# Preface

Extreme Environmental Events is an authoritative single source for understanding and applying the basic tenets of complexity and systems theory as well as the tools and measures for analyzing complex systems in understanding, predicting, monitoring and evaluating major phenomena and natural disasters affecting life on earth. These phenomena are earthquakes, tsunamis, volcanoes, climate change and weather. Early warning, damage, and the immediate response of human populations to these phenomena are also covered from a complexity (nonlinear) viewpoint. The content is presented in 61 articles and 1250 pages written by 110 of the world's experts in each field.

Extreme Environmental Events is written for an audience of advanced university undergraduate and graduate students, professors, and professionals in a wide range of fields including earth sciences, climatology, sociology, mathematics, physics and engineering. Each article was selected and peer reviewed by one of our Section Editors with advice and consultation provided by our Board Members and Editor-in-Chief. This level of coordination assures that the reader can have a level of confidence in the relevance and accuracy of the information far exceeding that generally found on the World Wide Web or any print publication. Accessibility is also a priority and for this reason each article includes a glossary of important terms and a concise definition of the subject. A list of the 61 articles and authors is presented on pages XV through XVII and a listing of the articles by section is shown on pages VII to VIII. A summary, perspective and roadmap for the articles on earthquakes, tsunamis and volcanoes is presented on pages 68 to 78. Also, a summary, perspective and roadmap for the articles on climate modeling, global warming and weather prediction is presented on pages 66 to 67.

Complex systems are systems that comprise many interacting parts with the ability to generate a new quality of collective behavior through self-organization, e.g. the spontaneous formation of temporal, spatial or functional structures. They are therefore adaptive as they evolve and may contain self-driving feedback loops. Thus, complex systems are much more than a sum of their parts. Complex systems are often characterized as having extreme sensitivity to initial conditions as well as emergent behavior that are not readily predictable or even completely deterministic. The conclusion is that a reductionist (bottom-up) approach is often an incomplete description of a phenomenon. This recognition, that the collective behavior of the whole system cannot be simply inferred from the understanding of the behavior of the individual components, has led to many new concepts and sophisticated mathematical and modeling tools for application to extreme environmental phenomena. These tools include fractals, cellular automata, solitons game theory, network theory and statistical physics.

## Acknowledgments

I wish to thank Springer management David Packer, Lydia Mueller and Sylvia Blago for selecting this project for publication and providing valuable advise and counsel.

# Sections

## **Climate Modeling, Global Warming and Weather Prediction,**

**Section Editors: Hartmut Grassl, Brian Dangerfield, and Marilda Sotomayor**

Abrupt Climate Change Modeling  
Climate Change and Agriculture  
Climate Change and Human Health  
Climate Change, Economic Costs of  
Climate Modeling, Global Warming and Weather Prediction, Introduction to  
Cryosphere Models  
Dynamic Games with an Application to Climate Change Models  
Regional Climate Models: Linking Global Climate Change to Local Impacts  
Single Column Modeling of Atmospheric Boundary Layers  
and the Complex Interactions with the Land Surface  
System Dynamics Models of Environment, Energy and Climate Change

## **Complexity in Earthquakes, Tsunamis, and Volcanoes, and Forecast,**

**Section Editors: William H. K. Lee, Daniel ben-Avraham, Shlomo Havlin,  
Mohamed A. Helal, Muhammad Sahimi, and M. Cristina Marchetti**

Brittle Tectonics: A Non-linear Dynamical System  
Complexity in Earthquakes, Tsunamis, and Volcanoes, and Forecast, Introduction to  
Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of  
Earthquake Clusters over Multi-dimensional Space, Visualization of  
Earthquake Damage: Detection and Early Warning in Man-Made Structures  
Earthquake Early Warning System in Southern Italy  
Earthquake Engineering, Non-linear Problems in  
Earthquake Forecasting and Verification  
Earthquake Location, Direct, Global-Search Methods  
Earthquake Magnitude  
Earthquake Monitoring and Early Warning Systems  
Earthquake Networks, Complex  
Earthquake Nucleation Process  
Earthquake Occurrence and Mechanisms, Stochastic Models for  
Earthquake Scaling Laws  
Earthquake Source: Asymmetry and Rotation Effects  
Earthquake Source Parameters, Rapid Estimates for Tsunami Warning  
Earthquakes, Dynamic Triggering of  
Earthquakes, Electromagnetic Signals of  
Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in  
Fractals in Geology and Geophysics  
Geo-Complexity and Earthquake Prediction  
GPS: Applications in Crustal Deformation Monitoring

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures  
Infrasound from Earthquakes, Tsunamis and Volcanoes  
Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of Percolation, and Faults and Fractures in Rock  
Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation  
Seismic Wave Propagation in Media with Complex Geometries, Simulation of Seismic Waves in Heterogeneous Earth, Scattering of  
Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates  
Space Seismicity, Statistical Physics Approaches to  
Slug Flow: Modeling in a Conduit and Associated Elastic Radiation  
Solitons, Tsunamis and Oceanographical Applications of  
Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy  
Tomography, Seismic  
Tsunami Earthquakes  
Tsunami Forecasting and Warning  
Tsunami Inundation, Modeling of  
Tsunamis, Inverse Problem of  
Volcanic Eruptions, Explosive: Experimental Insights  
Volcanic Eruptions: Cyclicity During Lava Dome Growth  
Volcanic Eruptions: Stochastic Models of Occurrence Patterns  
Volcanic Hazards and Early Warning  
Volcano Seismic Signals, Source Quantification of  
Volcanoes, Non-linear Processes in  
Wedge Mechanics: Relation With Subduction Zone Earthquakes and Tsunamis

**Complexity in Human Reaction to Extreme Events,  
Section Editors: Boris Kerner and Andrzej Nowak**

Evacuation as a Communication and Social Phenomenon  
Evacuation Dynamics: Empirical Results, Modeling and Applications  
Extreme Events in Socio-economic and Political Complex Systems, Predictability of  
Pedestrian, Crowd and Evacuation Dynamics

## About the Editor-in-Chief

### **Robert A. Meyers**

President: RAMTECH Limited  
Manager, Chemical Process Technology, TRW Inc.  
Post-doctoral Fellow: California Institute of Technology  
Ph. D. Chemistry, University of California at Los Angeles  
B. A., Chemistry, California State University, San Diego

### **Biography**

Dr. Meyers has worked with more than 25 Nobel laureates during his career.

### **Research**

Dr. Meyers was Manager of Chemical Technology at TRW (now Northrop Grumman) in Redondo Beach, CA and is now President of RAMTECH Limited. He is co-inventor of the Gravimelt process for desulfurization and demineralization of coal for air pollution and water pollution control. Dr. Meyers is the inventor of and was project manager for the DOE-sponsored Magnetohydrodynamics Seed Regeneration Project which has resulted in the construction and successful operation of a pilot plant for production of potassium formate, a chemical utilized for plasma electricity generation and air pollution control. Dr. Meyers managed the pilot-scale DoE project for determining the hydrodynamics of synthetic fuels. He is a co-inventor of several thermo-oxidative stable polymers which have achieved commercial success as the GE PEI, Upjohn Polyimides and Rhone-Polenc bismaleimide resins. He has also managed projects for photochemistry, chemical lasers, flue gas scrubbing, oil shale analysis and refining, petroleum analysis and refining, global change measurement from space satellites, analysis and mitigation (carbon dioxide and ozone), hydrometallurgical refining, soil and hazardous waste remediation, novel polymers synthesis, modeling of the economics of space transportation systems, space rigidizable structures and chemiluminescence-based devices.

He is a senior member of the American Institute of Chemical Engineers, member of the American Physical Society, member of the American Chemical Society and serves on the UCLA Chemistry Department Advisory Board. He was a member of the joint USA-Russia working group on air pollution control and the EPA-sponsored Waste Reduction Institute for Scientists and Engineers.

Dr. Meyers has more than 20 patents and 50 technical papers. He has published in primary literature journals including *Science* and the *Journal of the American Chemical Society*, and is listed in *Who's Who in America* and *Who's Who in the World*. Dr. Meyers' scientific achievements have been reviewed in feature articles in the popular press in publications such as *The New York Times Science Supplement* and *The Wall Street Journal* as well as more specialized publications such as *Chemical Engineering and Coal Age*. A public service film was produced by the Environmental Protection Agency of Dr. Meyers' chemical desulfurization invention for air pollution control.

### **Scientific Books**

Dr. Meyers is the author or Editor-in-Chief of 12 technical books one of which won the Association of American Publishers Award as the best book in technology and engineering.

### **Encyclopedias**

Dr. Meyers conceived and has served as Editor-in-Chief of the Academic Press (now Elsevier) *Encyclopedia of Physical Science and Technology*. This is an 18-volume publication of 780 twenty-page articles written to an audience of university students and practicing professionals. This encyclopedia, first published in 1987, was very successful, and because of this, was revised and reissued in 1992 as a second edition. The Third Edition was published in 2001 and is now on-line. Dr. Meyers has completed two editions of the *Encyclopedia of Molecular Cell Biology and Molecular Medicine* for Wiley VCH publishers (1995 and 2004). These cover molecular and cellular level genetics, biochemistry, pharmacology, diseases and structure determination as well as cell biology. His eight-volume *Encyclopedia of Environmental Analysis and Remediation* was published in 1998 by John Wiley & Sons and his 15-volume *Encyclopedia of Analytical Chemistry* was published in 2000, also by John Wiley & Sons, all of which are available on-line.

## Editorial Board Members

PROFESSOR BENOIT B. MANDELBROT  
Sterling Professor Emeritus of Mathematical Sciences at  
Yale University  
1993 Wolf Prize for Physics and the  
2003 Japan Prize for Science and Technology  
*Current interests include:* seeking a measure of order in  
physical, mathematical or social phenomena that are  
characterized by abundant data but wild variability.

RICHARD E. STEARNS  
1993 Turing Award for foundations  
of computational complexity  
*Current interests include:* computational complexity,  
automata theory, analysis of algorithms, and game theory.

MARIO J. MOLINA  
1995 Nobel Prize in Chemistry for atmospheric  
chemistry, particularly the formation and decomposition  
of ozone  
*Current interests include:* atmospheric chemical processes,  
and science-policy issues related to urban and regional air  
pollution and to global change.

STEPHEN WOLFRAM  
Founder and CEO, Wolfram Research  
Creator, Mathematica®  
Author, *A New Kind of Science*

JOSEPH P. S. KUNG  
Professor  
Department of Mathematics  
University of North Texas

WILLIAM H. K. LEE  
Scientist Emeritus  
US Geological Survey  
Menlo Park, CA 94025, USA

## Section Editors

### Climate Modeling, Global Warming and Weather Prediction

HARTMUT GRASSL  
Professor emeritus, Hamburg University  
Former Director of the Max Planck Institute of  
Meteorology, Hamburg  
Former Director World Climate Research Program  
1994–1999

### Complexity in Earthquakes, Tsunamis and Volcanoes and Forecast

WILLIAM H. K. LEE  
Scientist Emeritus, US Geological Survey, Menlo Park

## Contributing Section Editors

## Glossary

**Atmosphere** The atmosphere is involved in many processes of abrupt climate change, providing a strong non-linearity in the climate system and propagating the influence of any climate forcing from one part of the globe to another. Atmospheric temperature, composition, humidity, cloudiness, and wind determine the Earth's energy fluxes. Wind affects the ocean's surface circulation and upwelling patterns. Atmospheric moisture transport determines the freshwater balance for the oceans, overall water circulation, and the dynamics of glaciers.

**Oceans** Because water has enormous heat capacity, oceans typically store 10–100 times more heat than equivalent land surfaces. The oceans exert a profound influence on climate through their ability to transport heat from one location to another. Changes in ocean circulation have been implicated in abrupt climate change of the past. Deglacial meltwater has freshened the North Atlantic and reduced the ability of the water to sink, inducing long-term coolings.

**Land surface** The reflective capacity of the land can change greatly, with snow or ice sheets reflecting up to 90% of the sunlight while dense forests absorb more than 90%. Changes in surface characteristics can also affect solar heating, cloud formation, rainfall, and surface-water flow to the oceans, thus feeding back strongly on climate.

**Cryosphere** The portion of the Earth covered with ice and snow, the cryosphere, greatly affects temperature. When sea ice forms, it increases the planetary re-

flective capacity, thereby enhancing cooling. Sea ice also insulates the atmosphere from the relatively warm ocean, allowing winter air temperatures to steeply decline and reduce the supply of moisture to the atmosphere. Glaciers and snow cover on land can also provide abrupt-change mechanisms. The water frozen in a glacier can melt if warmed sufficiently, leading to possibly rapid discharge, with consequent effects on sea level and ocean circulation. Meanwhile, snow-covered lands of all types maintain cold conditions because of their high reflectivity and because surface temperatures cannot rise above freezing until the snow completely melts.

**External factors** Phenomena external to the climate system can also be agents of abrupt climate change. For example, the orbital parameters of the Earth vary over time, affecting the latitudinal distribution of solar energy. Furthermore, fluctuations in solar output, prompted by sunspot activity or the effects of solar wind, as well as volcanoes may cause climate fluctuations.

**Climate time scales** The climate system is a composite system consisting of five major interactive components: the atmosphere, the hydrosphere, including the oceans, the cryosphere, the lithosphere, and the biosphere. All subsystems are open and non-isolated, as the atmosphere, hydrosphere, cryosphere and biosphere act as cascading systems linked by complex feedback processes. Climate refers to the average conditions in the Earth system that generally occur over periods of time, usually several decades or longer. This time scale is longer than the typical response time of the atmosphere. Parts of the other components of the Earth system (ice, ocean, continents) have much slower response times (decadal to millennial).

**Climate variables and forcing** State variables are temperature, rainfall, wind, ocean currents, and many other variables in the Earth system. In our notation, the variables are described by a finite set of real variables in a vector  $x(t) \in \mathbb{R}^n$ . The climate system is subject to two main external forcings  $F(x, t)$  that condition its behavior, solar radiation and the action of gravity. Since  $F(x, t)$  has usually a spatial dependence,  $F$  is also a vector  $\in \mathbb{R}^n$ . Solar radiation must be regarded as the primary forcing mechanism, as it provides almost all the energy that drives the climate system. The whole climate system can be regarded as continuously evolving, as solar radiation changes on diurnal, seasonal and longer time scales, with parts of the system leading or lagging in time. Therefore, the subsystems of the climate system are not always in equi-

librium with each other. Indeed, the climate system is a dissipative, highly non-linear system, with many instabilities.

**Climate models** are based on balances of energy, momentum, and mass, as well as radiation laws. There are several model categories, full circulation models, low-order models, and models of intermediate complexity. Climate models simulate the interactions of the atmosphere, oceans, land surface, and ice. They are used for a variety of purposes from study of the dynamics of the weather and climate system, past climate to projections of future climate.

#### **Global climate models or General circulation models**

(GCMs) The balances of energy, momentum, and mass are formulated in the framework of fluid dynamics on the rotating Earth. GCMs discretize the equations for fluid motion and energy transfer and integrate these forward in time. They also contain parametrization for processes – such as convection – that occur on scales too small to be resolved directly. The dimension of the state vector is in the order of  $n \sim 10^5 - 10^8$  depending on the resolution and complexity of the model.

**Model categories** In addition to complex numerical climate models, it can be of great utility to reduce the system to low-order, box, and conceptual models. This complementary approach has been successfully applied to a number of questions regarding feedback mechanisms and the basic dynamical behavior, e. g. [48,84]. In some cases, e. g. the stochastic climate model of Hasselmann [32], such models can provide a null hypothesis for the complex system. The transition from highly complex dynamical equations to a low-order description of climate is an important topic of research. In his book “Dynamical Paleoclimatology”, Saltzman [77] formulated a dynamical system approach in order to differentiate between fast-response and slow-response variables. As an alternative to this method, one can try to derive phenomenologically based concepts of climate variability, e. g. [21,43]. In between the comprehensive models and conceptual models, a wide class of “models of intermediate complexity” were defined [12].

#### **Earth-system models of intermediate complexity**

(EMICs) Depending on the nature of questions asked and the pertinent time scales, different types of models are used. There are, on the one extreme, conceptual models, and, on the other extreme, comprehensive models (GCMs) operating at a high spatial and temporal resolution. Models of intermediate complexity bridge the gap [12]. These models are successful in de-

scribing the Earth system dynamics including a large number of Earth system components. This approach is especially useful when considering long time scales where the complex models are computationally too expensive, e. g. [47]. Improvements in the development of coupled models of intermediate complexity have led to a situation where modeling a glacial cycle, even with prognostic atmospheric CO<sub>2</sub> is becoming possible.

**Climate simulation** A climate simulation is the output of a computer program that attempts to simulate the climate evolution under appropriate boundary conditions. Simulations have become a useful part of climate science to gain insight into the sensitivity of the system.

**Climate variability pattern** Climate variability is defined as changes in integral properties of the climate system. True understanding of climate dynamics and prediction of future changes will come only with an understanding of the Earth system as a whole, and over past and present climate. Such understanding requires identification of the patterns of climate variability and their relationships to known forcing. Examples for climate variability patterns are the North Atlantic Oscillation (NAO) or the El Niño-Southern Oscillation (ENSO).

**Abrupt climate change** One can define abrupt climate change in the time and frequency domain. (a) Time domain: Abrupt climate change refers to a large shift in climate that persists for years or longer, such as marked changes in average temperature, or altered patterns of storms, floods, or droughts, over a widespread area that takes place so rapidly that the natural system has difficulty adapting to it. In the context of past abrupt climate change, “rapidly” typically means on the order of a decade. (b) Frequency domain: An abrupt change means that the characteristic periodicity changes. Also the phase relation between certain climate variables may change in a relatively short time. For both types of changes examples will be provided.

**Regime shifts** are defined as rapid transitions from one state to another. In the marine environment, regimes may last for several decades, and shifts often appear to be associated with changes in the climate system. If the shifts occur regularly, they are often referred to as an oscillation (e. g., Atlantic Multi-decadal Oscillation, Pacific Decadal Oscillation). Similarly, one can define a regime shift in the frequency domain.

**Anthropogenic climate change** Beginning with the industrial revolution in the 1850s and accelerating ever since, the human consumption of fossil fuels has elevated CO<sub>2</sub> levels from a concentration of  $\sim 280$  ppm

to more than 380 ppm today. These increases are projected to reach more than 560 ppm before the end of the 21st century. As an example, a concomitant shift of ocean circulation would have serious consequences for both agriculture and fishing.

**Multiple equilibria** Fossil evidence and computer models demonstrate that the Earth's complex and dynamic climate system has more than one mode of operation. Each mode produces different climate patterns. The evidence of models and data analysis shows that the Earth's climate system has sensitive thresholds. Pushed past a threshold, the system can jump from one stable operating mode to a completely different one.

**Long-term climate statistics** Starting with a given initial state, the solutions  $x(t)$  of the equations that govern the dynamics of a non-linear system, such as the atmosphere, result in a set of long-term statistics. If all initial states ultimately lead to the same set of statistical properties, the system is ergodic or transitive. If, instead, there are two or more different sets of statistical properties, where some initial states lead to one set, while the other initial states lead to another, the system is called intransitive (one may call the different states regimes). If there are different sets of statistics that a system may assume in its evolution from different initial states through a long, but finite, period of time, the system is called almost intransitive [50,51,53]. In the transitive case, the equilibrium climate statistics are both stable and unique. Long-term climate statistics will give a good description of the climate. In the almost intransitive case, the system in the course of its evolution will show finite periods during which distinctly different climatic regimes prevail. The almost intransitive case arises because of internal feedbacks, or instabilities involving the different components of the climatic system. The climatic record can show rapid step-like shifts in climate variability that occur over decades or less, including climatic extremes (e. g. drought) that persist for decades.

**Feedbacks** A perturbation in a system with a negative feedback mechanism will be reduced whereas in a system with positive feedback mechanisms, the perturbation will grow. Quite often, the system dynamics can be reduced to a low-order description. Then, the growth or decay of perturbations can be classified by the systems' eigenvalues or the pseudospectrum. Consider the stochastic dynamical system

$$\frac{d}{dt}x(t) = f(x) + g(x)\xi + F(x, t), \quad (1)$$

where  $\xi$  is a stochastic process. The functions  $f, g$  de-

scribe the climate dynamics, in this case without explicit time dependence. The external forcing  $F(x, t)$  is generally time-, variable-, and space-dependent. In his theoretical approach, Hasselmann [32] formulated a linear stochastic climate model

$$\frac{d}{dt}x(t) = Ax + \sigma\xi + F(t), \quad (2)$$

with system matrix  $A \in \mathbb{R}^{n \times n}$ , constant noise term  $\sigma$ , and stochastic process  $\xi$ . Interestingly, many features of the climate system can be well described by (2), which is analogous to the Ornstein–Uhlenbeck process in statistical physics [89]. In the climate system, linear and non-linear feedbacks are essential for abrupt climate changes.

**Paleoclimate** Abrupt climate change is evident in model results and in instrumental records of the climate system. Much interest in the subject is motivated by the evidence in archives of extreme changes. Proxy records of paleoclimate are central to the subject of abrupt climate change. Available paleoclimate records provide information on many environmental variables, such as temperature, moisture, wind, currents, and isotopic compositions.

**Thermohaline circulation** stems from the Greek words “thermos” (heat) and “halos” (salt). The ocean is driven to a large extent by surface heat and freshwater fluxes. As the ocean is non-linear, it cannot be strictly separated from the wind-driven circulation. The expressions thermohaline circulation (THC) and meridional overturning circulation (MOC) in the ocean are quite often used as synonyms although the latter includes all effects (wind, thermal, haline forcing) and describes the ocean transport in meridional direction. Another related expression is the ocean conveyor belt. This metaphor is motivated by the fact that the North Atlantic is the source of the deep limb of a global ocean circulation system [10]. If North Atlantic surface waters did not sink, the global ocean circulation would cease, currents would weaken or be redirected. The resulting reorganization would reconfigure climate patterns, especially in the Atlantic Ocean. One fundamental aspect of this circulation is the balance of two processes: cooling of the deep ocean at high latitudes, and heating of deeper levels from the surface through vertical mixing.

### Definition of the Subject

The occurrence of abrupt change of climate at various time scales has attracted a great deal of interest for its theoretical and practical significance [2,3,9]. To some extent, a defini-

tion of what constitutes an abrupt climatic change depends on the sampling interval of the data being examined [28]. For the instrumental period covering approximately the last 100 years of annually or seasonally sampled data, an abrupt change in a particular climate variable will be taken to mean a statistically highly significant difference between adjacent 10-year sample means. In the paleoclimate context (i. e. on long time scales), an abrupt climate change can be in the order of decades to thousands of years. Since the climate dynamics can be often projected onto a limited number of modes or patterns of climate variability (e. g., [21,22]), the definition of abrupt climate change is also related to spatio-temporal patterns.

The concept of abrupt change of climate is therefore applied for different time scales. For example, changes in climatic regimes were described associated with surface temperature, precipitation, atmospheric circulation in North America during the 1920s and 1960s [19,75]. Sometimes, the term “climate jump” is used instead of “abrupt climate change”, e. g. [92]. Flohn [25] expanded the concept of abrupt climate change to include both singular events and catastrophes such as the extreme El Niño of 1982/1983, as well as discontinuities in paleoclimate indices taken from ice cores and other proxy data. In the instrumental record covering the last 150 years, there is a well-documented abrupt shift of sea surface temperature and atmospheric circulation features in the Northern Hemisphere in the mid-1970s, e. g. [22,67,88]. Some of the best-known and best-studied widespread abrupt climate changes started and ended during the last deglaciation, most pronounced at high latitudes.

In his classic studies of chaotic systems, Lorenz has proposed a deterministic theory of climate change with his concept of the “almost-intransitivity” of the highly non-linear climate systems. In this set of equations, there exists the possibility of multiple stable solutions to the governing equations, even in the absence of any variations in external forcing [51]. More complex models, e. g. [11,20] also demonstrated this possibility. On the other hand, variations in external forcing, such as the changes of incoming solar radiation, volcanic activity, deglacial meltwater, and increases of greenhouse gas concentration have also been proposed to account for abrupt changes in addition to climate intransitivity [9,25,38,41,49]. A particular climate change is linked to the widespread continental glaciation of Antarctica during the Cenozoic (65 Ma to present) at about 34 Ma, e. g. [93]. It should be noted that many facets of regional climate change are abrupt changes although the global means are rather smoothly changing.

Besides abrupt climate change as described in the time domain, we can find abrupt shifts in the frequency do-

main. A prominent example for an abrupt climate change in the frequency domain is the mid-Pleistocene transition or revolution (MPR), which is the last major “event” in a secular trend towards more intensive global glaciation that characterizes the last few tens of millions of years. The MPR is the term used to describe the transition between 41 ky (ky =  $10^3$  years) and 100 ky glacial-interglacial cycles which occurred about one million years ago (see a recent review in [61]). Evidence of this is provided by high-resolution oxygen isotope data from deep sea cores, e. g. [45,83].

Another example is the possibility of greenhouse gas-driven warming leading to a change in El Niño events. Modeling studies indicate that a strong enhancement of El Niño conditions in the future is not inconceivable [85]. Such a shift would have enormous consequences for both the biosphere and humans. The apparent phase shifts during the 1970s seems unique over this time period, and may thus represent a real climate shift although the available time series is probably too short to unequivocally prove that the shift is significant [90]. The inability to resolve questions of this kind from short instrumental time series provides one of the strongest arguments for extending the instrumental record of climate variability with well-dated, temporally finely resolved and rigorously calibrated proxy data.

## Introduction

One view of climate change is that the Earth’s climate system has changed gradually in response to both natural and human-induced processes. Researchers became intrigued by abrupt climate change when they discovered striking evidence of large, abrupt, and widespread changes preserved in paleoclimatic archives, the history of Earth’s climate recorded in tree rings, ice cores, sediments, and other sources. For example, tree rings show the frequency of droughts, sediments reveal the number and type of organisms present, and gas bubbles trapped in ice cores indicate past atmospheric conditions.

The Earth’s climate system is characterized by change on all time and space scales, and some of the changes are abrupt even relative to the short time scales of relevance to human societies. Paleoclimatic records show that abrupt climate changes have affected much or all of the Earth repeatedly over the last ice-age cycle as well as earlier – and these changes sometimes have occurred in periods as short as a few years, as documented in Greenland ice cores. Perturbations at northern high latitudes were spectacularly large: some had temperature increases of up to 10–20°C and a local doubling of precipitation within decades.

In the frequency domain, abrupt climate shifts are due to changes in the dominant oscillations (as in the case of the MPR), or due to a shift in the phase between different climate signals. As an example, the phase between the Indian Monsoon and ENSO exhibits significant shifts for the past 100 years [59].

The period of regular instrumental records of global climate is relatively short (100–200 years). Even so, this record shows many climatic fluctuations, some abrupt or sudden, as well as slow drifts in climate. Climatic changes become apparent on many temporal and spatial scales. Most abrupt climate changes are regional in their spatial extent. However, regional changes can have remote impacts due to atmospheric and oceanic teleconnections. Some of these shifts may be termed abrupt or sudden in that they represent relatively rapid changes in otherwise comparatively stable conditions, but they can also be found superimposed on other much slower climatic changes.

The definition of “abrupt” or “rapid” climate changes is therefore necessarily subjective, since it depends in large measure on the sample interval used in a particular study and on the pattern of longer-term variation within which the sudden shift is embedded. It is therefore useful to avoid a too general approach, but instead to focus on different types of rapid transitions as they are detected and modeled for different time periods. Although distinctions between types are somewhat arbitrary, together they cover a wide range of shifts in dominant climate mode on time scales ranging from the Cenozoic (the last 65 millions of years) to the recent and future climate.

## A Mathematical Definition

### Time Domain

Abrupt climate change is characterized by a transition of the climate system into a different state (of temperature, rainfall, and other variables) on a time scale that is faster than variations in the neighborhood (in time). Abrupt climate change could be related to a forcing or internally generated. Consider  $x(t) \in \mathbb{R}^n$  as a multi-dimensional climate state variable (temperature, rainfall, and other variables). We define an abrupt climate shift of degree  $\epsilon$  and amplitude  $B$ , if

$$\frac{d}{dt}x_i(t) \quad \text{can be approximated by a function} \quad \frac{B}{\pi} \frac{\epsilon}{x_i^2 + \epsilon^2} \quad (3)$$

for one  $i \in \{1, \dots, n\}$  in a time interval  $[t_1, t_2]$ . The case  $\epsilon \rightarrow 0$  is called instantaneous climate shift, i. e.  $x_i(t)$  can be

approximated by the Heaviside step function. The degree of approximation can be specified by a proper norm.

An alternative way of defining an abrupt climate shift is through the identification of probable breaks in a time series (e. g., the surface temperature series). The formulation of a two-phase regression (TPR) test, e. g. [55,79], describing a series  $x(t)$  is given by

$$x(t) = \mu_1 + \alpha_1 t + \epsilon(t) \quad \text{for } t \leq c \quad (4)$$

$$x(t) = \mu_2 + \alpha_2 t + \epsilon(t) \quad \text{for } t > c. \quad (5)$$

Under the null hypothesis of no changepoint, the two phases of the regression should be statistically equivalent and both the difference in means  $\mu_{1,2}$ , and the difference in slopes,  $\alpha_{1,2}$ , should be close to zero for each possible changepoint  $c$ .

In a stochastic framework one may use an appropriate stochastic differential equation (Langevin equation)

$$\frac{d}{dt}x(t) = f(x) + g(x)\xi, \quad (6)$$

where  $\xi$  is a stationary stochastic process and the functions  $f, g: \mathbb{R}^n \rightarrow \mathbb{R}^n$  describe the climate dynamics. Abrupt climate change can be defined as a transition of a short period of time  $[t_1, t_2]$ , where the probability of an event is larger than a threshold. The properties of the random force are described through its distribution and its correlation properties at different times. In the Ornstein–Uhlenbeck process  $\xi$  is assumed to have a Gaussian distribution of zero average,

$$\langle \xi(t) \rangle = 0 \quad (7)$$

and to be  $\delta$ -correlated in time,

$$\langle \xi(t)\xi(t + \tau) \rangle = \delta(\tau). \quad (8)$$

The brackets indicate an average over realizations of the random force. For a Gaussian process only the average and second moment need to be specified since all higher moments can be expressed in terms of the first two. Note that the dependence of the correlation function on the time difference  $\tau$  assumes that  $\xi$  is a stationary process.

The probability density  $p(x, t)$  for the variable  $x(t)$  in (6) obeys the Fokker–Planck equation

$$\partial_t p = -\frac{\partial}{\partial x} [f(x)p] + \frac{\partial}{\partial x} \left[ g(x) \frac{\partial}{\partial x} \{g(x)p\} \right]. \quad (9)$$

Its stationary probability density of (6) is given by

$$p_{st}(x) = \mathfrak{N} \exp \left( -2 \int_{x_0}^x \frac{f(y) - g(y)g'(y)}{g(y)^2} dy \right), \quad (10)$$

where  $\aleph$  is a normalization constant.  $g'(y)$  stands for the derivative of  $g$  with respect to its argument. The extrema  $x_m$  of the steady state density obey the equation

$$f(x_m) - g(x_m)g'(x_m) = 0 \quad (11)$$

for  $g(x_m) \neq 0$ . Here is the crux of the noise-induced transition phenomenon: one notes that this equation is not the same as the equation  $f(x_m) = 0$  that determines the steady states of the system in the absence of multiplicative noise. As a result, the most probable states of the noisy system need not coincide with the deterministic stationary states. More importantly, new solutions may appear or existing solutions may be destabilized by the noise. These are the changes in the asymptotic behavior of the system caused by the presence of the noise, e. g. [84].

### Climate Variability and Climate Change

The temporal evolution of climate can be expressed in terms of two basic modes: the forced variations which are the response of the climate system to changes in the external forcing  $F(x, t)$  (mostly called climate change), and the free variations owing to internal instabilities and feedbacks leading to non-linear interactions among the various components of the climate system [68] (mostly called climate variability). The external causes  $F(x, t)$ , operate mostly by causing variations in the amount of solar radiation received by or absorbed by the Earth, and comprise variations in both astronomical (e. g. orbital parameters) and terrestrial forcings (e. g. atmospheric composition, aerosol loading). For example, the diurnal and seasonal variations in climate are related to external astronomical forcings operating via solar radiation, while ice ages are related to changes in Earth orbital parameters. Volcanic eruptions are one example of a terrestrial forcing which may introduce abrupt modifications over a period of 2 or 3 years. The more rapid the forcing, the more likely it is that it will cause an abrupt change. The resulting evolution may be written as

$$\frac{d}{dt}x(t) = f(x) + g(x)\xi + F(x, t). \quad (12)$$

$F(x, t)$  is independent of  $x$  if the forcing does not depend on climate (external forcing).

The internal free variations within the climate system are associated with both positive and negative feedback interactions between the atmosphere, oceans, cryosphere and biosphere. These feedbacks lead to instabilities or oscillations of the system on all time scales, and can either operate independently or reinforce external forcings. Investigations of the properties of systems which are far from

equilibrium show that they have a number of unusual properties. In particular, as the distance from equilibrium increases, they can develop complex oscillations with both chaotic and periodic characteristics. They also may show bifurcation points where the system may switch between various regimes. Under non-equilibrium conditions, local events have repercussions throughout the whole system. These long-range correlations are at first small, but increase with distance from equilibrium, and may become essential at bifurcation points.

When applying (12), different concepts of climate change are in the literature. Quite often, the dynamics is governed by the following stochastic differential equation

$$\frac{d}{dt}x(t) = -\frac{d}{dx}U(x) + \sigma\xi + F(t) \quad (13)$$

with potential

$$U(x) = a_4x^4 + a_3x^3 + a_2x^2 + a_1x. \quad (14)$$

If the potential is quadratic and  $F(t) = 0$ , the Orstein-Uhlenbeck process is retained. In contrast, a bistable non-linear system with two minima in  $U(x)$  has been assumed in which shifts between the two distinctly different states are triggered randomly by stochastic forcing, e. g. [7]. In such a system, climate variability and change in the potential can interact due to stochastic resonance [1,7]. Stochastic resonance occurs when the signal-to-noise ratio of a non-linear device is maximized for a moderate value of noise intensity  $\sigma$ . It often occurs in bistable and excitable systems with sub-threshold inputs. For lower noise intensities, the signal does not cause the device to cross threshold, so little signal is passed through it. For large noise intensities, the output is dominated by the noise, also leading to a low signal-to-noise ratio. For moderate intensities, the noise allows the signal to reach threshold, but the noise intensity is not so large as to swamp it.

Strictly speaking, stochastic resonance occurs in bistable systems, when a small periodic force  $F(t)$  (which is external) is applied together with a large wide-band stochastic force  $\sigma\xi$  (which is internal). The system response is driven by the combination of the two forces that compete/cooperate to make the system switch between the two stable states. The degree of order is related to the amount of periodic function that it shows in the system response. When the periodic force is chosen small enough in order to not make the system response switch, the presence of a non-negligible noise is required for it to happen. When the noise is small very few switches occur, mainly at random with no significant periodicity in the system response. When the noise is very strong a large number of

switches occur for each period of the periodic force and the system response does not show remarkable periodicity. Quite surprisingly, between these two conditions, there exists an optimal value of the noise that cooperatively concurs with the periodic forcing in order to make almost exactly one switch per period (a maximum in the signal-to-noise ratio).

Furthermore, non-linear oscillators have been proposed where the timing of the deterministic external forcing is crucial for generating oscillations [51,77,78]. Some aspects of non-equilibrium systems can be found in the climatic system. On the climatological scale, it exhibits abrupt jumps in the long-term rate of temperature change, which are often associated with changes in circulation patterns.

### Frequency Domain

In the frequency domain, there are different ways to describe abrupt climate change. A stationary process exhibits an autocovariance function of the form

$$\text{Cov}(\tau) = \langle (x(t + \tau) - \langle x \rangle)(x(t) - \langle x \rangle) \rangle \quad (15)$$

where  $\langle \rangle$  denotes the expectation or the statistical mean. Normalized to the variance (i. e. the autocovariance function at  $\tau = 0$ ) one gets the autocorrelation function  $C(\tau)$ :

$$C(\tau) = \text{Cov}(\tau) / \text{Cov}(0). \quad (16)$$

Many stochastic processes in nature exhibit short-range correlations, which decay exponentially:

$$C(\tau) \sim \exp(-\tau/\tau_0), \quad \text{for } \tau \rightarrow \infty. \quad (17)$$

These processes exhibit a typical time scale  $\tau_0$ .

As the frequency domain counterpart of the autocovariance function of a stationary process, one can define the spectrum as

$$S(\omega) = \widehat{\text{Cov}(\tau)}, \quad (18)$$

where the hat denotes the Fourier transformation. However, geophysical processes are furthermore often non-stationary. In this regard, the optimal method is continuous wavelet analysis as it intrinsically adjusts the time resolution to the analyzed scale, e. g. [16,59].

**Wavelet Spectra** A major question concerns the significance testing of wavelet spectra. Torrence and Compo [86] formulated pointwise significance tests against reasonable background spectra. However, Maraun and Kurths [58] pointed out a serious deficiency of pointwise significance

testing: Given a realization of white noise, large patches of spurious significance are detected, making it – without further insight – impossible to judge which features of an estimated wavelet spectrum differ from background noise and which are just artifacts of multiple testing. Under these conditions, a reliable corroboration of a given hypothesis is impossible. This demonstrates the necessity to study the significance testing of continuous wavelet spectra in terms of sensitivity and specificity. Given the set of all patches with pointwise significant values, areawise significant patches are defined as the subset of additionally areawise significant wavelet spectral coefficients given as the union of all critical areas that completely lie inside the patches of pointwise significant values. Whereas the specificity of the areawise test appears to be – almost independently of the signal-to-noise ratio – close to one, that of the pointwise test decreases for high background noise, as more and more spurious patches appear [58].

**Eigenvalues and Pseudospectrum** Another spectral method characterizing the abruptness of climate change is related to the resonance of the linear system (1). As we will see later in the context of atmosphere and ocean instabilities, an eigenvalue analysis is inappropriate in describing the dynamics of the system (12). Inspection of many geophysical systems shows that most of the systems fail the normality condition

$$A A^\dagger = A^\dagger A, \quad (19)$$

where  $\dagger$  denotes the adjoint-complex operator. If a matrix is far from normal, its eigenvalues (the spectrum) have little to do with its temporal evolution [71,87]. More about the dynamics can be learned by examining the pseudospectrum of  $A$  in the complex plane. The  $\epsilon$ -pseudospectrum of operator  $A$  is defined by two equivalent formulations:

$$\begin{aligned} \Lambda_\epsilon(A) &= \{z \in \mathbb{C} : \|(zI - A)^{-1}\| \geq \epsilon^{-1}\} \\ &= \{z \in \mathbb{C} : [\text{smallest singular value of } (zI - A)] \leq \epsilon\}. \end{aligned} \quad (20)$$

This set of values  $z$  in the complex plane are defined by contour lines of the resolvent  $(zI - A)^{-1}$ . The resolvent determines the system's response to a forcing as supplied by external forcing  $F(x, t)$ , stochastic forcing  $g(x)\xi$ , or initial/boundary conditions. The pseudospectrum reflects the robustness of the spectrum and provides information about instability and resonance. One theorem is derived from Laplace transformation stating that transient growth is related to how far the  $\epsilon$ -pseudospectrum extends into

the right half plane:

$$\|\exp(A t)\| \geq \frac{1}{\epsilon} \sup_{z \in \Lambda_\epsilon(A)} \operatorname{Real}(z). \quad (21)$$

In terms of climate theory, the pseudospectrum indicates resonant amplification. Maximal amplification is at the poles of  $(zI - A)^{-1}$ , characterized by the eigenfrequencies. In a system satisfying (19), the system's response is characterized solely by the proximity to the eigenfrequencies. In the non-normal case, the pseudospectrum shows large resonant amplification for frequencies which are not eigenfrequencies. This transient growth mechanism is important for both initial value and forced problems.

## Earth System Modeling and Analysis

### Hierarchy of Models

Modeling is necessary to produce a useful understanding of abrupt climate processes. Model analyses help to focus research on possible causes of abrupt climate change, such as human activities; on key areas where climatic thresholds might be crossed; and on fundamental uncertainties in climate-system dynamics. Improved understanding of abrupt climatic changes that occurred in the past and that are possible in the future can be gained through climate models. A comprehensive modeling strategy designed to address abrupt climate change includes vigorous use of a hierarchy of models, from theory and conceptual models through models of intermediate complexity, to high-resolution models of components of the climate system, to fully coupled earth-system models. The simpler models are well-suited for use in developing new hypotheses for abrupt climate change. Model-data comparisons are needed to assess the quality of model predictions. It is important to note that the multiple long integrations of enhanced, fully coupled Earth system models required for this research are not possible with the computer resources available today, and thus, these resources are currently being enhanced.

### Feedback

One particularly convincing example showing that the feedbacks in the climate system are important is the drying of the Sahara about 5000 years before present which is triggered by variations in the Earth's orbit around the sun. Numerous modeling studies, e. g. [31], suggest that the abruptness of the onset and termination of the early to mid-Holocene humid period across much of Africa north of the equator depends on the presence of non-linear feedbacks associated with both ocean circulation and changes

in surface hydrology and vegetation, e. g. [18]. Without including these feedbacks alongside gradual insolation forcing, it is impossible for existing models to come even close to simulating the rapidity or the magnitude of climatic change associated with the extension of wetlands and plant cover in the Sahara/Sahel region prior to the onset of desiccation around 5000 years before present.

## Climate Archives and Modeling

Systematic measurements of climate using modern instruments have produced records covering the last 150 years. In order to reconstruct past variations in the climate system further back in time, scientists use natural archives of climatic and environmental changes, such as ice cores, tree rings, ocean and lake sediments, corals, and historical evidence. Scientists call these records proxies because, although they are not usually direct measures of temperature or other climatic variables, they are affected by temperature, and using modern calibrations, the changes in the proxy preserved in the fossil record can be interpreted in terms of past climate.

Ice core data, coral data, ring width of a tree, or information from marine sediments are examples of a proxy for temperature, or in some cases rainfall, because the thickness of the ring can be statistically related to temperature and/or rainfall in the past. The most valuable proxies are those that can be scaled to climate variables, and those where the uncertainty in the proxy can be measured. Proxies that cannot be quantified in terms of climate or environment are less useful in studying abrupt climate change because the magnitude of change cannot be determined. Quite often, the interpretation of proxy data is already a model of climate change since it involves constraints (dating, representativeness etc.). Uncertainties in the proxies, and uncertainties in the dating, are the main reasons that abrupt climate change is one of the more difficult topics in the field of paleoclimatology.

## Example: Glacial-Interglacial Transitions

### Astronomical Theory of Ice Ages

Over the past half million years, marine, polar ice core and terrestrial records all highlight the sudden and dramatic nature of glacial terminations, the shifts in global climate that occurred as the world passed from dominantly glacial to interglacial conditions, e. g. [23,69]. These climate transitions, although probably of relatively minor relevance to the prediction of potential future rapid climate change, do provide the most compelling evidence available in the historical record for the role of greenhouse gas, oceanic

Abrupt Climate Change Modeling, Figure 1

Oxygen isotope record from a southern hemisphere ice core [23] showing the glacial-interglacial changes. Note the asymmetry: the state is longer in the cold (glacials) phases than in the warm phases (interglacials)

and biospheric feedbacks as non-linear amplifiers in the climate system. It is such evidence of the dramatic effect of non-linear feedbacks that shows relatively minor changes in climatic forcing may lead to abrupt climate response.

A salient feature of glacial-interglacial climate change is furthermore its asymmetry (Fig. 1). Warmings are rapid, usually followed by slower descent into colder climate. Given the symmetry of orbital forcings  $F(t)$ , the cause of rapid warming at glacial “terminations” must lie in a climate feedback [37,65]. Clearly, the asymmetric feedback is due to the albedo (reflectance) of ice and snow changing from high values under glacial climates to low values under warm climates. The albedo feedback helps explain the rapidity of deglaciations and their beginnings in spring and summer. Increased absorption of sunlight caused by lower albedo provides the energy for rapid ice melt. The build-up of snow and ice takes much longer than melting.

Many simplified climate models consist of only a few coupled ordinary differential equations controlled by carefully selected parameters. It is generally acknowledged that the “best” models will be those that contain a minimum of adjustable parameters [77] and are robust with respect to changes in those parameters. Rial [72] formulated a logistic-delayed and energy balance model to understand the saw-tooth shape in the paleoclimate record: A fast warm-

ing-slow cooling is described by

$$\frac{d}{dt}x(t) = R \left( 1 - \frac{x(t-\tau)}{K(t)} \right) x(t-\tau) \quad (22)$$

$$C \frac{d}{dt}T(t) = Q(1 - \alpha(x)) - (A + BT) \quad (23)$$

with  $x(t)$  for the normalized ice extent,  $\tau$  time delay,  $K(t) = 1 + e(t)T(t)$  carrying capacity,  $1/R$  response time of the ice sheet,  $T(t)$  global mean temperature,  $\alpha(x)$  planetary albedo, external parameter  $e(t)$ , and  $R\tau$  bifurcation parameter.  $A, B, C, Q$  are constants for the energy balance of the climate. The equation is calibrated so that for  $x(t) = 1$  the albedo  $\alpha(x) = 0.3$  and  $T(t) = 15^\circ\text{C}$ . With (23), saw-toothed waveforms and frequency modulation can be understood [72]. The delayed equation yields damped oscillations of  $x(t)$  about the carrying capacity for small  $\tau$ . If  $\tau$  becomes long compared to the natural response time of the system, the oscillations will become strong, and will grow in amplitude, period and duration. As in the logistic equation for growth, here the product  $R\tau$  is a bifurcation parameter, which when crossing the threshold value  $\pi/2$  makes the solutions undergo a Hopf bifurcation and settle to a stable limit cycle with fundamental period  $\sim 4\tau$  [73].

