma composition in the products of explosive and extrusive eruptions for a particular volcano. This suggests that the properties of magma that are conducive to the formation of lava domes are controlled by physico-chemical transformations that occurred during magma ascent to the surface.

Two other important factors that influence whether lava domes or flows form are topography and discharge rate. The same magma can form a dome if the discharge rate is low, and a lava flow if the rate is high [29,92]. The discharge rate is controlled by overall conduit resistance that is a function of viscosity, conduit size and shape, and driving pressure (the difference between chamber pressure and atmospheric pressure). Additionally the same magma can form a dome on low slopes, such as a flat crater (e. g. the mafic andesite dome of the Soufrière Volcano, St. Vincent; [40]) and a lava flow on steep slopes.

Prior to an eruption, magma is usually stored in a shallow crustal reservoir called a magma chamber. For several volcanoes magma chambers can be detected and characterized by earthquake locations, seismic tomography, petrology or interpretation of ground deformation data [55]. Typical depths of magma chambers range from a few kilometers to tens of kilometers. Volumes range from less than one to several thousand km<sup>3</sup> [55], but are usually less than a hundred km<sup>3</sup>. Magma chambers are connected to the surface by magma pathways called conduits. There is evidence that the conduits that feed lava dome eruptions can be both dykes or cylindrical. Dykes of a few meters width are commonly observed in the interior of eroded andesite volcanoes. Dyke feeders to lava domes have been intersected by drilling at Inyo crater, California, USA [56] and at Mount Unzen [67]. Geophysical studies point to dyke feeders; for example fault-plane solutions of shallow volcano-tectonic earthquakes indicate pressure fluctuations in dykes [75,76]. Deformation data at Unzen, combined with structural analysis, indicate that the 1991–1995 dome was fed by a dyke [68]. Dykes are also the only viable mechanism of developing a pathway through brittle crust from a deep magma chamber to the surface in the initial stages of an eruption [50,77].

Cylindrical conduits commonly develop during lava dome eruptions. The early stages of lava dome eruptions frequently involve phreatic and phreatomagmatic explosions that create near surface craters and cylindrical conduits [12,73,87,89,96,99]. These explosions are usually attributed to interaction of magma rising along a dyke with ground water. Cylindrical conduits formed by explosions

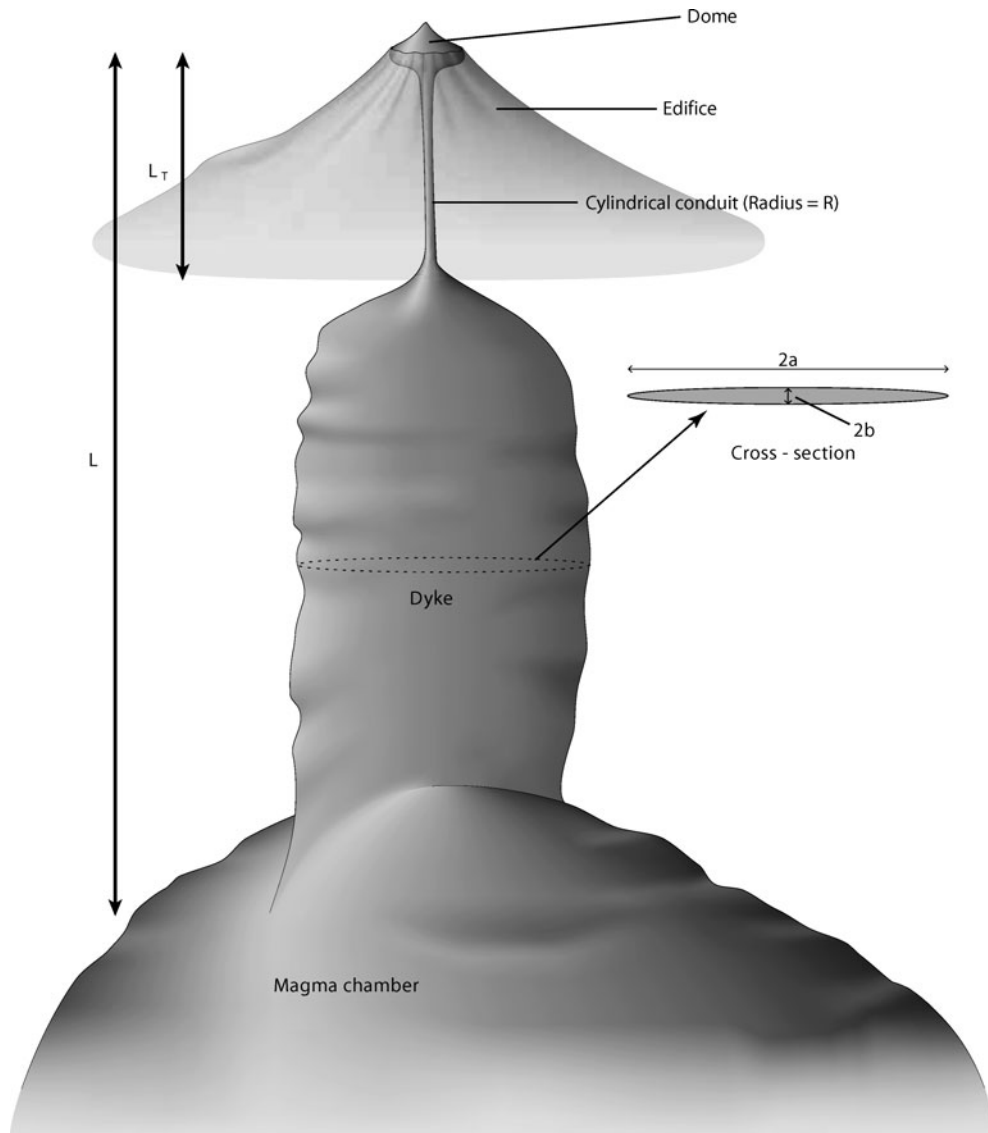

are confined to relatively shallow parts of the crust, probably of order hundreds of meters depth and < 1 km, as indicated by mineralogical studies [73]. Examples of such initial conduit forming activity include Mount Usu (Japan) Mt. St. Helens, and Soufrière Hills Volcano [12,87,99]. Many lava dome eruptions are also characterized by Vulcanian, sub-Plinian and even Plinian explosive eruptions. Examples include Mount Unzen, Mount St. Helens, Santiaguito and Soufrière Hills Volcano [68,87,89,96]. Here the fragmentation front may reach to depths of several kilometers [54] with the possibility of cylindrical conduit development due to severe underpressurization and mechanical disruption of conduit wallrocks. Subsequently domes can be preferentially fed along the cylindrical conduits created by earlier explosive activity. On the Soufrière Hills Volcano, early dome growth was characterized by extrusion of spines with nearly cylindrical shape [87].

Observations of magma discharge rate variations on a variety of time-scales highlight the need to understand the underlying dynamic controls. Research has increasingly focused on modeling studies of conduit flow dynamics during lava-dome eruptions. We will restrict our discussions here to mechanisms that lead to cyclic and quasi-periodic fluctuations in magma discharge rate on various timescales, mainly focusing on long-term cycles. Issues concerning the transition between explosive and extrusive activity are discussed in detail in [45,80,81,97] and in the special volume of *Journal of Volcanology and Geothermal Research* dedicated to modeling of explosive eruptions [79]. Several papers consider the processes that occur at the surface and relate dome morphology and dimensions with controlling parameters.

Combined theoretical, experimental and geological studies identify four main types of dome: spiny, lobate, platy, and axisymmetric [5,29,30]. These types of dome reflect different regimes which are controlled by discharge rates, cooling rates and yield strength, and the viscosity of the dome-forming material. In recent years mathematical modeling has been used to semi-quantitatively describe spreading of lava domes, including models based on the thin layer approximation [1,2] and fully 2D simulations of lava dome growth which account for visco-elastic and -plastic rheologies [32,33].

### Dynamics of Magma Ascent During Extrusive Eruptions

In order to understand the causes of cyclic behavior during extrusive eruptions, first we need to consider the underlying dynamics of volcanic systems, and discuss physical and chemical transitions during magma ascent.

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 1

Schematic view of the volcanic system. In the upper part the conduit is cylindrical with a radius  $R$ . A transition from the cylinder to a dyke occurs at depth  $L_T$ . The length scale for the transition from cylinder to dyke is  $w_T$ . The dyke has an elliptical cross-section with semi-axis lengths  $a_0$  and  $b_0$ . The chamber is located a depth  $L$ . In the text we used also the following auxiliary variables:  $D = 2R$  for conduit diameter,  $L_d = L - L_T$  for the dyke vertical length,  $W_d = 2a_0$  for the dyke width, and  $H_d = 2b_0$  for the dyke thickness. After [20]

The physical framework for the model of a volcanic system is shown in Fig. 1. Magma is stored in a chamber at depth  $L$ , with a chamber pressure  $P_{ch}$  that is higher than hydrostatic pressure of magma column and drives magma ascent. Magma contains silicate melt, crystals and dissolved and possibly exsolved volatiles. During ascent of the magma up the conduit the pressure decreases and volatiles exsolve forming bubbles. As the bubble concentration be-

comes substantial, bubble coalescence take place and permeability develops [27,45], allowing gas to escape from ascending magma, both in vertical (through the magma) and horizontal (to conduit wallrocks) directions. If magma ascends slowly, gas escape results in a significant reduction of the volume fraction of bubbles; such a process is termed open system degassing. In comparison closed system degassing is characterized by a negligible gas escape.

Reduction in bubble content, combined with relatively low gas pressures and efficient decoupling of the gas and melt phases, prevents magma fragmentation and, thus, development of explosive eruption [59,60,82].

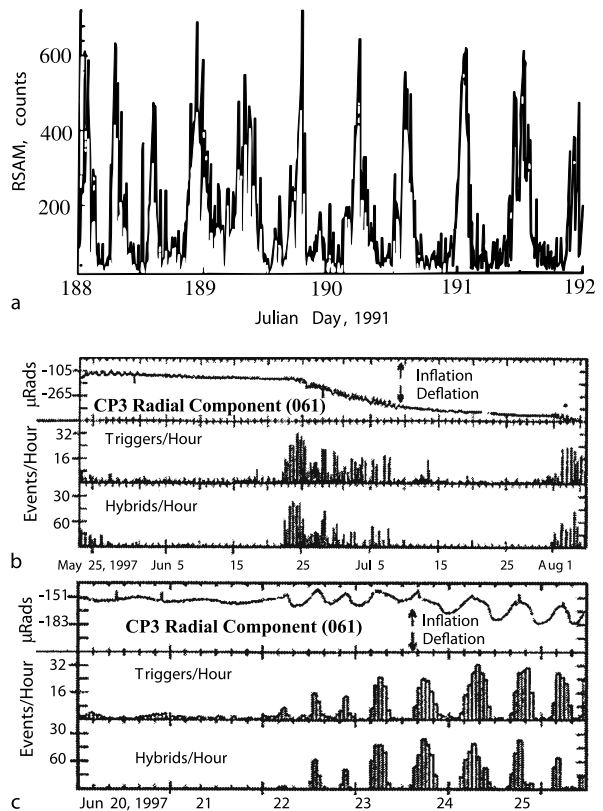

Due to typical low ascent velocities (from millimeters to a few centimeters per second) magma ascent times to the Earth's surface from the magma chamber range from a several hours to many weeks. These ascent times are often comparable with the times that are required for crystals to grow significantly and for heat exchange between magma and wallrocks. The main driving force for crystallization is related to exsolution of volatiles from the magma, leading to increase in the liquidus temperature  $T_L$ , and development of magma undercooling  $\Delta T = T_L - T$  [10]. Crystallization leads to release of latent heat, and magma temperature can increase with respect to the initial temperature [6]. As a consequence of increasing crystal content, magma viscosity increases by several orders of magnitude [16,20,21] and magma becomes a non-Newtonian fluid [78]. As will be shown later, crystallization induced by degassing can become a key process in causing variable flow rates.

Due to the long duration of extrusive eruptions, the magma chamber can be replenished with significant amounts of magma from underlying sources [41,65]. Replenishment can lead to pressure build-up in the magma chamber, volatile and heat exchange between host and new magmas. The composition of the magma can also change over time, due to differentiation, crustal rock assimilation, or magma mixing. Thus, any model that explains magma ascent dynamics needs to deal with many complexities. Of course there is no single model that can take into account all physical processes in a volcanic system. Additional complications arise from the fact that the physical properties of magma at high crystal contents, such as rheology or crystal growth kinetics and geometry of volcanic systems, are typically poorly constrained. Several issues regarding the dynamics of multiphase systems have not been resolved theoretically, especially for cases where the volume fractions of components of the multiphase system are comparable.

Below we will present a review of existing models that treat cyclic behavior during extrusive eruptions on different timescales.

### Short-Term Cycles

Cyclic patterns of seismicity, ground deformation and volcanic activity (Fig. 2 from [23]) have been documented at Mount Pinatubo, Philippines, in 1991 [37] and Soufrière Hills volcano, Montserrat, British West Indies, in 1996–

**Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 2** Examples of cyclic behavior in a lava dome eruption. RSAM records from Mt. Pinatubo, Philippines following its climatic eruption in June 1991 (a, after [23]). Radial tilt, triggered earthquakes, and hybrid earthquakes for 17 May to 6 August 1997, at Soufrière Hills Volcano (b, after [21,90]). Parts of three 5–7 week cycles are shown, with each cycle showing high amplitude tilt and seismicity pulsations with short time scale that last for several weeks after the start of the cycle. The onset of a cycle is rapid, as detailed in c for the cycle initiating on 22 June 1997

1997 [90,91]. At Soufrière Hills, periodicity in seismicity and tilt ranged from  $\sim 4$  to 30 h, and the oscillations in both records continued for weeks. Cyclic behavior was first observed in the seismicity (RSAM) records beginning in July 1996, when the record of dome growth constrained the average supply rate to between 2 and 3  $\text{m}^3/\text{s}$  [88]. The oscillations in the RSAM records initially had low amplitudes, and no tilt-measurement station was close enough to the vent to detect any pressure oscillations in the conduit. By August 1996, RSAM records showed strong oscillatory seismicity at dome-growth rates between 3 and 4  $\text{m}^3/\text{s}$ . Tilt data, taken close enough to the vent (i.e., Chances Peak [90]) to be sensitive to conduit pressure oscillations, are only available for February 1997 and May–August 1997. In the latter period dome growth rate in-

crease from  $\sim 5 \text{ m}^3/\text{s}$  in May to between 6 and  $10 \text{ m}^3/\text{s}$  in August. Both near-vent tilt and RSAM displayed oscillatory behavior during this period and were strongly correlated in time. Similar RSAM oscillations having periods of 7 to 10 h were observed at Mount Pinatubo following the climactic eruption in 1991 [37]. At both volcanoes, oscillation periods were observed that do not fit any multiple of Earth or ocean tides.

The cyclic activity at both Pinatubo and Soufrière Hills Volcano are strongly correlated with eruptive behavior and other geophysical phenomena. In the Pinatubo case and on Soufrière Hills Volcano in August, September and October 1997, the cycles were linked to short-lived volcanic explosions. In the case of the Soufrière Hills Volcano, explosions in August 1997 occurred at the peak in the tilt. The peak in tilt also marked the onset of episodes of increased rock falls [7,8] and [91] is attributed to increased magma discharge rates.  $\text{SO}_2$  flux data show that the cycles are linked to surges in gas release, which reach a peak about an hour after the tilt peak [93]. Green et al. [31] have shown that several families of near identical long period earthquakes occur during the tilt cycle, starting at the inflexion point on the up-cycle and finishing before the inflexion point on the down-cycle.

Several models [23,49,70,98,98] have been proposed to explain the observed cyclicity. In these models [23,98] the conduit is divided into two parts. Magma is assumed to be forced into the lower part of volcanic conduit at a constant rate. In Denlinger and Hoblitt [23] magma in the lower part of the conduit is assumed to be compressible. In Wylie et al. [98] the magma is incompressible but the cylindrical conduit is allowed to expand elastically. In both models the lower part of the conduit, therefore, acts like a capacitor that allows magma to be stored temporally in order to release it during the intense phase of the eruption. In the upper part of the conduit friction is dependent on magma discharge rate, with a decrease in friction resulting in an increase in discharge rate, over a certain range of discharge rates. In Denlinger and Hoblitt [23], when magma discharge rate reaches a critical value, magma detaches from the conduit walls and a stick-slip transition occurs. Rapid motion of magma leads to depressurization of the conduit and a consequent decrease in discharge rate, until at another critical value the magma again sticks to the walls. Pressure starts to increase again due to influx of new magma into the conduit. On a pressure-discharge diagram the path of eruption is represented by a hysteresis loop. In Wylie et al. [98] the friction is controlled by volatile-dependent viscosity. Volatile exsolution delay is controlled by diffusion. When magma ascends rapidly, volatiles have no time to exsolve and viscosity remains low. Depressur-

ization of the upper part of the conduit leads to a decrease in magma discharge rate and an increase in viscosity due to more intense volatile exsolution.

In Neuberger et al. [70] a steady 2D conduit flow model was developed. The full set of Navier–Stokes equations for a compressible fluid with variable viscosity was solved by means of a finite element code. Below some critical depth the flow was considered to be viscous and Newtonian, with a no-slip boundary condition at the wall. Above this depth a plug develops, with a wall boundary condition of frictional slip. The slip criterion was based on the assumption that the shear stress inside the magma overcomes some critical value. Simulations reveal that slip occurs in the shallow part of the conduit, in good agreement with locations of long-period volcanic earthquakes for the Soufrière Hills Volcano, [31]. However, some parameters used in the simulations (low crystallinity, less than 30% and high discharge rate, more than  $100 \text{ m}^3/\text{s}$ ) are inconsistent with observations.

Lensky et al. [49] developed the stick-slip model by incorporating degassing from supersaturated magma together with a sticking plug. Gas diffuses into the magma, which cannot expand due to the presence of a sticking plug, resulting in a build up of pressure. Eventually the pressure exceeds the strength of the plug, which fails in stick-slip motion and the pressure is relieved. The magma sticks again when the pressure falls below the dynamic friction value. In this model the time scale of the cycles is controlled by gas diffusion. The influence of permeable gas loss, crystallization and elastic expansion of the conduit on the period of pulsations was studied.

A shorter timescale of order of minutes was investigated in Iverson et al. [43] in relation to repetitive seismic events during the 2004–2006 eruption of Mount St. Helens. The flow dynamics is controlled by the presence of a solid plug that is pushed by a Newtonian liquid, with the possibility of a stick-slip transition. Inertia of the plug becomes important on such short timescales.

Models to explain the occurrence of Vulcanian explosions have also been developed by Connor et al. [15], Jaquet et al. [44] and Clarke et al. [13]. A statistical model of repose periods between explosions by Connor et al. [15] shows that data fit a log-logistic distribution, consistent with the interaction of two competing processes that decrease and increase gas pressure respectively. Jaquet et al. [44] show the explosion repose period data have a memory. The petrological observations of Clarke et al. [13] on clasts from Vulcanian explosions associated with short-term cycles support a model where pressure builds up beneath a plug by gas diffusion, but is opposed by gas leakage through a permeable magma foam. Although

these models include some of the key processes and have promising explanatory power, they do not consider the development of the magma plug explicitly. This process is considered in [24], where a model of magma ascent with gas escape is proposed.

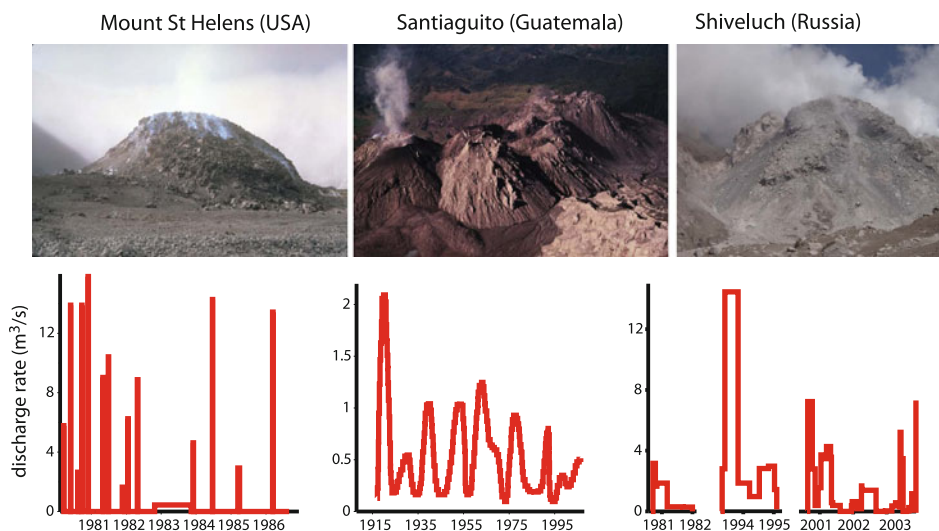

### Long-Term Cycles

Figure 3 shows views of three lava domes (Mount St. Helens, USA, Santiaguito, Guatemala and Shiveluch, Russia). Measurements of magma discharge rate variations with time are presented below [25,35,89]. Behavior at the first two volcanoes is rather regular, whereas at Shiveluch, long repose periods are followed by an initial rapid increase in eruptive activity with subsequent decrease and complete stop of the eruption. Growth of the lava dome at Unzen volcano, Japan, 1991–1995 was similar to Shiveluch [25,68].

There are three types of conceptual models that attempt to explain long term variation in magma discharge rate. Maeda [53], after [42], considers a simple system that contains a spherical magma chamber located in elastic rocks with a cylindrical conduit located in visco-elastic rocks. Magma viscosity is assumed to be constant. The magma chamber is replenished with a time dependent influx rate. The model reproduces discharge rate variation at Unzen volcano by assuming a bell-shaped form of influx rate dependence on time. There are two controversial assumptions in the model. First, the assumption that

the conduit wallrocks are visco-elastic, while the magma chamber wallrocks are purely elastic cannot be justified because near the chamber rock temperature is the highest and it is more reasonable to expect viscous properties for chamber wallrocks rather than for the conduit. The equation that links conduit diameter with magmatic overpressure assumes viscous rock properties up to infinity. If the chamber is located in visco-elastic rocks, oscillations in discharge rate are not possible. Second, in order to obtain reasonable timescales, the rock viscosity must be rather small, of order of  $10^{13}$  Pa s, which is only slightly higher than the typical viscosities of the magma.

Another set of models attribute cyclic behavior to heat exchange between ascending magma and wallrocks, which accounts for temperature dependent viscosity [17,95]. The idea of both models is that magma cools down as it ascends, and heat flux is proportional to the difference between the average temperature of the magma and the temperature of the wallrocks. If magma ascends quickly than heat loss is small in comparison with heat advection. Magma viscosity remains low as a consequence and allows high magma discharge rates. In contrast, when magma ascends slowly it can cool substantially and viscosity increases significantly. Both models suggest that, for a fixed chamber pressure, there can be up to three steady state solutions with markedly different discharge rates. Transition between these steady-state solutions leads to cyclic variations in discharge rate. Whitehead and Helfrich [95] demonstrated the existence of cyclic regimes in exper-

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 3

Observed discharge rate versus time for (a) Mount St. Helens dome growth and (b) Santiaguito volcano and Shiveluch (c). Photos: Mount St. Helens by Lyn Topinka (1985), Santiaguito by Gregg Bluth (2002), Shiveluch by Pavel Plechov (2001)

iments using corn syrup. In application to magma ascent in a volcanic conduit, these models have strong limitations, because a constant wall-rock temperature is assumed. However, as an eruption progresses the wallrocks heat up and heat flux decreases, a condition that makes periodic behavior impossible for long-lived eruptions. For such a long-lived eruption like Santiaguito (started in 1922) wallrocks are expected to be nearly equilibrated in temperature with the magma, and heat losses from magma became small. It is possible that this decrease in heat flux contributes to a slow progressive increase in temperature that is observed on timescales longer than the period of pulsations. For example, magma at Santiaguito becomes progressively less viscous, resulting in a transition from mainly lava dome to lava flow activity.

Models, developed by authors of this manuscript, consider that degassing-induced crystallization is a major controlling process for the long-term cyclicity during lava dome building eruptions. There is increasing evidence that there is a good correlation between magma discharge rate and crystallinity of the magma [10,68]. An increase in crystal content leads to an increase in magma viscosity [16,20,21] and, thus, influences magma ascent dynamics. First, we consider a simplified model of magma ascent in a volcanic conduit that accounts for crystallization and rheological stiffening.

### A Simplified Model

In Barmin et al. [3] the following simplifying assumptions have been made in order to develop a semi-analytical approach to magma ascent dynamics.

1. Magma is incompressible. The density change due to bubble formation and melt crystallization is neglected.
2. Magma is a viscous Newtonian fluid. Viscosity is a step function of crystal content. When the concentration of crystals  $\beta$  reaches a critical value  $\beta_*$  the viscosity of magma increases from value  $\mu_1$  to a higher value  $\mu_2$ . Later on we will consider magma rheology in more detail (see Sect. "Rheology of Crystal-Bearing Magma and Conduit Resistance"), but a sharp increase in viscosity over a narrow range of crystal content has been confirmed experimentally (e. g., [9,48]).
3. Crystal growth rate is constant and no nucleation occurs in the conduit. The model neglects the fact that magma is a complicated multi-component system and its crystallization is controlled by the degree of undercooling (defined as the difference between actual temperature of the magma and its liquidus temperature). Later in the paper a more elaborate model for magma crystallization will be considered.
4. The conduit is a vertical cylindrical pipe. Elastic deformation of the wallrocks is not included in the model. This assumption is valid for a cylindrical shape of the conduit at typical magmatic overpressures, but is violated when the conduit has a fracture shape. Real geometries of volcanic conduits and their inclination can vary significantly with depth.
5. The magma chamber is located in elastic rocks and is fed from below, with a constant influx rate. For some volcanoes, like Santiaguito or Mount St. Helens, average magma discharge rate remained approximately constant during several periods of pulsation. Thus the assumption of constant influx rate is valid. For volcanoes like Mount Unzen or Shiveluch, there is an evidence of pulse-like magma recharge [25,53].

With above simplification the system of equations for unsteady 1D flow is as follows:

$$\frac{\partial}{\partial t} \rho + \frac{\partial}{\partial x} \rho u = 0; \quad \frac{\partial}{\partial t} n + \frac{\partial}{\partial x} n u = 0 \quad (1a)$$

$$\frac{\partial p}{\partial x} = -\rho g - \frac{32\mu u}{\delta^2}; \quad \mu = \begin{cases} \mu_1, & \beta < \beta_* \\ \mu_2, & \beta \geq \beta_* \end{cases} \quad (1b)$$

$$\frac{\partial}{\partial t} \beta + u \frac{\partial \beta}{\partial x} = 4\pi n r^2 \chi = (36\pi n)^{\frac{1}{3}} \beta^{\frac{2}{3}} \chi \quad (1c)$$

Here  $\rho$  is the density of magma,  $u$  is the vertical cross-section averaged ascent velocity,  $n$  is the number density of crystals per unit volume,  $p$  is the pressure,  $g$  is the acceleration due to gravity,  $\delta$  is the conduit diameter,  $\beta$  is the volume concentration of crystals,  $\beta_*$  is a critical concentration of crystals above which the viscosity changes from  $\mu_1$  to  $\mu_2$ ,  $r$  is the crystal radii,  $\chi$  is the linear crystal growth rate, and  $x$  is the vertical coordinate. The first two Eqs. (1a) represent the conservation of mass and the number density of crystals, the second (1b) is the momentum equation with negligible inertia, and the third (1c) is the crystal growth equations with  $\chi = \text{constant}$ . We assume the following boundary conditions for the system (1):

$$x = 0: \quad \frac{dp_{\text{ch}}}{dt} = \frac{\gamma}{V_{\text{ch}}} (Q_{\text{in}} - Q_{\text{out}}); \quad \beta = \beta_{\text{ch}}; \quad n = n_{\text{ch}}$$

$$x = l: \quad p = 0$$

Here  $\gamma$  is the rigidity of the wall-rock of the magma chamber,  $V_{\text{ch}}$  is the chamber volume,  $\beta_{\text{ch}}$  and  $n_{\text{ch}}$  are the crystal concentration and number density of crystals per unit volume in the chamber,  $p_{\text{ch}}$  is the pressure in the chamber,  $l$  is the conduit length,  $Q_{\text{in}}$  is the flux into the chamber and  $Q_{\text{out}} = \pi \delta^2 u / 4$  is the flux out of the chamber into the conduit. Both  $\beta_{\text{ch}}$  and  $n_{\text{ch}}$  are assumed constant. We neglect the influence of variations of the height of the lava dome

on the pressure at the top of the conduit and assume that the pressure there is constant. As the magma is assumed to be incompressible, the pressure at the top of the conduit can be set to zero because the atmospheric pressure is much smaller than magma chamber pressure.

From the mass conservation equation for the case of constant magma density,  $u = u(t)$  and  $n = n_{ch}$  everywhere. Equations (1) can be integrated and transformed from partial differential equations to a set of ordinary differential equations with state-dependent delay representing a “memory” effect on crystal concentration (see [3] for details).

**Results and Applications**

The general steady-state solution for magma ascent velocity variations with chamber pressure is shown in Fig. 4a. Solutions at high magma ascent velocities, when the critical concentration of crystals is not reached inside the conduit, result in a straight line (CB), which is the same as for the classical Poiseuille solution for a fluid with constant viscosity. At low ascent velocities there is a quadratic relationship (OAC) between chamber pressure and ascent velocity (see [3] for derivation of the equation). A key feature of the steady-state solution is that, for a fixed chamber pressure, it is possible to have three different magma ascent velocities. We note that for  $\mu_2/\mu_1 = 1$  only the branch CB exists and for  $1 < \mu_2/\mu_1 \leq 2$  there is a smooth transition between the lower branch (ODA) and the upper branch (CB) and multiple steady-state regimes do not exist.

We first consider the case where chamber pressure changes quasi-statically and the value of  $Q_{in}$  is between  $Q_A$  and  $Q_C$ . Starting at point O the chamber pressure increases, because the influx into the chamber is higher than the outflux. At point A, a further increase in pressure is not possible along the same branch of the steady-state solution and the system must change to point B, where the outflux of magma is larger than the influx. The chamber pressure and ascent velocity decrease along BC until the point C is reached and the system must change to point D. The cycle DABC then repeats itself. Provided the chamber continues to be supplied at the same constant rate repetition of this cycle results in periodic behavior. The transitions AB and CD in a cycle must involve unsteady flow.

Oscillations in magma discharge rate involve large variations in magma crystal content. This relation is observed on many volcanoes. For example, pumice and samples of the Soufrière Hills dome that were erupted during periods of high discharge [88] have high glass contents (25 to 35%) and few microlites [65], whereas samples derived from parts of the dome that were extruded more slowly (days to weeks typically) have much lower glass contents (5 to 15%) and high contents of groundmass microlites. These and other observations [34,68] suggest that micro-lite crystallization can take place on similar time scales to the ascent time of the magma.

Of more general interest is to consider unsteady flow behaviour. We assume that the initial distribution of parameters in the conduit corresponds to the steady-state solution of system (1) with the initial magma discharge rate,  $Q_0$ , being in the lowest regime. The behaviour of an erup-

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 4  
 The general steady-state solution and possible quasi-static evolution of an eruption. After [3]. Different curves correspond to different values of dimensionless parameter  $\kappa = (\pi \delta^2 \gamma)/(4V_{ch} \rho g)$  (0.12 – thin line, 0.05 – dotted line, and 0.005 – bold line)

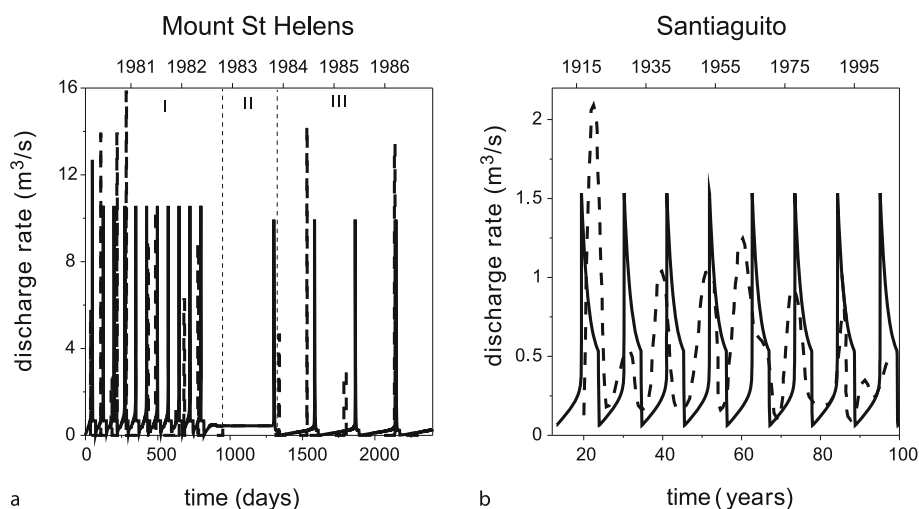

tion with time depends strongly on the value of  $Q_{in}$ . If  $Q_{in}$  corresponds to the upper or the lower branch of the steady state solution the eruption stabilizes with time with  $Q = Q_{in}$  and  $dp_{ch}/dt = 0$ . However, if  $Q_{in}$  corresponds to the intermediate branch of the steady-state solution, with  $Q_{in}$  between  $Q_A$  and  $Q_C$ , periodic behaviour is possible. Figure 4b shows three eruption scenarios for different values of the magma chamber volume  $V_{ch}$ . When  $V_{ch}$  is small the eruption stabilizes with time. In contrast, undamped periodic oscillations occur for values of  $V_{ch}$  larger than some critical value. For very large magma chamber volumes the transient solution almost exactly follows the steady-state solution, with unsteady transitions between the regimes. The time that the system spends in unsteady transitions in this case is much shorter than the period of pulsations. The maximum discharge rate during the cycle is close to  $Q_B$ , the minimum is close to  $Q_D$  and the average is equal to  $Q_{in}$ . The period of pulsations increases as the volume of magma chamber increases.

Now we apply the model to two well-documented eruptions: the growth of lava domes on Mount St. Helens (1980–1986) and on Santiaguito (1922–present). Our objective here is to establish that the model can reproduce the periodic behaviors observed at these two volcanoes. Estimates can be obtained for most of the system parameters. However, magma chamber size is not well-constrained and so the model can be used to make qualitative inferences on relative chamber size. Given the uncertainties in the parameter values and the simplifications in the model development, the approach can be characterized as

mimicry. Adjustments in some parameters were made to achieve best fits with observations, but the particular best-fits are not unique.

For Mount St. Helens our model is based on data presented by [89]. Three periods of activity can be distinguished during the period of dome growth. The first period consists of 9 pulses of activity with average peak magma discharge rates  $\sim 15 \text{ m}^3/\text{s}$  during 1981–1982. Each pulse lasted from 2 to 7 days (with a mean value of 4 days) with the average period between the pulses being 74 days and the average discharge rate during the period being  $Q_1 \sim 0.67 \text{ m}^3/\text{s}$ . The second period is represented by continuous dome growth and lasted more than a year (368 days) with a mean magma discharge rate of  $Q_2 \sim 0.48 \text{ m}^3/\text{s}$ . During the last period there were 5 episodes of dome growth with peak magma discharge rates up to  $\sim 15 \text{ m}^3/\text{s}$ , an average period of pulsation of  $\sim 230$  days and a mean discharge rate of  $Q_3 \sim 0.23 \text{ m}^3/\text{s}$ . We assume that the intensity of influx into the magma chamber,  $Q_{in}$ , is equal to the average magma discharge rate over the corresponding periods. There might have been a progressive decrease in the intensity of influx during the eruption, but, due to limitations of the model, we assume that  $Q_{in}$  changes as a step function between the periods.

The best-fit model for the eruption is presented in Fig. 5a, with the parameters used for the simulation summarized in Table 2 in [3]. During the first period of the eruption  $Q_{in} = Q_1$ . This corresponds to the intermediate branch of the steady-state solution and cyclic behaviour occurs. In the second period  $Q_{in} = Q_2$  the system moves

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 5

Discharge rate versus time for a Mount St. Helens dome growth and b Santiaguito volcano. Dotted lines represent the observed values of discharge rates and the solid lines are the best fit simulations. After [3]

to the lower regime and the eruption stabilizes with time. For the third period of the eruption the parameters of the system have been changed, so that  $Q_{in} = Q_3 < Q_2$ , corresponding to the intermediate regime once again and periodic behaviour occurs. This condition can be satisfied by a decrease in the diameter of the conduit, or a decrease in crystal growth rate, or the number density of crystals. All these mechanisms are possible: decrease in the diameter could be a consequence of magma crystallization on the conduit walls, while a decrease in either crystal growth rate or number density of crystals could be reflect observed changes in magma composition [89]. The influence of conduit diameter is the strongest because ascent velocity, for the same discharge rate, depends on the square of the diameter. The required change in diameter is from 18 to 12 m, but this change can be smaller if we assume a simultaneous decrease in crystal growth rate.

Since 1922, lava extrusion at Santiaguito has been cyclic [35]. Each cycle begins with a 3–6 year long high (0.5–2.1 m<sup>3</sup>/s) magma discharge rate phase, followed by a longer (3–11 years) low ( $\sim 0.2$  m<sup>3</sup>/s) discharge rate phase. The time-averaged magma discharge rate was almost constant at  $\sim 0.44$  m<sup>3</sup>/s between 1922 and 2000. The first peak in discharge rate had a value  $>2$  m<sup>3</sup>/s, whereas the second peak had a much smaller value. The value for the second peak is underestimated as it is calculated based on the dome volume only, but does not include the volume of dome collapse pyroclastic flows. Later peaks show an increase in magma discharge rate until 1960 (Fig. 5b, dashed line). Post-1960, the duration of the low discharge rate phase increased, the peak discharge and the time-averaged discharge rates for each cycle decreased, and the difference between discharge rates during the high and low discharge rate phases of each cycle decreased. Our best-fit model is shown in Fig. 5b and the parameters estimates are listed in Table 2 in [3]. The model reproduces the main features of the eruption, including the period of pulsations, the ratio between low and high magma discharge rates, and the range of observed discharge rates. We cannot, however, reproduce the decrease in the amplitude of pulsations within the framework of the model using fixed parameter values.

The theory provides a potential method to estimate magma chamber volumes. For Mount St. Helens our estimate of the chamber size ( $\sim 0.6$  km<sup>3</sup>) is comparable with the total erupted volume in the entire 1980–1986 eruption and is consistent with the fact that geophysical imaging did not identify a large magma body. Santiaguito volcano erupted more than 10 km<sup>3</sup> in the 1902 explosive eruption [96] and more than 1 km<sup>3</sup> of lava domes since 1922. The best-fit model estimate of a large (64 km<sup>3</sup>) chamber is consistent with much larger eruption volumes, long peri-

ods, and longevity of the eruption in comparison to Mount St. Helens. One limitation of the model is that the supply of deep magma from depth to the chamber is assumed to be constant.

### Model Development

In this section we further develop models to examine new effects and relax some of the simplifications of earlier models. We investigate a number of effects that were not fully explained or considered in previous studies [3,61,62]. The new model incorporates a more advanced treatment of crystallization kinetics based on the theoretical concepts developed in [38,46], and is calibrated by experimental studies in andesitic systems [22,34]. In particular, we distinguish growth of phenocrysts formed in the magma chamber from crystallization of microlites during magma ascent. Previous models have assumed that magma is always Newtonian, so we study models of conduit flow assuming non-Newtonian rheology, with rheological properties being related to crystal content. Latent heat is released during the crystallization of ascending magma due to degassing and we show that this can have an important influence on the dynamics. Elastic deformation of conduit walls leads to coupling between magma ascend and volcano deformations.

**System of Equations** We model magma ascent in a dyke-shaped conduit with elliptical cross-section using a set of 1D transient equations written for horizontally averaged variables [20,21]:

$$\frac{1}{S} \frac{\partial}{\partial t} (S \rho_m) + \frac{1}{S} \frac{\partial}{\partial x} (S \rho_m V) = -G_{mc} - G_{ph} \quad (2)$$

$$\frac{1}{S} \frac{\partial}{\partial t} (S \rho_{mc}) + \frac{1}{S} \frac{\partial}{\partial x} (S \rho_{mc} V) = G_{mc} \quad (3a)$$

$$\frac{1}{S} \frac{\partial}{\partial t} (S \rho_{ph}) + \frac{1}{S} \frac{\partial}{\partial x} (S \rho_{ph} V) = G_{ph} \quad (3b)$$

$$\frac{1}{S} \frac{\partial}{\partial t} (S \rho_d) + \frac{1}{S} \frac{\partial}{\partial x} (S \rho_d V) = -J \quad (4a)$$

$$\frac{1}{S} \frac{\partial}{\partial t} (S \rho_g) + \frac{1}{S} \frac{\partial}{\partial x} (S \rho_g V_g) = J \quad (4b)$$

Here  $t$  denotes time,  $x$  the vertical coordinate,  $\rho_m$ ,  $\rho_{ph}$ ,  $\rho_{mc}$ ,  $\rho_d$  and  $\rho_g$  are the densities of melt, phenocrysts, microlites, dissolved gas and exsolved gas respectively, and  $V$  and  $V_g$  are the velocities of magma and gas, respectively.  $G_{ph}$ ,  $G_{mc}$  represent the mass transfer rate due to crystallization of phenocrysts and microlites, respectively, and  $J$  the mass transfer rate due to gas exsolution,  $S$  is the cross-section area of the conduit. Equation (2) represents the mass con-

servation for the melt phase, Eqs. (3a) and (3b) are the conservation equations for microlites and phenocrysts respectively, Eqs. (4a) and (4b) represent the conservation of the dissolved gas and of the exsolved gas respectively.

$$\frac{\partial p}{\partial x} = -\rho g - F_c \quad (5)$$

$$V_g - V = -\frac{k}{\mu_g} \frac{\partial p}{\partial x} \quad (6)$$

Here  $p$  is the pressure,  $\rho$  the bulk density of magma,  $g$  the acceleration due to gravity,  $\mu$  is the magma viscosity,  $k$  is the magma permeability and  $\mu_g$  is the gas viscosity. Eq. (5) represents the equation of momentum for the mixture as a whole, in which the pressure drops due to gravity and conduit resistance are calculated for laminar flow in an elliptic pipe. Equation (6) is the Darcy law for the exsolved gas flux through the magma.

$$\begin{aligned} \frac{1}{S} \frac{\partial}{\partial t} (S\rho C_m T) + \frac{1}{S} \frac{\partial}{\partial x} (S\rho C_m VT) \\ = L_* (G_{mc} + G_{ph}) - C_m TJ - Q_{cl} + Q_{vh} \end{aligned} \quad (7)$$

Here  $C_m$  is the bulk specific heat of magma,  $T$  is the bulk flow-averaged temperature,  $L_*$  is latent heat of crystallization,  $Q_{cl}$  denotes the total heat loss by conduction to the conduit walls, and  $Q_{vh}$  denotes the total heat generation due to viscous dissipation. Here we consider the case of the latent heat release only. This assumption is valid when both  $Q_{cl} \approx 0$  and  $Q_{vh} \approx 0$  or when  $Q_{cl} + Q_{vh} \approx 0$ . The study of the effects of both heat loss and viscous heating, which are intrinsically two-dimensional [18,19], and their parametrization is the subject of ongoing research.

$$\rho_m = \rho_m^0 (1 - \alpha)(1 - \beta)(1 - c); \quad \rho_c = \rho_c^0 (1 - \alpha)\beta \quad (8a)$$

$$\rho_d = \rho_m^0 (1 - \alpha)(1 - \beta)c; \quad \rho_g = \rho_g^0 \alpha \quad (8b)$$

$$\rho = \rho_m + \rho_c + \rho_d + \rho_g \quad (8c)$$

$$\alpha = \frac{4}{3} \pi r_b^3 n; \quad \frac{\partial}{\partial t} (Sn) + \frac{\partial}{\partial x} (SnV) = 0; \quad p = \rho_g^0 RT \quad (9)$$

Here  $\alpha$  is the volume concentration of bubble,  $\beta$  is the volume concentration of crystals in the condensed phase (melt plus crystals), and  $c$  is mass concentration of dissolved gas (equal to volume concentration as we assume that the density of dissolved volatiles is the same as the density of the melt),  $\rho_m^m$  denotes the mean density of the pure melt phase,  $\rho_c^c$  is density of the pure crystal phase (with  $\rho_c = \rho_{ph} + \rho_{mc}$ ,  $\beta = \beta_{ph} + \beta_{mc}$ ),  $r_b$  is the bubble radius, and  $n$  the number density of bubble per unit

volume. Concerning the parametrization of mass transfer rate functions, we use:

$$J = 4\pi r_b n D \rho_m^0 (c - C_f \sqrt{p}) \quad (10)$$

$$\begin{aligned} G_{mc} = 4\pi \rho_c^0 (1 - \beta)(1 - \alpha) \\ \times U(t) \int_0^t I(\omega) \left( \int_0^t U(\eta) d\eta \right)^2 d\omega \end{aligned} \quad (11a)$$

$$G_{ph} = 3\gamma_s \left( \frac{4\pi N_{ph} \beta_{ph}^2}{3} \right)^{\frac{1}{3}} \rho_c^0 (1 - \beta)(1 - \alpha) U(t) \quad (11b)$$

Here  $J$  is parametrized using the analytical solution described in [69],  $U$  is the linear crystal growth rate ( $\text{m s}^{-1}$ ),  $I$  is the nucleation rate ( $\text{m}^{-3} \text{s}^{-1}$ ), which defines the number of newly nucleated crystal per cubic meter, and  $\gamma_s$  is a shape factor of the order of unity,  $D$  and  $C_f$  are the diffusion and the solubility coefficients, respectively. Concerning the mass transfer due to crystallization  $G_{mc}$ , we adapt a model similar to that described in [38]. Assuming spherical crystals, the Avrami–Johnson–Mehl–Kolmogorov equation in the form adopted by [46], for the crystal volume increase rate, is:

$$\frac{d\beta}{dt} = 4\pi Y_t U(t) \int_0^t I(\omega) \left( \int_0^t U(\eta) d\eta \right)^2 d\omega$$

where  $Y_t = (1 - \beta)(1 - \alpha)$  is the volume fraction of melt remaining uncrystallized at the time  $t$ . Therefore, we have  $G_{mc} = \rho_{mc} d\beta/dt$ . For the phenocryst growth rate  $G_{ph}()$  we assume that it is proportional to the phenocryst volume increase rate  $d\beta_{ph}/dt = 4\pi R_{ph}^2 N_{ph} U(t)$  times the crystal density  $\rho_c^0$  times the volume fraction of melt remaining uncrystallized at the time  $t$ . A detailed description of the parametrization used for the different terms is reported in [63].

For parametrizations of magma permeability  $k$  and magma viscosity  $\mu$  we use:

$$k = k(\alpha) = k_0 \alpha^j \quad (12)$$

$$\mu = \mu_m(c, T) \theta(\beta) \eta(\alpha, Ca) \quad (13)$$

where  $k$  is assumed to depend only on bubble volume fraction  $\alpha$ . Magma viscosity  $\mu$  depends on water content, temperature, crystal content, bubble fraction and capillary number as described in detail in the next section.

Regarding equations for semi-axes,  $a$  and  $b$ , we assume that the elliptical shape is maintained and that pressure change gradually in respect with vertical coordinate and time so that the plain strain analytical solution for an ellipse subjected to a constant internal overpressure [64,66],

remains valid:

$$a = a_0 + \frac{\Delta P}{2G} [-(1-2\nu)a_0 + 2(1-\nu)b_0] \quad (14a)$$

$$b = b_0 + \frac{\Delta P}{2G} [2(1-\nu)a_0 - (1-2\nu)b_0] \quad (14b)$$

where  $\Delta P$  is the overpressure, i. e. the difference between conduit pressure and far field pressure (here assumed to be lithostatic for a sake of simplicity),  $a_0$  and  $b_0$  are the initial values of the semi-axes,  $\nu$  is the host rock Poisson ratio, and  $G$  is the host rock rigidity.

Equations (2)–(14) are solved between the top of the magma chamber and the bottom of the lava dome that provides some constant load by using the numerical method described in [63]. The effects of dome height and morphology changes are not considered in this paper. We consider three different kinds of boundary conditions at the inlet of the dyke: constant pressure, constant influx rate and the presence of a magma chamber located in elastic rocks. The case of constant pressure is applicable when a dyke starts from either a large magma chamber or unspecified source, so that pressure variations in the source region remain small. An estimate of the volume of magma stored in the source region that allows pressure to be approximated as constant depends on wall-rock elasticity, magma compressibility (volatile content), and the total volume of the erupted material. If the magma flow at depth is controlled by regional tectonics, the case of constant influx rate into the dyke may be applicable if total variations in supply rate are relatively small on the timescale of the eruption.

For the case where magma is stored in a shallow magma chamber prior to eruption, and significant chamber replenishment occurs, the flow inside the conduit must be coupled with the model for the magma chamber. In this case, as explained in detail in [63], we assume that the relationship between the pressure at the top of the magma chamber  $p_{ch}$  and the intensity of influx  $Q_{in}$  and outflux  $Q_{out}$  of magma to and from the chamber is given by:

$$\frac{dp_{ch}}{dt} = \frac{4G \langle K \rangle}{\langle \rho \rangle V_{ch} (3 \langle K \rangle + 4G)} (Q_{in} - Q_{out}) \quad (15)$$

where  $V_{ch}$  is the magma chamber volume,  $\langle \rho \rangle$  and  $\langle K \rangle$  are the average magma density and magma bulk modulus, respectively, and  $G$  is the rigidity of rocks surrounding the chamber.

Cases of constant influx and of constant source pressure are the limit cases of Eq. (15) in the case of infinitely small and infinitely large magma chamber volume. We assume that the volume concentration of bubbles and phenocrysts are determined by equilibrium conditions and

that the temperature of the magma is constant. The effect of temperature change on eruption dynamics, due to interaction between silicic and basaltic magma, was studied in [63].

We use a steady-state distribution of parameters along the conduit as an initial condition for the transient simulation. The values are calculated for a low magma discharge rate, but the particular value of this parameter is not important because the system deviates from initial conditions to a cyclic or stabilized state, which does not depend on the initial conditions.

### Rheology of Crystal-Bearing Magma and Conduit Resistance

Magma viscosity is modeled as a product of melt viscosity  $\mu_m(c, T)$ , the relative viscosity due to crystal content  $\theta(\beta) = \Theta(\beta)\varphi(\beta)$ , and the relative viscosity due to the presence of bubbles  $\eta(\alpha, Ca)$ . The viscosity of the pure melt  $\mu_m(c, T)$  is calculated according to [36]. Viscosity increase due to the presence of the crystals is described through the function  $\Theta(\beta)$  [16,20,21]. As crystallization proceeds, the remaining melt becomes enriched in silica and melt viscosity increases. The parametrization of this effect is described by the function  $\varphi(\beta)$  in [21,25]. Effects of the solid fraction are parametrized as described in [21].

Effects due to the presence of bubbles are accounted for by adopting a generalization of [51] for an elliptical conduit [20,21].

In the case of Newtonian magma rheology, the friction force in an elliptical conduit can be obtained from a classical Poiseuille solution for low Reynolds number flow  $F_c = 4\mu(a^2 + b^2)/(a^2b^2)V$  [47]. High crystal or bubble content magmas may show non-Newtonian rheology. One possible non-Newtonian rheology is that of a Bingham material characterized by a yield strength  $\tau_b$  [4]. The stress-strain relation for this material is given by:

$$\begin{aligned} \tau_{ij} &= \left( \mu + \frac{\tau_b}{\gamma_b} \right) \gamma_{ij} \Leftrightarrow \tau > \tau_b \\ \gamma_{ij} &= 0 \Leftrightarrow \tau \leq \tau_b \end{aligned} \quad (16)$$

Here  $\tau_{ij}$  and  $\gamma_{ij}$  are the stress and strain rate tensors,  $\tau$  and  $\gamma_b$  are second invariants of corresponding tensors. According to this rheological law, the material behaves linearly when the applied stress is higher than a yield strength. No motion occurs if the stress is lower than a yield strength. In the case of a cylindrical conduit the average velocity can be calculated in terms of the stress on the conduit wall  $\tau_w$  [52]:

$$V = \frac{1}{12} \frac{r}{\tau_w^3 \mu} (\tau_b^4 + 3\tau_w^4 - 4\tau_b \tau_w^3) \quad (17)$$

Here  $r$  is the conduit radii. This form of equation gives an implicit relation between ascent velocity and pressure drop, and is not convenient to use. By introducing dimensionless variables  $\Pi = \mu V/\tau_b r$  and  $\Omega = \tau_w/\tau_b \geq 1$  relation (17) can be transformed into:

$$\Omega^4 - \frac{1}{6} (8 + 3\Pi) \Omega^3 + \frac{1}{3} = 0 \tag{18}$$

Following [63] a semi-analytical solution can be used for (18) and the conduit friction force can be expressed finally as:

$$F_c = \frac{2\tau_w}{r} = \frac{2\tau_b \Omega (\Pi)}{r}.$$

We note that a finite pressure gradient is necessary to initiate the flow in the case of Bingham liquid, in contrast to a Newtonian liquid.

**Results and Applications**

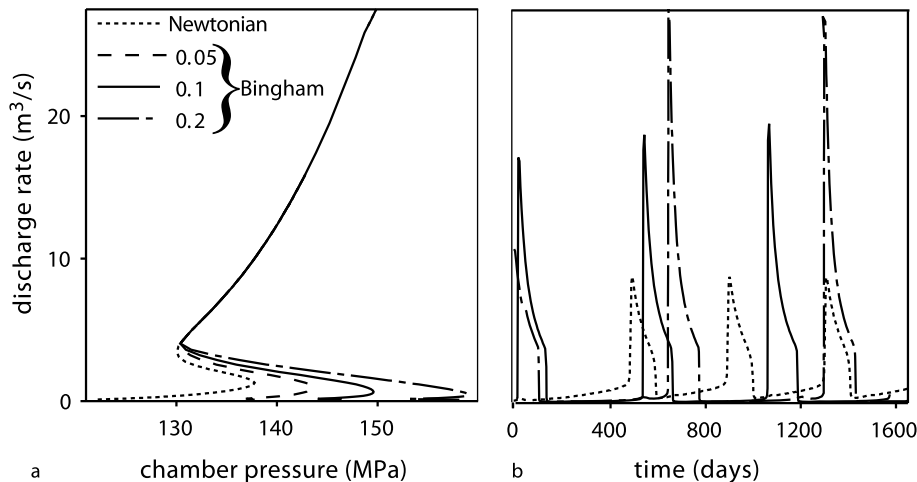

*Influence of non-Newtonian Properties on Eruption Behaviour* Now we compare the dynamics of magma extrusion in the cases of Newtonian and Bingham rheology. We will assume that yield strength is reached when the concentration of crystals reaches a critical value:

$$\tau = \begin{cases} \tau_b & \text{for } \beta > \beta_{cr} \\ 0 & \text{for } \beta \leq \beta_{cr} \end{cases} \tag{19}$$

Figure 6a shows a set of steady-state solutions for different values of  $\tau_b$ . Values of  $\tau_b$  and  $\beta_{cr}$  depend on crystal shape, crystal size distribution, magma temperature and other properties, but here are assumed to be constant. To illustrate the influence of Bingham rheology, the value of  $\beta_{cr} = 0.65$  was chosen so that, for discharge rate larger then  $\sim 5 \text{ m}^3/\text{s}$ , the magma has Newtonian rheology (see Fig. 6a). A more detailed study would require measurements of the rheological properties of magma for a wide range of crystal content and crystal size distributions. As the value of  $\tau_b$  the chamber pressure that is necessary to start the eruption increases.

Figure 6b shows the influence of these two rheological models on the dynamics of magma extrusion. In the case of Bingham rheology, magma discharge rate between the two pulses is zero until a critical chamber overpressure is reached. Then the magma discharge rate increases rapidly with decrease in crystal content, leading to a significant reduction of both magma viscosity and the length of the part of the conduit that is occupied by the Bingham liquid where  $\beta_c > \beta_{cr}$ . There is a transition in the system to the uppermost flow regime and the pressure then decreases quickly. Because the pressure at the onset of the pulse was significantly larger than in the case of a Newtonian liquid, the resulting discharge rate in the case of Bingham rheology is also significantly higher.

*Modeling of Conduit Flow during Dome Extrusion on Shiveluch Volcano* The maximum intensity of extrusion was

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 6  
**a** Steady-state solutions and dependence of discharge rate on time for Newtonian and Bingham rheology of the magma. Yield strength is a parameter marked on the curves (values in MPa). For Bingham rheology discharge rate remains zero between the pulses of activity. Bingham rheology results in much higher chamber pressures prior to the onset of activity and, therefore, much higher discharge rates in comparison with Newtonian rheology. **b** Comparison of the period of pulsation in discharge rate for Newtonian and Bingham rheologies. After [63]

reached at an early stage in all three eruptions (Fig. 3). We therefore suggest that dome extrusion was initiated by high overpressure in the magma chamber with respect to the lithostatic pressure. Depressurization of the magma chamber occurred as a result of extrusion. Without magma chamber replenishment, depressurization results in a decrease in magma discharge rate. In open system chambers replenishment of the chamber during eruption can lead to pulsatory behaviour [3]. The following account is derived from [25]. For the 1980–1981 eruption the monotonic decrease in discharge rate indicates that there was little or no replenishment of the magma chamber. During the 1993–1995 and 2001–2004 episodes, however, the magma discharge rate fluctuated markedly, suggesting that replenishment was occurring. The influx of new magma causes an increase in magma chamber pressure, and a subsequent increase in magma discharge rate. During the 2001–2004 eruption there were at least three peaks in discharge rate. Replenishment of the magma chamber with new hot magma can explain the transition from lava dome extrusion to viscous lava flow that occurred on Shiveluch after 10 May 2004, and which continues at the time of writing (2007).

We simulated dome growth during the 2001–2002, because this dataset is the most complete and is supported by petrological investigations [39]. We assume the shape of the influx curve:

$$Q_{\text{in}} = \begin{cases} 0, & t < t_s \\ Q_0, & t_s \leq t \leq t_f \\ 0, & t > t_f \end{cases} \quad (20)$$

Influx occurs with constant intensity  $Q_0$  between times  $t_s$  and  $t_f$ . We have examined many combinations of values of these parameters within the constraints provided by observations. The best simulation results use the following values of parameters:  $Q_0 = 3.8 \text{ m}^3/\text{s}$ ,  $t_s = 77$  and  $t_f = 240$  days. A more continuous influx, dependent on time, is plausible, but there is no geophysical evidence that allows us to constrain the intensity of the influx, because ground deformation data are absent for Shiveluch volcano. The output of the model gives a magma chamber volume of  $12 \text{ km}^3$ , assuming a spherical chamber. Figure 7a shows the time-dependence of magma discharge rate, and Fig. 7b shows the increase in the volume of erupted material with time after 6th June 2001. The timing of magma influx is in good agreement with the residence time of basaltic magma in the system, as calculated from the olivine reaction rims. For further details see [25].