The astronomical theory of ice ages – also called Milankovitch theory [62] – gained the status of a paradigm for explaining the multi-millennial variability. A key

element of this theory is that summer insolation at high latitudes of the northern hemisphere determines glacial-interglacial transitions connected with the waxing and waning of large continental ice sheets, e.g. [33,37], the dominant signal in the climate record for the last million years. Climate conditions of glacials and interglacials are very different. During the Last Glacial Maximum, about 20,000 years before present, surface temperature in the north Atlantic realm was 10–20°C lower than today [13]. A recent study of Huybers and Wunsch [36] has shown that the most simple system for the phase of ice volume  $x(t)$  is given by

$$x(t+1) = x(t) + \sigma \xi \quad (24)$$

with  $\xi$  a Gaussian white noise process, but with mean  $\mu = 1$ , and  $\sigma = 2$ .  $\xi$  represents the unpredictable background weather and climate variability spanning all time scales out to the glacial/interglacial. This highly simplified model posits 1-ky steps in ice volume  $x(t)$ . The non-zero mean biases the Earth toward glaciation. Once  $x(t)$  reaches a threshold, a termination is triggered, and ice-volume is linearly reset to zero over 10 ky. The following threshold condition for a termination makes it more likely for a termination of ice volume to occur when obliquity  $\Theta(t)$  is large:

$$x(t) \geq T_0 - a\Theta(t). \quad (25)$$

$\Theta(t)$  has a frequency of about 41 ky, and is furthermore normalized to zero mean with unit variance. The other parameters are: amplitude  $a = 15$ ,  $T_0 = 105$ . Furthermore, the initial ice volume at 700 ky before present is set to  $x(t = -700) = 30$ . Equation (24) resembles an order-one autoregressive process, similar to (2), plus the threshold condition (25). Models like (24), (25) are not theories of climate change, but rather attempts at efficient kinematic descriptions of the data, and different mechanisms can be consistent with the limited observational records. In the next section, the process of deglaciation is modeled in a three-dimensional model including the spatial dimension.

### Deglaciation

The question is what causes the abrupt warming at the onset of the Boelling as seen in the Greenland ice cores (Fig. 2). There is a clear antiphasing seen in the deglaciation interval between 20 and 10 ky ago: During the first half of this period, Antarctica steadily warmed, but little change occurred in Greenland. Then, at the time when Greenland's climate underwent an abrupt warming, the warming in Antarctica stopped. Knorr and Lohmann [42], also summarizing numerous modeling studies for deglaciation, describe how global warming (which may be induced by greenhouse gases and feedbacks) can induce a rapid intensification of the ocean cir-

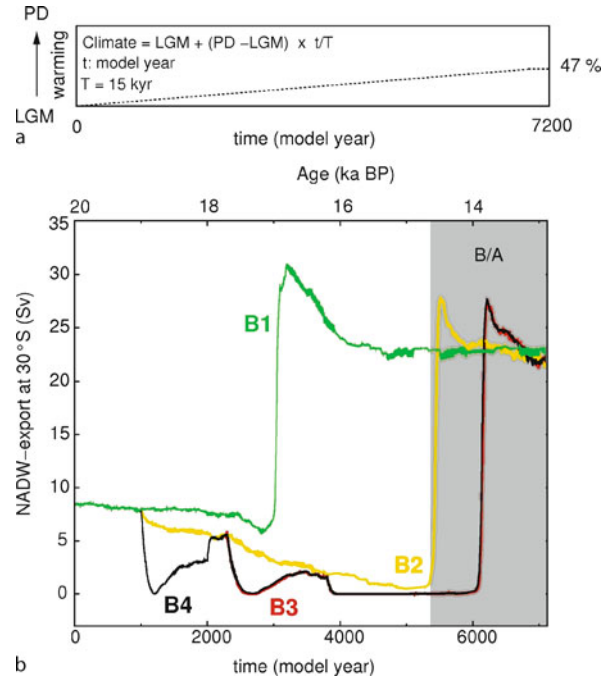

Abrupt Climate Change Modeling, Figure 2

Oxygen isotope record from a Greenland ice core record [64] using an updated time scale for this record [23]. Green: Sea-level derived rate of deglacial meltwater discharge [24] which is strong after deglacial warming

ulation (Fig. 3). During the Boelling/Alleroed, a sudden increase of the northward heat transport draws more heat from the south, and leads to a strong warming in the north. This “heat piracy” from the South Atlantic has been formulated by Crowley [15]. A logical consequence of this heat piracy is the Antarctic Cold Reversal (ACR) during the Northern Hemisphere warm Boelling/Alleroed. This particular example shows that an abrupt climate change of the ocean circulation (with large climate impacts in the North Atlantic) is related to a smooth global warming. To understand the dynamical behavior of the system, the concept of hysteresis is applied, using the global warming after the last ice ages as the control parameter [42]. The system exhibits multiple steady states (Fig. 4): a weak glacial ocean circulation and a stronger circulation (which is comparable in strength to the modern mode of operation). Deglacial warming induces a transition from a weak glacial THC state to a stronger THC state, characterizing the abrupt warming during the deglaciation.

### Millennial Climate Variability

Within glacial periods, and especially well documented during the last one, spanning from around 110 to 11.6ky ago, there are dramatic climate oscillations, including high-latitude temperature changes approaching the same magnitude as the glacial cycle itself, recorded in archives from the polar ice caps, high to middle latitude marine sediments, lake sediments and continental loess sections. These oscillations are usually referred to as the Dansgaard–Oeschger Cycle and occur mostly on 1 to 2 ky time scales, e. g. [6], although regional records of these transitions can show much more rapid change. The termination of the Younger Dryas cold event, for example, is manifested in ice core records from central Greenland as a near doubling of snow accumulation rate and a temperature shift of around 10°C occurring within a decade with world-wide teleconnections. One hypothesis for explaining these climatic transitions is that the ocean thermohaline circulation flips between different modes, with warm intervals reflecting periods of strong deep water formation in the northern North Atlantic and vice versa [29]. As an alternative approach, one can estimate the underlying dynamics (13), (14) directly from data [43]. The method is based on the unscented Kalman filter, a non-linear extension of the conventional Kalman filter. This technique allows one to consistently estimate parameters in deterministic and stochastic non-linear models. The optimization yields for the coefficients  $a_4 = 0.13 \pm 0.01$ ,  $a_3 = -0.27 \pm 0.02$ ,  $a_2 = -0.36 \pm 0.08$ , and  $a_1 = 1.09 \pm 0.23$ . The dynamical noise level of the system  $\sigma$  is estimated to

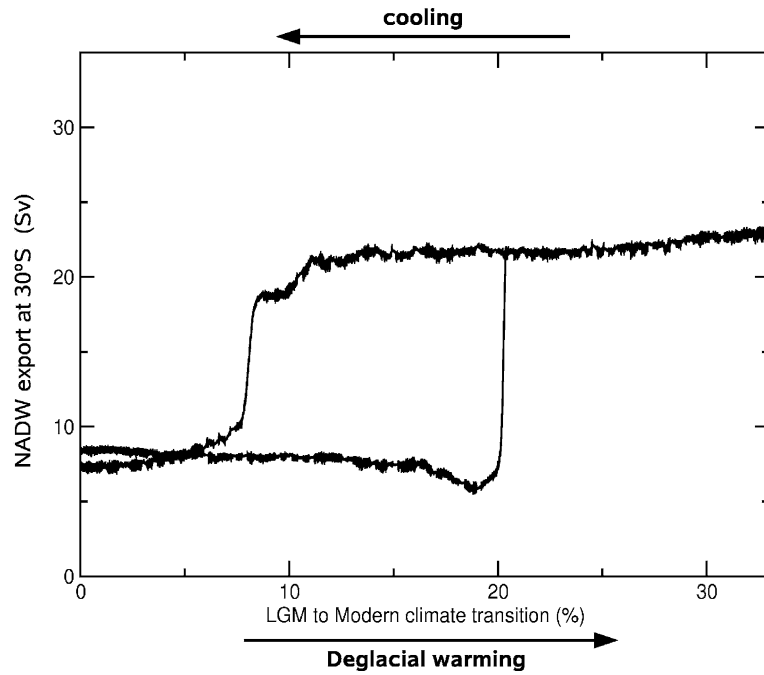

Abrupt Climate Change Modeling, Figure 3

Forcing and model response of the ocean overturning rate. **a** The background climate conditions are linearly interpolated between glacial (LGM), and modern (PD), conditions. Gradual warming is stopped after 7000 model years, which is related to  $\sim 47\%$  of the total warming. **b** Circulation strength (export at 30°S) versus time. The *green curve B1* represents the experiment without any deglacial freshwater release to the North Atlantic. Experiments *B2* (yellow curve), *B3* (red curve), and *B4* (black curve), exhibit different successions of deglacial meltwater pulse scenarios to the North Atlantic [42]

be 2.4. The potential is highly asymmetric and degenerate (that is, close to a bifurcation): there is one stable cold stadial state and one indifferently stable warm interstadial state (Fig. 5). This seems to be related to the fact that the warm intervals are relatively short-lasting.

Coming back to the ice cores and a potential linkage of the hemispheres, Stocker and Johnson [81] proposed a conceptual model linking the isotopic records from Antarctica and Greenland. The basis is an energy balance with temperatures in the North and South Atlantic Ocean, as well as a “southern heat reservoir”. It is assumed that the change in heat storage of a “southern heat reservoir”  $T_S$  is given by the temperature difference between the reservoir  $T_S$  and the Southern Ocean temperature  $T$ , with a characteristic time scale  $\tau$ :

$$\frac{d}{dt} T_S(t) = \frac{1}{\tau} [T - T_S] . \quad (26)$$

Abrupt Climate Change Modeling, Figure 4

Hysteresis loop of the ocean overturning strength (*black curve*) with respect to slowly varying climate background conditions. The transition values are given in % of a full glacial-interglacial transition [42]

Abrupt Climate Change Modeling, Figure 5

Potential derived from the data (*solid*) together with probability densities of the model (*dashed*) and the data (*dotted*)

$T_N$  denotes the time-dependent temperature anomaly of the North Atlantic. The Southern Ocean temperature  $T$  is assumed to be  $-T_N$  according to the bipolar seesaw (North Atlantic cold  $\leftrightarrow$  South Atlantic warm). Using Laplace transform, one can solve for  $T_S$

$$T_S = -\frac{1}{\tau} \int_0^t T_N(t-t') \exp(-t'/\tau) dt' + T_S(0) \exp(-t/\tau). \quad (27)$$

The reservoir temperature is therefore a convolution of the northern temperature using the time scale  $\tau$  ranging from 100 to 4000 years. Equation (27) demonstrates that  $T_S$  and  $T_N$  will have entirely different time characteristics. Abrupt changes in the north appear damped and integrated in time in the southern reservoir. A sudden reduction in the thermohaline circulation causes a cooling in the North Atlantic and a warming in the South, a situation similar to the Younger Dryas period [80], see also Fig. 2.

## Example: Cenozoic Climate Cooling

### Antarctic Glaciation

During the Cenozoic (65 million years ago (Ma) to present), there was the widespread glaciation of the Antarctic continent at about 34 Ma, e.g. [93]. Antarctic glaciation is the first part of a climate change from relatively warm and certainly ice-free conditions to massive ice sheets in both, the southern and northern hemispheres [44]. Opening of circum-Antarctic seaways is one of the factors that have been ascribed as a cause for Antarctic climate change so far [40,93]. Besides gateway openings, the atmospheric carbon dioxide concentration is another important factor affecting the evolution of the Cenozoic climate [17,93]. As a third component in the long-term evolution of Antarctic glaciation, land topography is able to insert certain thresholds for abrupt ice sheet build-up. Whereas tectonics, land topography, and long-term Cenozoic  $\text{CO}_2$ -decrease act as preconditioning for Antarctic land ice formation, the cyclicities of the Earth's orbital configuration are superimposed on shorter time scales and may have served as the ultimate trigger and pacemaker for ice-sheet growth at the Eocene-Oligocene boundary around 34 Ma [14].

DeConto and Pollard [17] varied Southern Ocean heat transport to mimic gateway opening instead of an explicit simulation of ocean dynamics. They found a predominating role of  $\text{pCO}_2$  in the onset of glaciation instead of a dominating tectonic role for "thermal isolation".

### Mid-Pleistocene Revolution

Glaciation in the Northern Hemisphere lagged behind, with the earliest recorded glaciation anywhere in the Northern Hemisphere occurring between 10 and 6 Ma and continuing through to the major increases in global ice volume around 2–3 Ma [60]. A recent compilation of 57 globally distributed records [45] is shown in Fig. 6. Let us focus now on the mid-Pleistocene transition or revolution (MPR), describing the transition from 41 ky to 100 ky glacial-interglacial cycles.

Milankovitch [62] initially suggested that the critical factor was total summer insolation at about  $65^\circ\text{N}$ , because for an ice sheet to grow some additional ice must survive each successive summer. In contrast, the Southern Hemisphere is limited in its response because the expansion of ice sheets is curtailed by the Southern Ocean around Antarctica. The conventional view of glaciation is thus that low summer insolation in the temperate North Hemisphere allows ice to survive summer and thus start to build up on the northern continents. If so, how then do we account for the MPR? Despite the pronounced change in Earth system response evidenced in paleoclimatic records, the frequency and amplitude characteristics of the orbital parameters which force long-term global climate change, e.g., eccentricity ( $\sim 100$  ky), obliquity ( $\sim 41$  ky) and precession ( $\sim 21$  and  $\sim 19$  ky), do not vary during the MPR [8]. This suggests that the cause of change in response at the MPR is internal rather than external to the global climate system.

The result of a wavelet spectral analysis (Fig. 7) suggests several abrupt climate changes in the frequency domain (shown as schematic arrows in the figure). These abrupt climate shifts represent major reorganizations in the climate system. Some of them are possibly linked to the development of Northern Hemisphere ice volume. The MPR marked a prolongation to and intensification of the  $\sim 100$  ky glacial-interglacial climate. Not only does the periodicity of glacial-interglacial cycles increase going through the MPR, but there is also an increase in the amplitude of global ice volume variations.

It is likely that the MPR is a transition to a more intense and prolonged glacial state, and associated subsequent rapid deglaciation becomes possible. The first occurrence of continental-scale ice sheets, especially on Greenland, is recorded as ice-rafted detritus released from drifting icebergs into sediments of the mid- and high-latitude ocean. After a transient precursor event at 3.2 Ma, signals of large-scale glaciations suddenly started in the subtropical North Atlantic in two steps, at 2.9 and 2.7 Ma, e.g. [5].

Abrupt Climate Change Modeling, Figure 6

A compilation of 57 globally distributed records by Lisiecki and Raymo [45]: The  $\delta^{18}\text{O}$  record reflects mainly the climate variables temperature and ice volume

Abrupt Climate Change Modeling, Figure 7

Lisiecki and Raymo [45]: The corresponding wavelet sample spectrum calculated using Morlet wavelet with  $\omega_0 = 6$ . *Thin and thick lines* surround pointwise and areawise significant patches, respectively

The ice volume increase may in part be attributed to the prolonging of glacial periods and thus of ice accumulation. The amplitude of ice volume variation is also accentuated by the extreme warmth of many interglacial pe-

riods. Thus, a colder climate with larger ice sheets should have the possibility of a greater sudden warming [45]. The MPR therefore marks a dramatic sharpening of the contrast between warm and cold periods. Note however, that

the amount of energy at the 40 ka period is hardly changed in the time after 1 Ma, and notably, one sees the addition of energy at longer periods, without any significant reduction in obliquity-band energy. After about 1 Ma, large glacial-interglacial changes begin to occur on an approximately 100 ka time scale (but not periodically) superimposed upon the variability which continues largely unchanged [91]. Why did 100 ka glacial-interglacials also become possible in addition to the ice volume variability? Lowering of global CO<sub>2</sub> below some critical threshold, or changes in continental configuration, or atmospheric circulation patterns, or all together, are among the conceivable possibilities, e. g. [70].

### Examples: Transient Growth

The former examples show the power of the combination of models, data analysis, and interpretation for abrupt climate change. In the next two examples, it is shown how important the transient growth mechanism is for abrupt climate change.

### Conceptual Model of the Ocean Circulation

In this section, a category of the non-linear models following the simple thermohaline model of Stommel [82] is analyzed. The common assumption of these box models is that the oceanic overturning rate  $\Phi$  can be expressed by the meridional density difference:

$$\Phi = -c(\alpha\Delta T - \beta\Delta S), \quad (28)$$

where  $\alpha$  and  $\beta$  are the thermal and haline expansion coefficients,  $c$  is a tunable parameter, and  $\Delta$  denotes the meridional difference operator applied to the variables temperature  $T$  and salinity  $S$ , respectively. Stommel [82] considered a two-box ocean model where the boxes are connected by an overflow at the top and a capillary tube at the bottom, such that the capillary flow is directed from the high-density vessel to the low-density vessel following (28).

The equations for temperature  $T$  and salinity  $S$  are the heat and salt budgets using an upstream scheme for the advective transport and fluxes with the atmosphere:

$$\frac{d}{dt}T = -\frac{\Phi}{V}\Delta T - \frac{F_{\text{oa}}}{\rho_0 c_p h} \quad (29)$$

$$\frac{d}{dt}S = -\frac{\Phi}{V}\Delta S - \frac{S_0}{h}(P - E), \quad (30)$$

where  $V$  is the volume of the box with depth  $h$ , and  $(P - E)$  denotes the freshwater flux (precipitation minus evaporation plus runoff).  $F_{\text{oa}}$  is the heat flux at the ocean-atmo-

sphere interface,  $S_0$  is a reference salinity, and  $\rho_0 c_p$  denotes the heat capacity of the ocean.

Denoting furthermore  $x \in \mathbb{R}^2$  for the anomalies of  $(\Delta T, \Delta S)$ , Lohmann and Schneider [48] have shown the evolution equation is of the following structure:

$$\frac{d}{dt}x = Ax + \langle b|x \rangle x. \quad (31)$$

The brackets  $\langle | \rangle$  denote the Euclidean scalar product. This evolution Equation (31) can be transferred to a

$$x(t) = \frac{1}{\gamma(t)} \exp(At)x_0, \quad (32)$$

with a scaling function  $\gamma(t, x_0)$ . The models of Stommel [82], and many others are of this type, and their dynamics are therefore exactly known.

It is worth knowing that (29), (30) is equivalent to the multi-dimensional Malthus–Verhulst model (also known as the logistic equation), which was originally proposed to describe the evolution of a biological population. Let  $x$  denote the number (or density) of individuals of a certain population. This number will change due to growth, death, and competition. In the simplest version, birth and death rates are assumed proportional to  $n$ , but accounting for limited resources and competition it is modified by  $(1 - x)$ :

$$\frac{d}{dt}x(t) = a(1 - x)x. \quad (33)$$

In climate, the logistic equation is important for Lorenz's [52] error growth model: where  $x(t)$  is the algebraic forecast error at time  $t$  and  $a$  is the linear growth rate.

It is useful to analyze the dynamics in the phase space spanned by temperature and salinity anomalies and investigate the model sensitivity under anomalous high latitude forcing, induced as an initial perturbation. The lines in Fig. 8 are phase space trajectories after perturbations of different magnitude have been injected into the North Atlantic. We notice that for most trajectories, the distances from zero  $(0, 0)$  increase temporarily, where the maximal distance from zero is after a decade. After about 10 years the trajectories in Fig. 8 point into a "mixed temperature/salinity direction", denoted further as  $e_1$ .

Figure 8 implies that the adjustment of the THC involves two phases: A fast thermal response and a slower response on the  $e_1$ -direction. The vector  $e_1$  is identical with the most unstable mode in the system. Because the scaling function  $\gamma(t)$  acts upon both temperature and salinity (32), the evolution of the non-linear model can be well characterized by the eigenvectors of the matrix  $A$ , which is discussed in the following.

Abrupt Climate Change Modeling, Figure 8

The basin of attraction (*white area*) and the dynamics in the thermohaline phase space. With initial conditions outside the gray area, the trajectories converge asymptotically to the origin corresponding to the thermally driven solution of the THC. Due to the fast thermal response during the first decade of relaxation, the distance of the trajectories from zero can increase temporarily

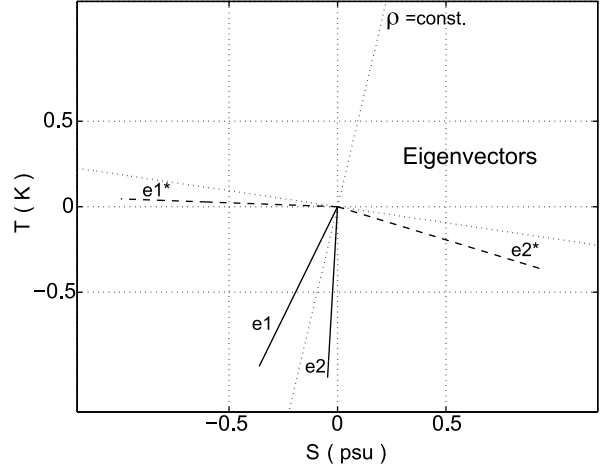

In our system, the operator  $A$  of the box model is found to be non-normal, and the eigenvectors are not orthogonal. One eigenvalue ( $e_2$ ) is closely related to temperature anomalies, whereas the other ( $e_1$ ) is a “mixed temperature/salinity eigenvector” (Fig. 9). The eigenvectors of the adjoint matrix  $A^\dagger$  are denoted by  $e_1^*$  and  $e_2^*$ , respectively. For the non-normal matrix  $A$  and  $A^\dagger$  do not coincide, but fulfill the “biorthogonality condition”:

$$e_1^* \perp e_2 \quad \text{and} \quad e_2^* \perp e_1. \quad (34)$$

Both eigenvalues  $\lambda_{1,2}$  are real and negative. Because of  $\lambda_2 < \lambda_1$ , the first term dominates for long time scales and the second for short time scales. Using the biorthogonality condition, we get furthermore the coefficients

$$c_i = \frac{\langle e_i^* | x_0 \rangle}{\langle e_i^* | e_i \rangle} \quad \text{for } i = 1, 2. \quad (35)$$

A perturbation is called “optimal”, if the initial error vector has minimal projection onto the subspace with fastest decaying perturbations, or equivalently if the coefficient  $c_1$  is maximal. This is according to (35) equivalent to  $x_0$  pointing into the direction of  $e_1^*$ . This unit vector

Abrupt Climate Change Modeling, Figure 9

Eigenvectors  $e_1, e_2$ , and adjoint eigenvectors  $e_1^*, e_2^*$  of the tangent linear operator  $A^\dagger$ . The *dotted lines* show the line of constant density and the perpendicular

$e_1^*$  is called the “biorthogonal” [66] to the most unstable eigenvector  $e_1$  which we want to excite. In order to make a geometrical picture for the mathematical considerations, assume that the tail of the vector  $x_0$  is placed on the  $e_1$ -line and its tip on the  $e_2$ -line. This vector is stretched maximally because the tail decays to zero quickly, whereas the tip is hardly unchanged due to the larger eigenvalue  $\lambda_1$ . The most unstable mode  $e_1$  and its biorthogonal  $e_1^*$  differ greatly from each other, and the perturbation that optimally excites the mode bears little resemblance to the mode itself.

It is remarkable that the optimal initial perturbation vector  $e_1^*$  does not coincide with a perturbation in sea surface density at high latitudes, which would reside on the dotted line perpendicular to  $\rho = \text{const}$  in Fig. 9. Even when using a space spanned by  $(\alpha T, \beta S)$  instead of  $(T, S)$ , to take into account the different values for the thermal and haline expansion coefficients, vector  $e_1^*$  is much more dominated by the scaled salinity anomalies than the temperature anomalies of the high latitudinal box.

Numerical simulations by Manabe and Stouffer [57] showed, for the North Atlantic, that between two and four times the preindustrial  $\text{CO}_2$  concentration, a threshold value is passed and the thermohaline circulation ceases completely. One other example of early Holocene rapid climate change is the “8200-yr BP” cooling event recorded in the North Atlantic region possibly induced by freshwater. One possible explanation for this dramatic regional cooling is a shutdown in the formation of deep water in the northern North Atlantic due to freshwater input caused by

catastrophic drainage of Laurentide lakes [4,46]. The theoretic considerations and these numerical experiments suggest that formation of deep water in the North Atlantic is highly sensitive to the freshwater forcing.

### Resonance in an Atmospheric Circulation Model

An atmospheric general circulation model PUMA [26] is applied to the problem. The model is based on the multi-level spectral model described by Hoskins and Simmons [35]. For our experiments we chose five vertical levels and a T21 horizontal resolution. PUMA belongs to the class of models of intermediate complexity [12]; it has been used to understand principle feedbacks [56], and dynamics on long time scales [76]. For simplicity, the equations are scaled here such that they are dimensionless. The model is linearized about a zonally symmetric mean state providing for a realistic storm track at mid-latitudes [27]. In a simplified version of the model and calculating the linear model  $A$  with  $n = 214$ , one can derive the pseudospectrum. Figure 10 indicates resonances besides the poles (the eigenvalues) indicated by crosses. The  $\text{Im}(z)$ -axis shows the frequencies, the  $\text{Re}(z)$ -axis the damping/amplification of the modes. Important modes for the climate system are those with  $-0.5 < \text{Im}(z) < 0.5$  representing planetary

Rosby waves. The basic feature is that transient growth of initially small perturbations can occur even if all the eigenmodes decay exponentially. Mathematically, an arbitrary matrix  $A$  can be decomposed as a sum

$$A = D + N \quad (36)$$

where  $A$  is diagonalizable, and  $N$  is nilpotent (there exists an integer  $q \in \mathbb{N}$  with  $N^q = 0$ ), and  $D$  commutes with  $N$  (i. e.  $DN = NA$ ). This fact follows from the Jordan–Chevalley decomposition theorem. This means we can compute the exponential of  $(A t)$  by reducing to the cases:

$$\exp(At) = \exp((D + N)t) = \exp(Dt) \exp(Nt) \quad (37)$$

where the exponential of  $Nt$  can be computed directly from the series expansion, as the series terminates after a finite number of terms. Basically, the number  $q \in \mathbb{N}$  is related to the transient growth of the system ( $q = 1$  means no transient growth).

The resonant structures are due to the mode interaction: It is not possible to change one variable without the others, because they are not orthogonal. Interestingly, one can also compute the  $A^\dagger$  model, showing the optimal

Abrupt Climate Change Modeling, Figure 10

Contours of  $\log_{10}(1/\epsilon)$ . The figure displays resonant structures of the linearized atmospheric circulation model. The modes extend to the right half plane and are connected through resonant structures, indicating the transient growth mechanism inherent in atmospheric dynamics

perturbation of a mode  $e_i$  through its biorthogonal vector (35).

The analysis indicates that non-normality of the system is a fundamental feature of the atmospheric dynamics. This has consequences for the error growth dynamics, and instability of the system, e. g. [48,66]. Similar features are obtained in shear flow systems [71,87] and other hydrodynamic applications. This transient growth mechanism is important for both initial value and forced problems of the climate system.

### Future Directions

Until now, details of abrupt climate change are not well known to accurately predict it. With better information, the society could take more confident action to reduce the potential impact of abrupt changes on agriculture, water resources, and the built environment, among other impacts. A better understanding of sea-ice and glacier stability, land-surface processes, and atmospheric and oceanic circulation patterns is needed. Moreover, to effectively use any additional knowledge of these and other physical processes behind abrupt climate change, more sophisticated ways of assessing their interactions must be developed, including:

**Better models.** At present, the models used to assess climate and its impacts cannot simulate the size, speed, and extent of past abrupt changes, let alone predict future abrupt changes. Efforts are needed to improve how the mechanisms driving abrupt climate change are represented in these models and to more rigorously test models against the climate record.

**More theory.** There are concepts to find the underlying dynamical system, to derive a theory from a high-order to low-order description similar to what is done in statistical physics (Mori–Zwanzig approach [63,94], Master equation), or in stochastic differential equations. A systematic reduction of the complex system into fewer degrees of freedom shall bring a deeper level of understanding about the underlying physics. A systematic approach was suggested by Saltzman [77]. Spectral and pseudo-spectral concepts have not been used too much in climate theory. There is a variety of phenomenological stochastic models in which non-linearity and fluctuations coexist, and in which this coexistence leads to interesting phenomena that would not arise without the complex interplay.

**Paleoclimatic data.** More climate information from the distant past would go a long way toward strengthening our understanding of abrupt climate changes and models of past climate. In particular, an enhanced effort is needed to expand the geographic coverage, temporal resolution,

and variety of paleoclimatic data. Although the present climate has no direct analogon to the past [54], the dynamical interpretation of data will improve the understanding of thresholds and non-linearities in the Earth system.

**Appropriate statistical tools.** Because most statistical calculations at present are based on the assumption that climate is not changing but is stationary, they have limited value for non-stationary (changing) climates and for climate-related variables that are often highly skewed by rapid changes over time such as for abrupt-change regimes. Available statistical tools themselves need to be adapted or replaced with new approaches altogether to better reflect the properties of abrupt climate change.

**Synthesis.** Physical, ecological, and human systems are complex, non-linear, dynamic and imperfectly understood. Present climate change is producing conditions outside the range of recent historical experience and observation, and it is unclear how the systems will interact with and react to further climate changes. Hence, it is crucial to be able to better understand and recognize abrupt climate changes quickly. This capability will involve improved monitoring of parameters that describe climatic, ecological, and economic systems. Some of the desired data are not uniquely associated with abrupt climate change and, indeed, have broad applications. Other data take on particular importance because they concern properties or regions implicated in postulated mechanisms of abrupt climate change. Research to increase our understanding of abrupt climate change should be designed specifically within the context of the various mechanisms thought to be involved. Focus is required to provide data for process studies from key regions where triggers of abrupt climate change are likely to occur, and to obtain reliable time series of climate indicators that play crucial roles in the postulated mechanisms. Observations could enable early warning of the onset of abrupt climate change. New observational techniques and data-model comparisons will also be required.

[Definition of the Subject](#)

[Introduction](#)

[Scaling Relations: Self-similarity](#)

[Earthquake and Fault Populations: Self-organization](#)

[Models of the System](#)

[Future Directions](#)

[Bibliography](#)

### Glossary

**Ductile shear zone** A quasi-planar tabular zone of localized shear deformation in the semi-brittle to fully plastic regimes.

**Earthquake** Dynamically running shear instability on a fault.

**Fault** A shear crack with friction between its interfaces.

**Mylonite** A metamorphic rock with a fabric produced by shear deformation.

**Suprafault** The shear relaxation structure that includes a fault and its associated ductile shear zone.

### Definition of the Subject

Brittle deformation is the primary mode of deformation of Earth's crust. At the long timescale it is manifested by faulting, and on the short timescale by earthquakes. It is one of the best-known examples of a system exhibiting self-organized criticality. A full understanding of this system is essential to the evaluation of earthquake hazard.

### Introduction

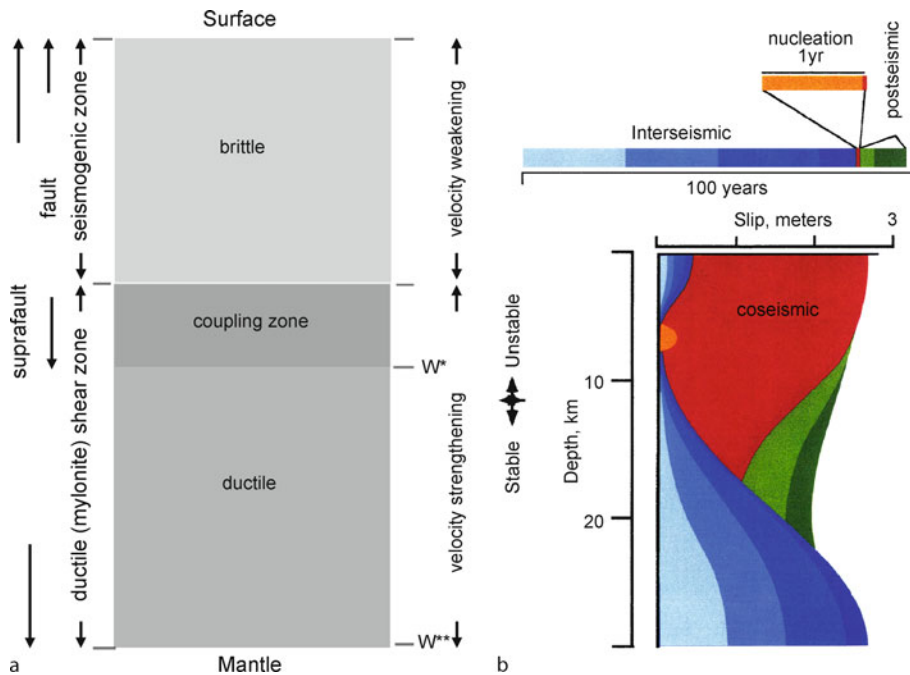

The upper part of Earth's crust is brittle and under a state of all-round compression. It responds to deformation by faulting: the formation and propagation of shear cracks. The crack walls support normal stresses and hence fault propagation must overcome not only the rupture resistance of the fault tips but friction between its interior interfaces. This friction is usually velocity weakening, such that any slippage results in stick-slip instability. The resulting

dynamically running crack-like shear instability radiates elastic waves, producing the shaking known as an earthquake. Thus brittle tectonics separates into two greatly different timescales: the long timescale of the faulting and the short timescale of the earthquakes. Faults propagate quasi-statically at rates set by tectonic driving rates, whereas earthquakes propagate at a rate set by the shear velocity of the rock. Almost all displacement on continental faults occurs by earthquakes, so that there is a coupling between the two timescales.

This system is illustrated in Fig. 1a. The term *fault* is usually restricted to the rupture of the brittle part, but large faults continue downwards as ductile shear zones, which, in the case of major faults, may extend as deep as the crust-mantle boundary. We will refer to the entire shear release structure, including both the fault and its corresponding ductile shear zone as the *suprafault*.

The division between brittle and ductile behavior occurs at what is usually called the brittle-ductile transition. This transition is gradual, with a change in deformation mechanism from brittle crack propagation and friction to fully plastic deformation through a region of mixed behavior known as semi-brittle. For our purposes, however, it is more useful to divide the suprafault into two regimes, of velocity weakening and velocity strengthening rheologies, at a depth  $S$ . These regions are predicted by a rate/state variable friction law that has been established in the laboratory (for a review, see [25]). Here, we also refer to the ductile regime as velocity strengthening because the creep law for velocity strengthening friction is the same form as for ductile creep.  $S$  corresponds to the upper onset of the brittle-ductile transition and it varies regionally because it depends on temperature (heat flow) and strain rate. For faults in continental crust it varies between about 10–20 kms. Earthquakes can only nucleate above  $S$ , so this constitutes the *seismogenic zone*. When earthquakes become large, they can, owing to the very high strain rates at their rupture tips, propagate below  $S$  to  $W^*$ , which defines the maximum width of earthquakes. Similarly, the maximum width of a suprafault is  $W^{**}$ .

Although the ductile region is velocity (strain-rate) strengthening, it is also, seemingly paradoxically, strain softening, which leads to strain localization into narrow shear zones. As the rock shears, it gradually reorganizes internally to form a mylonitic fabric, which facilitates further shearing. With finite strain, the mylonitic fabric develops further and the mylonitic foliation rotates closer to the plane of shear, progressively reducing the rock's resistance to shear in that particular direction and plane. It is this mechanism of *fabric weakening* that produces the shear localization.

Brittle Tectonics: A Non-linear Dynamical System, Figure 1

**a** A schematic longitudinal section of the rheological components of a crustal suprafault. **b** A simulation of a model with the properties of (a), shown throughout a seismic cycle (after Tse and Rice [37])

The system has two characteristic length scales,  $W^*$  and  $W^{**}$ . An earthquake nucleates within the seismogenic zone and initially propagates in all directions along its perimeter, acting as a 3D crack. When its dimension exceeds  $W^*$ , it has breached the free surface and penetrated to  $W^*$  and then is prohibited from growing deeper. It is then restricted to propagating in the horizontal direction, acting as a 2D crack. Thus there is a symmetry breakage at the dimension  $W^*$ . *Small* earthquakes, with dimensions smaller than  $W^*$ , are not self-similar with *large* earthquakes, those with lengths larger than  $W^*$ . The same occurs for suprafaults at the dimension  $W^{**}$ .

The coupling of the system is illustrated in Fig. 1b. This simulation shows the deformation of a strike slip suprafault (one in which the slip is horizontal), over the seismic cycle, i.e. the recurrence time of a large earthquake. The recurrence time depends on the long-term (geologic) slip rate of the suprafault. During the *interseismic* period, the ductile region shears at a constant rate and gradually propagates upwards. This loads the upper region until nucleation occurs above  $S$  as a quasi-static crack that eventually goes dynamic, resulting in an earthquake that propagates over  $S$  and down to  $W^*$ . The ductile region is instantaneously reloaded by the downward propagation of the earthquake. This results in *postseismic* relaxation that exponentially decays over a period of years to decades.

## Scaling Relations: Self-similarity

### Earthquakes

The primary scaling relation for cracks is that between the shear displacement (slip),  $D$ , for faults or  $\Delta D$  for earthquakes, and the dimension  $L$  of the rupture. The ratio of these parameters is a stress-drop  $\Delta\sigma$  normalized by an elastic constant. Figure 2 shows data for small earthquakes, in which seismic moment  $M_0 = \mu\Delta DA$  is plotted vs.  $L$  ( $\mu$  is the shear modulus and  $A$  is rupture area). Because these are 3D cracks the  $L^3$  lines are loci of equal stress-drop. Although there is considerable scatter, the data follow this trend. Thus, while  $\Delta\sigma$  varies by about 2 orders of magnitude among earthquakes, it is scale-invariant. These earthquakes are thus self-similar.

A plot of slip vs. length for large earthquakes is shown in Fig. 3. What is seen is that initially  $\Delta D$  increases linearly with  $L$  and, following a long crossover, becomes constant. From the static analysis of a 2D crack, we would expect, for constant stress-drop, that  $\Delta D$  be proportional to  $W^*$ , and hence constant on a plot like this, but this is seen only for the rare earthquakes with aspect ratios greater than 10. A static scaling analysis suggests that the crossover be complete by an aspect ratio of 4. A numerical model of dynamic shear cracking produced the same delayed crossover [30]. Further study of the same model

Brittle Tectonics: A Non-linear Dynamical System, Figure 2  
 A collection of data for small earthquakes showing the relationship between seismic moment  $M_0 = \mu \Delta D A$  and source radius. Dashed lines are of constant stress drop. From Hanks [15]

suggests that the long rollover results from significant slip below the seismogenic depth [31]. The scaling of large earthquakes thus exhibit two self-similar regimes, neither of which is self-similar with small earthquakes.

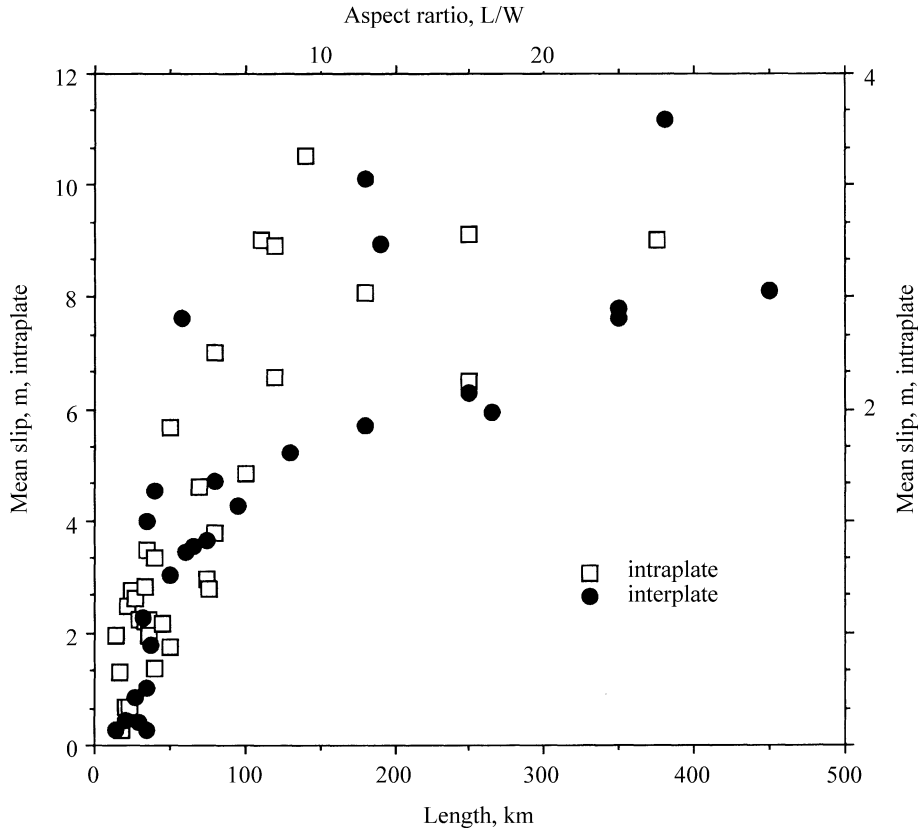

The two  $\Delta D$  scales in Fig. 3, for interplate and intraplate earthquakes, illustrate the rate effect on stress drop. Earthquakes on intraplate faults, for which geological sliding rates are several orders of magnitude less than for interplate faults, have, on average, stress drops about three times larger than interplate earthquakes. Such fault healing is expected from the rate/state friction constitutive law [4].

## Faults

The displacement profiles for some faults in the same rock type, ranging in length from 690 to 2200 m, are shown, normalized by length, in Fig. 4. The data collapse shows the self-similarity of these profiles. Displacement amplitude scales linearly with length, whereas the linear displacement tapers as the tips are approached are scale invariant. A global plot of  $D$  vs.  $L$  is shown in Fig. 5. There is, similar to earthquakes, considerable scatter, but the overall trend shows a linear relationship between  $D$  and  $L$ . Here more can be said about the origin of the scatter than in the case of earthquakes. Those faults with  $D/L$  ratios less than  $10^{-2}$  are in soft sedimentary rock at shallow depth; those with greater  $D/L$  are in strong metamorphic or igneous rock. Faults of length greater than 5 km extend increasingly deeper into the crust and exhibit an increase in  $D/L$  (stress-drop) owing to the increase of strength with pressure. Scatter is also produced by the interaction of faults through their stress fields, which distorts their displacement profiles (see pp. 126–129 in [27]). These effects of lithology and fault interaction also occur for the displacement tapers near the fault tips, which are another measure of strength [28]. In a study in which the faults are in a single lithology and were selected to be isolated [13], the scatter in both  $D/L$  and fault tip taper was correspondingly reduced (as in Fig. 4).

We do not have data for long enough faults to observe a crossover from 3D to 2D scaling, as we did for earthquakes. Because  $W^{**} \sim 40$  km, we would need data from faults of length exceeding 400 km to clearly see this effect. Although faults of that length and longer exist, they are predominately plate boundaries, which have no tips because their ends connect to other plate boundaries and are stress relieved by them. Therefore the scaling of Fig. 5 does not apply to them. The San Andreas fault in California, for example, terminates at its southern end at a spreading ridge. Its net slip is more than an order of magnitude greater than would be expected from simple application of the scaling shown in Fig. 5.

Faults, like earthquakes, are self-similar. The scaling parameters relating  $D$  and  $L$  differ greatly, however. For

Brittle Tectonics: A Non-linear Dynamical System, Figure 3

Mean slip vs. rupture length for large earthquakes. Two scaling regimes are observed. Slip increases approximately linearly with  $L$  up to an aspect ratio of about 10, and is independent of length thereafter. After Scholz [22]

Brittle Tectonics: A Non-linear Dynamical System, Figure 4  
 Displacement profiles along faults of different length in the Volcanic Tablelands of eastern California, normalized to length. Data from Dawers et al. [13]

faults it is  $\sim 10^{-2}$  and for earthquakes,  $10^{-4}$ – $10^{-5}$ . Both represent stress-drops. For faults, it is the stress-drop from the fracture strength of intact rock to the residual frictional strength. For earthquakes, it is the stress-drop from static to dynamic friction.

**Earthquake and Fault Populations:  
 Self-organization**

Earthquakes and faults both self-organize into populations with well defined statistical properties, thus exhibiting complexity in the physics of this system.

**Earthquakes**

The frequency  $N(M)$  of earthquakes greater than magnitude  $M$  has long been known to obey the Gutenberg-Richter law,  $\log N(M) = a - bM$  in which  $b \approx 1$  is found universally for small earthquakes. In laboratory experiments  $b$  is found to decrease with stress [21]. The fact that  $b$  is narrowly limited in the Earth’s crust may be be-

Brittle Tectonics: A Non-linear Dynamical System, Figure 5

Maximum slip vs. length for fault data sets from various tectonic settings. Modified from Schlishe et al. [20]

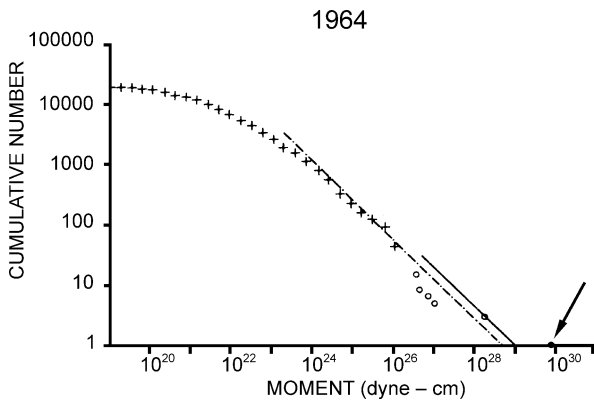

cause stress in the crust is limited to a narrow range by the frictional strength of faults [36].  $M$  is a logarithmic measure of energy  $E$  or seismic moment,  $M_0$ . In terms of  $M_0$  this relation is  $N(M_0) = aM_0^{-B}$  where  $B = 2/3b$ . However, as shown in Fig. 6, in the global catalog of earthquakes there is a crossover from  $b = 1$  to  $b = 1.5$  at about  $M7.5$ . This corresponds to a rupture dimension of about 50 km, which is an average value of  $W^*$  for subduction zones, which dominate this data set. For a subset of continental earthquakes, the same crossover is observed at  $M6.5$ , corresponding to a rupture length of 10–20 km, similar to  $W^*$  for crustal faults. Thus in terms of a linear measure of earthquake size like  $E$  or  $M_0$ , earthquakes have a power law size distribution. Where there is a breakdown of self-similarity between small and large

earthquakes there is a corresponding change in the exponent  $B$  in this distribution.

The size distribution discussed above applies to regions large enough to include many active faults or plate boundary segments. If we study instead a single fault or plate boundary segment that ruptures in a single large earthquake and consider earthquakes that occur within a single seismic cycle of that earthquake, a different picture emerges. An example is shown in Fig. 7. There we see that the small earthquakes during that interval obey a power law with  $B = 2/3$ , as usual, but that the single large earthquake is more than an order of magnitude greater than expected from extrapolation of the small events. This is another manifestation of large and small earthquakes belonging to different fractal sets.

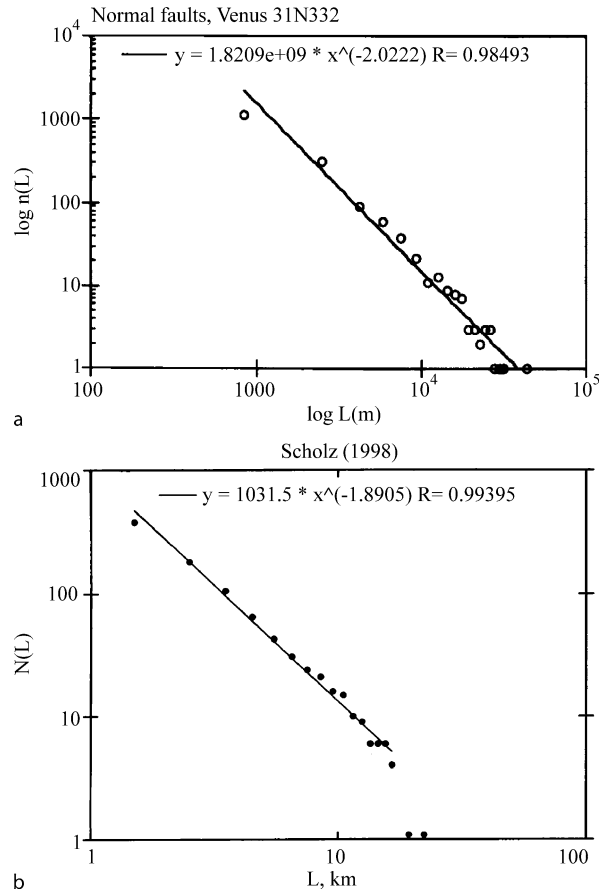

Brittle Tectonics: A Non-linear Dynamical System, Figure 6  
 The frequency size distribution from a global cataloger of Pacheco and Sykes [18] for two magnitude scales. From Pacheco et al. [19]

Brittle Tectonics: A Non-linear Dynamical System, Figure 7  
 Distribution of small earthquakes in the rupture zone of the 1964 Alaskan  $M_{9.4}$  earthquake, normalized to the recurrence time of that earthquake. An arrow indicates the 1964 earthquake. It is about  $1\frac{1}{2}$  times larger than an extrapolation of the small earthquakes would indicate. The roll off at  $M_0 < 3 \times 10^{23}$  dyne cm is cause by a lack of perceptibility of smaller events. From Davison and Scholz [11]

**Faults**

Fault data are usually obtained by geological mapping. Because mapping has a dynamic range limited to about one

Brittle Tectonics: A Non-linear Dynamical System, Figure 8  
 Power law size distributions of faults. a Frequency-length distribution for faults on the plains of Venus from a Magellan SAR image [23]. b Cumulative length distribution of subfaults of the San Andreas fault [26]

order of magnitude, it is difficult to convincingly demonstrate a power law size distribution with this method. When the results of mapping at several scales are combined [29], the case for a power law is strengthened, but the exponent is poorly determined. This problem was overcome with the data in Fig. 8a, from a Magellan SAR image of normal faults on the plains of Venus. This image has a far greater dynamic range, and unequivocally demonstrates a power law distribution, with an exponent  $-2$ . This is a frequency plot, rather than a cumulative plot such as shown in Fig. 7.

On close examination, faults are found to be not a continuous surface, but a complex of myriad strands or subfaults. A cumulative size distribution of the subfaults of the San Andreas fault is shown in Fig. 8b, where they are also shown to obey a power law. The upper fractal limit of the subfaults appears to be  $W^*$ .

Brittle Tectonics: A Non-linear Dynamical System, Figure 9  
 The distribution of faults at two places on the flanks of mid-ocean ridges. These distributions are exponential, rather than power law. From Cowie et al. [9]

The size distributions of earthquakes and faults are not unrelated. If one equates faults with large earthquakes and subfaults with small earthquakes, then by convolving over the fault distributions of Fig. 8 one can obtain the earthquake distributions of Figs. 6 and 7 [24,26].

Not all fault distributions are power law, however. Figure 9 shows the size distribution of faults on the flanks of the East Pacific Rise, obtained by sonar swath mapping. These clearly obey an exponential rather than a power law distribution. One can also find examples of periodic distributions, such as the regularly spaced faults of the Basin and Range province of the Western US. We show later that three regimes, characterized by power law, exponential, and periodic distributions, evolve with increasing strain.

### Models of the System

The first model of the earthquake system was a bench-top apparatus of a string of weights connected by springs and pulled along a frictional surface [6]. Their main finding was that this model obeyed the Gutenberg–Richter law. Interest in this result was revived by the paper of Bak, Tang, and Wiesenfeld [3], which introduced the concept of *self-organized criticality*.

Bak et al. [3] illustrated this concept with a cellular automata model of a sandpile, in which the cells are governed by a nearest neighbor rule for avalanches and the system is driven by the slow random addition of grains to the pile. The result was a power law distribution of avalanches and a  $1/f$  energy flux. From this they hypothesized that systems containing many interacting elements may exhibit general statistical properties that are described by power laws. They called this behavior self-organized

criticality (SOC). Although this concept is intuitively appealing, there is no clear-cut definition of what SOC is.

Because the Gutenberg–Richter law is the most famous of such power laws, adaptations of this cellular automata model to earthquakes soon followed (e. g. [2,5]). Carlson and Langer [7] explored a numerical spring-slider model that contained the full dynamics of the slider blocks. All these models reproduced the Gutenberg–Richter law and also explored other aspects of the system, for example, in the case of Brown et al. [5], the distribution of recurrence times of large earthquakes. Olami et al. [17] explored a non-conservative spring block model, and Christensen and Olami [8] showed how Omori’s law of aftershocks might be explained without having to appeal to an added viscosity as did Burridge and Knopoff. Sornette and Virieux [32], using a mean field theory approach, showed that the scaling difference between small and large earthquakes results in the change in  $b$  value shown in Fig. 6. Extended discussion of these models and their results can be found in Turcotte [38] and Jensen [16].

The study of the self-organization of faults was done first in an analog model of continental deformation by Davy et al. [12], who found a geometrically fractal fault distribution. Cowie et al. [10] studied a model simulating a brittle sheet undergoing stretching. For large strains this model converges on a single system size crack, but at small strains power law size crack distributions were observed.

Spyropoulos et al. [34] expanded on this with a spring-block model of the stretching of a brittle sheet supported by a ductile substrate. They found an evolution of the crack population with strain, from power law to exponential distributions and finally to a periodic distribution of system size cracks. In this model, the brittle layer contains only nearest neighbor interactions but the ductile substrate provides longer-range force interactions. It is the longer-range interactions that result in the evolution of the system and is what differs this model from the sandpile family of models. The evolution from a power law distribution to an exponential distribution of cracks has been demonstrated with physical models [1,33]. It has also been demonstrated in the field, for faults in the Asal rift of Ethiopia [14].

### Future Directions

Our understanding of brittle tectonics as a dynamical system is still very sketchy. Approaches to it tend to be piecemeal, which leads to self-limiting results. For example, although it is now well known that earthquakes interact through their stress fields (e. g. [35]), this phenomenon is modeled by assuming that the background ‘tectonic’ stress

field is uniform, thus ignoring the stress fields of faults, which also interact. The interaction of faults has so far been studied in only the simplest case, that of sub-parallel normal faults. For strike-slip faults, in which the fault tip stresses are asymmetric, more interesting possibilities exist, as yet unexplored. The San Andreas fault system in California is a complex of faults several hundred km wide that somehow act together to accommodate most of the Pacific-North America plate motion. How does this work? How do the faults interact in such a way to preserve continuity of plate motion along strike, as geodetic data indicate? How does the interaction between faults lead to the geometric evolution of fault patterns? Are fault slip rates stationary, as often assumed, or do they vary at intermediate time scales between that of earthquakes and that of the faults themselves? If so, can this explain the temporal clustering of earthquakes that seem to occur over spatial distances long compared to the stress fields of earthquakes? These are but a few of the problems one can imagine studying in the future, once the idea is accepted that the system must be considered in its entirety before being broken into digestible chunks.

### Glossary

**Anthropogenic emissions** Greenhouse gas emissions that are produced as a result of humans through such developments as industry or agriculture.

**Greenhouse gases** The gases of the atmosphere that create the greenhouse effect, which keeps much of the heat from the sun from radiating back into outer space. Greenhouse gases include, in order of relative abundance: Water vapor, carbon dioxide, methane, nitrous oxide, ozone, and CFCs. Greenhouse gases come from natural sources and human activity; present CO<sub>2</sub> levels are ~380 ppmv, approximately 100 ppmv higher than they were in pre-industrial times.

**Soybean cyst nematode** *Heterodera glycines*, a plant-parasite that infects the roots of soybean, with the female becoming a cyst. Infection causes various symptoms, including a serious loss of yield.

**El Niño-southern oscillation (ENSO)** A phenomenon in the equatorial Pacific Ocean characterized by a positive sea-surface temperature departure from normal (for the 1971–2000 base period) in the Niño 3.4 region greater than or equal in magnitude to 0.5°C, averaged over three consecutive months.

**North atlantic Oscillation (NAO)** A hemispheric, meridional oscillation in atmospheric mass with centers of action near Iceland and over the subtropical Atlantic.

**Vegetative index** A simple numerical indicator used to analyze remote sensing measurements, often from space satellites, to determine how much photosynthesis is occurring in an area.

**Soil organic carbon** All the organic compounds within the soil without living roots and animals.

### Introduction

The term climate change refers to an overall shift of mean climate conditions in a given region. The warming

trend associated with anthropogenic emissions of greenhouse gases and the enhanced greenhouse effect of the atmosphere can and should be regarded as a “climate change” when viewed on the time scale of decades or a few centuries.

Climate change exacerbates concerns about agricultural production and food security worldwide. At global and regional scales, food security is prominent among the human concerns and ecosystem services under threat from dangerous anthropogenic interference in the earth’s climate [17,29,50]. At the national scale, decision-makers are concerned about potential damages that may arise in coming decades from climate change impacts, since these are likely to affect domestic and international policies, trading patterns, resource use, regional planning, and human welfare.

While agro-climatic conditions, land resources and their management are key components of food production, both supply and demand are also critically affected by distinct socio-economic pressures, including current and projected trends in population and income growth and distribution, as well as availability and access to technology and development. In the last three decades, for instance, average daily per capita intake has risen globally from 2,400 to 2,800 calories, spurred by economic growth, improved production systems, international trade, and globalization of food markets [12]. Feedbacks of such growth patterns on cultures, personal tastes, and lifestyles have in turn led to major dietary changes – mainly in developing countries – where shares of meat, fat, and sugar in total food intake have increased significantly [13]. Thus, the consequences of climate change on world food demand and supply will depend on many interactive dynamic processes.

Agriculture plays two fundamental roles in human-driven climate change. It is one of the key human sectors that will be affected by climate change over the coming decades, thus requiring adaptation measures. Agriculture is also a major source of greenhouse gases to the atmosphere, including carbon dioxide (CO<sub>2</sub>) due to land-use change and farm operations; methane (CH<sub>4</sub>) from rice production and livestock husbandry, and nitrous oxide (N<sub>2</sub>O) from application of nitrogen fertilizer. As climate changes as well as socio-economic pressures shape future demands for food, fiber and energy, synergies can be identified between adaptation and mitigation strategies, so that robust options that meet both climate and societal challenges can be developed. Ultimately, farmers and others in the agricultural sector will be faced with the dual task of contributing to global reductions of carbon dioxide and other greenhouse gas

emissions, while coping with an already-changing climate.

A changing climate due to increasing anthropogenic emissions of greenhouse gases will affect both the productivity and geographic distribution of crop and pasture species. The major climate factors contributing to these responses include increasing atmospheric carbon dioxide, rising temperature, and increasing extreme events, especially droughts and floods. These factors in turn will affect water resources for agriculture, grazing lands, livestock, and associated agricultural pests. Effects will vary, depending on the degree of change in temperature and precipitation and on the particular management system and its location. Several studies have suggested that recent warming trends in some regions may have already had discernible effects on some agricultural systems [17].

Climate change projections are uncertain in regard to both the rate and magnitude of temperature and precipitation variation in the coming decades. This uncertainty arises from a lack of precise knowledge of how climate system processes will change and of how population growth, economic and technological developments, and land-use patterns will evolve in the coming century [16,17]. Despite these uncertainties, the ultimate significance of the climate change issue is related to its global reach, affecting agricultural regions throughout the world in complex ways. After approximately two decades of research, ten major conclusions may be drawn in regard to climate change and agriculture.

### **Effects on Agricultural Systems Will Be Heterogeneous**

Global studies on projected climate change effects on agriculture show that negative and positive effects will occur both within countries and across the world. In large countries such as the United States, Russia, Brazil, and Australia, agricultural regions will likely be affected quite differently. Some regions will experience increases in production and some declines (see, e.g., [34]). At the international level, this implies possible shifts in comparative advantage for production of export crops. This also implies that adaptive responses to climate change will necessarily be complex and varied. Due to differences in global climate model projections and decadal variability, it is impossible to project exact effects in any one location for any given decade.

### **Developing Countries Are More Vulnerable**

Despite general uncertainties about the rate and magnitude of climate change and especially about consequent hydrological changes, regional and global studies have

consistently shown that agricultural production systems in the mid and high latitudes are more likely to benefit in the near term (to mid-century), while production systems in the low-latitudes are more likely to decline (Fig. 1) [17]. In biophysical terms, rising temperatures will likely push many crops beyond their limits of optimal growth and yield. Higher temperatures will intensify the evaporative demand of the atmosphere, leading to greater water stress, especially in semi-arid regions. Since most developing countries are located in lower-latitude regions (some which are indeed semi-arid) while most developed countries are located in the more humid mid- to high latitudes, this finding suggests a divergence in vulnerability between these groups of nations, with far-reaching implications for future world food security [31,37].

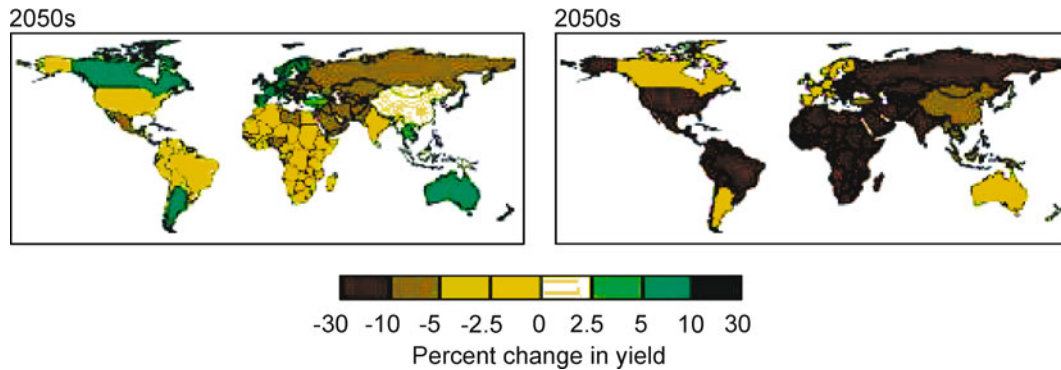

Furthermore, developing countries often have fewer resources with which to devise appropriate adaptation measures to meet changing agricultural conditions. The combination of potentially greater climate stresses and lower adaptive capacity in developing countries creates different degrees of vulnerability between rich and poor nations as they confront global warming. This difference is due in part to the potentially greater detrimental impacts of a changing climate in areas that are already warm (particularly if such areas are also dry), and in part to the generally lower levels of adaptive capacity in developing countries.

### **Development Path Matters**

Since climate is not the only driving force on agriculture, researchers now conduct scenario analysis that include linked sets of population projections, economic growth rates, energy technology improvements, land-use changes, and associated emissions of greenhouse gases [31]. Regional patterns related to economic development and adaptive capacity contribute to differing levels of climate change impacts [17]. Scenarios with higher economic growth rates and less attention to environmental issues lead to high temperatures and reduced adaptive capacity, which in turn lead to pronounced decreases in yields both regionally and globally. Scenarios with lower greenhouse gas emissions and greater attention to environmental issues lead to lower amounts of temperature rise and crop production declines.

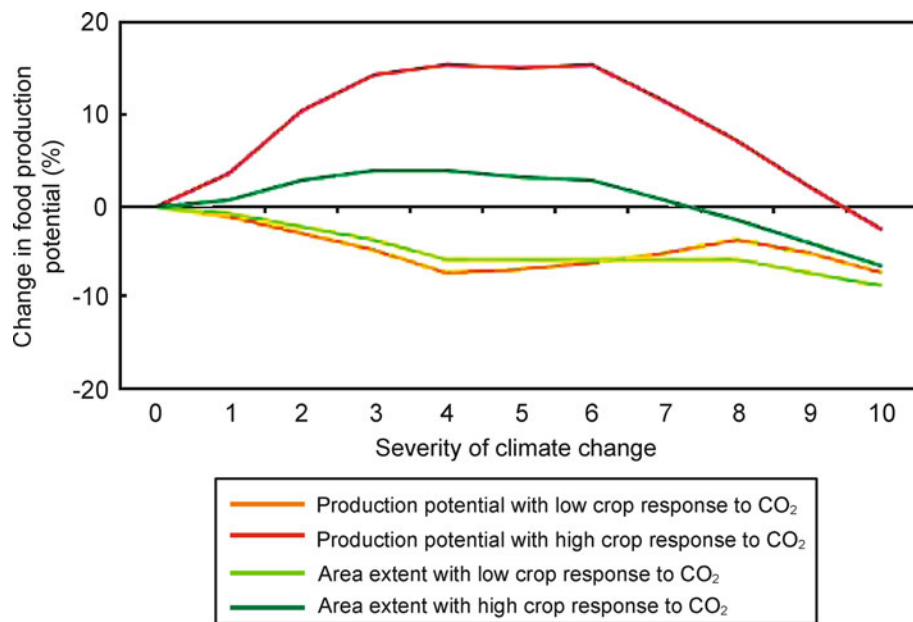

### **Long-Term Effects Are Negative for Both Developed and Developing Countries**

If the effects of climate change are not abated, production in the mid- and high-latitudes is likely to decline in the longer term (i.e., above  $\sim 3^{\circ}\text{C}$  warming) (Fig. 2) [16].

Climate Change and Agriculture, Figure 1

Potential changes (%) in national cereal yields for the 2050s (compared with 1990) under the HadCM3 SRES A1FI with (*left*) and without (*right*) CO<sub>2</sub> effects [31]

Climate Change and Agriculture, Figure 2

Change in food production potential in relation to severity of climate change [13]

These results are consistent over a range of temperature, precipitation, and direct CO<sub>2</sub> effects tested, and are due primarily to the detrimental effects of heat and water stress as temperatures rise. While the beneficial effects of CO<sub>2</sub> may eventually level out, the detrimental effects of warmer temperatures and greater water stress are more likely to be progressive in all regions. Although the precise levels of CO<sub>2</sub> effects on crops and their contribution to global crop production are still active areas of research [47], global im-

pacts are likely to turn negative in all regions sometime during the second half of the century, and perhaps before then for some major crops. For instance, by 2050 climate change is projected to have a downward pressure on yields of almonds, walnuts, avocados, and table grapes in California. Opportunities for expansion into cooler regions have been identified, but this adaptation would require substantial investments and may be limited by non-climatic constraints [24].

### Water Resources Are Key

Recent flooding and heavy precipitation events in the US and worldwide have caused great damage to crop production. If the frequency of these weather extremes were to increase in the near future, as recent trends for the US indicate and as projected by global climate models [17,48], the cost of crop losses in the coming decades could rise dramatically. US corn production losses due to excess soil moisture, already significant under current climate, may double during the next thirty years, causing additional damages totaling an estimated \$3 billion per year (Fig. 3) [41]. These costs may either be borne directly by those farmers affected or may need to be transferred to private or governmental insurance and disaster relief programs. There is also concern for tractability in the spring and water-logging in the summer in mid and high latitudes where precipitation is projected to increase.

Changes in crop water demand and water availability will affect the reliability of irrigation, which competes for growing municipal and industrial demands [42]. Studies link climate change scenarios with hydrologic, agricultural, and planning models to estimate water availability for agriculture under changing climate conditions, to explore changes in ecosystem services, and to evaluate adaptation strategies for the water resources and agriculture

sectors. Major irrigated agricultural regions are very likely to be affected by changing supplies of and demands for water due a changing climate especially under conditions of expansion of irrigated lands [42].

Cultivars are available for agricultural adaptation to the projected changes, but their demand for water may be higher than currently adapted varieties. Thus, even in relatively water-rich areas, changes in water demand due to climate change effects on agriculture and increased demand from urban growth will require timely improvements in crop cultivars, irrigation and drainage technology, and water management. In tropical regions, the use of agroforestry may be an economically feasible way to protect crop plants from extremes in microclimates and soil moisture [22].

### Agricultural Pests and Diseases May Spread

Increased pest damage arises from changes in production systems, enhanced resistance of some pests to pesticides, and the production of crops in warmer and more humid climatic regions where crops are more susceptible to pests. Changes in crop management techniques, particularly the intensification of cropping, reduction in crop rotations, and increase in monocultures, have increased the activity of pests. The expansion of worldwide trade in food and

Climate Change and Agriculture, Figure 3

Number of events causing damage to maize yields due to excess soil moisture conditions, averaged over all study sites, under current baseline (1951–1998) and climate change conditions. The Hadley Center (HC) and Canadian Center (CC) scenarios with greenhouse gas and sulfate aerosols (GS) were used. Events causing a 20% simulated yield damage are comparable to the 1993 US Midwest floods [41]

plant products has also increased the impact of weeds, insects, and diseases on crops. The geographical ranges of several important insects, weeds, and pathogens in the US have recently expanded, including soybean cyst nematode (*Heterodera glycines*) and sudden death syndrome (*Fusarium solani* f. sp. *glycines*) (Fig. 4) [15,39,43].

Current climate trends and extreme weather events may be directly and indirectly contributing to the increased pest damage [17,39,52]. Downy mildew (*Plasmopara viticola*) epidemics on grape, the most serious grapevine disease in northern Italy, may increase under climate change, even though reduced precipitation may have a counterbalancing effect on disease pressure [44].

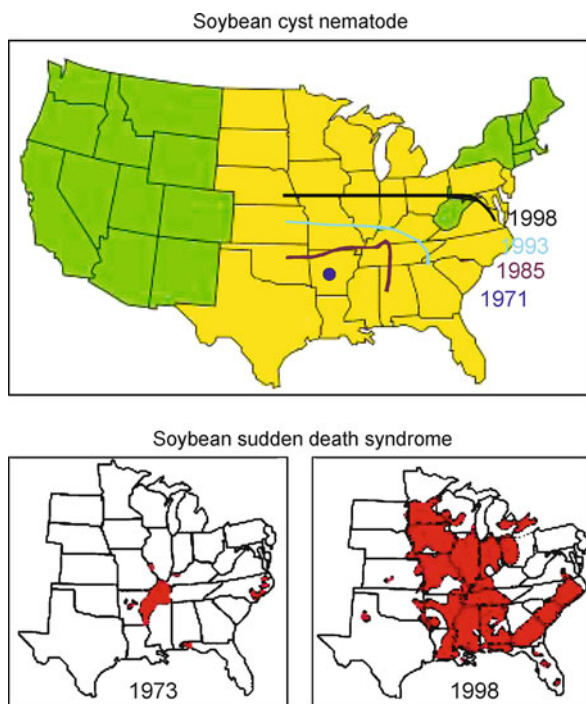

Such changes need to be put in the context of the global increases in pest-induced losses of crops in all regions since the 1940s [30,33] and the more than 33-fold increase in both the amount and toxicity of pesticide used over the same period [33]. Climate change thus may exacerbate environmental and public health issues related to agricultural chemicals [39], since increased applications of agricultural chemicals are likely to be needed in response to increasing disease pressure. Improved knowledge of the

effects of climate on host–pathogen interactions will contribute to the adaptive capacity of agro-ecosystems.

### Current Climate Stress Is a Key Entry Point for Climate Change

There is an important interplay between current and future climate stresses. Since farmers have dealt with climatic fluctuations since the advent of agriculture, improving strategies for dealing with present climate extremes – such as droughts, floods, and heatwaves – is an important way to prepare for climate change. Many agricultural regions are affected by the major climate variability systems, including the processes known as the El Niño–Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO) [36]. The El Niño phase of the ENSO cycle tends to bring rainfall to Uruguay, while La Niña brings drought, as shown in Fig. 5 for 1998, an El Niño year, and 2000, the following La Niña.

In terms of prediction tools, ENSO models provide the opportunity for testing and validation of climate prediction and assessment on shorter seasonal-to-interannual time-scales. Skill in predicting climate changes on shorter time-scales, particularly the ENSO periods of the last twenty years when good observations exist, may lend credence to projections of global warming over the longer-term. As global climate models are further developed with improved parametrizations and higher spatial resolution, they are likely to improve simulations of ENSO and other large-scale variability processes. The interaction of these systems with underlying anthropogenic trends caused by increasing greenhouse gas concentrations in the atmosphere is an active area of contemporary climate science. For regions directly affected by ENSO and other systems, such changes, if they do indeed occur, may become important manifestations of global warming.

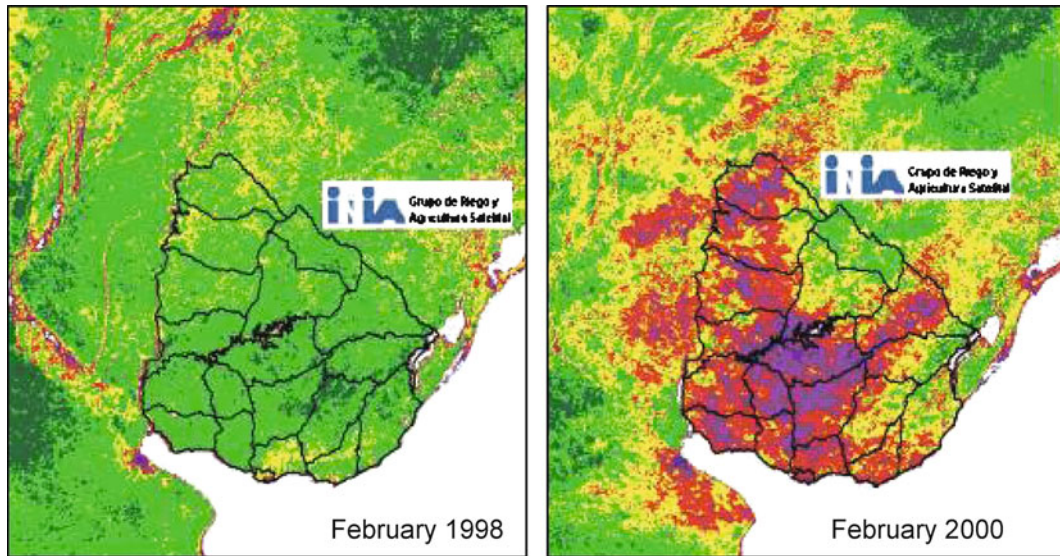

Climate Change and Agriculture, Figure 4  
Range expansion of soybean cyst nematode (*Heterodera glycines*) from 1971 to 1989 (top) and soybean sudden death syndrome (*Fusarium solani* f. sp. *Glycines*) from 1973 to 1998 (bottom) in North America [40]

### Adaptation Is Necessary

‘Coping range’ is a useful paradigm for improving responses to climate stresses of today and preparing for the climate changes of tomorrow [20]. An agricultural system may currently exist within a ‘coping range’ of climate variability that may be exceeded as incidence of extreme events increases under changing climate conditions (Fig. 6). The goal is to increase the coping range over which an agricultural system may thrive under such changes through the process of adaptation.

Adaptation can help farmers to minimize negative impacts of climate on human activities and ecosystems and to take advantage of potential beneficial changes. *Adaptation* to climate change can be defined as the range of ac-

Climate Change and Agriculture, Figure 5

Vegetative Index (NDVI) for El Niño (1998) and La Niña (2000) years in Uruguay. *Green* = adequate water conditions; *red/purple* = drought conditions [2]

Climate Change and Agriculture, Figure 6

Coping range of climate variability (adapted from [20])

tions taken in response to changes in local and regional climatic conditions [45]. Adaptation responses include both *autonomous adaptation* actions (i. e., those taken spontaneously and independently by individual farmers), and *planned adaptation* actions (i. e., those facilitated by climate-specific regulations and incentives put in place by regional, national and international policies) (see Table 1) [17]. In terms of the multiple factors impinging on agriculture, however, system responses to socio-economic, institutional, political or cultural pressures may outweigh response to climate change alone in driving the evolution of agricultural systems. The *adaptive capacity* of a system, in the context of climate change, can be viewed as the full set of system skills – i. e., technical solutions available to farmers in order to respond to climate stresses – as deter-

mined by the socio-economic and cultural settings, plus institutional and policy contexts, prevalent in the region of interest [17].

While current agronomic research confirms that at the field level crops would respond positively to elevated CO<sub>2</sub> in the absence of climate change (e. g., [1,17,19,21]), the associated impacts of high temperatures, altered patterns of precipitation, and possibly increased frequency of extreme events (such as drought and floods) are likely to require a range of adaptation responses, some of which are listed in Table 2.

#### Mitigation Reduces Long-Term Risk

Agriculture has an important role to play in mitigation of climate change. *Mitigation* is defined as intervention

Climate Change and Agriculture, Table 1  
Adaptation approaches to climate impacts on agriculture

Approach	Definition	Operation
Autonomous	Adaptation that does not constitute a conscious response to climatic stimuli but is triggered by ecological changes in natural systems and by market or welfare changes in human systems. Also referred to as spontaneous adaptation.	Crop calendar shifts (planting, input schedules, harvesting) Cultivar changes Crop-mix changes
Planned	Adaptation that is the result of a deliberate policy decision, based on an awareness that conditions have changed or are about to change and that action is required to return to, maintain, or achieve a desired state.	Land-use incentives Irrigation infrastructure Water pricing Germplasm development programs

Climate Change and Agriculture, Table 2  
Key agronomic impacts and adaptation responses

Agricultural impacts	Adaptation response
Biomass increase under elevated CO <sub>2</sub>	Cultivar selection and breeding to maximize yield
Acceleration of maturity due to higher temperature	Cultivar selection and breeding of slower maturing types
Heat stress during flowering and reproduction	Early planting of spring crops
Crop losses due to increased droughts and floods	Changes in crop mixtures and rotations; warning systems; insurance
Increased pest damage	Improved management; increased pesticide use; biotechnology

aimed at reducing the severity of climate change by reducing the atmospheric concentration of greenhouse gases, either by reducing emissions or by enhancing sinks. There are several major ways that the agricultural sector can contribute to climate change mitigation.

**Soil Carbon Sequestration** Of the approximately 150 GT of carbon that were lost in the last century due to land conversion to agriculture and subsequent production, about two thirds were lost due to deforestation and one-third, roughly 50 GT, due to cultivation of current agricultural soils and exports as food products [50]. The latter figure represents the maximum theoretical amount of carbon that could be restored in agricultural soils. In practice, as long as 40–50% of total above-ground grain or fruit production is exported as food to non-agricultural areas, the actual carbon amount that can be restored in agricultural soils is much lower.

Efforts to improve soil quality and raise soil organic carbon (SOC) levels include crop management and conservation tillage techniques. These practices have evolved as means to enhance sustainability and resilience of agricultural systems, rather than with soil carbon sequestration as primary motivation. They include so-called “best practice” agricultural techniques, such as use of cover crops and/or nitrogen fixers in rotation cycles, judicious use of fertilizers and organic amendments, soil water management improvements to irrigation and drainage, and improved varieties with high biomass production.

Conventional tillage is defined [27] as the mechanical manipulation of the topsoil that leaves no more than 15% of the ground surface covered with crop residues. In contrast, no-till management is defined as the avoidance of mechanical manipulation of the topsoil so as to leave it undisturbed and covered with surface residues from harvesting the prior crop to planting the new crop.

Best agricultural practices can result in a net augmentation of soil carbon and in enhanced productivity due to better soil structure and soil moisture management. The relevant practices include precise and timely applications and spatial allocation of fertilizers, use of slow-release fertilizers, prevention of erosion, shortening or elimination of fallow periods, use of high-residue cover crops and green-manure crops, and minimized mechanical disturbance of soil (e. g., zero tillage). Altogether, such practices may lead to partial or even complete restoration of the soil’s organic carbon content where it had been depleted. In some cases, it might even be possible to store more carbon than had originally been present in the “virgin” soil. Where the soils had been severely degraded and their agricultural productivity greatly impaired, they may be converted to grassland or afforested so as to serve as carbon sinks.

The overall potential for carbon storage depends in each case on such factors as climate, type of vegetation, topography, depth and texture of the soil, past use (or abuse), and current management.

Along with sequestering carbon, these practices have the potential to improve soils in developing countries. In

areas such as West Africa, soil fertility depletion has been described as the single most important constraint to food security [4]. Studies in smallholder agricultural farms in Africa have already illustrated significant increases in system carbon and productivity through organic-inorganic resources management (Roose and Barthes [35])

**Biofuels** Agriculture may help to mitigate anthropogenic greenhouse emissions through the production of biofuels. As has been demonstrated by ethanol based on corn production, issues involved with biofuel production include potential competition with food production, increased pollution from fertilizers and pesticides, and loss of biodiversity. Biofuels derived from low-input high-diversity mixtures of native grassland perennials can provide more usable energy, greater greenhouse gas reduction, and less agrichemical pollution per hectare than corn grain ethanol or soybean biodiesel [46]. The higher net energy results arise because perennial grasses require lower energy inputs and produce higher bioenergy yield. Furthermore, all aboveground biomass of the grasses can be converted to energy, rather than just the seed of either corn or soybean. These perennial grasses also sequester carbon at significant rates [46].

**Other Greenhouse Gases** Because of the greater global warming potential (GWP) of methane (21) and nitrous oxide (310) compared to carbon dioxide (1), reductions of non-CO<sub>2</sub> greenhouse gas emissions from agriculture can be quite significant and achieved via the development of more efficient rice (for methane) and livestock production systems (for both methane and nitrous oxide). In intensive agricultural systems with crops and livestock production, direct CO<sub>2</sub> emissions are predominantly connected to field crop production and are typically in the range of 150–200 kg C ha<sup>-1</sup> yr<sup>-1</sup> [14,51]. Recent full greenhouse gas analysis of different farm systems in Europe showed that such CO<sub>2</sub> emissions represent only 10–15% of the farm total, with emissions of CH<sub>4</sub> contributing 25–30% and emissions of N<sub>2</sub>O accounting for as much as 60% of total CO<sub>2</sub>-equivalent greenhouse gas emissions from farm activities. The N<sub>2</sub>O contribution arises from substantial nitrogen volatilization from fertilized fields and animal waste, but it is also a consequence of its very high GWP.

In Europe, methane emissions are mostly linked to cattle digestive pathways; its contribution also dominates that of CO<sub>2</sub>, due in part to methane's high GWP. Mitigation measures for methane production in livestock include improved feed and nutrition regimes, as well as recovery of bio-gas for on-farm energy production. Effective reduction of N<sub>2</sub>O emissions is more difficult, given the largely

heterogeneous nature of emissions in space and time and thus the difficulty of timing fertilizer applications and/or manure management. Large uncertainties in emission factors also complicate the assessment of efficient N<sub>2</sub>O-reduction strategies. Current techniques focus on reduction of absolute amounts of fertilizer nitrogen applied to fields, as well as on livestock feeding regimes that reduce animal excreta.

### Climate Change Effects on Agriculture Are Occurring Already

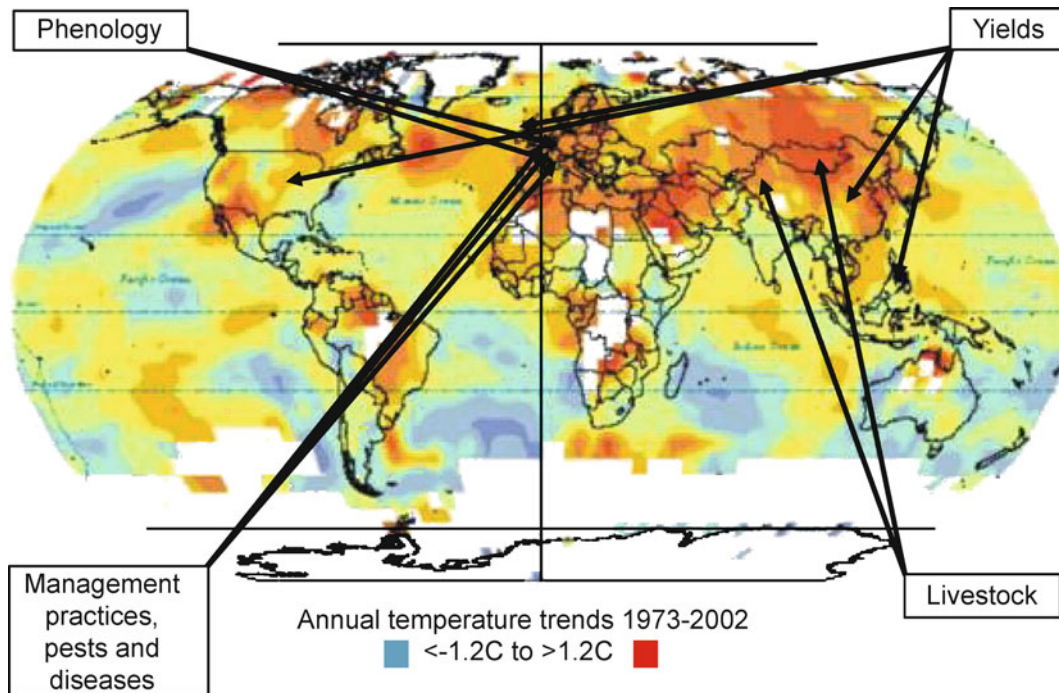

Agricultural effects of observed climate changes are being documented in many regions of the world (Fig. 7). Changes in crop phenology provide important evidence of responses to recent regional climate change. Such changes are apparent in perennial crops, such as fruit trees and wine-making varieties of grapes, which are less dependent on yearly management decisions by farmers than annual crops and are also often easier to observe.

Phenological changes are often observed in tandem with changes in management practices by farmers. Between 1951 and 2004 in Europe, agricultural crops have advanced 2.1 days/decade in response to recent warming in spring [28]. In Sahelian countries, increasing temperature in combination with rainfall reduction has led to a reduced length of vegetative period, no longer allowing present varieties to complete their cycle [5].

A negative effect of warming for local rice production has been observed by the International Rice Research Institute (IRRI) in the Philippines (yield loss of 15% for 1°C increase of growing-season minimum temperature in the dry season) [32]; a similar effect has been noted on hay yield in the UK (1°C increase in July–August led to a 0.33 t/ha loss) [6]. At the county level, US maize and soybean yields are demonstrating a positive effect of cooler and wetter years in the Midwest and hotter and drier years in the North-west plains [23]. In the case of the Sahel region of Africa, warmer and drier conditions have served as a catalyst for a number of other factors that have accelerated a decline in groundnut production [49]. For livestock, one study in Tibet reports a significant relationship of improved performance with warming in high mountainous conditions [9], while pasture biomass in Mongolia has been negatively affected by the warmer and drier climate, as observed at a local station [3] or at the regional scale by remote sensing [10].

### Conclusions

Climate change brings both challenges and opportunities to agriculture. Farmers and researchers are being

Climate Change and Agriculture, Figure 7

Locations of observed changes in agriculture in response to climate changes

called on to simultaneously adapt to and mitigate climate change through a myriad of activities involving management practices, crop breeding, and new production systems. Some of these can be mutually re-enforcing, especially in view of the projected increased climate variability under climate change. This is because, most mitigation techniques currently considered in agriculture, including reduced tillage, were originally designed as “best practice” management strategies, aimed at enhancing the long-term stability and resilience of cropping systems in the face of climate variability or of increased cultivation intensity. By increasing the ability of soils to hold soil moisture and to better withstand erosion, and by enriching ecosystem biodiversity through the establishment of more diversified cropping systems, mitigation techniques implemented locally for soil carbon sequestration may also help cropping systems to better withstand droughts and/or floods, both of which are projected to increase in frequency and severity in future warmer climates. As climate change progresses, agriculture will continue to play a leading role in responding to a dynamic environment.

### Future Directions

The time has come to incorporate climate as an essential factor in development planning and implementation. In the past, responses to climate variability were often too

narrowly focused and lacking in institutional fit. Development programs are now beginning to include recommendations to mainstream responses to climate variability and change.

Magalhães [25] gave as an example of the need for a broad focus when considering climate in planning the early drought policies in Northern Brazil. Responses had focused on improving the water-supply infrastructure (e.g. building dams and digging wells) rather than on redressing the social and economic vulnerabilities and the need to build human capital by means of education, institutions, and market incentives for sustainability. Adaptive policies should be broadly conceived so as to increase and secure household entitlements, to change land-use patterns that lead to degradation, and to develop means of support for inhabitants that are less sensitive to the vagaries of climate.

At what levels or scales of organization (national, regional, household, and individual) can the variability of climate and the sustainability of agricultural production be addressed effectively? Because many nations encompass several and often most numerous climatic zones, the challenge faced by national agricultural managers and policy make is to foster sustainability at the regional level while building a foundation from the bottom-up at the individual as well as at the household and community levels. Dil-

ley [8] believes that greater benefits of food security could be realized if knowledge were made more readily available at the household level, thereby improving the ability of more people to make even small adjustments based on anticipated climatic conditions. Multiple-scale efforts are clearly needed, with pathways of communication among the various levels and sectors of society.

Regions do not exist in isolation, as evidenced by the effects that extreme climate events occurring along the Atlantic coast of South America have on the sustainability of the inland Amazon rainforest. At least part of the pressure to deforest the Amazon region arises from the westward migration of farmers from Northern Brazil who suffer from ENSO-related droughts there (Magalhães [25]). Thus, policies related to sustainability and climate issues need to take regional interactions and their direct and indirect linkages into account.

Beyond interconnections among regions within a nation, there are the larger national concerns of economics, finance, and international relations that may affect the range of climate-adaptation policy choices. Engaging with the international community on issues of climate variability and change can lead to capacity building in both developed and developing countries, as climate and societal processes are studied and as improved understanding is incorporated into policies. This can be accomplished through interactions with international bodies dealing with climate variability and change, such as the World Meteorological Organization and the United Nations Framework Convention on Climate Change. There is a growing realization that climate plays an important role in sustainable development: It is a component of natural capital, an occasional trigger to socio-economic crises caused by extreme events, and a long-term component of global environmental change.

### Glossary

**Health** As defined by the World Health Organization (WHO) health is the state of complete physical, mental and social well-being and not merely the absence of disease or infirmity.

**Human bioclimate** The fundamental issue in human biometeorology is the assessment of the direct health effects of the atmospheric environment from heat exchange, to solar radiation and air pollution.

**Climate change related direct health effects** Climate change always impacts on human bioclimate, presently it leads to increased heat stress and heat stress frequency, higher ultraviolet radiation doses especially in summer, longer allergic pollen seasons and new allergens as well as intensified photo-smog.

**Thermal stress and mortality** Summer heat waves in mid-latitudes and elsewhere increase without doubt mortality; hence also highlight lack of correct adaptive measures, i. e. heat waves impact most strongly in societies with lack of social cohesion.

**Global expansion of tropical diseases** The observed recent global warming has increased the incidence and enlarged the distribution of some tropical diseases due to the expansion of suitable conditions for both vectors and pathogens. A northward spread has been observed for West Nile fever, Leishmaniasis and Chikungunya fever and a climate-driven spread has in parts also been recorded for malaria, dengue fever and other vector-borne infectious diseases.

**Vector-borne diseases** In epidemiology a vector is an organism transmitting a pathogen from one of its reservoirs (e. g. ruminants, birds) to another one (e. g. human) without falling ill. Such vectors for tropical diseases are: mosquitoes, biting flies, bugs, lice, flea's and

mites. Typical vector-borne diseases are malaria, yellow fever, dengue fever, West Nile fever, Leishmaniasis, Chikungunya fever. For some of these diseases global warming is the cause of the observed expansion or intensification. The complex web of reservoir organism, pathogens, vectors and infected organisms with different dependence on climate parameters often hinders a full understanding. Hence, surprises are and will be common.

**Arbo viruses** Arbo viruses are transmitted by arthropods (arthropod-borne) to vertebrates and hence in parts also to humans. Besides yellow fever, tick borne encephalitis and dengue fever about 150 other diseases are due to virus infections by insects and spiders (arthropods). In very complex transmission cycles climatic conditions play a central role. The occurrence of unusual arbo virus infections is often related to changes in climatic conditions. Therefore, the partly dramatic global increase of some arbo virus infections is also driven at least in part by the ongoing global anthropogenic climate change.