*5 to 7 Weeks Cycles on the Soufriere Hills Volcano: Evidence for a Dyke?* An approximately 5 to 7 week cyclic pattern of activity was recognized at the Soufrière Hills Volcano (SHV) [87,91] between April 1997 and March 1998 from peaks in the intensity of eruptive activity and geophysical data, including tilt and seismicity (Fig. 2).

In models discussed above, the time-scale of pulsations depends principally on the volume of the magma chamber, magma rheology and the cross-sectional area of the conduit. These models might provide an explanation for the 2–3 year cycles of dome extrusion observed at SHV, where deformation data indicate that the magma chamber regulates the cycles. However, the models cannot simulta-

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 7

**a** Comparison of calculated and measured discharge rates (**a**) and volumes of the dome (**b**) for the episode of the dome growth in 2001–2002. Influx into the magma chamber is shown by a dashed line in **a**. Time in days begins on 6th June, 2001. After [25]

neously explain the 5–7 week cycles. Thus another mechanism is needed.

The evidence for a dyke feeder at SHV includes GPS data [58], distribution of active vents, and seismic data [76]. We have assumed that, at depth, the conduit has an elliptical shape that transforms to a cylinder at shallow level. In order to get a smooth transition from the dyke at depth to a cylindrical conduit (see Fig. 1) the value of  $a_0$  in Eqs. (14) is parametrized as:

$$a_0(x) = A_1 \arctan\left(\frac{x - L_T}{w_T}\right) + A_2 \quad (21)$$

Here  $L_T$  and  $w_T$  are the position and the vertical extent of the transition zone between the ellipse and the cylinder and constants  $A_1$  and  $A_2$  are calculated to satisfy conditions  $a_0(L) = R$  and  $a_0(0) = a_0$ , where  $R$  is the radius of the cylindrical part of the conduit and  $a_0$  is the length of semi-major axis at the inlet of the dyke. The value of  $b_0$  is calculated in order to conserve the cross-section area of the unpressurized dyke, although it can also be specified independently.

In order to de-couple the influence of the dyke geometry from the oscillations caused by magma chamber pressure variations, we have assumed a fixed chamber pressure

as a boundary condition for the entrance to the conduit. This assumption is valid because the timescale of chamber pressure variations are much longer than the period of the cycle (2–3 years in comparison with 5–7 weeks).

Results presented in Figure 8 show that, even with a fixed chamber pressure, there are magma discharge rate oscillations. At the beginning of a cycle the magma discharge rate is at a minimum, while the overpressure (here presented for 1 km depth by a dashed line) and dyke width are at a maximum. At point A in Fig. 8a the crystal content and viscosity have reached their maximum values. Beyond this threshold condition, an increase in magma discharge rate results in decreasing pressure and dyke width. However, crystal content and viscosity also decrease and this effect decreases friction, resulting in flow rate increase and pressure decrease. At C the system reaches minimum viscosity and crystal content, which cannot decline further. Thereafter the magma discharge rate decreases, while the pressure and dyke width increase. The dyke acts like a capacitor, storing volume during this part of the cycle.

The period of oscillation depends on several parameters such as influx rate and dyke aspect ratio  $a/R$ . Typically the period decreases with increasing aspect ratio. The range of calculated periods varies between 38 and 51 days

Volcanic Eruptions: Cyclicity During Lava Dome Growth, Figure 8

**a** Dependence of magma discharge rate (solid line) and magmatic overpressure at depth of 1 km (dashed line) on time, for  $a = 240$  m and  $b = 2.25$  m at the inlet of the dyke. The period of cycle is 46 days, average discharge rate is  $6.2 \text{ m}^3/\text{s}$ , with peak rate about  $12 \text{ m}^3/\text{s}$ . **b** Profiles of cross-section areas of the conduit during one cycle. Curve A corresponds to the beginning of the cycle, B – to a point on the curve of ascending discharge rate, C – to maximum discharge, and D to the middle of descending discharge curve. At the beginning of the cycle, due to large viscosity of magma (at low discharge rate crystal content is high) large magmatic overpressure develops, reaching a maximum near the transition between the dyke and cylindrical conduit; the dyke inflates providing temporary magma storage. Minimum dyke volume corresponds to maximum discharge rate (curve C). After [21]

for semi major-axis lengths,  $a$ , from 175 to 250 m and semi minor-axes,  $b$ , from 2 to 4 m. These results match observed cyclicity at SHV. The start of a cycle is quite sharp (Fig. 2), with the onset of shallow hybrid-type (impulsive, low-frequency coda) earthquakes. The change to shorter period and higher amplitude tilt pulsations indicate a marked increase in average magma discharge rate [91,98]. The model cycles also have rapid onsets. The high-amplitude tilt pulsations lasted for several weeks [91], consistent with the duration of higher magma discharge rates early in each 5–7 week cycle. Tilt data (Fig. 2) are consistent with the model in that the episode of high magma discharge is associated with a marked deflation that lasts several weeks (see dashed curve at Fig. 8, representing magmatic overpressure at 1 km depth). The magma pressure builds up in the swelling dyke and then reaches a threshold, whereupon a surge of partly crystallized magma occurs, accompanied by elevated seismicity.

The models presented above have certain general features that are necessary to show cyclic behaviour. First of all, the resistance of the conduit must depend on magma discharge rate in a way that resistance decreases when discharge rate increases in some range of discharge rate. This dependence is reproduced by a sigmoidal curve. Resistance is a product of viscosity and velocity, and is linearly proportional to discharge rate. This means that magma viscosity must decrease as discharge rate strongly increases. There may be many reasons for this behaviour, including crystallization, temperature variation or gas diffusion. The second condition is that there must be some capacitor in the system that can store magma in a period of low discharge rate and release it in a period of high discharge rate. The role of this capacitor can be played by a magma chamber or dyke-shaped conduit located in elastic rocks, or by compressibility of the magma itself. The volumes of these capacitors are different and thus will cause pulsations with different periods. Currently there is no single model that can account for pulsations with multiple timescales.

### Future Directions

Our models indicate that magmatic systems in lava dome eruptions can be very sensitive to small changes in parameters. This sensitivity is most marked when the system is close to the cusps of steady-state solutions. If magma discharge rate becomes so high that gas cannot escape efficiently during magma ascent, then conditions for magma fragmentation and explosive eruption can arise. Empirical evidence suggests that conditions for explosive eruption arise when magma discharge rates reach approxi-

mately  $10 \text{ m}^3/\text{s}$  or more in dome eruptions [45,83]. Calculations show the possibility of such high discharge rates for the system parameters typical of lava dome-building eruptions.

We have illustrated model sensitivity of results by varying only one parameter at a time on plots of chamber pressure and discharge rate. However, magmatic systems have many controlling parameters that may vary simultaneously. Furthermore, some controlling parameters are likely to be interdependent (such as temperature, volatile content and phenocryst content, for example) and others may be independent (such as magma temperature and conduit dimensions). An eruption can be expected to move through  $n$ -parameter space, making simulation and its parameter depiction difficult. Our results are simplified, so system sensitivity and behaviour in the real world may be yet more complex. A volcanic system may be quite predictable when it is within a stable regime, but may become inherently unpredictable [84,85] when variations in the parameters move the system towards transition points and flow regime boundaries.

As in all complex systems there are many controlling parameters. Our models capture some of the key dynamics, but are still simplified in many respects, so do not fully capture the real variations. Our models do not, for example, consider variations in dome height, gas escape to surrounding rocks, strain-rate dependent rheological effects or time dependent changes in conduit diameter. The model for porosity is based on interpretation of measurements of porosity of erupted magma. The role of post-eruptive alterations of pore structure, for example, formation of cooling cracks, cannot be easily estimated. The model of bubble coalescence and permeability formation is important for understanding gas escape mechanisms and will provide constraints on transitions between extrusive and explosive activity. Because the model remains 1D, lateral distribution of parameters cannot be studied. These include: lateral pressure gradients, magma crystallization on the conduit walls, wallrocks melting or erosion, formation of shear zones and shear heating, heat flux to surrounding rocks. The models also make the simplifying assumption that influx into the chamber from a deep source is a constant, or given as a function of time. The dynamics of the magma chamber itself are oversimplified in all existing conduit flow models. Changes in magma properties in magma chamber can affect the long-term evolution of eruptions. We have considered water as the only volatile and the addition of other gas species (e. g.  $\text{CO}_2$  and  $\text{SO}_2$ ) would add further variability.

There are large uncertainties in some parameters, which are likely to be very strong controls, such as the rhe-

ological properties of high crystalline magmas and crystal growth kinetic parameters, notably at low pressures ( $< 30$  MPa) where experiments are very difficult to do (e.g. [22]). More experiments are necessary to understand the rheology of multiphase systems containing melt, crystals and bubbles. The effects of crystal shape, crystal size distribution and strain rate remain largely unclear. Some parameters, such as conduit geometry variation with depth, are highly uncertain. With so many parameters, good fits can be achieved by selecting plausible values for real systems. Barmin et al. [3], for example, were able to reproduce the patterns of discharge rate at Mount St. Helens and Santiaguito quite accurately. However, such models are not unique, partly because the actual values of some parameters may be quite different to the assumed values and partly because of the model simplifications.

Results obtained from waveform inversions of very-long-period seismic data over the past few years point to the predominance of a crack-like geometry for volcanic conduits [11], and it is becoming increasingly evident that the details of this geometry, such as conduit inclination, a sudden change in conduit direction, a conduit bifurcation, or a sudden increase in cross section, are all critically important in controlling magma flow dynamics. Future modeling attempts will need to be closely tied to information on conduit geometry derived from seismology to provide a more realistic view of volcanic processes.

The full simulation of any particular volcanic eruption in such a non-linear and sensitive system may appear a hopeless task. However, some reduction in uncertainties will certainly help to make the models more realistic. Further experimental studies of crystallization kinetics and the rheological properties of magma at high crystallinities are among the most obvious topics for future research. Advances in understanding the controls on magma input into an open-system chamber would be beneficial, since the delicate balance between input and output is a prime control on periodic behaviour.

Further model development includes 2D effects, elastic deformation effects in dyke-fed domes and coupling between magma chamber and conduit flow dynamics. Even with such improvements, large parameter uncertainties and modeling difficulties will remain. In such circumstances the logical approach is to start quantifying the uncertainties and sampling from them to produce probabilistic outputs based on ensemble models where numerical models of the kind discussed here can be run many times. A future challenge for numerical models will also be to produce simulated outputs which compare in detail with observations, in particular time series of magma discharge rates.

### Glossary

**Onset** The beginning of an eruption. The term **event** will be used interchangeably.

**Repose** Periods during which an eruption is not in progress.

**Onset time** Time at which an eruption begins. The  $i$ th onset time will be denoted  $t_i$ , for  $i = 1, \dots, n$ .

**Inter-onset time** Time between successive onsets, denoted by  $r_i = t_{i+1} - t_i$ , for  $i = 1, \dots, n - 1$ . In many papers this is termed the **repose time**, which we shall use interchangeably, although the latter is strictly the time between the *end* of one eruption and the *start* of the next.

**Polygenetic vent** Site of multiple events, in contrast to **monogenetic vents**, at which only one eruption occurs. The latter occur predominately in **volcanic fields**.

**Absolute time** is denoted by  $t$  or  $s$ , with the latter usually being the time of the last known event. The **elapsed time** since the last known event is denoted by  $u$ , or, equivalently,  $t - s$ .

**A parameter estimate** of the parameter  $\lambda$ , say, is denoted by  $\hat{\lambda}$ .

### Definition of the Subject

Depending on the definition, there are approximately 1300 Holocene (last 10,000 years) active volcanoes [83], some 55–70 of which are typically active in any given year. Being tectonic phenomena, they are spatially over-represented along littorals and in island arcs where populations congregate, and millions of lives are potentially at risk. Hence

the quantitative forecasting of hazard has long been a key aim of volcanology. This requires models to quantify the likelihood of future outcomes, which may involve the size, location and/or style of eruption, in addition to temporal occurrence. While a wide range of complex deterministic models exist to model various volcanic processes, these provide little in the way of information about future activity. Being the (partially) observed realization of a complex system, volcanological data are inherently stochastic in nature, and need to be modeled using statistical models. To paraphrase Decker [25] concerning potentially active volcanoes, geologists can find out what did happen, geophysicists can determine what is happening, but to find out what might happen requires statistics. Reminding ourselves that “all models are wrong, but some models are useful”, the most useful models for volcanic eruptions are ones that provide new insight into the physical processes, and can in turn be informed by our present understanding of those physical processes.

### Introduction

The hazard is a product of many elements, including the likelihood of an eruption, the distribution of the eruption size, and the style of the eruption. Depending on the nature of the volcanic products, climatological or geographical factors may also play a part.

The style of an eruption strongly determines the relative risks to life and property. Effusive eruptions of molten lava pose little threat to life with, for example, only one life being lost due to a volcanic eruption on Hawaii in the 20th century. However, in the same time period 5% of the island has been covered by new lava flows [25]. Explosive eruptions, in particular pyroclastic flows, travel at high speeds and can cause extensive fatalities such as the 29,000 killed in the Mont Pelee (West Indies) eruption of 1902. Lahars, or mudflows, such as those that killed 25,000 people in the Nevado del Ruiz (Columbia) eruption of 1985, are also a major danger.

Forecasting volcanic eruptions is easier than forecasting earthquakes on several grounds. First, at least in the case of polygenetic volcanoes, there need be no spatial element involved. Second, it is possible using geological techniques to look backward (often a long way, depending on geography and finances) to see what happened in the past. Thirdly, and of most importance for short-term warning, magma intrusions can be detected by seismic networks, although not all seismic signals indicate magma of course, and other monitoring techniques [25].

In this article we will limit our consideration to models of eruption occurrence, omitting techniques for fore-

casting the nature and effect of the eruption. As the track record of a potentially active volcano provides the best method of assessing its future volcanic hazards on a long-term basis [21,25], we will first briefly review the provenance and characteristics of the data available. Various taxonomies for stochastic models are possible. As the majority of models applied to volcanoes are purely temporal, and this also includes the simplest models, we will look at these first. Such models can be further broken down into (nonhomogeneous) Poisson processes, which consider absolute time relative to some fixed origin, and renewal processes, which consider only the time since the previous event. Markov processes, where the state of the process moves between various eruptive and repose states, and models based on eruptive volume, are the simplest ways of incorporating some element of eruption size into the model. Fractals have been used as a descriptive technique for volcanoes, and are reviewed next. The above models, with the exception of the nonhomogeneous Poisson process, all assume that the volcano is in steady state, i. e., that the activity pattern does not change over time. For volcanoes with lengthy records, this appears to be an untenable assumption over longer time scales [99]. This raises the issues of, first, how to detect a departure from stationary stochastic behavior, or change in volcanic regime and, secondly, how to model it, which are discussed in Sect. “**Volcanic Regimes**”, illustrated with results from Mount Etna. While purely temporal models are suitable for polygenetic volcanoes, monogenetic volcanic fields require a spatial element, to model the location, as well as the time, of future events. This is usually estimated using kernel smoothing, but in cases where the location can be treated as a discrete variable, such as summit versus flank eruptions, Markov chain techniques can be used. These are reviewed, along with methods for detecting clustering and linear alignments, in Sect. “**Spatial Aspects**”. A very high profile, particularly in the USA, exercise in volcanic hazard estimation concerns the risk to a proposed high-level radioactive waste repository planned for Yucca Mountain. The history of published hazard estimates is used in Sect. “**Yucca Mountain**” to illustrate the application of both temporal and spatio-temporal models. The final substantive section looks at methods for detecting links between volcanic eruptions and large earthquakes. Determining whether correlation in the occurrence patterns exists is a necessary precursor to formulating models to take advantage of any potential new information from the additional process.

The focus of this article is squarely on the techniques. Hence the applications jump around a bit, as they are those presented in the original paper(s) dealing with the tech-

nique. The examples of Mount Etna and Yucca Mountain were selected for more detailed examination partly on the basis that many, somewhat contradictory, results exist. Different models make different assumptions, and vary in how much information they can extract from data. In addition, the data used often varies from study to study, and the sensitivity of models to data is important, but too often ignored. Subjective judgments on the merits of various techniques is minimized, except for comments on details necessary to their application.

## Data

Information about past eruptions forms the basis of any stochastic model for future behavior. Using such data poses a number of challenges because of its inhomogeneity, particularly in the longer records. This inhomogeneity is due to incomplete observation, which becomes more incomplete the further back one goes, and by variations in dating and measurement precision, again becoming less precise the further into the past one looks. We will now outline the nature and limitations of the available information.

There are several functional distinctions in the types of data used in volcanic hazard models. The most fundamental is at the question of scale. Certain volcanoes, notably Stromboli (which lends its name to the behavior) and Soufriere Hills, erupt in distinct events separated by minutes or hours. Hence a catalog of hundreds of events may only cover a few days of activity. More commonly, eruptions are events with durations ranging from days to years. Eruptions are usually modeled simply as a point process of onsets, but a few studies consider duration, volume, or spatial extent.

A global catalog of Holocene volcanism is maintained by Seibert and Simkin [82]. This gives onset dates, of various precision, and Volcanic Explosivity Index (VEI) for all known eruptions. The VEI, as a logarithmic measuring scale of eruption size analogous to the magnitude of an earthquake, was proposed by Newhall and Self [68]. It is assigned to historical eruptions on the basis of (in decreasing order of reliability): explosion size; volume of ejecta; column height, classification (‘Hawaiian’, ‘Strombolian’, ‘Vulcanian’, ‘(Ultra-)Plinian’); duration; most explosive activity type; tropospheric and stratospheric injection. Many historical (i. e., observed and recorded at the time) observations also have a duration, and some an estimate of eruptive volume. Estimates of volume, where they exist, typically contain uncertainties of 10–50% [101] or more [54] and, provided the eruption styles are similar, the duration of an eruption can be used as a proxy [3,67].

The frequency of observed volcanic eruptions has increased over the last few hundred years, although this is largely an artifact of the global population increase [84], which indicates that many of the historical records are incomplete. A number of published catalogs for individual volcanoes are of greater detail, and probably more complete. Some of the better known are Etna [65,67,74] and Vesuvius [11,77] (Italy), Ruapehu (New Zealand) [5], Colima (Mexico) [27,63] and Kilauea/Mauna Loa (Hawaii) [46].

While it is reasonably easy, although sometimes controversial, to define events in an historical catalog, it is not so easy in pre-historical cases. Ideally events correspond to eruptions, but subsequent geologic processes can obscure, or even obliterate, the evidence of previous eruptions. The identification of events is dependent on looking in the right place. Pre-historical eruptions can be identified from a combination of stratigraphy (which provides an ordering for the eruptions) and dating techniques. Radiocarbon dating is feasible for material within the last 50,000 years, and provides an estimated age and (Gaussian) error given in  $C^{14}$  years. See [28] for an example of such a catalog. Because of the variable rate of  $C^{14}$  deposition, this has to be converted to calendar years [8], in

the process losing the Gaussian distribution (and possibly even becoming disjoint). One way [94] of dealing with the resulting untidiness is to treat the data in Monte Carlo fashion, repeatedly drawing random realizations of the eruption sequence from the distributions (ensuring that the stratigraphic ordering is not violated), and fitting the model to each realization to provide a population of hazard models. Beyond 50,000 years, dating is via a number of other techniques, such as K-Ar radiometric age determinations which, with resolutions of the order of  $10^6 - 10^7$  years, are much less precise. Conway et al. [20] take the approach of simulating event dates from a uniform distribution, bounded by the  $\pm 2\sigma$  error limits on the dates, in order to determine the uncertainty in the estimated recurrence rate.

Because of the expense, and due to the difficulty of finding suitable material in the sample to date, it is common to date only a portion of the samples. Geomorphology is then used to interpolate or bound the unknown dates. For example, in a single core, a spline can be fitted to the depth and known dates, representing the sediment deposition rate, and the unknown dates calculated from their depths [94], as shown in Fig. 1. This gets much more complicated when there is a spatial element involved [14].

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 1

Radiocarbon age versus depth model (mm) for tephra layers in the sediment core from Lake Umutekai (*inset A*: North Island of New Zealand and *inset B*: Taranaki – the lake is directly above the “k-” in “Lake”). The core stratigraphy is displayed at the top of the plot with white representing tephra deposits. Radiocarbon dated layers are indicated by dotted lines

While deposition cores can provide a complete (above a certain minimum size), and ordered tephra record for a given site, the record extracted from another site may only partially overlap. Various criteria of tephra composition and geochemistry can be used to identify common events. Composite records from many sources will almost certainly be incomplete due to missing events, and may well unknowingly contain duplicates of other events.

**Temporal Models**

Models for the occurrence of volcanic eruptions are based on the idea that the past behavior of a volcano is the best predictor of its future activity. This was dramatically illustrated by Crandell et al. [21] in their somewhat non-quantitative forecast of an eruption of Mount St Helens:

“The repetitive nature of the eruptive activity at Mount St. Helens during the last 4000 years, with dormant intervals typically of a few centuries or less, suggests that the current quiet period will not last a thousand years. Instead, an eruption is likely within the next hundred years, possibly before the end of this century.”

Published in 1975, as a warning that dormant intervals can be a recurring element in the life of a volcano, this foreshadowed the 1980 eruption and subsequent activity.

Let the number of events in a time interval  $(s, t)$  be denoted  $N(s, t)$ , where we use the shorthand  $N(t)$  if  $s = 0$ .

The *intensity* of a process is

$$\lambda(t) = \lim_{\Delta t \downarrow 0} \frac{\Pr(N(t, t + \Delta t) = 1)}{\Delta t}, \tag{1}$$

i. e., in the short period of time  $(t, t + \Delta t)$ , the probability of an event is approximately  $\lambda(t)\Delta t$ .

Guttorp and Thompson [35] provided a non-parametric method of estimating the intensity, based on the observed onset counts  $Y_k$  in intervals of length  $\Delta$ , indexed by  $k = 1, \dots, K$ . They first estimate the reporting probability  $p(t)$  by smoothing the observed onset counts (see [86] for an alternative approach assuming a non-decreasing reporting probability), and calculate  $Z_k = Y_k / \int_{(k-1)\Delta}^{k\Delta} p(t)dt$ . This is a reconstruction of the underlying process obtained by re-inflating the observed counts by the corresponding observance probability. Assuming that the intensity is locally fairly smooth, an estimate, based on the hanning operation from time-series analysis, is

$$\hat{\lambda}(j\Delta) = \frac{\sum_{i=1}^{K-j-1} Z_i Z_{i+j-1} + 2 \sum_{i=1}^{K-j} Z_i Z_{i+j} + \sum_{i=1}^{K-j+1} Z_i Z_{i+j-1}}{4\Delta(K-j) \sum_{k=1}^K Z_k / K}. \tag{2}$$

Application to the global catalog, assuming a constant rate of underlying events, produced the estimated observance probability in Fig. 2 that increases slowly from 1500 until the second half of the 18th century, and then more sharply at a constant rate to an assumed probability  $p(1980) = 1$ . The resulting estimated intensity for global eruption starts

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 2

did not differ from a Poisson (constant intensity) process. However, in order to see if more structure could be observed in a series of eruptions from a restricted area with homogeneous tectonic structure, the methodology was applied to a catalog of Icelandic eruptions. As expected, the estimated observance probability for the last 200 years was approximately constant, which resulted in a periodicity of about 40 years in the estimated intensity, as shown in Fig. 3.

There have been a few other attempts to discern periodic fluctuations in volcanic activity. Mauk and Johnston [62] examined the correlation of the onset dates of 680 eruptions 1900–1971 with the fortnightly solid earth tide. There was a statistically significant tendency for both andesitic and basaltic eruptions to occur at the maxima of the earth tide. In addition, basaltic eruptions had a significant peak at the minima of the earth tide. A more detailed examination of 18 Japanese volcanoes indicated that this may be related to Bouguer anomalies. Similarly, Martin and Rose [54], in Fig. 4, found that eruption onsets of Fuego Volcano, Guatemala were correlated with the fortnightly lunar tidal maxima, with 23 out of 48 eruptions occurring within  $\pm 2$  days of the peak gravity acceleration. Casetti et al. [12] binned eruptions at Mt Etna and examined the resulting statistics, in particular the month of an eruption. Eruptions were shown to be significantly more likely during March–April and November, when there is an increase in the earth-velocity rate. Although

Stothers [89] repeated this analysis for a global catalog of eruptions with  $VEI \geq 3$ , 1500–1980, and detected no significant monthly or seasonal variation, Mason et al. [61] found that seasonal fluctuations account for 18% of the historical average monthly eruption rate. The idea of a deterministic cycle is incorporated in a renewal model by Jupp et al. [45], but the result was not fitted to data.

### Poisson Processes

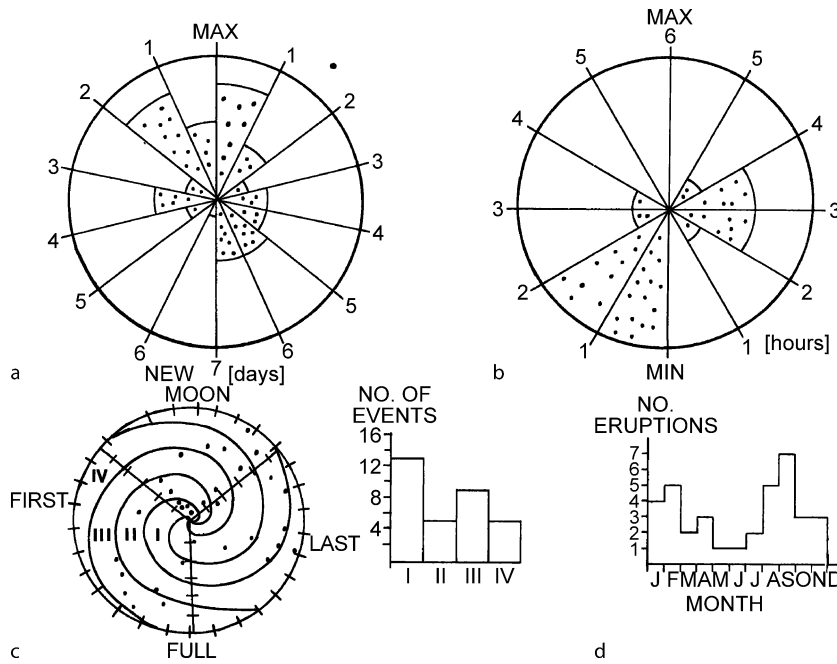

The simplest model is a *simple (homogeneous) Poisson process*, which is characterized by  $\lambda(t) = \lambda_0$ , a constant independent of  $t$ . In this case  $N(t)$  has a Poisson distribution with mean  $\mu = \lambda_0 t$ , and the inter-event times have an exponential distribution with mean  $1/\lambda_0$ . This is sometimes referred to as *Poissonian behavior*. The parameter is estimated as  $\hat{\lambda}_0 = N(T)/T$ , for an observed history spanning the time interval  $(0, T)$ .

In order to weaken the requirement that the mean and variance of  $N(t)$  be equal, Ho [36] suggested a Bayesian approach, in which the parameter  $\lambda_0$  has a gamma prior distribution. This leads to  $N(t)$  having a negative binomial distribution. Solow [87] augmented this to an empirical Bayes formulation by suggesting that an informative prior could be constructed from the eruption records of a group of similar volcanoes. Bebbington and Lai [6] introduced a generalized negative binomial distribution incorporating

**a** Lambert equal area polar histogram showing the percentage of eruptions of Fuego since 1800 in relationship to the fortnightly tidal maximum of the vertical gravity acceleration. **b** Lambert equal-area polar histogram showing the percentage of all the known times of the beginning of eruptions since 1957 compared to the 12.4-hour (semi-diurnal) minimum of the vertical gravity acceleration. **c** A spiral diagram indicating the position of an eruption in relation to the synodic month (days plotted around the circumference) and the reduced anomalistic age (days plotted as the radius, with perigee at the center), in which it occurred. There are 27.5 days in the anomalistic cycle, and 29.6 days in the synodic cycle. Right of the spiral diagram, is a histogram of the four spirals of the above diagram, which are drawn around  $\pm 3.5$  days of the maxima and minima of the 2 cycles. **d** Monthly histogram of Fuego’s eruptions which have occurred since 1800. Reprinted from [54] © 1981 Elsevier B.V., with permission from Elsevier

serial dependence and applied it to eruptions from Mount Sangay (Ecuador).

The Poisson process is stationary in time, in that the distribution of the number of events in an interval depends only on the length of the interval, not its location. In other words, events occur at the same average rate at all times, i.e., there is no trend in the occurrence rate with time. Marzocchi [55] analyzed possible trends by calculating the (biased) autocorrelation function

$$a(s) = \frac{\sum_{i=1}^{n-1-|s|} (r_i - \bar{r})(r_{i+|s|} - \bar{r})}{\sum_{i=1}^{n-1} (r_i - \bar{r})^2}, \tag{3}$$

for  $s = 0, \pm 1, \dots, \pm m$ , where  $r_i, i = 1, \dots, n - 1$  is the time between the  $i$ th and  $(i + 1)$ th onsets,  $\bar{r} = (1/(n - 1)) \sum_{i=1}^{n-1} r_i$  and  $m < n - 1$ . Under the null hypothesis that the process is purely random, the distribution of  $a(s)$  is asymptotically normal with mean zero and variance  $1/(n - 1)$  for  $s \neq 0$ .

More generally, a process can be a *nonhomogeneous Poisson process*, where  $N(t)$  has a Poisson distribution with

mean  $\mu(t) = \int_0^t \lambda(s) ds$ . Ho [37] used an example of a nonhomogeneous Poisson process known as the *Weibull Process* [2], with

$$\lambda(t) = \frac{\beta}{\theta} \left( \frac{t}{\theta} \right)^{\beta-1}, \tag{4}$$

where  $t$  is absolute time with respect to some fixed origin, not the elapsed time since the previous eruption. This includes the homogeneous Poisson process as a special ( $\beta = 1$ ) case, while if  $\beta \neq 1$  the process is non-stationary. The intensity (4) is monotonic, and hence can model either an increase or decrease in volcanic activity, but not both. Note that the parameter estimates,

$$\hat{\beta} = N(T) / \sum_{i=1}^{N(T)} \ln(T/t_i) \quad \text{and} \quad \hat{\theta} = T/N(T)^{1/\hat{\beta}}, \tag{5}$$

for the intensity (4) are sensitive to the position of the time origin [4]. Furthermore, estimates of  $\hat{\beta} > 2$ , which are quite feasible, indicate a constantly accelerating, or

convex, intensity. Neither of these properties is particularly desirable from a physical viewpoint, and hence the Weibull process is not suitable to model entire volcanic histories. Salvi et al. [73] used a statistical technique to identify that the most recent part of the Mount Etna sequence was non-stationary, and fitted the Weibull process to it. The Weibull process can be tested for goodness of fit to a series of data [4] either via a standard  $\chi^2$  test, or by using the fact that  $x_1, \dots, x_{n-1}$ , where  $x_i = \ln(t_n/t_{n-i})$ , should be a random sample from an exponential distribution of unknown mean.

Jaquet et al. [44] proposed a temporal occurrence model using the Cox process. This is a doubly stochastic process with

$$\Pr(N(s, s + t) = k) = \mathbb{E} \left( \frac{Z(s, s + t)^k}{k!} e^{-Z(s, s + t)} \right), \quad (6)$$

where

$$Z(s, s + t) = \int_s^{s+t} \omega(t) dt, \quad (7)$$

and  $\omega(t)$  is the conditional random frequency of events. The process of determining  $\omega(t)$  is not spelt out in detail, involving geostatistical methods, simulation, variograms and a conditioning technique. The advantage of (6) over the Poisson process is that it introduces the possibility of correlation in time.

### Renewal Processes

The homogeneous Poisson process without trend is a special case of a *renewal process*. In a renewal process, the intervals between events are independent and identically distributed, and so

$$\lambda(t) = \frac{f(t - s; \theta)}{1 - F(t - s; \theta)}, \quad t > s, \quad (8)$$

where the most recent event occurred at time  $s < t$ , and  $f = F'$  is a density with parameter vector  $\theta$ . This was first suggested for eruption onsets by Wickman [103], who coined the term *age-specific eruption rate* for (8). The character of the renewal process is that only the elapsed time since the last eruption controls the time to the next eruption. Previous eruptions exert an influence only through their contribution to the parameter estimates  $\hat{\theta}$ . A number of tests to check whether a series of eruptions is consistent with a renewal process can be found in the paper by Reymont [72]: One first checks for the existence of a trend using the standard normal statistic

$$U = \frac{\sum_{i=1}^n t_i/n - T/2}{T\sqrt{n/12}}, \quad (9)$$

where onsets are observed at times  $0 < t_1 < \dots < t_n < T$ . If no trend is observed, one can then examine the serial correlation coefficients

$$\rho_j = \frac{\text{Cov}(\mathbf{r}, \mathbf{r}^{(j)})}{\text{Var}(\mathbf{r})}, \quad (10)$$

where  $\mathbf{r} = (r_1 \dots r_{n-1-j})$ ,  $\mathbf{r}^{(j)} = (r_{1+j} \dots r_{n-1})$ , and  $r_i$  is the time between the  $i$ th and  $(i + 1)$ th onsets. For a renewal process, there should be no correlation, and  $\text{Var}(\rho_j) \sim 1/(n - j)$ . Hence a test of  $\rho_j = 0, j = 1, 2, \dots$  can be performed using the standard normal statistic  $\rho_j \sqrt{(n - j)}$ . One can also examine the periodogram [72]. The special case of a Poisson process can be tested in many ways, the easiest of which is to test the inter-onset intervals for exponentiality using, for example, the Kolmogorov–Smirnov statistic of the maximum distance between the empirical and hypothesized distribution functions. Other tests are mentioned in [4,5].

Given a density  $f(u; \theta)$  and observed inter-onset times  $r_i, i = 1, \dots, n - 1$ , the parameters  $\theta$  can be estimated by maximum likelihood. That is, the values are chosen, either algebraically or numerically, to maximize the likelihood

$$L(r_1, \dots, r_{n-1}, t - s; \theta) = [1 - F(t - s; \theta)] \prod_{i=1}^{n-1} f(r_i; \theta), \quad (11)$$

where the first term accounts for the current unfinished interval, and is often omitted. Occasionally other methods are used. The method of moments involves setting the parameter values to equalize the observed and theoretical moments. As many moments are used as one has parameters. For example, two parameters can be fitted using the mean and standard deviation. An alternative is based on minimizing the sum of squared differences between an observed curve and that produced by the model. This is usually done using linear regression, but direct numerical optimization is possible.

If  $f$  is the exponential density  $f(u) = \nu e^{-\nu u}$ , then

$$\lambda(t) = \frac{\nu e^{-\nu(t-s)}}{1 - (1 - e^{-\nu(t-s)})} = \nu, \quad (12)$$

and we recover the homogeneous Poisson process. Klein [46] tested the eruptive patterns of Hawaiian volcanoes against a Poisson process (random model) using this formulation, and showed that reposes following large eruptions differed significantly from the whole. The Eq. (12) is sometimes referred to as the memoryless property, as it says that the time elapsed since the last eruption provides no information about the time of the next eruption.

Thorlaksson [93] suggested that an over-dispersed (standard deviation  $\sigma$  greater than the mean  $\mu$ ) sequence of inter-onset intervals should be modeled by the Pareto density  $f(u) = a(1 + bu)^{-a/b-1}$ ,  $u > 0$ , with intensity

$$\lambda(t) = \frac{a}{1 + b(t-s)}, \quad t > s, \tag{13}$$

where  $\hat{a} = 2\sigma^2/(\mu^3 + \mu\sigma^2)$  and  $\hat{b} = (\sigma^2 - \mu^2)/(\mu^3 + \mu\sigma^2)$  are estimated by the method of moments. This models a decrease in eruption probability with time, and was applied to Colima by Medina Martinez [63]. For under-dispersed inter-onset intervals, Thorlaksson [93] suggested the density

$$f(u) = \begin{cases} (a + bu) \exp(-au - (b/2)u^2) & \sqrt{4/\pi - 1} < \sigma/\mu < 1 \\ b(u - a) \exp(-(b/2)(u - a)^2) & \sigma/\mu < \sqrt{4/\pi - 1} \end{cases}, \quad u > 0, \tag{14}$$

leading to the intensity

$$\lambda(t) = \begin{cases} a + b(t-s) & \sqrt{4/\pi - 1} < \sigma/\mu < 1 \\ b(t-s-a) H(t-s-a) & \sigma/\mu < \sqrt{4/\pi - 1} \end{cases}, \quad t > s, \tag{15}$$

where

$$H(x) = \begin{cases} 1 & x > 0 \\ 0 & x \leq 0 \end{cases} \tag{16}$$

is the Heaviside function. These imply an increase in eruption probability with time, while the case  $\sigma/\mu < \sqrt{4/\pi - 1}$  adds a loading time  $a$ , and the parameters can be estimated as  $\hat{a} = \mu - \sigma/\sqrt{4/\pi - 1}$  and  $\hat{b} = (2 - \pi/2)/\sigma^2$ . This latter case was applied to the volcanoes Hekla and Katla, which had ratios  $\sigma/\mu$  of 0.44 and 0.43 respectively. Of the other 28 volcanoes examined, none had a ratio less than 0.76, and 23 had a ratio of greater than unity.

Settle and McGetchin [78] fitted a Gaussian density to the inter-onset times of eruptions at Stromboli over four days. Note that the formulation (8) is always strictly positive, even for distributions such as the Gaussian whose support includes the negative axis. However, fitting and simulating such processes presents certain practical difficulties.

Bebbington and Lai [4] fitted renewal models to a number of volcanoes, using the Weibull density with scale parameter  $\beta$  and shape parameter  $\alpha$ ,

$$f(u) = \alpha\beta(\beta u)^{\alpha-1} \exp(-(\beta u)^\alpha), \quad u > 0. \tag{17}$$

The intensity is then

$$\lambda(t) = \alpha\beta(\beta(t-s))^{\alpha-1}, \quad t > s. \tag{18}$$

We see that while  $\alpha = 1$  is the exponential distribution,  $\alpha < 1$  corresponds to an ‘over-dispersed’, or clustering, distribution (cf. [34]), and  $\alpha > 1$  to a more periodic distribution with a mode at  $u = \beta^{-1}(1 - 1/\alpha)^{1/\alpha}$ . The density and intensity are shown in Fig. 5.

De la Cruz-Reyna and Carrasco-Nunez [28] suggested using the gamma density, which also allows for clustering and periodicity, but the computational details are more complex. Also, the Weibull is the consequence of a material failure model [98], and in any case, little qualitative difference is usually observed between Weibull and gamma distributions for small samples, such as eruptive records. Note that the intensity (18) is monotonic, and can model either increasing probability of eruption as the repose time increases, such as at Hekla [103], or decreasing probability with increasing repose time, such as at Colima [63]. Bebbington and Lai [4,5] provided a number of tests for assessing the applicability of the Weibull distribution, based on the fact that  $r_i^\beta$ , where  $r_i = t_{i+1} - t_i$ , should be exponentially distributed.

The lognormal density,

$$f(u) = \frac{1}{u\sigma\sqrt{2\pi}} \exp\left[-\frac{(\ln u - \mu)^2}{2\sigma^2}\right], \quad u > 0, \tag{19}$$

with intensity

$$\lambda(t) = \frac{\frac{\sqrt{2}}{(t-s)\sigma\sqrt{\pi}} \exp\left[-\frac{(\ln(t-s) - \mu)^2}{2\sigma^2}\right]}{\operatorname{erfc}\left(\frac{\ln(t-s) - \mu}{\sqrt{2}\sigma}\right)}, \quad t > s, \tag{20}$$

was also considered by Bebbington and Lai [4], and used by Marzocchi and Zaccarelli [59] and Eliasson et al. [30]. As the density (19) is unimodal at  $u = \exp(\mu - \sigma^2)$ , this works better for non-clustering events, such as the very large eruptions considered in [59]. Eliasson et al. [30] noted significant departure from the distribution in one of their models. The density and intensity are shown in Fig. 6. Note that (20) is ‘upside-down bathtub shaped’, i. e., that as  $t$  increases it rises to a maximum and then declines.

The log-logistic density,

$$f(u) = \frac{\eta\gamma u^{\gamma-1}}{(1 + \eta u^\gamma)^2}, \quad u > 0, \tag{21}$$

with a mode at  $u = \max\{0, (\gamma - 1)/((\gamma + 1)\eta)^{1/\gamma}\}$  was used by Connor et al. [18] to model the intervals between Vulcanian explosions of Soufriere Hills volcano, Montserrat.

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 5  
 Density  $f$  and conditional intensity  $\lambda$  for the Weibull distribution with  $\beta = 0.0025$  and  $\alpha = 0.75$  (solid line),  $\alpha = 1$  (dotted line),  $\alpha = 1.5$  (dashed line) and  $\alpha = 2.25$  (dot-dash line)

The density and the intensity

$$\lambda(t) = \frac{\eta\gamma(t-s)^{\gamma-1}}{1 + \eta(t-s)^\gamma}, \quad t > s, \tag{22}$$

are shown in Fig. 7. The intensity (22) has a maximum at  $t = s + \max\{0, ((\gamma - 1)/\eta)^{1/\gamma}\}$ , prior to which it is increasing, subsequently decreasing. Thus we can see that the logarithistic distribution possesses some of the character of the Weibull and of the lognormal distributions.

Pyle [71] used the power-law density

$$f(u | u > c) = \frac{u^{-1-1/b}}{bc^{-1/b}}, \quad u > c > 0 \tag{23}$$

to model the tail of the inter-onset distribution. Note that the density is not defined for  $c = 0$ . The intensity is

$$\lambda(t) = \frac{1}{b(t-s)}, \quad t > s, \tag{24}$$

from which we see that the parameter  $b$  controls the rate of decay of the intensity, or equivalently, the ‘thickness of the tail’.

Turner et al. [94] fitted a renewal density consisting of a mixture of Weibull densities, as exemplified in

Fig. 8, to model a multimodal repose distribution. Cronin et al. [22] proposed a variant on this, where onsets occurred in ‘episodes’, each of variable numbers of eruptions, with different repose distributions corresponding to inter- and intra-episode repose.

The drawback of renewal models is that they commonly fail to explain variations in eruption rate, corresponding to changes in activity level, although Wickman [103] did suggest using a small number of different levels. This idea was taken up in [3], where a renewal process with parameters controlled by a hidden Markov model was fitted to flank eruptions from Mt Etna. Using the Weibull distribution (17) for the inter-onset times, the preferred model had long sequences of approximately Poisson behavior, interspersed with shorter sequences of more frequent and regular eruptions.

### Markov Processes

A *Markov process* (continuous time Markov chain)  $Z(t), t \geq 0$  has transition intensity matrix  $Q = (q_{ij})$ ,

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 6  
 Density  $f$  and conditional intensity  $\lambda$  for the lognormal distribution with  $\mu = 6$  and  $\sigma = 2$  (solid line),  $\sigma = 1$  (dotted line),  $\sigma = 0.5$  (dashed line) and  $\sigma = 0.25$  (dot-dash line)

where

$$q_{ij} = \lim_{t \downarrow 0} \frac{\Pr(Z(s+t) = j \mid Z(s) = i)}{t} \geq 0, \quad (25)$$

for all  $i \neq j$ , and  $-q_i = q_{ii} = -\sum_{j \neq i} q_{ij}$ . Thus the sojourn time in state  $i$  is exponential with mean  $1/q_i$ , and when it ends, the process moves to state  $j$  with probability  $p_{ij} = q_{ij} / \sum_{k \neq i} q_{ik}$ .

Wickman [104] proposed the use of Markov processes to model eruption-repose patterns. This entailed defining a number of eruptive and repose states, with prescribed permitted transitions between them. The initial models [104] allowed for one or two magma chambers, with eruptions and ‘solidification’ of the vent occurring in Poisson processes of differing rate. In the two-state case this solidification can only be removed by an eruption from the second, larger and deeper, magma chamber. If the two magma chambers erupt at rates  $\nu$  and  $\mu$  ( $\nu > \mu$ ), respectively, and the vent solidifies at rate  $\eta$ , then the eruption rate can be derived as

$$\lambda(t) = \frac{\mu\eta + \nu(\mu + \nu + \eta) \exp[-(\nu + \eta)(t - s)]}{\eta + \nu \exp[-(\eta + \nu)(t - s)]}, \quad t > s, \quad (26)$$

where the previous eruption occurred at time  $s$ . The pa-

rameters can be estimated by numerically fitting this equation to the empirical renewal intensity.

Wickman [105] extended this to six possibilities modeled on various well-known volcano types, and simulated them to produce reasonable appearing synthetic data. The process of fitting these models to observed data has required manual identification of the various states in the data [11,54], but the use of hidden Markov model techniques to automate the process has been suggested [3]. In a Markov process, the time between onsets is the passage time through the eruptive and repose states, which will have a compound exponential distribution, i.e., be the sum of a number of exponential random variables of differing means.

### Time and Size Predictable Models

Bacon [1] noted that the intervals between rhyolitic and basaltic eruptions in the Coso Range (California) appeared to be proportional to the volume of the preceding eruption. This *time-predictable* behavior (cf. [81]) is most simply explained by assuming that the rate of magma input is constant, and an eruption occurs when a certain magma level is reached. However, Bacon [1] suggested the covariate of accumulated extensional strain as the controlling

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 7  
 Density  $f$  and conditional intensity  $\lambda$  for the log-logistic distribution with  $\eta = 0.0005$  and  $\gamma = 0.8$  (solid line),  $\gamma = 1$  (dashed line),  $\gamma = 1.2$  (dot-dash line) and  $\gamma = 1.4$  (dashed line)

variable, and considered eruptions a passive response of the magmatic system to the tectonic stress field.

Similar behavior was observed for Fuego Volcano, Guatemala [54], together with a weaker proportionality between volume and the length of repose before an eruption, although the authors did note that “the volume estimates probably have an error of less than  $\pm 1$  order of magnitude”. Martin and Rose [54] also examined a possible link between the length of repose before an eruption and its geochemical composition. Santacroce [75] found a similar phenomenon at the Somma-Vesuvius complex, and suggested that eruptions there occur in cycles, of approximately 3000 years, each initiated by a large-scale Plinian eruption, and terminated by a long repose of several centuries. Klein [46] found evidence of time-predictable behavior at both Kilauea and Mauna Loa (Hawaii).

Wadge and Guest [101] suggested that the time-predictable model has a limited predictive ability, based on drawing an empirical envelope on the recent eruptive volume curve. This has a slope determined as the mean eruptive volume rate, and limits defined by the extreme points of the curve in the considered history. This enables a forecast of both the longest the current repose is likely to

last, and the maximum volume of the next eruption, provided that steady-state is maintained. Figure 9 shows an example using flank eruptions from Mt Etna 1970–2006. Wadge [99] estimated, however, that volcanoes may spend only 1/4–1/2 of the time in steady-state, being dormant much of the remainder. Changes in eruptive rate have also been found in a number of historical records [9,26,65].

De la Cruz-Reyna [26] proposed a general *load-and-discharge* model, where the ‘energy’ of the volcano increases at a constant rate  $\sigma$  between eruptions. The  $i$ th eruption occurs when this exceeds the threshold  $H_i$ , during which the stored energy drops to the threshold  $L_i$ , releasing an energy  $\xi_i = H_i - L_i$ . The interval between eruptions is thus

$$r_i = t_{i+1} - t_i = \frac{H_{i+1} - H_i + \xi_i}{\sigma} . \tag{27}$$

Hence successive repose intervals are not independent, as they include a common threshold term, and should be negatively correlated. In general, the thresholds can be random, but this formulation includes the time-predictable model. In this, the thresholds  $H_i$  are constant, and

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 8  
 Histogram of 122,000 sampled inter-event times for Mt Taranaki based on 1000 Monte Carlo runs. Curves show the fitted densities for this data set: Dotted line = exponential distribution, dot-dash = lognormal, dashed = Weibull, solid = mixture of Weibulls

thus the interval

$$r_i = \xi_i / \sigma \tag{28}$$

is proportional to the energy of the preceding eruption, and successive intervals are independent. Alternatively, if the thresholds  $L_i$  are held constant ( $= L$ , say),  $H_i = \xi_i - L$  and from (27)

$$r_i = (H_{i+1} - L) / \sigma . \tag{29}$$

Thus successive intervals are again uncorrelated, and the energy drop of the eruption is proportional to the length of the interval preceding it. This is termed the *size-predictable* model.

In a global analysis of eruptions, De la Cruz-Reyna [26] noted the existence of a regression relationship  $\log \lambda_0 = 3.494 - 0.789\text{VEI}$  with correlation  $-0.999$ , where  $\lambda_0$  is the Poisson intensity for eruptions of a given VEI. This led De la Cruz-Reyna [27] (see also [28]) to model the onsets of different VEI events as independent Poisson processes, in a special case of the size-predictable model. This approach was also used in the quantification of volcanic risk due to Vesuvius by Scandone et al. [76], based on the sequence of

equilibrium states (repose, persistent activity, intermediate eruption, final eruption) identified by Carta et al. [11].

Burt et al. [9], in an examination of the basaltic volcano Nyamuragia (Zaire), formulated the ‘pressure-cooker’ and ‘water-butt’ models. The former, where an eruption occurs when the magma volume reaches a threshold determined by the rock strength and reservoir shape, is the time-predictable model, while the latter, where eruptions always drain the magma reservoir to the same level, is the size-predictable model. Burt et al. [9] suggested physical explanations for stochastic perturbations observed in these models, and proposed that a volcano could be tested for time-predictability by performing a regression analysis of  $(v_i^{(1)})$  on  $(r_i)$ , where  $r_i = t_{i+1} - t_i$ , and  $t_i, v_i^{(1)}$  are the onset time and eruptive volume of the  $i$ th eruption. Similarly the size-predictable model entails a regression analysis of  $(v_i^{(2)})$  on  $(r_i)$ , where  $v_i^{(2)} = v_{i+1}^{(1)}$ . Sandri et al. [74] generalized the test for time-predictability to a regression analysis of  $(\log v_i^{(1)})$  on  $(\log r_i)$ , so that an estimated slope of  $b$  significantly greater than zero implies a time-predictable relation  $v_i^{(1)} \propto r_i^b$ . Marzocchi and Zaccarelli [59] performed a similar regression analysis of  $(\log v_i^{(2)})$  on  $(\log r_i)$  for the size predictable model, resulting in a relation  $v_i^{(2)} \propto r_i^b$ . Be-

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 9  
 Volume-time curve for Mt Etna flank eruptions (solid line). Dashed limits based on 1970–1990 data were exceeded, or equivalently the volcano departed from steady-state, by the 1991 eruption. Dot-dash limits based on 1970–2006 data have a steeper slope and wider limits to accommodate the 1991 eruption. The dotted lines show that the method predicts the next eruption to occur by the end of February 2011, and the eruptive volume to be less than  $142.1 + 20.8t$  ( $10^6 \text{ m}^3$ ), where  $t$  is the number of years to the date of the eruption from January 2007

cause both the repose and volume distributions are highly skewed, the logarithmic transformation is advisable to reduce the high leverage of the tail points.

Marzocchi et al. [57] estimated the VEI of the next eruption of Mt Vesuvius by considering a) the global catalog, b) a catalog of ‘analog’ volcanoes, and c) the catalog of Vesuvius itself. In each case, the catalogs are trimmed to those eruptions following a repose interval of at least the presently observed 60 years. The estimated probability of an eruption of  $\text{VEI} \geq 5$  ranged from 1% to 20%, and could not be considered negligible. This has implications for the Emergency Plan of Mount Vesuvius, which assumes a maximal  $\text{VEI} = 4$ .

Marzocchi and Zaccarelli [59] proposed a renewal model based on the time-predictable model. In their *open conduit system* model, the probability density of the time  $u$  to the next eruption is conditional on the previous eruptive volume  $v$ . Using a log-normal distribution, this is

$$f(u | v) = \frac{1}{u\sigma\sqrt{2\pi}} \exp \left[ -\frac{(\log u - (a + bv))^2}{2\sigma^2} \right], \quad (30)$$

where  $a, b$  are the intercept and slope regression coefficients from the regression of  $(\log v_i^{(1)})$  on  $(\log r_i)$ .

### Chaos and Fractals

A sufficiently complicated deterministic model is indistinguishable by finite observation from a random process. However, it is possible to construct systems with few degrees of freedom, but very complex dynamics, which are known as *chaotic systems*, or *strange attractors*. This possibility can be tested by examining the correlation properties of the observation sequence. The underlying principle of fractals is one of *self-similarity*, i.e., that the statistical properties of the process are invariant at differing time (or space) scales.

Sornette et al. [88] computed the dimension  $D$  of the attractor as a function of the dimension  $d$  of the embedding phase space. Given onset times  $t_i$ , let  $X_i^{(k)} = r_{i+k-1}$  for  $k = 1, \dots, d - 1$ , where  $r_i = t_{i+1} - t_i$ , for  $i = 1, \dots, n - 1$ . Then the correlation function is determined as

$$C_d(w) = \frac{1}{n^2} \#\{i, j: \|\mathbf{X}_i - \mathbf{X}_j\| < w\}, \quad (31)$$

where  $\mathbf{X}_i$  is the vector  $(X_i^{(1)} \dots X_i^{(d)})$ . The correlation dimension is then defined by the power law relation

$$C(w) \sim w^{D(d)}. \quad (32)$$

If this saturates at some value  $D_{\max}$  as  $d$  increases, this is taken as evidence that the underlying dynamics is deterministic and has dimension of the order of  $D_{\max}$ . Applications to the volcanoes Piton de la Fournaise (La Reunion Island) and Mauna Loa/Kilauea (Hawaii) produced estimates of  $D_{\max}$  of 1.7 and 4.6, respectively. The latter value was interpreted as evidence of two independent dynamical systems for the two Hawaiian volcanoes, contradicting the conclusion of Klein [46]. Sornette et al. [88] also constructed a series of ‘return maps’ ( $r_{i+1}$  as a function of  $r_i$ ) by truncating the data in various ways.

Dubois and Cheminee [29] used the Cantor dust model for volcanic eruption onsets. In this method, the eruptive record is divided into segments of length  $T$ , and the fraction of these intervals containing at least one onset is denoted  $X$ . If fractal clustering with fractal dimension  $D$  is present, then  $X \sim T^{1-D}$ . This implies a renewal model with intensity  $\lambda(t) = D/(t - s)$ ,  $t > s$ , where the last eruption occurred at time  $s$  (cf. Eq. (24)). An obvious method for estimating  $D$  is a regression analysis of  $(\log X_i)$  against  $(\log T_i)$  for various interval lengths  $T_i$ . Applied to the Piton de la Fournaise (La Reunion Island), two slopes were observed, one with  $D \approx 0.5$  for  $T < 10$  months, and one with  $D \approx 0.7$  for  $T > 10$  months. Kilauea had two regimes with  $D = 0.58$  for  $T < 24$  months and  $D = 0.81$  for  $T > 24$  months, while Mauna Loa had  $D \approx 0.35$  for  $T < 6$  years and  $D \approx 0.85$  for  $T > 6$  years. The two regimes all indicated clustering at short repose lengths, and more regular activity for eruptions separated by longer repose. This was interpreted as evidence of multiple magma chambers, with different sizes and recharge rates, at different depths. Applied to a combined catalog of flank and summit eruptions of Mt Etna 1950–1987, the result was a single regime with  $D = 0.88$ . This high value of  $D$  was interpreted as being characteristic of the regular eruptive activity of the volcano.

Marzocchi [55] calculated the statistic

$$a_{\max} = \max_{1 \leq s \leq 5} a(s), \tag{33}$$

where  $a(s)$  is defined in (3), although a process might first be de-trended by subtracting an auto-regressive model. A value  $a_{\max} > a_c^*$  indicates a chaotic system, while a value  $a_{\max} < a_s^*$  indicates a stochastic system. Intermediate values provide insufficient evidence for either. The critical values  $a_c^*$  and  $a_s^*$  are determined by simulation. Both Vesuvius and Etna evidenced significantly stochastic behavior.

A multifractal analysis using the Grassberger-Procaccia algorithm was performed by Godano and Ci-

vetta [33]. The correlation interval is calculated as

$$C(t, q) = \frac{1}{n-1} \sum_{i=1}^{n-1} \left[ \frac{1}{n-2} \sum_{j \neq i} H(t - |r_i - r_j|) \right]^q, \tag{34}$$

where  $r_1, \dots, r_{n-1}$  are the inter-onset times, and  $H(\cdot)$  is the Heaviside function. The *generalized dimensions* are then evaluated as

$$D_{q+1} = \phi(q)/q, \tag{35}$$

where  $\phi(q)$  is the estimated slope from a regression analysis of  $\log C(t, q)$  versus  $\log t$ . The fractal, information, and correlation dimensions are  $D_0, D_1$  and  $D_2$ , respectively. More generally,  $D_{q+1}$  is constant as  $q$  varies for a homogeneous fractal distribution, but varies with  $q$  for a multifractal distribution. The latter implies that local clustering properties are different from global clustering properties. Applied to eruptions of Vesuvius, the estimated dimensions were  $D_0 = 1.05 \pm 0.07$ ,  $D_2 = 0.75 \pm 0.04 \approx D_\infty = 0.73 \pm 0.02$  and  $D_{-\infty} = 1.09 \pm 0.13$ . This indicates that at a global scale, the catalog exhibits Poissonian behavior ( $D = 1$ ), and the most intense clustering is not a particularly strong effect. The catalog exhibits only weak multifractal behavior, and this only for  $q < 1$ . Thus the cyclic behavior outlined by Carta et al. [11] cannot be identified statistically, as the intervals between events in a cycle are not distinguishable from those between cycles.

Nishi et al. [69] examined the long term memory of the time series of 3796 eruptions of Sakurajima 1981–1999 using the Hurst exponent. Let  $r_i = t_{i+1} - t_i$ ,  $i = 1, \dots, n-1$ , be the inter-onset times, and set

$$X(k, t, m) = \sum_{i=1}^k \left( r_{i+t-1} - \frac{1}{m} \sum_{j=1}^m r_{j+t-1} \right). \tag{36}$$

Then the *self-adjust range* is

$$R(t, m) = \max_{1 \leq k \leq t} X(k, t, m) - \min_{1 \leq k \leq t} X(k, t, m), \tag{37}$$

which is re-scaled by the standard deviation

$$S(t, m) = \sqrt{\frac{1}{t} \sum_{i=1}^t \left( r_{i+m-1} - \frac{1}{m} \sum_{j=1}^m r_{j+t-1} \right)^2}, \tag{38}$$

and averaging over the length of the time series, the *Hurst exponent*  $H$  is then defined by

$$\frac{\sum_{m=1}^{n-1} R(t, m)}{\sum_{m=1}^{n-1} S(t, m)} = \left( \frac{t}{2} \right)^H. \tag{39}$$

The value of  $H$  can be estimated by a regression analysis of (39), after taking logarithms. The Poisson process produces a value of  $H = 0.5$ . A value of  $H$  greater than this implies persistent behavior, with each value depending on the previous one. Anti-persistence behavior is characterized by  $H < 0.5$ . The Hurst exponents for Sakurajima were  $H = 0.72$  for the whole series, and  $H = 0.74$  for a ‘high frequency’ period 1983–1985. A Monte Carlo test consisting of randomly reordering the observed inter-onset times and recalculating  $H$  confirms that these values are significantly greater than 0.5. Telesca and Lapenna [92] performed the same analysis for eruptions of  $VEI \geq 0$  of 14 volcanoes worldwide. The requirements were a minimum of 40 events during 1800–2000. Seven of the volcanoes, with Hurst exponents ranging from 0.79 to 1.3, were characterized by persistent behavior, while the remainder, with Hurst exponents ranging from 0.60 to 0.73, were not significantly different from a Poisson process.

Telesca et al. [91] examined 35 sequences of  $VEI \geq 0$  eruptions (minimum 25 eruptions 1800–2000) using the Fano factor method. The Fano factor is defined as the variance of the number of events in a specified interval width  $\Delta$  divided by the mean,

$$FF(\Delta) = \frac{(\Delta/T) \sum_{i=1}^{T/\Delta} N_i^2 - \left( (\Delta/T) \sum_{i=1}^{T/\Delta} N_i \right)^2}{(\Delta/T) \sum_{i=1}^{T/\Delta} N_i}, \quad (40)$$

where  $N_i = N((i - 1)\Delta, i\Delta)$ . Telesca et al. [91] represented the FF of a fractal point process as a monotonic power law

$$FF(\Delta) = 1 + \left( \frac{\Delta}{\Delta_0} \right)^\alpha, \quad (41)$$

for  $\Delta > \Delta_0$ , where  $\Delta_0$  is the fractal onset time, marking the lower limit for significant scaling behavior, with negligible clustering below this. Again the fractal exponent  $\alpha$  is estimated by a regression analysis of (41), after taking logarithms. For Poisson processes, the FF is approximately one for all interval lengths, and so  $\alpha \approx 0$ . Of the 35 sequences examined, 30 had fractal exponents ranging from 0.2 to 0.9 (mean of 0.5). The remaining five exhibited no value  $\Delta_0$  above which (41) held.

Gusev et al. [34] examined clustering of eruptions on Kamchatka during the last 10,000 years using the Weibull density (17) for the inter-onset times, the correlation dimension (32), and the Hurst exponent (39). No self-similar behavior was found for intervals greater than 800 years, but for shorter delays there was a significant degree of clustering. Gusev et al. [34] also generalized the correla-

tion dimension by replacing (31) by a weighted version, where the contribution of a pair of events is proportional to the product of their eruptive volumes. This identified self-similar behavior over the entire range of inter-onset times (100–10,000 years).

Fractals have basically been used in volcanology as a descriptive technique. They can provide, at the level of a single volcano, some indication of the sort of stochastic model that might fit the observed behavior. Applied to multiple volcanoes, they can provide a similarity index, useful for sorting volcanoes into homogeneous groups.

### Volcanic Regimes

Apart from the nonhomogeneous model (4), the parametric models examined above have all been stationary, in the sense that the statistical properties of the intensity function do not vary over time. However, Wadge [99] postulated that, while a volcano could be in steady state on a time scale of years to decades, in the longer term the activity can wax and wane. Thus, particularly for long-term hazard forecasts, it is desirable to formulate methods of detecting (and modeling) such non-stationary activity.

Wickman [103] suggested that the activity of a volcano could change over time, perhaps in discrete steps, which we will term *regimes*. Mulargia et al. [65] addressed the importance of objectively identifying regimes of a volcano, noting however that a) the number of regimes is unknown, b) they may follow different distributions, and c) sample sizes are generally small. Different patterns of eruption and magma output are supposedly features of most volcanoes, and fundamental to the understanding and modeling of eruptions. These regimes may represent changes in the eruption mechanism, the mechanism for transport of magma to the surface, or the eruptive style (see, for example, the interpretation by Wadge et al. [102]). The estimated properties of such regimes can exclude certain models or mechanisms of volcanic eruption [46].

Various methods have been used to identify changes in regime, one based on cumulative eruptive volume [99,102] already having been illustrated in Fig. 9. Another uses a running mean of time between onsets. Suppose that the individual reposees are denoted by  $r_i = t_{i+1} - t_i$ ,  $i = 1, \dots, n - 1$ , and that  $\sum_{i=1}^{n-1} r_i = T$ . If the reposees are divided into disjoint groups of  $m$  consecutive reposees, then  $(2(n - 1)/T) \sum_{i=(k-1)m+1}^{km} r_i$ , for  $k = 1, \dots, \lfloor (n - 1)/m \rfloor$ , where  $\lfloor \cdot \rfloor$  is the greatest integer function, are independent and have a chi-square distribution with  $2m$  degrees of freedom [46].

Mulargia et al. [65] presented a method based on the theory of change-point problems. Suppose that we have

a time series of data  $X_1, \dots, X_n$ , which might be, for example, inter-onset intervals, eruptive volumes, or effusion rates. The algorithm begins by setting a significance level  $\alpha$ , and examining the time series to determine the most significant change point. If a change point is found, the time series is divided into two parts at this point, and each examined to determine the most significant change point. The algorithm proceeds recursively until no further significant change points are found. The most significant change point is identified by a search process: For  $m = 3, \dots, n-3$ , divide the time series into two segments  $X^{(1)} = X_1, \dots, X_m$ , and  $X^{(2)} = X_{m+1}, \dots, X_n$ , and calculate the Kolmogorov–Smirnov (two-tail) statistic as

$$J = \left( \frac{m(n-m)}{n} \right)^{1/2} \max_x |F_1(x; m) - F_2(x; n-m)|, \quad (42)$$

where  $F_j(x; k) = \#\{i: X_i^{(j)} \leq x\}/k$  is the empirical distribution function of the first segment, et cetera. For large  $m, n-m (> 30)$ , the approximate critical value  $J_\alpha$  of the statistic can be determined from

$$\Pr(J < J_\alpha) = \sum_{k=-\infty}^{\infty} (-1)^k \exp(-2k^2 J_\alpha^2) = 1 - \alpha. \quad (43)$$

Exact critical values for small  $m, n-m$  are also available.

Later approaches used the cumulative count of eruptions in a statistical control chart [39], applied by Burt et al. [9] to Nyamuragia, and rank order statistics for the size of event [71]. Bebbington [3] noted that a hidden Markov model for the activity, with the unobserved state representing the regime, provides for regime identification via the Viterbi algorithm, which finds the most likely path through the hidden states.

## Mount Etna

Mount Etna possesses one of the most complete records of volcanism known. A variety of eruption styles have been displayed, but since 1500 the activity has been predominantly effusive eruptions from lateral vents on the volcano's flanks, or from the central craters. The record of summit eruptions is incomplete prior to 1970 [101], but data for flank eruptions is considered complete since 1600 or so [65]. The volumes of all such eruptions have been estimated [74], and these have been shown to be well correlated with the observed duration [67]. As the summit eruptions appear to be of different style [102], and to have different mechanisms to the flank eruptions [66] the longer record of the latter can be analyzed in isolation. In addition,

only flank eruptions pose a major threat to inhabited areas [73].

Using the cumulative erupted volume curve, Wadge and Guest [101] found that the volume output was in steady state 1971–1981. Mulargia et al. [67] found that the events 1600 to 1980 were satisfactorily fit by a stationary Poisson process, but that the distribution of eruptive durations changed at the end of the 17th century, confirming the observation of Wadge et al. [102]. However, Mulargia et al. [65] identified a change point in the inter-onset times at 1865, both parts being consistent with a Poisson process, and, when augmented by volume data, change points at 1670 and 1750. Using the effusion rate (= volume/duration), Mulargia et al. [65] found a change point at 1950 in the 1600–1980 data, with the later sequence being of significantly lower rate. A repeat of the analysis by Gasperini et al. [31] for the data 1978–1987 identified a change point in the inter-onset times at November 1978, although no change point occurred in the volume series. Ho [39] fitted a statistical control chart based on the Weibull process, and found departures from the trend (4) in 1702 and 1759. Marzocchi [55] found some evidence of a trend in inter-onset times in the 1600–1994 data, while Sandri et al. [74] found no change points in the inter-onset times or eruptive volumes in the 1971–2002 data. Salvi et al. [73] determined that the activity 1536–2001 was not Poissonian, and although there was no trend 1536–1980, there was a trend in the data 1536–2001. They therefore concluded that the last 20 years of data is from a nonhomogeneous Poisson process, and fitted a Weibull process model with increasing trend.

The regime change points identified in the Mount Etna flank eruption data are summarized in Table 1. The lack of consistency is due to differences in both models and, via the fitting of them, in the coverage of the data. These models are 'first order' in the data being analyzed. Using hidden Markov models, Bebbington [3] was able to examine the 'second order' quantity of the correlation between durations and subsequent repose. The conclusion was that changes in volcanic regime may be more frequent and/or fleeting, and thus undetectable by change-point methods, than has been thought. Notably, the identified change points corresponded closely to those identified manually by Behncke and Neri [7], showing that these are statistically identifiable. The complex relation between the duration of an eruption and the subsequent repose appears to be at least partially explained by an open/closed conduit system model with transitions between them. On the other hand, the correlation between repose and subsequent durations may be sensitive to the longer of the two cycles identified by Behncke and Neri [7]. This would indi-

	Sandri et al. [74]	1971–2002	None

cate that flank eruptions are being fed from more than one magma chamber, of widely different sizes and recharge rates.

**Spatial Aspects**

In the case of polygenetic cones, the major aspect of hazard modeling is temporal. Spatial aspects are limited to the direction of flank eruptions (cf. [73]), and the likely paths of lava flows and lahars. In monogenetic volcanic fields, where cones correspond to single eruptions, there is a true spatio-temporal element to modeling occurrence data.

**Spatio-temporal Intensities**

The models used to describe spatio-temporal eruption occurrence have been largely nonparametric, or kernel-type. Connor and Hill [17] gave three methods:

1. Spatio-temporal nearest-neighbor estimate: Suppose we have  $n$  volcanoes, that the formation of the  $i$ th volcano occurred at time  $t_i$ , and let  $u_i$  be the area of a circle with radius equal to the distance between the point  $x$  of interest and the  $i$ th volcano. Further, let  $j = 1, \dots, m$  index the  $m$ th nearest neighbors to the point  $x$  using the distance metric  $u_i(t - t_i)$ . Then the estimated intensity at the point  $x$  is

$$\lambda(x, t; m) = \frac{m}{\sum_{j=1}^m u_j(t - t_j)}, \tag{44}$$

where  $m$  is the number of nearest neighbors used in the estimation, which was set equal to the number of volcanoes, although a smaller choice is possible. The temporal hazard for an area  $A$  can then be obtained by integrating the intensity (44) over the area. Note that in

practice, to avoid singularities,  $u_i > c$ , a constant, and the intensity is summed over a grid. The choice of  $c$  may be an interesting question.

Condit and Connor [14] proposed that the optimal  $m$  can be determined by matching the average recurrence rate  $\int_{x \in A} \lambda(x, t; m) dx$  to the observed average recurrence rate  $\bar{\lambda}(t) = N(t-s, t)/As$ , in a window of length  $s$ , for the area  $A$ . Further, Condit and Connor [14] also suggested that overestimation during rapidly waning stages of activity can be addressed by defining a threshold time beyond which prior eruptions are not included in the calculation.

2. Kernel estimate: If we have  $n$  volcanoes, then using the Epanechnikov kernel

$$\kappa_i = \max \left\{ 0, \frac{2}{\pi} \left[ 1 - \left( \frac{d_i}{h} \right)^2 \right] \right\}, \tag{45}$$

where  $d_i$  is the distance from  $x$  to the  $i$ th volcano, we have the spatial intensity

$$\lambda(x) = \frac{1}{e_h} \sum_{i=1}^n \frac{\kappa_i}{h^2}, \tag{46}$$

where  $e_h$  is an edge correction. Conway et al. [20] use the Gaussian kernel instead. The parameter  $h$  is a smoothing constant. A small value of  $h$  concentrates the probability close to existing volcanoes, while a large value distributes it more uniformly. Estimating the best value of  $h$  is a difficult task – see Vere-Jones [96] for an earth sciences based discussion.

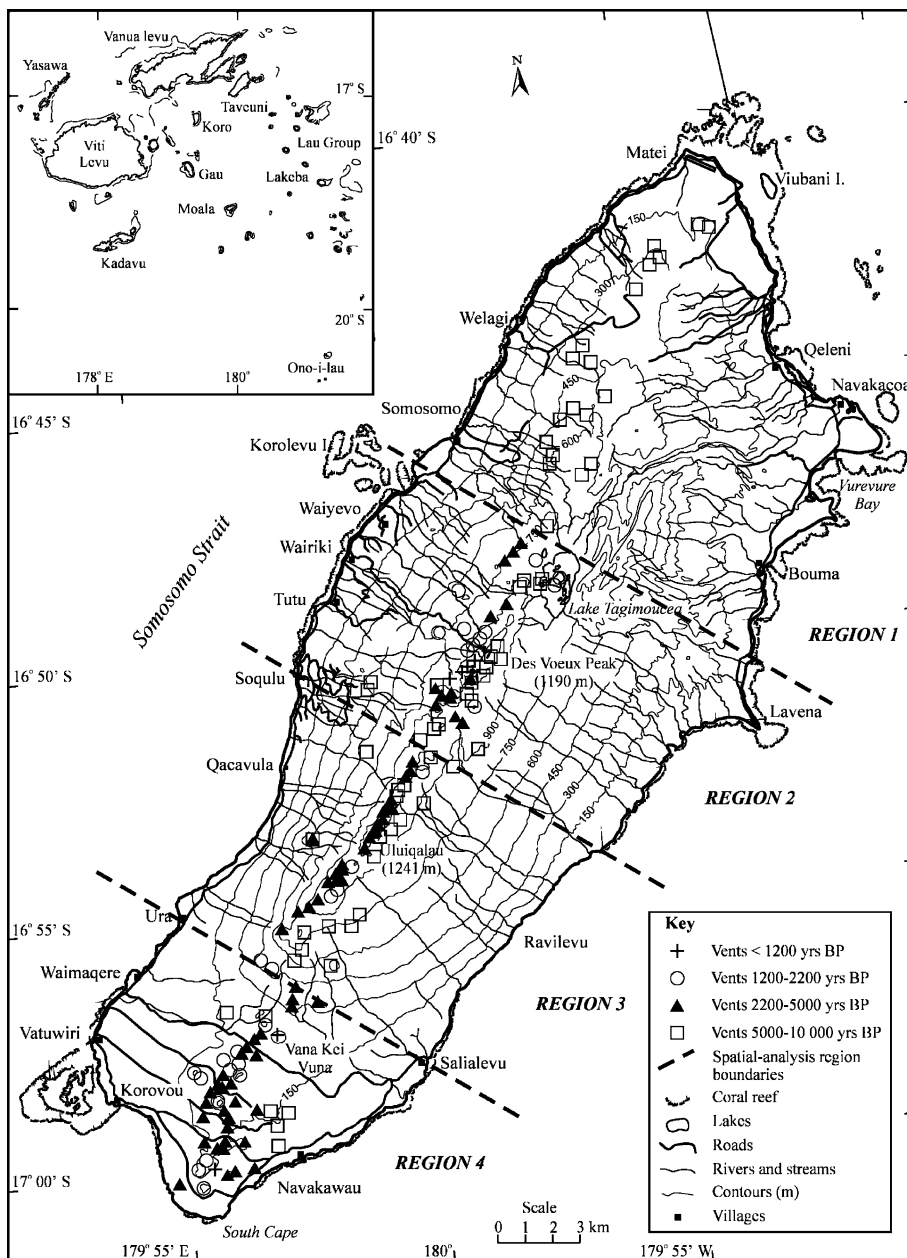

3. Nearest-neighbor kernel estimate: Here we replace the smoothing constant  $h$  in the Kernel estimate with  $d_{(m)}$ , the distance to the  $m$ th nearest neighbor using the  $d_i$  metric.

The two (spatial) kernel estimates above can then be made into spatio-temporal estimates by multiplying them by a spatially independent temporal rate  $\hat{\lambda}_0 = N/T$ , resulting in

$$\lambda(x, t) = \lambda(x)\hat{\lambda}_0 . \tag{47}$$

Ho and Smith [42] generalized (47) by replacing  $\hat{\lambda}_0$  by the Weibull process intensity (4).

Martin et al. [53] extended the spatio-temporal idea with a Bayesian formulation to incorporate information from other geophysical data such as P-wave velocity perturbations or geothermal gradients. The spatio-temporal

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 10

intensity (46) is used as an a priori intensity  $P(x)$ , and a likelihood function  $L(\theta | x)$  is generated by conditioning the geophysical data  $\theta$  on the locations of volcanic events. The a posterior intensity can then be obtained from Bayes' theorem as

$$P(x | \theta) = \frac{P(x)L(\theta | x)}{\int_{y \in A} P(y)L(\theta | y)dA}, \tag{48}$$

where  $A$  is the volcanic field.

**Markov Chains**

In the case where there is a geologically useful spatial classification, and sufficient data, a simple Markov chain approach can be used. If the  $i$ th eruption occurs in spatial region  $X_i$ , then the transition matrix is  $P = (p_{jk})$ , where  $p_{jk} = \text{Pr}(X_{i+1} = k | X_i = j)$ . The maximum likelihood estimates are  $\hat{p}_{jk} = N_{jk} / \sum_l N_{jl}$ , where  $N_{jk}$  is the number of transitions from  $j$  to  $k$  observed in the data. The Markov chain can be tested against a null hypothesis of independence using the statistic

$$\chi^2 = 2 \sum_j \sum_k N_{jk} \log \left[ \frac{N_{jk} / \sum_l N_{jl}}{\sum_l N_{lk} / \sum_l \sum_m N_{lm}} \right], \tag{49}$$

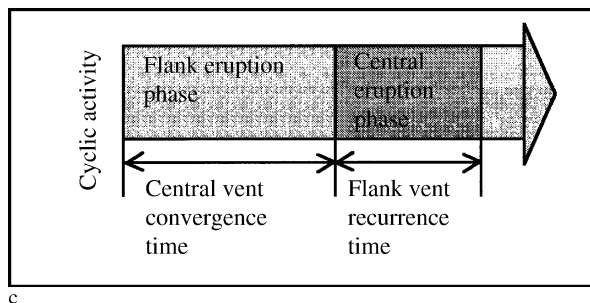

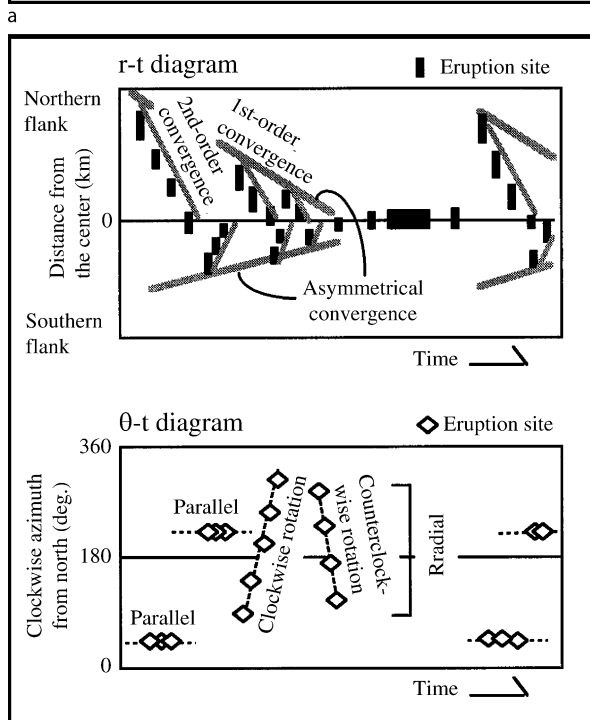

which asymptotically has a  $\chi^2$  distribution with  $K^2$  degrees of freedom, where  $K$  is the number of states. Cronin et al. [22] used this approach, made feasible by the essentially linear rift formation shown in Fig. 10, to estimate the hazard at the heavily populated south-west end of Taveuni,

Fiji. This was combined (cf. Eq. (47)) with a hierarchical renewal model for the temporal aspect to provide an alternative to the spatio-temporal hazard estimate from (44) shown in Fig. 11. Eliasson et al. [30] likewise divided the Katla caldera, Iceland, into three sectors to examine the spatial progression of volcanogenic flood events.

In the same vein, a few studies have considered possible correlations between multiple vents on the same volcano. Klein [46] showed using a runs test that eruptions and intrusions at Kilauea tend to cluster in time, and that intrusions occur in place of eruptions during long repose. By dividing Kilauea repose into summit-summit, summit-flank, flank-summit and flank-flank pairs, and finding that their distributions did not differ statistically, Klein [46] showed that the location of the previous event provided no information about the time of the next eruption. At Mauna Loa, however, repose following flank eruptions were significantly longer than those following summit eruptions, consistent with the fact that the former are generally more voluminous than the latter. Examination of the sequences of summit and flank eruptions disclosed that Kilauea summit eruptions tend to occur in runs, due solely to the long summit sequence of 1924–1954, while Mauna Loa displays no tendency for clustering or alternation of summit and flank eruptions. However, Lockwood [49], in an analysis of 170 well-dated prehistoric lava flows from Mauna Loa, identifies cycling between summit overflows and flank eruptions with a periodicity of about 2000 years.

Takada [90] proposed using time-series plots, as shown in Fig. 12, to visually express the temporal relationship between flank and summit eruptions, in particular plots of flank-vent distance and direction from the central vent. Central eruption phases, defined as periods where at least 70% of eruptions are central vent eruptions without accompanying flank eruptions, alternate with flank erup-

tion phases. Salvi et al. [73] considered the azimuth distribution of flank eruptions from Mount Etna, as in Fig. 13, determining that there is no significant difference in the pre- and post-1536 distributions.

Klein [46] also examined the relation between activity at the nearby volcanoes of Kilauea and Mauna Loa. Separating the record into three parts at the longest repose of each volcano disclosed that the activities were inversely related. The rank correlation of the number of events in five year periods 1915–1980 was  $-0.646$ , significant at a level of 0.01, which indicates that they share the same magma source. Bebbington and Lai [5] repeated this analysis for the New Zealand volcanoes Ruapehu and Ngauruhoe, finding that the combined eruption sequence was indistinguishable from a superposition of indepen-

dent Poisson processes. This independence of the eruption sequences argues for separate magma sources.

**Alignments and Clusters**

There has also been considerable interest in detecting alignments or clusters of volcanic vents, in the hope that these can be related to geological features.

Lutz [50] proposed the ‘two-point azimuth method’, where the azimuth between every two vents is measured, generating  $n(n-1)/2$  measurements for  $n$  vents. These are then binned in  $10^\circ$  intervals, although the bin size could vary, and the result tested for departure from randomness. As non-circular fields and/or a non-homogeneous density of points can produce a preferred orientation, a correction must be made in these cases. One way of doing this is to use Monte Carlo simulation of random points to produce a reference distribution from which departures can be detected. Lutz and Gutmann [51] noted that using kernel smoothing methods for the vent location provides an improved distribution from which to perform the Monte Carlo simulation.

Wadge and Cross [100] suggested the use of the Hough transform. In this technique, a point  $(x, y)$  is converted into the normal parameterization  $(\rho, \theta)$ , where  $\rho = x \cos \theta + y \sin \theta$ . Thus each point generates a curve in the  $(\rho, \theta)$  plane as  $\theta$  varies, and multiple (more than two curves) intersections of these define the alignment of co-linear points. In practice the scales for  $\rho$  and  $\theta$  are quantized into discrete bins, which allows for a small degree of departure from strict co-linearity. Significance levels can be obtained via Monte Carlo techniques.

Connor [15] suggested the use of uniform kernel density fusion cluster analysis, using the distance metric

$$d(i, j) = \begin{cases} \frac{1}{2} \left( \frac{1}{m_i(w)} + \frac{1}{m_j(w)} \right), & \|x_i - x_j\| < w \\ \infty, & \text{otherwise,} \end{cases} \quad (50)$$

where  $\|\cdot\|$  denotes map distance, and  $m_i(w)$  is the number of cones within a circle of radius  $w$  centered on the  $i$ th vent. Cones are linked into clusters starting with the smallest values of  $d$ . Clusters are only combined if the ‘density fusion’  $d$  between the clusters is greater than the maximum  $d$  between any two events within either cluster. This makes it possible to recognize overlapping clusters. The search radius  $w$  is determined experimentally.

Connor [15] and Connor et al. [16] used the two-point azimuth method, Hough transform and cluster analysis to map clusters of multiple cones with common alignments in the TransMexican volcanic belt and Springerville volcanic field (Arizona).

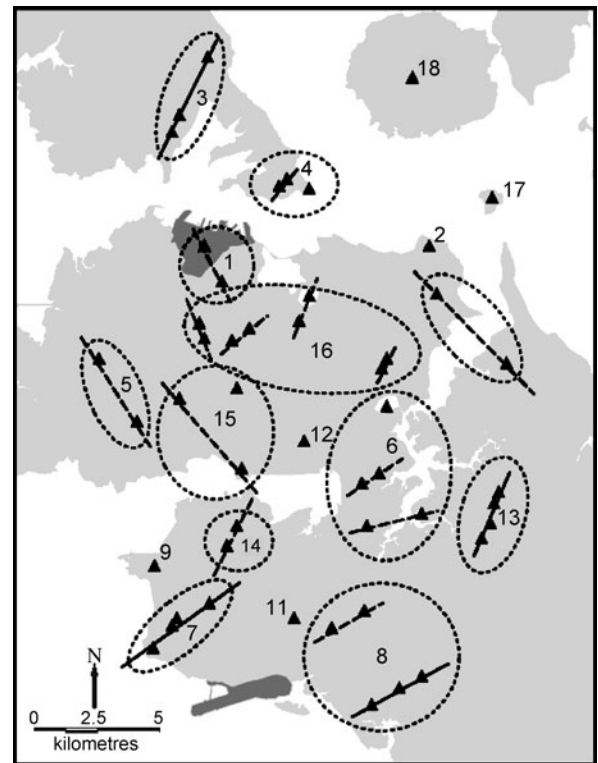

Magill et al. [52] measured vent clustering in the Auckland volcanic field using the statistic

$$L(d) = \sqrt{\frac{K(d)}{\pi}} - d, \quad (51)$$

where

$$K(d) = \frac{A}{n} \sum_{j=1}^n \sum_{i \neq j} \frac{H(d - d_{ij})}{w_{ij}} \quad (52)$$

is Ripley’s K-function,  $A$  is the area of the field,  $d_{ij}$  is the distance between the  $i$ th and  $j$ th vents,  $H(\cdot)$  is the Heaviside function, and  $w_{ij}$  is an edge correction. Peaks of positive  $L(d)$  indicate clustering, and troughs of negative values regularity, at that distance. The Auckland field exhibits clustering at between 900 and 1600 m, and spatial regularity at about 4600 m. This clustering was used to collapse

49 cones into 18 events. Magill et al. [52] then examined the distance separating consecutively erupted vents, and the distance between clustered eruptions, concluding that eruptions do not occur randomly, and occur preferentially closer to the previous eruption. Vent alignments in NE–SW and NW–SE directions were observed within clusters, as shown in Fig. 14. Using these observations, Magill et al. [52] constructed a Monte Carlo simulation model for the location of the next vent. Based on the last vent location (Rangitoto), the distance to the center of the next cluster was simulated from a distribution fitted to the observed distances. The number of vents was described by a negative binomial distribution, and vent locations were then simulated from a fitted distribution for the distance from the center of the cluster, modified by the observed alignment distribution, with the results shown in Fig. 15. Some 57% of the simulated eruption locations occur either on land, or within 1 km of the coast, rising to 69% if one considers the probability of at least one eruption from the next cluster falling within these limits.

### Yucca Mountain

After Mount Etna, the next most studied volcano is probably the volcanic field at Yucca Mountain, Nevada (cf. Fig. 16), due to the high-level radioactive waste repository planned there. The available data [13] consists of a large number of basaltic volcanoes, of ages 80,000 years to 10,500,000 years. These of course have large dating er-

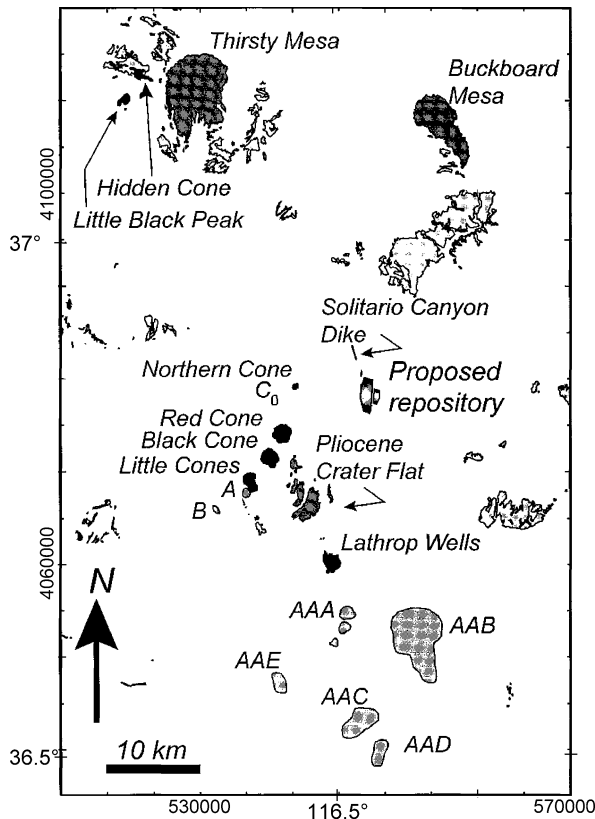

rors associated with them, but most analysis do not seem to have included this. The object is to estimate the probability of disruption of the repository by a volcanic intrusion. This is dependent on the probability of an intrusion, the distribution of the intrusion's dimensions, and on the dimensions of the repository itself.

The first analysis [23] used a Poisson process for the probability of an event, coupled with a Bernoulli probability of an event disrupting the repository:

$$\begin{aligned} \Pr(\text{no disruption before time } t) &= \sum_{n=0}^{\infty} \frac{(\lambda t)^n}{n!} (1-p)^n \\ &= e^{-\lambda t p}. \end{aligned} \quad (53)$$

The probability of an event being disruptive was estimated as  $p = a/A$ , where  $a$  is the area of the repository, and  $A$  the area, including the repository, used to define  $\lambda$ . The latter was estimated as  $N/T$ , where  $N$  is the number of scoria cones, and  $T$  the corresponding time period. Ho et al. [43] elaborated on means of estimating  $\lambda$  through event counts, repose intervals and magma volumes, and Ho [38] suggested a Bayesian framework for estimating  $p$ .

The next approach [38] attempted to incorporate a trend in the rate of volcanism using the Weibull process (4). As the data consisted of a number of clusters each containing several cones, but only the former had been dated, the event dates input to the Weibull process

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 16

consisted of multiples of each of a few dates. Depending on the details of the implementation, there was either a strong ( $\beta > 2$ ) increasing trend, or no significant trend at all. Notably, Ho [38] used a homogeneous Poisson process, with rate equal to the fitted Weibull process intensity at the present, for future prediction, although a continuing Weibull process was one possibility considered in the sensitivity analysis [40]. Ho and Smith [41] combined the Weibull process and Bayesian estimation of  $p$  in a formulation allowing the incorporation of ‘expert knowledge’.

Sheridan [80] included a spatial element by fitting a bivariate Gaussian distribution with five parameters (the  $(x, y)$  coordinates of the center, the length of the major and minor axes, and their orientation) to the volcanic field

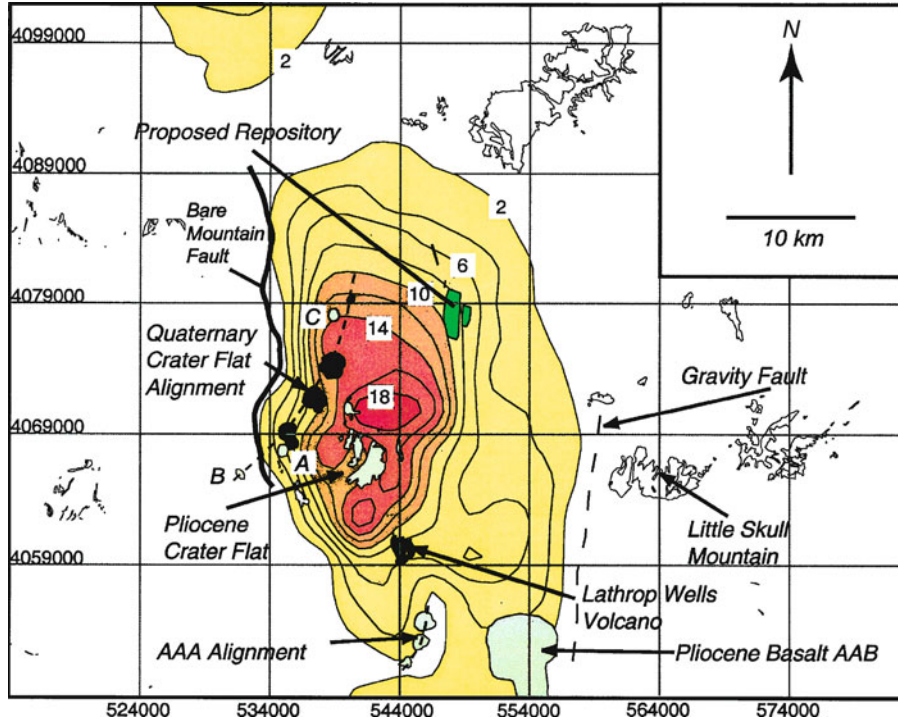

as a whole. Connor and Hill [17] used the spatio-temporal estimate (44), and integrated the resulting intensity over the area of the proposed repository, using a Gamma distribution for the area of a new volcano. The effects on the intensity of future events beyond the vicinity of the repository were ignored. Similar results were obtained using kernel-type estimators. Ho and Smith [42] elaborated on the latter by making the independent temporal component a Weibull process, while Connor et al. [19], while retaining the temporal Poisson process component, imposed a variety of geological constraints from crustal density, vent and fault alignments, and vent positions, on the spatial Gaussian kernel intensity in Fig. 17. A sensitivity analysis restricting the vent locations to various date-subsets was also conducted.

Crowe et al. [24], in their ‘final report’ of hazard studies at Yucca Mountain, summarized previous work, in particular that of Geomatrix Consultants [32]. They also fitted uniform, triangular (two varieties) and normal distributions to event count data, and simulated the results to obtain hazard estimates.

Smith et al. [85] suggested that the volcanism in the Yucca Mountain area could be episodic volcanism, and linked to an area of hot mantle. This would make possible another future peak of volcanism, with consequent underestimation of the recurrence rate. It was suggested that recurrence rates up to four times those previously used might be feasible. On the other hand, Coleman et al. [13] considered the lack of any detected dikes in or above the potential repository block, treating intrusions as an isolated Poisson process with zero observations in 13,000,000 years (although there was one ‘near-miss’). The conclusion was that high probabilities ( $10^{-6}$  per year) of disruption are ‘unrealistic’. Table 2 summarizes the published hazard estimates.

### Interactions with Earthquakes

A common question is whether an eruption is related to a preceding large regional earthquake (or vice-versa). Stress changes from earthquakes resolved at dike locations tend to be small, in fact smaller than those associated with solid earth tides. The exception are those earthquakes within a few fault-lengths. However, small increments of stress may of course advance the occurrence of an already imminent eruption. On a longer scale, as both eruptions and earthquakes are tectonic in nature, they must be related. Any such correlation may provide additional information about the likelihood of an imminent eruption which may be caused, or at least ‘detected’, by seismic activity. Alternatively, one might be interested in the likeli-

hood of potentially dangerous earthquakes during a period of volcanic activity.

Sharp et al. [79] considered the relationship between eruptions of Mount Etna and earthquakes from various

structural zones of southern Italy. Both the earthquakes and eruption onsets were treated as Poisson processes, an assumption that had to be tested, with intensities  $\lambda_a$  and  $\lambda_b$ , respectively. A variable  $\xi(t)$  is formed by summing the

number of A-series events in the intervals  $(B_i, B_i + t)$ , where  $(B_i)$  are the observed times of the B-series events. If the two series are independent, then  $\xi(t)$  should have a Poisson distribution with mean  $\hat{\lambda} = \hat{\lambda}_a \hat{\lambda}_b T$ , where  $T$  is the length of the observation period, and  $\hat{\lambda}_i = N_i(T)/T$ , for  $i = a, b$ . For example, if B-series events consistently lead A-series events by some interval less than  $t$ ,  $\hat{\xi}$  will be significantly larger than  $\hat{\lambda}$ . The significance of an observed  $\hat{\xi}(t)$ , or confidence limits, can be obtained from the null distribution, which is Poisson with mean  $\hat{\lambda}$ . Repeating the procedure for varying  $t$  identifies significant correlations. Sharp et al. [79] found that the earthquakes were not Poissonian, but could be represented as a non-stationary Poisson process. A significant relationship was found between local earthquakes and subsequent flank eruptions within a few hundred days. Also, summit eruptions were found to occur before flank eruptions not preceded by earthquakes, but the summit eruptions themselves were not correlated with earthquakes. This suggests two mechanisms for flank eruptions of Etna: Those preceded by summit eruptions may be caused by magma pressure in the reservoir, while those preceded by earthquakes may be due to fracturing of the flank by earthquakes caused by tensile forces associated with the east-west extension of eastern Sicily.

Klein [47] examined various precursors of volcanic eruptions at Kilauea by examining the ratio of these precursors preceding an eruption to their long-term average value. The candidates included summit tilt, daily counts of small caldera earthquakes, repose since the last eruption, earth tides, and rainfall, as shown in Fig. 18. The number of caldera earthquakes was highly significant as a short-term (10 days or less) predictor, but tilt rate was a better predictor beyond 20 days. The fortnightly earth tidal modulation was also significant (cf. [54]), as it appears to trigger a volcano that is nearly ready to erupt anyway. Similarly, Mulargia et al. [66] used a statistical non-parametric pattern-recognition algorithm to examine possible precursors of eruptions at Mount Etna 1974–1990, including the number of earthquakes in five surrounding tectonic regions, and their maximum magnitude. An eighty day interval straddling the eruption onset was considered, and the pattern of 12 factors in each interval noted. The only statistically significant result was that flank eruptions were linked to seismicity with more than six earthquakes in the surrounding regions during the 80 day period. All 11 of the flank eruptions considered satisfied this condition, but only 11 out of 24 (in a total of 62) windows with this level of seismicity corresponded to earthquakes. Summit eruptions possessed no discernable pattern.

Mulargia [64] used the intensity cross product for two series of events at times  $0 < s_1 < \dots < s_{M(T)} < T$  and

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 18

Kilauea volcano: Several parameters and eruption probability enhancement at an expanded time scale. The figure spans 10 months during 1979–1980 and includes the November 16, 1979, eruption (solid vertical line), and intrusions on August 12, 1979, and March 2 and 10, 1980 (dashed vertical lines). Intrusions, like eruptions, are generally accompanied by summit deflation, an earthquake swarm and harmonic tremor, but magma fails to reach the surface. The eruption probability enhancement is plotted as a 1-day outlook (solid line) and 30-day outlook (dashed line). The 1-day probability depends on the fortnightly tide and oscillates with it. The 30-day probability is a function of smoothed tilt and earthquake parameters and does not depend on the tide. Note that eruption probability enhancement was higher than average (greater than 1) for about 2 months prior to the November 1979 eruption and March 1980 intrusions. From [47], Figure 4 © 1984 by the American Geophysical Union

$0 < t_1 < \dots < t_{N(T)} < T$ . For a lag  $u$ , this is estimated by

$$\hat{p}_{MN}(u) = \frac{n(u, h)}{2hT}, \tag{54}$$

where  $n(u, h) = \#\{i: t_j + u - h \leq s_i \leq t_j + u + h, \text{ for some } j\}$  is the number of events from the process  $M$  that occur within a window of length  $2h$  of the lag of a point in the process  $N$ . Under a null hypothesis of two independent Poisson processes, the significance level can be calculated as

$$P = \sum_{k=n(u, h)}^{N(T)} \binom{k}{N(T)} \left(\frac{2hM(T)}{T}\right)^k. \tag{55}$$

This was applied to the flank eruptive activity and local seismicity at Mt Etna 1974–1990. The data consisted of 11 eruptions and 12 seismic sequences [31]. Using a window of length  $2h = 10$  days, Mulargia [64] found a highly significant association peak at a lag  $u$  between  $-7$  and  $3$  days. This indicates that local earthquakes and flank eruptions are largely concomitant phenomena.

Marzocchi et al. [58] examined the correlation between eruptions of Vesuvius and earthquakes of  $M > 5.4$  in the southern Apennines, Calabrian Arc and Sicily, 1631–1944. The eruptions and earthquakes were binned into intervals of 1, 2, 3 and 4 years, and the Spearman rank correlation

$$\rho_{XY}(k) = \frac{\sum_{i=1}^m R(X_{i+k})R(Y_i) - m(m+1)^2/4}{\left(\sum_{i=1}^m R(X_{i+k})^2 - m(m+1)^2/4\right)^{1/2} \cdot \left(\sum_{i=1}^m R(Y_i)^2 - m(m+1)^2/4\right)^{1/2}} \tag{56}$$

calculated, where  $X_i, Y_i$  are the total seismic moment and number of eruptions in the  $i$ th time bin,  $R(\cdot)$  is the rank, from smallest to largest, of the quantities, and  $k$  is the lag. Varying this lag produces the Spearman correlogram. Marzocchi et al. [58] observed changes in eruptive activity following increases in seismicity in the southern Apennines after 6–13 years, and with delays of 27–30 years and 36–39 years for earthquakes in Sicily and the Calabrian arc, respectively. Nostro et al. [70] investigated this coupling (cf. Fig. 19) in terms of the Coulomb stress change on a magma body beneath Vesuvius caused by a slip on Apennine normal faults (promoting eruptions by earthquakes) and on fault planes caused by voiding a buried magma body (promoting earthquakes by eruptions), as shown in Fig. 20. Using these results to select earthquakes and eruptions improved the significance of the Marzocchi et al. [58] analysis.

Cardaci et al. [10] used a cross-correlation technique to investigate the relation between seismic and volcanic data

at Mount Etna 1975–1987. The seismic and eruptive data were averaged over seven day intervals, with the cross-correlation being

$$\rho_{XY}(k) = \frac{\sigma_{XY}(k)}{\sqrt{\sigma_X^2 \sigma_Y^2}} \tag{57}$$

for  $k = 0, \pm 1, \dots, \pm K$ , where

$$\sigma_{XY}(k) = \begin{cases} (1/n) \sum_{i=1}^{n-k} (X_i - \mu_X)(Y_{i+k} - \mu_Y) & k = 0, 1, \dots, K \\ (1/n) \sum_{i=1-k}^n (X_i - \mu_X)(Y_{i+k} - \mu_Y) & k = -1, \dots, -K \end{cases} \tag{58}$$

is the cross covariance function and  $\mu_X, \mu_Y$  and  $\sigma_X^2, \sigma_Y^2$  are the means and variances, respectively, of the two time series  $X_1, \dots, X_n$  and  $Y_1, \dots, Y_n$ . The significance of the cross-correlation can be assessed from the fact that  $\rho_{XY}(k) \sqrt{(m-2)/(1-\rho_{XY}^2(k))}$ , is asymptotically distributed as a  $t$ -distribution with  $m-2$  degrees of freedom, where  $m$  is the number of overlapped positions between the two series. Cardaci et al. [10] arrived at a similar conclusion to Mulargia et al. [66], identifying low frequency events, whose rate of occurrence increases from 17 to 108 days prior to flank eruptions, as the best precursor. Summit events had a less clear relation with volcanic tremor rather than seismic activity.

Linde and Sacks [48] examined the historical record of eruptions ( $VEI \geq 2$ ) and large earthquakes, to see whether there are more of the former within two days of the latter. For earthquakes with ( $M \geq 8$ ), there are a significant excess of eruptions within 750 km of the epicenter, while for earthquakes with  $7.0 \leq M \leq 7.9$ , the effect is only observed within a radius of 200 km. In all, 20 such earthquake-volcano pairs are observed 1587–1974. In addition, Linde and Sacks [48] hypothesized that eruptions in unison of volcanoes separated by hundreds of kilometers could be due to the second eruption being triggered by earthquakes associated with the first. Marzocchi [56] elaborated on this analysis by defining a perturbation function

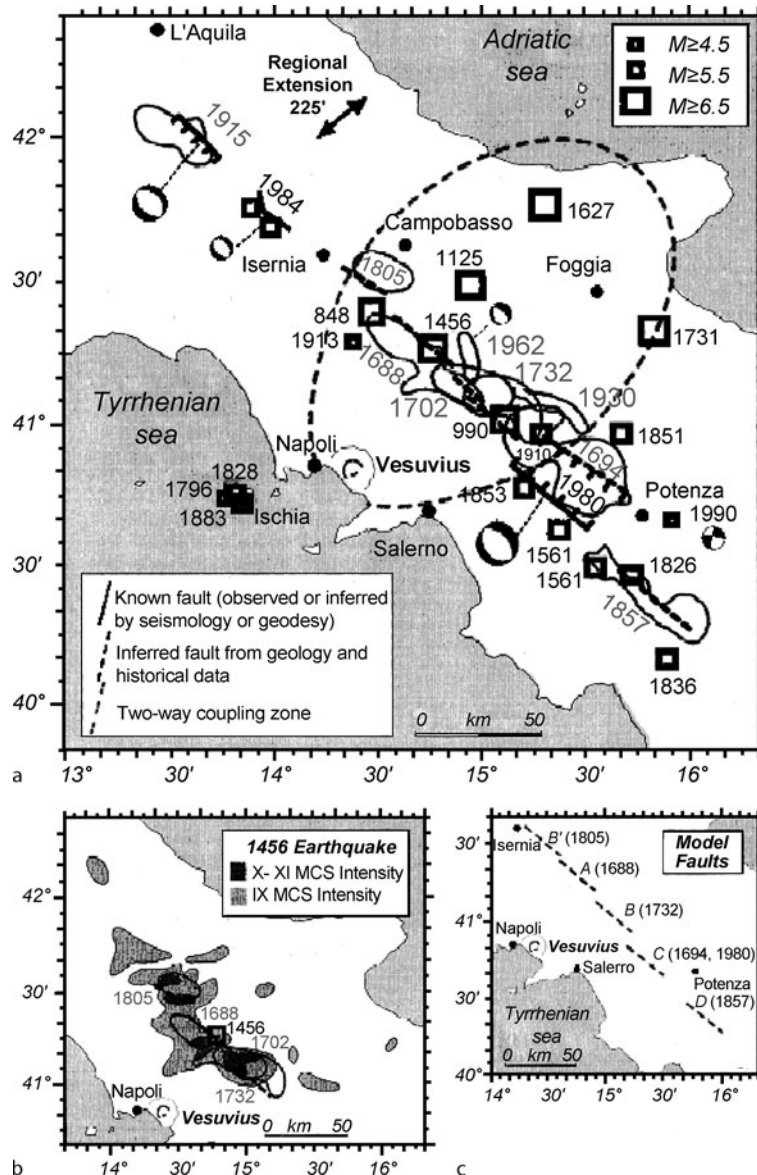

$$\phi_i^{(k)}(\Delta) = \sum_j M_j w(d_{jk}) \mathbf{I}_{((i-1)\Delta, i\Delta)}(t_k - s_j), \tag{59}$$

where

$$\mathbf{I}_A(x) = \begin{cases} 1 & x \in A \\ 0 & x \notin A \end{cases} \tag{60}$$

is the indicator function,  $s_j$  and  $M_j$  are the time and seismic moment of the  $j$ th earthquake,  $t_k$  is the onset time of

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 19  
**a** Sites of historical earthquakes in south central Italy, associated faults and Vesuvius volcano. Epicentres or, if unknown, isoseismals of modified Mercalli intensity, are shown. The coupling zone is the region in which normal-faulting earthquakes may promote Vesuvius eruptions and vice versa. **b** Isoseismals for the 1456 earthquake with 1688–1805 isoseismal zones. **c** Simplified model faults A–D used for calculations, with the dates of earthquakes associated with each fault segment. From [70], Figure 1 © 1998 by the American Geophysical Union

the  $k$ th eruption, and  $i$  is the lag. The distance between the epicenter of the  $j$ th earthquake and the  $k$ th eruption is  $d_{jk}$ , which is weighted by a (sharply) decreasing function  $w(\cdot)$ . The statistical significance of the calculated values is assessed by a randomization test. The idea is that the perturbation on the volcano by earthquakes is proportional to the seismic moment and decays with distance. Of the

eight eruptions with  $VEI \geq 5$  examined, using  $\Delta = 3$  and 5 years, five have a significant peak at 0–5 years in the perturbation function, calculated from earthquakes with  $M \geq 7$  (792 events, 1900–1999). Using an earthquake catalog with  $M \geq 6$  (3186 events, 1950–1997), two of four events have a significant peak at 30–35 years before the eruption. Marzocchi et al. [60] expanded this analysis to

Volcanic Eruptions: Stochastic Models of Occurrence Patterns, Figure 20

Schematic illustration of the response of a hypothetical Vesuvius magmatic system to a southern Apennine normal-faulting earthquake for (a) a buried dike in which at least one fissure or feeder conduit strikes NE and (b) a buried spherical magma chamber with a NE striking fissure. From [70], Figure 3 © 1998 by the American Geophysical Union

the 62 20th Century eruptions with  $VEI \geq 4$ , identifying peaks at 0–5 and 20–35 years. The perturbations for  $VEI \geq 4$  eruptions were shown to be significantly larger than those for  $VEI = 1$  and  $VEI = 2$  eruptions. This suggests that the likelihood of large explosive eruptions is affected by post-seismic stress variations induced by large earthquakes up to decades earlier and hundreds of km distant. No spatio-temporal clustering of the earthquakes and eruptions was detected.

### Future Directions

There are two places in the above review where the effect of a second process on the likelihood of eruptions has been identified, but an appropriate model incorporating this is lacking. These are deterministic (fortnightly and/or annual) cycles in the intensity, and correlation between eruptions and large earthquakes. A candidate to model the first is a cyclic Poisson process [97], and the second could be examined via a bivariate Point process, or perhaps a non-homogeneous hidden Markov model.

More generally, much of the relevant literature on stochastic processes has not been applied to problems in volcanology. In particular, (marked) point processes, alternating renewal processes, and semi-Markov processes would seem to be natural candidates for modeling volcanic activity. A number of techniques from time series analysis (see [106] for a brief review) may prove useful for the investigation of volcanic data at various time scales.

In the application of stochastic models, and the understanding to be gleaned from them, volcanology lags well behind seismology. This is despite the inherent advantages of a phenomenon in which spatial degrees of freedom can often be ignored. An obvious future direction is the borrowing of more techniques from seismology. Unlike seismology, a certain amount of effort (and money) can often produce additional data through coring and dating. This is a great advantage in statistical terms, especially as the data can be 'targeted' to some degree as required by the model. This additional data makes it possible in volcanology to detect, and forecast, non-stationary behavior, and to relate this to physical changes in the volcano [95].

Although this article has concentrated on models for occurrence patterns, actual volcanic hazard is dependent on the nature and behavior of volcanic products such as lava, ash fall, lahars and pyroclastic flows. Incorporating existing sophisticated numerical models of such behavior with stochastic models of occurrence, location/direction and magnitude will allow more accurate estimation of the hazard to life and property.

### Glossary

**Volcano hazards** Potentially damaging volcano-related processes and products that occur during or following eruptions [see [31,37] for overviews]. In quantitative hazards assessments, the probability of a given area being affected by potentially destructive phenomena within a given period of time.

**Volcano risk** Probability of harmful consequences – individual or societal – or expected losses (deaths, injuries, property, livelihoods, economic activity disrupted or environment damaged) resulting from interactions between volcano hazards, human development, and vulnerable conditions. Though definitions vary in detail, risk is conventionally expressed by the general relation:  $risk = hazards \times vulnerability$  [13].

**Vulnerability** The conditions determined by physical, social, economic, and environmental factors or processes, which increase the susceptibility of a community to the impact of hazards [13].

**Volcano status** The current activity or mode of behavior of a volcano. Status is commonly described as follows: *active* (having one or more recorded historical eruptions); *dormant* (currently inactive but having potential for renewed eruptive activity); and *extinct* (dormant for long time and not expected to erupt again). These terms, while commonly used in the scientific literature, are imperfect and are undergoing serious reexamination within the global volcanological community.

**Factual statement** Following the recommended definition of Swanson et al. [35], is the description of the current status and conditions of a volcano but does not anticipate future events.

**Forecast** As defined by Swanson et al. [35], is a comparatively imprecise statement of the time, place, and nature of expected activity; forecasts of eruptions and earthquakes sometimes are probabilistic (e. g., [43,47]). A forecast usually covers a longer time period than that for a prediction.

**Prediction** As defined by Swanson et al. [35], is a comparatively precise statement of the time, place, and, ideally, the nature and size of impending activity. Forecasts and predictions can be either *long term* (typically years to decades or longer) or *short term* (typically hours to months).

**Volcano unrest** Visual and (or) measurable physical and (or) chemical changes, surface or subsurface, in the status of the volcano, relative to its “normal” historical behavior; duration of unrest can vary from hours to decades. The initiation or escalation of volcano unrest, regardless of duration, may or may not culminate in eruption.

**Magma intrusion** The subsurface movement or injection of *magma* (molten rock containing associated crystals and gases) from one part of a volcanic system into another. Typically, an intrusion involves transport of magma from a central zone of storage (i. e., magma “reservoir”) into peripheral, structurally weaker zones (e. g., faults or rifts). Some intrusions culminate in surface eruptive outbreaks, others do not.

**Volcano monitoring** The systematic collection, analysis, and interpretation of visual observations and instrumental measurements of changes at volcanoes before, during, and after the onset of volcano unrest and (or) eruptive activity.

**“Baseline” monitoring data** Volcano-monitoring data acquired for a volcanic system documenting its range of variation during its “normal” behavior prior to volcano unrest and (or) eruptions. The longer the time span covered by “baseline” monitoring, the more diagnostic the dataset for identifying any significant departures from normal behavior in anticipating the possible outcomes of escalating volcano unrest.

**Volcanic crisis** An unstable situation or time of heightened public concern when the level of volcano unrest exceeds its “baseline” level, thereby increasing the prospects of possible eruption at some future, but indeterminate time. In general, during a crisis, emergency managers face a relatively narrow “decision win-

dow” in which to take timely mitigative actions to ensure public safety.

**“Decision window”** The period of time – typically weeks to months, but can be longer – during a developing volcanic crisis between the onset or escalation of volcano unrest. During this time, emergency managers are under high-stress political and public pressure to make decisions regarding mitigative actions, including possible evacuation of populations at risk.

**Warning** An official message issued by government authorities, usually given to a specific community or communities when a direct response to a volcanic threat is required. To be useful, warnings must be credible and effectively communicated – in clear, easily understandable language – with sufficient lead-time, ideally, well before the volcano unrest escalates into a volcanic crisis.

### Definition of the Subject

The hazards and risks posed by volcanic eruptions are increasing inexorably with time. This trend is the direct result of continuing exponential growth in global population and progressive encroachment of human settlement and economic development into hazardous volcanic areas. One obvious strategy in reducing volcano risk is the total abandonment of hazardous volcanic regions for human habitation. Clearly, this is utterly unrealistic; many hazardous volcanoes are located in densely populated areas, for most of which land-use patterns have been fixed by history, culture, and tradition for centuries or millennia. Moreover, people also are exposed to potential volcano hazards by simply being passengers aboard commercial airliners flying over volcanic regions and possibly encountering a drifting volcanic ash cloud from a powerful explosive eruption [5]. Thus, the only viable option in reducing volcano risk is the timely issuance of early warning of possible impending eruptions, allowing emergency-management officials to take mitigative actions. It is then imperative for volcanologists to effectively communicate the best-possible hazards information to emergency-management authorities, and to convince them to implement timely mitigative countermeasures, including evacuation, if necessary, of people at risk. However, volcanologists face daunting challenges in providing reliable, precise early warnings that government officials demand and need to make informed decisions to ensure public safety.

### Introduction

About 1500 volcanoes have erupted one or more times during the Holocene (i. e., past 10,000 years); since A.D.

1600, volcanic disasters have killed about than 300,000 people and resulted in property damage and economic loss exceeding hundreds of millions of dollars [39,40]. During recent centuries, on average 50 to 70 volcanoes worldwide are in eruption each year – about half representing activity continuing from the previous year and the other half new eruptive outbreaks [32]. Most of these erupting volcanoes are located in developing countries, which often lack sufficient scientific and economic resources to conduct adequate volcano-monitoring studies. Moreover, in any given year, many more volcanoes exhibit observable and (or) measurable anomalous behavior (*volcano unrest*) that does not lead to eruption.

For scientists and emergency-management authorities alike, the critical issues in providing early warning of possible eruption, or of possible escalation of an ongoing but weak eruption, involve basic questions such as (1) will the initiation of unrest at a currently dormant volcano culminate in eruption?; (2) if so, what would be its time of onset, eruptive mode (explosive, non-explosive, etc.) and duration?; (3) at an already restless or weakly erupting volcano, what are the prospects of escalation to major activity?; and (4) what would be the nature and severity of the associated hazards and which sectors of the volcano are the most vulnerable?