**Arbo viruses transmitted by Aedes mosquitoes** Aedes mosquitoes and Aedes-transmitted arbo viruses such as the dengue and yellow fever viruses are a growing global threat. The primary vector of these diseases, *Aedes aegypti*, has re-emerged throughout the tropics, but also *Aedes albopictus* has emerged as one of the worst invasive species taking the role of *Aedes aegypti*. Direct human activities like global trade are mainly responsible for the spread of these vectors and global warming – indirectly anthropogenic as well – cannot be ruled out as a contributor. With further warming temperate regions like Central Europe could also become areas for *Aedes albopictus*.

**Malaria and global warming** Although the Anopheles mosquitoes transmitting the protozoae (e. g. *Plasmodium falciparum*) causing malaria are strongly dependent on temperature and suitable small water reservoirs for the larvae, the spread of malaria in recent years is more a consequence of deficiencies in public health systems of many countries rather than due to the observed global warming and concomitant precipitation changes.

**Blue-tongue disease in Europe** Since August 2006 the blue-tongue-disease of cattle and sheep (serotype 8 from South Africa) spread within months from the Netherlands to Belgium, Luxembourg, France and Germany alone at the end of 2006. The vector carrying the virus is the ceratopogonid, biting midge, *Culicoides obsoletus*. The new disease for ruminants in Western and Central Europe is primarily a conse-

quence of globalization but the extremely warm winter 2006/2007 in Western and Central Europe supported further spreading.

**Carbon dioxide fertilization and quality of food** From field experiments at elevated carbon dioxide concentrations (close to a doubling of preindustrial values) it is known that agricultural yield increases for C3 plants by 10 to 30 percent; however, frequently also reduced nitrogen content in plant tissue including seeds is observed. Hence, food quality may be lowered.

**Changes in the pollen season and new pollen** The onset of flowering of plants in mid and high latitudes is mainly triggered by temperature. Therefore, warming in recent decades has caused an earlier start of pollen in the air, often also leading to a longer pollen season and for some pollen also to higher abundance stimulated by higher carbon dioxide concentration. Hence, susceptible individuals will suffer from pollen allergy longer and even perennial allergic symptoms may become possible.

## Introduction

The basis of our life is energy from the sun, water from the skies and biomass production by plants on land and in the oceans. If we ask for the key climate parameters – given the size of the planet and its mean distance to the sun – we get a very similar answer: energy flux density of the sun, precipitation and land surface parameters, mostly determined by vegetation. Hence, climate is the key natural resource. If this resource changes rapidly, as it does now, life in all its forms is affected as well. Therefore, it is a must for decision makers to deal with climate change. Here only one facet of climate change is discussed: the health of humans. It is rather astonishing that it has not already been studied intensively since the beginning of the climate change debate, as other environmental policy decisions were nearly totally driven by health consequences for humans [12].

The consequences of climate change for the health of humans, animals and plants are complex with direct and indirect relations between causes and impacts. As any organism on land is in permanent struggle with the local weather a rather strong capacity for adaptation exists; however, the organisms are trained only with existing weather and climate variability during the life-time of an organism. For new weather extremes accompanying any climate change this adaptation capability is no longer given. Hence, a changing climate will often become a threat to health. As several health related factors may change simultaneously, “multiplying” impacts, which – if alone – would not have gone beyond existing adaptive ca-

pability, may do so. An example is heat stress during heat waves accompanied not only by high ultraviolet radiation levels but also by high near surface concentrations of the strong oxidant ozone, exacerbating the heat stress.

According to the World Health Organization (WHO) “Health” is defined as “the state of complete physical, mental and social well being and not merely the absence of disease or infirmity”. This comprehensive and also ambitious understanding of the term health can also be applied to animals and plants as well as ecosystems (the terms ecosystem health and environmental health have been used very often in recent literature). Therefore, consequences of climate change on health are not confined to diseases but also include reduced well-being or reduced strength of an organism as well as weakened functions in an ecosystem or a socio-economic system.

This contribution to the Encyclopedia of Complexity does not focus exclusively on climate change and human health (see Sect. “Climate Change Impact on Human Health”) because climate change impacts on animals and plants (see Sect. “Climate Change Impacts on Plants with Consequences for Human Health”) also have consequences for human well-being and human health. An example of the complexity is the changed composition of nutrients in grains as a consequence of higher carbon dioxide levels in the atmosphere, in addition modulated by changed climate parameters that may in turn enhance infestations of plant diseases with consequences for the composition of our food. The section on Climate Change Impacts on Plants with Consequences for Human Health tries to collect known knowledge, reports on potential threats and chances for political reactions as well as pointing out major open research questions.

## Climate Change Impact on Human Health

Whenever climate changes all ecosystems have to react, i. e. they try to adapt to changed climate that must also include new weather extremes. Typical reactions are shift of biomes, altered ecosystem composition, new geographical patterns of animal and plant diseases, new relations between predator and prey. As major so-called natural climate changes have occurred also in the recent few million years the first major question in the present anthropogenic climate change era is: Can earlier so-called abrupt climate changes be used as an example for projections into the future? The answer is no, because the mean global temperature change rate to occur in the 21st century exceeds by far even the most rapid natural ones. The largest and most rapid *global* mean temperature change rates in the recent few million years have been the collapses of

the large northern hemisphere ice sheets that have led to a mean global warming of up to 5°C and a sea level rise of about 120 m in roughly 10,000 years. Projections for the 21st century without stringent climate policy [4] range between 1.5°C and about 4°C, i. e. an acceleration of at least a factor 30. Hence, the past cannot be used as an analogue. In other words: The key goal of the United Nations Framework Convention on Climate Change (UNFCCC) that speaks of avoidance of a dangerous interference with the climate system, cannot be met without globally coordinated climate policy. It requests, in addition, a climate policy helping to stabilize greenhouse gas concentrations within a time frame that firstly natural ecosystems are able to adapt to climate change, secondly food production is not generally threatened and a sustainable economic development remains possible.

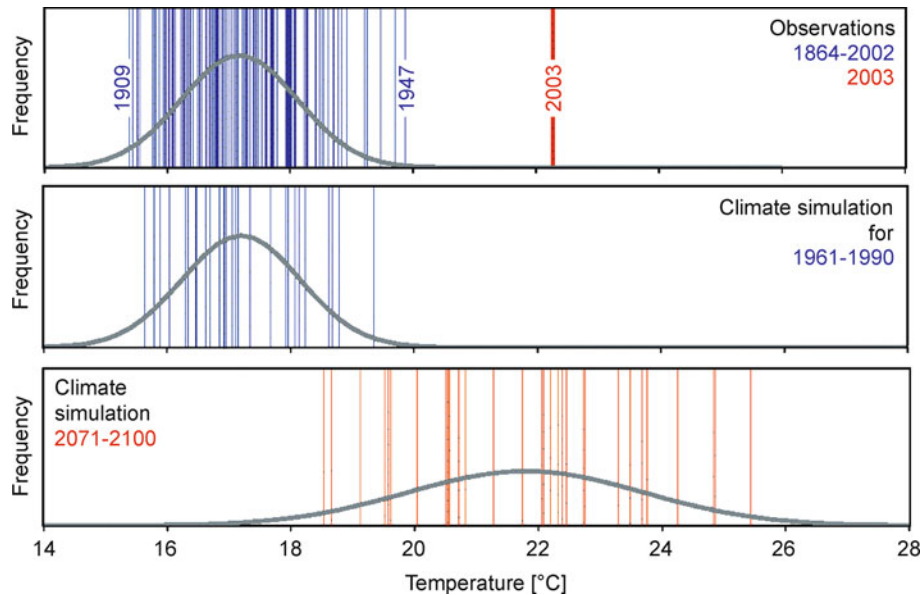

In this situation with ill-adapted forests, rapidly changed patterns of infectious diseases for plants, animals and humans looking back through climatic history does also not help directly. Besides intensified research on changed disease patterns in the very recent past a stringent globally coordinated climate policy under UNFCCC is the best insurance against massively altered disease patterns.

This paper will concentrate on climate change impacts on human health but will not exclude totally impacts on food production. Major points will be “thermal stress” be-

fore “vector-borne diseases” and also prolonged allergen seasons and new allergens are discussed.

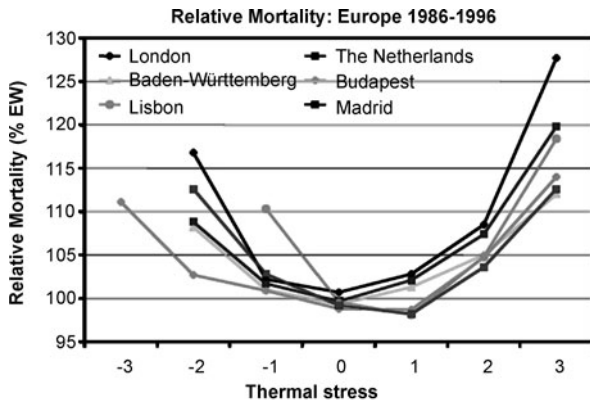

### Changed Thermal Stress

Heat or cold stress forces our body to adapt to keep the core body temperature within a narrow temperature interval of about five degrees centigrade (35 to a maximum of slightly above 40°C). While extreme cold stress events have diminished and will further diminish as a consequence of ongoing global warming, extreme heat stress will increase dramatically (see Fig. 1), when the frequency distributions of temperature at a certain location are shifted by only a few degrees centigrade and may be broadened. Up to now only very few places on the Earth’s surface exist where survival of a human being is nearly impossible. This would certainly happen if the wet bulb temperature (roughly equivalent to a ventilated sweating naked body) surmounts about 35°C. Under present climate conditions such areas do not exist, but coastal areas of the Red Sea come closest to it during on-shore winds after a sunny day that was heating surface waters to about 35°C. Hence, heat strokes can in principle be avoided by adequate behavior, if buildings are well insulated and properly ventilated and if an individual behaves. Therefore, the huge death toll caused by major heat waves, namely about 55,000 people

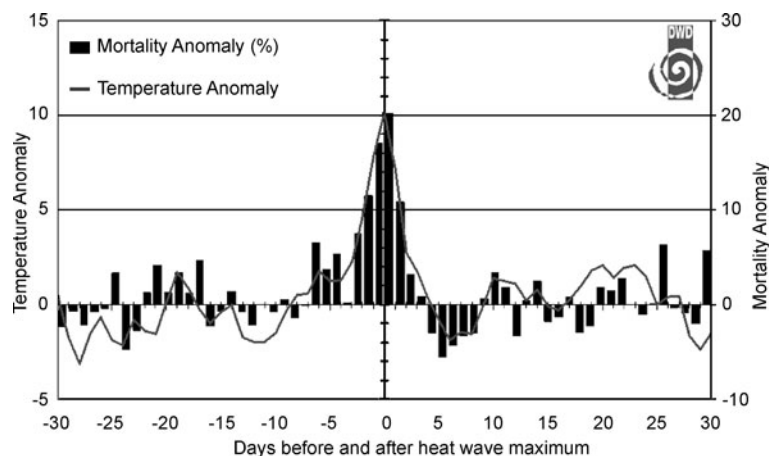

Climate Change and Human Health, Figure 1

Observed (*upper panel*) and modeled summer mean temperatures for the Swiss Plateau both for present climate (1961 to 1990) (*central panel*) and the last three decades of the 21st century for scenario A2. Please note that the exceptional summer 2003 would occur every second year, if globally coordinated climate policy would not exist. From [13]

Climate Change and Human Health, Figure 2  
 Mean relative mortality in percent for different thermal stress categories observed in Europe during 1986 to 1996. Please note that the mortality increases by more than a factor 2 when heat stress category 2 is replaced by category 3. From [5]

that died during the heat wave in summer 2003 in Europe [5] is rather an indication for “social freeze” and ill-adapted buildings in our industrialized or developing societies than for really intolerable thermal conditions. Many have died because of lack of care. New weather extremes always demask weaknesses in our security-related infrastructure. A famous example is the large difference in the number of people dying during a summer heat wave in 1995 in two US cities (Chicago and Philadelphia) just because of intensified public care in Philadelphia where the weak and poor citizens were brought by the city administration to the cooled malls during daytime.

Climate Change and Human Health, Figure 3  
 Mean mortality anomaly during a heat wave (30 days before and after its maximum) resulting from nine observed heat waves in the state of Baden Württemberg (Germany) for the period 1968 to 1997. Source: [5]

As Fig. 2 clearly demonstrates the mortality anomaly caused by heat waves is a fact observed over several decades (here in a developed country). Lowering the anomaly means not only investment in better warning systems but also enhanced social care in general.

Both heat and cold stress increase mortality as underlined by Fig. 3 for European countries. In the future heat stress category 3 will occur much more often and the lowering of the increased mortality will also be a sign of an improved public health system.

A further point to be made with respect to enhanced thermal stress as a consequence of climate change is the rapidly mounting heat stress in the inner tropics, where dew points of about 25°C will more often occur, if global warming also continues there. The ability to work with high efficiency is shrinking there rapidly with rising temperatures and dew points. As is well known economic development of developing countries needs a cooled or well-ventilated work place.

### Impact on Photochemical Smog

Photochemical smog is formed if solar radiation stimulates chemical reactions in a polluted atmosphere. Emissions of non-methane hydrocarbons and nitrogen oxides ( $\text{NO} + \text{NO}_2$ ) lead to the formation of ozone and other oxidizing toxic trace gases as well as aerosol particles. In mid-latitudes photochemical smog is typically strongest in late spring and summer and it has been the reason for some environmental policy making. Heat waves with intense solar radiation lead to major photochemical smog episodes. The higher frequency and longer duration of

heat waves during recent and foreseen global warming will intensify health problems already existing during heat waves. As Tables 1 and 2 demonstrate the hot summer in Germany in 2003 has increased the number of days for both ozone and aerosol load ( $\text{PM}_{10}$ ) where limit values have been surmounted in Germany dramatically [14,15], e. g. by a factor of 2 or more both for  $\text{PM}_{10}$  in rural areas and ozone in all areas.

Fighting against photochemical smog will become even more demanding in a warming world.

### Changed Ultraviolet Radiation

Ozone protects us to a large extent from the dangerous part of ultraviolet solar radiation through absorption in the ultraviolet (UV-B) range from 0.28 to  $0.32 \mu\text{m}$  wavelength. The observed latitude-dependent reduction of stratospheric ozone (from 8 to 50 km height in high latitudes), which constitutes about 90% of the total ozone column content and which is caused by chlorine compounds stemming from decay products of chlorofluorocarbons (CFCs) and other halocarbons, has increased UV-B radiation especially in spring of both hemispheres at higher latitudes. This stratospheric ozone decrease is strongest in Antarctic spring in the so-called ozone hole. This ozone depletion has certainly increased and still will increase the skin cancer and cataract incidence that has dramatically grown in recent decades. However, the ozone depletion contribution is largely buried in the variability and change of exposure of our body to UV radiation, which is due to changed behavior, especially in developed countries. The

key question for the forthcoming decades is: How fast will ozone column content recovery be after the banning of CFCs and other chlorine and bromine containing compounds? Present knowledge says: Full recovery after several decades with a chance of a super-recovery caused by a further increase of the greenhouse effect of the atmosphere, which lowers stratospheric temperatures.

### Health Effects

#### Caused by Other Changed Climate Parameters

Climate change shifts and reshapes frequency distributions of meteorological and hydrological parameters, thereby multiplying the occurrence of known extremes and leading to new ones (see Fig. 1, where this is demonstrated for temperature). Therefore, the health of many more millions is affected by intensified flooding, higher storm surges, and many other weather-related disasters.

While the highest death toll of weather-related disasters was – for thousands of years – due to droughts, with up to 10 million people dying per decade around 1930, the highest death toll is now caused by flooding and wind damage due to tropical cyclones and hurricanes (Red Cross, ...). The main reason for this change is – besides more dwellings in flood-prone areas, often already lying slightly below mean sea level – the international aid bringing food and seeds into the drought-affected areas; as long as civil war does not prevent this help.

Hence, climate change also calls – irrespective of globally coordinated climate change mitigation policies – for a coordinated climate change adaptation policy in the coming decades, because we have to adapt to the already unavoidable climate change. Mitigation measures meant to avoid the un-tolerable climate change will only become effective in decades due to the inertia of the climate system caused by the slow reaction of oceans and ice sheets. In other words: If flooding is prevented by strengthened dikes, anticipating shifted frequency distributions of precipitation, cholera epidemics will not occur. Diking has to become an international activity, as the emitters in industrialized countries are causing more flooding and sea level rise on a global scale, co-financed by the already existing but strongly to be increased adaptation fund under the UNFCCC, its Kyoto Protocol and the follow-up protocol envisaged to be signed in 2009.

As an aside I will here report on reactions of our body to high carbon dioxide levels in the atmosphere. Very often if many people are gathered in the same closed room and breathe the same air some will ask for fresh air (i. e. they require more oxygen). The need for fresh air is because of too high carbon dioxide levels. Regulations in some German states concerning ventilation in classrooms provide ventilation rules to avoid carbon dioxide concentrations above 1,500 ppm, a level after which concentration diminishes and some students may even develop signs of a beginning headache. The oxygen content of air has fallen by a bit more than a tenth of a percent only to about 20.84 percent at which point ventilation by opening windows becomes a must. Hence, ventilation of our living rooms means pushing out carbon dioxide.

### **Transmission of Infectious Diseases from Birds to Humans**

In recent years migratory birds have been named as a cause for the transmission of bird flu (avian influenza) to humans because they can in principle transmit the influenza virus to chickens, geese, turkeys and ducks in our farms from where the virus infects humans that come into close contact with the fowl or their products. However, very often the cause for the long-range transmission is global trade and tourism on the one hand plus industrialized animal husbandry in developed and emerging countries on the other. The latter has been found as the principal cause for the comparably rapid mutation of slightly pathogenic bird flu viruses to highly pathogenic ones (Bairlein and Metzger, 2008). These in turn can reach wild bird species which then can rapidly transmit them to new areas, if the viruses are only slightly pathogenic for them. But also pathogens, vectors or reservoir species can inadvertently be introduced by globalization to regions where no longer-term co-evolution could have taken place. Further global warming will intensify the shift of pathogens with the shift of (migratory) birds, but will only add to the further rapid distribution of pathogens caused by globalization (Smith et al., 2007).

### **Allergies Caused by Pollen**

In most countries allergies have recently increased dramatically. In Germany, for example, 20 to 30% of the population suffers from allergies. Most abundant is the allergic rhino conjunctivitis (hay fever), often turning into asthma bronchiale, caused by allergic pollen in air. Climate change has led to longer pollen seasons, in parts to more pollen, changed pollen spectrum and also new pollen [9].

From studies in Europe, North America and Japan an earlier flowering of 1 to 3 days per decade has been reported during the recent decades [11]. For some species, especially the late flowering ones a prolonged pollen season has been found [2,3], in parts caused also by long-range transport of the pollen. Consequently, for many people in mid-latitudes suffering from several pollen the pollen season became longer, sometimes already starting in December and ending only in October after the flowering of the neophyte ragweed (*Ambrosia artemisiifolia*) for Europe.

From differences between cities and rural areas as well as from laboratory studies it became known that pollen abundance increases with carbon dioxide concentration for some species.

In combination with air pollution allergic reactions have been shown to intensify [3].

**Invasion of Allergenic Neophytes** With ongoing global warming two processes combine for the spread of neophytes: Firstly, global trade and tourism transmitting plants and their seeds within days and weeks around the globe to all inhabited places and into ocean basins and secondly, increased temperatures allowing more and more often establishment of exotic species in new areas. A famous example where both mentioned processes work in combination is the invasion of the strongly allergenic ragweed (*Ambrosia artemisiifolia*) from North America to Europe in the 19th century with a large spread after the Second World War. Ragweed flowers from late August to September and its pollen also undergo long-range transport [1]. In recent decades it spread strongly in Central Europe facilitated by agricultural practice and by inadvertent transport with bird food as well as higher temperatures.

### **Indirect Health Effects Caused by Climate Change**

Many infectious diseases are transmitted by vectors, i. e. by animals (very often insects) transferring a pathogen from another animal and/or human without suffering from the pathogen themselves. The complicated web of hosts, pathogens, reservoirs and vectors is dependent on many factors, among them climate variables, foremost temperature and precipitation. Therefore, distribution patterns and incidence of infectious diseases will also be modified by climate change; however, disentangling the cause and effect relationships is often extremely difficult. Since tropical infectious diseases are the most common of these diseases and especially temperature sensitive they will be a focus in this section. The World Health Organization (WHO) points to a highly probable increase of morbidity

and mortality due to higher prevalence and a pole-ward shift of tropical infectious diseases due to further global warming.

### Increase of Vector-Borne Tropical Infectious Diseases

As always in scientific investigations it is especially difficult to derive long-term trends of certain variables influenced by many parameters like changes in land use, socio-economic conditions and climate or weather patterns. This is also true for tropical infectious diseases. Hence, only few trend analyses exist, e. g. for malaria reaching higher elevations in Africa.

The main vectors for infectious diseases are mosquitoes, biting flies, bugs, lice, fleas, and mites. Of about more than a million insect species roughly 17,000 have adapted to a blood-sucking mode of life. A small minority of these are vectors of pathogens. The pathogens are viruses, bacteria, protozoa or filarioses. Pathogens are either multiplied within the vectors without change of form (Arboviruses, Rickettsiae, Bacteria), multiplied with change of form (Protozoa) or changed without multiplication (Filaria). From uptake of a pathogen during a blood meal until the infective stage temperature is *the* factor determining duration, hence, higher temperatures can lead to enhanced spread of vector-borne diseases as for example observed for dengue fever.

According to number of people infected by blood-sucking insects *malaria* comes first with 300 to 500 million cases per year of which 1 to 2 million die, especially children. About 70 mosquito species of the genera *Anopheles* transmit four different protozoa (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*). The mosquito *Anopheles gambiae* in Africa is the most important vector. Because malaria has been eradicated in many developed countries in Europe an enhanced potential for malaria must not lead to a re-introduction there. However, in countries with a weak public health system higher prevalence and new malaria infected areas are highly probable.

About 120 million people in Asia, Africa, South and Central America are infected by *lymphatic filariasis* (elephantiasis) transmitted by different genera of mosquitoes. The larvae of the worm develop (from 0.4 to about 1.5 mm) in the vector and can be transmitted during the next blood meal to humans. The development period is temperature-dependent. Hence, a potential for a further spread exists, but the Global Program to Eliminate Lymphatic Filariasis (WHO, 2006) may reduce incidence strongly.

*Dengue fever* affects about 50 million persons per year and it is a clearly growing threat to human health in about

100 tropical and subtropical countries. The virus belonging to the flaviviruses is transmitted mainly by the *Aedes aegypti* mosquito. Vector and virus show strong temperature dependence in their development. But the disappearance of *Aedes aegypti* from Europe around 1950 points to the probably strong application of the insecticide DDT. As often, measures taken against infectious diseases can easily off-set climate influences.

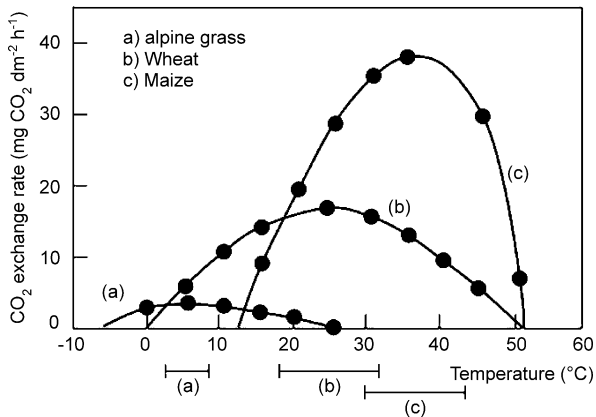

*Onchocerciasis* (in severe cases leading to river blindness) affects about 37 million persons, mainly in Africa, the microfilaria of the worm "*Onchocerca volvulus*" are taken up from the human skin by the vector, a simuliidae species, during a first blood meal, they develop through two skinings within the vector and are transmitted back to a human being during a further blood meal after about 7 to 10 days. Whether the vector, developing in running water and sucking blood during daylight, is already reacting to climate change is not known although a temperature and precipitation dependence clearly exists.

Many other tropical vector-borne infectious diseases exist, like loiasis affecting about 13 million people in tropical Africa, "Schlafkrankheit" with about 60,000 new cases per year or West Nile fever that has reached the USA. In all cases it is a complex mix of influencing factors with positive and negative feedbacks, which inhibits a clear separation of a climate contribution to changed patterns and severity. Hence, there will be many surprises often based both on transport of vectors by growing trade and tourism and better survival conditions in higher latitudes due to higher temperatures and/or changed moisture conditions.

The best means to cope with changed disease distribution patterns is a strong public health system and links between the systems in different countries.

### Climate Change Impacts on Plants with Consequences for Human Health

Our food is produced by plants on land and in the ocean, even if we eat meat or fish because animals also feed ultimately on plants. Hence, a climate change impact on plants may have strong indirect effects on human health. However, even if the climate change impact were small on certain plants, their way of reacting to enhanced CO<sub>2</sub> concentration could still have consequences for food production. In reality climate change and elevated CO<sub>2</sub> concentration act together and both have largely different impacts on plant types and species. The temperature dependence of photosynthesis rate as presented in Fig. 4 for very different plants, shows the rather steep decline of this rate for maize, a C4-plant, at high temperatures above about 40°C. Adding to this finding that there is nearly no pos-

Climate Change and Human Health, Figure 4  
**Temperature dependence of photosynthesis rate for an alpine grass, wheat and maize. Please note the strongly differing optimal temperature ranges. From [10]**

itive feedback to higher CO<sub>2</sub> levels for C<sub>4</sub>-plants, yield in tropical areas would be reduced if plants have to assimilate at leaf temperatures of about 40°C. Therefore, Working Group II of IPCC concluded [4]: “Crop productivity is projected to increase slightly at mid- to high latitudes for local mean temperature increases of up to 1–3°C depending on the crop, and then decrease beyond that in some regions. At lower latitudes, especially seasonally dry and tropical latitudes, crop productivity is projected to decrease for even small local temperature increases (1–2°C), which would increase the risk of hunger.”

If C<sub>3</sub>-plants (e. g. wheat, rice, potato, sugar beet) live at higher CO<sub>2</sub>-concentrations their photosynthesis rate increases rather linearly with CO<sub>2</sub>-concentration, if water stress and nutrient scarcity are not limiting their photosynthesis rate. Consequently, the delay of decades between CO<sub>2</sub>-concentration rise and full expression of the warming, to which we are already committed, is a “window of opportunity” for high crop yields of C<sub>3</sub>-plants. This may in the long-term also have global consequences, because the CO<sub>2</sub>-concentration could rise additionally if the (high latitude) forests (C<sub>3</sub>-plants), acting as a sink for anthropogenic CO<sub>2</sub> presently, would lose this capacity under higher climate change stress. Whether and when this will occur is not yet known.

### Changes in Food Composition for Main Crops at Elevated CO<sub>2</sub>-Concentration

An important consequence of elevated CO<sub>2</sub>-concentration would be changed composition of plant tissue, and especially of seeds, as it could have immediate health conse-

quences for animals and humans eating them. The sparse body of published studies is nearly unanimously pointing to a loss of nitrogen content in leaves and stems as well as in seeds (see Fig. 5 and [6] for an overview). The results of so-called Free Air Carbon Dioxide Enrichment (FACE) studies at roughly doubled CO<sub>2</sub>-concentrations (~ 550 ppm) are all reporting higher nitrogen content for plant tissue and a bit less for seeds. This negative consequence for our food is not yet fully acknowledged in the public, because of the very different impacts for different parts of society. For a grain-producing farmer the CO<sub>2</sub> fertilization effect leads to higher yields of C<sub>3</sub>-plants, a dampening of photo-smog yield reductions, higher water use efficiency for both C<sub>3</sub>- and C<sub>4</sub>-plants and thus less drought impact while for the baker the wheat quality for baking bread declines, and the cattle as well as the consumer get less healthy food.

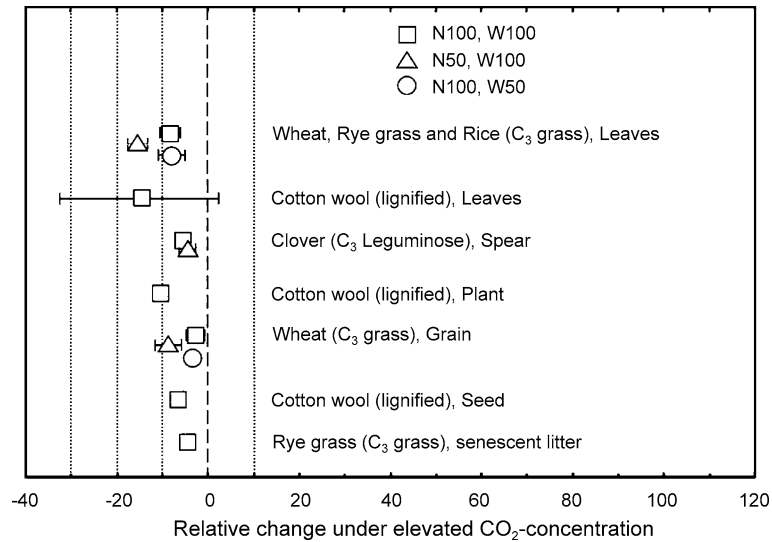

### Shift of Biomes and Migration

As already observed, precipitation is redistributed due to rather different warming patterns. And projections of precipitation changes in the 21st century, as published in the Fourth Assessment Report of [4], can be summarized in the following sentence: Rather humid areas will on average get more precipitation, especially in high latitudes, while semi-arid areas will get on average less (with strongly lowered soil moisture at higher temperatures). This is bad news for many millions of people in semi-arid zones of the tropics and subtropics. The main impact on plants is water stress, hence lower crop yields. But also less food for cattle in pasture lands, continued or enhanced malnutrition for the poor, aggravation of existing deficiencies in public health care systems in these areas will be the negative consequences of climate change impact on the biomes of these areas. In other words: Undermined public health systems, loss of livelihoods and finally migration will be the dire consequences of anthropogenic climate change. The socio-economic and political reactions to this threat cannot be foreseen in detail. However, the international economic cooperation between developing and industrialized countries has to take as a priority adaptation to unavoidable climate change as the best means to lower impacts on public health.

### Concluding Remarks

Although threat to human health was often the cause for environmental policy making, e. g. in the case of desulfurization of power plant exhaust, the manifold threats to human health as a consequence of global anthropogenic climate change have rarely been named as a key reason for

Climate Change and Human Health, Figure 5

climate change policy measures. What else is the partly still growing mal-nutrition of subsistence farming communities in the desertification-prone semi-arid tropics and subtropics than a threat to human health? On the other hand most new threats to our health caused by the spread of vector-borne infectious diseases due to higher temperatures or those caused by new weather extremes can be strongly reduced by proper health system up-grading and pre-cautionary measures that strengthen security-related infrastructure. However, this will probably not be the case in developing countries already suffering from (very) weak public health systems; unless the preliminary decisions of the 13th Conference of the Parties to the UNFCCC lead to a new international and binding protocol in 2009 as a follow-on to the Kyoto Protocol that then stipulates that a fixed portion of the revenues of international greenhouse gas emission trading should be used for adaptation measures in developing countries. A large share has to be invested in public health systems in poor developing countries in order to help the poorer parts of societies typically suffering most from epidemics and weather-related catastrophes.

If earlier tropical vector-borne infectious diseases, like the West Nile fever, reach developed countries, research to get proper vaccines will be stimulated within large pharmaceutical companies. If the threat remains confined to the poor South, this research effort will often not exist, because developing countries' normal population cannot afford the expensive new drugs or vaccines that remain

property right protected for years. It is high time that political summits deal with this problem and WHO helps to circumvent this barrier as pointed out recently by the Nobel Prize laureate for economics (Stiglitz, 2006).

### Glossary

**Direct costs** The direct cost equals quantity times price.

**Discount factor** The discount factor  $t$  years into the future equals one over one plus the discount rate, raised to the power  $t$ .

**Discount rate** The discount rate is the annual rate of decline of the value of consumption. It is roughly equal to the rate of interest, or the opportunity cost of capital. The discount rate consists of two components: the rate at which consumers get better off, and the rate of pure time preference (or impatience). The discount rate is not related to the rate of inflation, which is the annual rate of decline of the value of money.

**Economics** Economics is the social science which studies human behavior with regard to the relationship between ends and scarce means which have alternative uses.

**Equity weights** Equity weights are applied to aggregate national impacts to a global total. Equity weights are often set to unity, but sometimes equity weights equal the ratio of nationally average per capita income over global average per capita income.

**Indirect costs** The indirect costs equal all costs that are not direct costs. This includes the price change induced by the change in quantity (partial equilibrium effects), the changes in other markets (general equilib-

rium effects), and the changes at later times (dynamic effects).

**Marginal costs** The marginal cost of greenhouse gas emissions equals the first partial derivative of the net present value of the total costs of climate change to emissions.

**Monetary valuation** Monetary valuation is a set of techniques and their application that attempts to express in monetary terms the value to humans of changes in environmental goods and services. Negative impacts are typically expressed as an income loss that would give an equivalent loss in welfare.

**Neo-classical economics** Although historians would refer to neo-classical economics as the dominant form of economic research between 1860 and 1910, common usage has neo-classical economics as a synonym for mainstream or orthodox economics. In that sense, neo-classical economics is a style of research, characterized by empirical rigour, mathematical rigour, and micro-founded macro-relationships.

**Net present value** The net present value is the sum of all future costs and benefits, weighted by the discount factor.

**Total costs** The total cost of climate change equals the direct and the indirect costs of climate change, that is, the difference in welfare between a scenario with climate and a scenario without.

### Definition of the Subject

The economic costs of climate change include all positive and negative impacts of the enhanced greenhouse effect and the resulting changes in the atmosphere and ocean on all human consumers and producers. Total costs refer to the difference in human welfare between a scenario with climate change and a scenario without climate change. Marginal costs refer to the difference in human welfare between two scenarios with a slightly different climate, normalized by the amount of greenhouse gas emissions that would induce that difference. Estimates of the economic costs of climate change are important to assess the size of the climate problem relative to other problems, and to compare the costs of climate change to the costs of greenhouse gas emission reduction.

### Introduction

Calls for greenhouse gas emission reduction are often phrased as a moral imperative. While tempting, this is wrong. Firstly, there is no moral agreement. Emission reduction could save polar bears but it would cost coal miner's jobs and raise the price of food for the malnour-

ished. Moral imperatives are easy if a policy has only benefits. As soon as a policy has both costs and benefits, one has to make trade-offs and choose the lesser evil. Secondly, there is no avoiding dangerous interference with the climate system. Emission reduction would slow down the melting of the Greenland ice cap, and reduce the probability of a collapse of the West-Antarctic Ice Sheet – but it would not stop the melting or bring the change to zero. Thirdly, we have no obligations to future generations or poor people. Such duties are self-imposed. And even if we choose to help others, there are many ways to do this. Would our grandchildren prefer a richer but warmer world, or a poorer but colder one? Would the grandchildren of the Bangladeshis like us to reduce greenhouse gas emissions, help them to adapt to climate change, or help their grandparents grow rich?

This chapter looks into such questions. It is written from the thoroughly relativistic perspective of a neo-classical economist. The basic principles of the economic theory of climate change are quite simple. Greenhouse gas emissions are an externality. Externalities are unintended – we burn coal to make electricity, not to emit carbon dioxide – and uncompensated – carbon dioxide is freely dumped in the atmosphere – consequences of economic activity. Externalities should be internalized, that is, emitters should pay for their emissions. The price of emissions should equal the damage done by the emissions. That is all.

There is now a vast literature on the economics of climate change – started by Nordhaus [73,74]. A large part of that literature is about the deviation between the simple policy prescription of economic theory and the complexities of actual policy. Another large part of the literature is about the costs of greenhouse gas emission reduction. The literature on the economic costs of climate change is only a small one. It is reviewed here.

Section “**Issues**” discusses the methodological, conceptual, and moral issues one has to confront when estimating the economic impacts of climate change. Section “**Total Costs**” reviews estimates of the total economic impact. Section “**Marginal Costs**” surveys estimates of the marginal impacts. Section “**Policy Implications**” concludes by assessing the policy implications.

## Issues

### Scenarios

A scenario is a set of assumptions on future conditions that is coherent, internally consistent, and not implausible [70]. Climate scenarios are usually derived from modeling experiments with General Circulation Models (GCM). Climate scenarios include simple statistics such as the global

mean surface air temperature, and complex results such as spatial patterns of rainfall extremes. Climate scenarios may also include low-probability events, such as a disruption of the thermohaline circulation in the Atlantic Ocean, or the collapse of the West Antarctic Ice Sheet.

Scenarios also include population, economic activity, greenhouse gas emissions, and land use. Besides driving the climate models, these components are also important as they determine the vulnerability of social and economic systems to climate change over time. Although poorer societies are generally believed to be more vulnerable to climate change, this is by no means a simple relationship. Some impacts tend to fall with economic growth. The impacts of climate change on infectious diseases are a prime example. Malaria does not kill middle income people, because they can afford prevention and (if necessary) cure. Some impacts tend to rise with economic growth. The impact of climate change on biodiversity and species loss is one example. People tend to care more about these matters as their income grows, and further developed economies put more pressure on nature. Other impacts may rise first and then fall with economic growth. Urban air quality is one example. The very poor have nothing to foul the air with, and the very rich do not like foul air and have the wherewithal to prevent it. Climate change is likely to increase malaria, reduce biodiversity and worsen air quality. In some case, climate change and economic growth work together to increase the impacts, while in other cases they pull in opposite directions.

## Valuation Approach

There are various techniques for the monetary valuation of climate change impacts. Some values of impacts are directly based on observed prices. Agriculture and dike building are examples. Other values can be indirectly measured on the basis of observed market prices for surrogate products or services. One example is human health, which is not traded directly but indirectly through safety measures, labor markets, and health care. The challenge in these instances is to model future market prices that are consistent with the underlying socioeconomic scenario. For yet other impacts, no market values exist, and hypothetical prices are needed. Notable impacts are on non-commercial ecosystems and biodiversity.

Because it is practically impossible to estimate each exposure-response relationship or value at the respective geographical location of a climate change impact, data from previous studies focusing on different locations and different policy contexts are inevitable. Furthermore, most climate change impacts will take place in the future, for

which by definition no data are available. Therefore it is important to know when data from other studies can be used and under what conditions, and how to extrapolate values from today to tomorrow.

The majority of recent studies still adopt benefit transfer methods for the evaluation of climate impacts. However, benefit transfer is not very reliable [91]. For this reason, more attention should be given to original valuation research in the context of climate change.

An example of such a study is Li et al. [54] who analyze the willingness-to-pay (WTP) of American citizens for climate policy by means of the contingent valuation method. They find that the median American citizen is willing to pay about \$ 15/tC. Berrens et al. [7] find a willingness-to-pay between \$ 200 and \$ 1760 per US household per year (0.2–2.3% of income) for US ratification of the Kyoto Protocol. (Manne and Richels [60] estimate that the costs of US ratification would be 0.75% of GDP in 2010.) Hersch and Viscusi [46] find that Europeans are willing to pay up to 3.7% more for petrol if that helps combat climate change. Viscusi and Zeckhauser [117] find that Harvard students are willing to pay \$ 0.50/gallon (a 25% price increase) or 3% of their expected annual income for greenhouse gas emission reduction. (This study also showed that these students underestimate projected warming in Boston by about 50%, while the authors made them believe that carbon dioxide emission reduction would be effective for slowing climate change in the next 30 years.) There is scope for similar applications of WTP techniques, mainly to account for spatial and socio-economic differences in individuals' preferences.

### Direct and Higher Order Impacts

Most studies to date have estimated the direct costs of climate change. Direct costs equal the physical change (e. g., the dikes to be reinforced) times their price (in this example, the costs per dike length and dike height). Direct costs are easy to compute (but see Subsect. “**Valuation Approach**”), but probably underestimate the real economic costs.

The higher order impacts come in three kinds. Firstly, climate change may impact the market under consideration. For example, if dikes are being reinforced everywhere, then the costs of dike building is likely to go up as materials, machinery, and skilled labour is difficult to get. Secondly, the impact of climate change on one market may spill over into other markets. For example, dike building may increase the costs of construction, as the same materials and skills are used. Dike building is capital intensive and may drive up the interest rate. Thirdly, the impact of

climate change may affect economic growth. For example, money invested in dike building is not invested elsewhere.

A number of recent studies have examined the economy-wide implications of sea level rise [10], tourism [8], and health [9]. While it is perhaps too early to draw firm conclusions from this body of research, the studies suggest that the indirect effects of climate change impacts can both enlarge and diminish the direct economic impacts of climate change. The distribution of gains and losses is another difference between direct costs and general equilibrium effects. Whereas direct costs are limited to those directly affected, markets would spread the impact to their suppliers, clients, and competitors as well as to financial markets.

Fankhauser and Tol [35] show that the economic growth impact of climate change is as large as the direct impact of climate change. Acemoglu et al. [1] and Masters and McMillan [62] show that differences in climate explain part of observed differences in economic development. Easterly and Levine [28] show that the link is at most weak and indirect, and it is not clear whether the mechanisms that may have been active in the past, still hold for present and future.

### Adaptation

One cannot study the costs of climate change impact without also studying, or at least making assumptions about the costs of adaptation [109]. Studies focusing on costs of the impacts make widely differing assumptions about the amount of adaptation that will take place. While some studies completely ignore adaptation, other studies consider arbitrary levels of adaptation, or assume optimal adaptation. No studies use realistic models of adaptation [109]. There is little research that shows how adaptation costs compare to the potential damages of not adapting. The impacts of climate change and the capacity to adapt would be affected with the level of development and flexibility of the economy [123]. Hence, the future success and nature of adaptation depends on the assumed socio-economic scenario.

### Aggregation: Temporal

Climate change is a slow process. Today's emissions will affect the climate for decades to centuries, and sea level for centuries to millennia. As cause and effect are separated in time, so are costs (of emission reduction) and benefits (of avoided climate change). The procedure to make commensurate costs and benefits at different points in time is called discounting. Discounting is as common as it is controversial. See [3] for an excellent discussion.

Individuals discount future gains or losses because of two reasons. (People may also discount the future because it is more uncertain than the present, but in this case discounting is used as a shortcut for an uncertainty analysis.) First, money earns interest. Second, people are impatient. The first reason is widely accepted. Davidson [26] is one of the few exceptions. On the second reason, there is virtual consensus too. All ethical arguments show that people should not discount (e. g., [12]). All empirical evidence shows that people do nonetheless (e. g., [79,80]).

Climate change is a large-scale problem. Therefore, the discount rate of society is more relevant than the individual discount rate. The appropriate measure of the growth rate of money is the average growth rate of per capita consumption. Again, there is little dispute on this. But should the social rate of discount also include a measure of impatience? Again, philosophers agree: Impatience is immoral. However, this implies that a government would deviate from the will of the people. This may be defended with the argument that the government is the guardian of future, yet unborn people. However, the empirical evidence is clear in this case too: Governments are impatient [31].

Discounting is more profound over long periods than over short ones. Discounting implies that climate change damages that occur in a century or so are largely irrelevant. This realization has led people to rethink the fundamental principles of discounting, particularly

- (a) the notion that the procedure of discounting results from the intertemporal allocation of resources of an individual agent; and
- (b) the assumption that discounting is exponential.

To start with the individual perspective, Lind [56] and Lind and Schuler [55] argue that *earmarked* investment is a crucial assumption in discounting. The discount factor measures the trade-off between consumption now and consumption later, where consumption later is contingent on a specific investment plan. As the current generation cannot commit near-future generations to maintain their investments for the benefit of far-future generations, discounting breaks down between generations. Schelling [95] agrees. The alternative is to decide explicitly on the resource allocation between generations. Chichilnisky [19] shows that discounting coincides with a dictatorship of the present generation over future generations. Gerlagh and Keyzer [38] show that discounting is equivalent to the present generation owning all future resources. This is objectionable from a moral standpoint, but it is reality. This line of research has not led to practical alternatives to discounting.

Conventional discounting is exponential: The discount factor is  $(1 + r)^{-t}$ , where  $r$  is the discount rate and  $t$  is time. Some people argue that the functional specification of conventional discounting is wrong. The first component is empirical. Conventional exponential discounting has that the relative difference between two years is always equal, regardless of their distance from the present. That is, the difference between year 10 and 11 is the same as the distance between year 100 and 101. However, many people would in fact argue that the difference between year 10 and 11 is equal to the difference between year 100 and 110. Such hyperbolic discounting [22] is very similar to exponential discounting for short periods, but the difference is substantial for long periods. The similarity between exponential and hyperbolic discounting in the short run is important, because a switch to hyperbolic discounting would imply a drastic overhaul of long-term decisions only.

There are two further arguments for hyperbolic discounting cf. Dasgupta and Maskin [25]. The first is due to Weitzman [118]. He shows that, if one is uncertain what discount rate to use, then the lowest discount rate becomes increasingly dominant over time. The certainty-equivalent discount rate falls with time, and the difference between years shrinks in the more distant future. Consider the following example. After one year, the average of a 1% and a 10% discount rate is

$$1 - \left( \frac{(1.01^{-1} + 1.10^{-1})}{2} \right)^{1/1} = 5.0 \%$$

(and not 5.5%). After 100 years,

$$1 - \left( \frac{(1.01^{-100} + 1.10^{-100})}{2} \right)^{1/100} = 1.7 \%$$

That is, the average approaches the minimum as time progresses. One may criticize this as a short cut for a full uncertainty analysis. However, Gollier [39,40] shows that the same is true if a government somehow aggregates the individual discount rates of its citizens. In the long run, the preferences of the person with the lowest discount rate become increasingly important, and the discount rate declines over time.

Guo et al. [41] and Newell and Pizer [71] show that hyperbolic discounting leads to higher estimates of the social cost of carbon. However, the quantitative effect is limited by the fact that hyperbolic discount rates are high for the first decades.

### Aggregation: Spatial

Climate change is a global problem. Carbon dioxide and other greenhouse gases mix uniformly in the atmosphere.

This implies most of the impacts of one country's emissions fall on other countries. The same is true for the benefits of emission reduction. The impacts on different countries need to be aggregated somehow.