Systematic geoscience studies of a volcano’s geologic history and past behavior can provide answers to some of the above-listed and related questions relevant to *long-term* forecasts of a volcano’s present and possible future activity. In general, the fundamental premise applied in making long-term forecasts is that the volcano’s past and present behavior provides the best clues to its future behavior. However, data from volcano monitoring – showing increased activity relative to pre-crisis or “background” levels – constitute the only scientific basis for *short-term* forecasts or predictions of a possible future eruption or a significant change during an ongoing eruption. To respond effectively to a developing volcanic crisis, timely early warnings are absolutely essential, and these warnings must be reliable and precise. Improvement in the reliability and precision of warnings can be achieved only by a greatly improved capability for eruption prediction, which in turn depends on the quantity and quality of volcano-monitoring data and the diagnostic interpretation of such information [36,38,40].

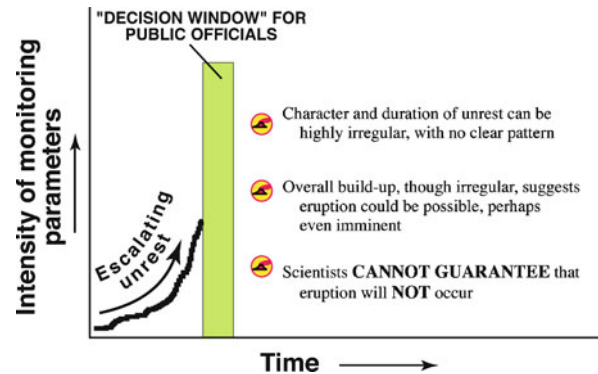

At the outset, it must be emphasized that, in this article, the term *prediction* is used in the strict sense (see Glossary) proposed by Swanson et al. [35]; thus, for a forecast or prediction to be genuine, it must be included in an official warning statement made publicly in advance of the predicted event. While retrospective forecasts and

predictions serve valid scientific purposes in testing or verifying theories or models, they are of little or no use to emergency-management authorities. It is beyond the scope of this brief paper to consider in detail volcano-monitoring studies and their applications to eruption prediction. Suffice it to say that instrumental volcano monitoring is a multi-faceted, multidisciplinary endeavor that involves the ground- and (or) satellite-based measurement of seismicity, ground deformation, gas and fluid chemistry, temperature variations, secular changes in micro-gravity and geomagnetism, etc. For more information about volcano-monitoring approaches, techniques, and instrumentation, interested readers are referred to numerous recent comprehensive reviews and references cited therein (e. g., [6,10,21,22,23,36] ► **Volcanoes, Non-linear Processes in**). Instead, this paper highlights the range in possible outcomes of volcano unrest and reviews some recent examples of the actual outcomes documented for several well-monitored volcanoes. Some implications from the observations discussed in this paper are considered in the final two parts of this article (Sect. “**Challenges in Achieving Refined Predictive Capability**” and “**Future Directions**”).

### Scope of Problem: Challenge for Emergency-Management Authorities

Because earthquake and eruption dynamics intrinsically involve non-linear processes (the focus of this volume), the attainment of a reliable capability to predict eruptions (especially explosive events) still eludes volcanologists. This dilemma persists despite notable advances in volcanology and the availability in recent decades of increasingly sophisticated models, stochastic and deterministic. Such models, which commonly involve pattern-recognition methodologies, are developed from theoretical or statistical analysis of volcano-monitoring data, eruption-occurrence patterns, or other time-space attributes for a volcanic system (e. g., [14,15,18,25,29,33,45,46] ► **Volcanic Eruptions: Stochastic Models of Occurrence Patterns**). The non-attainment of predictive capability to date reflects the reality that most volcanic systems are highly complex and that the relevant datasets for the vast majority of volcanoes are too inadequate and (or) incomplete to enable reliable and precise predictions.

Given the fact that the emerging science of eruption prediction is still nascent, scientists and emergency-management officials are at a substantial disadvantage when a long-dormant or weakly active volcano begins to exhibit unrest above its historical (i. e., “normal”) levels. A principal concern is that the heightened unrest, should it per-

Volcanic Hazards and Early Warning, Figure 1

A common scenario confronting emergency-management authorities when unrest initiates or escalates at a volcano, as documented by increasing intensity of monitoring parameters (seismicity, ground deformation, gas emission, thermal, microgravity, etc.) during a volcanic crisis. The “decision window”, though shown schematically, represents a very real and usually short timeframe during which emergency managers must decide and implement – by legal requirement, political and (or) citizen pressure, or moral conscience – strategies and actions to mitigate the potential risk from volcano hazards. (Figures 1 and 2 modified from unpublished conceptual sketches of C. Dan Miller, US Geological Survey)

sist or escalate, could culminate in renewed or greatly increased, possibly hazardous activity. Because of public-safety and socio-economic issues and consequences, emergency managers in particular must have a definitive answer to the question: What is the most likely outcome of the escalating unrest? The answer(s) to this critical question then shape(s) possible decisions they must make – within a narrow “decision window” (typically weeks to months), generally under confusing, stressful conditions – in managing the growing volcanic crisis.

Figure 1 depicts a common scenario during a volcanic crisis and lists some major factors that complicate the determination of the most likely outcome of the unrest. Unfortunately, despite advances in volcanology and volcano-monitoring techniques, scientists are unable to give emergency-management authorities the specific information they require. The greatest frustration for the authorities is that scientists cannot guarantee that an eruption will *not* occur. In the section below, I review some common possible outcomes of volcano unrest, and, in Sect. “**Some Recent Examples of Actual Outcomes of Volcano Unrest**”, some actual outcomes of recent episodes of volcano unrest.

### Variability in Possible Outcomes of Volcano Unrest

Experience worldwide for historical eruptions demonstrates a great range in possible outcomes of volcano un-

rest. The three types of outcomes discussed below – for which adequate eruptive-history and volcano-monitoring data exist – probably represent the commonest possibilities. Given the non-linear nature of eruptive phenomena, however, other scenarios can be envisaged.

### Culmination in Major Eruption or Return to Dormancy Following Short Duration of Unrest

Perhaps the simplest scenario – and certainly the most easily manageable for public officials – is when a volcano reawakens from a long dormancy (i. e., greater than a century) and begins to exhibit significant unrest. Such unrest then persists at a high level for a relatively short duration (several weeks or months) before culminating in a major eruption (Fig. 2a). With adequate volcano-monitoring studies, preferably in real time or near-real time, conducted during the precursory build-up, scientists may be able to make a short-term forecast or pre-

diction of the impending eruption. The emergency-management authorities then could have the needed guidance during the “decision window” in issuing early warnings and implementing mitigative countermeasures. Alternatively, diagnostic analysis of the volcano-monitoring data, combined with detailed knowledge of eruptive history, could lead the scientists to conclude that an eruption is not likely. In this situation, emergency managers also receive the required scientific input they need to make informed decisions to manage the volcanic crisis, including the declaration of the end of the crisis and the cancellation of any warnings in effect. In either case, scientists need sufficient information to try to determine whether an imminent eruption or a return of the volcano to dormancy is the most likely outcome. However, it must be emphasized that scientists in assessing possible outcomes can reach incorrect conclusions, even using abundant scientific data and constraints from quantitative models.

Volcanic Hazards and Early Warning, Figure 2  
**a** Two common possible outcomes of volcano unrest that are arguably the most tractable for public officials managing a volcanic crisis (see text). **b** Some other possible outcomes of volcano unrest that pose much greater challenges for scientists and public officials alike during a volcanic crisis (see text)

### Culmination in Major Eruption or Return to Dormancy Following a Long Lull in Unrest

A scenario fraught with greater uncertainty is one that, after an initial short period (weeks to months) of sustained and heightened volcano unrest, the volcano neither erupts nor quickly returns to quiescence. Instead, the volcanic system exhibits a decreased level of activity characterized by fluctuating but low-level unrest and (or) weak, non-hazardous eruptions that may persist for years or decades, before possibly exhibiting another episode of heightened unrest. Under such circumstances, scientists and public officials confront anew the crisis conditions and challenges inherent in attempting to anticipate the outcome of the renewed unrest.

This scenario is similar to that previously discussed above (Sect. “Culmination in Major Eruption or Return to Dormancy Following Short Duration of Unrest”) but differs by the complication posed by another possible outcome in addition to those of an imminent eruption or a return to dormancy: namely, the possibility that the volcano could revert to a mode of continuing uncertainty involving only low-level activity or cessation of unrest for an indeterminate period of time (Fig. 2b). The prolongation of the periods of uncertainty has some unfortunate consequences, including (1) the potential for scientists and public officials to lose credibility by incorrectly anticipating the outcomes during the pulses of heightened unrest and by issuing warnings (“false alarms”) of events that fail to materialize (see Sect. “The Dilemma of “False Alarms””); and (2) increased difficulty in maintain-

ing public interest in, and awareness of, potential hazards posed by some eventual volcanic crisis that actually culminates in eruption.

### Ongoing Unrest over Long Periods with no Clear Indication of Possible Future Activity

Some long-dormant volcanic systems undergo unrest that can persist for many years to decades, fluctuating in intensity but not showing any long-term definitive trend suggestive of possible renewed eruptive activity (Fig. 2b). It is extremely difficult, perhaps impossible, to anticipate possible outcomes of such long-duration, ongoing unrest. The reasons for this problem are simply that the eruptive histories and dynamics of long-dormant systems are poorly understood and (or) their eruption frequencies are longer than the time span of the available pre-eruption *baseline* monitoring data. Some examples of such modes of volcano unrest include: Three Sisters volcanic center, Oregon, USA [48]; Long Valley caldera, California, USA [2,12]; Yellowstone caldera, Wyoming–Montana, USA [48]; and Campi Flegrei Caldera, Italy [3,42].

### Some Recent Examples of Actual Outcomes of Volcano Unrest

The previous discussion of possible hypothetical outcomes of volcano unrest (Sect. “Variability in Possible Outcomes of Volcano Unrest”) has its basis in several recent examples of actual volcano unrest, as documented by detailed investigations. These examples are reviewed herein (Fig. 3).

Volcanic Hazards and Early Warning, Figure 3  
Some actual outcomes of recent episodes of volcano unrest at selected volcanoes. Even though these well-studied volcanoes are closely monitored in real time or near-real time by instrumental arrays, it was or is not possible to determine the outcome of the unrest at most of them (see text for discussion)

### Mount St. Helens (USA) and Mount Pinatubo (Philippines)

In 1975, on the basis of many years of detailed stratigraphic and dating studies, together with an analysis of repose intervals, scientists of the US Geological Survey (USGS) made a long-term forecast of possible renewed eruptive activity at Mount St. Helens Volcano, Washington State, which had been dormant since 1857. This forecast, albeit qualitative, was remarkably prescient, stating: “...an eruption is likely within the next hundred years, possibly before the end of this century” (see p. 441 in [7]). Five years after the forecast, phreatic eruptions began at Mount St. Helens in late March 1980 following a week of precursory seismicity. Sustained seismicity, accompanied by large-scale ground deformation of the volcano’s north flank, ultimately produced a cataclysmic magmatic eruption on 18 May 1980 (Fig. 4). This catastrophic event caused the worst volcanic disaster in the history of the United States (see [16] and chapters therein for detailed summary).

For Mount St. Helens, the volcano unrest, which was well monitored visually and instrumentally, lasted for only about three months before culminating in a major eruption (Fig. 3). Scientists monitoring Mount St. Helens were not able to make a precise prediction of the 18 May events (flank collapse, laterally directed blast, and vertical mag-

Volcanic Hazards and Early Warning, Figure 4  
19 km-high eruption column of the climactic magmatic eruption of Mount St. Helens Volcano, Washington State, USA, on 18 May 1980. This eruption occurred following about two months of volcano unrest that began after a 123-year quiet period. (Photograph by Austin Post taken about noon on 18 May 1980)

matic eruption). From analysis of the volcano-monitoring data and hazards assessments, however, they were able to give early warning and to convince emergency-management authorities to order evacuation and take other risk-reduction actions well within the “decision window” prior to the paroxysmal eruption.

Another illustrative example of a major eruptive activity following a brief duration of volcano unrest was the 1991 eruption of Mount Pinatubo, Luzon, Philippines (see [26], and chapters therein). Prior to 1991, Pinatubo had been quiescent for about 600 years with no recorded historical eruptions; it had been little studied and was not monitored. In March 1991, Pinatubo began to stir from its long sleep, as indicated by increased fumarolic activity and precursory earthquakes, some large enough to be felt by local inhabitants. Phreatic explosions began in early April, and the first magmatic activity (dome intrusion) was observed on 7 June. On the basis of the analysis and interpretation of data from volcano monitoring (initiated in late April), combined with observation of increased frequency of high (> 15 km) eruption columns, scientists of the Philippine Institute of Volcanology and Seismology (PHIVOLCS) and the USGS Volcano Disaster Assistance Program (VDAP) issued warnings and made a forecast on 12 June that a major eruption was imminent. The PHIVOLCS-USGS scientific team recommended to the Commandant of the US Clark Air Base and the Philippine emergency-management authorities to order major evacuations of the air base and other population centers around the volcano. In all, more than 300,000 people were evacuated from hazardous zones. Three days later on 15 June, Pinatubo’s climactic eruption occurred. Even though this eruption was the largest in the world since the 1912 eruption of Novarupta (Alaska, USA), the timely early warnings and evacuations saved many thousands of lives and minimized economic loss.

### Rabaul Caldera (Papua New Guinea)

The outcomes for the volcano unrest at Mount St. Helens (1980) and Pinatubo (1991) represent examples of simple (linear?) and relatively short progression (several months) from onset of precursory activity to major eruption. However, most other recent episodes of volcano unrest involve complex or uncertain outcomes; below I discuss one well-documented example of a complex outcome.

Rabaul caldera, Papua New Guinea, after being quiescent for several decades began to exhibit volcano unrest in the mid-1980s, as manifested by dramatically increased seismicity (Fig. 5) and accompanying caldera uplift of more than 1 m [20]. This intense and rapidly escalating

Volcanic Hazards and Early Warning, Figure 5  
Occurrences of earthquakes at Rabaul Caldera, Papua New Guinea, during the period 1972–1986 (modified from McKee et al. [20]). The dramatically increased seismicity during 1983–1985, together with significant ground deformation, constituted a serious volcanic crisis and prompted public officials to declare a “Stage-2 Alert” (see text). The time span bracketed by this alert (pink shading) is somewhat comparable to the “decision window” schematically shown in Figs. 1–3. However, the 1983–1985 unrest did not immediately culminate in eruption, which did occur ten years later

unrest prompted the scientists of the Rabaul Volcanological Observatory (RVO) to warn of possible imminent eruption. In response, emergency-management authorities declared in October 1983 a “Stage-2 Alert” (Fig. 5), stating that the volcano could erupt within weeks. Accordingly, the civil authorities implemented a number of mitigative measures – including widening of roads to serve as evacuation routes, preparation of contingency plans, conduct of evacuation drills, etc. – to prepare for the expected soon-approaching eruption. However, soon after the issuance of the alert, the volcano unrest, after peaking in early 1985, began to diminish sharply and returned to normal levels within 6 months (Fig. 5). No eruption occurred, and the “Stage-2 Alert” was lifted in November 1984.

The abrupt cessation of volcano unrest and the non-occurrence of the forecasted eruption were generally viewed as a needless, disruptive “false alarm”. As fallout from the unanticipated turn of events, the scientists of the RVO lost credibility with the emergency-response authorities, who in turn lost the confidence of the general population.

Ultimately however, the initially unsatisfactory outcome of the 1983–1985 unrest positively influenced the successful response to a later major eruption. After remaining at the normally low level of activity after for about ten years the mid-1980s crisis, Rabaul erupted suddenly on 19 September 1994 following only 27 hours of precur-

Volcanic Hazards and Early Warning, Figure 6  
View from space of the powerful explosive eruption of 19 September 1994 from Rabaul Caldera. (Photograph courtesy of astronauts aboard the NASA Shuttle)

sory seismicity [4]. This major eruption (Fig. 6) devastated nearly all of Rabaul City, but fortunately caused only 5 deaths. The lower-than-expected fatalities can in part be attributable to the fact that people largely “self-evacuated” without waiting for official advisories to do so. They apparently well remembered the lessons (e. g., enhanced awareness of volcano hazards, measures to take in case of eruption, evacuation drills) learned from the volcanic crisis ten years earlier.

### Ongoing Irregular Long-Duration Volcano Unrest but no Clear Indication of Possible Eruption

Recent volcano unrest at several calderas, which are well studied and systematically monitored in real time or near-real time by geophysical and geochemical networks, provide good examples of the difficulty in determining the most likely outcomes of unrest. Because of the abundance of historical observations and volcano-monitoring data, Campi Flegrei Caldera, Italy, located adjacent to Vesuvius Volcano in the Naples metropolitan area, is a particularly instructive example. During the early 1970s and again during 1983–1985, the caldera exhibited pronounced episodes of volcano unrest (Fig. 7) that generated scientific and public concern. Neither of these unrest episodes culminated in eruption, and each was followed by longer intervals of relatively low, fluctuating activity or net subsidence, hinting of an outcome whereby the restless volcano would return to dormancy.

From a recent study by Troise et al. [42], however, the post-1985 subsidence trend reversed in late 2005, and the

Volcanic Hazards and Early Warning, Figure 7  
Uplift and subsidence at Campi Flegrei Caldera, Italy, during the period 1969–2006 (modified from Fig. 1b in [42]). Vertical displacements measured by precise leveling, together with associated horizontal displacements and increased seismicity, indicate two episodes of caldera uplift, one during 1969–1973 and another during 1982–1985. Neither episode culminated in eruption (see text). Note that the current “baseline” level of activity is higher than that prior to 1982

caldera since has risen by a few centimeters (Fig. 7). Historical records, extending back in time for more than two millennia (see Fig. 1a in [42]), demonstrate a pattern of relatively short-duration uplifts (lasting years to decades) interspersed with long-lived gradual subsidence (lasting centuries). Of these several ups and downs of Campi Flegrei caldera over the past two millennia, only one episode of volcano unrest culminated in eruptive activity – the Monte Nuovo eruption in 1538 [9]. The historical behavior of Campi Flegrei emphasizes the challenging task of attempting to determine the outcome of volcano unrest with only a few years or decades of volcano-monitoring data.

Similarly, in recent years, ground-based and space-based geodetic data [e. g., Interferometric Synthetic Aperture Radar (InSAR) and GPS], combined with seismic monitoring and other geophysical and geochemical investigations, have documented uplift and (or) subsidence at several other well-monitored long-dormant volcanic systems (e. g., Three Sisters volcanic center, Oregon; Long Valley Caldera, California; and Yellowstone Caldera, Wyoming–Montana). For more information concerning these systems as well as other volcanic systems, the interested reader is referred to the following works: Wicks et al. [48,49]; Battaglia et al. [2]; Hill [12]; and Dzurisin [10 and chapters therein]. It is important to stress that, while the level and intensity at these restless volcanic systems have varied within the periods of systematic instrumental monitoring (only a few decades at most), the available datasets and interpretations are inadequate to determine whether or not the ongoing unrest will culminate in eruption.

### Kilauea Volcano, Hawaii (USA)

Brief mention should be made of frequently active volcanic systems – typically basaltic in composition – that are characterized by conspicuous and measurable unrest occurring nearly continuously over long time periods. Perhaps the best-studied volcanic systems exhibiting such behavior are those of Kilauea and Mauna Loa volcanoes on the Island of Hawaii (see [8] and chapters therein). These two volcanoes are among the most active in the world and have been well monitored since the establishment in 1912 of the Hawaiian Volcano Observatory, operated continuously by the USGS since 1948. Abundant “baseline” monitoring data, particularly for Kilauea, demonstrate well-defined patterns and outcomes of unrest (e. g., Fig. 5 in [41]; Fig. 8 in [37]). However, it must be emphasized that the behavior and outcomes of unrest observed for Kilauea – culminating either in subsurface intrusion only or in eruption – occur over much shorter time scales than those for the examples of explosive volcanoes discussed in this paper (e. g., Figs. 2, 3, and 7).

For Kilauea, because of its high eruption frequency and, at times, nearly continuous activity (e. g., [11]), the outcomes of its volcano unrest and the need to issue early warnings are manageable for the civil authorities with little or no anxiety. This fortunate situation reflects a positive circumstance: because of the volcano’s frequent and, at times, continuous eruptive activity, the dissemination of hazards information and early warnings is easily and routinely accomplished among the scientists, emergency-management officials, news media, and the affected public. Moreover, analyses of data for well-monitored, frequently active volcanoes, such as Kilauea, provide many case histories that can serve to test and refine volcano-monitoring techniques as well as eruption-forecasting methodologies. Nonetheless, it should be noted that eruptions at Kilauea and other basaltic volcanoes differ fundamentally from those of more explosive – hence, potentially more dangerous – stratovolcanoes that erupt more viscous materials of intermediate composition (e. g., Mount St. Helens, Mount Pinatubo).

### Challenges in Achieving Refined Predictive Capability

The discussion in the preceding sections paints a somewhat discouraging picture: namely, possibly with very rare exceptions (e. g., the Mount St. Helens and Pinatubo case histories), to date scientists still lack a reliable capability for precisely *and* accurately predicting the outcomes of unrest at explosive volcanoes with low eruption frequency. This unsatisfactory state of affairs does not well serve so-

cietal needs to reduce the risks of volcanic hazards and demands improvement. Considered below are some elements that I deem to be essential to achieve refined predictive capability and early warnings of possible eruptive activity.

### More Geologic Mapping and Dating Studies of Volcanoes

Of the world’s active and potentially active volcanoes, only a handful (mostly in the developed countries) have been studied sufficiently for the detailed and complete reconstruction of their past behavior, eruption frequencies, and associated hazards. Specifically, geologic mapping (at a scale of 1:25,000 or better) and dating studies of stratigraphically well-controlled eruptive products have been done for only a few volcanoes. Recorded historical eruptions for most volcanoes – especially those in the New World – rarely extend back in time for more than five centuries. Their eruptive histories generally are too short to serve as a comprehensive time-series dataset for quantitative statistical analysis of eruption frequency or repose intervals. Thus, it is essential to expand the time-series dataset by obtaining radiometric ages of prehistoric eruptive products. Moreover, in studies of eruption frequency, no matter how abundant the data used, the calculated frequencies obtained are necessarily *minima*, because the products of small eruptive events are lost to erosion and not preserved in the geologic record.

### More Volcano Monitoring at More Volcanoes: Importance of Establishing Long-Term “Baseline” Behavior

As noted by Tilling (see p. 9 in [40]), most volcanologists believe that “... if a volcano is monitored extensively in real- or near-real time by well-deployed instrumental networks, it should be possible to make much better forecasts of the outcomes of volcano unrest.” Unfortunately, many of the world’s active and potentially active volcanoes are poorly monitored, and some are not monitored at all. Thus, to advance our understanding of eruptive dynamics in order to make more precise early warnings, initiating or expanding volcano monitoring at many more volcanoes is imperative. Ideally, volcano monitoring should be conducted in real- or near-real time, and it should involve a combination of monitoring techniques rather than reliance on any single one [36]. Moreover, the longer the time span of volcano monitoring, the more diagnostic is the relevant database needed for detecting and interpreting any significant departure from the overall variation in the long-term “baseline” behavior of the volcano.

### The Dilemma of “False Alarms”

With the current state-of-the-art in volcanology and monitoring techniques, it is difficult, and generally impossible, for volcanologists to determine with any certainty: (1) the most likely outcome of onset of unrest at a long-dormant volcano; and (2) the eventual possible occurrence of a major eruption in the course of long-duration, but relatively low-level ongoing unrest. Nonetheless, scientists still have an obligation to emergency managers and the threatened populations to provide the best-possible hazards information, forecasts or predictions, and warnings within the limitations of available knowledge, technology, and volcano-monitoring techniques. In so doing, the scientists run the unavoidable risk of raising a “false alarm” and the associated criticism and loss of credibility when the forecasted event fails to materialize. On the other hand, emergency-management officials as well as the general public must be prepared to accept the disruptive socio-economic consequences and costs of occasional “false alarms”. The Rabaul case history (previously discussed in Sect. “[Rabaul Caldera \(Papua New Guinea\)](#)”) underscores the sentiment of Banks et al. (see p. 78 in [1]): “... False alarms themselves can provide, through objective assessment of the scientific and public response to a volcanic crisis that ended without eruption, valuable lessons useful ... for the next crisis, which could culminate in an eruption.” Even so, every attempt should be made to minimize “false alarms” to the extent possible, in order to maintain scientific credibility and the confidence of the emergency-management authorities and the populace at risk.

### Future Directions

An obvious critical need is the comprehensive geoscience studies of more volcanoes, to reconstruct their prehistoric eruptive histories, thereby extending the time-series database needed for quantitative analysis and interpretation. In addition, volcano monitoring, even if rudimentary – deploying only 1 to 3 seismometers and making simple field observations and measurements [34] – is needed for many more volcanoes, both to establish “baselines” and to provide early warning. Obviously, future research necessarily should also be focused on methodologies to make more robust the acquisition and processing of real- or near-real-time volcano-monitoring data, using or refining *existing* instrumentation and techniques, volcano databases, analytical tools, and empirical and theoretical models. An especially promising avenue of future research would require the wider utilization of broadband instruments in seismic-monitoring networks at active and potentially volcanoes. This would enable systematic and

quantitative analysis and interpretation of Long-Period (LP) and Very-Long-Period (VLP) seismicity, which from worldwide experience precedes and accompany nearly all eruptions ► [Volcanoes, Non-linear Processes in](#).

A long-standing and vexing problem for volcanologists is that, at present, no geophysical or geochemical criteria exist to identify the distinguishing characteristics between volcano unrest that merely ends in a subsurface intrusion of magma and unrest that culminates with magma breaking the surface to produce an eruption. From the vantage point of the emergency-management officials, subsurface intrusion or movement of magma, while of great academic interest to volcanologists in deciphering volcano dynamics, poses no threat to public safety. In contrast, the threat of an imminent eruption requires timely decisions and mitigative actions to ensure public safety. Thus, the future development, if possible, of quantitative criteria to distinguish the precursory pattern of a subsurface intrusion from that for an eruption would mark a quantum leap in the young science of volcanology. In this regard, an improved understanding of magma intrusion vs. eruptive dynamics might provide scientists more powerful tools in choosing between the various paths shown in Fig. 3 as the most likely outcome of volcano unrest.

In attempting to quantify estimates of the probabilities of specified hazardous volcanic events within specified timeframes (i.e., eruption predictions), scientists have made increasing use of “materials-failure” models (e.g., [25,45,46]), “event trees” (e.g., [27]), and more statistically rigorous variants of the “event-tree”, “decision-tree”, “pattern-recognition”, and “occurrence-pattern” approaches (e.g., [17,18,19,24,29] ► [Volcanic Eruptions: Stochastic Models of Occurrence Patterns](#)). Depending on the particular circumstances of the volcano(es) and eruptions under study, these and other statistical tools have their individual strengths and weaknesses. Taken together, however, the utility and potential successful application of such approaches are inherently hampered by the incompleteness and (or) too-short time span of the eruptive-history or volcano-monitoring datasets analyzed. Thus, to become more robust, the probabilistic methodologies must employ larger and more complete datasets. In any case, while useful, the existing techniques or models cannot yield results with the precision and accuracy that emergency-managers demand and need as they confront a “decision window” during a volcanic crisis. Simply stated, even if the calculated results prove to be accurate, their error bars generally exceed the time span bracketed by the “decision window”.

In recent years, the World Organization of Volcano Observatories (WOVO) – a Commission of the In-

ternational Association of Volcanology and Chemistry of the Earth's Interior – has launched an ambitious but poorly funded effort, called *WOVOdat*, to construct a global database of empirical data on volcanic unrest. This database is being developed as a user-friendly Internet-based system with query and analysis tools [30]. Even though a basic design and schema now exist for the construction of *WOVOdat* [44], the actual compilation and integration of data are just barely beginning. The *WOVOdat* project recently received major funding from the Singapore Government and Nanyang Technological University [28]. This favorable development brightens the prospects for it ultimately to become a powerful tool in evaluating patterns and possible outcomes of volcanic unrest. Nonetheless, until *WOVOdat* becomes fully operational, we must continue to rely on the available datasets – however imperfect – and to employ and refine the existing analytical methodologies and statistical models.

### Acknowledgments

This article has benefited from constructive reviews and helpful suggestions by L. J. Patrick Muffler and Fred Klein (both of the US Geological Survey, Menlo Park) on an earlier draft. To them, I offer them my sincere thanks. The views expressed in this article have been shaped by my personal involvement in responses to several of the volcanic crises in recent decades, and by enlightening and instructive interactions and discussions with many colleagues in the global volcanological community.

## Glossary

**Moment tensor** A point seismic source representation defined by the first-order moment of the equivalent body force or the stress glut. Slip on a fault as well as volumetric changes such as an isotropic expansion and tensile crack can be represented by the moment tensor.

**Waveform inversion** An approach to estimate source mechanisms and locations of seismic events by finding the best fits between observed and synthesized seismograms.

**Autoregressive equation** A difference form of the equation of motion of a linear dynamic system, which is a basic equation to determine the complex frequencies (frequencies and Q factors) of decaying harmonic oscillations in observed signals.

**Crack wave** A dispersive wave generated by fluid-solid interactions in a crack. The phase velocity of the crack wave is smaller than the acoustic velocity of the fluid in the crack.

## Definition of the Subject

Volcano seismicity produces a wide variety of seismic signals that provide glimpses of the internal dynamics of volcanic systems. Quantitative approaches to analyze and in-

terpret volcano-seismic signals have been developed since the late 1970s. The availability of seismic equipments with wide frequency and dynamic ranges since the early 1990s revealed a further variety of volcano-seismic signals in oscillation periods longer than a few seconds. Quantification of the sources of volcano-seismic signals is crucial to achieving a better understanding of the physical states and dynamics of magmatic and hydrothermal systems.

## Introduction

Volcanoes occur in tectonically active regions of the earth where magmatic and hydrothermal fluids display complex interactions with volcanic rocks and the atmosphere. Volcano seismicity is the manifestation of such complex interactions occurring inside of volcanic edifices. Volcano seismology aims at achieving a better understanding of the physical states and dynamics of magmatic and hydrothermal systems beneath active volcanoes through observation, analysis, and interpretation of volcano-seismic signals. It is well known that volcano-seismic signals have a wide variety of signatures (Fig. 1), which have been classified by various schemes e. g., [25,61,80,84]. The volcano-tectonic (VT) earthquake, low-frequency (LF) or long-period (LP) event, tremor, very-long-period (VLP) event, hybrid event, and explosion earthquake have been traditionally used to specify volcano-seismic signals. Here, LF denotes frequencies between 0.5 and 5 Hz [61], and LP and VLP denote periods between 0.2 and 2 s and longer than a few seconds, respectively [25].

In contrast to the various classification schemes, source processes of volcano-seismic signals may be classified into three main families: (i) brittle failure in volcanic rock triggered by fluid movement, (ii) transient pressure disturbance caused by mass transport and/or volumetric change, and (iii) resonance of a fluid-filled resonator excited by a pressure disturbance. These three processes may be linked to the signals as follows: (i) VT earthquake, (ii) VLP event and explosion earthquake, (iii) LF or LP event, tremor, and VLP event, and (i)+(iii) hybrid event. VT earthquakes, sometimes called high-frequency (HF) earthquakes, are indistinguishable from ordinary tectonic earthquakes, but occur in volcanic regions due to process (i). LF or LP events have signals characterized by decaying oscillations, whereas the signature of tremor shows continuous oscillations. These oscillatory signatures can be interpreted as process (iii), in which the excitations are impulsive for LF or LP events and successive for tremor. Most VLP events are characterized by impulsive signatures, which may be generated by process (ii). However, some VLP events show sustained oscillations or decay-

Volcano Seismic Signals, Source Quantification of, Figure 1

Various volcano-seismic signals: **a** volcano-tectonic earthquake that occurred between Miyakejima and Kozujima, Japan; **b** explosion earthquake observed at Asama volcano, Japan; **c** tremor that occurred beneath Mt. Fuji, Japan; **d** long-period event observed at Kusatsu-Shirane volcano, Japan; **e** long-period event observed at Guagua Pichincha volcano, Ecuador; **f** very-long-period event that occurred beneath Miyakejima, Japan (low-pass filtered at 20 s)

ing harmonic oscillations, which may reflect process (iii). Hybrid events show mixed characters of both VT earthquakes and LP events, suggesting that processes (i) and (iii) both take place at the source. Explosion earthquakes occur in association with eruptions in which process (ii) is dominant.

Recently, there have been remarkable advances in quantitative understanding of the sources of volcano-seismic signals. These advances were made possible by the development of source models and analysis techniques coupled with increased computer capacity and the availability of seismic observation equipment with wide frequency and dynamic ranges. Major studies that have contributed to these advances are summarized as follows: Detailed magma intrusion processes imaged by VT earthquakes e. g., [19,43,46,86,111,112,123]; Quantitative interpretations of oscillations in LP and VLP events and tremor to diagnose the states of fluids at the sources of these signals e. g., [2,7,21,22,23,24,28,29,38,39,40,41,42,44,52,53,65,66,67,70,71,73,77,78,85,87,88,90,91,92,93,94,95,98,134]; Tracking the sources of LP events and tremor e. g., [3,4,5,13,30,45,82,113,114]; Waveform analysis of

impulsive and oscillatory signatures in VLP events and explosion earthquakes to investigate source dynamics e. g., [6,8,9,10,11,31,32,33,34,36,47,48,49,51,54,55,56,57,58,59,60,64,69,72,76,97,102,103,105,107,108,110,120,122,126,132,133]. These volcano seismological studies have been reviewed by various authors [25,26,27,61,80,81,96].

The purpose of this article is to provide a systematic presentation of the theoretical basis for quantification of the sources of volcano-seismic signals suitable for readers, including graduate students and young researchers, who are new to the study of volcano seismology. I focus on four subjects: (1) phenomenological representation of seismic sources, (2) waveform inversion to estimate source mechanisms, (3) spectral analysis based on an autoregressive model, and (4) physical properties of fluid-solid coupled waves. Some additional notes are provided in Appendixes. These constitute the basic elements needed to quantify the sources of volcano-seismic signals. Applications of quantitative approaches are not fully reviewed in this manuscript. Readers are encouraged to consult both the original research papers and the review papers cited above.

## Phenomenological Representation of Seismic Sources

We first derive the phenomenological representation of seismic sources using single force and moment tensor. This representation provides the basis to study source processes of volcano seismicity. I follow the approach presented by Backus and Mulcahy [12] (hereafter referred to as BM) and Aki and Richards [1] for the moment tensor representation. The theory elaborated by Takei and Kumazawa [118,119] is used to introduce single force in seismic sources.

### Stress Glut

We consider indigenous seismic sources occurring within the closed earth system. This means that external bodies and detached mass are excluded. Let us assume an isotropic medium for the earth, which is represented by density  $\rho$  and Lamé's constants  $\lambda$  and  $\mu$ . The exact equation of motion of the earth is given by

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ni}^{\text{true}}}{\partial x_n}, \quad (1)$$

where  $u_i$  and  $\sigma_{ni}^{\text{true}}$  are the true displacement field and true stress tensor, respectively, actually produced in the earth. These are functions of space  $\mathbf{x} = (x_1, x_2, x_3)$  and time  $t$ . The summation convention for repeated subscripts is used throughout this paper unless otherwise stated. In BM's theory, the failure of the elastic stress-strain relationship in source processes, such as slip across a plane that can not be described by the linear elastodynamics, is represented by an equivalent body force. We use a model stress  $\sigma_{ni}^{\text{model}}$  given by the elastic stress-strain relationship as

$$\sigma_{ni}^{\text{model}} = \lambda \frac{\partial u_k}{\partial x_k} \delta_{ni} + \mu \left( \frac{\partial u_n}{\partial x_i} + \frac{\partial u_i}{\partial x_n} \right), \quad (2)$$

where  $\delta_{ni}$  is the Kronecker symbol ( $\delta_{ni} = 0$  for  $n \neq i$  and  $\delta_{ni} = 1$  for  $n = i$ ). By replacing the true stress by the model stress, Eq. (1) can be rewritten as follows:

$$\rho \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ni}^{\text{model}}}{\partial x_n} + f_i^S, \quad (3)$$

where  $f_i^S$  is the equivalent body force defined as

$$f_i^S = \frac{\partial}{\partial x_n} (\sigma_{ni}^{\text{true}} - \sigma_{ni}^{\text{model}}). \quad (4)$$

The difference between  $\sigma_{ni}^{\text{true}}$  and  $\sigma_{ni}^{\text{model}}$  is called the stress glut. The equivalent body force, which is the spatial derivative of the stress glut, describes the source and vanishes

outside the source region for motion in a completely elastic medium.

We introduce Green's function  $G_{ij}(\mathbf{x}, t; \boldsymbol{\eta}, \tau)$ , which is the  $i$ th component of displacement at  $(\mathbf{x}, t)$  excited by the unit impulse applied at  $\mathbf{x} = \boldsymbol{\eta}$  and  $t = \tau$  in the  $j$ -direction.  $G_{ij}(\mathbf{x}, t; \boldsymbol{\eta}, \tau)$  satisfies the following equation:

$$\rho \frac{\partial^2 G_{ij}}{\partial t^2} = \frac{\partial}{\partial x_n} \left\{ \lambda \frac{\partial G_{kj}}{\partial x_k} \delta_{ni} + \mu \left( \frac{\partial G_{nj}}{\partial x_i} + \frac{\partial G_{ij}}{\partial x_n} \right) \right\} + \delta(\mathbf{x} - \boldsymbol{\eta}) \delta(t - \tau) \delta_{ij}. \quad (5)$$

Note that  $G_{ij}(\mathbf{x}, t; \boldsymbol{\eta}, \tau) = G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0)$ . The displacement  $u_i$  can then be described by using the equivalent body force and Green's functions as follows ("Appendix A: Green's Functions"):

$$u_i(\mathbf{x}, t) = \int_{-\infty}^{\infty} \iiint_V f_j^S(\boldsymbol{\eta}, \tau) G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0) dV(\boldsymbol{\eta}) d\tau. \quad (6)$$

BM expanded  $f_j^S$  in terms of polynomial moments at a particular point  $\boldsymbol{\xi}_0$  as

$$\begin{aligned} f_j^S(\boldsymbol{\eta}, \tau) &= F_j^{S0}(\boldsymbol{\xi}_0, \tau) \delta(\boldsymbol{\eta} - \boldsymbol{\xi}_0) \\ &\quad + F_{jk}^{S1}(\boldsymbol{\xi}_0, \tau) \frac{\partial \delta(\boldsymbol{\eta} - \boldsymbol{\xi}_0)}{\partial \eta_k} + \dots \\ &= f_j^{S0}(\boldsymbol{\eta}, \tau) + f_j^{S1}(\boldsymbol{\eta}, \tau) + \dots \end{aligned} \quad (7)$$

This expansion is schematically shown in Fig. 2, which may help the reader to understand that  $F_j^{S0}$  and  $F_{jk}^{S1}$  have the dimensions of force and moment, respectively.

### Single Force

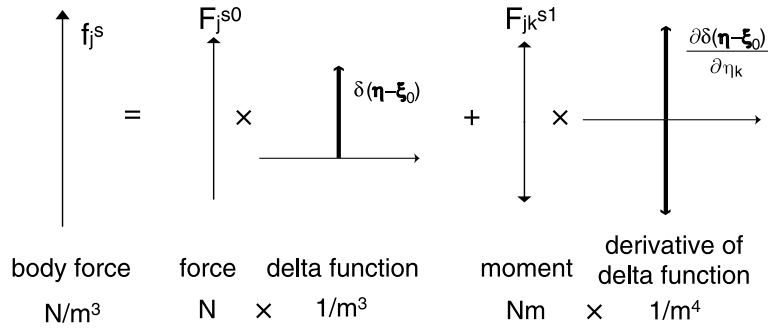

$F_j^{S0}$  is given as

$$F_j^{S0}(\boldsymbol{\xi}_0, \tau) = \iiint_V f_j^S(\boldsymbol{\eta}, \tau) dV(\boldsymbol{\eta}), \quad (8)$$

which is the total force. This must be zero because of the conservation of linear momentum (no force appears or disappears in the earth). Therefore,

$$\iiint_V f_j^S(\boldsymbol{\eta}, \tau) dV(\boldsymbol{\eta}) = 0. \quad (9)$$

This states that no single force exists in any indigenous seismic sources in the scheme presented by BM. However, we will see later that a single force exists in indigenous sources if the non-linear effect of mass advection is taken into account.

Volcano Seismic Signals, Source Quantification of, Figure 2  
Schematic diagram of the expansion of the equivalent body force  $f_j^s$  in terms of polynomial moments

**Moment Tensor**

We next examine the equivalent body force arising from the first-order moment,

$$f_j^{s1}(\eta, \tau) = F_{jk}^{s1}(\xi_0, \tau) \frac{\partial \delta(\eta - \xi_0)}{\partial \eta_k}. \tag{10}$$

If we consider a displacement discontinuity across a surface  $\Sigma$ ,  $f_j^{s1}$  may be expressed as [1]

$$f_j^{s1}(\eta, \tau) = - \iint_{\Sigma} m_{jk}(\xi, \tau) \frac{\partial}{\partial \eta_k} \delta(\eta - \xi) d\Sigma(\xi), \tag{11}$$

where  $m_{jk}$  is the moment density tensor given as

$$m_{jk} = \lambda v_l [u_l] \delta_{jk} + \mu (v_j [u_k] + v_k [u_j]). \tag{12}$$

Here,  $[u]$  is the displacement discontinuity defined by  $[u] = u|_{\Sigma+} - u|_{\Sigma-}$  and  $v = (v_1, v_2, v_3)$  is the unit vector normal to  $\Sigma$ , where  $u|_{\Sigma+}$  and  $u|_{\Sigma-}$  are displacements on the  $\Sigma+$  and the  $\Sigma-$  sides of  $\Sigma$ , respectively (see Fig. 3). An explicit expression of  $m_{jk}$  is

Volcano Seismic Signals, Source Quantification of, Figure 3  
An internal surface  $\Sigma$  across which a displacement discontinuity occurs. The displacement discontinuity is denoted by  $[u] = u|_{\Sigma+} - u|_{\Sigma-}$ , where  $u|_{\Sigma+}$  and  $u|_{\Sigma-}$  are displacements on the  $\Sigma+$  and  $\Sigma-$  sides of  $\Sigma$ , respectively [1]

$$m = \begin{pmatrix} \lambda v_k [u_k] + 2\mu v_1 [u_1] & \mu (v_1 [u_2] + v_2 [u_1]) \\ \mu (v_2 [u_1] + v_1 [u_2]) & \lambda v_k [u_k] + 2\mu v_2 [u_2] \\ \mu (v_3 [u_1] + v_1 [u_3]) & \mu (v_3 [u_2] + v_2 [u_3]) \\ & \mu (v_1 [u_3] + v_3 [u_1]) \\ & \mu (v_2 [u_3] + v_3 [u_2]) \\ & \lambda v_k [u_k] + 2\mu v_3 [u_3] \end{pmatrix}. \tag{13}$$

Therefore  $m_{jk} = m_{kj}$ . Using Green's functions, the displacement field due to  $f_j^{s1}$  is expressed as

$$\begin{aligned} u_i^{s1}(\mathbf{x}, t) &= \int_{-\infty}^{\infty} \iiint_V f_j^{s1}(\eta, \tau) G_{ij}(\mathbf{x}, t - \tau; \eta, 0) dV(\eta) d\tau \\ &= \int_{-\infty}^{\infty} \iiint_V \left[ - \iint_{\Sigma} m_{jk}(\xi, \tau) \frac{\partial}{\partial \eta_k} \delta(\eta - \xi) d\Sigma(\xi) \right] \\ &\quad \cdot G_{ij}(\mathbf{x}, t - \tau; \eta, 0) dV(\eta) d\tau \\ &= \int_{-\infty}^{\infty} \iint_{\Sigma} \left[ m_{jk}(\xi, \tau) \iiint_V - \frac{\partial}{\partial \eta_k} \delta(\eta - \xi) G_{ij}(\mathbf{x}, t - \tau; \eta, 0) dV(\eta) \right] d\Sigma(\xi) d\tau \\ &= \int_{-\infty}^{\infty} \iint_{\Sigma} m_{jk}(\xi, \tau) \frac{\partial}{\partial \xi_k} G_{ij}(\mathbf{x}, t - \tau; \xi, 0) d\Sigma(\xi) d\tau, \end{aligned} \tag{14}$$

where I used the following property:

$$\begin{aligned} \iiint_V \frac{\partial}{\partial \eta_k} \delta(\eta - \xi) G_{ij}(\mathbf{x}, t - \tau; \eta, 0) dV(\eta) \\ = - \frac{\partial}{\partial \xi_k} G_{ij}(\mathbf{x}, t - \tau; \xi, 0). \end{aligned} \tag{15}$$

We assume that the source is small compared to the wavelengths of seismic waves and approximate the source as

Volcano Seismic Signals, Source Quantification of, Figure 4  
Slip  $[u_1]$  in the plane  $\xi_3 = 0$

a point at  $\xi_0$ . Then, Eq. (14) can be written as

$$u_i^{S1}(\mathbf{x}, t) = \int_{-\infty}^{\infty} M_{jk}(\xi_0, \tau) \frac{\partial}{\partial \xi_k} G_{ij}(\mathbf{x}, t - \tau; \xi_0, 0) d\tau, \quad (16)$$

where  $M_{jk}$  is the moment tensor defined as

$$M_{jk}(\xi_0, \tau) = \iint_{\Sigma} m_{jk}(\xi, \tau) d\Sigma(\xi). \quad (17)$$

**Slip on a Fault** We consider slip  $[u_1]$  in the plane  $\xi_3 = 0$  (see Fig. 4). In this case,  $\mathbf{v} = (0, 0, 1)$  and  $[\mathbf{u}] = ([u_1], 0, 0)$ . Substituting  $\mathbf{v}$  and  $[\mathbf{u}]$  into Eq. (13), we obtain the moment density tensor  $m_{jk}$  as

$$\mathbf{m} = \begin{pmatrix} 0 & 0 & \mu[u_1(\xi, \tau)] \\ 0 & 0 & 0 \\ \mu[u_1(\xi, \tau)] & 0 & 0 \end{pmatrix}, \quad (18)$$

and the moment tensor  $M_{jk}$  as

$$\mathbf{M} = M(\xi_0, \tau) \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad (19)$$

where

$$M(\xi_0, \tau) = \mu \iint_{\Sigma} [u_1(\xi, \tau)] d\Sigma(\xi). \quad (20)$$

This is called the moment function or source-time function. The time history of slip across a plane is typically represented by a step-like function, and therefore  $M(\xi_0, \tau)$  displays a step-like function (Fig. 5a). We can also define the time derivative of  $M$  as

Volcano Seismic Signals, Source Quantification of, Figure 5  
Moment and moment-rate functions for slip across a plane in the form of a step-like function

$$\dot{M}(\xi_0, \tau) = \mu \frac{\partial}{\partial \tau} \iint_{\Sigma} [u_1(\xi, \tau)] d\Sigma(\xi). \quad (21)$$

This is called the moment-rate function, which is an impulsive function (Fig. 5b). After slip stops,  $M$  has a finite value  $M_0$  (Fig. 5a), which is given as

$$M_0 = \mu A \bar{u}_1. \quad (22)$$

$A$  and  $\bar{u}_1$  are the slip area and average slip, respectively, which are defined as

$$A = \iint_{\Sigma} d\Sigma, \quad (23)$$

$$\bar{u}_1 = \frac{\iint_{\Sigma} [u_1(\xi, \tau = \infty)] d\Sigma}{A}, \quad (24)$$

where  $\tau = \infty$  represents time after the termination of slip.  $M_0$  is called the seismic moment. When  $\tau = \infty$ ,  $M_{jk}$  becomes

$$\mathbf{M} = M_0 \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}. \quad (25)$$

This matrix can be diagonalized to

$$\mathbf{M}' = M_0 \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad (26)$$

where three eigenvalues (1, 0, and  $-1$ ) correspond to the T (maximum compression), B (null), and P (minimum compression) axes, respectively. As shown in Fig. 6, this

Volcano Seismic Signals, Source Quantification of, Figure 6  
**a** Force system for slip  $[u_1]$  in the plane  $\xi_3 = 0$ . **b** A double couple equivalent to the force system in Fig. 6a

system constitutes a double couple, which is equivalent to fault slip.

**Tensile Crack** We examine a crack such that slip  $[u_3]$  is nonzero in the plane  $\xi_3 = 0$  (a horizontal crack; see Fig. 7). In this case,  $\mathbf{v} = (0, 0, 1)$  and  $[\mathbf{u}] = (0, 0, [u_3])$ . Therefore, we find from Eq. (13) that

$$\mathbf{m} = \begin{pmatrix} \lambda[u_3(\xi, \tau)] & 0 & 0 \\ 0 & \lambda[u_3(\xi, \tau)] & 0 \\ 0 & 0 & (\lambda + 2\mu)[u_3(\xi, \tau)] \end{pmatrix}. \tag{27}$$

The moment tensor for a horizontal crack is given as

$$\mathbf{M} = M(\xi_0, \tau) \begin{pmatrix} \lambda/\mu & 0 & 0 \\ 0 & \lambda/\mu & 0 \\ 0 & 0 & \lambda/\mu + 2 \end{pmatrix}, \tag{28}$$

and

$$\begin{aligned} M(\xi_0, \tau) &= \mu \iint_{\Sigma} [u_3(\xi, \tau)] d\Sigma(\xi) \\ &= \mu A \bar{u}_3(\tau) \\ &= \mu \Delta V(\tau), \end{aligned} \tag{29}$$

where  $\Delta V$  represents the incremental volume change of the crack.

Figure 8a is a tensile crack with normal direction  $(\theta, \phi)$ , and we find that  $\mathbf{v} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$  and  $[\mathbf{u}] = [u](\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$ . Using Eqs. (13) and (17), we obtain the moment tensor for the crack:

$$\mathbf{M} = \mu \Delta V \begin{pmatrix} \lambda/\mu + 2 \sin^2 \theta \cos^2 \phi & & \\ 2 \sin^2 \theta \sin \phi \cos \phi & & \\ 2 \sin \theta \cos \theta \cos \phi & & \\ 2 \sin^2 \theta \sin \phi \cos \phi & 2 \sin \theta \cos \theta \cos \phi & \\ \lambda/\mu + 2 \sin^2 \theta \sin^2 \phi & 2 \sin \theta \cos \theta \sin \phi & \\ 2 \sin \theta \cos \theta \sin \phi & \lambda/\mu + 2 \cos^2 \theta & \end{pmatrix}, \tag{30}$$

where  $\Delta V = \iint_{\Sigma} [u] d\Sigma$ .

Volcano Seismic Signals, Source Quantification of, Figure 8  
Source coordinates and geometries for **a** a crack and **b** a cylinder

For a vertical crack ( $\theta = \pi/2$ ),

$$\mathbf{M} = \mu \Delta V \begin{pmatrix} \lambda/\mu + 2 \cos^2 \phi & 2 \sin \phi \cos \phi & 0 \\ 2 \sin \phi \cos \phi & \lambda/\mu + 2 \sin^2 \phi & 0 \\ 0 & 0 & \lambda/\mu \end{pmatrix}. \quad (31)$$

A tensile crack is equivalent to a superposition of three vector dipoles with amplitude ratios 1:1:( $\lambda + 2\mu$ )/ $\lambda$  (Fig. 7). If  $\lambda = \mu$ , the amplitude ratios are represented by 1:1:3. If  $\lambda = 2\mu$ , which may be appropriate either for volcanic rock near liquidus temperature or for a highly heterogeneous medium, the ratios become 1:1:2.

**Spherical Source** The moment tensor for a spherical source is given as

$$\mathbf{M} = (\lambda + 2\mu) \Delta V_s \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad (32)$$

where  $\Delta V_s = 4\pi R^2 \Delta_s$  is the volume change caused by the displacement  $\Delta_s$  of a spherical surface of ra-

dius  $R$  [89] (see “Appendix B: Moment Tensor for a Spherical Source”). The moment tensor for a spherical source may be useful to describe the source of explosion earthquakes e. g., [56].

**Cylindrical Source** The moment tensor for a vertical cylinder is

$$\mathbf{M} = \frac{\lambda + 2\mu}{\lambda + \mu} \mu \Delta V_c \begin{pmatrix} \lambda/\mu + 1 & 0 & 0 \\ 0 & \lambda/\mu + 1 & 0 \\ 0 & 0 & \lambda/\mu \end{pmatrix}, \quad (33)$$

where  $\Delta V_c = 2\pi R L \Delta_c$  is the volume change caused by the radial displacement  $\Delta_c$  of the surface of a cylinder of radius  $R$  and length  $L$  [89,126] (see “Appendix C: Moment Tensor for a Cylindrical Source”).

The moment tensor for a cylinder with axis orientation angles  $(\theta, \phi)$  (Fig. 8b) is given as

$$\mathbf{M} = \frac{\lambda + 2\mu}{\lambda + \mu} \mu \Delta V_c \times \begin{pmatrix} \lambda/\mu + (\cos^2 \theta \cos^2 \phi + \sin^2 \phi) & & \\ \sin^2 \theta \sin \phi \cos \phi & & \\ \sin \theta \cos \theta \cos \phi & & \\ \sin^2 \theta \sin \phi \cos \phi & \sin \theta \cos \theta \cos \phi & \\ \lambda/\mu + (\cos^2 \theta \sin^2 \phi + \cos^2 \phi) & \sin \theta \cos \theta \sin \phi & \\ \sin \theta \cos \theta \sin \phi & \lambda/\mu + \sin^2 \theta & \end{pmatrix} \quad (34)$$

(see “Appendix C: Moment Tensor for a Cylindrical Source”). Radial volumetric changes of a pipe may occur in association with mass transport in a cylindrical conduit e. g., [126].

### Inertial Glut

In the scheme presented by BM, no single force exists in indigenous seismic sources because of the requirement for conservation of linear momentum. However, Takei and Kumazawa [118] presented a theoretical justification for the existence of a single force in indigenous sources, if the non-linear effect of mass advection is taken into account.

Following the theory of Takei and Kumazawa [118], we consider the exact equation of motion of the earth, given as

$$\rho^{\text{true}} \frac{D^2 u_i}{Dt^2} = \frac{\partial \sigma_{ni}^{\text{true}}}{\partial x_n}, \quad (35)$$

where  $\rho^{\text{true}}$  is true density as a function of both space and time.  $\frac{D}{Dt}$  is the particle derivative:

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + v_k \frac{\partial}{\partial x_k}, \quad (36)$$

where  $v_k = \frac{Du_k}{Dt}$  is particle velocity. Using model density  $\rho^{\text{model}}$  and model stress  $\sigma_{ni}^{\text{model}}$  from Eq. (2), Eq. (35) can be rewritten as follows:

$$\rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ni}^{\text{model}}}{\partial x_n} + f_i^V. \quad (37)$$

This equation is similar to Eq. (3), but the equivalent body force  $f_i^V$  is defined in this case as

$$\begin{aligned} f_i^V &= \left( \frac{\partial \sigma_{ni}^{\text{true}}}{\partial x_n} - \frac{\partial \sigma_{ni}^{\text{model}}}{\partial x_n} \right) \\ &+ \left( \rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} - \rho^{\text{true}} \frac{D^2 u_i}{Dt^2} \right) \\ &= f_i^S + f_i^I. \end{aligned} \quad (38)$$

Here,  $f_i^V$  is  $f_i^S$ , arising from the stress glut, plus  $f_i^I$ , representing the difference between the inertia terms, which is called the inertial glut [118].

In the same way as presented by BM, we expand  $f_i^I$  in terms of polynomial moments at a particular point  $\xi_0$  as

$$f_i^I(\eta, \tau) = F_i^{I0}(\xi_0, \tau) \delta(\eta - \xi_0) + \text{higher-order terms}, \quad (39)$$

where

$$\begin{aligned} F_i^{I0} &= \iiint_V f_i^I(\eta, \tau) dV(\eta) \\ &= - \iiint_V \left( \rho^{\text{true}} \frac{D^2 u_i}{Dt^2} - \rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} \right) dV(\eta). \end{aligned} \quad (40)$$

By using mass conservation

$$\frac{\partial \rho^{\text{true}}}{\partial t} + \frac{\partial}{\partial x_k} (\rho^{\text{true}} v_k) = 0 \quad (41)$$

and Gauss' theorem

$$\iiint_V \frac{\partial v_k}{\partial x_k} dV = \iint_{S_e} v_k v_k dS_e, \quad (42)$$

the first integral of Eq. (40) is expressed as

$$\begin{aligned} \iiint_V \rho^{\text{true}} \frac{D^2 u_i}{Dt^2} dV &= \frac{\partial}{\partial t} \iiint_V \rho^{\text{true}} v_i dV \\ &+ \iint_{S_e} (\rho^{\text{true}} v_i v_k) v_k dS_e, \end{aligned} \quad (43)$$

where  $S_e$  is the surface of the earth. The second term in the right-hand side of Eq. (43) vanishes because it is a surface integral of a non-linear term, which is infinitesimal. Therefore, we find that

$$\begin{aligned} \iiint_V \rho^{\text{true}} \frac{D^2 u_i}{Dt^2} dV &= \frac{\partial}{\partial t} \iiint_V \rho^{\text{true}} v_i dV \\ &= \dot{L}_i^t. \end{aligned} \quad (44)$$

Here,  $\dot{L}_i^t$  is the time derivative of the total linear momentum, which is zero at any given time because of conservation of linear momentum of the earth. The second integral in Eq. (40) is given as

$$\begin{aligned} \iiint_V \rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} dV &= \frac{\partial}{\partial t} \iiint_V \rho^{\text{model}} \frac{\partial u_i}{\partial t} dV \\ &= \dot{L}_i^m, \end{aligned} \quad (45)$$

which is the time derivative of linear momentum defined by the model density. Therefore, Eq. (40) is written as

$$\begin{aligned} F_i^{I0} &= -(\dot{L}_i^t - \dot{L}_i^m) \\ &= \dot{L}_i^m, \end{aligned} \quad (46)$$

which shows that force  $F_i^{I0}$  exists as an apparent change of the total linear momentum of the earth referred to a biased model density structure.

Takei and Kumazawa [118] stated that  $F_i^{I0}$  originates from (a) the difference of density structure of the prescribed model from the actual value in the source region before the event, and from (b) a temporal change of the density structure in the source region caused by finite displacement of mass during the event. The latter is a non-linear effect caused by mass advection, which may occur by fluid flow, especially in volcanic regions.