Two methods dominate the literature. In the first and oldest method, regional impacts are quantified in local currencies, converted to dollars, say, and added up [33,103]. This is simple, but the disadvantage is that similar impacts are treated differently. Most disturbingly, climate-change-induced deaths in rich countries receive a greater weight than climate-change-induced deaths in poor countries. The second method, known as equity weighing, corrects for this [6,36]. Rather than simply adding regional estimates, the regional utility-equivalents are added and then converted back to money according to an assumed global welfare function. A big disadvantage of this method is that climate-change-induced deaths are treated differently than deaths by other, national causes. The reason for this discrepancy is that equity weighing, as practiced in the literature, explicitly assumes a global decision maker.

In the meta-analysis of Tol [107], the median estimate of the marginal damage costs of carbon dioxide is \$ 10/tC without equity weights, and \$ 54/tC with equity weights. So, equity weighing is obviously important. The reason is simple. Poor countries are more vulnerable to climate change. Poor countries have little economic weight. Equity weights correct for this.

Morally, this may be the right thing to do. However, national governments also have a certain obligation to defend the interests of their citizens. A narrow interpretation of self-interest would suggest that impacts abroad be ignored (unless they spill over, e. g., through international migration). Then, climate change policy would be very limited, as most impacts will be abroad. However, the principle of good neighborhood is well established, both morally and legally. This entails that one should avoid doing harm to others; and should pay compensation if harm is done nonetheless (e. g., [113]).

A rational actor would avoid doing harm if that is cheaper than the compensation paid. From a national perspective, the relevant damages are then the impacts on the own country plus the compensation paid to other countries. Schelling [93] forcefully argues that compensation should equal the welfare loss of the victim rather than the welfare loss that the culprit would have experienced had she been the victim. This argues for aggregation of monetized impact estimates without equity weighing.

However, compensation would need to be paid only once. Furthermore, a country would also reasonably expect to be compensated itself. This implies that the dam-

age to a country equals the global damage times its share in causing the problem. Defining the latter is a thorny issue, as the cause-effect chain is long, complex, and uncertain. One would need to make arbitrary decisions on cause, effect and their connection.

### Uncertainty

Climate change is plagued by uncertainty [16]. Partly, this is because our understanding of climate change and its impacts is incomplete. For the larger part, however, this is because climate change will take place in the future, partly driven by future emissions, and impacting a future world. Future research and observations may reduce the uncertainty, although surprises may increase the uncertainty just as well, but uncertainty will never disappear. Learning and irreversibility play a crucial role in how to deal with uncertainty. Events that may or may not occur in some distant future, but whose consequences can be alleviated once it becomes clear if they would occur, should not worry us too much. On the other hand, if an effect is irreversible (e. g., species extinction), we may want to prevent it regardless of how uncertain it is and regardless of what future research will show (according to the "precautionary principle"). Another crucial part of dealing with uncertainty is risk aversion. Essentially, this determines how much weight we place on negative surprises. A risk neutral decision maker would cancel negative surprises against positive ones, but a risk adverse decision maker would not. Recent work has shown that the marginal damage costs of carbon dioxide are indeed very sensitive to the assumed degree of risk aversion. Although uncertainty and risk are often emphasized – often in a casual way – only few studies seek to quantify its implications (e. g., [51]).

In a recent paper, Weitzman [120] shows that, under a wide range of standard assumptions, the uncertainty about climate change is so large that the expected value of the social costs of climate change is infinite. Earlier, Tol [106] showed this for a specific model. This implies that uncertainty should take central stage in the analysis of climate policy. The Weitzman result throws up a number of methodological issues that will need to be resolved before the policy implications of this work become clear.

### Completeness

The impacts of climate change that have been quantified and monetized include the impacts on agriculture and forestry, water resources, coastal zones, energy consumption, air quality, and human health. Obviously, this list is incomplete. Also within each impact category, the as-

assessment is incomplete. Studies of the impacts of sea level rise on coastal zones, for instance, typically omit saltwater intrusion in groundwater [72]. Furthermore, studies typically compare the situations before and after climate change, but ignore that there will be a substantial period during which adaptation is suboptimal – the costs of this are not known.

Some of the missing impacts are most likely negative. Diarrhoea impacts have been quantified recently [57]. Like malaria, diarrhoea is a disease that is driven by poverty but sensitive to climate. Including diarrhoea tightens the link between development and climate policy. Increasing water temperatures would increase the costs of cooling power plants [101]. Redesigning urban water management systems, be it for more or less water, would be costly [4], as would implementing the safeguards against the increased uncertainty about future circumstances. Roads and bridges would suffer from weather conditions for which they were not designed; this would imply either disruption of traffic or expensive retrofits. Extratropical storms may well increase, leading to greater damage and higher building standards [27]. Expenditures on these things are relatively small. Even if climate change would double or triple the cost, the impact would be small. Ocean acidification would reduce marine biodiversity, and may well harm fisheries [52]. Ocean fisheries are only a small, and declining fraction of GDP, while there are ready substitutes for wild fish protein (notably fish farming). The value of biodiversity is unclear (see below).

Other missing impacts are probably positive. Higher wind speeds in the mid-latitudes would decrease the costs of wind and wave energy [11,44]. Less sea ice would improve the accessibility of arctic harbours, would reduce the costs of exploitation of oil and minerals in the Arctic, and may even open up new transport routes between Europe and East Asia [121]. Warmer weather would reduce expenditures on clothing and food, and traffic disruptions due to snow and ice [15]. Also in these cases, the impact of climate change is likely to be small relative to the economy.

Some missing impacts are positive in some places, and negative in others. Tourism is an example. Climate change may well drive summer tourists towards the poles and up the mountains [42,43]. People, however, are unlikely to change the time and money spent on holiday making. The effect is a redistribution of tourist revenue [8]. The global impact is close to zero, but regional impacts are measured in tens of billions of dollars – positive in temperate, rich countries, and negative in tropical, poor countries. This exacerbates the already skewed distribu-

tion of climate impacts. Some ski resorts may go out of business, and others would need expensive snowmaking equipment [29,97]. Other ski resorts would profit from the reduced competition. Although regional impacts may be substantial, at the global scale positives and negatives cancel.

Other impacts are simply not known. Some rivers may see an increase in flooding, and others a decrease [53]. At the moment, only a limited number of rivers have been studied in detail, and it is unclear how to extrapolate to other rivers. It is clear though, that land use and water management may greatly increase or reduce impacts. Although river floods wreak substantial havoc and damages of a single event can reach substantial numbers, average flood damage is in fact small relative to the economy [112]. Tropical storms do more damage, although a substantial share of the impact is due to bad planning rather than bad weather [14]. Nonetheless, tropical storms may prevent capital accumulation and the plantation of lucrative crops such as banana [30,69]. Unfortunately, it is not known how climate change would alter the frequency, intensity, and spread of tropical storms [63,89].

The missing impacts discussed above are probably small. There are also bigger gaps in the coverage of climate change impact studies. Climate change is likely to have a profound impact on biodiversity, but quantitative predictions are rare [13]. Although the economic impact of a small change in biodiversity is known to be small [88], the value of large biodiversity changes is unknown but could well be substantial [18]. There is a small but unknown chance that climate change will be more dramatic than is typically assumed in the impacts literature. This may be because of shutdown of the thermohaline circulation [61], a collapse of the Greenland or West-Antarctic Ice Sheet [84], or a release of large amounts of methane [45]. The economic analysis of such scenarios has only just begun [57]. It may be that climate change would lead to large-scale migration [64] and violent conflict, although there is only weak empirical support for this [49,124]. Finally, climate change impact studies stop at the end of the 21st century. In 2100, impacts are negative, and getting more negative at an accelerating pace. It is not known how rapidly things would get worse in the 22nd century without emission abatement.

Although the sign of the aggregate unknown impacts is not known, risk aversion would lead one to conclude that greenhouse gas emission reduction should be more stringent than suggested by a cost-benefit analysis based on the quantified impacts only. However, the size of the bias is unknown too – so the main policy implication is that more research is needed.

## Total Costs

The first studies of the welfare impacts of climate change were done for the USA [21,74,98,102]. Although Nordhaus [74] (see also Ayres and Walter [5]) extrapolated his US estimate to the world, the credit for the first serious study of the global welfare impacts goes to Fankhauser [32,33], although Hohmeyer and Gaertner [48] earlier published some low quality estimates. Other global estimates include those by Nordhaus [76,77], Tol [103], Nordhaus and Yang [82], Plambeck and Hope [90], Nordhaus and Boyer [81], Mendelsohn et al. [66,68], Tol [105], Maddison [59], Hope [50], Rehdanz and Maddison [92] and Nordhaus [78]. Note that Stern et al. [100] is based on Hope [50].

This is a rather short list of studies, and an even shorter list of authors. This problem is worse if one considers that Nordhaus and Mendelsohn are colleagues; that Fankhauser, Maddison and Tol are students of Pearce; and that Rehdanz is a student of Maddison and Tol; while Hope's (and Stern's) estimates are averages of Fankhauser's and Tol's. Although most fields are dominated by a few people, dominance is here for want of challengers. The effect of this is hard to gauge. The reasons are lack of funding (this work is too applied for academic sources, while applied agencies do not like the typical results and pre-empt this by not funding it), lack of daring (this research requires making many assumptions, and taking on well-entrenched incumbents), and lack of reward (the economics profession frowns on the required interdisciplinarity). In addition, many people, including many economists, would argue that climate change is beyond cost-benefit analysis and that monetary valuation is unethical.

Table 1 shows some characteristics of these studies. A few insights emerge. First, the welfare impact of a doubling of the atmospheric concentration of carbon dioxide on the current economy is relatively small. Although the estimates differ, impacts are not more than a few percent of GDP. The estimates of Hope [50], Mendelsohn et al. [66,68] and Tol [105] even point to initial benefits of climate change. (Studies published after 1995 all have regions with net gains and net losses due to global warming, whereas earlier studies only find net losses.) With such estimates, it is no surprise that cost-benefit analyses of climate change recommend only limited greenhouse gas emission reduction – for instance, Nordhaus [75] argues that the optimal rate of emission reduction is 10–15%, one of the more contentious findings of the climate economics literature.

Second, although the impact is relatively small, it is

not negligible. A few per cent of GDP in annual damage is a real concern.

Third, climate change may initially have positive impacts. This is partly because the higher ambient concentration of carbon dioxide would reduce water stress in plants and may make them grow faster – although this effect is now believed to be weaker [58]. Another reason is that the global economy is concentrated in the temperate zone, where a bit of warming may well be welcomed because of reductions in heating costs and cold-related health problems. At the same time, the world population is concentrated in the tropics, where the impacts of initial climate change are probably negative. Even though initial *economic* impacts are positive, it does not necessarily follow that greenhouse gas emissions should be subsidized. The climate responds rather slowly to changes in emissions, so the initial impacts cannot be avoided. Impacts start falling – that is, additional climate change reduces global welfare – roughly at the same time as climate change can be influenced by present and future emission reduction [47].

The fourth insight is that relative impacts are higher in poorer countries (see also Yohe and Schlesinger [122]). This is because poorer countries have a lower adaptive capacity [2], particularly in health [108], and have a greater exposure to climate change, particularly in agriculture and water resources. Furthermore, poorer countries tend to be hotter and therefore closer to temperature limits and short on spatial analogues should it get warmer still. At the same time, there are fewer studies on the impacts of climate change on developing countries than on developed countries. Although research is scarce [83], there is little reason to assume that climate change impacts would be homogeneous within countries; certainly, certain economic sectors (e.g., agriculture), regions (e.g., the coastal zone) and age groups (e.g., the elderly) are more heavily affected than others. This has two policy implications. Firstly, recall that greenhouse gas mix uniformly in the atmosphere. It does not matter where they are emitted or by whom, the effect on climate change is the same. Therefore, any justification of stringent emission abatement is an appeal to consider the plight of the poor and the impacts imposed on them by the rich [94,95]. While this makes for wonderful rhetoric and fascinating research (e.g., [104]), reality shows little compassion for the poor by the rich. Secondly, if poverty is the root cause for vulnerability to climate change, one may wonder whether stimulating economic growth or emission abatement is the better way to reduce impacts. Indeed, Tol and Yohe [115] argue that the economic growth foregone by stringent abatement more than offsets the avoided impacts of climate change, at least for malaria,

Climate Change, Economic Costs of, Table 1  
Economic impact estimates of climate change; numbers in brackets are either standard deviations or confidence intervals

Study	Warming	Impact	Minimum	Region	Maximum	Region
Nordhaus [76]	3.0	-1.3				
Nordhaus [77]	3.0	-4.8 (-30.0 to 0.0)				
Fankhauser [33]	2.5	-1.4	-4.7	China	-0.7	Eastern Europe and the former Soviet Union

Nordhaus [78]	2.5	-0.9 (0.1)				

<sup>a</sup>Note that the global results were aggregated by the current author.

<sup>b</sup>The top estimate is for the "experimental" model, the bottom estimate for the "cross-sectional" model.

<sup>c</sup>Note that Mendelsohn et al. only include market impacts.

<sup>d</sup>Note that the national results were aggregated to regions by the current author for reasons of comparability.

<sup>e</sup>Note that Maddison only considers market impacts on households.

while Tol [108] shows that development is a cheaper way of reducing climate-change-induced malaria than is emission reduction. Moreover, richer countries may find it easier and cheaper to compensate poorer countries for the climate change damages caused, than to reduce greenhouse gas emissions. Such compensation may be explicit and financial, but would more likely take the shape of technical and financial assistance with adaptation (cf. [85]).

The agreement between the studies is remarkable if one considers the diversity in methods. The studies of Fankhauser, Hope, Nordhaus, and Tol all use the enumerative method: 'physical' impact estimates are obtained one by one, from 'natural science' papers based on 'process-based' models or 'laboratory experiments'. These physical impacts are multiplied with their respective prices, and added up. The 'prices' are obtained by benefit transfer. In contrast, Mendelsohn's work is based on direct, empirical estimates of the welfare impacts, using observed variations in prices and expenditures to discern the effect of climate (e. g., [67]). Mendelsohn estimates are done

per sector and then added up, but physical modelling and benefit transfer are avoided. Nordhaus [78] uses empirical estimates of the *aggregate* climate impact on income, while Maddison [59] looks at patterns of *aggregate* household consumption. Like Mendelsohn, Nordhaus and Maddison rely exclusively on observations, but they assume that all climate effects are aggregated by the economy into incomes and expenditures. Rehdanz and Maddison [92] also empirically estimate the aggregate impact, but use self-reported happiness as an indicator; their approach is similar to that of Nordhaus and Maddison, but the indicator is subjective rather than objective. The enumerative studies of Fankhauser etc rely on controlled experiments (albeit with detailed, process-based models in most cases). This has the advantages of ease of interpretation and physical realism, but the main disadvantage is that certain things are kept constant that would change in reality; adaptation is probably the key element. The statistical studies of Mendelsohn etc rely on uncontrolled experiments. This has the advantage that everything varies as

in reality, but the disadvantages are that the assessment is limited to observed variations (which may be small compared to projected changes, particularly in the case of carbon dioxide concentration) and that effects may be spuriously attributed to climate. Therefore, the variety of methods enhances confidence, not in the individual estimates, but in the average.

The shortcomings of the estimates are at least as interesting. Welfare losses are approximated with direct costs, ignoring general equilibrium and even partial equilibrium effects (see below). In the enumerative studies, impacts are assessed independently of one another, even if there is an obvious overlap as between water resources and agriculture. Estimates are often based on extrapolation from a few detailed case studies, and extrapolation is to climate and levels of development that are very different from the original case study. Valuation is based on benefit transfer, driven only by difference in per capita income. Realistic modelling of adaptation is problematic, and studies either assume no adaptation or perfect adaptation. Many impacts are unquantified, and some of these may be large (see below). The uncertainties are unknown – only 4 of the 14 estimates in Table 1 have some estimate of uncertainty. These problems are gradually solved, but progress is slow. Indeed, the above list of caveats is similar to that in Fankhauser and Tol [34].

### Marginal Costs

Although the number of studies of the *total* costs of climate change is small, a larger number of studies estimate the *marginal* costs. The marginal damage cost of carbon dioxide is defined as the net present value of the incremental damage due to an infinitesimally small increase in carbon dioxide emissions. If this is computed along the optimal trajectory of emissions, the marginal damage cost equals the Pigou tax. Marginal damage cost estimates derive from total cost estimates – the fact that there are more estimates available, does not imply that we know more about the marginal costs than we do about the total costs. In fact, some of the total cost estimates [59,66,68,78,92] have yet to be used for marginal cost estimation, so that the empirical basis is actually smaller.

Tol [110] gathers 211 estimates of the SCC from 47 studies. The studies were grouped in those that were peer-reviewed and those that were not. Some studies are based on original estimates of the total costs of climate change, while other studies borrow total costs estimates from other studies. Most studies use incremental or marginal calculus to estimate the SCC, as they should, while a few others use average impacts or an unspecified method. Some studies

assume that climate changes but society does not, while other studies include a dynamic model of vulnerability. A few studies use entirely arbitrary assumptions about future climate change, while most studies are based on internally consistent scenarios. These classifications are used as quality indicators. More recent studies were given a higher weight. Many studies report multiple estimates. Most of the estimates are sensitivity analyses around a central estimate, and some estimates are only included to (approximately) reproduce an earlier study. Tol [110] introduces additional weights to account for this.

Tol [110] adjusts a Fisher–Tippett kernel density estimator to 211 data points, weighted as describe above. The 211 estimates provide the modes. Only a few of the studies provide an estimate of the uncertainty. Therefore, the standard deviation is set equal to the sample standard deviation.

Table 2 shows selected characteristics of the kernel distribution for the whole sample and selected sub-samples.

Splitting the sample by discount rate used has the expected effect: A higher discount rate implies a lower estimate of the SCC and a thinner tail. Table 2 also shows that estimates in the peer reviewed literature are lower and less uncertain than estimates in the gray literature.

Splitting the sample by publication date, shows that the estimates of the SCC published before AR2 [87] were larger than the estimates published between AR2 and AR3 [99], which in turn were larger than the estimates published since. Note that these differences are not statistically significant if one considers the means and standard deviation. However, the kernel distribution clearly shifts to the left. Therefore, AR4 [96] were incorrect to conclude that the economic estimates of the impact of climate change have *increased* since 2001. In their words (pp. 781): “There is some evidence that initial new market benefits from climate change will peak at a lower magnitude and sooner than was assumed for the TAR, and it is likely that there will be higher damages for larger magnitudes of global mean temperature increases than was estimated in the TAR.” It is unclear how Schneider et al. [96] reached this conclusion, but it is not supported by the data presented here.

The SCC estimate by Stern et al. [100] is almost an outlier in the entire sample (excluding, of course, the Stern estimate itself). Depending on the kernel density, the Stern estimate lies between the 90th and the 94th percentile. It fits in better with estimates that use a low discount rate and were not peer-reviewed – characteristics of the Stern Review – but even in comparison to those studies, Stern et al. [100] are on the high side. The Stern estimate also fits in better with the older studies. This is no sur-

Climate Change, Economic Costs of, Table 2

Selected characteristics (mode, mean, standard deviation, median, 90-percentile, 95-percentile, 99-percentile, percentile of the Stern estimate) of the joint probability density of the social cost of carbon for the whole sample (all) and selected subsamples (pure rate of time preference, review process, and publication date)

prise, as the PAGE model (e. g., [50]) is calibrated to [87] and [99]. Other criticism of the Stern Review can be found in [24,65,79,80,115,119,120].

### Policy Implications

The policy implications of the above findings are several, and not necessarily in line with the conceived wisdom of climate policy. First and foremost, the economic impacts literature points out that climate change is a problem. Initial climate change may be beneficial, but it cannot be avoided. This is a sunk benefit. The avoidable part of climate change is in all likelihood negative. This justifies greenhouse gas emission reduction.

Second, the estimates of the marginal damage costs justify some emission abatement, but not too much. For instance, the future price of carbon dioxide emission permits in the European Trading System is around \$ 100/tC. Using the market rate of discount, the expected social cost of carbon is only \$ 24/tC. This climate policy has a benefit-cost ratio of 0.24. EU climate policy is therefore too stringent. Of course, European climate policy does pass the cost-benefit test according to CEC [17], but this study does not meet conventional standards of academic quality [111]. Earlier, Pearce [89] similarly concluded that the UK cost-benefit analysis [20] is deficient, while also the *Stern Review* [100] has been criticized in the academic literature (e. g., [80,119]).

Third, climate policy is about ethics rather than about economics [37,116]. The judgment what to do about greenhouse gas emissions rests on the values one attaches to far-flung countries and distant futures. The ethics are not straightforward, however. If one places a lot of weight on the future, one should make a trade-off between increasing investment in capital goods, education, emission

reduction, or technology. If one places a lot of weight on people in poor countries, one should make a trade-off between adaptation, development, emission reduction, and trade reform.

Fourth, the uncertainties about the economic impact of climate change are profound. Partly, this is because the subject is complex. A large share of the uncertainty can be explained, however, by the dearth of research funding. Although climate change is often said to be the largest (environmental) challenge of our times, very few researchers are funded to substantiate or refute that claim.

### Future Directions

Further research is therefore needed. Several problems with past and present research are identified above. Firstly, research into the economic impact of climate change is rightly classified as “applied research”. This implies, however, that research funding comes from bodies with a stake in the result, and that quality and independence are not necessarily overriding concerns. The *Stern Review* is the most prominent example in the recent past of a study that started with the conclusions and worked back to identify the required assumptions. The new *Centre for Climate Change Economics and Policy* at the *London School of Economics* may fall into the same trap. Because the stakes in climate policy are large, academic quality of research must be guaranteed.

Secondly, there are only two groups of independent academics who study the economic impact of climate change. These groups are not sufficiently funded. More importantly, these groups are rarely challenged. Combined with the first problem, it is therefore important to establish a third group of independent, academic economists to study the impact of climate change.

Thirdly, research on the impact of climate change, economic and otherwise, has been lamp-posting. After the groundbreaking work in the early 1990s, researchers have refined previous estimates. Little attention has been paid to those impacts for which no previous estimates exist. While this is the normal procedure of gradual progress in scientific research, the study of the impact of climate change is still in its formative stages. Not just *more*, but particularly *different* research is needed – into the economic effects of climate change on biodiversity, on violent conflict, on ice shelves and ocean current, and on economic development in the long term.

### Acknowledgments

My thoughts on this subject were shaped by discussions with Hadi Dowlatabadi, Tom Downing, Sam Fankhauser, David Maddison, Rob Mendelsohn, Bill Nordhaus, David Pearce, Steve Schneider, Joel Smith, and Gary Yohe.

## Climate Modeling, Global Warming and Weather Prediction, Introduction to

HARTMUT GRASSL  
Max Planck Institute for Meteorology,  
Hamburg, Germany

All systems operating away from thermodynamic equilibrium develop structures. The planet Earth will always be far away from thermodynamic equilibrium because of the strongly differing solar radiation input as a function of latitude and season. Hence, the differential heating of the surface and also the atmosphere must lead to temperature gradients, in turn causing pressure gradients that create currents in the ocean and the wind in the atmosphere. On a rotating sphere (in reality the geoid, which is close to a rotational ellipsoid) these flows form low and high pressure systems both in the ocean and the atmosphere which are able to reduce latitudinal gradients but never come close to thermodynamic equilibrium because of continuing differential heating. The average temperatures and flow fields, as well as their strong spatial and temporal variability, are a function of land/sea distribution and atmospheric composition, especially depending on water and ice in clouds. The strongly climatically relevant gases in the atmosphere are, to a large extent, a consequence of life on Earth.

Ranking all radiatively active gases in the atmosphere according to their influence on weather and climate shows the exceptional composition of the atmosphere: Water vapor ( $\text{H}_2\text{O}$ ) in all three phases but largely as a gas, carbon dioxide ( $\text{CO}_2$ ), ozone ( $\text{O}_3$ ), nitrous oxide ( $\text{N}_2\text{O}$ ) and methane ( $\text{CH}_4$ ) constitute only three thousandths of the atmospheric mass, yet they largely determine how much solar radiation reaches the surface, e. g., through clouds, and how much thermal or terrestrial radiation leaves from there to space, again a strong function of clouds and the above-mentioned gases. The average surface temperature is thus strongly depending on the concentration of the gases mentioned, which are all greenhouse gases. They do not strongly absorb solar radiation but do absorb terrestrial radiation, thereby forcing the surface and the lower atmosphere to warm in order to reach nearly equilibrium between absorbed and emitted energy. Any growth or reduction of greenhouse gas concentrations increases or decreases average surface temperature and thus changes climate.

The climate system, i. e., its interacting components at atmosphere, ocean, land, vegetation, soils and crust, shows

both a remarkable stability and high sensitivity. Over many million years the greenhouse effect of about 30 K has varied only by about  $\pm 5$  K with respect to present interglacial temperatures, thus has been stable in terms of temperature varying only from 283 to 293 K.  $+5$  K however meant melting of all inland ice sheets and  $-5$  K a new strong glaciation with major ice sheets reaching 40 to  $50^\circ$  N (see ► [Cryosphere Models](#)).

The observed strong increases of all long-lived naturally occurring greenhouse gases ( $+35\%$  for  $\text{CO}_2$ ,  $+120\%$  for methane, and  $+10\%$  for  $\text{N}_2\text{O}$  since 1750) have stimulated a mean global warming which now has emerged from strong climate variability. In 2007, the Fourth Assessment Report of the Intergovernmental Panel on Climate Change concluded: “The understanding of anthropogenic warming and cooling influences has improved . . . leading to very high confidence that the global average net effect of human activities since 1750 has been one of warming”. On the other hand, the high sensitivity of the climate system is demonstrated in so called abrupt climate change events (see ► [Abrupt Climate Change Modeling](#)).

The strongest global one of these – besides the impact of celestial bodies – is deglaciation after an intense glaciation in about 5000 to 10 000 years with a concomitant temperature increase of 4 to 5 K, caused by the slow latitudinal redistribution of solar radiation due to Earth orbit parameter changes as a consequence of slowly changing gravitational forcing by the neighboring planets, mainly Venus, Jupiter and Saturn. Because climate is a key natural resource for plants, animals and humans, any rapid climate change threatens life on Earth. Therefore agriculture (see ► [Climate Change and Agriculture](#)), forestry and all economic activities (see ► [Climate Change, Economic Costs of](#)) will be impacted by anthropogenic climate change in the 21st century, leading to strong consequences in societal behavior vis-a-vis this challenge, e. g., the one caused by growing inequity between those societies causing climate change, the industrialized countries, and those suffering first or more strongly such as subsistence farmers in semi-arid tropical areas. Climate Models developed so far include many physical processes (see ► [Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface](#) as an example), parts of atmospheric chemistry, and vegetated land surface atmosphere interactions, but still lack reaction of ocean biomass production to enhanced  $\text{CO}_2$  levels. Finally, it is apparent that global warming will have an effect on human health and that this will include effects on food crops and animals (see ► [Climate Change and Human Health](#)).

The low horizontal resolution of global climate models has stimulated nested regional climate models (see ► [Re-](#)

gional Climate Models: Linking Global Climate Change to Local Impacts) delivering enhanced output in areas with strong topography or sea/land contrasts. The slowly emerging Earth System Models are no longer driven by changed atmospheric composition alone but by emissions, i. e., they can calculate resulting greenhouse gas concentrations. However they are still not advanced enough to answer the question: When will growing climate change stress turn the present uptake of anthropogenic CO<sub>2</sub> into forests through the CO<sub>2</sub>-fertilization into an additional CO<sub>2</sub> source for the atmosphere due to a generally weakened vegetation? It is common knowledge that weather, for example the passage of a coldfront at a certain location, can be forecast only for up to two weeks because of the intrinsically chaotic behavior of atmospheric flow. The accuracy of present day weather forecast models, which are very similar to the atmospheric component of climate

models, has advanced strongly, driven by higher spatial resolutions and better parametrizations of sub-grid scale processes in the models, assimilation of more (and especially satellite data) into the models and ensemble forecasting. This has recently led to the same forecast accuracy up to about 10 days in the southern hemisphere, where an in situ observing system for the starting fields of the model is largely lacking.

The increased attention the topic climate change has finally attracted in the political arena will certainly accelerate progress in this field, despite the complex nature of the functioning of the Earth system.

There are two additional articles on climate change which were recruited for other sections. These articles are: ► [Dynamic Games with an Application to Climate Change Models](#) and ► [System Dynamics Models of Environment, Energy and Climate Change](#).

## Complexity in Earthquakes, Tsunamis, and Volcanoes, and Forecast, Introduction to

WILLIAM H. K. LEE  
US Geological Survey (Retired), Menlo Park, USA

### Article Outline

[Introduction](#)  
[Earthquakes](#)  
[Tsunamis](#)  
[Volcanoes](#)  
[Discussions](#)

This Introduction is intended to serve as a ‘road map’ for readers to navigate through the 42 Encyclopedia articles on earthquakes, tsunamis, and volcanoes. Selecting the topics and authors was somewhat subjective, as it is not possible to cover the vast existing literature with only 42 articles. They are, however, representative of the wide range of problems investigated in connection with these natural phenomena. I will introduce these articles by grouping them into sections and then into subsections. However, some articles belong to more than one section or one subsection, reflecting the inter-related nature of earthquakes, tsunamis and volcanoes. For the benefit of the readers, I will point to certain issues discussed in some of the articles which, in my view, have not been settled completely. I have also taken the liberty of quoting or paraphrasing sentences from many of these articles when introducing them, but I do not claim to be accurate. It is best for these articles to speak for themselves.

I wish to thank Bernard Chouet for helping me in planning and reviewing the manuscripts of the volcanoes section. I am grateful to Bernard Chouet, Edo Nyland, Jose Pujol, Chris Stephens, and Ta-liang Teng for their helpful comments that greatly improved this manuscript.

### Introduction

Earthquakes, tsunamis, and volcanic eruptions are complex and often inter-related natural phenomena with disastrous impact to society rivaling those caused by the worst floods or storms. The 1556 Huaxian earthquake in the Shansi province of China claimed over 830,000 lives. The total economic loss of the 1995 Kobe earthquake in Japan was estimated at US \$200 billion. The 2004 Indian Ocean tsunami (triggered by the Sumatra–Andaman earthquake of December 26) brought devastation thousands of miles away with fatalities exceeding 280,000. The 79 AD erup-

tion of Mount Vesuvius near Naples, Italy buried the towns of Pompeii and Herculaneum. The 1902 eruption of Mount Pelée, Martinique, totally destroyed the town of St. Pierre.

Insurance companies classify major natural catastrophes as storms, floods, or earthquakes (including tsunamis, and volcanic eruptions). Since 1950, about 2.5 million people have died due to these catastrophes and overall economic losses have totaled about US \$2 trillion in current dollar values. Earthquakes, tsunamis, and volcanic eruptions have accounted for about half of the fatalities and more than one third of the total economic losses. Geoscientists have attempted to predict these events, but with limited success. There are many reasons for such slow progress: (1) systematic monitoring of earthquakes, tsunamis and volcanoes requires large capital investment for instruments and very long-term support for operation and maintenance; (2) catastrophic earthquakes, tsunamis and volcanic eruptions occur rarely, and (3) politicians and citizens are quick to forget these hazards in the face of other more frequent and pressing issues. But with continuing rapid population growth and urbanization, the loss potential from these natural hazards in the world is quickly escalating.

With advances in nonlinear dynamics and complexity studies, geoscientists have applied modern nonlinear techniques and concepts such as chaos, fractal, critical phenomena, and self-organized criticality to the study of earthquakes, tsunamis and volcanoes. Here we sample these efforts, mainly in seismicity modeling for earthquake prediction and forecast, along with articles that review recent progress in studying earthquakes, tsunamis, and volcanoes. Although predictability is desirable, it is also possible to reduce these natural hazards with more practical approaches, such as early warning systems, hazard analysis, engineering considerations, and other mitigation efforts. Several articles in this Encyclopedia discuss these practical solutions.

### Earthquakes

When a sudden rupture occurs in the Earth, seismic waves are generated. When these waves reach the Earth’s surface, we may feel them as a series of vibrations, which we call an earthquake. Instrumental recordings of earthquakes have been made since the latter part of the 19th century by seismographic stations and networks from local to global scales. The observed data have been used, for example, (1) to compute the source parameters of earthquakes, (2) to determine the physical properties of the Earth’s interior, (3) to test the theory of plate tectonics,

(4) to map active faults, (5) to infer the nature of damaging ground shaking, (6) to carry out seismic hazard analyzes, and (7) to predict and forecast earthquakes. A satisfactory theory of the complex earthquake process has not yet been achieved, and realistic equations for modeling earthquakes do not exist at present. There is, however, good progress towards a physical foundation for the earthquake source process, partly as a result of research directed toward earthquake prediction.

### **Earthquake Monitoring, and Probing the Earth's Interior**

Earthquakes are complex natural phenomena, and their monitoring requires an interdisciplinary approach, including using tools from other scientific disciplines and engineering. In ► **Earthquake Monitoring and Early Warning Systems**, W.H.K. Lee and Y.M. Wu presented a summary of earthquake monitoring, a description of the products derived from the analysis of seismograms, and a discussion of the limitations of these products. The basic results of earthquake monitoring are summarized in earthquake catalogs, which are lists of origin time, hypocenter location, and magnitude of earthquakes, as well as other source parameters. Lee and Wu describe the traditional earthquake location method formulated as an inverse problem. In ► **Earthquake Location, Direct, Global-Search Methods**, Lomax et al. review a different approach using direct-search over a space of possible locations, and discuss other related algorithms. Direct-search earthquake location is important because, relative to the traditional linearized method, it is both easier to apply to more realistic Earth models and is computationally more stable. Although it has not been widely applied because of its computational demand, it shows great promise for the future as computer power is advancing rapidly.

The most frequently determined parameter after 'location' is 'magnitude', which is used to characterize the 'size' of an earthquake. A brief introduction to the quantification of earthquake size, including magnitude and seismic moment, is given in ► **Earthquake Monitoring and Early Warning Systems** by Lee and Wu. Despite its various limitations, magnitude provides important information concerning the earthquake source. Magnitude values have an immense practical value for realistic long-term disaster preparedness and risk mitigation efforts. A detailed review, including current practices for magnitude determinations, appears in ► **Earthquake Magnitude** by P. Bormann and J. Saul.

Besides computing earthquake source parameters, earthquake monitoring also provides data that can be used

to probe the Earth's interior. In ► **Tomography, Seismic**, J. Pujol reviews a number of techniques designed to investigate the interior of the Earth using arrival times and/or waveforms from natural and artificial sources. The most common product of a tomographic study is a seismic velocity model, although other parameters, such as attenuation and anisotropy, can also be estimated. Seismic tomography generally has higher resolution than that provided by other geophysical methods, such as gravity and magnetics, and furnishes information (1) about fundamental problems concerning the internal structure of the Earth on a global scale, and (2) for tectonic and seismic hazard studies on a local scale.

In ► **Seismic Wave Propagation in Media with Complex Geometries, Simulation of**, H. Igel et al. present the state-of-the-art in computational wave propagation. They point to future developments, particularly in connection with the search for efficient generation of computational grids for models with complex topography and faults, as well as for the combined simulation of soil-structure interactions. In addition to imaging subsurface structure and earthquake sources, 3-D wave simulations can forecast strong ground motions from large earthquakes. In the absence of deterministic prediction of earthquakes, the calculation of earthquake scenarios in regions with sufficiently well-known crustal structures and faults will play an important role in assessing and mitigating potential damage, particularly those due to local site effects.

In addition to the classical parametrization of the Earth as a layered structure with smooth velocity perturbation, a new approach using scattered waves that reflect Earth's heterogeneity is introduced by H. Sato in his article on ► **Seismic Waves in Heterogeneous Earth, Scattering of**. For high-frequency seismograms, envelope characteristics such as the excitation level and the decay gradient of coda envelopes and the envelope broadening of the direct wavelet are useful for the study of small-scale inhomogeneities within the Earth. The radiative transfer theory with scattering coefficients calculated from the Born approximation and the Markov approximation for the parabolic wave equation are powerful mathematical tools for these analyzes. Studies of the scattering of high-frequency seismic waves in the heterogeneous Earth are important for understanding the physical structure and the geodynamic processes that reflect the evolution of the solid Earth.

### **Earthquake Prediction and Forecasting**

A fundamental question in earthquake science is whether earthquake prediction is possible. Debate on this question

has been going on for decades without clear resolution. Are pure observational methods without specific physical understanding sufficient? Earthquakes have been instrumentally monitored continuously for about 100 years (although not uniformly over the Earth), but reliable and detailed earthquake catalogs cover only about 50 years. Consequently, it seems questionable that earthquakes can be predicted solely on the basis of observed seismicity patterns, given that large earthquakes in a given region have recurrence intervals ranging from decades to centuries or longer. Despite progress made in earthquake physics, we are still not able to write down all the governing equations for these events and lack sufficient information about the Earth's properties. Nevertheless, many attempts have been and are being made to predict and forecast earthquakes. In this section, several articles based on empirical and physics-based approaches will be briefly introduced.

In ► **Geo-complexity and Earthquake Prediction**, V. Keilis-Borok et al. present an algorithmic prediction method for individual extreme events having low probability but large societal impact. They show that the earthquake prediction problem is necessarily intertwined with problems of disaster preparedness, the dynamics of the solid Earth, and the modeling of extreme events in hierarchical complex systems. The algorithms considered by Keilis-Borok et al. are based on premonitory seismicity patterns and provide alarms lasting months to years. Since the 1990s, these alarms have been posted for use in testing such algorithms against newly occurred large earthquakes. Some success has been achieved, and although the areas for the predicted earthquakes are very large and the predicted time windows are very long, such predictions can be helpful for the officials and the public to undertake appropriate preparedness.

Stochastic models are a practical way of bridging the gap between the detailed modeling of a complex system and the need to fit models to limited data. In ► **Earthquake Occurrence and Mechanisms, Stochastic Models for**, D. Vere-Jones presents a brief account of the role and development of stochastic models of seismicity, from the first empirical studies to current models used in earthquake probability forecasting. The author combines a model of the physical processes generating the observable data (earthquake catalogs) with a model for the errors, or uncertainties, in our ability to predict those observables.

D.A. Yuen et al. propose the use of statistical approaches and data-assimilation techniques to earthquake forecasting in their article on ► **Earthquake Clusters over Multi-dimensional Space, Visualization of**. The nature of the spatial-temporal evolution of earthquakes may be assessed from the observed seismicity and geodetic mea-

surements by recognizing nonlinear patterns hidden in the vast amount of seemingly unrelated data. The authors endeavor to bring across the basic concept of clustering and its role in earthquake forecasting, and conclude that the clustering of seismic activity reflects both the similarity between clusters and their correlation properties.

In ► **Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space**, G. Zoeller et al. present a combined approach to understanding seismicity and the emergence of patterns in the occurrence of earthquakes based on numerical modeling and data analysis. The discussion and interpretation of seismicity in terms of statistical physics leads to the concept of 'critical states', i. e. states in the seismic cycle with an increased probability for abrupt changes involving large earthquakes. They demonstrate that numerical fault models are valuable for understanding the underlying mechanisms of observed seismicity patterns, as well as for practical estimates of future seismic hazard.

D. Sornette and M.J. Werner in ► **Seismicity, Statistical Physics Approaches to** stress that the term 'statistical' in 'statistical physics' has a different meaning than as used in 'statistical seismology'. Statistical seismology has been developed as a marriage between probability theory, statistics, and earthquake occurrences without considerations of earthquake physics. In statistical physics approaches to seismicity, researchers strive to derive statistical models from microscopic laws of friction, damage, rupture, etc. Sornette and Werner summarize some of the concepts and tools that have been developed, including the leading theoretical physical models of the space-time organization of earthquakes. They then present several examples of the new metrics proposed by statistical physicists, underlining their strengths and weaknesses. They conclude that a holistic approach emphasizing the interactions between earthquakes and faults is promising, and that statistical seismology needs to evolve into a genuine physically-based statistical physics of earthquakes.

In ► **Earthquake Networks, Complex**, S. Abe and N. Suzuki discuss the construction of a complex earthquake network obtained by mapping seismic data to a growing stochastic graph. This graph, or network, turns out to exhibit a number of remarkable physical and mathematical behaviors that share common traits with many other complex systems. The scale-free and small-world natures are typical examples in complex earthquake networks.

Electromagnetic phenomena associated with earthquakes, such as earthquake light have been reported throughout almost all human history. Until rather recently, however, most such observations were unreliable and best described as folklore. In ► **Earthquakes, Electro-**

**magnetic Signals of**, S. Uyeda et al. summarize the scientific search for electromagnetic precursors for earthquake prediction. The presumption is that since earthquakes occur when slowly increasing tectonic stress in the Earth's crust reaches a critical level; the same stress may give rise to some electromagnetic phenomena. Research on possible relationships was initiated in several countries around the world in the 1980s. Two main approaches are (1) the monitoring of possible emissions from focal regions in a wide range of frequency from DC to VHF, and (2) the monitoring of possible anomalies in the transmission of man-made electromagnetic waves of various frequencies over focal regions. Despite much circumstantial evidence, earthquake-related electromagnetic signals, in particular those at a pre-seismic stage are not yet widely accepted to be associated with earthquakes.

Observational programs focused on searching for reliable precursory phenomena in seismicity, seismic velocities, tilt and strain, electromagnetic signals, chemical emissions and animal behavior, claim some successes but no systematic precursors have been identified. In ► **Earthquake Forecasting and Verification**, J.R. Holliday et al. stress that reliable earthquake forecasting will require systematic verification. They point out that although earthquakes are complex phenomena, systematic scaling laws such as the Gutenberg–Richter frequency-magnitude relation have been recognized. The Gutenberg–Richter relation is given by:  $\log N(M) = a - bM$ , where  $M$  is the earthquake magnitude,  $N(M)$  is the number of earthquakes with magnitude greater than or equal to  $M$ , and  $a$  and  $b$  are constants. Since  $b \approx 1$ , this means that the number of earthquakes increase tenfold for each decrease of one magnitude unit. This suggests that *large* earthquakes occur in regions where there are large numbers of *small* earthquakes. On this basis, the regions where large earthquakes will occur can be forecast with considerable accuracy, but the Gutenberg–Richter relation provides no information about the precise occurrence times.

### **Earthquake Engineering Considerations and Early Warning Systems**

Since seismic hazards exist in many regions of the world, three major strategies are introduced to reduce their societal impacts: (1) to avoid building in high seismic-risk areas, (2) to build structures that can withstand the effects of earthquakes, and (3) to plan for earthquake emergencies. The first strategy is not very practical because, with rapid population growth, many economically productive activities are increasingly located in high seismic-risk areas. However, by mapping active faults and by studying

past earthquakes, we may estimate the risk potential from earthquakes and plan our land use accordingly. The second strategy depends on the skills of engineers, and also requires seismologists to provide realistic estimates of the ground motions resulting from expected earthquakes. The third strategy includes attempting to predict earthquakes reliably well in advance to minimize damage and casualties, and also requires the cooperation of the entire society. Although we are far from being able to predict earthquakes reliably, earthquake early warning systems can provide critical information to reduce damage and casualties, as well as to aid rescuing and recovery efforts.

Accurate prediction of the level and variability of near-source strong-ground motions in future earthquakes is one of the key challenges facing seismologists and earthquake engineers. The increasing number of near-source recordings collected by dense strong-motion networks exemplifies the inherent complexity of near-field ground shaking, which is governed by a number of interacting physical processes. Characterizing, quantifying, and modeling ground-motion complexity requires a joint investigation of (1) the physics of earthquake rupture, (2) wave-propagation in heterogeneous media, and (3) the effects of local site conditions. In ► **Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures**, P.M. Mai discusses briefly the beginnings of strong-motion seismology and the recognition of ground-motion complexity. Using two well-recorded recent earthquakes, the author introduces the observational aspects of near-field ground shaking and describes the basic mathematical tools used in the computation of ground motion. The key elements for characterizing and modeling ground-motion complexity are also explained, supplemented by a concise overview of the underlying physical processes.

With increasing urbanization worldwide, earthquake hazards pose ever greater threats to lives, property, and livelihoods in populated areas near major active faults on land or near offshore subduction zones. Earthquake early-warning (EEW) systems can be useful tools for reducing the impact of earthquakes, provided that the populated areas are favorably located with respect to earthquake sources and their citizens are properly trained to respond to the warning messages. Under favorable conditions, an EEW system can forewarn an urban population of impending strong shaking with lead times that range from a few seconds to a few tens of seconds. A lead time is the time interval between issuing a warning and the arrival of the  $S$ - and surface waves, which are the most destructive due to their large amplitudes. Even a few seconds of advance warning is useful for pre-programmed emergency measures at various critical facilities, such as the deceler-

ation of rapid-transit vehicles and high-speed trains, the orderly shutoff of gas pipelines, the controlled shutdown of some high-technological manufacturing operations, the safe-guarding of computer facilities, and bringing elevators to a stop at the nearest floor.

Recent advances in early warning methodologies are summarized by W.H.K Lee and Y.M. Wu in the second part of their article, ► [Earthquake Monitoring and Early Warning Systems](#). In ► [Earthquake Early Warning System in Southern Italy](#), A. Zollo et al. analyze and illustrate the main scientific and technological issues related to the implementation and management of the earthquake early warning system under development in the Campania region of southern Italy. The system is designed to issue alerts to distant coastal targets using data from a dense seismic network deployed in the Apennine belt region. The authors note that earthquake early warning systems can also help mitigate the effects of earthquake-induced disasters such as fires, explosions, landslides, and tsunamis. Earthquake early warning systems can be installed at relatively low cost in developing countries, where even moderate-size earthquakes can cause damage comparable to that caused by much larger earthquakes in developed countries.

Nonlinear problems in structural earthquake engineering deal with the dynamic response of meta-stable, man-made buildings subjected to strong earthquake shaking. During earthquakes, structures constructed on soft sediments and soils deform together with the underlying soil. Strong shaking forces the soil-structure systems to evolve through different levels of nonlinear response, with continuously changing properties that depend upon the time history of excitation and on the progression and degree of damage. In ► [Earthquake Engineering, Non-linear Problems in](#), M.D. Trifunac first briefly discuss the literature on complex and chaotic dynamics of simple mechanical oscillators, and then introduces the dynamic characteristics and governing equations of the meta-stable structural dynamics in earthquake engineering. He describes the nature of the solutions of the governing equations in terms of both the vibrational and the wave representations. The author also addresses the dynamic instability, material and geometric nonlinearities, and complexities of the governing equations associated with nonlinear soil-structure interaction.

Structural health monitoring and structural damage detection refers to the processes of determining and tracking the structural integrity and assessing the nature of damage in a structure. An important and challenging problem is being able to detect the principal components of damage in structures (as they occur during or soon af-

ter the earthquake) before physical inspection. In the article, ► [Earthquake Damage: Detection and Early Warning in Man-Made Structures](#), M.I. Todorovska focuses on global methods and intermediate-scale methods, which can point to the parts of the structure that have been damaged. Recently, structural identification and health monitoring of buildings based on detecting changes in wave travel time through the structure has received renewed attention and has proven to be very promising.

### Earthquake Physics

Brittle deformation, which is the primary mode of deformation of the Earth's crust in response to tectonic stress, is manifested by faulting at the long timescale and by earthquakes at the short timescale. It is one of the best-known examples of a system exhibiting self-organized criticality. A full understanding of this system is essential for evaluating earthquake hazards, but our current understanding is sketchy. In ► [Brittle Tectonics: A Non-linear Dynamical System](#), C.H. Scholz shows that an earthquake dynamic system has two characteristic length scales,  $W^*$  and  $W^{**}$ . An earthquake nucleates within the seismogenic zone and initially propagates in all directions along its perimeter, acting as a 3D crack. When its dimension exceeds  $W^*$ , the rupture is restricted to propagating in the horizontal direction, acting as a 2D crack. Thus a symmetry breakage occurs at the dimension  $W^*$ . *Small* earthquakes, with dimensions smaller than  $W^*$ , are not self-similar with *large* earthquakes, those with lengths larger than  $W^*$ . The same occurs for suprafaults at the dimension  $W^{**}$  (a suprafault is the shear relaxation structure that includes a fault and its associated ductile shear zone).

Earthquake prediction is desirable for reducing seismic hazards, but we lack an understanding of how and why earthquakes begin and grow larger or stop. Theoretical and laboratory studies show that a quasi-static rupture growth precedes dynamic rupture. Thus, detecting the quasi-static rupture growth may lead to forecasting the subsequent dynamic rupture. In ► [Earthquake Nucleation Process](#), Y. Iio reviews studies that analyze the early portions of observed waveforms, and summarizes what we presently understand about earthquake nucleation process. An earthquake initiates over a small patch of a fault, and then their rupture fronts expand outward until they stop. Some large earthquakes have a rupture extent greater than 1000 km, while fault lengths of small microearthquakes range over only a few meters. Surprisingly, the concept that earthquakes are self-similar is widely accepted despite fault length ranging over 6 orders of magnitude. One example of such similarity is the proportionality

of average fault slip to fault length, which implies a constant static stress drop, independent of earthquake size.

The self-similarity law raises a fundamental question, namely what is the difference between large and small earthquakes? One end-member model represents earthquakes as ruptures that grow randomly and then terminate at an earlier stage for smaller earthquakes, but continue longer for larger earthquakes. This type of model has been proposed mainly to explain the frequency–magnitude distribution of earthquakes (the Gutenberg–Richter relation), but it implies that it is impossible to forecast the final size of an earthquake at the time the rupture initiates. However, the other end-member model predicts that larger earthquakes have a larger ‘seed’ than smaller earthquakes, and that large and small earthquakes are different even at their beginnings.

Geoscientists have long sought an understanding of how earthquakes interact. Can earthquakes trigger other earthquakes? The answer is clearly yes over short time and distance scales, as in the case of mainshock–aftershock sequences. Over increasing time and distance scales, however, this question is more difficult to answer. In ► [Earthquakes, Dynamic Triggering of](#), S.G. Prejean and D.P. Hill explore the most distant regions over which earthquakes can trigger other earthquakes. This subject has been the focus of extensive research over the past twenty five years, and offers a potentially important key to improving our understanding of earthquake nucleation. In this review, the authors discuss physical models and give a description of documented patterns of remote dynamic triggering.

Models of the earthquake source have been successfully used in predicting many of the general properties of seismic waves radiated from earthquakes. These general properties can be derived from a simple omega-squared spectral shape. In ► [Earthquake Scaling Laws](#), R. Madariaga derives general expressions for energy, moment and stress in terms of measured spectral parameters, and shows that earthquake sources can be reduced to a single family with the three parameters of moment, corner frequency and radiated energy. He suggests that most of the properties of the seismic spectrum and slip distribution can be explained by a simple crack model. Whether an earthquake is modeled as a simple circular crack or as a complex distribution of such cracks, the result is the same.

In ► [Earthquake Source: Asymmetry and Rotation Effects](#), R. Teisseyre presents a consistent theory describing an elastic continuum subjected to complex internal processes, considers all the possible kinds of the point-related motions and deformations, and defines a complex rotation field including spin and twist. Also included in the discus-

sion is a new description of the source processes, including the role of rotation in source dynamics, an explanation of co-action of the slip and rotation motions, and a theory of seismic rotation waves. Rotational seismology is an emerging field, and a progress report is provided in the Appendix in ► [Earthquake Monitoring and Early Warning Systems](#) by W.H.K. Lee and Y.M. Wu.

### Some New Tools to Study Earthquakes

The Global Positioning System (GPS) is a space-based Global Navigation Satellite System. Using signals transmitted by a constellation of GPS satellites, the positions of ground-based receivers can be calculated to high precision, making it possible to track relative movements of points on the Earth’s surface over time. Unlike older geodetic surveying methods (which involved periodically but infrequent measuring angles, distances, or elevations between points), GPS can provide precise 3-D positions over a range of sampling rates and on a global scale. GPS equipment is easy to use and can be set up to collect data continuously. Since its early geophysical applications in the mid-1980s, this versatile tool, which can be used to track displacements over time periods of seconds to decades, has become indispensable for crustal deformation studies, leading to many important insights and some surprising discoveries. In ► [GPS: Applications in Crustal Deformation Monitoring](#), J. Murray-Moraleta focuses on applications of GPS data to the studies of tectonic, seismic, and volcanic processes. The author presents an overview of how GPS works and how it is used to collect data for geophysical studies. The article also describes a variety of ways in which GPS data have been used to measure crustal deformation and investigate the underlying processes.

The concept of a seismic cycle involves processes associated with the accumulation and release of stress on seismogenic faults, and is commonly divided into three intervals: (1) the coseismic interval for events occurring during an earthquake, (2) the postseismic interval immediately following an earthquake, and (3) the interseismic period in between large earthquakes. In ► [Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of](#), R. Lohman explores how we can draw conclusions about fault zone slip at depths far greater than are directly accessible to us, based on how the Earth’s surface deforms during, before, and after earthquakes.

Atmospheric sound can be radiated by the displacement or rupture of the Earth’s surface induced by earthquakes, tsunamis, and volcanoes, and by the flow and excitation of fluids during volcanic eruptions. These complex and potentially cataclysmic phenomena share some

common physics, yet represent different ways of converting energy into atmospheric sound. In ► **Infrasound from Earthquakes, Tsunamis and Volcanoes**, M. Garces and A. LePichon discuss some of the signal features unique to earthquakes, tsunamis, and volcanoes captured by the present generation of infrasound arrays. They also discuss contemporary methods for the analysis, interpretation, and modeling of these diverse signals, and consider some of the associated geophysical problems that remain unsolved.

### Tsunamis

Tsunamis are oceanic gravity waves generated by seafloor deformation due to earthquakes, volcanic eruptions, landslides, or asteroid impacts. Earthquake tsunamis, such as the 2004 Indian Ocean tsunami (caused by the Sumatra–Andaman earthquake of December 26), are the most frequent type of tsunamis. However, large volcanic eruptions, such as the 1883 Krakatau eruption (in the Sunda strait between the islands of Java and Sumatra) also cause ocean-wide tsunamis. Landslides (which are often triggered by earthquakes) cause large tsunamis locally, but their effects are usually limited to the immediate vicinity of the source.

### Modeling: Forward and Inverse Approaches

Forward-modeling of a tsunami starts from given initial conditions, computes its propagation in the ocean, and calculates the tsunami arrival times and/or water run-up heights along the coasts. Once the initial conditions are provided, the propagation and coastal behavior can be numerically computed for an actual bathymetry. These calculations are useful for early tsunami warning and for detailed hazard estimations. However, the initial conditions associated with tsunami generation processes are still poorly known, because large tsunamis are rare and the tsunami generation in the open ocean is not directly observable. Currently, the tsunami source is estimated indirectly, mostly on the basis of seismological analysis, but a more direct estimation of the tsunami source is essential to better understand the tsunami generation process and to more accurately forecast the effects of a tsunami along the coasts.

In ► **Tsunamis, Inverse Problem of**, K. Satake reviews inverse methods used in the quantification of tsunami sources from the observations. The author describes the tsunami generation by earthquakes, with an emphasis on the fault parameters and their effects on tsunami propagation, including shallow water theory and numerical computation. The author then summarizes the tsunami observations, including instrumental sea-level data and run-

up height estimates for modern, historical and prehistoric tsunamis. He also describes methods for modeling and quantifying a tsunami source, and for analyzing tsunami travel times, amplitudes and waveforms. He concludes with an estimation of earthquake fault parameters derived from waveform inversion of tsunami data, and a discussion of heterogeneous fault motion and its application for tsunami warning.

Tsunami inundation is the one of the final stages of tsunami evolution, when the wave encroaches upon and floods dry land. It is during this stage that a tsunami is most destructive and takes the vast majority of its victims. To gauge the near-shore impact of tsunami inundation, engineers and scientists rely primarily on three different methods: (1) field survey of past events, (2) physical experimentation in a laboratory, and (3) numerical modeling. In ► **Tsunami Inundation, Modeling of**, P.J. Lynett focuses on numerical simulations. He reviews tsunami generation and open ocean propagation, and discusses the physics of near-shore tsunami evolution, hydrodynamic modeling of tsunami evolution, moving shoreline algorithms, and effect of topographical features on inundation.

### Tsunami Forecasting and Warning

The original definition of ‘tsunami earthquake’ was given by H. Kanamori (Phys Earth Planet Inter 6:346–359, 1972) as “an earthquake that produces a large-size tsunami relative to the value of its surface wave magnitude ( $M_S$ )”. The true damage potential that a tsunami earthquake represents may not be recognized by conventional near real-time seismic analysis methods that utilize measurements of relatively high-frequency signals, and thus the threat may only become apparent upon the arrival of the tsunami waves on the local shores. Although tsunami earthquakes occur relatively infrequently, the effect on the local population can be devastating, as was most recently illustrated by the July 2006 Java tsunami earthquake, which was quickly followed by tsunami waves two to seven meters high, traveling as far as two kilometers inland and killing at least 668 people.

It is important to note that the definition of ‘tsunami earthquake’ is distinct from that of ‘tsunamigenic earthquake’. A tsunamigenic earthquake is any earthquake that excites a tsunami. Tsunami earthquakes are a specific subset of tsunamigenic earthquakes. In ► **Tsunami Earthquakes**, J. Polet and H. Kanamori describe the characteristics of tsunami earthquakes and the possible factors involved in the anomalously strong excitation of tsunamis by these events. They also discuss a possible model for these infrequent, but potentially very damaging events.

Tsunamis are among nature's most destructive hazards. Typically generated by large, underwater shallow earthquakes, tsunamis can cross an ocean basin in a matter of hours. Although difficult to detect, and not dangerous while propagating in open ocean, tsunamis can unleash awesome destructive power when they reach coastal areas. With advance warning, populations dwelling in coastal areas can be alerted to evacuate to higher ground and away from the coast, thus saving many lives.

Tsunami travels at about the same speed of a commercial airliner, however, seismic waves can travel at speeds more than 40 times greater. Because of this large disparity in speed, scientists rely on seismic methods to detect the possibility of tsunami generation and to warn coastal populations of an approaching tsunami well in advance of its arrival. The seismic P-wave for example, travels from Alaska to Hawaii in about 7 min, whereas a tsunami will take about 5.5 hours to travel the same distance. Although over 200 sea-level stations reporting in near-real time are operating in the Pacific Ocean, it may take an hour or more, depending on the location of the epicenter, before the existence (or not) of an actual tsunami generation is confirmed. In other ocean basins where the density of sea-level instruments reporting data in near real-time is less, the delay in tsunami detection is correspondingly longer. However, global, regional, and local seismic networks, and the infrastructure needed to process the large amounts of seismic data that they record, are well in place around the world. For these reasons, tsunami warning centers provide initial tsunami warnings to coastal populations based entirely on the occurrence of a large shallow offshore earthquake. It is well-known, however, that large shallow offshore earthquakes may or may not be tsunamigenic.

In ► **Tsunami Forecasting and Warning**, O. Kami-gaichi discusses the complexity problem in tsunami forecasting for large local events, and describes the Tsunami Early Warning System in Japan. Tsunami disaster mitigation can be achieved effectively by the appropriate combination of software and hardware countermeasures. Important issues for disaster mitigation includes: (1) improving people's awareness of the tsunami hazards, (2) imparting the necessity of spontaneous evacuation when people notice an imminent threat of tsunami on their own (feeling strong shaking near the coast, seeing abnormal sea level change, etc), (3) giving clear directions on how to respond to the tsunami forecast, and (4) conducting tsunami evacuation drills. The author notes that in tsunami forecasting, a trade-off exists between promptness and accuracy/reliability.

In ► **Earthquake Source Parameters, Rapid Estimates for Tsunami Warning**, B. Hirshorn and S. Weinstein de-

scribe the basic method used by the Pacific Tsunami Warning Center (PTWC) mainly for large teleseismic events. Software running at the PTWC processes in real time seismic signals from over 150 seismic stations worldwide provided by various seismic networks. Automatic seismic event detection algorithms page the duty scientists for any earthquake occurring worldwide over about Magnitude 5.5. Other automatic software locates these events, and provides a first estimate of their magnitude and other source parameters in near real time. Duty scientists then refine the software's automated source parameter estimates and issue a warning if necessary. The authors also describe their ongoing efforts to improve estimates of earthquake source parameters.

### **Wedge Mechanics, Submarine Landslides and Slow Earthquakes**

A study of the mechanics of wedge-shaped geological bodies, such as accretionary prisms in subduction zones and fold-and-thrust belts in collision zones, is interesting because they enable us to use the observed morphology and deformation of these bodies to constrain properties of the thrust faults underlying them. The fundamental process described in wedge mechanics is how gravitational force, in the presence of a sloping surface, is balanced by basal stress and internal stress. The internal state of stress depends on the rheology of the wedge. The most commonly assumed wedge rheology for geological problems is perfect Coulomb plasticity, and the model based on this rheology is referred to as the Coulomb wedge model.

The connection between wedge mechanics and great earthquakes and tsunamis at subduction zones is an emerging new field of study. In their article, ► **Wedge Mechanics: Relation with Subduction Zone Earthquakes and Tsunamis**, Wang et al. cover the topics of stable and critical Coulomb wedges, dynamic Coulomb wedge, stress drop and increase in a subduction earthquake, and tsunamigenic coseismic seafloor deformation. Better constraints are needed to quantify how stresses along different down-dip segments of the subduction fault evolve with time throughout an earthquake cycle and how the evolution impacts wedge and seafloor deformation. Submarine monitoring in conjunction with land-based monitoring at subduction zones that are currently in different phases of earthquake cycles will allow us to better understand the evolution of fault and wedge stresses during the inter-seismic period. In this regard, cabled seafloor monitoring networks including borehole observatories being designed or implemented at different subduction zones will surely yield valuable data in the near future.

The term ‘submarine landslide’ encompasses a multitude of gravitational mass failure features at areal scales from square meters to thousands of square kilometers. The term ‘slow earthquake’ describes a discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking. Recently, a GPS network on the south flank of Kilauea volcano, Hawaii, recorded multiple slow earthquakes on the subaerial portion of a large landslide system that extends primarily into the submarine environment. Since catastrophic failure of submarine landslides can cause a tsunami they represent significant hazards to coastal zones. Because submarine landslide systems are among the most active as well as spatially confined deforming areas on Earth, they are excellent targets for understanding the general fault failure process. In ► **Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy**, B.A. Brooks et al. present a review of this interdisciplinary topic of interest in geodesy, seismology, tsunamis, and volcanology.

## Volcanoes

About 1,500 volcanoes have erupted one or more times during the past 10,000 years, and since A.D. 1600, volcanic disasters have killed about 300,000 people and resulted in property damage and economic loss exceeding hundreds of millions of dollar. Articles in this section are intended to summarize recent research in: (1) volcano seismology, (2) physical processes involved in volcanoes, and (3) modeling volcanic eruptions and hazards warning.

## Volcano Seismology

Magma transport in a volcano is episodic due to the inherent instability of magmatic systems at all time scales. This episodicity is reflected in seismic activity, which originates in dynamic interactions between gas, liquid and solid along magma transport paths that involve complex geometries. The description of the flow processes is governed by the nonlinear equations of fluid dynamics. In volcanic fluids, further complexity arises from the strong nonlinear dependence of magma rheology on temperature, pressure, and water and crystal content, and nonlinear characteristics of associated processes underlying the physico-chemical evolution of liquid-gas mixtures constituting magma.

In ► **Volcanoes, Non-linear Processes in**, B. Chouet presents a brief review of volcano seismology and addresses basic issues in the quantitative interpretation of processes in active volcanic systems. Starting with an introduction of the seismic methodology used to quantify

the source of volcano seismicity, the author then focuses on sources originating in the dynamics of volcanic fluids. A review of some of the representative source mechanisms of Long-Period (LP) and Very Long-Period (VLP) signals is followed by a description of a mesoscale computational approach for simulating two-phase flows of complex magmatic fluids. Refined understanding of magma and hydrothermal transport dynamics therefore requires multidisciplinary research involving detailed field measurements, laboratory experiments, and numerical modeling. Such research is fundamental to monitoring and interpreting the subsurface migration of magma that often leads to eruptions, and thus would enhance our ability to forecast hazardous volcanic activity.

Volcano seismicity produces a wide variety of seismic signals that provide glimpses of the internal dynamics of volcanic systems. Quantitative approaches to analysis and interpret volcano-seismic signals have been developed since the late 1970s. The availability of seismic equipments with wide frequency and dynamic ranges since the early 1990s has revealed a variety of volcano-seismic signals over a wide range of periods. Quantification of the sources of volcano-seismic signals is crucial to achieving a better understanding of the physical states and dynamics of magmatic and hydrothermal systems. In ► **Volcano Seismic Signals, Source Quantification of**, H. Kumagai provides the theoretical basis for a quantification of the sources of volcano-seismic signals. The author focuses on the phenomenological representation of seismic sources, waveform inversion to estimate source mechanisms, spectral analysis based on an autoregressive model, and physical properties of fluid-solid coupled waves.

Among various eruptive styles, Strombolian activity is easier to study because of its repetitive behavior. Since Strombolian activity offers numerous interesting seismic signals, a growing attention has been devoted to the application of waveform inversion for imaging conduit geometry and retrieving eruption dynamics from seismological recordings. Quantitative models fitting seismological observations are a powerful tool for interpreting seismic recordings from active volcanoes. In ► **Slug Flow: Modeling in a Conduit and Associated Elastic Radiation**, L. D’Auria and M. Martini discuss the mechanism of generation of Very-Long Period (VLP) signals accompanying Strombolian explosions. This eruptive style, occurring at many basaltic volcanoes worldwide, is characterized by the ascent and the bursting of large gas slugs. The mechanism of formation, ascent and explosion of bubbles and slugs and their relation with eruptive activity has been studied theoretically and by analogue simulations. The authors report results from numerical simulations, focusing on the

seismic signals generated by pressure variations applied to the conduit walls.

### Physical Processes in Volcanoes

The dynamics of solid-liquid composite systems are relevant to many problems, including how melts or aqueous fluids migrate through the mantle and crust toward the surface, how deformation and fracture in these regions are influenced by the existence of fluids, and also how these fluids can be observed in seismic tomographic images. In ► **Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems** in, Y. Takei introduces a general continuum mechanical theory for macroscopic dynamics of solid-liquid composite systems, and emphasizes on how such interactions with pore geometry can be studied. The author then discusses the determinability of porosity and pore geometry from seismic tomographic images, and presents a practical method to assess porosity and pore geometry from tomographic  $V_p$  and  $V_s$  images.

A volcano consists of solids, liquids, gases, and intermediate materials of any two of these phases. Mechanical and thermodynamical interactions between these phases are essential in the generating a variety of volcanic activities. In particular, the gas phase is mechanically distinct from the other phases and plays an important role in dynamic phenomena in volcanoes. In ► **Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation**, M. Ichihara and T. Nishimura discuss several bubble dynamics phenomena from the viewpoint that a bubbly fluid acts as an impulse generator of observable signals, such as earthquakes, ground deformations, airwaves, and an eruption itself. The authors focus on the notion that the impulse is excited by non-linear coupling between internal processes in a bubbly fluid and an external perturbation. The importance of these processes has recently become noticed as a possible triggering mechanism of eruptions, earthquakes, and inflation of a volcano.

Our capability to mitigate volcano hazards relies in large part on forecasting explosive events, a process which requires a high degree of understanding of the physicochemical factors operating during explosive volcanism. The approaches taken to gain an understanding of explosive volcanism have relied on a combination of field observations, theoretical models and laboratory models of materials and mechanisms. In ► **Volcanic Eruptions, Explosive: Experimental Insights**, S.J. Lane and M.R. James first review aspects of the volcanic materials literature, with the aim of illustrating the nature of molten rock, the complexity of which underpins most explosive volcanic processes. Experimental modeling of these processes can then

build on the materials understanding. Such experiments involve investigation of the behavior of natural volcanic products at laboratory time and length scales, including the response of magma samples to rapid changes in pressure and temperature, the fall behavior of silicate particles in the atmosphere, and the generation and separation of electrostatic charge during explosive eruptions.

In ► **Volcanic Eruptions: Cyclicity During Lava Dome Growth**, O. Melnik et al. consider the process of slow extrusion of very viscous magma that forms lava domes. Dome-building eruptions are commonly associated with hazardous phenomena, including pyroclastic flows generated by dome collapses, explosive eruptions, and volcanic blasts. These eruptions commonly display fairly regular alternations between periods of high and low or no activity with time scales from hours to years. Usually hazardous phenomena are associated with periods of high magma discharge rate. Hence, understanding the causes of pulse activity during extrusive eruptions is an important step towards forecasting volcanic behavior, and especially the transition to explosive activity when magma discharge rate increases by a few orders of magnitude. In recent years the risks have escalated because the population density in the vicinity of many active volcanoes has increased.

### Modeling Volcanic Eruptions and Hazards Warning

While a wide range of complex deterministic models exists to model various volcanic processes, these provide little in the way of information about future activity. Being the (partially) observed realization of a complex system, volcanological data are inherently stochastic in nature, and need to be modeled using statistical models. In ► **Volcanic Eruptions: Stochastic Models of Occurrence Patterns**, M.S. Bebbington considers models of eruption occurrence, omitting techniques for forecasting the nature and effect of the eruption. As the track record of a potentially active volcano provides the best method of assessing its future long-term hazards, the author first briefly reviews the provenance and characteristics of the data available, and then discusses various taxonomies for stochastic models. The examples of Mount Etna and Yucca Mountain are selected for more detailed examination partly because many, somewhat contradictory, results exist. Different models make different assumptions, and vary in how much information they can extract from data. In addition, the data used often varies from study to study, and the sensitivity of models to data is important, but too often ignored.

In ► **Volcanic Hazards and Early Warning**, R.I. Tilling highlights the range in possible outcomes of volcano un-

rest and reviews some recent examples of the actual outcomes documented for several well-monitored volcanoes. The author also discusses the challenge for emergency-management authorities, as well as challenges in achieving refined predictive capability. To respond effectively to a developing volcanic crisis, timely and reliable early warnings are absolutely essential; they can be achieved only by a greatly improved capability for eruption prediction. This in turn depends on the quantity and quality of volcano-monitoring data and the diagnostic interpretation of such information.

### Discussions

The terms ‘Prediction’ and ‘forecasting’ are often used interchangeably. However, the commonly accepted definition of an ‘earthquake prediction’ is a concise statement, in advance of the event, of the time, location, and magnitude of a future earthquake. To be practically useful to the society, the time window must be short (in days or months), the location extent small (within tens of kilometers), and the magnitude precise ( $\pm 0.5$  unit). A ‘forecast’, on the other hand, is more loosely defined as the probability of an occurrence of a large earthquake in a given region (e.g., southern California) during the coming decades or centuries. The broader time intervals associated with forecasts allows society to consider and implement mitigation efforts over a large region.

As an observational seismologist and on a personal note, I am skeptical that earthquakes can be reliably predicted before (1) we have collected accurate data of their occurrences over a sufficiently long period of time, and (2) we have a good understanding of the physical processes that create them. Although earthquakes have been

known from antiquity, accurate earthquake catalogs exist only since about the 1960s. Since the recurrence of a damaging earthquake in a given area is often more than 100 years (some even thousands of years), it is obvious that we lack the necessary observed data. C. Lanczos (*Linear Differential Operators*, Van Nostrand-Reinhold, 1961) said it well in general: “a lack of information cannot be remedied by any mathematical trickery”. Nevertheless, we must apply new concepts and tools to extract as much useful information as possible from the existing data. Indeed, we must thank many pioneers for enlightening us with many interesting and tentative results about earthquakes, tsunamis and volcanoes that they managed to extract from inadequate and insufficient data.

Because most tsunamis are generated by earthquakes, successes in predicting tsunamis depend on predicting earthquakes and recognizing them as tsunamigenic. Predicting a volcanic eruption is a little easier, as the location is known and there are often some observable phenomena preceding it. However, the exact time and the intensity and extent of an eruption are difficult to predict because the volcanic processes are very complex involving gas, liquid and solid phases.

Fortunately, earthquake, tsunami and volcano hazards can be reduced by employing sound engineering practices, early warning systems, and hazard analysis, using many of the tools and concepts that were developed for prediction. Since fatalities and economic loss from a single catastrophic event can reach 100,000 or more, and \$100 billion or more, respectively, it is imperative that governments should support long-term monitoring with modern instruments and research, including complexity studies of earthquakes, tsunamis and volcanoes.

**Cascadia** The region of the Pacific Northwest dominated by the Cascade Range and affected by subduction of the Juan de Fuca plate beneath North America.

**Coseismic** Occurring during an earthquake.

**Elastic** A form of behavior of a solid when subjected to stress. Elastic solids deform in response to stress by an amount proportional to a constant known as the “rigidity”. When any applied stress is removed, an elastic solid recovers its original shape.

**Geodesy** The study of the shape and area of the Earth, including large-scale variations that affect the rotation dynamics of the planet of the whole, down to smaller length scales of earthquakes, landslides, etc.

**Forward model** A description of what a model of some process would predict about behavior of the system, e. g., how a given distribution of subsurface slip on a fault during an earthquake should affect observations of ground deformation at the surface.

**GPS** Global Positioning System. A network of satellites that transmit a signal that can be used by receivers (small transportable and/or permanent affixed to the ground) to infer three-dimensional positions.

**InSAR** Interferometric Synthetic Aperture Radar. The combination of Synthetic Aperture Radar imagery (generally acquired from airborne or satellite-based platforms) to infer changes in ground deformation, digital elevation models, variations in atmospheric water vapor, etc.

**Interseismic deformation** Occurs in the time period between earthquakes, usually associated with gradual in-

crease in elastic stress to be released in future earthquakes.

**Inverse theory** The approach to determining the values for parameters of a given physical model that best describe observations of the system of interest.

**Leveling** The field of geodesy involved in the determination of variations in angle from horizontal between nearby fixed points on the Earth’s surface, usually converted to changes in elevations.

**Locked zone** The portion of the fault zone that does not slip during the interseismic period, therefore accumulating stress and eventually rupturing coseismically.

**Paleoseismology** The study of individual earthquakes that occurred in the past, usually before the advent of instrumental recordings of seismic events.

**Plate tectonics** The theory governing how discrete plates on the Earth’s surface move relative to each other over geologic time.

**Postseismic deformation** Deformation occurring in the hours to years following an earthquake.

**Seismic cycle** The combination of strain build-up and release that occurs on plate margins and along faults within plates, accommodated by processes within the coseismic, postseismic and interseismic time scales.

**Seismogenic** The region of a fault zone that is capable of producing earthquakes. Also refers to effects caused by an earthquake.

**Subduction** The process by which one tectonic plate descends beneath another, usually accompanied by volcanism and seismicity.

**Triangulation** The field of geodesy related to measuring horizontal angles and changes in angles between networks of fixed points.

**Trilateration** The field of geodesy related to measuring distance and changes in distance between networks of fixed points.

**Viscoelastic** A material behavior that is a combination of viscous and elastic behavior, resulting in some permanent deformation when the material is subjected to changes in stress.

**Viscosity** A material property describing its ability to flow in response to an applied stress. A measure of the response of a material to a stress, resulting in permanent deformation. The deformation rate of a viscous material depends on both the viscosity and applied stress.

## Definition of the Subject

The seismic cycle consists of the processes associated with the accumulation and release of stress on seismogenic faults. The cycle is commonly divided into 3 periods: the

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 1

**Cartoon illustrating map view (view from overhead) of ground deformation during the seismic cycle for a strike-slip fault (after [73]). Similar models exist for other fault types**

coseismic interval for events occurring during an earthquake, the postseismic interval after an earthquake, and the interseismic period in between earthquakes (Fig. 1). Some of this deformation during these different periods is related directly to the motion on the fault during the earthquake – the ground is translated in one direction or another, there is crushing of rock, rotation or heaving of blocks of earth, and landslides triggered by the shaking. There is also ground deformation that results because of secondary effects – movement of ground water within the crushed and strained rock, cascades of earthquakes triggered by stress changes during the first event, continued slip on the fault interface, as well as flow of deeper, more ductile layers of the crust and mantle in response to the changes in stress. By examining these different behaviors and studying crustal deformation we can learn more about the underlying cause.

Earthquakes and other motion along fault zones are some of the ways that the Earth's crust accommodates far-field forcings due to plate tectonic motions. One of the prime features of interest as we study the seismic cycle is the magnitude of motion along these fault zones at different temporal and length scales. However, the only place where we can directly observe this motion is within the shallowest (< several meters) parts of the fault zone, through maps of features that are offset across the fault. The field of paleoseismology involves the search for information about previous earthquakes on a fault zone, often through trenches dug across the fault and the use of radiogenic dating to determine how frequently earthquakes have occurred in the past.

In order to infer what is occurring throughout the whole seismogenic zone (often the upper ~15 km within the continental crust), we rely on an arsenal of tools that

include seismology (the study of how seismic waves travel through the earth) and geodesy (the study of changes to the shape of the earth's surface). In this chapter, we will explore how we can draw conclusions about fault zone slip at depths far greater than are directly accessible to us, based on how the earth's surface deforms during, before and after earthquakes.

## Introduction

Ground shaking due to earthquakes can be felt over most of the Earth's surface, both on land and underwater. Earthquakes are also associated with volcanic activity, landslides and tsunami – they are often concentrated near discrete tectonic plate boundaries but also occupy diffuse zones where the Earth's crust is deforming [12,57]. The seismic energy that is released during an earthquake passes through deep portions of the Earth and helps us to learn about material properties we could not illuminate any other way, including details of the structure of the Earth's crust, core and everything in between. However, the destructive cost of large earthquake requires that the primary goal of earthquake research is that of determining when and where damaging earthquakes will occur [99]. To achieve this goal, we first have to understand what happens during each earthquake, i. e., where it was located, how big it was, how it's location relates to the distribution of previous earthquakes, etc.

One of the most common methods that we use to study earthquakes relies on the feature most apparent to humans – the rapid and often destructive movements of the ground that occur during the earthquake. Seismology studies how the ground shakes during earthquakes and how we can use that information to better understand seismogenesis. However, this ground shaking is also always accompanied by some amount of permanent deformation of the ground. After all, the primary driving force behind most earthquakes is the slow motion of tectonic plates relative to each other. In this chapter we will not cover seismology, although combinations of seismic data and observations of geodetic displacements are often very powerful tools. Instead, we cover the geodetic observations of ground deformation during earthquakes and some of the methods that we use to interpret this deformation in terms of what actually happened on and around the fault zone.

## Highlights of Earthquake Geodesy

Geodesy is defined as the branch of mathematics concerned with the shape and area of the Earth. In this chapter we will examine how the use of geodesy to quantify changes in the shape of the Earth can help us learn about

earthquakes. We begin with a brief history of how the use of geodesy to study earthquakes has evolved, along with a description of some of the more interesting individual earthquakes and other seismic cycle behaviors that have been observed geodetically. We then explain the mechanics of how we use these measurements of surface deformation to understand processes deep beneath the Earth's surface.

### Observations of Coseismic Displacements

The history of earthquake geodesy begins even before we really understood what earthquakes were. The key observations began when scientists began to associate earthquakes with observable deformation of the terrain. In Charles Lyell's *Principles of Geology* [46], he noted that earthquakes often accompany abrupt changes in the ground surface. The 1819 Ran of Cutch, India [64] and 1855 Wairarapa, New Zealand earthquakes were some of the first events where the accompanying ground deformation was observed. In 1835, during Charles Darwin's voyage on the *H.M.S. Beagle*, he experienced a large earthquake near Concepcion, Chile. During his reconnaissance of the area, he noted that the coastline had risen several meters in areas, exposing barnacles that had previously been underwater. He also found fossils hundreds of meters above sea level, indicating that numerous earthquakes had raised the cliffs over many millennia.

Several large earthquakes in the second half of the 19th century helped to advance the theory that earthquakes were caused by motion on faults. The 1872 Owens Valley, California, earthquake [19], the 1888 Amuri/Marlborough, New Zealand, earthquake [50], the 1891 Nobi, Japan, earthquake [36] and the 1893 Baluchistan earthquake [21] were each accompanied by visible deformation of the ground surface. These observations, and the fact that much of the deformation was consistent with regional, long-term topographic relief, helped counter arguments that earthquakes were primarily caused by volcanic activity [48].

Around the same time interval, the practice of surveying was coming into more widespread use, notably in India where Britain was involved in mapping the areas under its control. Surveyors installed permanent "monuments" or benchmarks, which they could then return to and re-survey at a later date. The May 17, 1892 Tapanuli, Sumatra, earthquake occurred during a triangulation survey by JJA Muller [58]. They noted changes in their surveyed angles between benchmarks that were consistent with two meters of deformation on a branch of the great Sumatran fault. In the foothills of the Himalaya, triangulation/leveling surveys measured deformation due to the

1897 Assam earthquake [64] and the 1905 Kangra earthquake [53]. In Italy, the 1915 Avezzano earthquake [94] was also spanned by early geodetic surveys.

In North America, the first great earthquake to be surveyed was the 1906 earthquake that destroyed most of the city of San Francisco, CA [40]. HF Reid [72] used three sets of triangulation surveys across San Andreas Fault to show that there had been approximately 3.2 meters of slip across the fault. During the 1920s and 1930s, there was a great deal of leveling work done in Japan which captured deformation associated with the 1927 Tango earthquake, and the 1944 and 1946 earthquakes associated with oceanic plate subduction in southwestern Japan [63,93]. Tide gauges along the coasts have also proved useful in earthquake studies, especially near subduction zones.

There was a boom in the use of the three main ground-based geodetic techniques (triangulation, trilateration and leveling) in the middle of the twentieth century, with observations of the 1940 Imperial Valley and 1962 Tehachapi earthquakes in California and the first observation of shallow interseismic creep on faults in the San Francisco Bay Area and in the Salton Trough/Imperial Valley region in Southern California. Next, the development of space-based geodesy began to allow for more precise and spatially extensive surveys of areas before and after earthquakes. Very Long Baseline Interferometry (VLBI) stations scattered around the world placed strong constraints on the relative motion of individual tectonic plates, as did the widespread use of Global Positioning System (GPS) [22,83].

GPS can be used either in continuous mode at permanent stations, which allows for high precision observations that can catch temporal changes in deformation, or in survey/campaign mode, where researchers take GPS receivers out to fixed benchmark stations in the field (sometimes previously studied using earlier surveying methods). Some of the first large earthquakes to be studied using GPS were the Ms 6.6 Superstition Hills, CA, earthquake in 1987 [39] and the 1989 Mw 7.1 Loma Prieta, CA earthquake [3]. The precise locations and descriptions of ground deformation allowed researchers to begin to examine how individual earthquakes fit in with the long-term topography, including the estimation of possible recurrence intervals [35,41].

**InSAR** The advent of Interferometric Synthetic Aperture Radar (InSAR), and its application to the 1992 Landers, California, earthquake [17,49], ushered in a new era of geodesy with its unparalleled spatial density of deformation observations [23,76]. Synthetic Aperture Radar (SAR) images are acquired from a variety of platforms that send

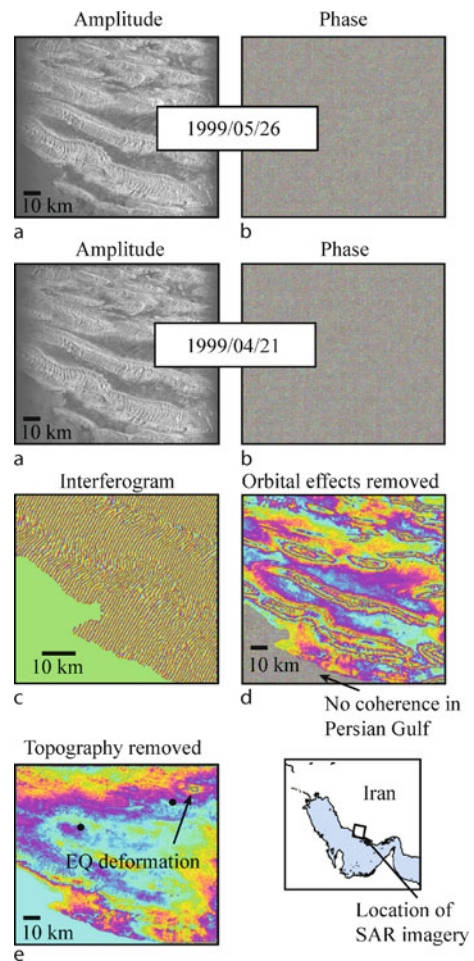

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 2

**Formation of a Synthetic Aperture Radar (SAR) interferogram:** Two satellite radar images of the ground surface, separated by a spatial baseline,  $B$ , are combined to solve for the  $\delta\rho$ , the difference in line length ( $\rho$ ) between the satellite and the ground along the satellite viewing direction ( $\alpha$ ). Knowledge of the satellite orbital path and the relative distance between the two image acquisitions ( $B$ ) is necessary to convert  $\delta\rho$  to elevation. If the two images are obtained simultaneously, or over a small time interval, the interferogram will only reflect topographic relief throughout the imaged area. However, if changes in ground surface elevation (e.g., the volcanic inflation shown in this figure between the *blue* and *red*), or changes in the atmosphere/ionosphere (e.g., water vapor content) occur between the two image acquisitions, this will also be reflected in the final interferogram

out radar signals, including satellites and airplanes (Fig. 2), and contain information about the phase and amplitude of the reflected return from the earth's surface.

A SAR interferogram is the difference in phase between two SAR images, and reflects a variety of factors that change the path length between the satellite and the ground. After correcting for some of these factors, such as topography (Fig. 3), the resulting interferometric phase is a function of any ground deformation that occurred between the two SAR acquisitions, in addition to variations in atmospheric water vapor, the ionosphere, etc. [11,20,100]. The high spatial resolution of InSAR (pixels commonly  $5\text{ m} \times 20\text{ m}$  or smaller) combined with its large areal coverage ( $\sim 100\text{ km}$ ) produces images with so many pixels that they can become unwieldy to deal with computationally, especially when multiple interferograms are studied at once. Most researchers use various down-

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 3

**Overview of steps in forming and interpreting an interferogram.** An interferogram requires the combination of two sets of amplitude *a* and phase *b* observations from two separate image acquisitions (here, on two different dates separated by a month over an area along the Persian Gulf, Iran). While phase in the individual SAR images appear to be random noise, when the two images are combined, the phase changes vary coherently to form the interferogram in *c*. If we remove the effects of the satellite orbital geometry (the "curved earth effect"), we are left with *d*, which reflects both topography, ground surface deformation and any atmospheric changes between the two image acquisitions. The area in the *lower left* still looks like white noise due to the fact that water (here, the Persian Gulf) changes its reflectivity over short time scales and the phase does not remain coherent. If we remove the effects of topography *e* we are left with a map that clearly shows the effects of a small  $M_w 5$  earthquake that occurred during this time interval (*black dots* show the seismically-determined locations for this event). Other features are due primarily to changes in atmospheric water vapor

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 4

Illustration of how the inherent  $2\pi$  ambiguity affects the observed deformation. The “true” ground deformation vs. distance profile (black signal) would appear as the segmented blue curve (“wrapped” signal) when viewed using InSAR, since interferometry only retains information about the relative phase within a  $2\pi$  cycle, not about the absolute phase, or number of cycles between the satellite and the ground. Reconstructing the original deformation field requires a process known as phase unwrapping, and there will also be an ambiguity as to the absolute value of the deformation field as a whole

sampling methods to reduce the number of data points considered without significantly reducing the amount of information retained [43].

The interferometric phase is only sensitive to ground deformation towards or away from the satellite, in a direction known as the satellite line of sight (LOS). Also, since the interferometric phase can only be measured as a fraction of the radar wavelength, an interferogram does not immediately give us an absolute measurement of the magnitude of ground deformation (Fig. 4). We need to add up the interferometric “fringes” to solve for the total deformation field. This “unwrapped” deformation field, along with information about the line-of-sight direction, can be combined in attempts to model the earthquake source parameters, or for models of deformation throughout other parts of the seismic cycle.

InSAR observations have improved the spatial complexity of these observations, allowing over a dozen large earthquakes to be studied in detail by a wide range of observers. Some noteworthy events that had various portions of their coseismic-postseismic activity covered by combinations of InSAR and GPS include the 1992 Landers, CA, earthquake [13,17,49], the 1995 Antofagasta, Chile, earthquake [70,77], the 1997 Hector Mine, CA earthquake [85],

the 1999 Chi-Chi, Taiwan earthquake [8,98], the 2003 Bam, Iran earthquake [18], and the 2005 Nias–Simeulue earthquake [28]. In other cases, InSAR can help to determine the location of small- to moderate-sized earthquakes in areas with little other geophysical or field-based information [44].

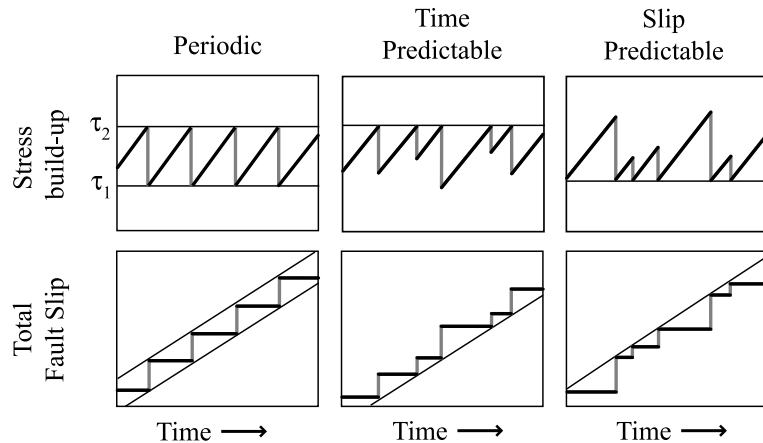

## Observations Throughout the Seismic Cycle

**Early Models** As the body of information about earthquakes grew, scientists were able to begin hypothesizing about the processes controlling their occurrence. Reid’s observations of the 1906 San Francisco earthquake led him to propose his elastic rebound theory [73], where he hypothesized that the crust behaves like an elastic solid driven from the far field at a constant rate, which ruptures in earthquakes at periodic intervals to allow the two blocks to slide past each other (Fig. 1). In the interseismic period, the ground deforms smoothly in a manner that depends on the relative plate velocities, the thickness of the elastic plate, the elastic plate rigidity, etc. The size of the largest potential earthquake on a fault would depend on the length and depth of the elastic zone, and the timing until the next earthquake would depend on how much strain had built up since the last one.

This simple model, where each earthquake releases all of the built-up stress along the fault zone at a regular interval, does not seem to hold in the real world. On most faults, the magnitude of fault slip and rupture area appears to vary significantly between earthquakes (Fig. 5). Additionally, large amounts of accelerated deformation and other types of postseismic behavior are observed to occur immediately after earthquakes, indicating that stress release is not accommodated in a simple manner. Observations such as these can help us improve and expand on the models that we utilize to explain earthquake occurrence.

**Postseismic Behavior** Earthquakes may primarily release built-up strain due to plate motions, but they also produce stress increases in both the near-field within the crust and within the underlying mantle. Observations of postseismic deformation, which is driven by the preceding coseismic stress changes [25,79,92], span a wide range of behaviors that may be explained by equally large range of constitutive properties. For some shallow strike-slip earthquakes, the observed postseismic deformation is as large as the fault slip during the earthquake [38,86].