### Single Force Defined by Action and Reaction

We further consider the single force from the viewpoint of the interaction force between the source volume and the rest of the earth. Following Takei and Kumazawa [119], we define the source region  $V_s$  enclosed by a surface  $S$  and the remaining part of the earth  $\bar{V}$  (Fig. 9). Using Eqs. (38), (9), (44), and (45), we obtain

$$\begin{aligned} \iiint_V f_i^V dV &= \iiint_V (f_i^S + f_i^I) dV \\ &= \iiint_V f_i^I dV \\ &= -\frac{\partial}{\partial t} \iiint_V \left( \rho^{\text{true}} v_i - \rho^{\text{model}} \frac{\partial u_i}{\partial t} \right) dV \\ &= -\frac{\partial}{\partial t} \left[ \iiint_{V_s} \left( \rho^{\text{true}} v_i - \rho^{\text{model}} \frac{\partial u_i}{\partial t} \right) dV \right. \\ &\quad \left. - \iiint_{\bar{V}} \left( \rho^{\text{true}} v_i - \rho^{\text{model}} \frac{\partial u_i}{\partial t} \right) dV \right], \end{aligned} \quad (47)$$

where infinitesimal surface integral terms are omitted. The second integral in the right-hand side of Eq. (47) vanishes because  $\rho^{\text{true}} = \rho^{\text{model}}$  and  $v_i = \partial u_i / \partial t$  in  $\bar{V}$ .  $f_i^V$  exists

Volcano Seismic Signals, Source Quantification of, Figure 9  
The earth  $V$  divided into a source volume  $V_s$  enclosed by a surface  $S$  and the remainder of the earth  $\bar{V}$

only in the source region, and thus the volume integral of  $f_i^V$  in the left hand side of Eq. (47) can be limited to  $V_s$ . Therefore, Eq. (47) is written as

$$\iiint_{V_s} f_i^V dV = -\frac{\partial}{\partial t} \iiint_{V_s} \left( \rho^{\text{true}} v_i - \rho^{\text{model}} \frac{\partial u_i}{\partial t} \right) dV. \quad (48)$$

This equation is then rewritten as

$$\begin{aligned} \frac{\partial}{\partial t} \iiint_{V_s} \rho^{\text{true}} v_i dV &= \frac{\partial}{\partial t} \iiint_{V_s} \rho^{\text{model}} \frac{\partial u_i}{\partial t} dV \\ &\quad - \iiint_{V_s} f_i^V dV \\ &= \iiint_{V_s} \left( \rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} - f_i^V \right) dV. \end{aligned} \quad (49)$$

From Eq. (37), we find that the integrand of the right-hand side of Eq. (49) equals  $\partial \sigma_{ni}^{\text{model}} / \partial x_n$ . Therefore, we obtain

$$\begin{aligned} \frac{\partial}{\partial t} \iiint_{V_s} \rho^{\text{true}} v_i dV &= \iiint_{V_s} \frac{\partial \sigma_{ni}^{\text{model}}}{\partial x_n} dV \\ &= \iint_S \sigma_{ni}^{\text{model}} v_n dS. \end{aligned} \quad (50)$$

This indicates that a temporal change of linear momentum in the source region is equivalent to the total force exerted on the boundary  $S$ . Therefore,  $\iint_S \sigma_{ni}^{\text{model}} v_n dS$  can be regarded as the action force originating from non-linear

processes in the source volume  $V_s$ . In  $\bar{V}$ , the reaction force opposite to  $\iint_S \sigma_{ni}^{\text{model}} v_n dS$  acts through the boundary  $S$ . We define traction  $P_i$  on  $S$ , which satisfies the following condition:

$$\sigma_{ni}^{\text{model}} v_n = -P_i \quad \text{on } S. \quad (51)$$

Then, we find that

$$\begin{aligned} \iint_S P_i dS &= -\iint_S \sigma_{ni}^{\text{model}} v_n dS \\ &= -\frac{\partial}{\partial t} \iiint_{V_s} \rho^{\text{true}} v_i dV, \end{aligned} \quad (52)$$

which is the reaction force opposite to the action force.

If the source is small compared to the wavelengths of seismic waves, the action force originating in a closed small source volume  $V_s$  may not be observable outside the source volume  $\bar{V}$ . Instead, the traction  $P_j$  exerted on  $S$  may be viewed in  $\bar{V}$  as a traction discontinuity on  $S$ . As shown by Aki and Richards [1], a traction discontinuity is the source of seismic waves represented by an equivalent body force. We consider seismic waves in  $\bar{V}$ , and the equation of motion in  $\bar{V}$  may be expressed as

$$\rho^{\text{model}} \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ni}^{\text{model}}}{\partial x_n} + f_i \quad \text{in } \bar{V}, \quad (53)$$

where  $f_i$  is the equivalent body force due to the traction discontinuity on  $S$ , given as

$$f_i(\boldsymbol{\eta}, \tau) = \iint_S P_i(\boldsymbol{\xi}, \tau) \delta(\boldsymbol{\eta} - \boldsymbol{\xi}) dS(\boldsymbol{\xi}). \quad (54)$$

Note that

$$\iiint_{\bar{V}} f_i(\boldsymbol{\eta}, \tau) dV(\boldsymbol{\eta}) = \iint_S P_i(\boldsymbol{\xi}, \tau) dS(\boldsymbol{\xi}), \quad (55)$$

which is the total force acting through  $S$  in  $\bar{V}$ .

We may use Green's functions estimated from the model structure because the effect of the true structure in the source volume is negligible in the point source approximation. Therefore, by using Eq. (54), the displacement field  $u_i^f$  due to the single force may be described as

$$\begin{aligned} u_i^f(\mathbf{x}, t) &= \int_{-\infty}^{\infty} \iiint_{\bar{V}} f_j(\boldsymbol{\eta}, \tau) G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0) dV(\boldsymbol{\eta}) d\tau \\ &= \int_{-\infty}^{\infty} \iiint_{\bar{V}} \left[ \iint_S P_j(\boldsymbol{\xi}, \tau) \delta(\boldsymbol{\eta} - \boldsymbol{\xi}) dS(\boldsymbol{\xi}) \right] \\ &\quad \cdot G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0) dV(\boldsymbol{\eta}) d\tau \\ &= \int_{-\infty}^{\infty} \iint_S P_j(\boldsymbol{\xi}, \tau) G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\xi}, 0) dS(\boldsymbol{\xi}) d\tau, \end{aligned} \quad (56)$$

or, equivalently,

$$u_i^f(\mathbf{x}, t) = \int_{-\infty}^{\infty} F_j(\xi_0, \tau) G_{ij}(\mathbf{x}, t - \tau; \xi_0, 0) d\tau, \quad (57)$$

where

$$\begin{aligned} F_j(\xi_0, \tau) &= \iint_S P_j(\xi, \tau) dS(\xi) \\ &= -\frac{\partial}{\partial t} \iiint_{V_s} \rho^{\text{true}} v_i dV \\ &= -\dot{L}_j^s. \end{aligned} \quad (58)$$

Here,  $L_j^s$  is the total linear momentum inside the source volume. This single force representation in terms of the traction  $P_j$  is consistent with the relationship between the traction modes and equivalent body force given by Takei and Kumazawa [119] in small-source and long-wavelength approximations.

$F_j$  is the reaction force opposite to the action force generated by non-linear processes in the source volume. A simple example is dense materials falling in a magma chamber (Fig. 10a). During the acceleration stage of falling dense materials,  $\dot{L}_j^s$  is a downward force and we therefore observe an upward single force as the reaction force; during the deceleration stage, we observe a downward single force (Fig. 10a). In the case of lighter materials ascending

in a magma chamber, we observe a downward single force during the acceleration stage of ascending lighter materials, and an upward single force is observed during the deceleration stage of ascending lighter materials (Fig. 10b).

**Summary**

Here, we summarize the phenomenological representation of indigenous seismic sources. For point sources, the displacement field  $u_i$  can be expressed by the superposition of the displacement fields excited by single force  $u_i^f$  of Eq. (57) and moment tensor  $u_i^{S1}$  of Eq. (16):

$$\begin{aligned} u_i(\mathbf{x}, t) &= \int_{-\infty}^{\infty} F_j(\xi_0, \tau) G_{ij}(\mathbf{x}, t - \tau; \xi_0, 0) d\tau \\ &+ \int_{-\infty}^{\infty} M_{jk}(\xi_0, \tau) \frac{\partial}{\partial \xi_k} G_{ij}(\mathbf{x}, t - \tau; \xi_0, 0) d\tau, \end{aligned} \quad (59)$$

where

$$F_j(\xi_0, \tau) = \iint_S P_j(\xi, \tau) dS(\xi) \quad (60)$$

and

$$M_{jk}(\xi_0, \tau) = \iint_{\Sigma} m_{jk}(\xi, \tau) d\Sigma(\xi). \quad (61)$$

Here,  $P_j$  is the traction exerted on the boundary  $S$  between the source volume and the rest of the earth and  $m_{jk}$  is the moment density tensor defined by the displacement discontinuity across the surface  $\Sigma$ .  $F_j$  is related to the total linear momentum within the source volume  $L_j^s$  as

$$F_j = -\dot{L}_j^s \quad (j = 1, 2, 3). \quad (62)$$

$M_{jk}$  is the moment tensor consisting of six independent components:

$$\mathbf{M} = \begin{pmatrix} M_{11} & M_{12} & M_{13} \\ M_{12} & M_{22} & M_{23} \\ M_{13} & M_{23} & M_{33} \end{pmatrix}. \quad (63)$$

**Waveform Inversion**

Waveform inversion is a quantitative tool used to estimate the source mechanisms and locations of volcano-seismic signals. The source parameters are determined by finding the best fits between observed and synthetic seismic waveforms. This can be performed by solving an inverse problem by using the concept of linear inverse theory e. g., [83].

We may reasonably assume that the source of a tectonic earthquake is represented by the moment tensor corresponding to a double couple. However, volcano-seismic

Volcano Seismic Signals, Source Quantification of, Figure 10 Schematic illustration of the reaction force ( $F_j$ ) opposite to the action force ( $\dot{L}_j^s$ ) generated by nonlinear processes in a source volume: a dense materials falling in a magma chamber and b light materials ascending in a magma chamber

signals may be generated by complex source processes, requiring a general source representation consisting of single force and moment tensor. Furthermore, while we can assume a step-like function for the source-time function of a tectonic earthquake, we must determine the complex time history at the source of volcano-seismic signals, which involves more unknowns. Waveform inversion of volcano-seismic signals is thus a more complicated task than the inversion of a tectonic earthquake.

We assume a single force and moment tensor at a particular source location, and obtain from Eq. (59) the following relationship:

$$u_i(t) = \int_{-\infty}^{\infty} [F_j(\tau)G_{ij}(t-\tau) + M_{jk}(\tau)G_{ij,k}(t-\tau)] d\tau, \tag{64}$$

where  $G_{ij,k} = \partial G_{ij} / \partial \xi_k$ . We rewrite Eq. (64) in the following form:

$$u_i(t) = \sum_{j=1}^9 \int_{-\infty}^{\infty} m_j(\tau) \Gamma_{ij}(t-\tau) d\tau, \tag{65}$$

where

$$m_j = [F_1, F_2, F_3, M_{11}, M_{22}, M_{33}, M_{12}, M_{23}, M_{13}] \tag{66}$$

and

$$\Gamma_{ij} = [G_{i1}, G_{i2}, G_{i3}, G_{i1,1}, G_{i2,2}, G_{i3,3}, G_{i1,2} + G_{i2,1}, G_{i2,3} + G_{i3,2}, G_{i1,3} + G_{i3,1}]. \tag{67}$$

We discretize  $t$  and  $\tau$  as  $t = k\Delta t$  ( $k = 0, \dots, N_t - 1$ ) and  $\tau = l\Delta t$  ( $l = 0, \dots, N_t - 1$ ), respectively, where  $\Delta t$  is the sampling interval. This yields the discrete form of Eq. (65) given as

$$u_i(k\Delta t) = \sum_{j=1}^9 \sum_{l=0}^{N_t-1} m_j(l\Delta t) \Gamma_{ij}(k\Delta t - l\Delta t) \Delta t. \tag{68}$$

If we have  $N_c$  traces of  $u_i$ , Eq. (68) is written in matrix form

$$\mathbf{u} = \mathbf{\Gamma} \mathbf{m}, \tag{69}$$

where

$$\mathbf{u} = [u_1(0), \dots, u_1((N_t - 1)\Delta t), \dots, u_{N_c}(0), \dots, u_{N_c}((N_t - 1)\Delta t)]^T, \tag{70}$$

$$\mathbf{m} = [m_1(0), \dots, m_1((N_t - 1)\Delta t), \dots, m_9(0), \dots, m_9((N_t - 1)\Delta t)]^T, \tag{71}$$

$$\mathbf{\Gamma} = \begin{bmatrix} \Gamma_{11}(0) & \dots & \Gamma_{11}((1 - N_t)\Delta t) & \dots \\ \vdots & \vdots & \vdots & \vdots \\ \Gamma_{11}((N_t - 1)\Delta t) & \dots & \Gamma_{11}(0) & \dots \\ \vdots & \vdots & \vdots & \vdots \\ \Gamma_{N_{c1}}(0) & \dots & \Gamma_{N_{c1}}((1 - N_t)\Delta t) & \dots \\ \vdots & \vdots & \vdots & \vdots \\ \Gamma_{N_{c1}}((N_t - 1)\Delta t) & \dots & \Gamma_{N_{c1}}(0) & \dots \\ \dots & \Gamma_{19}(0) & \dots & \Gamma_{19}((1 - N_t)\Delta t) \\ \vdots & \vdots & \vdots & \vdots \\ \dots & \Gamma_{19}((N_t - 1)\Delta t) & \dots & \Gamma_{19}(0) \\ \vdots & \vdots & \vdots & \vdots \\ \dots & \Gamma_{N_{c9}}(0) & \dots & \Gamma_{N_{c9}}((1 - N_t)\Delta t) \\ \vdots & \vdots & \vdots & \vdots \\ \dots & \Gamma_{N_{c9}}((N_t - 1)\Delta t) & \dots & \Gamma_{N_{c9}}(0) \end{bmatrix} \Delta t. \tag{72}$$

Here  $T$  denotes transpose.  $\mathbf{\Gamma}$  is called the data kernel, which is an  $N \times M$  matrix, and  $\mathbf{u}$  and  $\mathbf{m}$  are vectors of lengths  $N$  and  $M$ , respectively, where  $N = N_c N_t$  and  $M = 9N_t$ .

We denote observed waveforms as  $\mathbf{u}^{obs}$ , which satisfy the following equation:

$$\mathbf{u}^{obs} - \mathbf{\Gamma} \mathbf{m} = \mathbf{e}, \tag{73}$$

where  $\mathbf{e}$  is the prediction error or misfit. In the case of  $N > M$ , we estimate  $\mathbf{m}$  by minimizing the residual  $R$ , defined as

$$R = \frac{\mathbf{e}^T \mathbf{e}}{\mathbf{u}^{obs T} \mathbf{u}^{obs}} = \frac{\sum_{i=1}^N e_i^2}{\sum_{i=1}^N u_i^{obs}}, \tag{74}$$

where

$$\mathbf{e}^T \mathbf{e} = (\mathbf{u}^{obs} - \mathbf{\Gamma} \mathbf{m})^T (\mathbf{u}^{obs} - \mathbf{\Gamma} \mathbf{m}). \tag{75}$$

To minimize  $R$  is to find values of  $\mathbf{m}$  that satisfy the following equations:

$$\frac{\partial R}{\partial m_q} = 0 \quad (q = 1, \dots, M). \tag{76}$$

This leads to the following relationship (the normal equation)

$$\mathbf{\Gamma}^T \mathbf{\Gamma} \mathbf{m} - \mathbf{\Gamma}^T \mathbf{u}^{obs} = 0. \tag{77}$$

Therefore, we have the following solution:

$$\mathbf{m}^{est} = [\mathbf{\Gamma}^T \mathbf{\Gamma}]^{-1} \mathbf{\Gamma}^T \mathbf{u}^{obs}, \tag{78}$$

which is the least-squares solution. This least-squares approach in the time domain has been used in many volcano

seismological studies e. g., [32,33,48,69,71,72,73,92,94,102, 105,107,108,120,122].

As can be seen from Eq. (68),  $u_i$  is calculated by the convolution of  $m_j$  with  $\Gamma_{ij}$ . This means that the displacement  $u_i(k\Delta t)$  includes the entire effect of the time history of the single force and moment tensor as well as Green's functions before time  $k\Delta t$ . This may be easily understood if we consider  $u_i((N_t - 1)\Delta t)$  in Eq. (68):

$$u_i((N_t - 1)\Delta t) = \Delta t \sum_{j=1}^9 [m_j(0)\Gamma_{ij}((N_t - 1)\Delta t) + m_j(\Delta t)\Gamma_{ij}((N_t - 2)\Delta t) + \dots + m_j((N_t - 2)\Delta t)\Gamma_{ij}(\Delta t) + m_j((N_t - 1)\Delta t)\Gamma_{ij}(0)]. \tag{79}$$

The convolution relationship leads to the large matrix of  $\mathbf{F}$  of Eq. (69), which requires long computation time to obtain the least-squares solution. A better alternative is to solve the inverse problem in the frequency domain [11,95, 116]. The Fourier transform of Eq. (65) is given by

$$\bar{u}_i(\omega) = \sum_{j=1}^9 \bar{m}_j(\omega)\bar{\Gamma}_{ij}(\omega), \tag{80}$$

where  $\omega$  is the angular frequency and  $\bar{u}_i, \bar{m}_j$ , and  $\bar{\Gamma}_{ij}$  are the Fourier transforms of  $u_i, m_j$ , and  $\Gamma_{ij}$ . This frequency domain equation is discretized as follows:

$$\bar{u}_i(k\Delta\omega) = \sum_{j=1}^9 \bar{m}_j(k\Delta\omega)\bar{\Gamma}_{ij}(k\Delta\omega), \tag{81}$$

where  $\Delta\omega = 2\pi/(N_t\Delta t)$  and  $k = 0, \dots, N_t/2$ . Note that the Fourier transformed components are complex and we have a set of the equations corresponding to real and imaginary parts; therefore, Eq. (81) consists of  $N_t$  equations. We further note that  $\bar{u}_i, \bar{m}_j$ , and  $\bar{\Gamma}_{ij}$  in Eq. (81) depend only on  $k\Delta\omega$ . This indicates that individual frequency components of  $\bar{u}_i, \bar{m}_j$ , and  $\bar{\Gamma}_{ij}$  are independent of each other and Eq. (81) can be solved separately. This is different from the time-domain Eq. (65):  $u_i$  is a function of  $k\Delta t$ , whereas  $m_j$  is a function of  $l\Delta t$ , and  $\Gamma_{ij}$  is a function of  $k\Delta t$  and  $l\Delta t$ , so we cannot separate the time-domain equation in individual values of  $k\Delta t$ . The use of the frequency-domain equation results in a smaller size of the data kernel, as shown below.

If we have  $N_c$  traces of  $\bar{u}_i$ , Eq. (81) is written in matrix form

$$\bar{\mathbf{u}} = \bar{\mathbf{F}} \bar{\mathbf{m}}. \tag{82}$$

Here,  $\bar{\mathbf{u}}$  is a vector consisting of  $\bar{u}_i$ , which is arranged in individual frequency components as follows:

$$\bar{\mathbf{u}} = [\bar{u}_1(0), \bar{u}_2(0), \dots, \bar{u}_{N_c}(0), \bar{u}_1(\Delta\omega), \bar{u}_2(\Delta\omega), \dots, \bar{u}_{N_c}(\Delta\omega), \dots, \bar{u}_1((N_t/2)\Delta\omega), \bar{u}_2((N_t/2)\Delta\omega), \dots, \bar{u}_{N_c}((N_t/2)\Delta\omega)]^T \tag{83}$$

or, equivalently,

$$\bar{\mathbf{u}} = [\bar{\mathbf{u}}(0), \bar{\mathbf{u}}(\Delta\omega), \dots, \bar{\mathbf{u}}(k\Delta\omega), \dots, \bar{\mathbf{u}}(N_t/2\Delta\omega)]^T, \tag{84}$$

where

$$\bar{\mathbf{u}}(k\Delta\omega) = [\bar{u}_1(k\Delta\omega), \bar{u}_2(k\Delta\omega), \dots, \bar{u}_{N_c}(k\Delta\omega)]^T. \tag{85}$$

Similarly,  $\bar{\mathbf{m}}$  is a vector consisting of  $\bar{m}_j$ , which is arranged in individual frequency components as

$$\bar{\mathbf{m}} = [\bar{m}_1(0), \bar{m}_2(0), \dots, \bar{m}_9(0), \bar{m}_1(\Delta\omega), \bar{m}_2(\Delta\omega), \dots, \bar{m}_9(\Delta\omega), \dots, \bar{m}_1((N_t/2)\Delta\omega), \bar{m}_2((N_t/2)\Delta\omega), \dots, \bar{m}_9((N_t/2)\Delta\omega)]^T \tag{86}$$

or

$$\bar{\mathbf{m}} = [\bar{\mathbf{m}}(0), \bar{\mathbf{m}}(\Delta\omega), \dots, \bar{\mathbf{m}}(k\Delta\omega), \dots, \bar{\mathbf{m}}((N_t/2)\Delta\omega)]^T, \tag{87}$$

where

$$\bar{\mathbf{m}}(k\Delta\omega) = [\bar{m}_1(k\Delta\omega), \bar{m}_2(k\Delta\omega), \dots, \bar{m}_9(k\Delta\omega)]^T. \tag{88}$$

Accordingly,  $\bar{\mathbf{F}}$  is given as

$$\bar{\mathbf{F}} = \begin{bmatrix} \bar{\Gamma}^{\bar{}}(0) & & & & & & & & \\ & \bar{\Gamma}^{\bar{}}(\Delta\omega) & & & & & & & 0 \\ & & \ddots & & & & & & \\ & & & \bar{\Gamma}^{\bar{}}(k\Delta\omega) & & & & & \\ & & & & \ddots & & & & \\ & & 0 & & & \ddots & & & \\ & & & & & & \bar{\Gamma}^{\bar{}}((N_t/2)\Delta\omega) & & \end{bmatrix}, \tag{89}$$

where  $\bar{\mathbf{F}}(k\Delta\omega)$  is

$$\bar{\mathbf{F}}(k\Delta\omega) = \begin{bmatrix} \bar{\Gamma}_{11}^{\bar{}}(k\Delta\omega) & \cdots & \bar{\Gamma}_{19}^{\bar{}}(k\Delta\omega) \\ \vdots & \ddots & \vdots \\ \bar{\Gamma}_{N_c1}^{\bar{}}(k\Delta\omega) & \cdots & \bar{\Gamma}_{N_c9}^{\bar{}}(k\Delta\omega) \end{bmatrix}. \tag{90}$$

Since  $\bar{\mathbf{F}}$  is the block diagonal matrix, Eq. (82) can be reduced to

$$\bar{\mathbf{u}}(k\Delta\omega) = \bar{\mathbf{F}}(k\Delta\omega)\bar{\mathbf{m}}(k\Delta\omega) \quad (k = 0, \dots, N_t/2). \tag{91}$$

The dimension of matrix  $\bar{\mathbf{F}}(k\Delta\omega)$  is  $N_c \times 9$ , which is  $N_t^2$  times smaller than that of  $\mathbf{F}$  in the time domain (Eq. (72)).

This is because convolution in the time domain is equivalent to the multiplication in the frequency domain. The smaller size of  $\tilde{\mathbf{F}}(k\Delta\omega)$  contributes to faster computation of the least-squares solution. We denote the  $k\Delta\omega$  component of the Fourier transform of observed seismograms as

$$\tilde{\mathbf{u}}^{\text{obs}}(k\Delta\omega) = [\tilde{u}_1^{\text{obs}}(k\Delta\omega), \tilde{u}_2^{\text{obs}}(k\Delta\omega), \dots, \tilde{u}_{N_c}^{\text{obs}}(k\Delta\omega)]^T. \quad (92)$$

The least-squares solution in the frequency domain for the  $k\Delta\omega$  component is then given by

$$\tilde{\mathbf{m}}^{\text{est}}(k\Delta\omega) = [\tilde{\mathbf{F}}^H(k\Delta\omega)\tilde{\mathbf{F}}(k\Delta\omega)]^{-1} \cdot \tilde{\mathbf{F}}^H(k\Delta\omega)\tilde{\mathbf{u}}^{\text{obs}}(k\Delta\omega), \quad (93)$$

where  $H$  denotes the adjoint (Hermitian conjugate). We perform the inverse Fourier transform of  $\tilde{\mathbf{m}}^{\text{est}}(k\Delta\omega)$  ( $k = 0, \dots, N_t/2$ ) to obtain the solution in the time domain.

The use of appropriate Green's functions is critically important to obtain the correct solution  $\mathbf{m}^{\text{est}}$  in either the time or frequency domains. If the source is located in a medium that can be approximated by a homogeneous or layered structure with a flat surface, Green's functions can be calculated by using propagator matrices e.g., [63] and the discrete wavenumber method e.g., [16,17,20]. However, this situation is not common in volcanic regions, and we need to take into account the steep topographies and heterogeneous structures of volcanoes. The boundary integral equation method e.g., [18] and boundary element method e.g., [62] can be used to quantify the effect of three-dimensional topography in a homogeneous or layered structure. To treat both topography and structural heterogeneity simultaneously, the finite-difference method e.g., [106,109] and the discrete lattice method [104] are suitable. Once Green's functions (and their spatial derivatives) are calculated, we can obtain the least-squares solution  $\mathbf{m}^{\text{est}}$  through Eq. (78) or (93). This solution is, however, obtained for a particular source point and a grid search in space is required to find the best-fit source location.

An example of waveform inversion is provided in Figs. 11 and 12. The source mechanism of VLP signals observed by a dense broadband seismic network at Stromboli volcano, Italy, was estimated by using the waveform inversion method in the time domain [32]. In the inversion, VLP waveforms from 18 stations (Fig. 11) were used, and six moment tensor and three single force components for a point source were assumed. Green's functions were calculated by the finite-difference method [106] using the topography of the volcano. The inversion result (Fig. 12)

points to volumetric changes accompanying a dominantly vertical single force at the source of the VLP signals. The mechanism is interpreted as the movement of a magma column in response to the piston-like rise of a slug of gas in an inclined crack-like conduit of Stromboli volcano [32].

The waveform inversion approach discussed above might be successful if we have many (more than 10) stations covering the entire edifice of a volcano. However, such dense seismic networks exist at only a limited number of volcanoes. Many volcanoes are monitored by networks of just a few seismic stations. It is also possible that signals would be detected by only a few stations close to the source even in a dense seismic network. Nakano and Kumagai [92] proposed a practical approach for quantifying the source of volcano-seismic signals observed by a small number of seismic stations. In this approach, possible source geometries such as a crack and pipe, are assumed as a priori information in waveform inversion. This assumption reduces the number of free parameters and enables us to estimate the source mechanism and location with waveform data from 2 to 3 three-component seismic stations. Their approach is summarized as follows. The moment tensors for a crack and pipe are given in Eqs. (30) and (34), respectively. If we assume a value for  $\lambda/\mu$ , free parameters in the moment tensors are the source-time function,  $\theta$ , and  $\phi$ . We can determine the source-time function by the waveform inversion discussed above, in which a grid search with respect to  $\theta$  and  $\phi$  is conducted to find the best-fit angles at a fixed location. A grid search in space is also conducted to find the combination of the best-fit angles and source location, and their residuals are compared to adopt the best model. The applicability of this simple approach has been demonstrated by synthetic tests and observed seismograms [92].

## Spectral Analysis

Volcano-seismic signals often show harmonic oscillatory signatures, which are interpreted as oscillations of fluid-filled resonators at the source of these signals. To determine the frequency characteristics of observed oscillations is essential to quantify the characteristic properties of the resonator systems. The discrete Fourier transform (DFT) has traditionally been used for this purpose. In DFT, the discrete time series  $u(k\Delta t)$  ( $k = 0, \dots, N_t - 1$ ) is transformed into the discrete frequency series

$$\tilde{u}(l\Delta\omega) = \Delta t \sum_{k=0}^{N_t-1} u(k\Delta t) e^{2\pi i l k / N_t} \quad (l = 0, \dots, N_t-1), \quad (94)$$

Volcano Seismic Signals, Source Quantification of, Figure 11

**a** Locations of broadband seismic stations at Stromboli Volcano, Italy. **b** Observed VLP velocity waveforms (*thick lines*) bandpassed between 2 and 20 s and the best-fit synthetic seismograms (*thin lines*) obtained from waveform inversion assuming six moment tensor and three single force components for the source mechanism [32]

Volcano Seismic Signals, Source Quantification of, Figure 12  
 Source-time functions of six moment tensor and three single force components estimated by waveform inversion for the VLP signals shown in Fig. 11b [32]

where  $\Delta\omega = 2\pi/(N_t\Delta t)$  and  $i = \sqrt{-1}$ . DFT is the decomposition of time series into a linear combination of the orthogonal basis functions  $e^{2\pi i k/N_t}$  in the frequency domain. Because of the stationary nature of the basis functions, DFT is especially useful to analyze stationary periodic signals. However, volcano-seismic signals often show decaying harmonic oscillations. These may be viewed as the impulsive response of a resonator system, which inherently contains dissipation mechanisms. A decaying harmonic oscillation can be represented by the complex frequency, which cannot be directly estimated by DFT based on the real frequency. The complex frequencies can be determined by solving an inverse problem for parameters in an appropriate model of a given time series. The Sompi method [75] is one such approach that is based on an autoregressive (AR) model of a linear dynamic system. This method has been successfully used to determine the complex frequencies of decaying harmonic oscillations in LP and VLP events. We follow the theory of Sompi presented by Kumazawa et al. [75] and Hori et al. [50].

Let us consider the equation of motion for a linear dynamic system consisting of a block and spring:

$$b \frac{d^2}{dt^2}x(t) + v \frac{d}{dt}x(t) + \kappa x(t) = 0, \tag{95}$$

where  $b$  is the mass of a block,  $\kappa$  is the spring constant, and  $v(dx(t)/dt)$  represents a dissipation term caused by friction, which is proportional to velocity. We set  $x(t) = e^{i\omega t}$  in Eq. (95), which is an eigenfunction of this system. We

then obtain

$$b(i\omega)^2 + v(i\omega) + \kappa = 0. \tag{96}$$

This is the characteristic equation of the system. If we consider oscillation solutions ( $v^2 - 4bk < 0$ ), Eq. (96) has two characteristic solutions:

$$i\omega_1 = \frac{-v + i\sqrt{4bk - v^2}}{2b}, \quad i\omega_2 = i\omega_1^*, \tag{97}$$

where  $*$  denotes the complex conjugate. If we set  $\omega = 2\pi(f - ig)$ , we obtain

$$f_1 = -f_2 = \frac{1}{2\pi} \sqrt{\frac{\kappa}{b} - \frac{v^2}{4b^2}}, \tag{98}$$

$$g_1 = g_2 = -\frac{1}{2\pi} \frac{v}{2b}. \tag{99}$$

Let us consider the following difference equation:

$$\sum_{j=0}^2 a(j)x((k-j)\Delta t) = 0 \tag{100}$$

or

$$a(0)x(k\Delta t) + a(1)x(k\Delta t - \Delta t) + a(2)x(k\Delta t - 2\Delta t) = 0. \tag{101}$$

If we set  $x(k\Delta t) = z^k$ , where  $z = e^{i\omega\Delta t}$ , Eq. (100) is given as

$$a(0)z^k + a(1)z^{k-1} + a(2)z^{k-2} = 0 \tag{102}$$

or, equivalently,

$$a(0)z^2 + a(1)z + a(2) = 0. \quad (103)$$

Equation (103) is the characteristic equation of the difference equation. If we consider oscillation solutions ( $a^2(1) - 4a(0)a(2) < 0$ ), Eq. (103) has the following two characteristic solutions:

$$z_1 = \frac{-a(1) + i\sqrt{4a(0)a(2) - a^2(1)}}{2a(0)}, \quad z_2 = z_1^*. \quad (104)$$

These two solutions constitute complex conjugate pairs. By setting  $\omega = 2\pi(f - ig)$ , we obtain

$$f_1 = -f_2 = \frac{1}{2\pi\Delta t} \tan^{-1} \left( -\sqrt{\frac{4a(0)a(2)}{a^2(1)} - 1} \right), \quad (105)$$

$$g_1 = g_2 = \frac{1}{2\pi\Delta t} \ln \sqrt{\frac{a(2)}{a(0)}}. \quad (106)$$

These solutions are equivalent to the solutions of the linear dynamic system given in Eqs. (98) and (99). Therefore, Eq. (100) is a difference form of the equation of motion (95).

We further consider a dynamic system consisting of two block-spring subsystems, which are coupled to each other. The equations of motion for this system are written as

$$M_1 \frac{d^2}{dt^2} x_1(t) + L_1 \frac{d}{dt} x_1(t) + K_1 x_1(t) = C(x_2 - x_1), \quad (107)$$

$$M_2 \frac{d^2}{dt^2} x_2(t) + L_2 \frac{d}{dt} x_2(t) + K_2 x_2(t) = C(x_1 - x_2), \quad (108)$$

where  $M_i$ ,  $L_i$ , and  $K_i$  are the mass, dissipation coefficient, and spring constant of the  $i$ th block and  $C$  is the spring constant between the blocks. The set of the equations of motion (107) and (108) can be equivalently given in the following form:

$$\begin{pmatrix} M_1 \frac{d^2}{dt^2} + L_1 \frac{d}{dt} + K_1 + C & -C \\ -C & M_2 \frac{d^2}{dt^2} + L_2 \frac{d}{dt} + K_2 + C \end{pmatrix} \cdot \begin{pmatrix} x_1(t) \\ x_2(t) \end{pmatrix} = 0. \quad (109)$$

These equations have non-trivial solutions of  $x_i(t)$  if, and only if,

$$\det \begin{vmatrix} M_1 \frac{d^2}{dt^2} + L_1 \frac{d}{dt} + K_1 + C & -C \\ -C & M_2 \frac{d^2}{dt^2} + L_2 \frac{d}{dt} + K_2 + C \end{vmatrix} = 0. \quad (110)$$

This leads to the following 4th-order differential equation:

$$\left[ \left( M_1 \frac{d^2}{dt^2} + L_1 \frac{d}{dt} + K_1 + C \right) \cdot \left( M_2 \frac{d^2}{dt^2} + L_2 \frac{d}{dt} + K_2 + C \right) - C^2 \right] x_i(t) = 0, \quad (111)$$

where  $i = 1, 2$ . Each 4th-order differential equation has four complex frequencies, of which two are complex conjugates. Therefore, each block has two independent complex frequencies in this dynamic system. Similarly, a dynamic system consisting of  $m$  block-spring subsystems, which are all connected to each other, can be described by the following  $2m$ -order differential equation:

$$\sum_{j=0}^{2m} b_j \frac{d^j}{dt^j} x_i(t) = 0 \quad (i = 1, 2, \dots, m), \quad (112)$$

where  $b_j$  denotes the coefficients determined by the characteristic properties of the system. Each block has  $m$  independent complex frequencies in this case. A difference form of Eq. (112) is

$$\sum_{j=0}^{2m} a(j) x_i(k\Delta t - j\Delta t) = 0, \quad (113)$$

which is a homogeneous  $2m$ -order AR equation. Although we have considered block-spring systems as an example, Eq. (112) is a general equation to describe the free oscillations of any linear systems. We use its difference form, Eq. (113), as the basic equation to determine the characteristic complex frequencies of linear systems from time series records.

Hereafter, I set  $\Delta t = 1$  to simplify the following notations. We assume that observed discrete time series  $u(k)$  consists of signal  $x(k)$  and white noise  $e(k)$ :

$$u(k) = x(k) + e(k) \quad (k = 0, 1, \dots, N_t - 1), \quad (114)$$

and  $x(k)$  satisfies the following homogeneous AR equation:

$$\sum_{j=0}^{2m} a(j) x(k - j) = 0. \quad (115)$$

To determine the  $2m + 1$  AR coefficients, we minimize the residual  $R$ :

$$R = \frac{1}{N_t - 2m} \sum_{k=2m}^{N_t-1} \left[ \sum_{j=0}^{2m} a(j) u(k - j) \right]^2. \quad (116)$$

Since Eq. (115) is homogeneous, we cannot determine absolute values of the AR coefficients. To avoid the trivial solution  $a(j) = 0$  ( $j = 0, 1, \dots, 2m$ ), we impose the condition

$$\sum_{j=0}^{2m} a^2(j) = 1. \tag{117}$$

To minimize the residual  $R$  under the condition of Eq. (117) is a conditional minimization problem. This problem can be solved by minimizing the residual  $R'$ :

$$R' = R - \beta \left( \sum_{j=0}^{2m} a^2(j) - 1 \right), \tag{118}$$

where  $\beta$  is a constant. Consequently, we solve the following equation:

$$\frac{\partial}{\partial a(l)} R' = 0 \quad (l = 0, 1, \dots, 2m). \tag{119}$$

This equation leads to an eigenvalue problem

$$\mathbf{P}\mathbf{a} = \beta\mathbf{a}, \tag{120}$$

where  $\mathbf{a} = (a(0), a(1), \dots, a(2m))^T$  and  $\mathbf{P}$  is a non-Toeplitz matrix given by

$$\mathbf{P} = \frac{1}{N_t - 2m} \begin{bmatrix} \sum_{n=2m}^{N_t-1} u(n)u(n) & \cdots & \sum_{n=2m}^{N_t-1} u(n-2m)u(n) \\ \vdots & \ddots & \vdots \\ \sum_{n=2m}^{N_t-1} u(n)u(n-2m) & \cdots & \sum_{n=2m}^{N_t-1} u(n-2m)u(n-2m) \end{bmatrix}. \tag{121}$$

By solving the eigenvalue problem of Eq. (120) we obtain  $2m + 1$  eigenvalues  $\beta^{(r)}$  ( $r = 1, 2, \dots, 2m + 1$ ) and corresponding eigenvectors  $\mathbf{a}^{(r)}$  ( $r = 1, 2, \dots, 2m + 1$ ). Note that the residual  $R$  in Eq. (116) is given as

$$R = \mathbf{a}^T \mathbf{P}\mathbf{a} = \mathbf{a}^T \beta\mathbf{a} = \beta. \tag{122}$$

Therefore, each eigenvector gives a local minimum of the residual  $R$ . We therefore adopt the eigenvector corresponding to the minimum eigenvalue, which minimizes the residual  $R$ . Hereafter,  $\mathbf{a}$  denotes the eigenvector corresponding to the minimum eigenvalue.

The next step is to determine the complex frequencies from the eigenvector  $\mathbf{a}$ . The characteristic equation of the  $2m$ -order homogeneous AR equation is given as

$$\sum_{j=0}^{2m} a(j)z^{-j} = 0. \tag{123}$$

This equation is the  $2m$ -degree algebraic equation for  $z^{-1}$ , and has  $2m$  complex solutions, which can be solved by a numerical procedure. As mentioned before, a complex solution is always accompanied by its complex conjugate, and therefore there are  $m$  independent solutions  $z_l$  ( $l = 1, 2, \dots, m$ ) in Eq. (123). These solutions are related to the complex frequencies ( $f_l - ig_l$ ) as

$$z_l = e^{2\pi i(f_l - ig_l)} \tag{124}$$

or

$$f_l - ig_l = \ln z_l / (2\pi i). \tag{125}$$

The  $Q$  factor is defined through the complex frequencies as

$$Q_l = f_l / (-2g_l). \tag{126}$$

The final step is to determine the amplitudes of the solutions  $z_l$ . If we set a conjugate pair as  $z_l = z_{m+l}^*$ , the general solution of Eq. (123) is given as

$$\begin{aligned} x(k) &= \sum_{l=1}^m (\alpha_l z_l^k + \alpha_{m+l} z_{m+l}^k) \\ &= \sum_{l=1}^m (\alpha_l z_l^k + (\alpha_l z_l^k)^*). \end{aligned} \tag{127}$$

Here  $\alpha_l$  is the complex amplitude given as

$$\alpha_l = r_l e^{i\phi_l}, \tag{128}$$

where  $r_l$  and  $\phi_l$  are the real amplitude and phase, respectively. This is equivalently written as

$$\alpha_l = \alpha_l^r + i\alpha_l^i, \tag{129}$$

where  $\alpha_l^r$  and  $\alpha_l^i$  are the real and imaginary parts of  $\alpha_l$ , respectively. Then, the general solution of Eq. (127) can be rewritten

$$x(k) = \sum_{l=1}^m (2\alpha_l^r C_l(k) - 2\alpha_l^i S_l(k)), \tag{130}$$

where  $C_l(k) = e^{2\pi g_l k} \cos(2\pi f_l k)$  and  $S_l(k) = e^{2\pi g_l k} \sin(2\pi f_l k)$ . The observed time series thus satisfies the following equation

$$u(k) - \sum_{l=1}^m (2\alpha_l^r C_l(k) - 2\alpha_l^i S_l(k)) = e(k) \tag{131}$$

$(k = 0, 1, \dots, N_t - 1)$

or, in matrix form

$$\mathbf{u} - \mathbf{A}\boldsymbol{\alpha} = \mathbf{e}, \tag{132}$$

where

$$\mathbf{u} = (u(0), u(1), \dots, u(N_t - 1))^T, \tag{133}$$

$$\boldsymbol{\alpha} = (2\alpha_1^r, \dots, 2\alpha_m^r, 2\alpha_1^i, \dots, 2\alpha_m^i)^T, \tag{134}$$

$$\mathbf{e} = (e(0), e(1), \dots, e(N_t - 1))^T, \tag{135}$$

and

$$\mathbf{A} = \begin{bmatrix} C_1(0) & \dots & C_m(0) \\ \vdots & & \vdots \\ C_1(N_t - 1) & \dots & C_m(N_t - 1) \\ & -S_1(0) & \dots & -S_m(0) \\ & \vdots & & \vdots \\ & -S_1(N_t - 1) & \dots & -S_m(N_t - 1) \end{bmatrix}. \tag{136}$$

We estimate  $\boldsymbol{\alpha}$  by minimizing the residual  $R_a$  as follows:

$$R_a = (\mathbf{u} - \mathbf{A}\boldsymbol{\alpha})^T(\mathbf{u} - \mathbf{A}\boldsymbol{\alpha}). \tag{137}$$

This is an ordinary least-squares problem, and the solution is given as

$$\boldsymbol{\alpha} = [\mathbf{A}^T\mathbf{A}]^{-1}\mathbf{A}^T\mathbf{u}. \tag{138}$$

The real amplitudes  $r_l$  and phases  $\phi_l$  at  $k = 0$  are determined from estimated  $\boldsymbol{\alpha}$  as

$$r_l = \sqrt{(\alpha_l^r)^2 + (\alpha_l^i)^2} \quad (l = 1, \dots, m), \tag{139}$$

$$\phi_l = \tan^{-1}(\alpha_l^i/\alpha_l^r) \quad (l = 1, \dots, m). \tag{140}$$

An example of the Sompi analysis of a VLP waveform (Fig. 13a) is shown in Fig. 14. The VLP waveform in Fig. 13a shows decaying harmonic oscillations, which are interpreted as the resonances of a magmatic dike triggered by a time-localized excitation [65,72]. The amplitude spectrum of the VLP waveform based on DFT is shown in Fig. 13b, which indicates two dominant peaks. As such,

Volcano Seismic Signals, Source Quantification of, Figure 14  
 An example of the Sompi spectral analysis of the VLP waveform of Fig. 13a, in which Sompi was applied to the waveform after the time of the maximum amplitude indicated by the dashed line in Fig. 13a. **a** A frequency-growth rate diagram for estimated complex frequencies using trial AR orders between 4 and 60. Solid lines represent lines along which the Q factor is constant. We can identify two densely populated regions, which represent the signal, while other scattered points represent incoherent noise. **b** Amplitudes and **c** phases at the time of the maximum amplitude using the two complex frequencies determined at an AR order of 40

DFT provides frequency and amplitude information simultaneously. Q values may be determined by the bandwidths of these spectral peaks at halves their peak amplitudes. The estimated Q values, however, can be biased, because the whole waveform including the tail of decaying oscillations as well as the onset of growing oscillations is

used in this approach. A box-car window can be applied to extract the decaying oscillations, but this distorts the spectrum and may lead to biased estimations of Q values.

In Sompi, on the other hand, we delete the onset portion of the signal and use the decaying harmonic oscillations only, which satisfy the homogeneous assumption of the AR equation. Since the number of signals (oscillations) is not known a priori, we use trial AR orders and solve the eigenvalue problems for individual trial AR orders to determine the complex frequencies, which are plotted in a frequency-growth rate (f-g) diagram. Figure 14a is the f-g diagram of the complex frequencies determined from the VLP waveform by using trial AR orders between 4 and 60. Densely populated regions on the f-g diagram represent the signal for which the complex frequencies are stably determined for different AR orders, while scattered points represent incoherent noise. Sompi then determines the complex amplitudes  $re^{i\phi}$  by using the estimated complex frequencies. The optimum AR order and the number of signals may be determined by the two-parameter Akaike information criterion (AIC) [79] or the extended information criterion (EIC) [128]. Figure 14b and c plot the amplitudes  $r$  and phases  $\phi$ , respectively, at the beginning of the decaying harmonic oscillations and using the two complex frequencies determined at an AR order of 40.

Some remarks on the theory of the Sompi method may be required. Although Hori et al. [50] and Kumazawa et al. [75] stated that Sompi is a new spectral method. This may be incorrect, as suggested by Ulrych and Sacchi [128]. Let us consider again the AR Eq. (115), which is equivalently rewritten as

$$x(k) = \sum_{j=1}^{2m} a'(j)x(k-j), \tag{141}$$

where  $a'(j) = -a(j)/a(0)$ . From Eq. (114), we have

$$u(k) = x(k) + e(k) = \sum_{j=1}^{2m} a'(j)x(k-j) + e(k). \tag{142}$$

Substituting  $u(k-j) = x(k-j) + e(k-j)$  into Eq. (142) we obtain

$$u(k) = \sum_{j=1}^{2m} a'(j)u(k-j) + e(k) - \sum_{j=1}^{2m} a'(j)e(k-j). \tag{143}$$

This is the special autoregressive-moving average (ARMA) model discussed by Ulrych and Clayton [127], who showed that the AR coefficients in Eq. (143) can be determined by an eigenvalue problem that is essentially the

same as that given in Eq. (120). In this sense, Sompi is not a new method. However, the Sompi theory, which is based not only on mathematics or information theory but also on physical concepts, yielded a systematic approach to estimate the complex frequencies and complex amplitudes, which can be directly related to the characteristic properties of a linear dynamic system and the system excitation. This approach has been favorably used in analysis of LP and VLP events to estimate the complex frequencies and their temporal variations e. g., [38,65,66,70,72,78,85, 91,93].

**Fluid-Solid Interactions**

Understanding the physics of the fluid-solid interactions is crucial to interpreting source mechanisms and spectral characters of volcano-seismic signals. The pioneering study on the fluid-solid interaction was by Biot [14], who studied seismic waves in a fluid-filled borehole and showed the existence of a slow wave propagating along the borehole boundary. This is called the tube wave. Aki et al. [2] first studied a fluid-filled crack, although the motion of the fluid in the crack was not adequately treated in their study. Chouet [22,23,24] fully studied the fluid-filled crack and demonstrated the existence of a slow wave in the fluid-filled crack, which was called the crack wave. We first consider a fluid layer sandwiched between two homogeneous elastic half-spaces following Ferrazzini and Aki [39] to examine the physical properties of the crack wave. Then, we examine the resonance of a crack of finite size containing a fluid by using the approach proposed by Chouet [22]. For simplicity, we assume an inviscid fluid.

**Crack Wave**

Let us consider a compressible fluid layer of thickness  $d$ , which is sandwiched between two elastic half-spaces bounded at  $x_3 = -d/2$  and  $x_3 = d/2$  (Fig. 15). The equation of motion for the fluid is given by

$$\rho_f \frac{\partial^2 u_1^f}{\partial t^2} = -\frac{\partial p}{\partial x_1}, \tag{144}$$

$$\rho_f \frac{\partial^2 u_3^f}{\partial t^2} = -\frac{\partial p}{\partial x_3}. \tag{145}$$

Here,  $\rho_f$  is the fluid density,  $u_1^f$  and  $u_3^f$  are the  $x_1$  and  $x_3$  components of the displacement in the fluid, respectively, and  $p$  is the fluid pressure satisfying the following continuity equation:

$$p = -b \left( \frac{\partial u_1^f}{\partial x_1} + \frac{\partial u_3^f}{\partial x_3} \right), \tag{146}$$

Volcano Seismic Signals, Source Quantification of, Figure 15  
**A fluid layer of thickness  $d$  sandwiched between two elastic half-spaces bounded at  $x_3 = -d/2$  and  $x_3 = d/2$**

where  $b$  is the bulk modulus of the fluid. The equation of motion for the solid is

$$\rho_s \frac{\partial^2 u_1}{\partial t^2} = \frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{13}}{\partial x_3}, \tag{147}$$

$$\rho_s \frac{\partial^2 u_3}{\partial t^2} = \frac{\partial \sigma_{13}}{\partial x_1} + \frac{\partial \sigma_{33}}{\partial x_3}. \tag{148}$$

Here,  $\rho_s$  is the solid density,  $u_1$  and  $u_3$  are the  $x_1$  and  $x_3$  components of the displacement in the solid, respectively, and  $\sigma_{11}$ ,  $\sigma_{33}$ , and  $\sigma_{13}$  are the components of stress:

$$\sigma_{11} = \lambda \left( \frac{\partial u_1}{\partial x_1} + \frac{\partial u_3}{\partial x_3} \right) + 2\mu \left( \frac{\partial u_1}{\partial x_1} \right), \tag{149}$$

$$\sigma_{33} = \lambda \left( \frac{\partial u_1}{\partial x_1} + \frac{\partial u_3}{\partial x_3} \right) + 2\mu \left( \frac{\partial u_3}{\partial x_3} \right), \tag{150}$$

$$\sigma_{13} = \mu \left( \frac{\partial u_1}{\partial x_3} + \frac{\partial u_3}{\partial x_1} \right). \tag{151}$$

The boundary conditions at the fluid-solid interfaces ( $x_3 = \pm d/2$ ) are

$$u_3 = u_3^f, \tag{152}$$

$$\sigma_{33} = -p, \tag{153}$$

$$\sigma_{13} = 0. \tag{154}$$

The first and second conditions mean that the normal displacement and stress across the interface are both continuous. The third condition states that the shear stress vanishes at the interface.

For waves propagating in the  $x_1$  direction, the displacements in the fluid may be written in the forms

$$u_1^f = r_1(x_3; k, \omega)e^{i(kx_1 - \omega t)}, \tag{155}$$

$$u_3^f = ir_2(x_3; k, \omega)e^{i(kx_1 - \omega t)}, \tag{156}$$

Substituting these equations into Eq. (146) we obtain

$$p = -ir_3e^{i(kx_1 - \omega t)}, \tag{157}$$

where  $k$  and  $\omega$  are the wavenumber and angular frequency, respectively

$$r_3 = b \left( kr_1 + \frac{dr_2}{dx_3} \right). \tag{158}$$

Substituting Eqs. (155) and (156) into Eqs. (144) and (145), respectively, and using Eq. (158) we have

$$\rho_f \omega^2 r_1 = kr_3, \tag{159}$$

$$-\rho_f \omega^2 r_2 = \frac{dr_3}{dx_3}. \tag{160}$$

Equations (158), (159), and (160) can be arranged in the following matrix form:

$$\begin{bmatrix} \frac{dr_2}{dx_3} \\ \frac{dr_3}{dx_3} \end{bmatrix} = \begin{bmatrix} 0 & \frac{1}{b} - \frac{k^2}{\rho_f \omega^2} \\ -\rho_f \omega^2 & 0 \end{bmatrix} \begin{bmatrix} r_2 \\ r_3 \end{bmatrix}. \tag{161}$$

For the solid, the displacement components of waves propagating in the  $x_1$  direction may be written as

$$u_1 = y_1(x_3; k, \omega)e^{i(kx_1 - \omega t)}, \tag{162}$$

$$u_3 = iy_2(x_3; k, \omega)e^{i(kx_1 - \omega t)}. \tag{163}$$

Substituting these equations into Eqs. (147), (148), (149), (150), and (151) we obtain the relationship:

$$\begin{bmatrix} \frac{dy_1}{dx_3} \\ \frac{dy_2}{dx_3} \\ \frac{dy_3}{dx_3} \\ \frac{dy_4}{dx_3} \end{bmatrix} = \begin{bmatrix} 0 & k & \frac{1}{\mu} & 0 \\ \frac{-k\lambda}{\lambda+2\mu} & 0 & 0 & \frac{1}{\lambda+2\mu} \\ k^2\zeta - \rho_s\omega^2 & 0 & 0 & \frac{k\lambda}{\lambda+2\mu} \\ 0 & -\rho_s\omega^2 - k & 0 & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ y_4 \end{bmatrix}, \tag{164}$$

where  $\zeta = \frac{4\mu(\lambda+\mu)}{\lambda+2\mu}$  and

$$y_3 = \mu \left( \frac{dy_1}{dx_3} - ky_2 \right), \tag{165}$$

$$y_4 = (\lambda + 2\mu) \frac{dy_2}{dx_3} + k\lambda y_1. \tag{166}$$

The boundary condition Eqs.(152), (153), and (154) can then be written as

$$y_2 = r_2, \tag{167}$$

$$y_4 = r_3, \tag{168}$$

$$y_3 = 0, \tag{169}$$

respectively, at  $x_3 = \pm d/2$ . The systems of Eqs. (161) and (164) are to be solved under the boundary conditions of Eqs. (167), (168), and (169), in which we seek solutions satisfying the following two additional conditions

$$r_2(-x_3) = -r_2(x_3) \quad -d/2 \leq x_3 \leq d/2, \tag{170}$$

$$y_1, y_2 \rightarrow 0 \quad x_3 \rightarrow \pm\infty. \tag{171}$$

The first condition means that motion in the fluid layer is symmetric with respect to  $x_3$ . There is the antisymmetric motion in the fluid layer with respect to  $x_3$ . This motion is the same as that observed in a fluid layer overlying a solid half-space, such as ocean, and has been investigated by Biot [15] and Tolstoy [124]. This motion does not produce the slow wave, and I do not discuss it here.

The solution for the systems of Eqs. (161) and (164) under the conditions mentioned above can be determined by the following numerical procedure, which was proposed by Takeuchi and Saito [121]. Since we assume symmetric motion in the fluid layer, it is enough to consider the region  $x_3 \geq 0$ . We choose  $x_3 = h$ , where  $h$  is appropriately far from the fluid-solid interface to satisfy  $y_1 = y_2 = 0$ . At  $x_3 = h$ , we assume two independent initial values  $y_1 = y_2 = y_4 = 0, y_3 = 1$  and  $y_1 = y_2 = y_3 = 0, y_4 = 1$  and integrate the equation for the solid (164) with values of  $k$  and  $\omega$  by the Runge-Kutta method. Then, we have two independent solutions  $y_i^A(x_3; k, \omega)$  and  $y_i^B(x_3; k, \omega)$  ( $i = 1, 2, 3, 4$ ). Any solution of Eq. (164) may be expressed as a linear combination of the two solutions:

$$y_i(x_3; k, \omega) = Ay_i^A(x_3; k, \omega) + By_i^B(x_3; k, \omega) \quad (i = 1, 2, 3, 4), \tag{172}$$

where  $A$  and  $B$  are arbitrary constants of integration for the two solutions. At  $x_3 = 0$ , we assume initial values  $r_2 = 0$  and  $r_3 = 1$ , and integrate the equation for the fluid (161) with values of  $k$  and  $\omega$ . Then, we have a solution  $r_i^C(x_3; k, \omega)$  ( $i = 1, 2$ ), and any solution of Eq. (161) may be given as

$$r_i(x_3; k, \omega) = Cr_i^C(x_3; k, \omega) \quad (i = 2, 3), \tag{173}$$

where  $C$  is an arbitrary constant of integration. From the boundary conditions of Eqs. (167), (168), and (169), we have the following relationships at  $x_3 = d/2$ :

$$\begin{aligned} Ay_2^A(d/2; k, \omega) + By_2^B(d/2; k, \omega) - Cr_2^C(d/2; k, \omega) &= 0, \\ Ay_4^A(d/2; k, \omega) + By_4^B(d/2; k, \omega) - Cr_3^C(d/2; k, \omega) &= 0, \\ Ay_3^A(d/2; k, \omega) + By_3^B(d/2; k, \omega) &= 0. \end{aligned} \quad (174)$$

These equations have a nontrivial solution if, and only if,

$$\det \begin{vmatrix} y_2^A(d/2; k, \omega) & y_2^B(d/2; k, \omega) & -r_2^C(d/2; k, \omega) \\ y_4^A(d/2; k, \omega) & y_4^B(d/2; k, \omega) & -r_3^C(d/2; k, \omega) \\ y_3^A(d/2; k, \omega) & y_3^B(d/2; k, \omega) & 0 \end{vmatrix} = 0. \quad (175)$$

The dispersion relation of the fluid-solid coupled waves can be determined by searching for  $k$  and  $\omega$  that satisfy Eq. (175). From Eq. (174) we have

$$\frac{B}{A} = -\frac{y_3^A(d/2; k, \omega)}{y_3^B(d/2; k, \omega)}, \quad (176)$$

$$\frac{C}{A} = \frac{y_2^A(d/2; k, \omega)}{r_2^C(d/2; k, \omega)} - \frac{y_3^A(d/2; k, \omega)}{y_3^B(d/2; k, \omega)} \frac{y_2^B(d/2; k, \omega)}{r_2^C(d/2; k, \omega)}, \quad (177)$$

and the eigenfunctions are given as

$$y_i(x_3; k, \omega)/A = y_i^A(x_3; k, \omega) + (B/A)y_i^B(x_3; k, \omega) \quad (i = 1, 2, 3, 4), \quad (178)$$

$$r_i(x_3; k, \omega)/A = (C/A)r_i^C(x_3; k, \omega) \quad (i = 2, 3). \quad (179)$$

The dispersion relationship and eigenfunctions of the crack wave calculated by the above procedure are shown in Figs. 16 and 17, respectively. In this example, I used the following parameter values:  $\rho_s = 1.10\rho_f$ ,  $b = 0.06\mu$ , and  $\lambda = 2\mu$ , which mimic a dike containing basaltic magma with a gas-volume fraction of 15%. The dispersion relationship in Fig. 16 clearly indicates that the phase velocity of the fluid-solid coupled wave depends on the wavelength, in which the velocity decreases as the wavelength increases. This wave is called the crack wave. Figure 17 displays dimensionless normal displacements ( $y_2$  and  $r_2$ ) and normal stress and pressure ( $y_4$  and  $r_3$ ) as a function of dimensionless  $x_3$ . Figure 17 indicates that the normal displacement is symmetric with respect to  $x_3$ . This motion causes the deformation of the fluid-solid boundary. The deformation has the effect of lowering the phase velocity, which is examined below.

The phase velocities of the acoustic wave (dashed line) and crack wave (solid line). These are normalized by the fluid acoustic velocity, and plotted as a function of the wavelength normalized by the thickness of the fluid layer

### Fluid-Filled Crack Model

Chouet [22,23,24] studied the motion of a finite crack containing a fluid in an infinite elastic medium. Following Chouet [22], we consider a crack set in the plane  $x_3 = 0$ , which extends from  $-W/2$  to  $W/2$  along the  $x_1$  axis and from 0 to  $L$  in the  $x_2$  direction (Fig. 18). The thickness of the crack is  $d$ , which is much smaller than  $L$ . Chouet [22] used the equations of motion for the solid given as

$$\rho_s \frac{\partial v_i}{\partial t} = \frac{\partial \sigma_{ij}}{\partial x_j}, \quad (180)$$

with the stress-strain relationship

$$\frac{\partial \sigma_{ij}}{\partial t} = \lambda \frac{\partial v_k}{\partial x_k} \delta_{ij} + \mu \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right), \quad (181)$$

where  $v_j$  is particle velocity of the solid and  $i = 1, 2, 3$ . The equations of motion for the fluid are given as

$$\rho_f \frac{\partial^2 u_i^f}{\partial t^2} = -\frac{\partial p}{\partial x_i}, \quad (182)$$

with the equation of continuity

$$p = -b \frac{\partial u_k^f}{\partial x_k}. \quad (183)$$

The boundary conditions on the crack surface  $S_1$  are

$$u_3^f = u_3, \quad \sigma_{33} = -p, \quad \sigma_{13} = \sigma_{23} = 0, \quad (184)$$

Volcano Seismic Signals, Source Quantification of, Figure 17

Dimensionless normal displacements, normal stress, and pressure as a function of  $x_3$  normalized by the thickness of the fluid layer. *Thin solid lines* represent the boundaries between the fluid and solid, and *thick dashed and solid lines* represent the functions in the fluid and solid regions, respectively

Volcano Seismic Signals, Source Quantification of, Figure 18

Coordinates and geometry of a crack set in the plane  $x_3 = 0$ , which extends from  $-W/2$  to  $+W/2$  on the  $x_1$  axis and from  $0$  to  $L$  on the  $x_2$  axis

which are the continuity of normal displacement and stress and the vanishment of shear stress on  $S_1$ . Let us introduce  $u_d$ , which represents the normal displacement of the crack wall and is identical to  $u_3^f = u_3$  on  $S_1$ .

We integrate Eq. (183) with respect to  $x_3$  within the crack and divide it by  $d$ :

$$\begin{aligned} & \frac{1}{d} \int_{-d/2}^{d/2} p dx_3 \\ &= -b \frac{1}{d} \int_{-d/2}^{d/2} \left[ \frac{\partial u_1^f}{\partial x_1} + \frac{\partial u_2^f}{\partial x_2} + \frac{\partial u_3^f}{\partial x_3} \right] dx_3. \end{aligned} \quad (185)$$

If we define

$$P = \frac{1}{d} \int_{-d/2}^{d/2} p dx_3 \quad (186)$$

and

$$U_i^f = \frac{1}{d} \int_{-d/2}^{d/2} u_i^f dx_3 \quad (i = 1, 2), \quad (187)$$

Eq. (185) is written as

$$P = -b \left( \frac{\partial U_1^f}{\partial x_1} + \frac{\partial U_2^f}{\partial x_2} + \frac{1}{d} \int_{-d/2}^{d/2} \frac{\partial u_3^f}{\partial x_3} dx_3 \right). \quad (188)$$

Since  $u_3^f$  is symmetric with respect to  $x_3(u_3^f(-x_3) = -u_3^f(x_3))$ , we find that

$$\int_{-d/2}^{d/2} \frac{\partial u_3^f}{\partial x_3} dx_3 = \int_{-d/2}^{d/2} du_3^f = [u_3^f]_{-d/2}^{d/2} = 2u_3^f(d/2). \tag{189}$$

Note that  $u_3^f(d/2) = u_3(d/2) = u_d$  from the boundary condition of Eq. (184) and, therefore, we have

$$P = -b \left( \frac{\partial U_1^f}{\partial x_1} + \frac{\partial U_2^f}{\partial x_2} + \frac{2}{d} u_d \right). \tag{190}$$

From Eq. (182) we obtain

$$\rho_f \frac{\partial^2 U_1^f}{\partial t^2} = -\frac{\partial P}{\partial x_1}, \tag{191}$$

$$\rho_f \frac{\partial^2 U_2^f}{\partial t^2} = -\frac{\partial P}{\partial x_2}. \tag{192}$$

Using the fluid velocity, Eqs. (191), (192), and (190) can be equivalently written as

$$\rho_f \frac{\partial V_1^f}{\partial t} = -\frac{\partial P}{\partial x_1}, \tag{193}$$

$$\rho_f \frac{\partial V_2^f}{\partial t} = -\frac{\partial P}{\partial x_2}, \tag{194}$$

$$\frac{\partial P}{\partial t} = -b \left( \frac{\partial V_1^f}{\partial x_1} + \frac{\partial V_2^f}{\partial x_2} + \frac{2}{d} v_d \right), \tag{195}$$

where  $V_i^f = \partial U_i^f / \partial t$  ( $i = 1, 2$ ) and  $v_d$  is the normal velocity of the crack wall.

Thus, the three-dimensional equations of motion and continuity are reduced to two-dimensional equations with respect to  $V_1^f, V_2^f, P$ , and  $v_d$ . In this problem, the boundary conditions are

$$\sigma_{33} = -p, \quad \sigma_{13} = \sigma_{23} = 0, \quad \text{on } S_1, \tag{196}$$

$$u_3 = 0, \quad \sigma_{13} = \sigma_{23} = 0, \quad \text{on } S_2, \tag{197}$$

where  $S_1$  denotes the crack surface and  $S_2$  denotes the crack plane outside the crack. The latter condition expresses that the displacement in the solid is symmetric with respect to  $x_3$ . In addition to these boundary conditions, Chouet [22] assumed zero mass transfer in and out of the crack, which are as follows:

$$V_1^f = v_1 \quad \text{along } |x_1| = W/2, 0 \leq x_2 \leq L, \tag{198}$$

$$V_2^f = v_2 \quad \text{along } -W/2 \leq x_1 \leq W/2, x_2 = 0, x_2 = L. \tag{199}$$

The equations of motion and stress-strain relationship for the solid in the form of Eqs. (180) and (181) and the equations of motion and continuity for the fluid in the forms of Eqs. (193), (194) and (195) are solved under the boundary conditions of Eqs. (196), (197), (198), and (199). Chouet [22] solved this problem by using a finite-difference method, in which the following scaling was used:

$$\bar{x}_i = x_i/L, \tag{200}$$

$$\bar{t} = \alpha t/L, \tag{201}$$

$$\bar{\sigma}_{ij} = \sigma_{ij}/\sigma_0, \tag{202}$$

$$\bar{u}_i = u_i \mu / (L \sigma_0), \tag{203}$$

$$\bar{v}_i = v_i \mu / (\alpha \sigma_0), \tag{204}$$

where nondimensional variables are indicated by a bar,  $\sigma_0$  is an effective stress, and  $\alpha$  is the compressional wave velocity  $\alpha = \sqrt{(\lambda + 2\mu)/\rho_s}$ . Let us define the first-order difference operators in time and space as:

$$\Delta_t f(l; i, j, k) = f(l + 1; i, j, k) - f(l; i, j, k), \tag{205}$$

$$\Delta_{x1} f(l; i, j, k) = f(l; i + 1, j, k) - f(l; i, j, k), \tag{206}$$

$$\Delta_{x2} f(l; i, j, k) = f(l; i, j + 1, k) - f(l; i, j, k), \tag{207}$$

$$\Delta_{x3} f(l; i, j, k) = f(l; i, j, k + 1) - f(l; i, j, k), \tag{208}$$

where  $f(l; i, j, k)$  represents any function at time  $l\Delta t$  and position  $[i\Delta, j\Delta, k\Delta]$  or  $[i\Delta_a, j\Delta_a, k\Delta_a]$ . Here,  $\Delta t$  is the time increment and  $\Delta$  and  $\Delta_a$  are the grid spacings for the solid and fluid, respectively. A difference form of Eq. (195) is then obtained as

$$\frac{\Delta_t P}{\Delta t} = -b \left( \frac{\Delta_{x1} V_1^f}{\Delta_a} + \frac{\Delta_{x2} V_2^f}{\Delta_a} + \frac{2}{d} v_d \right) \tag{209}$$

or

$$\Delta_t P = -b H_a \left( \Delta_{x1} V_1^f + \Delta_{x2} V_2^f \right) - 2 \frac{b}{d} \Delta t v_d, \tag{210}$$

where  $H_a = \Delta t / \Delta_a$ . Using the scaling given by Eqs. (200) to (204), Eq. (210) can be further modified to a nondimensional form:

$$\Delta_t \bar{P} = - \left( \frac{b}{\mu} \right) \alpha H_a \left( \Delta_{x1} \bar{V}_1^f + \Delta_{x2} \bar{V}_2^f \right) - 2C \Delta \bar{t} \bar{v}_d, \tag{211}$$

where  $C = (b/\mu)(L/d)$  is called the crack stiffness [2]. In a similar manner, we obtain nondimensional difference forms of equations of motion for the fluid (193) and (194) as

$$\Delta_t \bar{V}_1^f = - \left( \frac{a}{\alpha} \right)^2 \left( \frac{\mu}{b} \right) \alpha H_a \Delta_{x1} \bar{P}, \tag{212}$$

$$\Delta_t \bar{v}_2^f = -\left(\frac{a}{\alpha}\right)^2 \left(\frac{\mu}{b}\right) \alpha H_a \Delta_{x2} \bar{P}, \quad (213)$$

where  $a = \sqrt{b/\rho_f}$  is the acoustic velocity of the fluid and the ratios  $\alpha/a$  and  $b/\mu$  are related to  $\rho_f$  and  $\rho_s$  through the relationship

$$\frac{\rho_f}{\rho_s} = \left(\frac{\mu}{\lambda + 2\mu}\right) \left(\frac{\alpha}{a}\right)^2 \left(\frac{b}{\mu}\right). \quad (214)$$

Nondimensional difference forms of the equations of motion and the stress-strain relationship for the solid (Eqs. (180) and (181)) are

$$\Delta_t \bar{v}_i = \frac{1}{2 + (\lambda/\mu)} \alpha H \Delta_{xi} \bar{\sigma}_{ij}, \quad (215)$$

$$\Delta_t \bar{\sigma}_{ij} = \alpha H \left[ \frac{\lambda}{\mu} \Delta_{xk} \bar{v}_k \delta_{ij} + (\Delta_{xi} \bar{v}_i + \Delta_{xj} \bar{v}_j) \right], \quad (216)$$

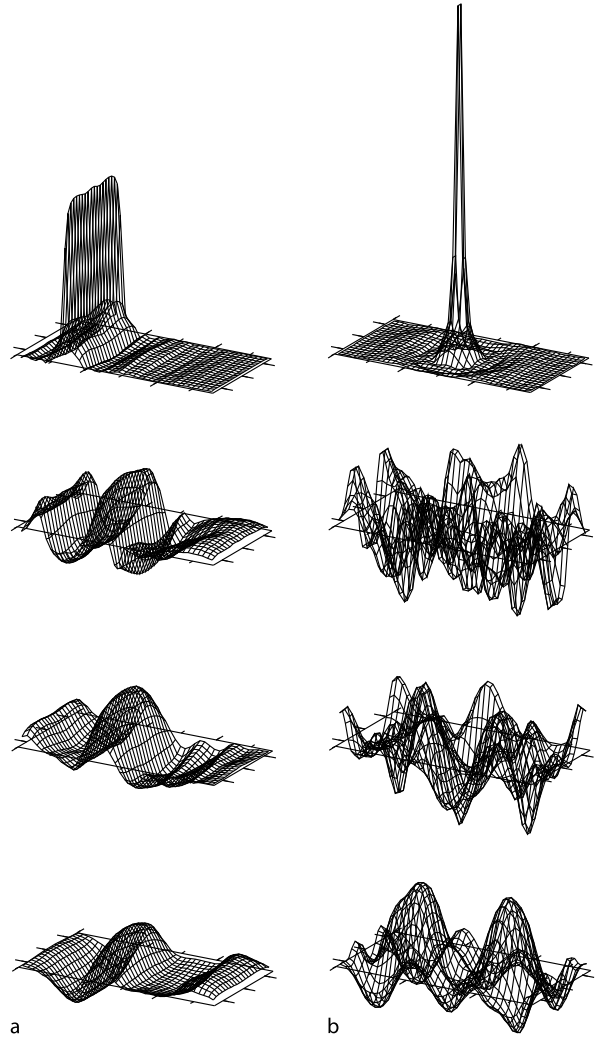

where  $H = \Delta t/\Delta$ . To satisfy the conditions for numerical stability in the solid and fluid, Chouet [22] used the following relationships:

$$H = \frac{\Delta t}{\Delta} = \frac{1}{4\alpha}, \quad (217)$$

$$H_a = \frac{\Delta t}{\Delta_a} = \frac{1}{2a}. \quad (218)$$

Applying a step increase in the fluid pressure over an area of the crack, the nondimensional difference equations for the solid and fluid are solved by a finite-difference method with a staggered grid scheme [129] to determine the normal velocity of the crack wall  $v_d$ . This source space-time function is used to synthesize the ground response to the fluid-filled crack. Note that Chouet [22] added an artificial dissipation term to the equations for particle velocities in the solid (Eq. (215)) and for fluid velocities (Eqs. (212) and (213)) to suppress spurious numerical oscillations associated with discretization in time and space in the finite difference calculations.

Snapshots of the normal velocity of the crack wall  $v_d$  for a fluid-filled crack excited by a step increase in the pressure applied over a strip extending over the entire width of the crack are shown in Fig. 19a. The results show that the crack oscillation is dominated by the longitudinal modes with wavelengths  $L$  and  $2L/5$ . Figure 19b shows snapshots of  $v_d$  for the crack with the excitation applied over a small area at the center of the crack. The crack oscillation shown in Fig. 19b displays more complex spatial patterns than those of Fig. 19a, in which both the longitudinal and transverse modes with wavelengths  $2L/3$  and  $2W/3$ , respectively, are dominantly excited. Chouet [22] showed that the dimensionless phase velocity  $v/a$  of the crack wave

Volcano Seismic Signals, Source Quantification of, Figure 19 **a** Snapshots of the normal velocity of the crack wall  $v_d$  for a fluid-filled crack excited by a step increase in the pressure applied over a strip extending over the entire width of the crack. **b** Snapshots of  $v_d$  for the crack with the excitation applied over a small area at the center of the crack (modified from Nakano et al. [95])

sustaining the crack resonance depends on the crack stiffness  $C$ . The  $Q$  factor of the crack resonance almost monotonically increases with the increasing  $\alpha/a$  [67,68].

The slow wave and its dependence on the crack stiffness may be understood by the following simple theoretical consideration. Using Eqs. (190), (191), and (192), we obtain the following relationship:

$$\frac{\partial^2}{\partial t^2} \left( P + \frac{2b}{d} u_d \right) = \left( \frac{b}{\rho_f} \right) \left( \frac{\partial^2 P}{\partial x_1^2} + \frac{\partial^2 P}{\partial x_2^2} \right). \quad (219)$$

Note that  $a = \sqrt{b/\rho_f}$  is the acoustic velocity of the fluid.

Let us consider a simple case for which  $u_d$  is proportional to  $P$ :

$$u_d = \epsilon P, \quad (220)$$

where  $\epsilon$  is a proportionality constant. Using the scaling given in Eqs. (202) and (203), the constant  $\epsilon$  may be written in a nondimensional form as

$$\epsilon = \bar{\epsilon} L / \mu, \quad (221)$$

where  $\bar{\epsilon}$  is a nondimensional proportionality constant. Using Eqs. (220) and (221), Eq. (219) can be written as

$$\left(1 + 2\bar{\epsilon} \frac{bL}{\mu d}\right) \frac{\partial^2 P}{\partial t^2} = \left(\frac{b}{\rho_f}\right) \left(\frac{\partial^2 P}{\partial x_1^2} + \frac{\partial^2 P}{\partial x_2^2}\right) \quad (222)$$

or, equivalently,

$$\frac{\partial^2 P}{\partial t^2} = \left(\frac{b_e}{\rho_f}\right) \left(\frac{\partial^2 P}{\partial x_1^2} + \frac{\partial^2 P}{\partial x_2^2}\right), \quad (223)$$

where  $b_e$  is an effective bulk modulus defined as

$$b_e = b / (1 + 2\bar{\epsilon} C). \quad (224)$$

Here,  $C = (b/\mu)(L/d)$  is the crack stiffness. Equation (223) is the two-dimensional wave equation with phase velocity  $a_e = \sqrt{b_e/\rho_f}$ . If no deformation of the crack wall occurs ( $\bar{\epsilon} = 0$ ), the phase velocity  $a_e$  is equal to the fluid acoustic velocity  $a$ . If the deformation of the crack wall occurs such that the wall moves inward to increase fluid pressure ( $\bar{\epsilon} < 0$ ),  $a_e$  becomes smaller than  $a$  through a reduction of the effective bulk modulus, which depends on the crack stiffness as given in Eq. (224).

The slow crack wave leads to more realistic estimates of the size and volume of a fluid-filled resonator as compared to a resonator with spherical geometry e. g. [35,40,41,115]. The slow wave has been used to interpret spectral characteristics of LP and VLP events observed at various active volcanoes [29,44,52,65,66,67,70,72,73,85,88,91,98,117,131].

### Future Directions

Recent volcano seismological studies have contributed greatly to achieving a better understanding of magmatic and hydrothermal systems. It is clear that the theoretical development of source models and analysis techniques has played an essential role in recent advances. The current studies in volcano seismology may be summarized as follows: (a) physical understanding and modeling of source dynamics of LP and VLP events [34,99,100,125], (b) development of a waveform inversion method of volcano-seis-

mic signals for an extended source to achieve a better understanding of the resonance characteristics and triggering mechanisms [95], (c) extension of the crack model to incorporate more realistic fluid acoustic properties [65,131], and (d) dense broadband seismic observation and the use of waveform inversion techniques to monitor active volcanoes e. g., [11,37,74]. Future studies building on these will contribute further to our ability to quantify the sources of volcano-seismic signals, which will help us in our efforts to predict eruptive behavior and thus mitigate volcanic hazards through improved seismic monitoring of magmatic and hydrothermal activity.

### Acknowledgment

I am deeply grateful to Masaru Nakano for numerous discussions on all the subjects presented in this manuscript. I thank Yasuko Takei for constructive comments on the phenomenological source representation. Comments from Pablo Palacios, Luca D'Auria, Takeshi Nishimura, and an anonymous reviewer helped improve the manuscript. I used the Generic Mapping Tools (GMT) [130] in the preparation of figures.

### Appendix A: Green's Functions

Here, I briefly explain the relationship between the displacement and Green's functions. To simplify the explanation, I use two-dimensional equations in an infinite medium. The extension of the equations into three-dimension is straightforward. Green's functions defined by Eq. (5) are explicitly written as

$$\rho \frac{\partial^2 G_{11}}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 G_{11}}{\partial x_1^2} + (\lambda + \mu) \frac{\partial^2 G_{21}}{\partial x_2 \partial x_1} + \mu \frac{\partial^2 G_{11}}{\partial x_2^2} + \delta(\mathbf{x} - \boldsymbol{\eta}) \delta(t - \tau), \quad (A1)$$

$$\rho \frac{\partial^2 G_{21}}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 G_{21}}{\partial x_2^2} + (\lambda + \mu) \frac{\partial^2 G_{11}}{\partial x_2 \partial x_1} + \mu \frac{\partial^2 G_{21}}{\partial x_1^2}, \quad (A2)$$

$$\rho \frac{\partial^2 G_{12}}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 G_{12}}{\partial x_1^2} + (\lambda + \mu) \frac{\partial^2 G_{22}}{\partial x_2 \partial x_1} + \mu \frac{\partial^2 G_{12}}{\partial x_2^2}, \quad (A3)$$

$$\rho \frac{\partial^2 G_{22}}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 G_{22}}{\partial x_2^2} + (\lambda + \mu) \frac{\partial^2 G_{12}}{\partial x_2 \partial x_1} + \mu \frac{\partial^2 G_{22}}{\partial x_1^2} + \delta(\mathbf{x} - \boldsymbol{\eta}) \delta(t - \tau). \quad (A4)$$

Note that  $(G_{11}, G_{21})$  represents the  $x_1$  and  $x_2$  components of the wavefield at  $(\mathbf{x}, t)$ , which is excited by the impulse in the  $x_1$  direction applied at  $\mathbf{x} = \boldsymbol{\eta}$  and  $t = \tau$ . Similarly,  $(G_{12}, G_{22})$  represents the  $x_1$  and  $x_2$  components of the wavefield excited by the impulse in the  $x_2$  direction at  $\mathbf{x} = \boldsymbol{\eta}$  and at  $t = \tau$ . Therefore,  $i$  and  $j$  in  $G_{ij}$  represent the component and direction of the impulse, respectively. To specify the relationship between the receiver and source, we use the notation  $G_{ij}(\mathbf{x}, t; \boldsymbol{\eta}, \tau)$ . We obtain  $G_{ij}(\mathbf{x}, t; \boldsymbol{\eta}, \tau) = G_{ij}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0)$ , since Green's functions are independent of the time of origin.

The displacement  $u_i(\mathbf{x}, t)$  satisfies Eq. (3), which is explicitly written as

$$\rho \frac{\partial^2 u_1}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 u_1}{\partial x_1^2} + (\lambda + \mu) \frac{\partial^2 u_2}{\partial x_1 \partial x_2} + \mu \frac{\partial^2 u_1}{\partial x_2^2} + f_1^S(\mathbf{x}, t), \quad (\text{A5})$$

$$\rho \frac{\partial^2 u_2}{\partial t^2} = (\lambda + 2\mu) \frac{\partial^2 u_2}{\partial x_2^2} + (\lambda + \mu) \frac{\partial^2 u_1}{\partial x_1 \partial x_2} + \mu \frac{\partial^2 u_2}{\partial x_1^2} + f_2^S(\mathbf{x}, t). \quad (\text{A6})$$

Equation (6) indicates that  $u_i$  is described by the following relationships:

$$u_1(\mathbf{x}, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [f_1^S(\boldsymbol{\eta}, \tau) G_{11}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0) + f_2^S(\boldsymbol{\eta}, \tau) G_{12}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0)] d\eta_1 d\eta_2 d\tau, \quad (\text{A7})$$

$$u_2(\mathbf{x}, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [f_1^S(\boldsymbol{\eta}, \tau) G_{21}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0) + f_2^S(\boldsymbol{\eta}, \tau) G_{22}(\mathbf{x}, t - \tau; \boldsymbol{\eta}, 0)] d\eta_1 d\eta_2 d\tau. \quad (\text{A8})$$

We can verify that the displacement given by Eqs. (A7) and (A8) satisfies Eqs. (A5) and (A6) in the following way. We can rewrite Eqs. (A5) and (A6) as

$$f_1^S(\mathbf{x}, t) = \rho \frac{\partial^2 u_1}{\partial t^2} - (\lambda + 2\mu) \frac{\partial^2 u_1}{\partial x_1^2} - (\lambda + \mu) \frac{\partial^2 u_2}{\partial x_1 \partial x_2} - \mu \frac{\partial^2 u_1}{\partial x_2^2}, \quad (\text{A9})$$

$$f_2^S(\mathbf{x}, t) = \rho \frac{\partial^2 u_2}{\partial t^2} - (\lambda + 2\mu) \frac{\partial^2 u_2}{\partial x_2^2} - (\lambda + \mu) \frac{\partial^2 u_1}{\partial x_1 \partial x_2} - \mu \frac{\partial^2 u_2}{\partial x_1^2}. \quad (\text{A10})$$

We denote the right-hand side of Eq. (A9) as  $L_1$ , which is derived from Eqs. (A7) and (A8) as

$$L_1 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ \rho \left( f_1^S \frac{\partial^2 G_{11}}{\partial t^2} + f_2^S \frac{\partial^2 G_{12}}{\partial t^2} \right) - (\lambda + 2\mu) \left( f_1^S \frac{\partial^2 G_{11}}{\partial x_1^2} + f_2^S \frac{\partial^2 G_{12}}{\partial x_1^2} \right) - (\lambda + \mu) \left( f_1^S \frac{\partial^2 G_{21}}{\partial x_1 \partial x_2} + f_2^S \frac{\partial^2 G_{22}}{\partial x_1 \partial x_2} \right) - \mu \left( f_1^S \frac{\partial^2 G_{11}}{\partial x_2^2} + f_2^S \frac{\partial^2 G_{12}}{\partial x_2^2} \right) \right] d\eta_1 d\eta_2 d\tau. \quad (\text{A11})$$

This equation can be modified as follows:

$$L_1 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[ f_1^S \left\{ \rho \frac{\partial^2 G_{11}}{\partial t^2} - (\lambda + 2\mu) \frac{\partial^2 G_{11}}{\partial x_1^2} - (\lambda + \mu) \frac{\partial^2 G_{21}}{\partial x_1 \partial x_2} - \mu \frac{\partial^2 G_{11}}{\partial x_2^2} \right\} + f_2^S \left\{ \rho \frac{\partial^2 G_{12}}{\partial t^2} - (\lambda + 2\mu) \frac{\partial^2 G_{12}}{\partial x_1^2} - (\lambda + \mu) \frac{\partial^2 G_{22}}{\partial x_1 \partial x_2} - \mu \frac{\partial^2 G_{12}}{\partial x_2^2} \right\} \right] d\eta_1 d\eta_2 d\tau. \quad (\text{A12})$$

From Eq. (A3), we find that the second integral of Eq. (A12) is zero. Therefore, Eq. (A12) from Eq. (A1) becomes

$$L_1 = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_1^S(\boldsymbol{\eta}, \tau) \delta(\mathbf{x} - \boldsymbol{\eta}) \delta(t - \tau) d\eta_1 d\eta_2 d\tau = f_1^S(\mathbf{x}, t). \quad (\text{A13})$$

Similarly, we can show that the right-hand side of Eq. (A10) is equivalent to  $f_2^S(\mathbf{x}, t)$ , and thus the displacement in the forms of Eqs. (A7) and (A8) satisfies the equation of motion (A5) and (A6).

## Appendix B: Moment Tensor for a Spherical Source

Let us consider the moment density tensors for three tensile cracks in the planes  $\xi_1 = 0$ ,  $\xi_2 = 0$ , and  $\xi_3 = 0$ . If we sum and average these three tensors and assume that  $[u_1] = [u_2] = [u_3] = D_s$ , we obtain the following moment density tensor:

$$\mathbf{m} = D_s \begin{pmatrix} \lambda + 2\mu/3 & 0 & 0 \\ 0 & \lambda + 2\mu/3 & 0 \\ 0 & 0 & \lambda + 2\mu/3 \end{pmatrix}. \quad (\text{B1})$$

This represents the moment density tensor for the isotropic expansion of a cubic element. Following Müller [89], we consider a spherical crack surface of radius  $R$

Volcano Seismic Signals, Source Quantification of, Figure A1  
**A spherical crack surface of radius  $R$  where a constant radial expansion  $D_s = (d_s + \Delta_s)$  occurs. Here, the inner wall of the crack moves inward by  $d_s$  and the outer wall moves outward by  $\Delta_s$  [89]**

where a constant radial expansion  $D_s = (d_s + \Delta_s)$  occurs (Fig. A1). Here, the inner wall of the crack moves inward by  $d_s$  and the outer wall moves outward by  $\Delta_s$ . The moment tensor of the spherical expansion may be obtained by integration of the moment density tensor (B1) over the surface  $R$ :

$$\mathbf{M} = \Delta V \begin{pmatrix} \lambda + 2\mu/3 & 0 & 0 \\ 0 & \lambda + 2\mu/3 & 0 \\ 0 & 0 & \lambda + 2\mu/3 \end{pmatrix}, \quad (\text{B2})$$

where  $\Delta V$  is the volume given as

$$\Delta V = 4\pi R^2 D_s = 4\pi R^2 (d_s + \Delta_s). \quad (\text{B3})$$

The volume  $4\pi R^2 d_s$  is caused by the inward motion, which compresses the sphere. The volume  $\Delta V_s = 4\pi R^2 \Delta_s$ , on the other hand, is caused by the outward motion, which excites seismic waves in the region outside the sphere.  $\Delta V_s$  can be determined by solving an elastostatic boundary-value problem in the following way. We assume an isotropic medium, and denote the regions inside and outside the sphere as regions 1 and 2, respectively. Since the motion is radial only, the equation of motion is given as e. g., [121]

$$\rho \frac{\partial^2 u}{\partial t^2} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \sigma_{rr}) - \frac{1}{r} (\sigma_{\theta\theta} + \sigma_{\phi\phi}) \quad (\text{B4})$$

and

$$\sigma_{rr} = (\lambda + 2\mu) \frac{\partial u}{\partial r} + \lambda \frac{2}{r} u, \quad (\text{B5})$$

$$\sigma_{\theta\theta} = \sigma_{\phi\phi} = \lambda \frac{\partial u}{\partial r} + (\lambda + \mu) \frac{2}{r} u, \quad (\text{B6})$$

where  $u$  is the radial displacement and  $\sigma_{rr}$ ,  $\sigma_{\theta\theta}$ , and  $\sigma_{\phi\phi}$  are the stress components in the spherical coordinate. Equations (B4) and (B5) apply to both regions 1 and 2. Substituting Eq. (B5) into Eq. (B4) and setting  $\rho(\partial^2 u_r / \partial t^2) = 0$ , we obtain the following static equilibrium equation:

$$\frac{\partial^2 u}{\partial r^2} + \frac{2}{r} \frac{\partial u}{\partial r} - \frac{2}{r^2} u = 0. \quad (\text{B7})$$

This equation has two solutions:  $u = ar$  and  $u = b/r^2$ , where  $a$  and  $b$  are constants. The former is the interior solution for region 1 ( $r \leq R$ ), and the latter is the exterior solution for region 2 ( $r \geq R$ ). I denote the interior and exterior solutions as  $u_i$  and  $u_e$ , respectively. The constants  $a$  and  $b$  are determined by the boundary conditions for the radial displacement and the continuity of the radial stress at  $r = R$ :

$$u_e(R) - u_i(R) = \frac{b}{R^2} - aR = D_s, \quad (\text{B8})$$

$$\sigma_{rr}^i(R) - \sigma_{rr}^e(R) = -\frac{4\mu}{R^3} b - (3\lambda + 2\mu)a = 0, \quad (\text{B9})$$

where  $\sigma_{rr}^i$  and  $\sigma_{rr}^e$  are the radial stresses in regions 1 and 2, respectively. Accordingly, we obtain

$$u_i(r) = -\frac{4\mu D_s}{3(\lambda + 2\mu)} \frac{r}{R} \quad (r \leq R), \quad (\text{B10})$$

$$u_e(r) = \frac{(\lambda + 2\mu/3) D_s}{\lambda + 2\mu} \frac{R^2}{r^2} \quad (r \geq R). \quad (\text{B11})$$

Then, we obtain

$$d_s = -u_i(R) = \frac{4\mu D_s}{3(\lambda + 2\mu)}, \quad (\text{B12})$$

$$\Delta_s = u_e(R) = \frac{(\lambda + 2\mu/3) D_s}{\lambda + 2\mu}. \quad (\text{B13})$$

Equation (B3) can be modified as

$$\Delta V = 4\pi R^2 \Delta_s (D_s / \Delta_s) = \frac{\lambda + 2\mu}{\lambda + 2\mu/3} \Delta V_s. \quad (\text{B14})$$

Finally, we obtain the moment tensor for the spherical expansion as

$$\mathbf{M} = (\lambda + 2\mu) \Delta V_s \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (\text{B15})$$

### Appendix C: Moment Tensor for a Cylindrical Source

We consider the moment density tensors for two tensile cracks in the planes  $\xi_1 = 0$  and  $\xi_2 = 0$ , where  $\xi_1$  and  $\xi_2$

**Volcano Seismic Signals, Source Quantification of, Figure A2**  
**A vertical cylinder of length  $L$  and radius  $R$ . The cylinder surface can be regarded as a cylindrical crack, where the radial expansion  $D_c = (d_c + \Delta_c)$  occurs. Here, the inner wall of the crack moves inward by  $d_c$  and the outer wall moves outward by  $\Delta_c$  [89]**

are two horizontal axes. If we sum and average these two tensors and assume that  $[u_1] = [u_2] = D_c$ , we obtain

$$m = D_c \begin{pmatrix} \lambda + \mu & 0 & 0 \\ 0 & \lambda + \mu & 0 \\ 0 & 0 & \lambda \end{pmatrix}. \tag{C1}$$

This represents the moment density tensor for the expansion of a cubic element in the two horizontal directions. Let us consider a vertical cylinder of length  $L$  and radius  $R$ . The cylinder surface at radius  $R$  can be regarded as a cylindrical crack, where the radial expansion  $D_c = (d_c + \Delta_c)$  occurs (Fig. A2). The moment tensor for the radial expansion of the cylinder may be obtained by integration of the moment density tensor (C1) over the surface  $R$ :

$$M = \Delta V \begin{pmatrix} \lambda + \mu & 0 & 0 \\ 0 & \lambda + \mu & 0 \\ 0 & 0 & \lambda \end{pmatrix}, \tag{C2}$$

where  $\Delta V$  is the volume given as

$$\Delta V = 2\pi R L D_c = 2\pi R L (d_c + \Delta_c). \tag{C3}$$

We obtain the static equilibrium equation for the radial expansion of the cylinder  $u$  as

$$\frac{\partial^2 u}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} - \frac{1}{r^2} u = 0. \tag{C4}$$

This equation has internal and external solutions, which are given as  $u = ar$  and  $u = b/r$ , respectively. The constants  $a$  and  $b$  are determined by the boundary conditions

$$u_e(R) - u_i(R) = \frac{b}{R} - aR = D_c, \tag{C5}$$

$$\sigma_{rr}^i(R) - \sigma_{rr}^e(R) = -\frac{2\mu}{R^2} b - 2(\lambda + \mu)a = 0, \tag{C6}$$

where superscripts  $i$  and  $e$  denote the interior and exterior solutions. We then obtain

$$d_c = -u_i(R) = \frac{\mu D_s}{(\lambda + 2\mu)}, \tag{C7}$$

$$\Delta_c = u_e(R) = \frac{(\lambda + \mu) D_c}{\lambda + 2\mu}, \tag{C8}$$

and

$$\Delta V = \frac{\lambda + 2\mu}{\lambda + \mu} \Delta V_c. \tag{C9}$$

The moment tensor for the vertical cylinder is therefore given as

$$M = \frac{\lambda + 2\mu}{\lambda + \mu} \Delta V_c \begin{pmatrix} \lambda + \mu & 0 & 0 \\ 0 & \lambda + \mu & 0 \\ 0 & 0 & \lambda \end{pmatrix}. \tag{C10}$$

Let us rotate the vertical cylinder with axis orientation angles  $\phi$  and  $\theta$  (Fig. 8b). This can be done in the following steps: (1) fix the cylinder and (2) rotate the  $\xi_1$  and  $\xi_2$  axes around the  $\xi_3$  axis through an angle  $-\phi$ , and (3) further rotate the  $\xi_1$  and  $\xi_3$  axes around the  $\xi_2$  axis through an angle  $-\theta$ . The rotation matrix  $R$  is given as

$$R = \begin{pmatrix} \cos \theta & 0 & -\sin \theta \\ 0 & 1 & 0 \\ \sin \theta & 0 & \cos \theta \end{pmatrix} \begin{pmatrix} \cos \phi & -\sin \phi & 0 \\ \sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{pmatrix} \tag{C11}$$

$$= \begin{pmatrix} \cos \theta \cos \phi & -\cos \theta \sin \phi & -\sin \theta \\ \sin \phi & \cos \phi & 0 \\ \sin \theta & -\sin \theta \sin \phi & \cos \theta \end{pmatrix}. \tag{C12}$$

Using the matrix  $R$ , we obtain the moment tensor for a cylinder with the axis orientation angles  $(\phi, \theta)$  as

$$M' = R^T M R, \tag{C13}$$

which leads to Eq. (34).

**Bubbly liquid** Liquid-gas mixture in which the gas phase is distributed as discrete bubbles dispersed in a continuous liquid phase.

**Choked flow** Flow condition where the transonic flow of a compressible fluid through a constriction becomes choked. As the fluid flows through a narrowing channel, it accelerates at a rate that depends on the ratio of channel inlet pressure to channel outlet pressure. At a critical pressure ratio, which is a function of the fractional change of cross-sectional area, the speed of the fluid accelerating through the nozzle-like constriction reaches a maximum value equal to its sound speed. This flow condition is termed choked flow.

**Crack wave** A dispersive wave generated by fluid-solid interaction in a fluid-filled crack embedded in an elastic solid. The crack-wave speed is always smaller than the acoustic speed of the fluid.

**Diffuse interface** Thin mixing layer constituting the interface between two immiscible fluids. Interface dynamics is governed by molecular forces and is described by the mixing energy of the two fluid components.

**Gas slug** A gas bubble whose diameter is approximately the diameter of the pipe in which the slug is flowing. In a slug ascending a vertical pipe, the nose of the bubble has a characteristic spherical cap and the gas in the rising bubble is separated from the pipe wall by a falling film of liquid.

**Long-period (LP) event** A seismic event originating under volcanoes with emergent onset of *P* waves, no distinct *S* waves, and a harmonic signature with periods in the range 0.2–2 s as compared to a tectonic earthquake

of the same magnitude. LP events are attributed to the involvement of fluid such as magma and/or water in the source process (see also VLP event).

**Magma** Molten rock containing variable amounts of dissolved gases (principally water vapor, carbon dioxide, and sulfur dioxide), crystals (principally silicates and oxides), and, occasionally, preexisting solid rock fragments.

**Moment tensor** A symmetric second-order tensor that completely characterizes an internal seismic point source. For an extended source, it represents a point-source approximation and can be quantified from an analysis of seismic waves whose wavelengths are much longer than the source dimensions.

**Nonlinear process** Process involving physical variables governed by nonlinear equations that reflect the fundamental micro-scale dynamics of the system. Nonlinear phenomena can arise from a number of different sources, including convective acceleration in fluid dynamics, constitutive relations, boundary conditions representing gas-liquid interfaces, nonlinear body forces, and geometric nonlinearities arising from large-scale deformation.

**Phase-field method** Method treating the interface between two immiscible fluids as a diffuse thin layer; also known as the diffuse interface method. In this approach, the physical and chemical properties of the interfacial layer are defined by a phase-field variable  $\phi$ , whose dynamics are expressed by the Cahn–Hilliard convection-diffusion equation. Use of the phase-field variable avoids the necessity of tracking the interface and yields the correct interfacial tension from the free energy stored in the mixing layer.

**Very-long-period (VLP) event** A seismic event originating under volcanoes with typical periods in the range 2–100 s. VLP events are attributed to the involvement of fluid such as magma and/or water in the source process. Together with LP events, VLP events represent a continuum of fluid oscillations, including acoustic and inertial effects resulting from perturbations in the flow of fluid through conduits.

**Volatile** A chemical compound that is dissolved in magma at high pressure and exsolves from the melt and appears as a low-density gas at low pressure. The most common volatiles in magma are water, carbon dioxide, and sulfur dioxide.

**Waveform inversion** Given an assumed model of the wave-propagation medium, a procedure for determining the source mechanism and source location of a seismic event based on matching observed waveforms with synthetics calculated with the model.

## Definition of the Subject

Magma transport is fundamentally episodic in character as a result of the inherent instability of magmatic systems at all time scales. This episodicity is reflected in seismic activity, which originates in dynamic interactions between gas, liquid and solid along magma transport paths involving complex geometries. The geometrical complexity plays a central role in controlling flow disturbances and also providing specific sites where pressure and momentum changes in the fluid are effectively coupled to the Earth.

Recent technological developments and improvements in the seismological instrumentation of volcanoes now allow the surface effects of subterranean volcanic processes to be imaged in unprecedented detail. Through detailed analyzes of the seismic wavefields radiated by volcanic activity, it has become possible for volcano seismologists to make direct measurements of the volcanic conduit response to flow processes, thus opening the way for detailed modeling of such processes.

However, unlike the description of seismic waves, which is based on the linear equations of elastodynamics, the description of the flow processes underlying the observed seismic source mechanisms is governed by the nonlinear equations of fluid dynamics. In the classic Navier–Stokes equations of fluid mechanics, the nonlinearity resides in the convective acceleration terms in the equations of conservation of momentum. In volcanic fluids, further complexity arises from the strong nonlinear dependence of magma rheology on temperature, pressure, and water and crystal content, and nonlinear characteristics of associated processes underlying the physico-chemical evolution of liquid-gas mixtures constituting magma. An example of nonlinearity in two-phase fluid mixtures are the changing boundary conditions associated with the internal surfaces separating the phases, a situation commonly encountered during the spinodal decomposition of binary fluids [61]. Spinodal decomposition occurs when a mixture of two species *A* and *B* of fluid forming a homogeneous mixture at high temperature undergoes spontaneous demixing following a temperature drop (quench) below some critical temperature. As the temperature drops below the critical temperature, the initially homogeneous mixture becomes locally unstable, and a period of interdiffusion is initiated, which leads to the formation of patches of *A*-rich and *B*-rich fluids separated by sharp interfaces. In the late stages of demixing following a deep quench, the interfacial thickness reaches a molecular scale and the interfacial tension approaches an equilibrium surface tension. As it approaches local equilibrium, the mixture continues to evolve to-

ward a minimization of energy by reducing its interfacial area, and stresses arising from changes in the local interfacial curvature drive fluid motion. A smooth evolution of the interfacial structure ensues, occasionally interrupted by local coalescence, breakup and reconnection, until final equilibrium is reached between the two bulk domains. Similar processes underlie the physics that governs the vesiculation, fragmentation, and collapse of bubble-rich suspensions to form separate melt and vapor in response to decreasing pressure along the ascent path of magma.

All of the above factors contribute to a diversity of oscillatory processes that intensifies as magma rheology becomes more complex; increasingly diverse behavior also characterizes hydrothermal fluids. Heat transfer to the hydrothermal system from magmatic gases streaming through networks of fractures pervading the rock matrix may induce boiling in ground water, resulting in the formation of steam bubbles and attendant bubble oscillations, thereby generating sustained tremor of hydrothermal origin.

Refined understanding of magma and hydrothermal transport dynamics therefore requires multidisciplinary research involving detailed field measurements, laboratory experiments, and numerical modeling. The comprehensive breadth of seismology must be used to understand and interpret the wide variety of seismic signals encountered in various volcanic processes. This effort must then be complemented by laboratory experiments and numerical modeling to better understand the complex flow dynamics at the origin of the source mechanisms imaged from seismic data. Such research is fundamental to monitoring and interpreting the subsurface migration of magma that often leads to eruptions, and thus enhances our ability to forecast hazardous volcanic activity.

## Introduction

Degassing is the main driving force behind most volcanic phenomena. The separation of vapor and melt phases leads to the formation of bubbles, the presence of which decreases magma density, enhances magma buoyancy and propels magma ascent [140]. Bubbles in magma also naturally increase magma compressibility, resulting in a low acoustic speed of the bubbly mixture compared to that of the liquid phase [28,36,37,56]. At shallow depths, the high compressibility of the bubbles may further contribute to the generation of pressure oscillations in bubble clouds [28,145]. Bubble coalescence and fragmentation can also contribute to pressure disturbances [85]. In hydrothermal fluids, the collapse of small vapor bub-

bles can be the source of pressure pulses and sustained tremor [70,72].

Bubble dynamics play a key role in the transport of magmatic and hydrothermal fluids, not only as sources of acoustic energy, but also in providing a sharp contrast in velocity between the fluid and encasing solid, which facilitates the entrapment of acoustic energy at the source. This aspect of the source often manifests itself in the form of long-lasting, long-period harmonic oscillations produced by sustained resonance at the source.

Other types of gaseous fluid mixtures also favor source resonance. For example, gases laden with solid particles, or gases mixed with liquid droplets, may produce velocity contrasts that are similar to, or stronger, than those associated with bubbly liquids. Indeed, dusty gases made of micron-sized particles, or misty gases made of micron-sized droplets, can sustain resonance at the source over durations that far exceed those achieved with bubbly fluids [77].

Large gas slugs bursting at the liquid surface can act as active sources of acoustic and seismic radiation [59, 118,136]. Gas slugs traversing discontinuities in conduit geometry can also cause transient liquid motions inducing pressure and momentum changes [60], which radiate elastic waves via their coupling to the conduit walls [32,35,109]. In magmas where a high fluid viscosity impedes flow, the diffusion of volatiles from a super-saturated melt may result in gradual pressurization of the melt and attendant deformation of the encasing rock matrix [33,34,104,124]. The fluid motions resulting from unsteady slug dynamics, large degassing bursts, and diffusion-dominated processes typically produce signals with characteristic periods longer than those commonly associated with acoustic resonance.

Oscillatory processes are thus ubiquitous during magma flow and are a natural expression of the release of thermo-chemical and gravitational energy from volcanic fluids. The radiated elastic energy reflects both active and passive processes at the source, and features a large variety of signals over a wide range of periods.

Seismic signals originating in the dynamics of magmatic and hydrothermal fluids typically include Long-Period (LP) events and tremor [27,28]. LP events resemble small tectonic earthquakes in duration but differ in their characteristic frequency range and harmonic signature. Tremor is characterized by a harmonic signal of sustained amplitude lasting from minutes to days, and sometimes for months or even longer. In many instances, LP events and tremor are found to have essentially the same temporal and spectral components, suggesting that a common source process, differing only in duration, underlies these

two types of events. Accordingly, LP events and tremor are often grouped under the common appellation LP seismicity. The periods in which LP seismicity is observed typically range from 0.2 to 2 seconds, and the characteristic oscillations of LP signals are commonly viewed as a result of acoustic resonance in a fluid-filled cavity. Slower processes involving inertial forces associated with unsteady mass transport may radiate seismic signals extending to periods much longer than 2 seconds. These types of signals commonly fall under the appellation of Very-Long-Period (VLP) seismicity. Collectively, LP and VLP seismicities provide a comprehensive view of mass transport dynamics under a volcano.

The present chapter offers a brief review of the state of the art in volcano seismology and addresses basic issues in the quantitative interpretation of processes operative in active volcanic systems. The chapter starts with an introduction of the seismic methodology used to quantify the source of volcano seismicity, with emphasis on sources originating in the dynamics of volcanic fluids. A review of some of the representative source mechanisms of LP and VLP signals and of their implications for volcanic processes follows in Sects. “Sources of Long-Period Seismicity” and “Source Processes of Very-Long-Period Signals”. A final section describes a mesoscale computational approach for simulating two-phase flows of complex magmatic fluids. This method, called the phase-field method, grew out of the original work of [19], and relies on an energy-based variational formalism to treat interfacial dynamics and complex rheology in a unified framework. The phase-field method has been successfully applied to the modeling of complex micro-structured two-phase fluids in the field of engineering materials and appears well adapted to the numerical simulation of nonlinear volcanic processes.

## Description of Seismic Sources in Volcanoes

A general kinematic description of seismic sources in volcanoes is commonly based on a moment-tensor and single-force representation of the source [3] (Fig. 1a). The seismic-moment tensor consists of nine force couples, with each corresponding to one set of opposing forces (dipoles or shear couples). This symmetric second-order tensor allows a description of any generally oriented discontinuity in the Earth in terms of equivalent body forces. For example, slip on a fault can be represented by an equivalent force system involving a superposition of two force couples of equal magnitudes – a double couple (Fig. 1b). Similarly, a tensile crack has an equivalent force system made of three vector dipoles, with dipole magnitudes with

Volcanoes, Non-linear Processes in, Figure 1

**a** The nine possible couples corresponding to the moment-tensor components describing the equivalent force system for a seismic source in the Earth. **b** Slip on a fault can be described by a superposition of two force couples, in which each force couple is represented by a pair of forces offset in the direction normal to the force. Sources involving slip on a fault thus have an equivalent force system in the form of a double couple composed of four forces. **c** A tensile crack has a representation in the form of three vector dipoles, in which each dipole consists of a pair of forces offset in the direction of the force

ratios  $1:1:(\lambda + 2\mu)/\lambda$ , in which  $\lambda$  and  $\mu$  are the Lamé coefficients of the rock matrix [28], and where the dominant dipole is oriented normal to the crack plane (Fig. 1c). Injection of fluid into the crack will cause the crack to expand and act as a seismic source. In general, magma movement between adjacent segments of conduit can be represented through a combination of volumetric sources of this type. Because mass-advection processes can also generate forces on the Earth, a complete description of volcanic sources commonly requires the consideration of single forces in addition to the volumetric source components expressed in the moment tensor. For example, a volcanic eruption can induce a force system that includes a contraction of the conduit/reservoir system in response to the ejection of fluid, and a reaction force from the eruption jet [64] (Fig. 2). Some volcanic processes can be described by a single-force mechanism only. An example is the single-force mechanism attributed to the massive landslide observed at the start of the 1980 eruption of Mount St. Helens [63,66]. A single-force source model was also proposed by Uhira et al. [134] to explain the mechanism of dome collapses at Unzen Volcano, Japan. In general terms, a single force can be generated by an exchange of linear momentum between the source and the rest of the Earth [129]. Thus, a single force on the Earth may result from an acceleration of the center of mass of the source in the direction opposite to the force, or deceleration of the center of mass of the source in the same direction as the force [129].

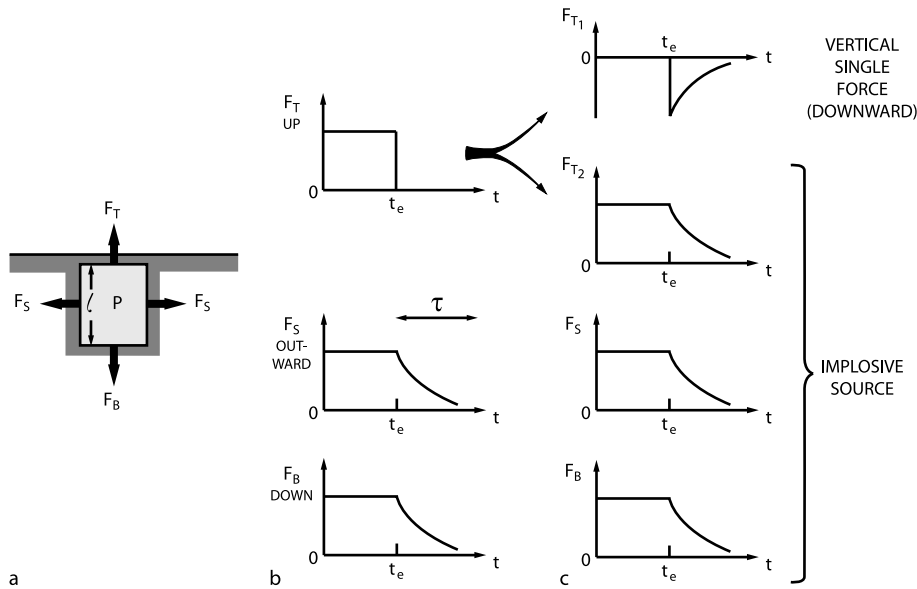

## Waveform Inversion

Waveform inversions solving for the amplitudes and time histories of the moment-tensor and single-force components of the source have become the primary tool to identify and understand the mechanisms of generation of LP and VLP signals recorded by broadband seismometers. When the wavelengths of observed seismic waves are much longer than the spatial extent of the source, the source may be approximated by a point source, and the force system represented by the moment-tensor and single-force components is localized at this point. The waveform inversion procedure requires a calculation of the impulse responses (Green's functions) of the medium to this force system for each receiver component. The displacement field generated by a seismic source is described by the representation theorem which, for a point source, may be written as e. g., Chouet, [28]

$$u_n(t) = F_p(t) * G_{np}(t) + M_{pq}(t) * G_{np,q}(t),$$

$$p, q = x, y, z, \quad (1)$$

where  $u_n(t)$  is the  $n$ -component of seismic displacement at a receiver at time  $t$ ,  $F_p(t)$  is the time history of the force applied in the  $p$ -direction,  $M_{pq}(t)$  is the time history of the  $pq$ -component of the moment tensor, and  $G_{np}(t)$  is the Green tensor which relates the  $n$ -component of displacement at the receiver position with the  $p$ -component of impulsive force at the source position. The notation,  $q$ , indicates spatial differentiation with respect to the

Volcanoes, Non-linear Processes in, Figure 2

Force system equivalent to a volcanic eruption (after [64]). **a** Pressurized cavity model for a volcanic eruption. A shallow vertically oriented cylindrical cavity initially sealed at the top by a lid contains a pressurized inviscid fluid which exerts an upward vertical force  $F_T$  on the lid, a horizontal outward force  $F_S$  on the sidewall, and a vertical downward force  $F_B$  on the bottom of the cylinder. **b** Time histories of forces acting on the top, side, and bottom cavity walls of the cavity. The eruption is simulated by the sudden removal of the lid at time  $t = t_e$ , at which point the force  $F_T$  vanishes instantaneously and the fluid pressure in the cylinder starts to decrease with a characteristic time constant  $\tau$  fixed by the mass flux of the eruption, i.e.,  $\tau \sim \ell/v$ , where  $\ell$  is the length of the cylinder and  $v$  is the mean fluid velocity inside the cylinder. Since the forces  $F_S$  and  $F_B$  are both proportional to pressure, they decrease with the same time constant  $\tau$ . **c** Decomposition of the force system to a downward single force and implosive source. The force  $F_T$  in **b** is decomposed into a vertical downward component  $F_{T1}$  and vertical upward component  $F_{T2}$  in such a way that  $F_{T2}$  has the same time history as  $F_S$  and  $F_B$ . As a result, the three forces  $F_{T2}$ ,  $F_S$ , and  $F_B$  form an implosive source so that the eruption mechanism is represented by the superposition of a downward vertical force (the reaction force of the volcanic jet) with this volumetric implosion

$q$ -coordinate and the symbol  $*$  denotes convolution. Summation over repeated indices is implied.

A common approach to the quantification of the seismic source mechanism relies on a discretized representation of the volcanic edifice based on a digital elevation model. Using this model, Green's functions are then calculated by the finite difference method [107]. Once the Green's functions are known, the nine independent mechanisms in Eq. (1) are retrieved through least-squares inversion expressing the standard linear problem  $\mathbf{d} = \mathbf{Gm}$  in this equation [32].

### Sources of Long-Period Seismicity

Long-Period (LP) seismicity, including individual LP events and tremor, is commonly observed in relation to magmatic and hydrothermal activities in volcanic areas and is recognized as a precursory phenomenon for eruptive activity (e. g., Chouet, [27]). The waveform of the LP event is characterized by simple decaying harmonic oscil-

lations except for a brief interval at the event onset (Fig. 3). This signature is commonly interpreted as oscillations of a fluid-filled resonator in response to a time-localized excitation. By the same token, tremor may be viewed as oscillations of the same resonator in response to a sustained excitation. LP events are particularly useful in the quantification of magmatic and hydrothermal processes because the properties of the resonator system at the source of this event can be inferred from the properties of the decaying oscillations in the tail of the seismogram. The damped oscillations in the LP coda are quantified by two parameters,  $T$ , and  $Q$ , where  $T$  is the period of the dominant mode of oscillation, and  $Q$  is the quality factor of the oscillatory system representing the combined effects of intrinsic and radiation losses.

Interpretations of the oscillating characteristics of LP sources have mostly relied on a model of fluid-driven crack [23,24,25]. This model, which has the most natural geometry that satisfies mass-transport conditions at depth beneath a volcano, is supported by results from

Volcanoes, Non-linear Processes in, Figure 3

Typical signatures of long-period events observed at Kusatsu-Shirane, Galeras, Kilauea, and Redoubt Volcanoes. The signatures are all characterized by a harmonic coda following a signal onset enriched in higher-frequencies

inversions of LP waveforms recorded at several volcanoes [80,82,97,137]. A simplified two-dimensional model of fluid-driven crack was originally proposed by Aki et al. [2]. Although this model considered both the driving excitation and geometry appropriate for transport, the fluid inside the crack was only treated as a passive cushion that did not support the acoustic propagation of the pressure disturbance caused by the motion of the crack wall. An extension of this model including active fluid participation was proposed by Chouet and Julian [22], who considered a simultaneous solution of the elastodynamics and fluid dynamics for a two-dimensional crack. This model was further extended to three dimensions by Chouet [23] and was extensively studied by Chouet [24,25].

Chouet's three-dimensional model consists of a single isolated rectangular crack embedded in an infinite elastic body and assumes zero mass transfer in and out of the crack (Fig. 4). Crack resonance is excited by a pressure transient applied symmetrically on both walls over a small patch of crack wall. In this model, the crack aperture is assumed to be much smaller than the seismic

Volcanoes, Non-linear Processes in, Figure 4

Geometry of the fluid-filled crack model of Chouet [23]. The crack has length  $L$ , width  $W$ , and aperture  $d$ , and contains a fluid with sound speed  $a$  and density  $\rho_f$ . The crack is embedded in an elastic solid with compressional wave velocity  $\alpha$  and density  $\rho_s$ . Excitation of the crack is provided by a pressure transient applied symmetrically on both walls over the small areas such as that indicated by the gray patch and dotted small square

wavelengths of interest and the motion of the fluid inside the crack is treated as two-dimensional in-plane motion. The fluid dynamics are represented by the conservation of mass and momentum for the two in-plane components of fluid velocity averaged over the crack aperture, and convective terms in the momentum equations are neglected assuming their contributions are negligibly small compared to the time derivatives of pressure and flow velocity. A solution of the coupled equations of fluid dynamics and elastodynamics is then obtained by using a finite-difference approach. As formulated, the model accounts for the radiation loss only; intrinsic losses due to dissipation mechanisms within the fluid are treated separately [77].