Observed postseismic behaviors include poroelastic deformation [13,33], where fluid flow following gradients in coseismic stress changes results in ground deformation, frictional afterslip [5,28,55,81,82] and viscoelastic relax-

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 5

Cartoon illustrating theories governing the temporal distribution of large earthquakes [88], each assuming a constant increase in stress vs. time in the interseismic interval (*black lines*), and coseismic behavior (*gray*) that depends on the accumulated stress in various ways. In the periodic model [73], earthquakes occur at constant intervals and always have the same magnitude, releasing the same amount of built-up stress. In the time-predictable model, earthquakes always occur when a maximum stress,  $\tau_2$ , is reached, but the slip in each event varies. The time of the next earthquake depends on how much stress was released in the previous event. In the slip-predictable model, earthquakes occur at varying times, but always release the amount of built-up stress down to the minimum level,  $\tau_1$ . The amount of slip, therefore, depends on the time since the previous earthquake

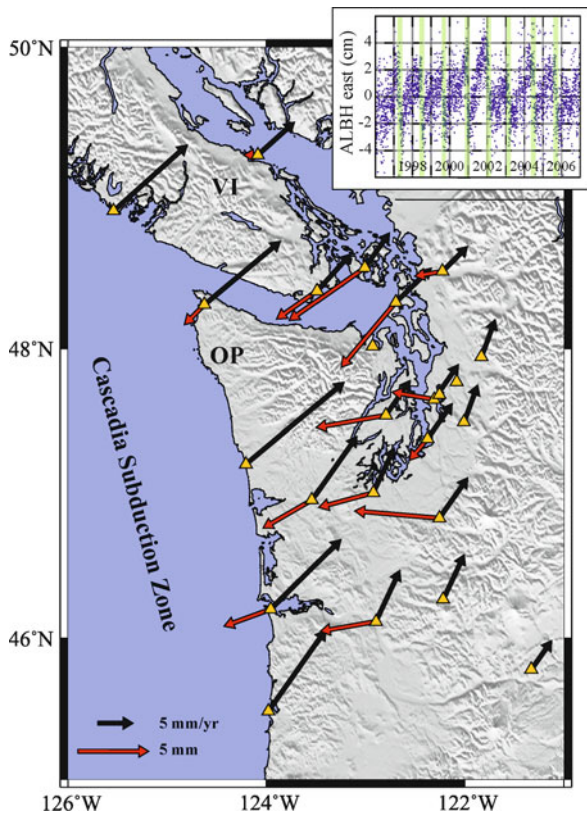

ation of the lower crust [25,26,68,74,79]. Afterslip is sometimes triggered not only on the fault that caused the earthquake, but also on surrounding faults within the stress field [1,12]. Another very noticeable consequence of an earthquake is the series of aftershocks following it, which may be triggered by combinations of stress changes as the lower crust relaxes after an earthquake as well as those due to motion during the earthquake itself [90].

In cases where the coseismic slip distribution (and it's associated stress change) is well-constrained by combinations of geodetic and seismic data, we can explore models of crustal and mantle properties, or place bounds on laboratory-derived rock mechanics laws [7], in order to fit the postseismic response to the coseismic stress change. For instance, the distribution of afterslip places constraints on the frictional behavior of the fault zone [32,55]. However, any such study requires good understand of the processes occurring during the earthquake itself.

**Interseismic Behavior** Although it is usually less dramatic than deformation occurring during and immediately after earthquakes, interseismic deformation can also tell us a great deal about the fault zone. The depth of the “locked” or “coupled” zone that will eventually rupture seismically [24,29], the rate at which stress is accumulating along the fault zone [59,92], and even variations in crustal elastic properties when rocks of different types are brought into contact across the fault zone [14], can all be addressed

by examination of interseismic deformation across a fault. In addition, data types that span a finite amount of time, such as InSAR or campaign GPS observations, will always contain some amount of interseismic strain that may need to be removed before studying measurements spanning an earthquake. The steadiest interseismic deformation is mainly due to flow of the lower crust and mantle beneath the elastic upper crust, but there are also observations of steady creep in the shallowest portions of several strike-slip fault zones [31,37,47,73].

**Transient Behavior** One of the most intriguing fault behaviors observed recently are isolated deformation events that are often not directly associated with an earthquake at all. These “slow” or “silent” earthquakes have been observed around the world in subduction zones, especially within the Cascadia subduction zone ([51,54], Fig. 6), Japan [27,56,65], Mexico [45], and Chile [64]. Along-strike variations in the amount of plate convergence that is taken up by these aseismic slip processes vs. large coseismic events may persist over very long timescales, as is indicated by the correlation of potentially aseismic “seismic gaps” in subduction zones and gravity anomalies [89,95]. Although most transient fault zone activity has been noticed along subduction zones, there are also observations of transient aseismic creep along the San Andreas Fault [60] and within the Imperial Valley, CA [42]. Further observations will help us understand how great of a contribution

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 6  
 Episodic slow slip events in Cascadia. OP=Olympic Peninsula, VI=Vancouver Island. *Black arrows* indicate interseismic convergence, *red arrows* indicate motion during one of the slow slip events recorded by continuous GPS (*yellow triangles*). *Inset* shows detrended component of deformation recorded by stations ALBH on Vancouver Island, with more than a decade of regular slow slip events (*vertical green bars*). Figure after [54]

combinations of steady interseismic and transient aseismic behaviors make to the release of plate motion across many of the major tectonic boundaries around the world.

## Modeling of Geodetic Observations

### Overview of Inverse Theory

All of the observations discussed above involve measurements of surface deformation. We can learn nothing about processes occurring below the surface, within fault zones, without the ability to infer how those observations were generated. Inverse theory spans the range of problems relating to identifying which model of real-world behavior is consistent with observed data. Some of the simplest inverse problems include that of fitting a line to a series of

data points, or even calculating the mean value of a set of observations. Good treatments of the field of inverse theory and its applications to geophysical problems in general can be found in books by Parker [66] and Menke [52], as well as in key papers by Backus and Gilbert [4] and Tarantola and Valette [91].

Before a geophysical inversion can be performed (i. e., determining the size of an earthquake based on ground deformation) the “forward model” must be defined and understood. A forward model is a description of how we believe the system of interest, here, the Earth’s crust, will behave in response to the process we are studying (i. e., fault slip). For inversions for fault slip, the forward model is our best guess at how the deformation field produced by motion on the fault surface will propagate through the solid earth to the ground surface where we can observe it. Laboratory, seismological and field observations support the idea that the crust behaves as an elastic solid on the short timescales associated with earthquakes and their immediate aftermath, although parts of the crust deform viscously at longer time scales under prolonged stress. The response of the elastic crust surrounding a plane that undergoes fault slip can be described mathematically [62]. Figure 7 shows the predicted ground deformation for strike-slip motion on fault “patches” at varying depths. The ground deformation response is linear, i. e., the deformation from multiple sources is just the sum of deformation from the individual fault patches. Therefore, we can predict the expected ground deformation from arbitrarily complicated fault zone geometries and slip distributions.

In an inverse problem, we consider the behavior of a forward model or family of forward models from a number of possible sources that could potentially explain our data, and we find the combination these sources that best fits the data. In this section, the family of forward models is represented by slip on a fault plane that has been divided up into a number of fault patches, and the best-fit model would be the distribution of fault slip magnitude along this fault plane that best matches the observed ground deformation.

**Linear vs. Nonlinear** Inverse problems can be divided up into two major families: Linear and Nonlinear. In a linear problem, we solve for the sum of forward models that best fits the data, without any size constraints on the individual contributions from each forward model (fault patch). One example of a linear problem is where we find the best-fit fault slip distribution on a fixed fault plane, without any constraints such as requiring that the fault slip has a positive or negative sign (i. e., right-lateral vs. left lateral). Linear problems are essentially extensions of the

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 7

**Predicted ground surface deformation for a vertical, left-lateral strike-slip fault a, using Okada [62]. Fault slip on a shallow fault patch (red, panel b) produces a larger amount of deformation over a smaller area than does fault slip on a deeper region of the fault plane c. Here, deformation of the grid indicates vertical deformation and color indicates the amount of northward (red) or southward (blue) deformation. The amount of total deformation from a complicated fault slip distribution is achieved by summing the components from all parts of the fault d**

problem of fitting a line to a set of data, and are quite easy to solve [52].

Nonlinear problems exist when the functional shape and form of the predicted data varies with the parameter choice. An inversion for the location of the fault plane itself, where quantities such as the  $x, y, z$ , location or fault plane strike and dip are varied, is very nonlinear. The

process of solving a nonlinear problem involves finding a model that best fits the data in some pre-defined way, usually by finding the model that produces the lowest sum of squared residuals with the data (least-squares fit). Nonlinear problems may have multi-dimensional misfit functions with poorly defined or multiple minima, and the only way to find the absolute or “global” minimum is by exhaustively searching the parameter space.

Methods for searching the parameter space in a nonlinear problem fall into two main camps. Gradient-based methods determine the slope and gradient of the misfit surface (often in many dimensions) and follow it downhill in an iterative way. These methods work well if the misfit surface has a single, well defined minimum. If the search begins near one of the local minima, it is possible that the true, global minimum will never be found. Global methods involve variations that range from simply sampling the parameter space very densely, to iterative methods that track many initial samples or families of samples in gradient-based searches. One method that performs very well in the  $\sim 9$ -dimensional parameter space of finding the best-fit fault plane and slip that fits data for a small earthquake is the Neighborhood Algorithm [44,78]. In the Neighborhood Algorithm (NA), the misfit values at many initial points are used to iteratively focus in on regions of the parameter space with lower misfit values. The NA method has the strength of being able to track and define multiple minima instead of just choosing one. A survey of several other nonlinear optimization methods applied to earthquake location problems can be found in Cervelli [6].

**Smoothing** The specific problem of inverting for fault slip on a particular fault plane has an interesting twist to it that is shared by many geophysical inverse problems. Just as an inversion for the best-fit line to data usually requires at least two data points, other inversions also effectively require the existence of more data than unknown quantities. For fault-slip problems the question does not boil down to simple numbers of data points vs. the number of fault patches – parts of the fault plane are better-resolved than others, and some data points contribute more information than is provided by their neighbors. For instance, if we had a thousand GPS receivers within 100 feet of the fault zone, but extended our target fault plane down to 100 km, the GPS data would be able to tell us little about what was going on at depth, even if we only divided the fault plane up into a few fault patches. Conversely, data points very close together and far from the fault contribute essentially the same information about what occurred – combining them can help to reduce noise, but it does not help us to isolate variations in fault slip along the fault.

Because of these inherent variations in resolution, both in model and data, an inversion can run into problems if we simply solve for the best-fit fault slip distribution on a finely-divided fault plane. Since the forward models for two fault patches at great depth are very similar on the surface, the inversion cannot determine the relative strength of fault slip that should be assigned to each. The difference between  $[0 \ 1]$  and  $[-1000 \ 1001]$  is very small when you propagate it up to the surface, often smaller than the noise in the data (or even machine precision!). Therefore, the “best-fit” model would have unrealistically large variations that have nothing to do with what really occurred during the earthquake (Fig. 8). This effect is often known as “checkerboarding”. While some of the features in the inferred slip distribution are related to the earthquake, much of the complexity is due to the attempt of the inversion to fit noise within the data.

There are several methods for dealing with this effect, all of which place some bounds on how large or spatially rough the variations in fault slip can be. The simplest method (although one of the hardest to optimize) is to parametrize the fault plane in a way that the fault patches are never so small that there are large tradeoffs in their predicted surface deformation [70]. The extreme of this would be to only use one fault patch. In most cases where we have a lot of data, this solution would not fit the data well nor tell us much about the earthquake.

Another method is to place a penalty during the least squares inversion on fault slip solutions that are very large (usually involving large variations) or that are spatially rough. These “regularized” inversions result in spatially smooth slip distributions that usually fit the data almost as well as the rough, unregularized inversions. Regularization always involves some choice of how much weight needs to be placed on the roughness penalty vs. the fit to the data, which can be a difficult procedure. Too large of a penalty weight and the slip distribution will be too smooth and will not fit the data (the logical extension of this is the single fault patch model discussed above). Too small of a weighting and the slip distribution will be arbitrarily rough, with unrealistic changes in sign throughout the fault zone.

There are two main families of methods for choosing the appropriate smoothing weight (apart from random guessing, which often performs surprisingly well!). In general, as the amount of regularization is increased, the fault slip distribution becomes smoother and the fit to the data worsens. Ideally, we would choose the value where the proportion of the slip distribution that is just fitting data noise is as small as possible, without smoothing so much that we fit neither the noise nor the underlying signal due to the earthquake. The first method re-

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 8

**Example of how noisy data can affect fault slip inversion. *Top*: Deformation from a vertical strike slip fault, with added noise. *Middle*: Best fit slip distribution inferred from noisy data. The large fluctuations mostly cancel each other out at the surface, producing (*bottom*) predicted data that matches both the underlying deformation signal and the noise**

quires choosing the smoothing weight from a plot of data fit vs. model roughness, often referred to as an “L-curve” because of the characteristic shape of such curves (Fig. 9). The smoothing value at the corner of the “L” generally fits the data well without being “too rough”. This type of parameter choice is slightly arbitrary and not easy to auto-

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 9

**Typical L-curve.** Each point on the curve corresponds to a slip distribution inferred using a different value of  $\lambda$ . In most cases, the "penalty error" will be a measure of model roughness

mate, but it does allow the researcher to include some intuition about characteristics of the earthquake.

The other family relies on the concept that a good choice of smoothing would be able to reproduce another, independent set of data spanning the earthquake fairly well. Too much smoothing and the slip model would fit neither the original nor the additional data sets well. If the choice of smoothing were too small, the resulting complex slip distribution would mainly be fitting noise in the original data set and would not, therefore, fit the independent noise in the second data set.

Of course, we rarely have the luxury of multiple data sets – if they do exist, we should use them for the main inversion! Data resampling procedures, known variously as the bootstrap, jackknife or cross-validation [10] are used to simulate the existence of multiple, independent data sets in cases where only one exists. Du et al. [9] compared cross-validation and other techniques for choosing smoothing parameters for geodetic data spanning the 1983 Borah Peak earthquake. Another powerful parameter choice method is the Akaike Bayesian Information Criterion (ABIC) that can be used to choose smoothing weights or other inversion characteristics [1,30,97].

**Noise** Although finding the best-fit model to our data is certainly important, knowing how confident we are in that estimate is just as crucial. Studies of postseismic behavior, for instance, rely on good estimates of the coseismic

slip distribution [25], and are improved further when we know what constraints we can place on that slip distribution. A variety of techniques exist for estimating these confidence limits – for linear problems, and when we know the character of the noise (magnitude, spatial correlation), it is quite simple to propagate data errors through to error bounds on the inversion results [52]. However, for nonlinear problems, and for cases where we are not quite sure how much of our signal is noise (usually the case with InSAR data), we need to rely on other methods for estimating the noise.

The same data resampling procedures described above can be used to generate multiple sets of inversion results that should reflect the noise structure of the data, even when it is not understood ahead of time. For nonlinear problems, such as the 3-D location of the best fit fault plane and earthquake mechanism for a particular earthquake, knowledge about the data noise can be used to construct multiple synthetic data sets that can then each be inverted using the nonlinear method of choice. Any conclusions about the problem (i. e., error bounds on fault slip) should be drawn from the ensemble as a whole [44].

### Case Examples

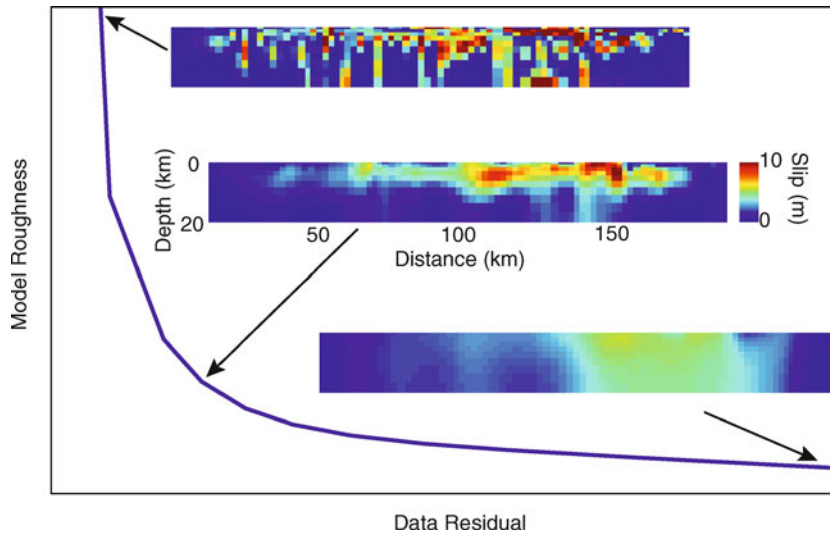

Here we examine case examples for two earthquakes. In each case, we review the data and discuss characteristics of the inferred slip distributions.

**Mw 7.6 Manyi, Tibet, Earthquake** The 1997 strike-slip earthquake that occurred Tibet produced a very long rupture (170 km) with up to 7 meters of offset. It was such a long rupture that it takes three overlapping SAR tracks

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 10

**Three overlapping interferograms spanning the 1997 Manyi earthquake**

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 11

L-curve for the Manyi EQ, showing slip distributions inferred using 3 different values of smoothing, each with the same color scale. Small  $\lambda$  (top panel) produces an unrealistically rough slip distribution, whereas very large  $\lambda$  (bottom panel) produces a smooth model that doesn't fit the data

(Fig. 10) to cover its full length! Here, we show the effects of variations in the spatial smoothing weights ( $\lambda$ ) on an inversion of the deformation field for fault slip. Figure 11 illustrates the differences in inferred slip distributions for various magnitudes of  $\lambda$ , resulting in a spectrum between very smooth slip distributions that do not fit the data very well, to impossibly rough slip distributions that only fit the data marginally better than the “optimal” model (center panel). Our optimal model predicts up to 10 meters of fault slip with most slip occurring in the upper 10 km. Here, we chose the optimal value of  $\lambda$  using cross-validation, but the other methods discussed above can also be applied to this problem.

Asymmetries in the profiles of deformation across the fault during the Manyi earthquake have led some researchers to think that the elastic behavior of the crust may be different on one side of the fault vs. the other [67]. The magnitude of horizontal ground motion for a straight, vertical, strike-slip fault should be symmetric across the fault, if there are no other complications. However, variations in fault plane dip can affect the resulting ground deformation as much as variations in crustal properties, requiring that such studies carefully consider the fault geometry used in their inversions.

**Mw 7.1 Hector Mine, CA, Earthquake** The 1999 Hector Mine earthquake [16,85] occurred in the Mojave Desert of Southern California, and was widely studied due to its

proximity to large population centers and the San Andreas fault, it's very complete data coverage (GPS, InSAR, seismic data), and the fact that it occurred only a few years after another very large earthquake on a neighboring fault (1992 Landers earthquake). The combination of the two earthquakes within such a short time interval suggests that series of earthquakes may occur separated by long intervals of quiescence instead of events always occurring at semi-regular time intervals of strain buildup and release [61,69].

In Fig. 12, we show a subset of the available InSAR data spanning the Hector Mine earthquake. Both continuous and campaign GPS data were also recorded on either side of the Y-shaped rupture. In Fig. 13, we show the results of inverting the GPS and all the InSAR data for the best-fit fault slip distribution, with up to 6 meters of fault slip. Note how the maximum fault slip is not at the surface, but peaks at a few km depth. If we plot the average slip vs. depth (Fig. 14), the profile clearly shows how the shallow slip deficit is robust even given the amount of noise in the data.

### Future Directions

The spatial and temporal coverage of geodetic data sets such as InSAR and GPS is increasing to the point where we can observe new types of fault zone behavior and solve for characteristics on a scale and precision that could hardly have been imagined a few decades ago. As we increase

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 12

Three representations of the Hector Mine EQ. **a** "Ascending" and **b** "descending" wrapped interferograms, where the satellite is moving in the direction indicated by the *yellow arrow* and viewing in the direction of the *black arrow*. Note how the same deformation field looks very different depending on the viewing direction. Color cycles correspond to  $\sim 3$  cm of deformation. **c** Unwrapped version of interferogram in **b**. Now the color scale corresponds to 3 meters and spans the entire dynamic range of the data

our ability to understand and describe the kinematics of crustal deformation, we can begin to explore the dynamic processes driving seismic and volcanic deformation in tec-

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 13

Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of, Figure 14

Fault slip during the Hector Mine earthquake, averaged along strike and plotted vs. depth. *Red dashed lines* indicate the expected error bounds introduced by atmospheric noise

tonically active regions around the world. Three of the main fields that show the most promise in the near future are discussed below:

### Transient Deformation and Slow, Silent Earthquakes

The episodic slow slip events that show up with amazing regularity ( $\sim 14$  months) in Cascadia ([51,54], Fig. 6), and that are also observed in Japan [27,56,65] and Mexico [45], are some of the most exciting new types of fault

zone behavior that scientists have observed in recent years. The idea that earthquakes contained energy that was released by slower ruptures was noticed using seismic data far earlier than it was ever observed geodetically (1960 Chilean earthquake [34]). The slow slip events are often associated with heightened levels of spatially-correlated, low-level seismicity, or seismic tremor [87]. Currently, the process that allows these slow earthquakes to initiate and propagate at the observed speeds is still unknown, although they may be occurring at depths where dehydration of subducted sediments becomes important.

Apart from their intrinsic interest (since we always seek to explain processes that we do not understand), these slow/silent events release a not insignificant amount of the accumulated strain across the fault boundaries. In some ways this is a boon to people living nearby – any plate tectonic motion that is accommodated aseismically means that there is that much less accumulated strain that could be released in a destructive earthquake. However, there are indications that aseismic slip events are often closely followed by earthquakes [42,75], indicating that the changes in stress during the slow event can push other, nearby, regions past the brink until they rupture coseismically. This, also, can be seen in a positive light – perhaps close monitoring of aseismic deformation along active plate boundaries can serve as an early warning system, or at least a signal to raise the forecasted earthquake hazard whenever heightened activity is observed.

### Reduction or Modeling of Atmospheric Noise

One of the largest hurdles for researchers approaching InSAR data is the atmospheric noise present in all interferograms. GPS data is affected by this problem as well, but the atmospheric signal can be solved for or averaged out due to the long observation times allowed by GPS. An area of active research is the modeling and removing of the atmospheric noise signal from InSAR data, using a variety of tools that range from other satellite-based observations of atmospheric water vapor content to simplistic models of correlations between elevation and interferometric phase [96].

The first-order layering of the atmosphere results in profiles of water vapor that tend to decrease vs. elevation in a manner that often appears essentially linear when two SAR images are combined in an interferogram. However, lateral variations with distance from water bodies and gradients from one side of a mountain belt to the other, result in the fact that the appropriate elevation vs. signal can vary quite a bit across a typical SAR image. For some target problems, such as the location of a small earthquake or

the fault slip distribution for an earthquake in a relatively flat area, these elevation-dependent signals will likely affect the inversion to only a limited extent. However, in studies where the signal of interest is correlated with elevation, such as fold growth or subsidence caused by lake loading, great care should be taken when removing overly simple models of atmospheric water vapor from the data.

A more promising, albeit still problematic, approach is the modeling of water vapor content based on observations from satellite-based platforms. Water vapor measurements are made by a variety of satellites, but two in particular have the spatial scale and temporal resolution that make them potentially very useful in InSAR applications. The Moderate Resolution Imaging Spectroradiometer (MODIS) instruments on both the Terra and Aqua satellites acquire almost daily observations over most of the Earth's surface at fairly high resolution (1 km spacing). They are not acquired at exactly the same time as the SAR images, but they can still be used to track seasonal trends or to seek individual features that may persist between the SAR and MODIS image acquisition times. While these cannot be used to quantitatively remove the atmospheric signal, they can be very useful from a qualitative standpoint in determining whether a particular interferometric signal may or may not be tectonic in origin.

The Medium Resolution Imaging Spectrometer (MERIS) is physically located on the same satellite (ENVISAT) that acquires much of the SAR imagery used today. Since MERIS observations are made at essentially the same time as the SAR imagery, they see the same atmosphere and can not only be used in the same qualitative way as MODIS, but also show promise of allowing the actual removal of atmospheric contributions to the interferometric phase. Some difficulties lie in the fact that MERIS and MODIS measurements of atmospheric water vapor can only be made in cloud-free images, and that “double-bounce” effects of the signal bouncing off the base of both visible and invisible clouds can bias the observations and introduce spurious water vapor features. Still, these satellite-based methods show great promise. The most robust method for reducing the contribution from atmospheric noise to our inversions remains the use of multiple independent data sets, whenever available.

### Data Assimilation

As mentioned in Sect. “**Highlights of Earthquake Geodesy**”, the vast quantity of data now available to us can prove troublesome – if it takes hours to perform one forward model of a possible earthquake scenario with the available data, then the inverse problem quickly becomes

unmanageable (or at least can begin to extend past the length of a normal graduate thesis). Parallel computing methods and the rapid decrease in cost for computing resources now makes the operation of large, multi-processor machines feasible within individual research departments. These large machines allow us to approach inverse problems with the “big hammer” of stochastic, or Monte Carlo, methods, which rely on the use of many randomly generated simulations of a system [6]. However, the expected continuing increase of both spatial and temporal coverage of deformation observations requires that we need to continue developing new tools that allow us to capitalize on data time series as well as individual snapshots of ground deformation.

Kalman filters and related methods are one very powerful tool now in widespread use, especially within the GPS community [51,84]. The incorporation of InSAR data into such methods is slightly more difficult, in part because of the large number of data points, but also because of the varying character of noise between interferograms and difficulties in dissociating the description of noise vs. modeling of the geophysical signal of interest. Data assimilation methods developed in the atmospheric sciences, which also deal with data sets of varying spatial and temporal scales and resolutions, are a potentially rich source of tools that the geodetic community can explore in the near future.

### Glossary

**Cryosphere** All forms of terrestrial snow and ice.  
**Newtonian viscous body** A body whose stress at each point is linearly proportional to its strain rate at that point.

### Definition of the Subject

The cryosphere comprises all terrestrial forms of snow and ice – snow cover, floating ice, glaciers, ice sheets, frozen ground and permafrost. It is a critical element of the climate system because of its high reflectivity, its insulating effects on the land and ocean, and its storage of water on short and long time scales. Numerical models of components of the cryosphere have been developed over the last 30 years or so, and some elements of these are now incorporated in coupled climate models and earth system models.

### Introduction

Currently there are no comprehensive models of the entire cryosphere. Rather there is a wide range of models of components of the cryosphere – snow cover, floating ice, glaciers, ice sheets, frozen ground and permafrost – and various components are treated with varying degrees of detail in coupled atmosphere-ocean-land models. Cryospheric processes are generally parametrized in such earth system models.

Models developed for each of the main cryospheric components are discussed in turn.

### Snow Cover

Snow cover is observed in situ at hydrometeorological stations, from daily depth measurements, (monthly) snow courses and in special automated networks such as the western United States Snow Telemetry (SNOTEL) network of snow pressure pillows. Its extent is also observed and mapped daily (since June 1999) over the Northern Hemisphere from operational satellites of the National Oceanic and Atmospheric Administration (NOAA) in the USA. Snow covers about 47 million km<sup>2</sup> at maximum in January and there is only a small area in South America in July. Hemispheric snow water equivalent estimates are routinely made from passive microwave data (1979-present) with a 25-km resolution (Armstrong et al. [4]).

There are numerous models of the formation and disappearance of snow cover. Many have a hydrological focus aimed at estimating seasonal runoff. Some use simple temperature degree-day formulations while others incorporate a full energy balance calculation. Dozier and Painter [14] examine the use of multispectral and hyperspectral remote sensing to estimate the snow's spectral albedo, along with other properties such as grain size, contaminants, temperature, liquid water content, and depth or water equivalent.

The U.S. Army Cold Regions Research and Engineering Laboratory Model SN THERM (SNow THERmal Model) is a 1-D energy balance model for snow and soil that is forced by meteorologically determined surface fluxes [41]. It simulates in-snow properties and processes, such as heat conduction, water flow, melt, vapor flow, compaction, grain growth, and solar absorption (see Fig. 1). The output provides snow depth, profiles of snow temperature, water content, density, grain size, and surface fluxes of sensible heat and evaporation. Surface boundary conditions require: incoming solar and longwave radiation; wind speed, air temperature and humidity at some reference height; and precipitation. The model will estimate solar and longwave radiation from cloud cover, if data on these variables are not available. Lower boundary conditions include soil textural properties (currently clay or sand used as defaults), wetness and temperature profile.

A comparative study of three snow models with different complexities was carried out by Jin et al. [39] to assess how a physically detailed snow model can improve snow modeling within general circulation models. The three models were (a) SN THERM; (b) a simplified three-layer model, Snow-Atmosphere-Soil Transfer (SAST), which includes only the ice and liquid-water phases; and (c) the snow submodel of the Biosphere-Atmosphere Transfer Scheme (BATS), which calculates snowmelt from the en-

Cryosphere Models, Figure 1  
The snowpack energy balance as characterized by SNTHERM (US Army Corps of Engineers)

ergy budget and snow temperature by the force–restore method. SNTHERM gave the best match to observations with the SAST simulation being close. BATS captured the major processes in the upper layers of a snow pack where solar radiation is the main energy source and gave satisfactory seasonal results.

CROCUS is a model of the Centre d'Etudes de la Neige, Grenoble [10]. It is a 1-D physical model that determines mass and energy balance for a snow cover and is used for operational avalanche forecasting. The snow cover is represented as a pile of layers parallel to the ground. Energy exchanges are projected orthogonally to the slope. The model describes the evolution of the internal state of the snow cover as a function of meteorological conditions. The variables describing the snow cover are temperature, density, liquid water content, and snow type of each layer. To match the natural layers, the thickness and number of layers are adjusted by the model. The model simulates the heat conduction, melting/refreezing of snow layers, settlement, metamorphism, and percolation. It simulates dry and wet snow metamorphism with experimental laws derived from laboratory data. Snow grains are characterized by their size and type. This allows an accurate albedo of the snow cover to be calculated.

Bartelt and Lehning [7] also present a 1-D physical model of the snow pack (SNOWPACK) with equations for heat transfer, water transport, vapor diffusion and mechanical deformation. New snow, snow drift and ablation are treated. The snow layers are treated in terms of height,

density and microstructure (grain size, shape and bonding). The model is used for avalanche warnings in Switzerland.

### Interception Models

A physically-based snowfall interception model that scales snowfall interception processes from branch to canopy is now available [25]. It takes account of the persistent presence and subsequent unloading of intercepted snow in cold climates. To investigate how snow is intercepted at the forest stand scale, measurements of wind speed, air temperature, above- and below-canopy snowfall, accumulation of snow on the ground and the load of snow intercepted by a suspended, weighed, full-size conifer were collected from spruce and pine stands in the southern boreal forest. Interception efficiency is found to be particularly sensitive to snowfall amount, canopy density and time since snowfall. Further work resulted in process-based algorithms describing the accumulation, unloading and sublimation of intercepted snow in forest canopies (Pomeroy et al. [70]). These algorithms are unique in that they scale up the physics of interception and sublimation from small scales, where they are well understood, to forest stand-scale calculations of intercepted snow sublimation.

### Blowing Snow Models

Physically-based treatments of blowing snow and wind are used to develop a distributed model of blowing snow

transport and sublimation over complex terrain for an Arctic tundra basin by Essery et al. [18]. A reasonable agreement with results from snow surveys is obtained when sublimation processes are included. Sublimation typically removes 15–45% of the seasonal snow cover. The model is able to reproduce the distributions of snow mass, classified by vegetation type and landform, which can be approximated by lognormal distributions. The representation used for the downwind development of blowing snow with changes in wind speed and surface characteristics is shown to have a moderating influence on snow redistribution.

Spatial fields of snow depth have power spectra in one and two dimensions that occur in two frequency intervals separated by a scale break between 7 and 45 m [84]. The break in scaling is controlled by the spatial distribution of vegetation height when wind redistribution is minimal and by the interaction of the wind with surface concavities and vegetation when wind redistribution is dominant.

In mountainous regions, wind plays a prominent role in determining snow accumulation patterns and turbulent heat exchanges, strongly affecting the timing and magnitude of snowmelt runoff. Winstral and Marks [90] use digital terrain analysis to quantify aspects of the upwind topography related to wind shelter and exposure. They develop a distributed time-series of snow accumulation rates and wind speeds used to force a distributed snow model. Terrain parameters were used to distribute rates of snow accumulation and wind speeds at an hourly time step for input to ISNOBAL, an energy and mass balance snow model. ISNOBAL forced with accumulation rates and wind fields generated from the terrain parametrizations accurately models the observed snow distribution (including the formation of drifts and scoured wind-exposed ridges) and snowmelt runoff. By contrast, ISNOBAL forced with spatially constant accumulation rates and wind speeds taken from the sheltered meteorological site at Reynolds Mountain in southwest Idaho, a typical snow-monitoring site, overestimated peak snowmelt inputs and tended to underestimate snowmelt inputs prior to the runoff peak.

### Avalanche Models

Avalanches range in size from sluffs with a volume of  $< 10 \text{ m}^3$  to extreme releases of  $10^7$ – $10^8 \text{ m}^3$ ; corresponding impact pressures range from  $< 10^3$ – $10^6 \text{ Pa}$ . There are two main types – loose snow avalanches and slab avalanches. Commonly, they begin with the failure of snow layers with densities less than  $300 \text{ kg m}^{-3}$ . An avalanche path comprises a starting zone, the track, and a runout–deposition

zone. Loose snow avalanches are initiated when the angle of repose is exceeded – about  $45^\circ$ . The angle increases as temperatures rise due to increased cohesion. Slush avalanches can occur on slopes  $< 10^\circ$ . Downslope propagation continues to the kinetic angle of repose at about  $17^\circ$  [52,69]. Slab avalanches occur when a cohesive slab is released over an extensive plane of weakness on slopes of  $35$ – $40^\circ$ . Slab thicknesses are  $0.1$ – $4 \text{ m}$  and have a mean density of  $\sim 200 \text{ kg m}^{-3}$ . Bed surface temperatures are near  $0^\circ\text{C}$ .

The variables of interest for forecasting are velocity, run-out distance and impact pressure. The acceleration of an avalanche is resisted by surface friction, air drag at the front and upper boundary, and ploughing at the advancing front and underneath surface. According to Perla [69], maximum velocities range from  $20$ – $30 \text{ m s}^{-1}$  for path lengths up to  $500 \text{ m}$  and slope angles of  $25$ – $35^\circ$ . The mean run-out length on 67 Colorado avalanche paths was  $380 \text{ m}$  (Bovis and Mears [9]). On occasion, the run-out may cross a valley floor and continue up the facing slope. Impact pressures are a maximum at  $1$ – $2 \text{ m}$  above the surface and range in value from about  $1$ – $10 \times 10^5 \text{ Pa}$  (Perla [69]).

### Land Surface Schemes in GCMs

Snow cover is treated in Land Surface Models (LSMs), but snow and ice albedo parametrizations differ widely in their complexity [5]. A Snow Model Intercomparison was conducted using 24 snow cover models developed in ten different countries [17]. The models differ as to being multi-layer or not, the inclusion of a soil model, variable heat conductivity, variable snow density, and the treatment of liquid storage. Only four of the models met all five criteria.

27 atmospheric general circulation models (GCMs) were run under the auspices of the Atmospheric Model Intercomparison Project (AMIP). The AMIP models reproduce a seasonal cycle of snow extent similar to the observed cycle. However, GCMs tend to underestimate autumn and winter snow extent (especially over North America) and overestimate spring snow extent (especially over Eurasia). The majority of models displays less than half of the observed interannual variability. No temporal correlation is found between simulated and observed snow extent, even when only months with extremely high or low values are considered [20]. The second generation AMIP-II simulations gave better results [21].

### Floating Ice

Lake ice formation is dependent on the density characteristics of fresh water, which reaches a maximum den-

Cryosphere Models, Figure 2  
The elements of a model of lake ice [47]

sity at 4°C. As a water body cools in the autumn it becomes isothermal at 4°C. Further cooling of the surface allows a less dense layer to form and eventually frazil ice or sheet ice forms depending on the wind conditions. Snow accumulation on lake ice depresses the ice surface below the water level, causing the snow to become saturated and leading to the formation of white snow-ice (in contrast with the black lake water ice). In rivers the flow motion leads to frazil ice, which builds up into pancakes. A 1-D energy balance model of lake ice growth is described by Liston and Hall [47] that treats lake-ice freeze-up, break-up, total ice thickness and ice type (Fig. 2). The model is forced by daily atmospheric data on precipitation, wind speed and air temperature.

Sea ice grows thermodynamically by freezing of sea water at near  $-1.8^\circ\text{C}$  due to the salinity, by the accumulation of snow cover on its surface, and by dynamic processes such as ridging and rafting. It decays thermodynamically, by wave action and by export to areas of warmer ocean. Ice types include new ice, young ice, first year and multi-year ice (World Meteorological Organization [91]). Typical first year ice thickness in the spring in the Arctic is about 1.5–2 m; multi year unridged ice may be 3–4 m thick. Ridging produces keels that may extend to 20–30 m depth. Ice draft (below the sea surface) is measured by upward looking sonars that are moored or deployed on submarines in the Arctic. Ice extent and concentration – the fractional coverage of ice – are determined by aerial reconnaissance, and primarily by satellite remote sensing (optical, passive microwave, synthetic aperture radar, scatterometry and laser altimetry). Weekly or 10-day charts of ice conditions are produced by national operational ice services (see [94]).

Modeling sea ice in either a stand-alone model or a GCM involves the solution of the following equations [19]:

- for momentum, to obtain the ice velocity fields;
- for thermodynamic processes to obtain net ice growth/melt; and
- conservation equations including deformation and transport of ice, plus the thermodynamic sources and sinks.

Ice dynamics is based on five stresses: wind stress, water stress, internal ice stress, Coriolis force, and the stress from the tilt of the sea surface. The Coriolis force and the tilt term are an order of magnitude less than the other three terms. The air and water stresses assume a constant turning angle of  $25^\circ$  in the Arctic and  $-25^\circ$  in the Antarctic [28]. Internal ice stress is highly variable depending on ice conditions. It can be negligible when the ice cover is not compact and there are “free-drift” conditions, but it can be the largest force when there is thick, compact ice cover. The force due to ice resistance to deformation involves the relationship between stress and strain rate, which is termed the rheology (Flato [19]). Early work assumed that stress is linearly dependent on strain rate as in a linear viscous fluid [12]. Pritchard et al. [71] used an elastic-plastic rheology where the stress is linearly dependent on strain up to a yield strength where failure occurs. Hibler [27] developed a viscous-plastic model with an elliptical yield curve; the pre-yield stress states are linearly related to the strain rate. Advances by Hunke and Dukowicz [35] address the response of the ice on the timescales associated with wind forcing through an elastic viscoplastic (EVP) rheology. The model was modified so that it reduces to the viscous-plastic model at these timescales, whereas at shorter timescales the adjustment process takes place by a mathematically efficient elastic wave mechanism. Recently, Lagrangian [33,45] sea ice models using a granular rheology have been developed (Tremblay and Mysak [83]; Overland et al. [65]). They have advantages in that they model individual sea ice “floes”, but are also computationally intensive and are still in their infancy.

Ice dynamics have been extensively treated by Hibler [27]. He couples the dynamics to the ice thickness characteristics by allowing the ice interaction to become stronger as the ice becomes thicker and/or contains a lower area percentage of thin ice. The dynamics in turn causes high/low oceanic heat losses in regions of ice divergence/convergence. The ice is considered to interact in a plastic manner with the plastic strength depending on the ice thickness and concentration. These in turn evolve according to continuity equations that in-

clude changes in ice mass and percent of open water due to advection, ice deformation and thermodynamic effects. Anisotropic dynamic behavior of sea ice has also been investigated [13,30], though such approaches are computationally intensive and currently are not commonly used in models. The standard model treats sea ice as a viscoplastic material that flows plastically under typical stress conditions but behaves as a linear viscous fluid where strain rates are small and the ice becomes nearly rigid. The standard viscous–plastic model has poor dynamic response to forcing on a daily timescale. Models do not generally account for high-frequency (sub-daily) inertial and tidal effects on dynamics, though research has shown that such effects can be important in the evolution of the ice cover [26,43]. The thermodynamics and dynamics are coupled through the ice thickness distribution. Essentially, deformation leads to pressure ridging and the formation of open water areas while thermodynamic processes act to ablate ridges and remove open water by ice formation in winter and create thinner ice/open water in summer. Thus, deformation acts to spread out the thickness distribution by promoting thick and thin ice categories while thermodynamic processes work towards a central ice thickness value [28].

Sea ice models typically feature processes of ice thermodynamics and dynamics although the earliest studies essentially used only thermodynamic ice growth and decay. The steady state Stefan relationship is written after Hibler and Flato [29]:

$$\rho_I L \frac{dH}{dt} \approx \frac{k_i}{H} (T_m - T_B),$$

where  $L$  = latent heat of fusion,  $T_m$  = melting point of the ice,  $T_B$  = upper boundary temperature of the ice,  $H$  = ice thickness,  $k_i$  = ice conductivity and  $\rho_I$  = ice density. Ice growth/melt at the underside is a result of the difference between the upward ocean heat flux and the heat conducted away from the ocean/ice interface into the ice. The first 1-D model of sea ice thermodynamics was developed by Maykut and Untersteiner (1971) [51]. A fuller treatment was made by Parkinson and Washington [66]. The model had four layers – ice, snow, ocean, and atmosphere – and 200 km horizontal resolution.

The incorporation of detailed thermodynamic processes includes the presence of snow on the sea ice, leads and polynyas, melt ponds, the effect of internal brine-pocket melting on surface ablation, the storage of sensible and latent heat inside the snow-ice system, and the transformation of snow into slush ice when the snow-ice interface sinks below the waterline due to the weight of snow. Models with enthalpy conservation improve the thermo-

dynamic component of sea ice models [8]. These are starting to be included in larger-scale climate models.

An intermediate one-dimensional thermodynamic sea ice model developed by Ebert and Curry [15] includes leads and a surface albedo parametrization that interacts strongly with the state of the surface, and explicitly includes meltwater ponds (see Fig. 3). Four important positive feedback loops were identified: (1) the surface albedo feedback, (2) the conduction feedback, (3) the lead-solar flux feedback, and (4) the lead fraction feedback. The destabilizing effects of these positive feedbacks were mitigated by two strong negative feedbacks: (1) the outgoing longwave flux feedback, and (2) the turbulent flux feedback. A review of thermodynamic models is given by Steele and Flato [80].

Conservation equations are needed for ice area (concentration) and ice volume (thickness).

$$\begin{aligned} \partial h / \partial t &= -\nabla \bullet (\mathbf{u}h) + S_h \\ \partial A / \partial t &= -\nabla \bullet (\mathbf{u}A) + S_A, \end{aligned}$$

where  $\mathbf{u}$  is the ice velocity vector and  $S_h$  and  $S_A$  are source terms for mean ice thickness and concentration, respectively. The second equation must also have the constraint that the area  $A \leq 1$ . The ice strength is parametrized only in terms of ice thickness  $h$  and  $A$  [27].

An atmospheric GCM was coupled to a global 1-degree, 20-level ocean GCM with dynamic and thermodynamic sea ice by Washington and Meehl [86] and run with increasing atmospheric  $\text{CO}_2$ . The Coupled Model Intercomparison Project (CMIP) allows a comparison of predicted Arctic sea ice [53]. Of the 12 models, only seven include sea ice motion and only four of these have a prognostic solution to the momentum equation. Apart from errors and approximations in the sea ice representation, the models also suffer from errors in the atmospheric and oceanic forcing fields. While the northern hemisphere ice extent in winter is well simulated overall, the ice thickness does not capture the proper spatial distribution with thicker ice toward North America and Greenland and thinner ice in the Eurasian basin. The simulations for the southern hemisphere show a wider range of extents and thickness. Flato [19] examines the sea ice extent simulated by two GCMs for AD 1900–2100 with the ‘business as usual’ scenario of greenhouse gases and aerosol concentrations. Both show a progressive decrease in ice in both hemispheres although the two models differ significantly in the initial southern hemisphere ice extent.

Martin and Gerdes [50] make a comparison of sea ice drift results from different Arctic Ocean Model Intercomparison Project (AOMIP) sea ice-ocean coupled models

Elbert and Curry: One-dimensional Thermodynamic Sea Ice Model

Cryosphere Models, Figure 3  
 The configuration of a one-dimensional thermodynamic model of sea ice a winter; b summer [15]

and observations for 1979–2001. The models are capable of reproducing realistic drift pattern variability. However, one class of models has a realistic mode at drift speeds around  $3 \text{ cm s}^{-1}$  and a short tail toward higher speeds. Another class shows unrealistically a more even frequency distribution with large probability of drift speeds of 10 to  $20 \text{ cm s}^{-1}$ . Reasons for these differences lie in discrepancies of wind stress forcing as well as sea ice model characteristics and sea ice-ocean coupling. Hunke and Holland [36] underscore the sensitivity of Arctic sea ice and ocean to small changes in forcing parameters. A comparison of three sets of forcing data, all variants of National Centers for Environmental Prediction (NCEP) forcing, give significant differences in ice thickness and ocean circulation using a global, coupled, sea ice-ocean model.

A study of GCMs used for the IPCC Fourth Assessment Report shows that while they produce reasonably similar ice extents in the Arctic, their equilibrium ice thickness values have a wide range due to differences in downwelling infrared radiation [16]. Holland et al. [32] found that in some scenarios of future  $\text{CO}_2$  concentrations the sea ice cover can respond non-linearly with large decreases in extent within only 5–10 years, indicating that the current fitted to observations linear trends may not hold in the future. Stroeve et al. [81] showed that the IPCC models substantially underestimate the observed decline in Arctic sea ice extent compared to observations over the past 50 years. Hence their application in future scenarios is questionable.

Johnson et al. [40] examine the simulated sea ice concentration from nine ice-ocean numerical models in the AOMIP. The models have similar characteristics in winter (100% cover is produced), and most models reproduce an observed minimum in sea ice concentration for September 1990.

An assessment of coupled climate models with respect to the development of Arctic sea ice thickness during the 20th century is examined by Gerdes and Koerberle [22]. Model behavior is compared with results from an ocean–sea ice model using the AOMIP atmospheric forcing for the period 1948–2000. The hindcast exhibits virtually no trend in Arctic ice volume over its integration period 1948–2000. Most of the coupled climate models show a negative trend over the 20th century that accelerates towards the end of that century.