Figure 5 shows snapshots of the normal component of particle velocity on the crack wall obtained at four different times following the onset of crack resonance. In this particular example, the crack excitation is triggered by a step in pressure applied at a point located a quarter of the crack width from the left edge of the crack and a quarter of the crack length from the front edge of the crack. The first snapshot at the upper left shows the propagation of the elastic disturbance on the crack surface shortly after the onset of the pressure transient. The second snapshot at the lower left shows the motion of the crack wall following the first reflections from the front, left and right edges of the crack. The third snapshot at the upper right represents the wall motion immediately preceding the reflection

Volcanoes, Non-linear Processes in, Figure 5

Snapshots of the normal component of particle velocity on the surface of a fluid-filled crack excited by a step in pressure applied over a small patch of the crack wall. The snapshots (1–4) show the propagation of the disturbance on the crack wall at four different times in the history of crack oscillation specified by the number of time steps,  $N$ , in the finite-difference solution obtained by Chouet [23]. The time step has size  $\Delta t = 0.003125L/\alpha$  (see Fig. 4 for explanation of symbols). Depicted are the shape of the wall motion at  $N = 72$  (snapshot 1),  $N = 312$  (snapshot 2),  $N = 560$  (snapshot 3), and  $N = 1200$  (snapshot 4). (See text for discussion)

from the back edge of the crack, and the fourth snapshot at the lower right depicts the shape of the lateral and longitudinal modes of crack resonance, which by then are well established.

The excitation of modes in the crack model depends on the position of the pressure transient, the extent of crack surface affected by the transient, the temporal characteristics of the transient, and crack stiffness  $C = (b/\mu)(L/d)$ , where  $b$  is the bulk modulus of the fluid,  $\mu$  is the rigidity of the rock,  $L$  is the crack length, and  $d$  is the crack aperture [2,23]. An example of synthetic seismogram representing the vertical ground velocity response in the near field of a fluid-filled crack excited into resonance by a step transient in pressure is shown in Fig. 6. The synthetics display sustained oscillations that bear strong resemblance to observed LP waveforms (compare with Fig. 3), convincingly demonstrating the critical involvement of active fluid participation in the source process of volcanic signals.

Chouet's studies demonstrated the existence of a slow wave propagating along the crack wall, which he named the "crack wave". The asymptotic behavior of this wave was investigated by Ferrazini and Aki [42] in an analytical study of normal modes trapped in a liquid layer sandwiched between two elastic half spaces. The crack wave speed is slower than the sound velocity of the liquid and decreases with increasing crack stiffness and increasing wavelength; this result reflects the elasticity of the crack wall, whose effect is to decrease the effective bulk modulus of the fluid. These slow characteristics of the crack wave lead to more realistic estimates of crack dimensions compared to estimates based on the sound speed of a fluid embedded in a resonator with perfectly rigid walls. Source dimensions estimated from LP data based on this model

Volcanoes, Non-linear Processes in, Figure 6

Synthetic velocity waveform observed at an epicentral distance of 500 m and azimuth of  $45^\circ$  from the crack trace for a vertical crack (vertical extent  $L = 150$  m and horizontal extent  $W = 75$  m) buried at a depth of 500 m in a homogeneous half space. The aspect ratio is  $L/d = 10^4$ , and the parameters of the fluid and solid are  $a = 300$  m/s,  $\rho_f = 2120$  kg/m<sup>3</sup>, and  $\alpha = 4500$  m/s,  $\rho_s = 2650$  kg/m<sup>3</sup>. (Reproduced from [77])

typically range from tens to several hundred meters [79, 82,120]. Detailed analyzes of the dependence of crack resonance on fluid composition carried out by Kumagai and Chouet [77], and systematic investigations of LP signatures based on their results, suggest that dusty gases or bubbly basalt are common fluids in LP events of magmatic origin [27,45,76], and that wet gases, steam and bubbly water are typically representative of the source of LP events of hydrothermal origin [79,120].

The model of Chouet [23] does not address the excitation mechanism of LP events or tremor. Rather, the spatio-temporal properties of the pressure transient triggering the crack resonance are preset as kinematic conditions in the model. The usefulness of this model is thus restricted to a quantification of the crack resonance and properties of the fluids at the source of LP events. For a better perspective of the excitation mechanism of LP seismicity, observations of the source over a wider band of frequencies are necessary, along with an adequate sampling of the evolutionary characteristics of volcanic seismicity. Observations carried out in different volcanic settings point to a wide variety of LP excitation mechanisms originating in magmatic-hydrothermal interactions, as well as magmatic instabilities.

### Magmatic-Hydrothermal Interactions

In hydrothermal systems, LP seismicity can be induced by surges in the heat transfer from an underlying magma body. Kusatsu-Shirane Volcano in central Japan provides a prime example of the character of such interactions. Three crater lakes (Yugama, Mizugama, and Karagama) occupy the summit of the volcano along with numerous hot springs, pointing to an active magmatic system and enhanced circulation of hydrothermal fluids. Geochemical studies provide further support for hydrothermal activity resulting from the interaction of hot volcanic gases with groundwater [55,106]. LP events marked by nearly monochromatic oscillatory signatures have been frequently observed at this volcano (see Fig. 3) [43,46], and temporal variations in the decay characteristics of these events have also been documented [96]. Kumagai et al. [79] performed a systematic study of the temporal characteristics of LP events observed at Kusatsu-Shirane over a period from August 1992 through January 1993, and Kumagai et al. [80] carried out waveform inversions of a typical event during this time interval. Results from these studies point to the repeated excitation of a fixed sub-horizontal crack at depths near 200 m under the Yugama crater lake, and consistently explain temporal variations in LP signatures by the dynamic response of this crack

to a magmatic heat pulse. In this interpretation, the crack contains an initially wet gas, which became gradually drier with time, suggesting a “drying out” of the hydrothermal system in response to the heat pulse. Further analyzes by Nakano et al. [97] based on waveform inversions of the effective excitation functions (the signal components remaining after removal of the resonance characteristics) of individual LP events confirm the crack mechanism imaged by Kumagai et al. [80] and shed further light on the source process. This process involves a collapse and recovery of the sub-horizontal crack accompanied by an upward-directed force, and is consistent with a gradual buildup of pressure in the crack causing repeated discharges of steam from the crack. The vertical force imaged with the volumetric component of the source reflects the release of gravitational energy that occurs as a slug of steam ejected from the crack ascends toward the surface and is replaced by a downward flow of cooler water within a conduit linking the crack to the base of the Yugama crater lake. In this scenario, crack resonance is triggered by the sudden collapse of the crack induced by the venting of steam.

Similar mechanisms of interaction between magmatic and hydrothermal systems have been inferred for Kilauea, Mount St. Helens, and Redoubt Volcanoes. At Kilauea Volcano, Hawaii, Almendros et al. [4] imaged a shallow hydrothermal system from frequency-slowness analyses of LP seismicity recorded on three small-aperture seismic arrays deployed in the summit caldera. Located within the top 500 m below the caldera floor, this reservoir is perched immediately above the shallowest segment of magma conduit identified by [109] from inversions of VLP signals produced during a transient in the magma flow feeding the long-lived and ongoing east rift eruption of this volcano [48]. Episodic deflations of the Kilauea summit during brief pauses in the flow of magma are commonly followed by rapid reinflation of the summit during the resumption of flow, and subsequent slower deflation back to an original state preceding the pause [21]. Larger summit reinflation episodes associated with more energetic surges of magma are accompanied by the emission of VLP signals, production of shallow brittle failure earthquakes, and enhanced LP seismicity in the hydrothermal reservoir [39,109]. Detailed analyses of seismic array data by Almendros et al. [5] further document the persistence of low-amplitude tremor generated by shallow hydrothermal activity in response to the flux of heat from the underlying magma conduit. Additional support for this scenario also comes from analyses of the source process of a hydrothermal LP event [82], which point to the resonance of a horizontal crack at depth of  $\sim 150$  m immediately above the conduit imaged by Ohminato et al. [109]. The observed

frequencies and attenuation characteristics of crack resonance are consistent with a crack filled with either bubbly water or steam [82].

The inferred scenario of magmatic-hydrothermal interactions at Kilauea, which is in harmony with all of the above observations, involves a chain of causes and effects that starts with a volumetric deformation of the underlying shallow segment of magma conduit induced by the surging magma. This conduit response causes brittle fractures in the surrounding rock matrix, and thus enhances the upward transport of magmatic gases through the fractured medium to shallow depths, where the hot gases heat and activate the hydrothermal system. The boiling of groundwater and attendant production of steam then raise the overall pressure of hydrothermal fluids in fractures permeating the medium, thereby leading to repeated impulsive discharges of fluid and resonant excitation of individual fractures.

The current dome-building eruption of Mount St. Helens Volcano, Washington, is marked by the extrusion of a stiff plug of dacitic magma [40,91] accompanied by shallow, repetitive LP events that have been dubbed “drumbeats” by scientists monitoring Mount St. Helens [94]. VLP signals commonly accompany the LP events, but are generally detected only in the immediate vicinity of the crater. Using high-quality data from a temporary broadband seismic network deployed in 2004–2005, Waite et al. [137] carried out systematic waveform inversions for both LP and VLP signals. Results from these inversions point to the perturbation of a common crack system linking the magma conduit and shallow water-saturated region of the volcano. A scenario consistent with the imaged source mechanisms involves the repeated pressurization of a sub-horizontal crack that lies beneath the growing lava dome in the southern part of the crater. Steam produced by the heating of ground water, as well as steam exsolved from the magma, feed into the crack and pressurize it. Upon reaching a critical pressure threshold, steam is vented out of the crack through fractures leading to the surface. The drop in pressure triggers a partial collapse of the crack, which resonates for 5 to 10s of seconds. The collapse of the crack in turn induces sagging of the overlying dome and triggers a passive response in the magma conduit that is observed in the VLP band. The observed force and volumetric components of this VLP response are both consistently explained as the result of a perturbation in an otherwise smooth steady flow of magma upward through a dike and into a sill underlying the old dome. In this model, the dike represents the top of the old conduit that fed the 1980–1986 dome-building eruptions, and the sill represents a bypass below the old dome. Accord-

ing to this interpretation, at the start of renewed activity in September 2004, magma moving up the conduit found an easier pathway to the surface by breaking out of the conduit near the surface and pushing sub-horizontally to the south rather than intruding the older dome complex. The imaged sill represents this segment of conduit, and the hydrothermal crack represents an extension of this fracture into the shallow water-soaked region beneath the crater floor. This picture of Mount St. Helens as a steam engine is quite distinct from an earlier model in which the seismic drumbeats were assumed to represent stick-slip motion between the extruding lava and conduit walls (see below). A sustained supply of heat and fluid from the magmatic system is necessary to keep the crack pressurized and keep the drumbeats beating in the model elaborated by Waite et al. [137]. As for Kilauea, a proper interpretation of this activity has important implications for the assessment of the potential for phreatic eruptions at Mount St. Helens.

Another perspective on a different type of instability presumed to be associated with dome growth activity at Mount St. Helens was proposed by Iverson et al. [57]. Their model, originally developed before results from the detailed seismic analyses by Waite et al. [137] became available, hypothesizes that repetitive stick-slip motion along the perimeter of the extruding solid plug may cause observable earthquakes. Although not supported by the character of LP seismicity observed at Mount St. Helens, this model nevertheless offers an intriguing view into a possible oscillatory behavior of plug flow. Oscillations in extrusion velocity originate in the interaction of plug inertia, a variable upward force due to magma pressure, and downward force due to plug mass. Assuming that a steady ascent of compressible magma drives the upward extrusion of a solidified plug exhibiting nonlinear rate-weakening friction along its margins, Iverson et al. [57] infer that stick-slip oscillations might be an inevitable component of such an extrusion process; however, the predicted amplitude of individual slip events, estimated at a few millimeters, suggests this mechanism may be difficult to detect. The seismic source associated with a stick-slip extrusion event may manifest itself as a combination of a near-vertical force (assuming vertical spine growth) representing the reaction force on the Earth due to the upward acceleration of mass, and double couple resulting from shear near the plug margins where viscosity is very high and magma is in the glass transition. This particular mechanism does not involve LP source resonance and is apparently not part of the dominant expression of seismicity at Mount St. Helens, but could possibly be operating at a level below the threshold of seismic detection. Such mechanism may be observable in dome-building eruptions where the extrusion rate

is sufficiently large and unsteady to produce oscillations of this type.

The reawakening of Redoubt Volcano, Alaska on 13 December, 1989, after 23 years of quiescence, was heralded by a rapidly accelerating swarm of repetitive LP events that merged into sustained tremor a few hours before the eruption onset [26,126]. These LP events were interpreted by Chouet et al. [26] as the resonant excitation of a crack linking a shallow, low-pressure hydrothermal system to a deeper supercharged magma-dominated reservoir. The initiation of the swarm was attributed by these authors to the failure of a barrier separating the two reservoirs. The actual mechanism triggering the LP excitation in this model is the unsteady choking of a supersonic flow of magmatic steam driven by the pressure gradient existing between the two reservoirs. Unsteady choking itself is the result of fluctuations in crack outlet pressure associated with the reaction of the hydrothermal system to the injection of mass and heat from below. Similarly, the emergence of sustained tremor late in the swarm is interpreted as a change in choked-flow regime related to a gradual weakening of the pressure gradient driving the flow [92]. Numerical simulations of the transonic flow through a crack featuring a nozzle-like constriction were performed by Morrissey and Chouet [95] using the Navier–Stokes equations representing a mixture of gas and suspended solid particles. In these simulations, shock waves develop immediately downstream from the nozzle-like constriction, and the flow acts as an energy transducer that converts smooth low-amplitude fluctuations of outlet flow pressure into strongly-amplified and repetitive step-like pressure transients applied to the crack wall immediately downstream from the nozzle. The magnitude of the pressure transient at the walls is fixed by the pressure of the supplying reservoir and the geometry of the nozzle aperture, presumably remaining constant as long as these conditions prevail. The temporal pattern of outlet pressure fluctuations controls the areal extent of the crack wall impacted by shock waves and, given a roughly constant shock magnitude, fixes the amplitude of the force applied to the wall by the fluid. This variable force applied at a fixed location along the crack wall is viewed as the force responsible for the scaling of amplitudes and the similarity of waveforms observed in the LP swarm at Redoubt [26].

### Magmatic LP Events

In low-viscosity basaltic systems, LP seismicity may be part of a broadband source process associated with the unsteady transport of magma and gases through conduits. This is well illustrated in a broadband seismic record ob-

tained at Kilauea (Fig. 7); most interesting is the displacement record shown at bottom of figure. This record, obtained after filtering the raw broadband signal (top trace in Fig. 7) with a 0.125 Hz low-pass filter, features a repetitive sawtooth signal with rise time of 2–3 min and drop time of 5–10 s. The observed repetitiveness of the VLP signal is a clear indication of the repeated action of a non-destructive source. Noteworthy also are the characteristic LP signatures obtained by filtering the broadband signal with a 0.33-Hz high-pass filter (third trace from the top). These LP events display a fixed dominant period of 2.5 s, whose onsets coincide with the start of the dropdown in the VLP sawtooth displacement signals. Such coincidence is strongly suggestive of a causative relationship between the VLP and LP signals.

The data in Fig. 7 are part of a seismic sequence observed during a surge in the magma flow feeding the ongoing east rift eruption of Kilauea, and the source mechanism of the VLP signals obtained by Ohmiato et al. [109] from waveform inversions of these data points to a repeated cycle of deformation of a sub-horizontal crack located roughly 1 km below the floor of the summit caldera. Each sawtooth in the recorded displacement signal represents a slow dilation of the crack, followed by a rapid collapse of the crack. The volume change associated with individual sawtooths ranges from 1000 to 4000 m<sup>3</sup> [109].

A conceptual model consistent with the seismic source mechanism imaged by Ohmiato et al. [109] is shown in Fig. 8. This model involves the injection of a large slug of gas into a sub-horizontal crack with a narrow constricted

Volcanoes, Non-linear Processes in, Figure 7

Broadband record and associated filtered signals obtained at Kilauea Volcano during a volcanic event on February 1, 1996. The broadband signal represents ground velocity and is filtered in various frequency bands to produce five records for the same 7-min time interval. The top trace shows the broadband signal ( $0.01 < f < 25$  Hz), which is dominated by the oceanic wave-action microseism with dominant periods in the range 3 to 7 s. The second trace shows the signal obtained after application of a high-pass filter ( $f > 0.83$  Hz). The result is equivalent to a typical short-period record and shows a series of events superimposed on a background of tremor. The third trace also has a high-pass filter applied but with a lower corner frequency ( $f > 0.33$  Hz); LP signals with a dominant period of about 2.5 s are enhanced in this record. The fourth trace shows the signal when a low-pass filter is applied ( $f < 0.125$  Hz); a repetitive VLP signal consisting of pulses with period of about 20 s is observed. The fifth trace is the corresponding displacement record obtained with the same low-pass filter ( $f < 0.125$  Hz), showing a repetitive sawtooth pattern with rise time of 2–3 min and drop time of 5–10 s. Notice that the onset of the LP signal seen above coincides with the onset of the dropdown in the VLP displacement. (Reproduced from [38])

Volcanoes, Non-linear Processes in, Figure 8

Conceptual model of separated gas-liquid flow through a converging-diverging nozzle under choked conditions (see pp. 71–74 in [138]). **a** Inflation phase showing gas accumulation upstream of the nozzle, leading to pressure buildup and deformation of the crack. The gas slug is essentially stationary and the Mach number of the gas is  $M_g \ll 1$ . This stage coincides with the upgoing ramp in the sawtooth displacement signal at the bottom of Fig. 7. **b** Separated gas-liquid flow through the nozzle under compound choked conditions. The gas flow is choked ( $M_g = 1$ ) in the nozzle defined by the gas-liquid interface and upper solid wall, and is supersonic ( $M_g > 1$ ) immediately downstream of the nozzle. There exists a maximum possible gas flow rate that is fixed by the rate of liquid discharge for given upstream conditions and fixed throat geometry. In the limit, liquid fills the duct entirely and there is no gas flow. (Reproduced from [109])

outlet; both liquid magma and gas flow through this outlet constriction. Initially, liquid magma occupies the entire outlet cross section and gas accumulates in the crack, forming a layer of gas on top of the liquid and deforming the crack walls as the back pressure of gas increases in the crack. Eventually, when the back pressure buildup in the crack reaches a critical threshold, the gas slug deforms and rapidly squeezes past the constriction along with the liquid, triggering a rapid deflation (collapse) of the crack in the process. This sequence is then repeated with the next gas slug. In this scenario, the restraining force of the liquid on the gas acts like a self-activated viscosity-controlled valve. In the stratified flow through the nozzle, the liquid moves at a steady slow pace on the order of m/s but the gas flow itself is choked in the narrow opening between the liquid/gas interface and the upper wall [138]. The formation of a shock associated with compound choking of the flow is viewed here as a trigger of acoustic oscillations of the liquid/gas mixture, which is at the origin of the LP signature

with characteristic period of 2.5 s observed in conjunction with the rapidly downgoing part of the sawtooth displacement signal shown in Fig. 7.

At Stromboli Volcano, Italy, broadband seismic signals including strong VLP and LP components are seen to accompany explosions. Waveform inversions of the VLP signals performed by Chouet et al. [32] show that the processes associated with eruptions involve volumetric changes marking a cycle of pressurization-depressurization-repressurization of the conduit, coupled with a single force component, both of which may be viewed as the result of a piston-like action of the magma associated with the disruption of a gas slug transiting through a sudden enlargement in conduit aperture in the steeply-inclined upper segment of conduit [32,60] (see Sect. “**Slug Distribution at Stromboli**” for details). The LP signal in that case is attributed to the oscillatory response of the shallowest segment of the fluid-filled conduit associated with the rapid expansion and ejection of the slug [29].

LP seismicity is also intimately linked with Vulcanian activity. The complex magma rheology, marked by a strong nonlinear dependence of viscosity on water content and temperature [49,147], finite yield strength, strain-rate dependent viscosity, and transition to brittle solid behavior at high strain rates [133] contributes to widely varying oscillatory behaviors seen in Vulcanian systems. At Galeras Volcano, Colombia, LP events displaying extended quasi-monochromatic coda were found to be linked to the release of ash-laden gases from a shallow magma body through a preexisting system of cracks bisecting the dome capping the vent [45]. Similar to Galeras, eruptive activity at Popocatepetl Volcano, Mexico, is dominated by emissions of steam, gas and ash, and by repeated formation and destruction of lava domes, all of which generate a wide variety of signals [10,11]. LP events accompanying degassing bursts are commonly associated with VLP signals and display waveform features that remain stationary from event to event. The source of these events coincides with, or is very close to, the source of VLP signals, 1.5 km below the crater floor [11,33]. This LP activity represents an integral part of a degassing process similar to that inferred for Galeras, where the sudden expulsion of a pressurized pocket of gases induces elastic deformation of the conduit coupled with acoustic resonance of the conduit (see further discussion in Sect. “**Coupled Diffusive-Elastic Pressurization at Popocatepetl Volcano**”).

LP events at Soufrière Hills, Montserrat, have been linked to the action of a repetitive, non-destructive, stationary source 1.5 km below the crater floor [100]. The temporal relationship between LP events and tilt patterns at Soufrière Hills clearly shows that LP seismicity starts in synchronicity with the passage of tilt through a turning point marked by a maximum in time derivative of the tilt signal. Seismicity subsequently ceases as tilt goes through a second turning point [100]. This correlation between LP events and inflation-deflation cycles is evidence of a strong relationship linking LP seismicity to magma movement and pressure conditions at depth. Based on these observations, [100] proposed a mechanism of LP excitation originating in the brittle failure of a highly viscous magma under high strain rate. In their model, loss of gas and heat from the magma at the conduit wall leads to the generation of a sharp viscosity gradient at the wall. This in turn leads to a buildup of shear stress near the wall, where the flowing magma undergoing glass transition can fail in a brittle manner. The resulting brecciated zone along the conduit boundary provides a natural pathway for escaping gases. The LP events may then be viewed as an expression of acoustic resonance occurring in well-defined channels in this zone, or possibly as an expression of acoustic energy

trapped in an adjacent region of conduit filled with bubbly magma [36,56].

The LP sources described so far all represent shallow sources occurring in the top 2 km below the surface. Although thoroughly documented, such sources do not represent the total expression of LP seismicity. An activity of deep (> 5 km depth) LP events has also been noted in several areas of the world. In particular, episodes of deep (30–60 km) and intermediate-depth (5–15 km) LP seismicity are often observed under Kilauea [74,75]. Analyses of the intermittency of LP activity were carried out by Shaw and Chouet [122] and Shaw and Chouet [123], who viewed such tremor episodes as the relaxation oscillations of a percolation network of coupled magma-filled fractures. In their interpretation, each individual fracture in the network acts as a source of LP events, and sets of fractures give rise to multiple LP events and episodes of tremor. The aggregate nature of fracture propagation and vibration then lead to the existence of universal scaling laws that give rise to the long-recognized frequency invariance of LP events [122,123].

Other episodic bursts have been noted at depths of 10–20 km under Mammoth Mountain, California, where LP and VLP events have been seen to occur synchronously with spasmodic bursts of small brittle failure earthquakes [54]. A process involving the transport of a slug of CO<sub>2</sub>-rich hydrous magmatic fluid derived from a plexus of basaltic dikes and sills has been invoked to explain such occurrences [54]. LP events at depths near 30 km under Mount Pinatubo, Philippines, have been attributed to a basaltic intrusion thought to have triggered processes leading to the cataclysmic eruption of June 15 [139]. Small LP events attributed to magmatic activity have also been detected at depths of 25–40 km beneath active volcanoes in northeastern Japan [47], and at depths of 10–45 km below volcanoes of the Aleutian Arc [114]. In all these instances, the occurrence of deep LP events appears to be more directly related to deep magma supply dynamics than near-surface or surface activity. Because of our lack of knowledge concerning the character and dynamics of deep-seated fluid transport under volcanoes, the actual origins of these events remain enigmatic.

### Summary of Inferred Excitation Mechanisms for LP Seismicity

Shallow hydrothermal LP events at Kusatsu-Shirane, Kilauea, and Mount St. Helens all share a common excitation mechanism involving the repeated pressurization of a steam-filled fracture, causing the venting of steam, collapse of the fracture and recharge, in response to heat

transfer from an underlying magma body. At Mount St. Helens, where the LP source is located very close to the magma conduit, LP activity is also seen to trigger a passive response of the conduit itself. LP seismicity observed at Redoubt represents a more energetic form of magmatic-hydrothermal interaction where an unsteady choked flow of magmatic gases provides a natural source of pressure perturbation at the origin of LP events and tremor. Magmatic LP events produced during bursts of ash-laden gases associated with Vulcanian activity at Galeras and Popocatepetl involve a pumping mechanism in shallow fractures similar to that inferred for hydrothermal LP events at Kusatsu-Shirane, Kilauea, and Mount St. Helens. LP events accompanying endogenous dome growth at Soufrière Hills appear to be related to a more complex process involving the production of shear fractures in highly viscous magma at the glass transition, injection of dusty gases into these fractures, and resonance of the fracture network and/or possibly resonance of a bubble-rich magma excited by the energy release from the brittle failure. Magmatic LP events in the basaltic systems at Kilauea and Stromboli are the result of pressure disturbances generated during the transit of large slugs of gas through conduit discontinuities.

A nonlinear excitation mechanism of LP seismicity by fluid flow has also been proposed by Julian [62]. Using a simple lumped-parameter model, Julian investigated the elastic coupling of the fluid and solid as a means to produce self-excited oscillations in a viscous incompressible liquid flowing through a channel with compliant walls. In his model, an increase in flow velocity leads to decrease of fluid pressure via the Bernoulli effect. As a result, the channel walls move inward and constrict the flow, causing an increase in fluid pressure and forcing the channel open again. The cyclic repetition of this process is the source of sustained oscillations in Julian's model. Julian demonstrated that with increasing driving pressure the model can exhibit various oscillatory behaviors resembling tremor.

As illustrated in the above examples, magmatic-hydrothermal interactions and magmatic oscillations can take on a variety of forms. Studies of the mechanisms of tremor excitation are still very much in their infancy, owing to the paucity of accurate and detailed seismic observations essential in documenting and analyzing such processes.

### Source Processes of Very-Long-Period Signals

Unlike the LP signals, which are mainly interpreted as manifestations of acoustic resonance, VLP signals are viewed as the results of inertial forces associated with per-

turbations in the flow of magma and gases through conduits. An increasingly widespread use of broadband seismometers on volcanoes has led to an increasing number of observations, and VLP signals have by now been documented in volcanic areas all over the world, including Sakurajima [67,68], Unzen [134], Aso [65,69,86,143], Satsuma-Iwojima [108,110], Iwate [101], Miyakejima [44,78], Usu [144], Bandai [103], Hachijo [81,83], and Asama [111] in Japan; Stromboli [14,30,32,35,99] in Italy; Merapi [50,51,52] in Indonesia; Kilauea [6,7,38,39,109] in Hawaii; Long Valley [53,54] and Mount St. Helens [137] in the United States; Erebus [13,119] in Antarctica; Popocatepetl [9,10,33] in Mexico; and Cotopaxi and Tungurahua [84] in Ecuador.

The wavelengths of VLP signals are in the range of tens to hundreds of kilometers, which greatly facilitates their analysis. Inversions of VLP waveforms have imaged crack geometries at the source in the forms of dikes or sills [32,81,109,143], as well as more complicated geometrical configurations involving a composite of a dike intersecting a sill [33], or composites of intersecting dikes [7,35], or two chambers connected to each other by a narrow channel [101]. Based on the characteristic period of VLP signals recorded at Hachijo Island, Japan, Kumagai [83] estimated a source with dimensions of a few km. The decaying harmonic oscillations with periods near 10 s and duration up to 300 s of the VLP signals seen at Hachijo are similar to the features of LP events with periods near 1 s (see Fig. 3) and appear consistent with the resonance of a dike containing a bubbly basalt. In that sense, these VLP signals probably represent a unique end member of the family of sources associated with resonant conduit excitation. Interestingly, the dominant periods and associated decay characteristics of the VLP signals at Hachijo were both found to vary with time, and these temporal variations were attributed by Kumagai [83] to a change in source dimensions, assuming fixed acoustic properties of the fluid at the source. A spread of about 4 km was also estimated by Chouet et al. [101] for two chambers at Iwate Volcano. The modeling of VLP waveforms at Stromboli by Nishimura et al. [35] points to two point sources, each involving two intersecting dikes, whose relative positions and orientations represent individual conduit segments with dimensions of a few hundred meters. Systematic modeling of sustained VLP tremor accompanying episodes of deflation-inflation-deflation at Kilauea has suggested a complex magma pathway composed of a plexus of intersecting dikes extending over the depth range 0.6–1.6 km below the summit caldera [7]. A crack-like conduit extending over the depth range 0.3–2.5 km has also been inferred under Aso Volcano, Japan [143].

Contrasting the above-discussed findings are results obtained by Ohminato [111] from waveform inversions of VLP signals produced by Vulcanian explosions at Asama Volcano, Japan. At Asama, the contribution from a vertical single force with magnitude  $10^{10} - 10^{11}$  N was found to dominate the observed waveforms, and no obvious volumetric component was identified at the source. The depth of the VLP source is  $\sim 200$  m beneath the summit crater, and the source-time history features two downward force components separated by an upward force component. The initial downward component was attributed by Ohminato [111] to the sudden removal of the lid capping the pressurized conduit (this force is analogous to the force  $F_{T_1}$  in Fig. 2), and the subsequent upward force was interpreted by these authors as a drag force induced by viscous magma moving up the conduit. Ohminato [111] also attributed the final downward force component to an explosive fragmentation of the magma, whose effect is to effectively cancel viscous drag so that the downward force due to jet recoil again dominates the VLP signal.

Available studies demonstrate that detailed investigations of the VLP oscillation characteristics of the source are critically important to our understanding of volcanic fluid dynamics. Below, I review two in-depth investigations of VLP signals representative of Vulcanian degassing bursts at Popocatepetl and gas-slug transport dynamics at Stromboli.

### Coupled Diffusive-Elastic Pressurization at Popocatepetl Volcano

Vulcanian degassing bursts at Popocatepetl Volcano, Mexico, have been observed to be closely linked to the degassing of a sill-shaped volume of magma at a depth of 1.5 km below its summit crater [33]. The variations in volume of this sill were interpreted by Chouet et al. [33] as reflecting cyclic pressure oscillations originating in the magma filling the sill. Based on these observations, these authors proposed a model in which static magma in the sill becomes supersaturated because of groundmass crystallization. In this conceptual view, volatile exsolution and diffusion of gas from the melt into bubbles increase the internal pressure of the bubbles, because bubble expansion is impeded by the viscous resistance of the surrounding liquid and by the confining effects due to the finite yield strength of the overlying column of magma and surrounding solid rock. Elastic inflation of the sill occurs as a result of bubble pressurization, and this inflation proceeds until the critical yield strength of the magma column is exceeded and magma starts flowing out of the sill. Magma fragmentation induced by viscous shear near the conduit

wall then causes coalescence and collapse of bubbles intersected by fractures, allowing gas escape through a transient network of fractures. This, in turn, induces a pressure decrease in the sill, which results in the collapse and welding of the fracture network that shuts down the gas-escape pathway. Repeated cycles of shear-induced fracture and welding of magma provide a ratchet mechanism by which the separated gas phase in the magma can be recharged and evacuated.

The expansion dynamics of bubbles in supersaturated magma have been addressed in many previous studies under conditions of constant melt pressure [87,88,90,115,117,121,125], or constant decompression rate [116,131,132]. A canonical model of bubble growth in magma that includes the effect of finite spacing of bubbles in the melt was first developed by Proussevitch et al. [115]. This model considers a suspension of gas bubbles in an incompressible volatile-bearing liquid. The suspension is modeled as a three-dimensional lattice of closely-packed spherical cells, where each identical elementary cell is composed of a gas bubble surrounded by a shell of liquid. A step drop in pressure in the melt induces volatile exsolution and bubble expansion is driven by the diffusion of gas into the bubble. In this model, only the volatiles contained in the shell of liquid surrounding the bubble contribute to the bubble expansion so that bubble growth is limited by how closely packed the bubbles are in the liquid. Using the model of Proussevitch et al. [115], Chouet et al. [34] and Shimomura et al. [124] obtained a dynamic solution that includes the effect of melt compressibility. In their model, pressure recovery is driven by bubble growth in a supersaturated magma that is stressed by the surrounding crust as the magma volume increases with bubble expansion. Both models consider the pressure recovery following an instantaneous pressure drop in the melt. The magma is embedded in an infinite, homogeneous, elastic solid and consists of a melt containing numerous small spherical gas bubbles of identical size. No new bubbles are created and no bubbles are lost during pressure recovery, and the gas in the bubbles is assumed to be a perfect gas. Gravity and other body forces are not considered.

The conduit geometry considered by Chouet et al. [34] applies specifically to the observation made at Popocatepetl [33] and consists of a penny-shaped crack containing a melt with an isotropic distribution of bubbles (Fig. 9a). The initial oversaturation of the melt resulting from a pressure drop  $\Delta P_0$  is distributed uniformly in the melt, and each bubble grows by diffusion of volatiles from a surrounding shell of melt with finite radius (Fig. 9b). As diffusion is a slow process, with time scale much longer than that of heat transfer into the bubble [56], bubble

Volcanoes, Non-linear Processes in, Figure 9  
**Model used by Chouet et al. [34] to interpret the source mechanism of Vulcanian degassing bursts at Popocatepetl Volcano, Mexico. a** Schematic illustration (cross section) of penny-shaped crack embedded in an elastic solid. The crack is under confining pressure  $P_s$ , and contains a melt with an isotropic distribution of gas bubbles of identical sizes. **b** Detailed view of the distribution of elementary cells composing the bubbly liquid (after [115]). Each cell (as in gray-shaded example) consists of a gas bubble surrounded by a finite volume of melt. The elementary cells are organized in a three-dimensional lattice with slight overlap of the cells, where the volumes of intersecting melt and gaps are equal, so that the gas-volume fraction is  $(R/S)^3$ , where  $R$  is the bubble radius and  $S$  is the outer shell radius

growth is assumed to be isothermal. The mathematical model describing an elementary cell therefore consists of three equations: (1) a diffusion equation governing the transfer of volatiles in the melt shell; (2) an equation expressing the radial motion of the bubble; and (3) a relation representing the ideal gas approximation. These equations are then subjected to three boundary conditions expressing the phase equilibrium at the bubble wall, mass flux at the bubble wall, and zero mass flux through the outer shell wall. As the bubble grows by mass transfer from the melt, melt is compressed and the surrounding rock matrix is deformed as a result. The pressure in the melt is balanced by the stress applied by the surrounding elastic medium, and in both Chouet et al. [34] and Shimomura et al. [124], this is formalized by assuming a quasi-static deformation of the magma conduit. Melt shrinkage from dehydration [105] is assumed to be negligible compared to melt compression due to bubble growth and is not considered.

In their treatment of the initial condition in the bubble, Chouet et al. [34] follow Proussevitch et al. [115] and assume an instantaneous drop in gas pressure inside the bubble. This induces an instantaneous drop in volatile concentration at the bubble wall, thereby producing a step-like gradient of concentration that kick-starts the diffusion process. This condition is different from that assumed by Shimomura et al. [124], who follow the model of Navon and Lyakhovsky [98], in which the bubble initially retains the original gas pressure and immediately expands in response to the difference between internal and external pressures. The relaxation expansion of the bubble then induces a decrease in gas pressure inside the bubble, which leads to the establishment of a gradient in volatile concentration at the bubble wall that starts the diffusion. Although this leads to distinct features in the instantaneous bubble response, this has essentially no effect on the volumetric response of the bubble at longer time scales.

Figure 10 shows the pressure recovery calculated by Chouet et al. [34] for input step drops  $\Delta P_0 = 0.01, 0.1,$  and  $1$  MPa applied to a bubbly rhyolitic melt encased in a penny-shaped crack with radius  $100$  m and thickness  $5$  m under ambient pressure  $P_s = 40$  MPa appropriate for the depth of the source imaged for Popocatepetl Volcano [33]. The bubbles have a fixed initial radius  $10^{-6}$  m, and the bubble number density is  $10^{12} \text{ m}^{-3}$ . Melt density, viscosity, and diffusivity are  $2300 \text{ kg m}^{-3}$ ,  $10^6 \text{ Pa s}$ , and  $10^{-11} \text{ m}^2 \text{ s}^{-1}$ , respectively; surface tension is  $0.2 \text{ Nm}^{-1}$ , and the bulk modulus of melt and elastic rigidity of the rock are both  $10^{10} \text{ Pa}$ . The amplitude ratio of pressure recovery to initial pressure drop displays a strong nonlinear sensitivity to the magnitude of the input pressure drop, resulting in magnifications ranging from about  $1$  to nearly  $30$  over the range of input transients considered (Fig. 10). This overpressurization upon recovery was previously noted in a static solution obtained earlier by Nishimura [104] and becomes largest for tiny bubbles and a stiff elastic medium [34,124]. Figure 10 also indicates that the speed of recovery is a function of the input transient, with the crack response becoming markedly slower for small pressure transients compared to larger ones.

The variation of time and amplitude scales seen in Fig. 10 suggests that a wide range of responses may be possible for cracks containing melts with a wider population of bubble sizes than the single-size bubble populations considered by Chouet et al. [34]. The net drop in volatile concentration associated with diffusion-driven bubble growth is quite small. Indeed, the results obtained by Chouet et al. [34] point to concentration drops  $\sim 0.003 - 0.035 \text{ wt\%}$  for initial bubble radii of  $10^{-5} - 10^{-7}$  m in penny-shaped cracks with aperture to radius ratios

Volcanoes, Non-linear Processes in, Figure 10  
Dependence of pressure recovery on the size of the input transient,  $\Delta P_0$ , in the model of Chouet et al. [34]. The magnification factor for each response is indicated at the upper right of each pressure trace

0.01 – 0.25. The net concentration drop is small because pressure recovery in the melt acts to raise the saturation level of volatiles in the melt. This has important implications for the overall history of degassing in a Vulcanian system, as it suggests that this process may be repeated many times without significantly depleting the gases in the melt body.

The source process imaged under Popocatepetl involves a sequence of inflation, deflation, and reinflation, reflecting a cycle of pressurization, depressurization, and repressurization within a time interval of 3–5 min [33]. The volumetric component of the source processes in the sill associated with an eruption on 23 May 2000 is shown in Fig. 11. Other eruptions were found to produce similar waveform characteristics, hence the event in Fig. 11 may be viewed as an appropriate representation of overall source dynamics associated with these Vulcanian eruptions. For comparison, Fig. 11 also shows the volume change of a magma-filled sill calculated with the model of Chouet et al. [34]. The sill response has been band-pass filtered in the same band as the observed signal, and is illustrated for three distinct pressure drops. The model parameters in Fig. 11 are identical to those used in Fig. 10. A realistic fit of the peak-to-trough amplitude of the volume change imaged at Popocatepetl is obtained for an input pressure drop  $\Delta P_0 = 3.25$  MPa.

Unfortunately, the longer-period components and other specific features of the sill response in the model are lost in the band-limited version of the signal compatible with observations made at Popocatepetl, so that the responses obtained in this band for different model param-

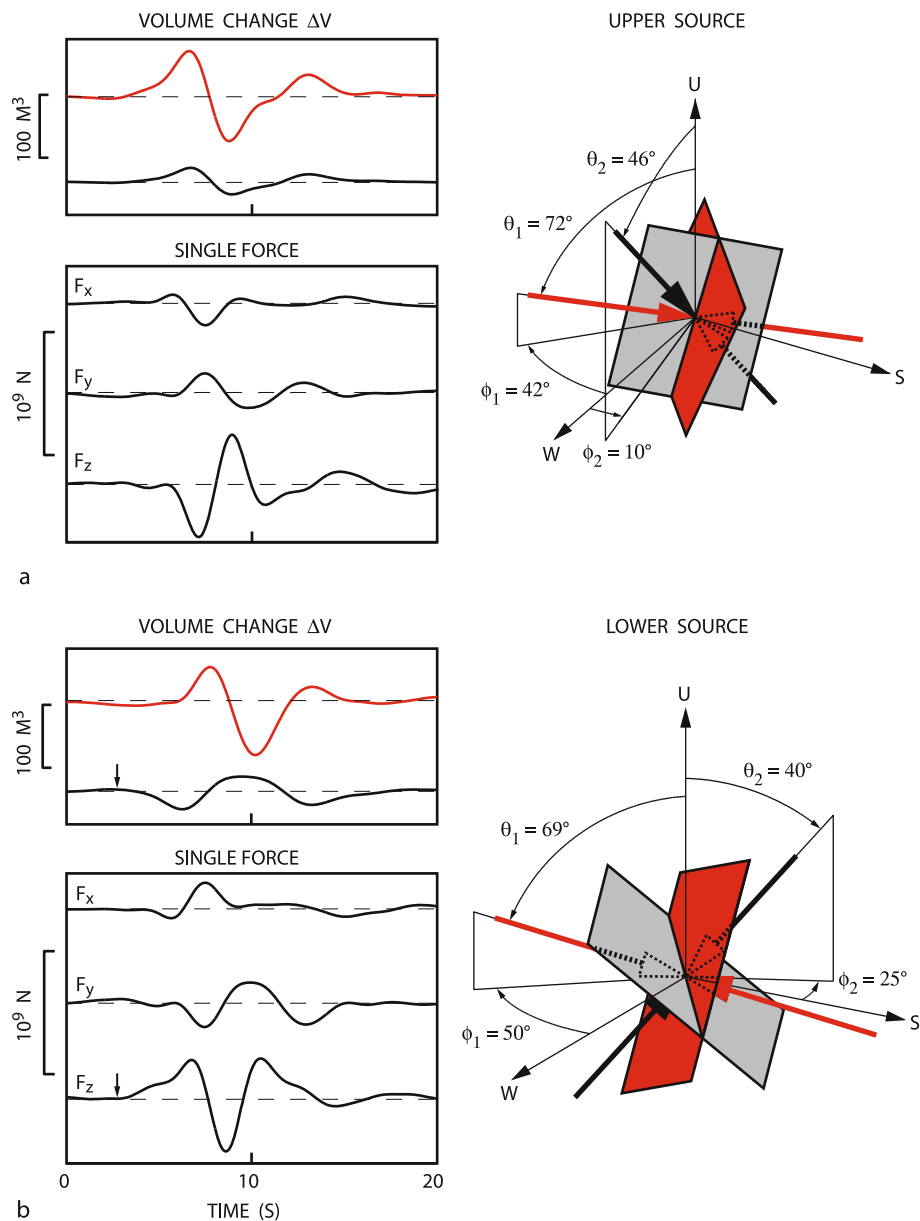

Volcanoes, Non-linear Processes in, Figure 11  
Source-time function of volume change obtained by Chouet et al. [33] for a sill under Popocatepetl Volcano during a degassing burst on 23 May 2000 (black line), and corresponding volume changes in a sill filled with a bubbly melt in response to a step drop  $\Delta P_0$  in pressure (colored lines). The data from Popocatepetl and solutions from the crack model have both been band-pass filtered in the 15–70 s band

eters are all very similar [34]. Although it is not possible to infer specific values of melt viscosity, volatile diffusivity, initial bubble radius, bubble number density, or sill aperture to radius ratio based on available seismic data, these results strongly support the idea that diffusion pumping of bubbles in the magma under Popocatepetl provides a viable mechanism for pressure recovery following a pressure drop induced by a degassing event.

### Slug Disruption at Stromboli

Eruptive behavior at Stromboli is characterized by mild, intermittent explosive activity, during which well-collimated jets of gases laden with molten lava fragments burst in short eruptions typically lasting 5–15 s. Modeling of VLP seismic data recorded during explosive activity in 1997 has imaged two distinct dike structures representative of explosive eruptions from two different vents located near the northern and southern perimeters of the summit crater [32,35].

Figures 12 and 13 show two representations of the conduit geometry underlying the northern vent area. Figure 12 shows the seismic source mechanisms obtained from inversion of VLP waveforms; the mechanisms include two point sources, each of which marks a flow disruption site along the upper conduit. The upper source (Fig. 12a) is located 300 m below the crater floor and represents a bifurcation in the conduit; this is the main flow disruption site for gas slugs ascending toward the northern vent. The lower source (Fig. 12b), located roughly 500 m below the upper source, involves a sharp corner in the conduit and represents a secondary flow disruption site.

Volcanoes, Non-linear Processes in, Figure 12

Seismic source mechanisms imaged for the two flow disruption sites in the shallow conduit structure underlying the northern vent area at Stromboli. The two point-source mechanisms were obtained by Chouet et al. [35] from inversions of VLP waveforms recorded during explosions at Stromboli, and are positioned at different depths in the volcanic edifice (see text for details). Each source consists of two intersecting cracks and a single force with components  $F_x$  (east),  $F_y$  (north), and  $F_z$  (up). Volume changes are color-coded with the color of the cracks they represent in each source. Crack orientations are provided by the azimuth  $\phi$  and polar angle  $\theta$  of the dominant dipole normal to the crack plane, with arrow directions marking crack deflation (see Fig. 1c). The reference coordinates are W (west), S (south), and U (up). **a** Upper source. **b** Lower source. Small arrows in left panels mark the onset of deflation of the lower dike (gray dike in right panel) and synchronous start of the upward force. (Reproduced from [35])

Volcanoes, Non-linear Processes in, Figure 13

Geometry of the upper 1 km of conduit underlying the northern vent area of Stromboli. A semi-transparent view of the northwest quadrant of the volcanic edifice provides the reference for the location and geometry of the conduit, which is derived from the seismic source mechanisms in Fig. 12. Thin black line indicates sea level. The summit of the volcano is 924 m above sea level (no vertical exaggeration). The two flow disruption sites that are sources of VLP elastic radiation are indicated by small circles. The irregular red and blue lines, respectively, represent the surface traces of the dominant and subdominant dike segments constituting the shallowest portions of the conduit system. The eruptive vent is marked by an arrow, and vents temporarily active during the flank eruption in 2002–2003 are marked by green squares. The lateral extents of individual dike segments are unknown and are shown for illustrative purpose only. **a** East-looking view. **b** South-looking view

Both upper and lower sources feature a dominant crack sustaining the largest volume change (colored red), and a subdominant crack undergoing a smaller volume change (shaded gray). Both cracks in Fig. 12a display a similar sequence of inflation-deflation-inflation. The dominant crack in the lower source displays a volumetric response similar to that seen in the dominant crack at the upper source, but delayed by about 1 s with respect to the upper source. This implies a propagation speed of roughly 500 m/s between the two sources, consistent with the slow speed expected for the crack wave.

Figure 13 shows a picture of the upper conduit geometry consistent with the seismic source mechanisms imaged

in Fig. 12. The closely matching dips of the two dominant cracks in Fig. 12 point to a conduit that extends essentially straight from 80 m below sea level to the crater floor, 760 m above sea level. At a depth of 80 m below sea level the conduit features a sharp corner leading into a dike segment dipping  $40^\circ$  to the southeast. The upper dominant dike segment, and deep segment below the abrupt corner both strike northeast-southwest along a direction parallel to the elongation of the volcanic edifice and a prominent zone of structural weakness, as expressed by lineaments, dikes, and brittle structures. The surface trace of the main dike segment trends through the northern vent area, while that of the upper subsidiary segment extends

northwest-southeast in rough alignment with several vents active in the northwest quadrant of Stromboli in 2002–2003 [1]; the subsidiary dike trace intersects the main dike trace  $\sim 170$  m north of the northern vent area.

A striking aspect of the mechanisms imaged for the two sources in Fig. 12 is the presence of dominantly vertical single-force components with common-looking time histories, except for a polarity reversal in one source compared to the other. The upper source (Fig. 12a) displays an initially downward force followed by an upward force, while an upward force followed by a downward force is manifest in the lower source (Fig. 12b). These force components compensate each other so that the total momentum in the overall source volume is conserved. In contrast to the delay of  $\sim 1$  s in the volumetric components noted above, no significant delay is noted in the onsets of the vertical forces at the two sources, suggesting that transmission of the force between the two sources occurs via the faster speed (3.5 km/s [32]) of the compressional wave in the rock matrix.

Laboratory simulations carried out by James et al. [60] provide insights into the origin of the initial pressurization and downward force observed at the upper source in Fig. 12a. These experiments investigate the ascent of a slug of gas in a vertical liquid-filled tube featuring a flare that abruptly doubles the cross sectional area. The tube is instrumented with pressure transducers mounted flush with the inner tube wall, and one accelerometer mounted on the exterior of the tube, and the whole assembly is free to move in the vertical direction. Detailed measurements of the flow transients obtained by James et al. [60] show that the transit of a gas slug through the tube flare involves complex changes in flow pattern. A characteristic pinching of the slug tail is observed to occur synchronously with strong pressure and acceleration transients at the time the slug clears the flare, a picture consistent with the downward and inward motion of a liquid piston formed by the thickening film of liquid falling past the slug expanding in the wider tube. The sudden deceleration of the liquid annulus as it impinges the narrower inlet to the lower tube segment generates a pressure pulse in the liquid below the flare and also induces a downward force on the apparatus. These observations are consistent with the pressurization phase and initial downward force imaged for the upper source at Stromboli and a similar funneling mechanism was inferred by Chouet et al. [35] to be operative there. The repeatability of recorded pressure data and dependence of the magnitude of the pressure transient on slug size seen in the experiments of James et al. [60] are also in harmony with the observed spatio-temporal properties of VLP signals at Stromboli [32,35].

At the lower source, the start of the vertical force signal is synchronous with the onset of deflation of the lower dike segment (see arrows in the left panels in Fig. 12b). As the amplitude of the upward force increases, the lower dike segment continuously deflates. During the same interval, the dominant dike (red-colored volumetric trace in Fig. 12b) remains in a slightly deflated state. The lower dike reaches maximum deflation at the time the upper dike segment goes through a transition from weak contraction to expansion, and the upward force reaches its peak amplitude  $\sim 0.5$  s later. This picture is consistent with a compression of the lower dike synchronous with a downward acceleration of the liquid mass, both of which are suggestive of increasing external pressure on the conduit wall resulting from the downward vertical force acting at the upper source. Compression of the lower dike segment proceeds unimpeded until this process is overprinted by the arrival of the much slower volumetric expansion signal from the upper source.

Although not illustrated here, a similar slug disruption mechanism was imaged in the dike system underlying the southern vent [35]. In both conduit systems, the early response of the lower source relative to the volumetric disturbance arriving from the upper source may be interpreted as the passive response of the liquid to the movement of the conduit wall induced by elastic radiation from the force acting at the upper source. The scenario emerging from these dynamics is that of an upper source representing an active fluid phase and passive solid phase, and a lower source representing an active solid phase and passive fluid phase. The overall seismic source process associated with eruptions at Stromboli may then be summarized as follows. A slug of gas formed in the deeper reaches of conduit [18] rises through the lower conduit corner (the lower seismic source). At this point, the slug is most likely a few meters long and traverses this corner aseismically; past this corner, the slug expands on its way to the upper conduit bifurcation (the upper seismic source). The transit time from the lower to the upper seismic source is probably in the range of 5–15 minutes [60], hence related changes in magmatic head are well beyond the capability of broadband seismometers to detect and are not apparent within the VLP band imaged in Fig. 12. As it traverses the upper seismic source, the slug length has expanded to tens of meters and the slug is by then seismically noisy. Gravitational slumping of the liquid occurs as the slug expands through a flare in the conduit at this location. The slumping liquid rapidly decelerates in the narrowing dike neck, increasing the liquid pressure and inducing a volume expansion in the main conduit and its subsidiary branch. The rapid deceleration and associated pressurization of

the liquid couples to the conduit wall via the flare shoulders and induces a downward vertical force on the Earth. The volumetric signal propagates along the conduit at the slow speed of the crack wave, while the force signal itself propagates in the solid at the much higher speed of the compressional wave in the rock matrix, arriving at the lower conduit corner well before the crack wave. At this corner, the downward displacement of the rock induced by the force acting at the upper source impinges the bottom dike and squeezes this segment of conduit; this segment essentially acts like a spring that absorbs the downward motion of the rock. This scenario is consistent with both the small volume change of the lower dike segment, as well as its early response. The subsequent conduit response then reflects the combined effects of volumetric and mass oscillations of this liquid/gas/solid system, which are damped and eventually terminated by changing flow conditions.

The analyses carried out by Chouet et al. [35] illuminate the subsurface processes driving eruptions at Stromboli and clearly point to the key role played by the conduit geometry in controlling fluid motion and resultant processes. Each irregularity or discontinuity in the conduit provides a site where pressure and momentum changes resulting from flow processes associated with the transit of a gas slug through the discontinuity are coupled to the Earth, or where the elastic response of the conduit can couple back into pressure and momentum changes in the fluid. The resulting processes are naturally oscillatory and involve diverse dynamics that reflect the complex physico-chemical behavior of the volcanic system from the surface downward.

### Future Directions

Seismology alone cannot directly see into the conduit and resolve details of the actual fluid dynamics at the origin of the seismic source mechanisms revealed by analyses of LP or VLP signals. To develop a better understanding of fluid behavior responsible for these signals, laboratory experiments are required to explore the links between known flow processes and the resulting pressure and momentum changes. The pressure and momentum changes generated under laboratory conditions may then be compared with the pressure and momentum changes estimated from the time-varying moment-tensor and single-force components imaged from seismic data, yielding clues about the physical flow processes linked to the seismic source mechanism. Recent laboratory studies [59,60,85] have elucidated self-excitation mechanisms inherent to the fluid nonlinearity that are providing new

insights into the mechanisms imaged from seismic data. In particular, the results obtained by James et al. [60] demonstrate that direct links between the moment-tensor and single-force seismic-source mechanism and fluid-flow processes are possible and could potentially provide a wealth of information not available from seismic data alone. Together with these laboratory advances, numerical studies of multiphase flows are required to shed light on both the micro- and macrophysics of such flows (e. g., Badalassi [15]), along with models exploring the coupled dynamics of fluid and solid [102]. The key to a better understanding of volcanic processes lies in a sustained effort aimed at cross-fertilization between increasingly realistic numerical and experimental models of the fluid dynamics and elastodynamics, spatially and temporally dense field measurements of diverse geophysical signals at all frequencies, and chemical and physical evidence recorded in the eruptive products. In the next section, I present a brief summary of a modeling approach to two-phase fluids that holds great promise for the quantification of volcanic and hydrothermal source processes.

### Phase-Field Method

Liquid-gas mixtures are an ubiquitous feature of magmatic and hydrothermal systems. A major challenge in addressing these types of fluids is the description of the moving and deforming interface between the two components of fluid. Traditional fluid dynamics treats these as sharp interfaces on which matching boundary conditions must be imposed, which generally leads to intractable problems. Another difficulty is posed by the complex rheology of each component, whose internal microstructure is coupled with the flow field. The *phase-field method*, also known as the *diffuse-interface model*, circumvents these difficulties by considering the interface between components as a thin diffuse layer within which the two components are mixed and store a mixing energy. This idea follows from the original work of van der Waals [135] and expresses the properties of the interface by molecular forces and a mixing energy. In the limit of an interface width approaching zero, the diffuse-interface model reduces to the classical sharp-interface model and results in the proper expression for interfacial tension. Lowengrub and Truskinovsky [89] provide a detailed formulation of the conservative dynamics of the diffuse-interface model based on the classical procedure of Lagrangian mechanics. A review of diffuse-interface methods and related applications can also be found in Anderson et al. [8]. Noteworthy are the more recent applications by Kendon et al. [71], Xu et al. [141], Xu et al. [142], and Yue et al. [146]. The following

discussion is restricted to a brief description of the basic principles of the method based on the work of Kendon et al. [71], who consider the evolution of a symmetric binary fluid mixture after a deep quench.

**Equilibrium State** A two-phase mixture is described by two scalar fields  $n_A$  and  $n_B$  expressing the local molar densities of the fluid components  $A$  and  $B$ . The corresponding local density,  $\rho$ , is given by:

$$\rho = m_A n_A + m_B n_B, \quad (2)$$

where  $m_A$  and  $m_B$  are the molecular weights of phases  $A$  and  $B$ , respectively. The local composition of the fluid is quantified by a dimensionless parameter,  $\phi$ ,

$$\phi = \frac{n_A - n_B}{n_A + n_B}, \quad (3)$$

called the order parameter; the values of  $\phi$  span the range  $[-1, +1]$  with the value  $+1$  denoting the pure phase  $A$  and the value  $-1$  denoting the pure phase  $B$ .

The chemical equilibrium between the two phases is described through a minimization of the free energy  $\mathcal{F}$ , which represents the integral over the body of the local free-energy density (with units of  $\text{Jm}^{-3}$  or, equivalently,  $\text{Nm}^{-2}$ ), a function of the fluid composition and its gradient [19]:

$$\mathcal{F} = \int \left\{ f_0(\phi, P) + \frac{1}{2} \kappa (\nabla \phi)^2 \right\} \text{d}\mathbf{r}. \quad (4)$$

The term  $f_0(\phi, P)$  in the above equation represents the bulk free-energy density, which is assumed to take the form of a double-well with respect to  $\phi$ . The detailed functional form of the double-well potential is not important [17,71,127,128,141,142,146] and may be set as [71,141]:

$$f_0(\phi, P) = \frac{a}{2} \phi^2 + \frac{b}{4} \phi^4 + P \ln \frac{P}{P_0}, \quad (5)$$

where the polynomial terms represent the bulk properties of the fluid. The parameter  $a < 0$  and parameter  $b$  is always positive [141]. The term in  $P$  yields a positive background pressure and does not affect the phase behavior (see discussion of pressure below). The form of this latter term is selected here for convenience, with  $P_0$  representing an arbitrary reference pressure. As defined above, the function  $f_0$  features two minima for  $\phi = \pm \sqrt{-a/b}$  that correspond to the coexisting pure bulk phases. As-

suming  $b = -a$ , one obtains the equilibrium values  $\phi = \pm 1$  [141].

The squared gradient term in Eq. (4), with  $\kappa$  a positive constant, represents weakly non-local interactions between the components. The effect of these interactions favors mixing of the components in contrast to the tendency of the bulk free energy  $f_0$ , which is toward total separation of the phases into domains of pure components [146].

According to the model represented by Eq. (5), minimization of the free energy is achieved through the creation of two bulk domains at compositions  $\phi = \pm 1$  separated by interfaces across which the composition varies smoothly from one phase to the other. The change in  $\mathcal{F}$  induced by a small local change in composition is described by the chemical potential,  $\mu$ ,

$$\mu = \frac{\delta \mathcal{F}}{\delta \phi}, \quad (6)$$

and equilibrium between the coexisting bulk phases is reached when  $\mu$  is everywhere zero [19,71]. Using Eqs. (4) and (5), one obtains the following expression for  $\mu$ :

$$\mu = a\phi + b\phi^3 - \kappa \nabla^2 \phi. \quad (7)$$

The equilibrium interfacial profile is given by  $\phi(x) = \tanh(2x/\xi)$ , where  $x$  is the coordinate normal to the interface [141]. With the choice  $b = -a$ , this yields an interfacial width,  $\xi = 2\sqrt{-2\kappa/a}$ , and surface tension,  $\sigma = (2/3)\sqrt{-2a\kappa}$  [141]. The interface thickness may then be defined as the width over which 90% of the variation of  $\phi$  occurs; this yields an equilibrium interface thickness of  $1.47222\xi$ .

As interfaces in the fluid can exert non-isotropic forces, pressure is a tensor. The thermodynamic pressure tensor  $P_{ij}^{\text{th}}$  is obtained from the free energy as [41,71,127]

$$\begin{aligned} P_{ij}^{\text{th}} &= \left( P \frac{\delta \mathcal{F}}{\delta P} + \phi \frac{\delta \mathcal{F}}{\delta \phi} - \left[ f_0(\phi, P) + \frac{1}{2} \kappa (\nabla \phi)^2 \right] \right) \delta_{ij} \\ &\quad + \kappa \frac{\partial \phi}{\partial x_i} \frac{\partial \phi}{\partial x_j} \\ &= P + P_{ij}^{\text{chem}}, \end{aligned} \quad (8)$$

where  $P$  is the bulk pressure, and  $P_{ij}^{\text{chem}}$  is the chemical pressure component given by

$$\begin{aligned} P_{ij}^{\text{chem}} &= \left[ \frac{1}{2} a \phi^2 + \frac{3}{4} b \phi^4 - \kappa \phi \nabla^2 \phi - \frac{1}{2} \kappa (\nabla \phi)^2 \right] \delta_{ij} \\ &\quad + \kappa \frac{\partial \phi}{\partial x_i} \frac{\partial \phi}{\partial x_j}, \end{aligned} \quad (9)$$

in which  $\delta_{ij}$  is the Kronecker symbol ( $\delta_{ij} = 0$  for  $i \neq j$ , and  $\delta_{ij} = 1$  for  $i = j$ ). Note that the expression be-

tween brackets contributes to the isotropic fluid pressure and that only the last term is anisotropic.

**Conservation Equations** The temporal evolution of the fluid composition  $\phi$  is described by the Cahn–Hilliard diffusion-advection equation [20]

$$\frac{\partial \phi}{\partial t} + \mathbf{v} \cdot \nabla \phi = \nabla \cdot (\gamma \nabla \mu), \quad (10)$$

where  $\gamma$  is the order-parameter mobility and  $\mathbf{v}(\mathbf{r})$  is the fluid velocity.

The dynamics of the fluid are described by the Navier–Stokes equations, whose exact forms depend on the system considered. The equations describing a viscous, compressible, isothermal flow are the conservation of mass:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (11)$$

and conservation of momentum:

$$\rho \left[ \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right] = -\nabla \cdot \mathbf{P}^{\text{th}} + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g}, \quad (12)$$

where  $\mathbf{g}$  is the acceleration of gravity vector,  $\mathbf{P}^{\text{th}}$  is the thermodynamic pressure tensor with components given by Eqs. (8) and (9), and  $\boldsymbol{\tau}$  is the viscous stress tensor, which for a newtonian fluid is given by

$$\tau_{ij} = \lambda e_{kk} \delta_{ij} + 2\eta e_{ij}, \quad (13)$$

where  $\eta$  is the coefficient of viscosity (dynamic viscosity) and  $\lambda$  is the second coefficient of viscosity generally defined as  $\lambda = -(2/3)\eta$  [130]. Summation over repeated indices is implied. In this equation  $e_{ij}$  is the strain rate tensor given by:

$$e_{ij} = \frac{1}{2} \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right). \quad (14)$$

The field variables are the order parameter  $\phi$ , the three components of fluid velocity  $\mathbf{v}$ , density  $\rho$ , and bulk pressure  $P$ . Under isothermal conditions  $P$  may be specified through a van der Waals equation of state. The diffusion-advection Eq. (10), continuity Eq. (11), and the three momentum Eqs (12), along with an equation of state for  $P$ , therefore provide a complete description of the physico-chemical evolution of the binary fluid mixture. All other quantities can be obtained from the relations (2), (3), (7), (8), (9), (13), and (14). For non-isothermal flow, a complete description is obtained from Eqs. (10–12), along with two additional equations describing the conservation of energy and entropy production [8].

The thermodynamic properties of the two-phase system enter the above equations through the chemical potential  $\mu = \delta \mathcal{F} / \delta \phi$ , and pressure tensor  $\mathbf{P}^{\text{th}}$ , which are both obtained from the free energy Eq. (4). As a result, interfaces between the different fluid phases appear naturally within the model and do not need to be put in as boundary conditions. The procedure is quite general and may conceivably be applied to any complex fluid with a properly defined free energy.

The coupled Cahn–Hilliard/Navier–Stokes system of equations representing binary fluid systems is analytically intractable, and efforts have mainly been directed toward the development of robust, stable numerical schemes. The description of the fluid in terms of a smooth variation of the composition  $\phi(\mathbf{r})$  provides a coarse-grained representation of the fluid where the smallest length scale is larger than the average distance between molecules. Under dynamical conditions, care must be taken to ensure that this coarse-grained description adequately represents the underlying microscopic physics. For the nominal interfacial thickness representing 90% of the variation of  $\phi$  this typically requires 7–10 grids to resolve [146]. Numerical applications include the Lattice Boltzmann Method (LBM) [16,71,112,113,127,128,141,142], and various finite-difference approaches based on an Implicit-Explicit (IMEX) discretization [12], semi-implicit discretization [15,146], fully implicit discretization [73], or fully explicit central-differenced staggered-grid discretization [58].

An example of application of this method that may provide a useful metaphor for the process of Vulcanian degassing discussed in Sect. “**Coupled Diffusive-Elastic Pressurization at Popocatepetl Volcano**” is the 3D spinodal decomposition of a density-matched binary fluid mixture in a channel under shear [15]. A remarkable feature of this type of flow is the formation of string-like structures. Similar structures have been observed in immiscible viscoelastic systems subjected to complex flow fields [93], and such process may also play a role in the formation of degassing channels in a rhyolitic bubbly magma driven by slow pressurization in response to crystallization and degassing. A 2D application of the method to the dynamics of a gas slug ascending in a liquid-filled conduit featuring a flare is described in the chapter by *D’Auria and Martini*. The numerical results obtained by these authors reproduce the basic behavior observed in the experimental simulations of James et al. [59] and James et al. [60] and hold great potential as a key link between the seismic source mechanisms imaged at Stromboli (see Sect. “**Slug Disruption at Stromboli**”) and the underlying volcanic fluid dynamics.

## Acknowledgment

I am grateful to Phil Dawson for his assistance in drafting figures. I am indebted to Robert Tilling and David Hill for careful reviews and helpful suggestions.

**Subduction zone earthquake cycle** Megathrust fault, the interface between the two converging lithospheric plates at a subduction zone, moves in a stick-slip fashion. In the “stick” phase, the fault is locked or slips very slowly, allowing elastic strain energy to be accumulated in both plates around the fault. Every few decades or centuries, the fault breaks as high-rate “slip” to release the strain energy, causing a large or great earthquake, usually accompanied with a tsunami. An interseismic period and the ensuing earthquake together is called a subduction zone earthquake cycle. The word cycle by no means implies periodicity. Neighboring segments of the same subduction zone may exhibit different temporal patterns of earthquake cycles.

**Accretionary wedge (prism)** At some subduction zones, as one plate subducts beneath the other, some sediment is scraped off the incoming plate and accreted to the leading edge of the upper plate. Because of its wedge shape, the accreted sedimentary body is called the accretionary wedge (or accretionary prism). If all the sediment on the incoming plate is subducted, there is still a sedimentary wedge in the frontal part of the upper plate, but it is usually very small and consists of sediments derived from the upper plate by surface erosion.

**Coulomb plasticity** Coulomb plasticity is a macroscopic, continuum description of the most common type of permanent deformation of Earth materials such as sand, soil, and rock at relatively low temperature and pressure and is widely used in civil engineering and Earth science. In detail, the deformation mechanism is actually brittle shear failure, with or without emitting elastic wave energy. The macroscopic yield criterion is the Coulomb’s law, in which shear strength increases linearly with confining pressure. If the strength does not change with permanent deformation, the material is said to be perfectly plastic. Note that in Earth science the word plasticity is also used to indicate thermally activated creep, but it is very different from the meaning used herein.

**Velocity-weakening and strengthening** These are macroscopic descriptions of dynamic frictional behavior of contact surfaces. Velocity-weakening, featuring a net decrease in frictional strength with increasing slip rate, is the necessary condition for a fault to produce earthquakes. It differs from slip-weakening in that a velocity-weakened fault will regain its strength when the slip slows down or stops. Velocity-strengthening is the opposite of velocity-weakening and is the necessary condition for a fault to resist earthquake rupture. Detailed physical processes on the contact surfaces or within the fault zones controlling their frictional behavior are still being investigated.

## Definition of the Subject

Mechanics of wedge-shaped geological bodies such as accretionary prisms at subduction zones and fold-and-thrust belts at collision zones is of great scientific interest, mainly because it enables us to use the observed morphology and deformation of the wedge-shaped bodies to constrain properties of the thrust faults underlying them. Davis et al. [12] drew analogy between these wedge-shaped bodies and the sand wedge in front of a moving bulldozer and established a mathematical model. Their work triggered wide applications of wedge mechanics to geology. The fundamental process described in wedge mechanics is how gravitational force, in the presence of a sloping surface, is balanced by basal stress and internal stress. The internal state of stress depends on the rheology of the wedge. The most commonly assumed wedge rheology for geological problems is perfect Coulomb plasticity [12], and the model based on this rheology is referred to as the Coulomb wedge model.

The Coulomb wedge model was designed to explain geological processes of timescale of hundreds of thousands

of years. The state of stress is understood to be an average over time, and the wedge is assumed to be in a critical state, that is, uniformly at the Coulomb yield stress. In the application of the model to the sedimentary wedges at subduction zones, attention is now being paid to the temporal changes in stress and pore fluid pressure associated with great subduction earthquakes which have recurrence intervals of decades to centuries. To account for the short-term stress changes, Wang and Hu [50] expanded the Coulomb wedge model by introducing the elastic – perfectly Coulomb plastic rheology. The expanded Coulomb wedge model links long-term geology with coseismic processes and provides a new perspective for the study of subduction zone earthquakes, tsunami generation, frontal wedge structure, and forearc hydrogeology.

**Introduction**

Sloping surfaces are commonly dealt with in engineering problems such as dam design and landslide hazard mitigation. In the presence of a sloping surface, materials under gravitational force tend to “flow” downhill and thus generate tensile stress, but whether collapse actually occurs depends on the strength of the material. Materials used in construction can easily sustain stresses caused by the presence of a vertical surface, but a material of no shear strength such as stationary water cannot support any surface slope. A geological wedge, such as the accretionary prism at a subduction zone (see Fig. 1a), overlies a dipping fault, and hence its internal stress is controlled by the strength of the fault as well. If the basal fault is a thrust fault and is strong relative to the strength of the wedge material, the wedge can undergo compressive failure. Wedge mechanics thus consists of two aspects: the frictional behavior of the basal fault and the deformation of the wedge itself. Given a wedge with density  $\rho$ , surface slope angle  $\alpha$ , and basal dip  $\beta$  (see Fig. 1b), Elliot [16], Chapple [8], and later workers all considered the following equations of force balance (exact form varies between publications depending on the assumed coordinate systems)

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} - \rho g \sin \alpha = 0, \tag{1a}$$

$$\frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} + \rho g \cos \alpha = 0, \tag{1b}$$

where  $g$  is gravitational acceleration,  $\sigma_x$  and  $\sigma_y$  are normal stresses, and  $\tau_{xy}$  is shear stress.

It was Davis et al. [12] who introduced Coulomb plasticity into wedge mechanics. Coulomb plasticity was initially proposed by French engineer Coulomb in 1773 to describe the mechanical strength of soil and sand. The

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 1

**a** Schematic illustration of a subduction zone accretionary wedge. **b** Coordinate system used in this article ( $x, y$ ). The surface of the wedge and the subduction fault are simplified to be planar, with slope angle  $\alpha$  and dip  $\beta$ , respectively, and the  $x$  axis is aligned with the upper surface.  $\psi_0$  is the angle between the maximum compressive stress  $\sigma_1$  and the upper surface.  $D$  is water depth.  $\rho$  and  $\rho_w$  are densities of the wedge material and overlying water, respectively.  $\mu, \lambda, \mu_b$  and  $\lambda_b$  are as defined in Eqs. (2) and (3)

Coulomb failure criterion in its simplest form is

$$\tau = S - \mu(\sigma_n + P) = S - \mu \bar{\sigma}_n, \tag{2}$$

where  $\tau$  is shear strength,  $\sigma_n$  is normal stress,  $S$  is cohesion, and  $\mu = \tan \varphi$  is the coefficient of internal friction with  $\varphi$  called the internal friction angle.  $P$  is the pressure of fluids present in the pore space between solid grains and in various small fractures and is loosely referred to as the pore fluid pressure. Note that the effective stress  $\bar{\sigma}_n = \sigma_n + P$  is normal stress with  $P$  subtracted. The plus sign is due to the custom in mechanics (except rock mechanics) that compressive stress is defined to be negative, but pressure, although also compressive, is defined to be positive. Here the plane on which the stress is evaluated is oriented in any arbitrary direction, but failure will start on the set of planes that meets the above criterion. This is a generalization of the Coulomb friction criterion for a fixed fault plane

$$\tau_b = S_b - \mu_b(\sigma_{n_b} + P_b) = S_b - \mu_b \bar{\sigma}_{n_b}, \tag{3}$$

where  $S_b$  is the cohesion of the fault,  $\mu_b = \tan \varphi_b$  is its friction coefficient, and  $P_b$  is fluid pressure along the fault.  $S_b$  is usually negligibly small and almost always taken to be

zero, and  $\mu_b$  is normally significantly lower than  $\mu$ . A well developed fault such as a plate boundary fault is a zone of finite thickness filled with gouge material, so that the “friction” described by (3) or other friction laws is actually the shear deformation of the gouge in the fault zone, and  $P_b$  is actually pore fluid pressure of the gouge. Fault gouge is often made very weak by the presence of hydrous minerals [5,42], such that the collective strength of the fault zone material is much less than the strength of the rocks on both sides. Another process that may weaken the fault is that the local hydrogeological regime may dynamically maintain  $P_b$  in the fault zone to stay higher than  $P$  on both sides [14]. For both Coulomb plasticity and Coulomb friction, strength increases with depth because of the increasing pressure thus normal stress.

It has long been recognized that Coulomb plasticity, featuring strong depth dependence, applies to the shallow part of Earth’s lithosphere. The most common example is the use of Byerlee’s law of rock friction [6] to describe brittle strength in “Christmas-tree”-like vertical strength-depth profiles of the lithosphere. The Byerlee’s law is an empirical Coulomb friction law. By assuming that faults, i. e., potential failure planes, are oriented in all directions, we regard the brittle part of the lithosphere as being Coulomb plastic. This example also illustrates how a system of numerous discrete structures can be regarded as a continuum at a much larger scale. Similarly, although a geological wedge actually consists of numerous blocks divided by fractures, Coulomb plasticity can be used to describe its overall rheology. However, specific values of friction parameters for submarine wedges may be quite different from those in the Byerlee’s law.

The Coulomb wedge model explains how the geometry (taper) of the wedge is controlled by the interplay between the gravitational force, the strength of the wedge material, and the strength of the basal fault. The wedge strength and fault strength are both strongly influenced by pore fluid pressure, and the most popular application of the model is to estimate pore fluid pressure from observed wedge geometry. Since the work of Davis et al. [12], more rigorous analytical solutions have been derived [9,10,18,50,55], and some extensions have been proposed, e. g., [2,3,17,54]. Lithospheric scale numerical models are often used to study the evolution of geological wedges including such effects as erosion and sedimentation in collision or subduction zone settings, e. g., [20,53]. Utilizing the bulldozer – sand wedge analogy, important physical insights have been obtained from sandbox experiments [7,11,29,30,31,35,41,52]. For a list of applications of the Coulomb wedge model to subduction-zone accretionary prisms, see [50].

### Stable and Critical Coulomb Wedges

Depending on the state of stress, a Coulomb wedge can be at a critical state, that is, everywhere at Coulomb failure, or a stable (also referred to as supercritical) state, that is, everywhere not at failure (see Fig. 2). The taper of a critical wedge will not change if the stress does not change; note that a critical wedge of stable geometry should not be confused with a stable wedge. Stress solutions have been derived for both critical and stable states. Here we only summarize the simplest, exact solution for a cohesionless wedge ( $S = 0$ ) derived in the coordinate system shown in Fig. 1b, because of the convenience of its application as compared to other solutions. The wedge is assumed to be elastic – perfectly Coulomb plastic. If it is at the critical state, it obeys (2); if it is at the stable state, it obeys the Hooke’s law of elasticity. The basal thrust fault obeys (3). The wedge is assumed to be under water of density  $\rho_w$  and depth  $D$  (a function of  $x$ ; see Fig. 1b). By defining a Hubbert–Rubey fluid pressure ratio within the wedge [9]

$$\lambda = \frac{P - \rho_w g D}{-\sigma_y - \rho_w g D}, \tag{4}$$

and a similar parameter along the basal fault [51]

$$\lambda_b = \frac{P_b - \rho_w g D + \lambda H}{-\sigma_y - \rho_w g D + H}, \tag{5a}$$

where

$$H = \frac{\sigma_y - \sigma_n}{1 - \lambda}, \tag{5b}$$

and assuming  $S_b = 0$ , we can rewrite (3) into

$$\tau_b = -\mu_b \bar{\sigma}_{n-b} = -\mu'_b \bar{\sigma}_n, \tag{6a}$$

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 2

An example to show how stresses in an elastic – perfectly Coulomb-plastic wedge, with  $\alpha = 5^\circ$ ,  $\beta = 4^\circ$ ,  $\mu = 0.6$ , and  $\lambda = 0.86$ , are affected by basal friction  $\mu'_b = \mu_b(1 - \lambda_b)$ . Converging arrows represent principal stresses, with the larger one being  $\sigma_1$ . **a** Compressively stable state. **b** Compressively critical state. *Dot-dashed* lines are plastic slip lines (potential failure planes)

where

$$\mu_b'' = \frac{1 - \lambda_b}{1 - \lambda} \mu_b = \frac{\mu_b'}{1 - \lambda}. \tag{6b}$$

The strength of the basal fault is represented by  $\mu_b' = \mu_b(1 - \lambda_b)$  which always appears as a single parameter and is commonly referred to as the effective friction coefficient. The hydrological process in the fault zone may differ from that in the wedge and thus cause a sharp gradient in fluid pressure across the wedge base. By allowing  $\lambda_b$  to be different from  $\lambda$ , we use a pressure discontinuity to approximate the sharp gradient. Because stress is continuous across the basal fault, the discontinuity in pore fluid pressure leads to a discontinuity in effective stress. The second equality of Eq. (6a) shows the relation between the effective stress along the fault ( $\bar{\sigma}_{n,b}$ ) and the effective stress just above the fault ( $\bar{\sigma}_n$ ). The establishment of (6) allows the following exact stress solution to be derived. In this expression, all stress components are normalized by  $\rho gy$  (e.g.,  $\bar{\sigma}'_x = \bar{\sigma}_x/\rho gy$ ).

$$\bar{\sigma}'_x = -m(1 - \lambda) \cos \alpha, \tag{7a}$$

$$\bar{\sigma}'_y = -(1 - \lambda) \cos \alpha, \tag{7b}$$

$$\tau'_{xy} = (1 - \rho') \sin \alpha, \tag{7c}$$

where  $\rho' = \rho_w/\rho$ , and the effective stress ratio  $m = \bar{\sigma}_x/\bar{\sigma}_y$  depends on whether the wedge is stable or critical. If the wedge is in a stable state (elastic) [50],

$$m = 1 + \frac{2(\tan \alpha' + \mu_b'')}{\sin 2\theta(1 - \mu_b'' \tan \theta)} - \frac{2 \tan \alpha'}{\tan \theta}, \tag{8}$$

where  $\theta = \alpha + \beta$ , and,

$$\tan \alpha' = \frac{1 - \rho'}{1 - \lambda} \tan \alpha. \tag{9}$$

The angle  $\psi_0$  between the most compressive stress  $\sigma_1$  and the upper surface is uniform (see Fig. 1b). A more general solution for a purely elastic wedge can be found in [23]. If the wedge is in a critical state (perfectly plastic) [9]

$$m = m^c = 1 + \frac{2 \tan \alpha'}{\tan 2\psi_0^c}, \tag{10}$$

where  $\psi_0^c$  is the value of  $\psi_0$  in the critical state and is given by the following relation

$$\frac{\sin \varphi \sin 2\psi_0^c}{1 - \sin \varphi \cos 2\psi_0^c} = \tan \alpha'. \tag{11}$$

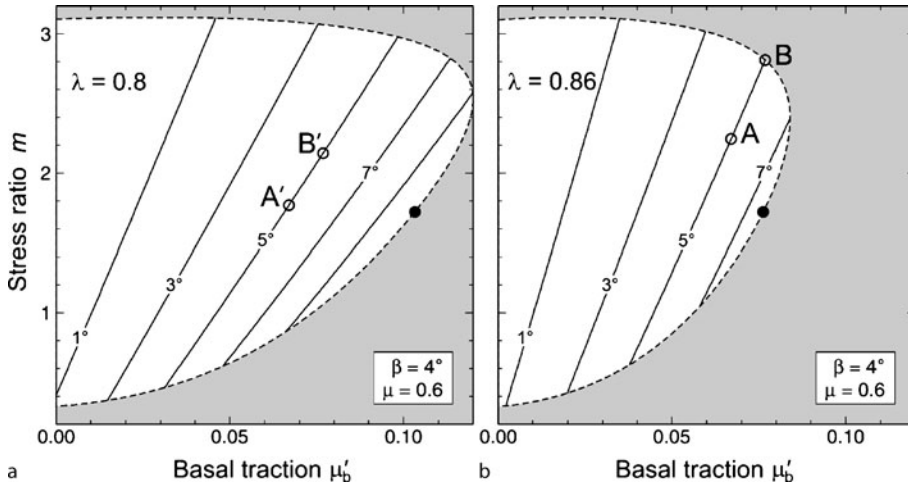

In the above expressions, superscript c indicates critical state. If the wedge has a cohesion that is proportional to depth, (10) and (11) will be modified only slightly [50,55].

A wedge of fixed geometry has two  $m^c$  values. The lower one defines the extensionally critical state, in which the wedge is on the verge of gravitational collapse. This occurs if friction along the basal fault is very low relative to the strength of the wedge material. The higher one defines the compressively critical state, in which the wedge is everywhere on the verge of thrust failure. If  $m$  lies between these two critical values, the wedge is in a stable state and only experiences elastic deformation. A change of basal friction  $\mu_b'$  will cause a change in  $m$  and thus may potentially cause the wedge to switch between the stable and critical states (see Fig. 3). An example of a wedge being in a stable or compressively critical state as controlled by basal friction is shown in Fig. 2. The plastic slip lines (potential failure planes) in the critical wedge (see Fig. 2b) are reminiscent of the out-of-sequence faults in a real accretionary prism (see Fig. 1a).

If we fix the values of all material properties, the critical-wedge solution ( $m = m^c$ ) defines a relation between  $\alpha$  and  $\beta$  representing all possible geometries of a critically tapered wedge (dashed line in Fig. 4). This is a very commonly used diagram, in which the lower branch of the  $\alpha - \beta$  curve represents compressively critical states, and the upper branch represents extensionally critical states. Combinations of  $\alpha$  and  $\beta$  outside of the stability region comprise unstable geometries and cannot exist in steady state. If sedimentary wedges of subduction zones are compressively critical, their observed  $\alpha - \beta$  pairs should line up with the lower branch. However, it has been shown that most of them fall in the stable or even extensionally unstable region of this type of diagram [30,44]. To fit observations, we need to move the lower branch upward by a significant amount. In order to do this, we need to assume either a weaker wedge or a stronger basal fault, or both. This is more simply illustrated by Fig. 3. Given wedge geometry and internal friction, if the state of the wedge is to be changed from stable to compressively critical, we need to have a higher friction ( $\mu_b'$ ) along the basal fault (i.e., greater stress coupling) and/or higher pore fluid pressure within the wedge (i.e., greater  $\lambda$  weakening the wedge material by reducing effective pressure). Wang and Hu [50] proposed that higher  $\mu_b'$  and  $\lambda$  can occur at the time of a great earthquake and introduced the concept of dynamic Coulomb wedge.

### Dynamic Coulomb Wedge

The concept of dynamic Coulomb wedge is based on the widely recognized frictional behavior of subduction faults. Ignoring the presence of along-strike variations of frictional properties, we can summarize the frictional

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 3

Effective stress ratio  $m$  (Eq. (7)) as a function of basal friction  $\mu'_b = \mu_b(1 - \lambda_b)$  for wedges of the same basal dip ( $\beta = 4^\circ$ ) but different surface slope angles ( $\alpha$ ) as labelled on the curves (solid lines). a and b are for two different pore fluid pressure ratio values within the wedge. Each curve is terminated at the extensionally critical state at a lower  $\mu'_b$  and the compressively critical state at a higher  $\mu'_b$ . The end points (connected by a dashed line) outline the stable region (white). No solution exists outside this region. The solid circle marks the state in which the surface slope is at the angle of repose. It divides the line of critical states (dashed line) into the compressive part (above) and extensional part (below). Open circles in b labelled A and B mark the states shown in Fig. 2a and b, respectively. State A' in (a) is for the same wedge with the same basal friction as state A in (b) except for a lower pore fluid pressure ratio, and state B' in (a) corresponds to state B in (b) in the same fashion. Comparison of B with B' shows how an increase in pore fluid pressure weakens the wedge

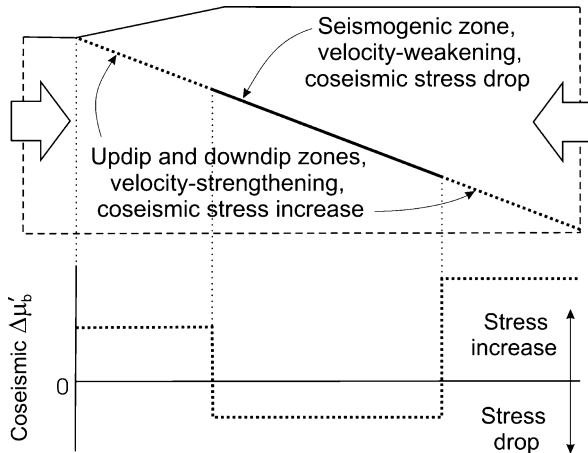

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 4

Possible wedge geometry ( $\alpha$  and  $\beta$ ) given material strength and basal friction. The dashed line indicates critical wedge geometry, with the upper and lower branches representing extensionally and compressively critical states, respectively. Contours of  $\psi_0$  (in degrees) are shown in the stable region (white)

behavior in a simplified cross-section view (see Fig. 5). The seismogenic zone exhibits velocity-weakening behavior: It weakens in response to high-rate slip, resulting in

slip instability, that is, earthquakes. The segments updip and downdip of the seismogenic zone exhibits velocity-strengthening: They strengthen at the time of the earthquake to develop higher stress to resist rupture, but they may slip aseismically after the earthquake to relieve the high stress attained during the earthquake. We assume that the actively deforming sedimentary wedge overlies the updip segment (also see Fig. 1a).

Microscopic mechanisms for the velocity-weakening behavior of the seismogenic zone and the velocity-strengthening behavior of the aseismic zones are subjects of intense research. The aseismic behavior of the deeper part of any fault is intuitively easy to comprehend; higher temperature at greater depths increasingly enhances viscous deformation and inhibits brittle faulting. There are different physical explanations for the velocity-weakening behavior of the seismogenic zone as summarized in [37]. The mechanism responsible for the velocity-strengthening behavior of the updip segment is yet to be identified, although it is widely accepted that the presence of clay minerals has something to do with it [24,33,34,45,46]. Laboratory experiments indicate that dilatancy of granular fault zone material during fast slip can lead to velocity-strengthening [32]. We think part of the reason for the velocity-strengthening behavior of the updip segment may be its

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 5

Schematic illustration of the subduction zone model considered in this work. Large arrows represent interseismic strain accumulation. An earthquake is represented by a sudden decrease in the effective friction coefficient  $\mu'_b$  of the seismogenic zone by  $\Delta\mu'_b$ . Coseismic strengthening of the updip and downdip zones is represented by a sudden increase in their  $\mu'_b$  values

inability to localize into a very thin slip zone. Seismic rupture occurs along very thin slip zones of a few millimeters thickness that are parts of a thicker fault zone [40]. Fast slip of the updip segment, if triggered by the rupture of the deeper seismogenic zone, may tend to drag along fault zone materials over a more distributed band and thus meet greater resistance. This view is different from the velocity-strengthening process described by laboratory-derived rate- and state-dependent friction laws [15,39] in which dynamic changes in the thickness of the slip zone plays no role.

Regardless of the microscopic mechanisms, the downdip variation of the frictional behavior is expected to bring direct consequences to wedge deformation. In an earthquake, thrust motion of the seismogenic zone causes the frontal wedge to be pushed from behind, and velocity-strengthening of the updip megathrust segment gives rise to higher stress at its base. If the wedge is originally in a stable state, the coseismic strengthening of the basal fault may increase the  $m$  value in (7a) from subcritical to critical. After the earthquake, when the seismogenic zone has returned to a locked state, the stress along the updip segment will relax. The decrease in  $\mu'_b$  leads to a smaller  $m$ , and therefore the frontal wedge returns to a stable state.

If we ignore the change in fluid pressure, the above described process can be seen as the stress ratio  $m$  moving up-and-down along one of the solid lines in Fig. 3 in re-

sponse to changes in  $\mu'_b$  in earthquake cycles. During a big earthquake, it will hit the upper end of the line ( $m^c$ ). The state of stress for a stable wedge before the earthquake ( $m < m^c$ ) and that for a compressively critical wedge during the earthquake ( $m = m^c$ ) are illustrated by examples in Fig. 2a and b, respectively. Fluid pressure variation should not be ignored, however. For example, the same basal friction as shown in Fig. 2b (also see point B in Fig. 3b) will not drive the wedge to failure if the pore fluid pressure is lower, as shown by point B' in Fig. 3a.

During an earthquake, the sudden compression of the frontal wedge will cause its internal pore fluid pressure to increase, coseismically weakening the wedge material. By comparing Fig. 3a and b, we can see that if the pore fluid pressure ratio in the wedge is higher, the increase in basal friction required to push the wedge into a critical state can be smaller. We may envisage the following scenario. The pore fluid pressure in a frontal wedge may decrease to some degree over the interseismic period due to fluid drainage through fractures and stress relaxation, and the mechanical state of the wedge before an earthquake can be represented by point A' in Fig. 3a as opposed to point A in Fig. 3b. An earthquake not only causes the basal friction to increase but also the pore fluid pressure within the wedge to rise, such that the wedge enters a critical state represented by point B in Fig. 3b. Therefore, the coseismic strengthening of the basal fault and coseismic weakening of the wedge both work toward bringing the wedge to failure.

All previous applications of the Coulomb wedge model to subduction zones assume  $m = m^c$ . The dynamic Coulomb wedge model of [50] explains the meaning of this long-term  $m^c$ : At least as an end-member scenario, it is the value of  $m$  briefly achieved in numerous large earthquakes. The “average” basal stress that determines the wedge geometry in long-term Coulomb wedge models is actually the peak stress achieved at the time of large earthquakes. Thus, the common illustration of the peaceful scene of a bulldozer pushing a sand wedge in classical Coulomb wedge papers (see Fig. 6a) should be modified to reflect the unpleasant reality of the world (see Fig. 6b).

### Stress Drop and Increase in a Subduction Earthquake

It is important to know the possible amount of stress increase in the frontal wedge for a given earthquake. The increase cannot be arbitrarily large; it is limited by the level of the “push” on the wedge from behind during an earthquake. For this purpose, a numerical model of a larger scale embracing the essential components of the subduc-

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 6

Cartoon illustrating the difference between the classical Coulomb wedge model and the dynamic Coulomb wedge model for subduction zone accretionary prisms. In the classical wedge model,  $m = m^c$ . In the dynamic wedge model,  $m < m^c$  in the interseismic period but  $m = m^c$  at the time of a large earthquake. See Eqs. (7) and (10) for definition of  $m$  and  $m^c$

tion fault as shown in Fig. 5 must be considered, because the stress interaction between the frontal wedge and the material overlying the seismogenic zone cannot be handled by the analytical Coulomb wedge solutions. For an illustration, we consider the following model geometry, representative of most subduction zones. The subduction fault has a constant dip  $\beta = 4^\circ$ . The frontal 50 km of the upper plate has a surface slope  $\alpha = 5^\circ$ , representing the sedimentary wedge, and the rest of the upper plate has a flat surface. We wish to focus on the process of stress transfer from the seismogenic zone to the updip segment during an earthquake, and a static, uniform, and purely elastic model suffices. For simplicity, the effect of pore fluid pressure change on deformation is neglected.

We use a 2D plane-strain finite element model and simulate Coulomb friction along the fault using the method of Lagrange-multiplier Domain Decomposition [48]. The model boundaries are set sufficiently far away so that the model resembles a half-space. For numerical stability, we invoke gravity (assuming a rock density of  $2800 \text{ kg/m}^3$  only when determining yield stress along the fault but exclude it from the deformation calculation. The effect of gravity on coseismic elastic deformation is very small and is neglected in most earthquake cycle deformation models, but gravity is important in the calculation of frictional slip of the fault.

We first generate a pre-stress field by moving the remote seaward and landward model boundaries toward each other against a locked fault. At this stage of “interseismic” strain accumulation, we use a  $\mu'_b$  of 0.04 for the seismogenic and updip segments and 0.004 for the deeper segment. The low strength of the subduction fault is based on the weak fault argument as summarized in Wang and Hu (2006). The nearly zero strength of the deeper part represents a relaxed state after a long time of locking of the seismogenic zone. However, the absolute strength of the fault has no effect on our results. It is the incremental change in fault strength ( $\Delta\mu'_b$ ) at the time of the earthquake that is relevant. A negative  $\Delta\mu'_b$  represents the net effect of weakening, and a positive  $\Delta\mu'_b$  represents the net effect of strengthening. The velocity-dependent evolution of  $\Delta\mu'_b$  through time is not explicitly simulated.

Three examples are shown in Fig. 7. In all cases,  $\Delta\mu'_b = -0.01$  is assigned to the 150-km wide seismogenic zone. This value is chosen to produce an average stress drop of a few MPa (see Fig. 7a), typical of values observed for great subduction earthquakes. The stress drop releases elastic strain energy initially stored in the system, leading to fault slip that represents an earthquake rupture. The deepest segment is assigned a sufficiently large positive  $\Delta\mu'_b$  so that it cannot slip. The examples differ in the  $\Delta\mu'_b$  values assumed for their 50 km wide updip segment, which is the coseismic increase in basal friction in the dynamic Coulomb wedge model.

*Example 1* No trench-breaking rupture (solid line in Fig. 7b). In this case, the strengthening of the updip segment is  $\Delta\mu'_b = 0.036$ . This particular value of  $\Delta\mu'_b$  creates a situation in which the entire updip segment is at failure but is just short of breaking the trench. This is the minimum value of the  $\Delta\mu'_b$  of the updip segment required to prevent trench-breaking rupture and is denoted  $\Delta\mu'_{b,t}$ . The value of  $\Delta\mu'_{b,t}$  depends on the product of the stress drop and the area of the seismogenic zone, a quantity we refer to as “force drop”. That is, if the upper edge of the seismogenic zone is fixed, increasing its downdip width or stress drop gives the same result. For the same model geometry as used for this example,  $\Delta\mu'_{b,t}$  as a function of force drop per unit strike length is shown in Fig. 8, assuming the upper edge of the seismogenic zone is fixed. Using a different model geometry or position of the seismogenic zone upper edge will change the slope of this function.

*Example 2* Trench-breaking rupture (dashed line in Fig. 7b). Given the same force drop in the seismogenic zone, if  $\Delta\mu'_b$  of the updip segment is less than  $\Delta\mu'_{b,t}$ , the rupture will break the trench. Knowing whether coseismic trench-breaking rupture exists or is common awaits future

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 7

Three examples of the stress transfer model. The examples differ in the coseismic strength increase of the updip fault segment, indicated in (b) as  $\Delta\mu'_b$ . a Shear stress drop (or increase) along the fault. b Slip distribution along the fault. c Central portion of the finite element mesh (*thin lines*). The “*thick line*” along the plate interface is actually a group of very densely spaced elements. *Thick gray lines* indicate deformed fault and surface after the earthquake (exaggerated by a factor of 2000)

seafloor monitoring observations. This example shows that a trench-breaking rupture does not necessarily indicate the updip segment exhibits velocity-weakening. Conceivably, the slip of the velocity-strengthening updip segment may be slower than that of the seismogenic zone and may not generate much seismic waves.

**Example 3** Fully buried rupture (dotted line in Fig. 7b). If  $\Delta\mu'_b$  of the updip segment is greater than  $\Delta\mu'_{b,t}$ , rupture may only extend into its lower part. For a very high  $\Delta\mu'_b$ , most of the segment does not slip at all, because a tiny portion immediately updip of the seismogenic zone is sufficient to stop the rupture. This is just the buried-rupture scenario of the crack model commonly used in earthquake simulation [21]. Because most of the updip segment is “protected” and does not experience coseismic stress increase, this scenario is not applicable to the dynamic Coulomb wedge model. A very large stress increase just updip of the seismogenic zone is considered unrealistic.

These examples show the consequences of changes in the strength of the basal fault of the frontal wedge result-

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 8

Minimum increase in  $\Delta\mu'_{b,t}$  of the updip megathrust segment (denoted  $\Delta\mu'_{b,t}$ ) required to prevent trench-breaking rupture as a function of force drop along the seismogenic zone for the model shown in Fig. 7c, with the upper edge of the seismogenic zone fixed at 50 km from the trench

ing from the rupture of the seismogenic zone. Whether the given strength increase  $\Delta\mu'_b$  can drive the wedge from a stable state into a critical state depends on two factors. First, it depends on the value of  $\mu'_b$  before the earthquake. The value of 0.04 used in the above examples is only one of the numerous possible values. If  $\mu'_b$  is already near a critical value, that is,  $m$  in Fig. 3 for a given  $\alpha$  is already near  $m^c$ , a small increase will do. Conceivably,  $\mu'_b$  before an earthquake may be relatively high if the strengthened state of the fault caused by the previous earthquake has not fully relaxed. Second, given  $\mu'_b$ , it depends on the strength of the wedge material. A weaker wedge becomes critical at a lower  $\Delta\mu'_b$ . The average internal friction value  $\mu$  of an actively deforming frontal prism is lower than the rest of the lithosphere because of its low degree of consolidation and high degree of fracturing. The pore fluid pressure within it, represented by  $\lambda$  in the Coulomb wedge model, may increase due to coseismic compression of the prism, further weakening the wedge, as discussed in Sect. “**Dynamic Coulomb Wedge**”.

### Tsunamiogenic Coseismic Seafloor Deformation

To understand the process of tsunami generation by a great subduction zone earthquake, we must know how the seafloor deforms at the time of the earthquake. Despite the dramatic worldwide improvement of geodetic, seismological, and oceanographic monitoring networks over the past few decades, our knowledge of coseismic seafloor deformation (CSD) is surprisingly poor and is based almost

entirely on theoretical models. The problem is the rarity of near-field observations. Except for seafloor pressure sensor records at the time of the M8.2 Tokachi-oki earthquake of 2003 [1] and continuous GPS measurements from islands very near the Sumatra trench at the time of the M8.7 Nias-Simeulue earthquake of 2005 [4,22], most observations are made at sites too remotely located to resolve reliably CSD within about 100 km of the trench. The lack of near-field CSD information causes severe nonuniqueness in the inversion of tsunami, seismic, and geodetic data to determine coseismic slip patterns of the shallow part of the subduction fault, for which the only cure is to introduce a priori constraints on the basis of theoretical models. Until the situation is improved by the establishment of seafloor monitoring systems, we must continue to resort to what we are able to deduce from these models.

The largest uncertainty in our knowledge of the processes that control CSD is how coseismic slip along the subduction fault varies in the downdip direction [21,49]. It may overshadow uncertainties in our knowledge of the timescale of the deformation and the spatial variation of mechanical properties of the rock medium. In comparison, along-strike variations of the coseismic slip, usually described in terms of “asperities”, are much easier to determine using high-density terrestrial monitoring networks. Theoretical models discussed above can help us understand the downdip slip distribution. Using the same type of model as shown in Fig. 5 and Fig. 7 but with a realistic, curved fault, we illustrate how the frictional behavior of the updip segment affects the CSD (see Fig. 9). The simulated earthquakes in the two shown examples have the same “size”, quantified by the seismic moment – the product of rigidity, slip area, and average slip, but they cause very different CSD patterns.

*Example 4* No trench-breaking rupture (solid line in Fig. 9a). This model is similar to the first example in the preceding section in that the updip segment is assumed to strengthen by  $\Delta\mu'_{b,t}$ , and the rupture is on the verge of breaking the trench.

*Example 5* Full trench-breaking rupture (dashed line in Fig. 9a). In this model, there is no velocity-strengthening updip segment, and the seismogenic zone extends to the trench. The stress drop of the resultant much wider seismogenic zone features a monotonic increase from the trench.

The model of full trench-breaking rupture yields much smaller vertical CSD than does the model of no trench-breaking rupture. The reason is two-fold. First, without a velocity-strengthening updip segment to resist rupture, the maximum slip occurs in the most shallowly dipping

Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis, Figure 9

Two examples showing how the frictional behavior of the updip segment (see Fig. 5) affects CSD. In one example (solid line), the segment strengthens by  $\Delta\mu'_{b,t}$ , and in the other example (dashed line), the segment weakens and thus becomes part of the seismogenic zone. The simulated earthquakes in both examples have the same seismic moment. a Surface uplift. b Stress drop (or increase) along the fault. c Slip distribution along the fault. d Central part of the finite element mesh (thin lines). The two vertical “thick lines” at distances 50 km and 200 km bracketing the seismogenic zone of the model of no trench-breaking rupture are actually groups of very densely spaced elements

near-trench part of the fault where seafloor displacement is predominantly horizontal. This effect would not be obvious had a straight fault geometry been used in the model. Second, without the resistance of an updip segment, the upper plate does not experience horizontal compression and the resultant vertical expansion. If we rescale the two models so that they have the same maximum slip, the model of full trench-breaking rupture will have a greater seismic moment but still a much lower vertical CSD [49]. This result demonstrates the importance of the frictional behavior of the shallowest fault segment in affecting seafloor uplift. However, it addresses only one aspect of tsunamigenic CSD. Many other factors con-

tribute to tsunami generation. For example, although the full trench-breaking model yields very low vertical CSD, its horizontal CSD may contribute to tsunami generation. If the seafloor slopes at angle  $\alpha$ , its horizontal motion  $D$  in the slope direction should raise the seafloor by  $D \tan \alpha$  relative to a fixed water column above, an effect addressed by Tanioka and Satake [43]. The speed of the coseismic slip is also an important factor in tsunami generation. In some rare cases, the rupture is too low to generate much seismic wave energy yet fast enough to generate rather large tsunamis, giving rise to a class of earthquake called tsunami earthquakes [27].

Elastic deformation of the ocean floor as discussed above is the primary cause of tsunami generation during subduction earthquakes, but inelastic deformation can be locally important. For example, although the lower continental slope of active margins is on average the expression of a critically tapered Coulomb wedge, seafloor topography at these margins is rugged at smaller scales due to sedimentation, erosion, and deformation processes, and where the local surface slope is sufficiently high earthquake shaking may trigger gravitational failure. Such submarine “landslides” may have a locally significant effect on tsunami generation. Another potentially important inelastic process is the coseismic activation of out-of-sequence thrust faults (splay faults) in the accretionary prism (Fig. 1a). Splay faults are much more steeply dipping, and their thrust motion will serve to “redirect” the low-angle slip of the megathrust to a higher angle and thus may greatly enhance local seafloor uplift and contribute to tsunami generation [19,36]. As mentioned in the Introduction, from the continuum perspective, such faulting is a manifestation of Coulomb plasticity. At the local scale, it is actually frictional sliding of a contact surface with elastically deforming rocks on both sides. By comparison of the splay faults schematically illustrated in Fig. 1a and the potential failure planes of the critical wedge in Fig. 2b, we can see that some of the splay faults are oriented optimally for thrust failure if the frontal wedge is compressed during a megathrust earthquake.

### Future Directions

The connection between wedge mechanics and great earthquakes and tsunamis at subduction zones is an emerging new field of study. It leads to challenges in both theoretical development and experimental design and thus excellent research opportunities. We need better constraints on how stresses along different downdip segments of the subduction fault evolve with time throughout an earthquake cycle and how the evolution impacts wedge

and seafloor deformation. A number of outstanding questions are to be addressed: Can we constrain the updip limit of the seismogenic zone using wedge morphology? What is the timescale of stress relaxation along the updip segment of the megathrust after an earthquake? Does the seismogenic zone stay locked in the interseismic period? How does pore fluid pressure evolve in an earthquake cycle? How is the transfer of material from the incoming plate to the upper plate (accretion), from the subducted plate to the upper plate (underplating), or from the upper plate to the subducted plate (tectonic erosion) accomplished? What determines the dominant mode of material transfer? What does the spatial change in wedge morphology tell us about changes in the mechanical state of the wedge and the megathrust fault? These questions should be put in the proper context of larger-scale processes such as the viscoelastic relaxation of the mantle following a megathrust earthquake and the deformation of the subducting plate in earthquake cycles [47].

Sandbox experiments designed to study wedge mechanics and dynamic friction experiments designed to study fault mechanics are traditionally separate research activities addressing processes of vastly different timescales. The linkage between subduction earthquakes and submarine wedge evolution suggests the need to combine these experiments. Rapid motion used to simulate earthquakes has begun to be introduced into sandbox experiments [38].

The most promising type of field observation is continuous monitoring of deformation, such as strain and tilt, and fluid pressure using submarine borehole and seafloor observatories. Seafloor elevation change in response to the 2003 Tokachi-oki, northeast Japan, earthquake (M8.2), continuously recorded by two seafloor pressure sensors, clearly indicated coseismic strengthening behavior of the shallowest segment of the subduction fault [1]. Formation fluid pressure changes detected at subsea borehole observatories at the Nankai Trough subduction zone, southwest Japan, have been interpreted to indicate transient aseismic motion of a part of the locked seismogenic zone and/or dynamics of the incoming plate [13]. A number of very-low-frequency earthquakes have been remotely detected within the Nankai Trough accretionary prism using land-based seismic networks [25], revealing the need for near-field observation using seafloor systems. Submarine monitoring in conjunction with land-based monitoring at subduction zones that are currently in different phases of earthquake cycles will allow us to understand the evolution of fault and wedge stresses during the interseismic period. In this regard, cabled seafloor monitoring networks including borehole observatories, being designed or implemented at dif-

ferent subduction zones [26,28] will surely yield valuable data in the near future.

# List of Glossary Terms

## A

A parameter estimate 1104  
Abrupt climate change 2  
Absolute time 1104  
Accretionary wedge (prism) 1207  
Active fault 278  
Agglomerative (hierarchical) clustering algorithm 127  
Andesite 1082  
Anthropogenic climate change 2  
Anthropogenic emissions 31  
Apparent stress 364  
Aqueous fluid 462  
Arbo viruses 42  
Arbo viruses transmitted by Aedes mosquitoes 42  
Arrival time 230  
Aseismic 79  
Assortative mixing and disassortative mixing 313  
Atmosphere 1  
Atmospheric boundary layer 844  
Attenuation factor  $Q^{-1}$  788  
Attenuation relation (ground-motion prediction equation) 623  
Autoregressive equation 1146

## B

Basalt 1082  
“Baseline” monitoring data 1135  
Bayesian analysis 805  
Beach profile 1008  
Binary forecast 218  
Bingham liquid 1082  
Blue-tongue disease in Europe 42  
Body waves 278  
Bore 1008  
Bore solitons 873  
Bottleneck 517  
Boussinesq equations 1008  
Branching process 338

Bubble collapse 731  
Bubbly flow 1082  
Bubbly liquid 1179

## C

Carbon dioxide fertilization and quality of food 43  
Cascade model 320  
Cascadia 79  
Celerity 663  
Centroid 230  
Centroid moment tensor solution 982  
CGCM 908  
Changes in the pollen season and new pollen 43  
Chaos 573, 825  
Choked flow 1179  
Climate change 109  
Climate change related direct health effects 42  
Climate models 2, 753  
Climate simulation 2  
Climate time scales 1  
Climate variability pattern 2  
Climate variables and forcing 1  
Cluster 127  
Clustering 127  
Clustering coefficient 312  
CMT centroid moment tensor 406  
CO<sub>2</sub> 908  
Coda attenuation factor  $Q_C^{-1}$  788  
Coda waves 278, 788  
Collective intelligence 697  
Community 484  
Community empowerment 484  
Community safety group 484  
Complex and evolving structural systems 201  
Complexity 551, 573  
Computational fluid dynamics 858  
Conduit 1035, 1082  
Confidence ellipse 589

Connectivity distribution or degree distribution 312  
 Continuous phase transitions 825  
 Continuum forecast 218  
 Convolution 406  
 Corner frequency 255, 364  
 Coseismic 79  
 Coulomb plasticity 1207  
 Crack wave 1146, 1179  
 Critical earthquake concept 805  
 Critical exponents 825  
 Critical phenomena 825  
 Critical point 680  
 Crowd 517, 697  
 Crowd disaster 517  
 Crowd turbulence 697  
 Cryosphere 1, 95  
 Crystallization 1082

**D**

Data mining 126  
 Data space 127, 230  
 Data transmission system 175  
 Data vector 127  
 “Decision window” 1136  
 Declustering 825  
 Deconvolution 406  
 Deep earthquake 406  
 Degassing n. (degas v.) 1082  
 Differentiation 1082  
 Diffuse interface 1179  
 Diffuse interface theory 858  
 Dimensionless density 717  
 Direct costs 52  
 Direct search 230  
 Disaster 484  
 Disaster lead time 484  
 Disaster threat 484  
 Discontinuous Galerkin method 765  
 Discount factor 52  
 Discount rate 52  
 Dispersion 255  
 Dispersion, amplitude 1008  
 Dispersion, frequency 1008  
 Diurnal cycle 844  
 Dome 1082  
 Downscaling 753  
 Ductile shear zone 22  
 Dyke 1082  
 Dynamic rupture model 623  
 Dynamic stress change 425

Dynamic stress drop 320, 364  
 Dynamical scaling and exponents 825

**E**

Earthquake 22, 573  
 Earthquake catalog 126  
 Earthquake early warning 982  
 Earthquake early warning system (EEMS) 175, 278  
 Earthquake early-warning 230  
 Earthquake forecasting 573  
 Earthquake forecast/prediction 805  
 Earthquake location 175, 230  
 Earthquake magnitude 175  
 Earthquake mechanism 338  
 Earthquake precursor 278  
 Earthquake prediction 278, 447, 573  
 Earthquake preparedness 573  
 Earthquake quantities 680  
 Earthquake size 255  
 Earthquake source 255  
 Earth-system models of intermediate complexity 2  
 Economics 52  
 Effective risk communication 484  
 El Niño-southern oscillation (ENSO) 31  
 Elastic 79  
 Electro-kinetic effect 447  
 Emergence 697  
 Emergency 484  
 Energy release rate 364  
 Envelope broadening 788  
 Epicenter 230, 278  
 Equilibrium 109  
 Equity weights 52  
 Error 230  
 Evacuation 484, 517  
 Evolutionary optimization 697  
 Excluded volume 717  
 Explosive eruption 1082  
 External factors 1  
 Extreme events 551, 573  
 Extrusive flow or eruption 1082

**F**

Factual statement 1135  
 Failure to predict 218  
 False alarm 218  
 Far-field 278  
 Fast acceleration of unemployment (FAU) 551  
 Faster-is-slower effect 697  
 Fault 22, 278

Fault model 805  
 Fault parameters 1022  
 Fault slip 278  
 Fault strength 320  
 Feature extraction 127  
 Feature space 127  
 Feature vector 127  
 Features 127  
 Feedbacks 3  
 Finite size scaling 825  
 Flow 517  
 Focal mechanism 278  
 Forecast 1135  
 Forecast point 982  
 Forward model 79  
 Fractal 568, 825  
 Fractal dimension 568  
 Fracture network 717  
 Freezing-by-heating effect 697  
 Frequency bands of electromagnetic waves 447  
 Fundamental diagram 517  
 Fundamental modes 255

## G

Game horizon 109  
 Gas slug 858, 1179  
 GCM 908  
 Geodesy 79  
 GHG 908  
 Global climate models or General circulation models 2  
 Global expansion of tropical diseases 42  
 Global search 230  
 Global seismographic network (GSN) 126  
 GNSS 589  
 GPS 79, 889  
 Greenhouse gases 31  
 Grid 126  
 Grid generation 765  
 Ground deformation 731  
 Ground motion intensity measures 623  
 Ground motion uncertainty 623  
 GT 908

## H

Hazard 484  
 Hazard zone 484  
 Health 42  
 Hierarchical organization 312  
 Human bioclimate 42  
 Hypocenter 230, 278, 406

## I

Importance sampling 230  
 Impulse 731  
 Independent events 338  
 Indirect costs 52  
 Infrasound 663  
 Infrasound array 663  
 Initial rupture process 320  
 InSAR 79  
 Intensity, earthquake 278  
 Interactive visualization 126  
 Interferometric synthetic aperture radar (InSAR) 589  
 Intergovernmental coordination group 982  
 Internal solitons 873  
 International GNSS service (IGS) 589  
 Inter-onset time 1104  
 Interseismic deformation 79  
 Inter-story drift 150  
 Inverse problem 1022  
 Inverse problem, inversion 230  
 Inverse theory 79  
 Ionosphere 447, 589  
 IPCC 908  
 IPCC emission scenario 753

## K

Kinematic GPS 589  
 Kinematic rupture model 623  
 k-Means clustering 127

## L

Land surface 1  
 Lane formation 517  
 Leveling 79  
 Likelihood function 230  
 Lithosphere 573  
 Local tsunami 406  
 Locked zone 79  
 Long period seismic events 731  
 Long-period (LP) event 1179  
 Long-term climate statistics 3  
 LP 663

## M

Macroscopic models 517  
 Mafic 1083  
 Magma 1035, 1083, 1179  
 Magma chamber 731, 1083  
 Magma intrusion 1135

Magma, melt, liquid 731  
 Magnitude 255, 406  
 Magnitude, earthquake 278  
 Magnitude saturation 967  
 Malaria and global warming 42  
 Marginal costs 52  
 Marogram 406  
 Mean field theory 680  
 Mean-Field 826  
 Mechanisms for power laws 826  
 Mega-thrust earthquake 589  
 Melt 462, 1083  
 Meta-stability of man-made structures 201  
 Microlite 1083  
 Microscopic models 517  
 Misfit function 230  
 Mitigation 484  
 Model categories 2  
 Model space 230  
 Model test 338  
 Modeling 858  
 Moment magnitude ( $M_w$ ) 589  
 Moment tensor 278, 1146, 1179  
 Moment-tensor 858  
 Monetary valuation 52  
 Multidimensional scaling 127  
 Multiple equilibria 3  
 Multi-resolutional clustering analysis 127  
 Mylonite 22

## N

Navier–Stokes equations 1008  
 N-body solver 127  
 Near-field 278  
 Neo-classical economics 52  
 Net present value 52  
 Network or graph 312  
 Newtonian liquid 1083  
 Newtonian viscous body 95  
 Nonlinear process 1179  
 Non-equilibrium phase transitions 826  
 Non-hierarchical clustering algorithm 127  
 North atlantic Oscillation (NAO) 31  
 Nucleation process 320  
 Nucleation zone 320  
 Numerical methods 765

## O

Objective function 230  
 Oceans 1

Onset 1104  
 Onset time 1104  
 OpenGL 126  
 Origin time 230

## P

Paleoclimate 3  
 Paleoseismology 79  
 Panic 697  
 Parallel algorithms 765  
 Partially molten rock 462  
 Path effects 623  
 Pattern recognition 126  
 Pattern recognition of rare events 551  
 Payoffs 109  
 PDF 218  
 Pedestrian 517  
 Percolation and percolation threshold 717  
 Phase transitions 826  
 Phase-field method 1179  
 Phenocryst 1083  
 Piezo-electric effect 447  
 Plane convex fractures 717  
 Plate tectonics 79, 278  
 Players 109  
 Point process 338  
 Polygenetic vent 1104  
 Posterior pdf 231  
 Postseismic deformation 79  
 Precursory signal 338  
 Prediction 1135  
 Preferential attachment rule 312  
 Premonitory patterns 551  
 Premonitory seismicity patterns 573  
 Preslip model 320  
 Prevention 484  
 Prior pdf 230  
 Probabilistic seismic hazard analysis 278  
 Probability 805  
 Probability density function – PDF 176  
 Probability density function – pdf 230  
 Probability forecast 338  
 Problem solving environment (PSE) 126  
 Projection 753  
 Pyroclastic flow or surge 1083

## R

Radiated or seismic energy 364  
 Radiative transfer theory 788  
 Ramp-up preparations 484

- Random media 788  
 Ray path 231  
 Receiver or station 231  
 Recession 551  
 Rectified diffusion and rectified heat transfer 731  
 Reference frame 589  
 Refraction and inverse refraction diagrams (travel timemap) 1022  
 Regime shifts 2  
 Regional tsunami 406  
 Renormalization group (RG) 680  
 Renormalization group theory 826  
 Repose 1104  
 Resonant frequencies of vibration 150  
 Rheology 1035  
 Rise time 623  
 Risk treatment options 484  
 Rossby solitons 873  
 Run-up height 967  
 Runup, or runup height 1008  
 Rupture 589  
 Rupture duration 624  
 Rupture velocity 624
- S**
- Satellite laser ranging (SLR) 589  
 Saturation 255  
 Scaling 1035  
 Scattering coefficient  $g$  788  
 Scientific visualization 126  
 Seafloor geodesy 889  
 Seismic body waves 406  
 Seismic cycle 79  
 Seismic data-logger 176  
 Seismic energy 255  
 Seismic hazard 176, 279, 805  
 Seismic hazard analysis 279  
 Seismic hazard map 279  
 Seismic magnitude 967  
 Seismic moment 279, 320, 364, 406, 680, 967  
 Seismic moment  $M_0$  256  
 Seismic phase 231  
 Seismic potency 680  
 Seismic radiation 364  
 Seismic risk 279  
 Seismic sensors 176  
 Seismic spectrum 364  
 Seismic surface waves 407  
 Seismic tomographic image 462