## Glaciers

Glaciers are built up from snow that persists over many years. Initial densification leads to firn (densities of  $400\text{--}830 \text{ kg m}^{-3}$ ) and at some depth, where the air passages be-

tween grains are sealed off ( $\sim 15\text{--}70 \text{ m}$  according to wetness), to glacier ice with a density of  $830\text{--}917 \text{ kg m}^{-3}$  [67]. The glacier has upper accumulation and lower ablation areas, that are annually varying, and the ice slowly flows downhill towards the glacier terminus. Some glaciers occasionally display surges when the ice advances rapidly for a year or two and then stabilizes or retreats.

Glacier models consider either the mass balance and the rate of change of total mass, or the glacier dynamics and interactions between the ice and the bed. The flow velocity is modeled along the centerline of the glacier.

Glacier flow is determined from a relation between the shear strain rate ( $\epsilon_{xy}$ ) and shear stress ( $\tau_{xy}$ ) known as Glen’s flow law [23]:

$$\dot{\epsilon}_{xy} = A \tau_{xy}^n,$$

where  $n \sim 3$ .  $A$  depends on ice temperature, impurities and crystal orientation.

Recommended values of  $A$  decrease from  $6.8 \times 10^{15} \text{ s}^{-1} \text{ kPa}^{-3}$  at  $0^\circ\text{C}$  to  $3.6 \times 10^{-18}$  at  $-50^\circ\text{C}$  (see Table 5.2 in [67]). Stress causes ice to deform by extension/compression, and shear leading to rotation.

Ice flows only by internal deformation when the bed is frozen, but where temperate conditions exist at the base, sliding becomes important. The sliding law relates basal velocity, shear stress, water pressure and the glacier bed characteristics. Weertman’s [88] theory of sliding involved regelation and plastic deformation. Regelation operates over small bumps in the bed ( $< 1 \text{ m}$  dimension). All the ice is at pressure melting point. There is excess pressure on the upstream side of the bump so that the ice there is colder than on the downstream side. This causes heat to flow towards the upstream side through the bump and surrounding ice. The heat transferred melts ice on the upstream side and melt water flows around the bump, refreezing on the downstream side because it is colder than the ice there. Ice also deforms plastically. Near a bump, the longitudinal stress in the ice and, therefore, the strain are above average. The greater the distance over which the stress is enhanced, the greater is the ice velocity. This mechanism works best over larger bumps. Both processes are equally effective at the “controlling obstacle” size, about 1–10 cm.

Paterson [67] shows that the sliding velocity:

$$u = \text{constant} (\tau^{0.5}/R)^4,$$

where  $R$  = roughness and  $\tau$  = basal shear stress.

Water from surface ablation penetrates to the glacier bed and has been shown to lift the ice by as much as 40 cm on the Unteraargletscher, Switzerland (Iken et al. [38]). During rapid uplift events the glacier velocity increased 3–

6 times. When the water pressure at the bed exceeds a certain value (the separation pressure) that depends on the bed roughness, cavities form in the lee of bumps. When the water pressure exceeds a second critical value, sliding becomes unstable.

A numerical ice flow model has recently been used to study the advance of tidewater glaciers into a deep fiord [56]. The results suggest that irrespective of the calving criterion and the accumulation rate in the catchment, the glacier cannot advance into deep water (>300 m) unless sedimentation at the glacier front is included.

Using a first-order theory of glacier dynamics, Oerlemans [61] related changes in glacier length to changes in air temperature. He constructed a temperature history for different parts of the world from 169 records of glacier length. The reconstructed warming in the first half of the 20th century is 0.5°C. The warming signals from glaciers at low and high elevations appear to be very similar.

## Ice Sheets

There are currently two major ice sheets in Greenland and Antarctica, but during the Last Glacial Maximum about 20,000 years ago there were massive ice sheets over northern North America and Fennoscandia. The Antarctic ice sheet covers 12.4 million km<sup>2</sup> and reaches thicknesses in excess of 4500 m; it represents a sea level equivalent of 64.3 m. The Greenland ice sheet has an area of 1.8 million km<sup>2</sup> and a maximum thickness of 3200 m; it has a sea level equivalent of 7.5 m. Both ice sheets have a parabolic profile and gentle slopes (1–2°) away from the margins.

Greenland has a suite of snow facies; from the interior outward these are: the dry-snow zone, percolation zone, wet-snow zone, superimposed ice zone, and the ablation area. The equilibrium line is between the ablation area and the higher zones. At its base, Greenland is close to sea level except for fringing coastal mountains, through which the ice reaches the sea in some 20 major outlet glaciers. Antarctica is mostly dry snow and is little affected by melting except at the margins and in the Antarctic Peninsula. In the Antarctic there are major ice shelves (e. g. the Ross Ice Shelf and the Filchner–Ronne Ice Shelf) that buttress large sections of the ice sheet (see Fig. 4) and extend around 44% of the coastline of the continent.

The major problems in ice sheet dynamics, following Paterson (see p. 238 in [66]), are (i) to calculate the distribution of ice thickness and velocity that will maintain a steady state, given the accumulation and ablation rates and surface temperature. The flow parameters, ice thickness at the ice divide, and geothermal heat flux must be specified. Flow lines, the time that ice takes to travel along them, and the age of the ice at different depths, can be calculated from the velocity distribution. (ii) to determine how the system will react to changes in accumulation, ablation or surface temperature.

The earliest ice sheet models assumed that ice deformed as a Newtonian viscous body. Orowan [64] and Nye [59] assumed that ice behaved as a perfectly plastic material, but Glen [23] established the relationship between strain rate and stress in ice as non-linear (see above).

The surface profile of an ice sheet on a horizontal bed of half width  $L$ , thickness  $h$  and thickness at the centre  $H$

Cryosphere Models, Figure 4  
Schematic of an ice sheet and shelf showing the processes at work (after Wikipedia)

is:

$$h^2 = \frac{2\tau_0}{\rho g}(L - x),$$

where  $\rho$  = density,  $g$  = acceleration due to gravity,  $\tau_0$  = the basal shear stress ( $\sim 0$ –100 kPa), and  $(L - x)$  is the distance from the edge measured along a flow line. The equation describes a parabola. The ice thickness at the centre is  $H = (2\tau_0 L / \rho g)^{0.5}$ .

The mass balance ( $B$ ) can be expressed in a mass conservation equation as:

$$B = \frac{\partial q}{\partial x} + \frac{\partial h}{\partial t},$$

where  $h$  = ice thickness,  $t$  = time, and the flux  $q = h \mathbf{u}$ , where  $\mathbf{u}$  is the velocity averaged over the ice thickness (see p. 246 in Paterson [67]).

If the flow term  $\partial q / \partial x$  is small, then the surface elevation will vary in response to the local accumulation/ablation, which will determine the profile. ‘Balance velocities’ are steady state velocities that are calculated from accumulation rate and ice thickness. Paterson [67] shows that for a 1000 km radius circular ice sheet, of perfectly plastic ice with a yield stress of 199 kPa, an accumulation rate of 150 mm of ice/year, and ablation by ice-berg calving at the margin, the ice in the centre would be 4700 m thick. Balance velocities would increase from 1.5 m  $\text{a}^{-1}$  at 100 km from the centre to 45 m  $\text{a}^{-1}$  at 900 km and the travel time for ice to move from the center to the edge would be 150,000 years.

In Greenland and Antarctica much of the ice transport is accomplished by fast flowing ice streams – regions where the ice flow is much faster than on either side. Most occupy deep channels with beds below sea level and terminate either as a floating glacier tongue (an outlet glacier) or become part of an ice shelf. Morgan et al. [54] indicate that while ice streams and outlet glaciers account for only 13% of the coastline of Antarctica, they drain about 90% of the accumulation of the interior.

A hierarchy of land ice models is presented by van der Veen and Payne [85]. The simple lamellar flow model, involves a balance between driving stress and basal drag. The surface and bed topography must be nearly level for lamellar flow, which is a good approximation to conditions in the interior of an ice sheet. In cases where an ice stream is bounded by a rock wall or stagnant ice on one or both sides, lateral drag needs to be incorporated. The proportion of driving stress that is supported by drag at the bed is termed the shape factor [60]; it is less than one for narrow ice streams. An important issue in Antarctica is the inter-

action between the ice sheet and ice shelves. The peripheral ice shelves are thought to exert a back stress that stabilizes the inland ice sheet where it is grounded below sea level, as in most of West Antarctica [82]. Where the bedrock slopes down towards the ice sheet interior, the grounding line is unstable; If the grounding line initially retreats, the ice at the grounding line becomes thicker due to the bedrock slope, and the creep thinning (thinning associated with along-flow gradients in the ice velocity) increases causing the grounding line to retreat further – a positive feedback. The dynamics of ice sheet grounding lines is examined by Schoof [76]. A boundary layer theory for ice flux through the transition zone shows that the flux increases sharply with ice thickness at the grounding line. He finds that marine ice sheets have well-defined, discrete equilibrium profiles, and steady grounding lines cannot be stable on reverse bed slopes. Also, marine ice sheets with over-deepened beds may undergo hysteresis with variations in sea level, accumulation rate, bed slipperiness and ice viscosity.

Two general types of an ice sheet model have been developed. One is prognostic, based on the original work by Budd et al. [11]; the other category is diagnostic, addressing specific aspects of ice sheet processes. Prognostic models involve four sets of equations (van der Veen and Payne [85]). These are: (i) diagnostic equations for the horizontal velocity components as functions of local ice geometry and ice rheology (Glen’s law); (ii) prognostic equations for the evolution of internal ice temperature, given appropriate boundary conditions at the upper and lower ice surfaces; (iii) a diagnostic equation for ice vertical velocity via the divergence of the horizontal velocity; and (iv) a prognostic equation for ice thickness based on the snow accumulation, snow/ice melt and the divergence/convergence of horizontal ice flow. The effects of bedrock depression under the changing weight of the ice load must also be taken into account. Such models have been used to reconstruct ice sheet history over glacial cycles, as well as to assess the responses to future climate change.

Diagnostic models do not address time evolution of the ice sheet and treat the internal stress regime in much greater detail, particularly the contributions of longitudinal and lateral stresses. Recently, models have been developed that do not assume negligible vertical shear. Huybrechts and de Wolde [38] have combined prognostic model elements with a detailed diagnostic model to study the multi-century behaviour of the Antarctic and Greenland ice sheets. A fully dynamic 3-D thermo-mechanical ice sheet model was coupled to a two-dimensional climate model.

A model validation exercise was undertaken by the European Ice Sheet Modeling Initiative (EISMINT). Payne et al. [68] examined the effects of thermo-mechanical coupling while MacAyeal et al. [49] test ice shelf models for the Ross Ice Shelf. Overall, the models agreed in the main features that were simulated.

### Frozen Ground and Permafrost

The surface layers of soil and rock may be seasonally or perennially frozen. Perennially frozen ground or permafrost is frozen for at least two successive summers. The ground need not contain ice but may be rock below 0°C. Ground ice may be segregated, in veins, or massive in occurrence. The spatial extent of permafrost ranges from continuous (>90% of the surface is underlain), to discontinuous (50–90% of the surface), sporadic (10–50%) and isolated (<10%). Continuous permafrost is associated with mean annual temperatures below about -7°C. Its thickness ranges from a few meters up to 1500 m in Yakutia. Subsea permafrost also occurs offshore in the Eurasian shelf seas and in the Beaufort Sea; it is a relic of previous glacial intervals when the sea bed was exposed by sea level lowering of up to 135 m under low temperature conditions.

Ground temperatures are largely determined by heat conduction, although in areas of seasonal freezing and discontinuous permafrost localized circulation of groundwater may need to be considered. The thermal properties of the ground vary with the mineral composition, organic content, moisture content (as vapor, water and ice), and temperature, as well as the overlying vegetation and snow cover. A frozen soil algorithm has been developed [92] to detect the near-surface soil freeze/thaw cycle over snow-free and snow-covered land in the United States (see Fig. 5).

The conductive heat transfer is given [89] as:

$$G = -K(dT/dz)$$

where  $K$  = the thermal conductivity ( $W m^{-1} K^{-1}$ ).

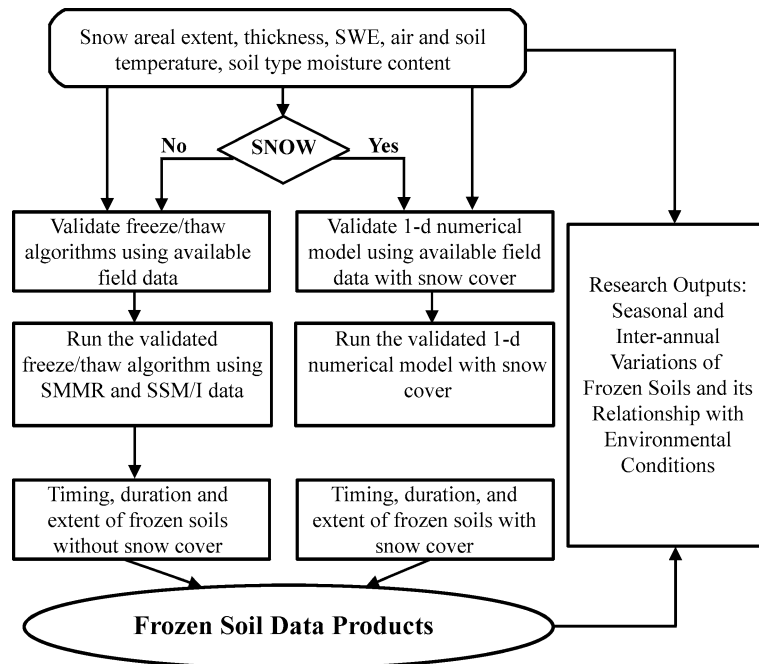

For steady state conditions, the temperature at depth  $T_z$  is written:

$$T_z = T_s + (G/K)z$$

where  $T_s$  = surface temperature.

The heat conduction equation is:

$$\partial T/\partial t = \kappa \partial^2 T/\partial z^2$$

Cryosphere Models, Figure 5

The flowchart of a model processing the effects of snow cover on frozen soil, used to study the timing, duration, number of days, and areal extent of near-surface soil freeze/thaw status [92]

where  $\kappa$  = thermal diffusivity ( $\text{m}^2 \text{s}^{-1}$ ), the coefficient of heat diffusion. To simulate soil freezing and thawing processes, soil water phase change has to be considered (for details, see Lunardini [48]).

Permafrost models can be broadly classified as either equilibrium or process-based transient models according to their underlying methodology. Equilibrium models are based on empirical and semi-empirical relationships between permafrost occurrence and topoclimatic factors (altitude, slope, aspect) and mean air temperature, freezing and thawing indices, and snow cover. They are often used to predict the lateral “boundaries” of permafrost distribution, or to estimate “average” geocryological parameters, thawing indices, snow cover and solar radiation, for example [77]. A ‘frost index’ model was developed by Nelson and Outcalt [55] for the Arctic and has been applied to mountain areas [31]. A wide spectrum of explicit equilibrium permafrost models is available to estimate the thickness of the active layer. The simplest approaches are based on several variations of the analytical Stefan solution to the heat conduction problem with phase change. These methods have been used to estimate regional-scale active layer thickness [56,79]. Kudryavtsev et al. [42] developed a more comprehensive equilibrium permafrost model with analytical solutions that has been adapted and used with Geographical Information System (GIS) technology to estimate active layer thickness at regional [74,78] and circum-arctic [2] scales. The advantages of equilibrium models are their relative simplicity and low data requirements. The major drawback of such models is their inability to resolve seasonal and inter-annual variability [77], which is frequently required for ecological and hydrological studies in the Arctic. These limitations have led to recent spatial adaptations of process-based transient numerical models.

Process-oriented transient models detail one-dimensional heat transfer in soils with phase change driven by either surface temperature [24] or the energy balance components [46]. They account for the major physical processes governing development of the ground thermal regime, simulate soil freezing/thawing processes, and provide insight into the response of soil thermal regime to changes in environmental conditions. These models can provide good results for simulating active layer thickness and permafrost temperatures when driven with known boundary conditions and forcing parameters measured at site-specific locations [73,93]. Recently, such one-dimensional heat transfer models with phase change have been used to simulate regional-scale soil thermal regime [62,63]. However, their adaptation from point-specific to regional-scale is not a straightforward process. It

requires simplification, careful selection of climate forcing data, and treatment of surface and subsurface parameters with largely unknown distributions over the modeled domain.

Most GCMs do not treat permafrost dynamics. However, Nikolsky et al. [58] show that in the Community Land Model (CLM3) GCM improvements can be made to the representation of permafrost dynamics and their climate feedbacks. They do this by increasing the total soil depth by adding new layers, incorporating a surface organic soil layer, and modifying the model’s numerical scheme to include unfrozen water dynamics and more realistic treatment of the model phase changes between ice and water.

The Community Climate System Model (CCSM) has a 5-layer snow model over a 10 layer 3.4 m deep soil model that treats thermal and hydrologic frozen soil processes. A projection made for the 21st century shows severe degradation of the permafrost in the Northern Hemisphere.

Some models address only the active layer that is the top layer of soil that thaws during the summer and freezes again during the autumn. The thaw depth can be analyzed by the Stefan solution for heat transfer in a medium with phase change (Anisimov et al. [3]):

$$z = [(2n\lambda tT)/(\rho wL)]^{0.5}$$

where  $z$  = active layer thickness (m),  $n$  = the ratio of seasonal ground surface and air temperature degree-day sums,  $\lambda$  = thermal conductivity of thawed soil ( $\text{W m}^{-1} \text{K}^{-1}$ ),  $t$  = warm season duration  $>0^\circ\text{C}$  (s),  $T$  = mean warm season temperature ( $^\circ\text{C}$ ),  $\rho$  = soil density ( $\text{kg m}^{-3}$ ),  $w$  = relative water content (decimal proportion) and  $L$  = latent heat of fusion ( $\text{J kg}^{-1}$ ).

A dynamic 3-D terrain model is currently being developed and tested in Svalbard (Humlum [34]). The model takes topographic data, terrain surface characteristics (geomorphology and vegetation) and meteorological variables (air temperature, wind speed and direction, and cloud cover) as input and provides output on phenomena such as terrain surface net radiation balance, snow cover thickness and duration, glacier mass, active layer thickness, stable permafrost thickness and the amount of summer melt water discharge.

A stochastic model was developed by Anisimov et al. [3] and used to calculate the probability density function of active-layer thickness (ALT). Equations for the mean, variance, and higher moments of ALT were derived by applying stochastic averaging to a semi-empirical model of seasonal thawing. The stochastic model was ap-

plied in a case study in the Kuparuk River basin, north-central Alaska.

Shiklomanov et al. [77] compare three models of active layer thickness (ALT) for northern Alaska. One model (NSIDC) is very accurate in the topographically homogeneous Coastal Plain but overestimates (ALT) in the Brooks Range Foothills. The UAF-GIPL 2.0 model reproduced site-specific active layer values well but overestimated ALT on the Coastal Plain. Large differences in ALT fields mainly result from differences in model approaches for characterizing largely unknown spatial distribution of surface (vegetation, snow) and subsurface (soil properties and moisture) conditions.

Data set limitations are a major problem (Anisimov et al. [3]). A permafrost model, forced with available climate data sets, was used to calculate the large-scale characteristics of permafrost in northern Eurasia. Zonal-mean air and ground temperatures, depth of seasonal thawing, and area occupied by near-surface permafrost in Eurasia north of 45° N were analyzed. The 0.5–1.0 °C difference in zonal-mean air temperature between the data sets translates into a 10–20% uncertainty in estimates of near-surface permafrost area, which is comparable to the extent of changes projected for the following several decades.

GCMs have been used to simulate changes in permafrost conditions with global warming. Anisimov and Nelson [1] were the first to study this. Most recently, Saito et al. [74] use a coupled global climate model at high horizontal resolution (0.5° land mesh) with a five-layer, 4.0 m deep soil to evaluate changes in the distribution of frozen ground and subsurface hydrothermal regimes under global warming. Two types of frozen ground were classified according to monthly soil temperatures: “permafrost” for regions with a maximum active layer thickness less than 4 m and “seasonally frozen ground.” Approximately 60% of present-day permafrost would degrade into seasonally frozen ground by 2100 in the circum-Arctic basins.

### Future Directions

In the next 5–10 years we can expect to see more comprehensive treatment of cryospheric processes in climate models. Already, steps are being taken to incorporate ice sheet processes and to enhance the treatment of frozen ground and permafrost. Increased model resolution will place new demands for cryospheric data sets for boundary conditions and as validation data. Mountain glaciers, as well as lake ice, will need to be incorporated especially in regional climate models.

### Glossary

**Players** The agents who take actions. These actions can be – depending on application – the choice of capital stock, greenhouse emissions, level of savings, level of Research & Development expenditures, price level, quality and quantity of effort, etc.

**Strategies** Full contingent plans for the actions that players take. Each strategy incorporates a choice of action not just once but rather a choice of action for every possible decision node for the player concerned.

**Payoffs** The utility or returns to a player from playing a game. These payoffs typically depend on the strategies chosen – and the consequent actions taken – by the player herself as well as those chosen by the other players in the game.

**Game horizon** The length of time over which the game is played, i. e., over which the players take actions. The horizon may be finite – if there are only a finite number of opportunities for decision-making – or infinite – when there are an infinite number of decision-making opportunities.

**Equilibrium** A vector of strategies, one for each player in the game, such that no player can unilaterally improve her payoffs by altering her strategy, if the others' strategies are kept fixed.

**Climate change** The consequence to the earth's atmosphere of economic activities such as the production and consumption of energy that result in a build-up of greenhouse gases such as carbon dioxide.

### Definition of the Subject

The study of dynamic games is an important topic within game theory. Dynamic games involve the study of problems that are a) inherently dynamic in nature (even without a game-theoretic angle) and b) are naturally studied from a strategic perspective. Towards that end the structure generalizes dynamic programming – which is the most popular model within which inherently dynamic but non-strategic problems are studied. It also generalizes the model of repeated games within which strategic interaction is often studied but which structure cannot handle dynamic problems. A large number of economic problems fit these two requirements.

In this paper we examine the dynamic game model. The structure is discussed in detail as well as its principal results. Then the paper introduces a leading important application, the economics of climate change. It is shown that the problem is best studied as a dynamic commons game. Some recent models and associated results are then discussed.

We begin the analysis with a recall of the familiar model of repeated games (whose main results have been presented elsewhere in this volume). That is followed by the generalization of that framework to the model of dynamic – also known as stochastic or Markovian – games. These games may be thought of as “repeated games with a state variable”. The presence of a state variable allows the analysis of situations where there is a fundamental dynamic intrinsic to the problem, a situation – or “state” – that changes over time often on account of the players' past actions. (In contrast to repeated games where an identical stage game is played period after period.) Such a state variable maybe capital stock, level of technology, national or individual wealth or even environmental variables such as the size of natural resources or the stock of greenhouse gases. To provide a concrete illustration of the dynamic game concepts and results, this paper will provide a fairly detailed overview of ongoing research by a number of authors on the very current and important topic of the economics of global climate change.

Section “[The Dynamic – or Stochastic – Game Model](#)” recalls the repeated games structure, introduces the subject of dynamic games and presents the dynamic games model. Section “[The Dynamic – or Stochastic – Game: Results](#)” presents – mostly with proofs – the main results from the theory of dynamic games. Section “[Global Climate Change – Issues, Models](#)” then introduces the problem of climate change, argues why the dynamic game framework is appropriate for studying the problem and presents a family of models that have been recently stud-

ied by Dutta and Radner – and in a variant by Dockner, Long and Sorger. Finally, Sect. “Global Climate Change – Results” presents the main results of these analyzes of the climate change problem. Future directions for research are discussed in Sect. “Future Directions” while references are collected in Sect. “Bibliography”.

## Introduction

In this paper we examine the dynamic game model. The structure is discussed in detail as well as its principal results. Then the paper introduces a leading important application, the economics of climate change. It is shown that the problem is best studied as a dynamic commons game. Some recent models and associated results are then discussed.

## The Dynamic – or Stochastic – Game Model

The most familiar model of dynamic interaction is the Repeated Game model (described elsewhere in this volume). In that set-up players interact every period for many periods – finite or infinite in number. At each period they play exactly the same game, i. e., they pick from exactly the same set of actions and the payoff consequence of any given action vector is identical. Put differently, it is as if there is an intrinsic static set-up, a “state” of the system that never changes. The only thing that changes over time is (potentially) every player’s response to that fixed state, i. e., players (can) treat the game dynamically if they so wish but there is no inherent non-strategic reason to do so. An impartial “referee” choosing on behalf of the players to achieve some optimization aim indeed would pick the same action every period.

Things change in a set-up where the state can change over time. That is the structure to which we now turn. This set-up was introduced by Shapley [26] under the name of Stochastic Games. It has since also been called Markovian Games – on account of the Markovian structure of the intrinsic problem – or Dynamic Games. We will refer to the set-up (for the most part) as Dynamic Games.

## Set-Up

There are  $I$  players, and time is discrete. Each period the players interact by picking an action. Their action interaction take place at a given state which state changes as a consequence of the action interaction. There is a payoff that each player receives in each period based on the action vector that was picked and the state.

The basic variables are:

### Definition

- $t$  Time period  $(0, 1, 2, \dots, T)$ .
- $i$  Players  $(1, \dots, I)$ .
- $s(t)$  State at the beginning of period  $t$ ,  $s(t) \in S$ .
- $a_i(t)$  Action taken by player  $i$  in period,  $a_i(t) \in A_i$
- $a(t)$   $(a_1(t), a_2(t), \dots, a_I(t))$  vector of actions taken in period  $t$ .
- $\pi_i(t)$   $\pi_i(s(t), a(t))$  payoff of player  $i$  in period  $t$ .
- $q(t)$   $q(s(t+1) | s(t), a(t))$  conditional distribution of state at the beginning of period  $t+1$ .
- $\delta$  The discount factor,  $\delta \in [0, 1)$ .

The state variable affects play in two ways as stated above. In any given period, the payoff to a player depends not only on the actions that she and other players take but it also depends on the state in that period. Furthermore, the state casts a shadow on future payoffs in that it evolves in a Markovian fashion with the state in the next period being determined – possibly stochastically – by the state in the current period and the action vector played currently.

The initial value of the state,  $s(0)$ , is exogenous. So is the discount factor  $\delta$  and the game horizon,  $T$ . Note that the horizon can be finite or infinite. All the rest of the variables are endogenous, with each player controlling its own endogenous variable, the actions. Needless to add, both state as well as action variables can be multi-dimensional and when we turn to the climate change application it will be seen to be multi-dimensional in natural ways.

*Example 1*  $S$  infinite – The state space can be countably or uncountably infinite. It will be seen that the infinite case, especially the uncountably infinite one, has embedded within it a number of technical complications and – partly as a consequence – much less is known about this case.

$S$  finite – In this case, imagine that we have a repeated game like situation except that there are a finite number of stage games any one of which gets played at a time.

*Example 2* When the number of players is one, i. e.,  $I = 1$ , then we have a dynamic programming problem. When the number of states is one, i. e.,  $\#(S) = 1$ , then we have a repeated game problem. (Alternatively, repeated games constitute the special case where the conditional distribution brings a state  $s$  always back to itself, regardless of action.) Hence these two very familiar models are embedded within the framework of dynamic games.

## Histories and Strategies

**Preliminaries** – A *history* at time  $t$ ,  $h(t)$ , is a list of prior states and action vectors up to time  $t$  (but not including

$a(t)$ )

$$h(t) = s(0), a(0), s(1), a(1), \dots, s(t).$$

Let the set of histories be denoted  $H(t)$ . A *strategy* for player  $i$  at time  $t$ ,  $\sigma_i(t)$ , is a complete conditional plan that specifies a choice of action for every history. The choice may be probabilistic, i. e., may be an element of  $P(A_i)$ , the set of distributions over  $A_i$ . So a strategy at time  $t$  is

$$\sigma_i(t): H(t) \longrightarrow P(A_i).$$

A strategy for the entire game for player  $i$ ,  $\sigma_i$ , is a list of strategies, one for every period:  $\sigma_i = (\sigma_i(0), \sigma_i(1), \dots, \sigma_i(t), \dots)$ . Let  $\sigma = (\sigma_1, \sigma_2, \dots, \sigma_I)$  denote a vector of strategies, one for each player.

A particular example of a strategy for player  $i$  is a pure strategy  $\sigma_i$  where  $\sigma_i(t)$  is a deterministic choice (from  $A_i$ ). This choice may, of course, be conditional on history, i. e., may be a map from  $H(t)$  to  $A_i$ . Another example of a strategy for player  $i$  is one where the player's choice  $\sigma_i(t)$  may be probabilistic but the conditioning variables are not the entire history but rather only the current state. In other words such a strategy is described by a map from  $S$  to  $P(A_i)$  – and is called a Markovian strategy. Additionally, when the map is independent of time, the strategy is called a stationary Markovian strategy, i. e., a stationary Markovian strategy for player  $i$  is described by a mapping  $f_i: S \longrightarrow P(A_i)$ .

*Example 3* Consider, for starters, a pure strategy vector  $\sigma$ , i. e., a pure strategy choice for every  $i$ . Suppose further that  $q$  the conditional distribution on states is also deterministic. In that case, there is, in a natural way, a unique history that is generated by  $\sigma$ :

$$h(t; \sigma) = s(0), a(0; \sigma), s(1; \sigma), a(1; \sigma), \dots, s(t; \sigma)$$

where  $\mathbf{a}(\tau; \sigma) = \sigma(\tau; h(\tau; \sigma))$  and  $s(\tau + 1; \sigma) = q(s(\tau + 1) | s(\tau; \sigma), \mathbf{a}(\tau; \sigma))$ . This unique history associated with the strategy vector  $\sigma$  is also called the *outcome path* for that strategy. To every such outcome path there is an associated lifetime payoff

$$R_i(\sigma) = \sum_{t=0}^T \delta^t \pi_i(s(t; \sigma), \mathbf{a}(t; \sigma)). \quad (1)$$

If  $\sigma$  is a mixed strategy, or if the conditional distribution  $q$ , is not deterministic, then there will be a joint distribution on the set of histories  $H(t)$  generated by the strategy vector  $\sigma$  and the conditional distribution  $q$  in the obvious way. Moreover, there will be a marginal distribution on the state and action in period  $t$ , and under that

marginal, an expected payoff  $\pi_i(s(\tau; \sigma), \mathbf{a}(\tau; \sigma))$ . Thereafter lifetime payoffs can be written exactly as in Eq. 1.

Consider the game that remains after every history  $h(t)$ . This remainder is called a *subgame*. The restriction of the strategy vector  $\sigma$  to the subgame that starts after history  $h(t)$ , is denoted  $\sigma | h(t)$ .

### Equilibrium

A strategy vector  $\sigma^*$  is said to be a Nash Equilibrium (or NE) of the game if

$$R_i(\sigma^*) \geq R_i(\sigma_i, \sigma_{-i}^*), \quad \text{for all } i, \sigma_i. \quad (2)$$

A strategy vector  $\sigma^*$  is said to be a Subgame Perfect (Nash) Equilibrium of the game – referred to in short as SPE – if not only is Eq. 2 true for  $\sigma^*$  but it is true for every restriction of the strategy vector  $\sigma^*$  to every subgame  $h(t)$ , i. e., is true for  $\sigma^* | h(t)$  as well. In other words,  $\sigma^*$  is a SPE if

$$R_i(\sigma^* | h(t)) \geq R_i(\sigma_i, \sigma_{-i}^* | h(t)), \quad \text{for all } i, \sigma_i, h(t). \quad (3)$$

As is well-known, not all NE satisfy the further requirement of being a SPE. This is because a NE only considers the outcome path associated with that strategy vector  $\sigma^*$  – or, when the outcome path is probabilistic, only considers those outcome paths that have a positive probability of occurrence. That follows from the inequality Eq. 2. However, that does not preclude the possibility that players may have no incentive to follow through with  $\sigma^*$  if some zero probability history associated with that strategy is reached. (Such a history may be reached either by accident or because of deviation/experimentation by some player.) In turn that may have material relevance because how players behave when such a history is reached will have significance for whether or not a player wishes to deviate against  $\sigma^*$ . Eq. 3 ensures that – even after a deviation –  $\sigma^*$  will get played and that deviations are unprofitable.

Recall the definition of a stationary Markovian strategy (SMS) above. Associated with that class of strategies is the following definition of equilibrium. A stationary Markov strategy vector  $f^*$  is a Markov Perfect Equilibrium (MPE) if

$$R_i(f^*) \geq R_i(f_i, f_{-i}^*), \quad \text{for all } i, f_i.$$

Hence, a MPE restricts attention to SMS both on and off the outcome path. Furthermore, it only considers – implicitly – histories that have a positive probability of occurrence under  $f^*$ . Neither “restriction” is a restriction when  $T$  is infinite because when all other players play

a SMS player  $i$  has a stationary dynamic programming problem to solve in finding his most profitable strategy and – as is well-known – he loses no payoff possibilities in restricting himself to SMS as well. And that best strategy is a best strategy on histories that have zero probabilities of occurrence as well as histories that have a positive probability of occurrence. In particular therefore, when  $T$  is infinite, a MPE is also a SPE.

**The Dynamic – or Stochastic – Game: Results**

The main questions that we will now turn to are:

1. Is there always a SPE in a dynamic – or stochastic – game?
2. Is there a characterization for the set of SPE akin to the Bellman optimality equation of dynamic programming? If yes, what properties can be deduced of the SPE payoff set?
3. Is there a Folk Theorem for dynamic games – akin to that in Repeated Games?
4. What are the properties of SPE outcome paths?

The answers to questions 1–3 are very complete for finite dynamic games, i. e., games where the state space  $S$  is finite. The answer is also complete for questions 1 and 2 when  $S$  is countably infinite but when the state space is uncountably infinite, the question is substantively technically difficult and there is reason to believe that there may not always be a SPE. The finite game arguments for question 3 is conceptually applicable when  $S$  is (countably or uncountably) infinite provided some technical difficulties can be overcome. That and extending the first two answers to uncountably infinite  $S$  remain open questions at this point. Not a lot is known about Question 4.

**Existence**

The first result is due to Parthasarathy [23] and applies to the infinite horizon model, i. e., where  $T = \infty$ . When  $T$  is finite, the result and arguments can be modified in a straightforward way as will be indicated in the remarks following the proof.

**Theorem 1** *Suppose that  $S$  is countable,  $A_i$  are finite sets, and the payoff functions  $\pi_i$  are bounded. Suppose furthermore that  $T$  is infinite. Then there is a MPE (and hence a SPE).*

*Proof* The proof will be presented by way of a fixed point argument. The domain for the fixed point will be the set of

stationary Markovian strategies:

$$M_i = \{f_i : S \rightarrow P(A_i), \text{ s.t. for all } s, \sum_{a_i} f_i(a_i; s) = 1, f_i(a_i; s) \geq 0\}.$$

□

**Properties of  $M_i$ :** In the pointwise convergence topology,  $M_i$  is compact. That this is so follows from a standard diagonalization argument by way of which a subsequence can be constructed from any sequence of SMS  $f_i^n$  such that the subsequence, call it  $f_i^{n'}$  has the property that  $f_i^{n'}(s)$  converges to some  $f_i^0(s)$  for every  $s$ . Clearly,  $f_i^0 \in M_i$ . The diagonalization argument requires  $S$  to be countable and  $A_i$  to be finite.

$M_i$  is also clearly convex since its elements are probability distributions on  $A_i$  at every state.

The mapping for which we shall seek a fixed point is the best response mapping:

$$B_i(f) = \{g_i \in M_i : R_i(g_i, f_{-i}) \geq R_i(f_i, f_{-i}), \text{ for all } f_i.$$

Since the best response problem for player  $i$  is a stationary dynamic programming problem, it follows that there is an associated value function for the problem, say  $v_i$ , such that it solves the optimality equation of dynamic programming

$$v_i(s) = \max_{\lambda_i} \left\{ \pi_i(s, \lambda_i, f_{-i}(s)) + \delta \sum_{s'} v_i(s') q(s' | s, \lambda_i, f_{-i}(s)) \right\} \quad (4)$$

where

$$\pi_i(s, \lambda_i, f_{-i}(s)) = \sum_{a_{-i}} \left[ \sum_{a_i} \pi_i(s, a_i, a_{-i}) \lambda_i(a_i) \right] f_i(a_{-i}, s) \quad (5)$$

where  $\lambda_i(a_i)$  is the probability of player  $i$  picking action  $a_i$  whilst  $f_i(a_{-i}, s)$  is the product probability of players other than  $i$  picking the action vector  $a_{-i}$ . Similarly.

$$q(s' | s, \lambda_i, f_{-i}(s)) = \sum_{a_{-i}} \left[ \sum_{a_i} q(s' | s, a_i, a_{-i}) \lambda_i(a_i) \right] f_i(a_{-i}, s). \quad (6)$$

Additionally, it follows that the best best response, i. e.,  $g_i$ , solves the optimality equation, i. e.,

$$v_i(s) = \pi_i(s, g_i, f_{-i}(s)) + \delta \sum_{s'} v_i(s') q(s' | s, g_i, f_{-i}(s)) \quad (7)$$

where  $\pi_i(s, g_i, f_{-i}(s))$  and  $q(s' | s, g_i, f_{-i}(s))$  have the same interpretations as given by Eqs. 5 and 6.

**Properties of  $B_i$ :**  $B_i$  is a correspondence that is convex-valued and upper hemi-continuous. That  $B_i$  is convex-valued follows from the fact that we are operating in the set of mixed strategies, that every convex combination of mixed strategies is itself a mixed strategy and that every convex combination of best responses is also a best response.

To show that  $B_i$  is upper hemi-continuous, consider a sequence of other players' strategies  $f_{-i}^n$ , an associated best response sequence of player  $i$ ,  $g_i^n$  with value function sequence  $v_i^n$ . Note that each of these best responses  $g_i^n$  satisfies the Eqs. 6 and 7 (for the value function  $v_i^n$ ). By diagonalization there exist subsequences and subsequential pointwise convergent limits:  $f_{-i}^n \rightarrow f_{-i}^0$ ,  $g_i^n \rightarrow g_i^0$ , and  $v_i^n \rightarrow v_i^0$ . It suffices to show that

$$v_i^0(s) = \max_{\lambda_i} \left\{ \pi_i(s, \lambda_i, f_{-i}^0(s)) + \delta \sum_{s'} v_i^0(s') q(s' | s, \lambda_i, f_{-i}^0(s)) \right\} \quad (8)$$

and

$$v_i^0(s) = \pi_i(s, g_i^0, f_{-i}^0(s)) + \delta \sum_{s'} v_i^0(s') q(s' | s, g_i^0, f_{-i}^0(s)). \quad (9)$$

Equation. 9 will be proved by using the analog of Eq. 7, i. e.,

$$v_i^n(s) = \pi_i(s, g_i^n, f_{-i}^n(s)) + \delta \sum_{s'} v_i^n(s') q(s' | s, g_i^n, f_{-i}^n(s)). \quad (10)$$

Clearly the left-hand side of Eq. 10 converges to the left-hand side of Eq. 9. Lets check the right-hand side of each equation. Evidently

$$\begin{aligned} & \sum_{a_{-i}} \left[ \sum_{a_i} \pi_i(s, a_i, a_{-i}) g_i^n(a_i) \right] f_i^n(a_{-i}; s) \\ & \rightarrow \sum_{a_{-i}} \left[ \sum_{a_i} \pi_i(s, a_i, a_{-i}) g_i^0(a_i) \right] f_i^0(a_{-i}; s) \end{aligned}$$

since each component of the sum converges and we have a finite sum. Finally,

$$\begin{aligned} & \left| \sum_{s'} v_i^n(s') q(s' | s, g_i^n, f_{-i}^n(s)) \right. \\ & \quad \left. - \sum_{s'} v_i^0(s') q(s' | s, g_i^0, f_{-i}^0(s)) \right| \\ & \leq \left| \sum_{s'} [v_i^n(s') - v_i^0(s')] q(s' | s, g_i^n, f_{-i}^n(s)) \right| \quad (11) \\ & \quad + \left| \sum_{s'} v_i^0(s') [q(s' | s, g_i^n, f_{-i}^n(s)) \right. \\ & \quad \left. - q(s' | s, g_i^0, f_{-i}^0(s))] \right|. \end{aligned}$$

The first term in the right-hand side of the inequality above goes to zero by the dominated convergence theorem. The second term can be re-written as

$$\begin{aligned} & \sum_{s'} v_i^0(s') q(s' | s, a_i, a_{-i}) \\ & \quad \cdot \sum_{a_{-i}} \sum_{a_i} [g_i^n(a_i) f_i^n(a_{-i}; s) - g_i^0(a_i) f_i^0(a_{-i}; s)] \end{aligned}$$

and goes to zero because each of the finite number of terms in the summation over action probabilities goes to zero. Hence the RHS of Eq. 10 converges to the RHS of Eq. 9 and the proposition is proved.

*Remark 1* Note that the finiteness of  $A_i$  is crucial. Else, the very last argument would not go through, i. e., knowing that  $[g_i^n(a_i) f_i^n(a_{-i}; s) - g_i^0(a_i) f_i^0(a_{-i}; s)] \rightarrow 0$  for every action vector  $a$  would not guarantee that the sum would converge to zero as well.

*Remark 2* If the horizon were finite one could use the same argument to prove that there exists a Markovian strategy equilibrium, though not a stationary Markovian equilibrium. That proof would combine the arguments above with backward induction. In other words, one would first use the arguments above to show that there is an equilibrium at every state in the last period  $T$ . Then the value function so generated,  $v_i^T$ , would be used to show that there is an equilibrium in period  $T-1$  using the methods above thereby generating the relevant value function for the last two periods,  $v_i^{T-1}$ . And so on.

The natural question to ask at this point is whether the restriction of countable finiteness of  $S$  can be dropped (and – eventually – the finiteness restriction on  $A_i$ ). The answer, unfortunately, is not easily. The problems are two-fold:

1. *Sequential Compactness of the Domain Problem* – If  $S$  is uncountably infinite, then it is difficult to find a domain  $M_i$  that is sequentially compact. In particular, diagonalization arguments do not work to extract candidate strategy and value function limits.
2. *Integration to the Limit Problem* – Note as the other players change their strategies,  $f_{-i}^n$ , continuation payoffs to player  $i$  change in two ways. They change first because the value function  $v_i^n$  changes, i. e.,  $v_i^n \neq v_i^m$  if  $n \neq m$ . Second, the expected continuation value changes because the measure over which the value function is being integrated,  $q(s' | s, \lambda_i, f_{-i}^n(s))$ , itself changes, i. e.,  $q(s' | s, \lambda_i, f_{-i}^n(s)) \neq q(s' | s, \lambda_i, f_{-i}^m(s))$ . This is the well-known – and difficult – integration to the limit problem: simply knowing that  $v_i^n$  “converges” to  $v_i^0$  in some sense – such as pointwise – and knowing that the integrating measure  $q^n$  “converges” to  $q^0$  in some sense – such as in the weak topology – does not, in general, imply that

$$\int v_i^n dq^n \rightarrow \int v_i^0 dq^0. \tag{12}$$

(Of course in the previous sentence  $q^n$  is a more compact stand-in for  $q(s' | s, \lambda_i, f_{-i}^n(s))$  and  $q^0$  for  $q(s' | s, \lambda_i, f_{-i}^0(s))$ .) There are a limited number of cases where Eq. 12 is known to be true. These results typically require  $q^n$  to converge to  $q^0$  in some strong sense. In the dynamic game context what this means is that very strong convergence restrictions need to be placed on the transition probability  $q$ . This is the underlying logic behind results reported in [7,20,22,24].

Such strong convergence properties are typically not satisfied when  $q$  is deterministic – which case comprises the bulk of the applications of the theory. Indeed simply imposing continuity when  $q$  is deterministic appears not to be enough to generate an existence result. Harris et al. [16] and Dutta and Sundaram [14] contain results that show that there may not be a SPE in finite horizon dynamic games when the transition function  $q$  is continuous. Whether other often used properties of  $q$  and  $\pi_i$  – such as concavity and monotonicity – can be used to rescue the issue remains an open question.

**Characterization**

The Bellman optimality equation has become a workhorse for dynamic programming analysis. It is used to derive properties of the value function and the optimal strategies. Moreover it provides an attractive and conceptually simple way to view a multiple horizon problem as a series of

one-stage programming problems by exploiting the recursive structure of the optimization set-up. A natural question to ask, since dynamic games are really multi-player versions of dynamic programming, is whether there is an analog of the Bellman equation for these games. Abreu, Pearce and Stachetti – APS (1988), in an important and influential paper, showed that this is indeed the case for repeated games. They defined an operator, hereafter the APS operator, whose largest fixed point is the set of SPE payoffs in a repeated game and whose every fixed point is a subset of the set of SPE payoffs. (Thereby providing a necessary and sufficient condition for SPE equilibrium payoffs in much the same way that the unique fixed point of the Bellman operator constitutes the value function for a dynamic programming problem.) As with the Bellman equation, the key idea is to reduce the multiple horizon problem to a (seemingly) static problem.

In going from repeated to dynamic games there are some technical issues that arise. We turn now to that analysis pointing out along the way where the technical pitfalls are. Again we start with the infinite horizon model, i. e., where  $T = \infty$ . When  $T$  is finite, the result and arguments can be modified in a straightforward way as will be indicated in a remark following the proof.

But first, some definitions. Suppose for now that  $S$  is countable.

*APS Operator* – Consider a compact-valued correspondence,  $W$  defined on domain  $S$  which takes values that are subsets of  $\mathbb{R}^I$ . Define the APS operator on  $W$ , call it  $LW$ , as follows:

$$LW(s) = \left\{ \begin{array}{l} v \in \mathbb{R}^I : \exists \widehat{f} \in P(A) \text{ and} \\ w : S \times A \times S \rightarrow W, \\ \text{uniformly bounded, s.t. } v_i = \pi_i(s, \widehat{f}) \\ + \delta \sum_{s'} w_i(s, \widehat{f}, s') q(s' | s, \widehat{f}) \\ \geq \pi_i(s, a_i, \widehat{f}_{-i}) + \delta \sum_{s'} w_i(s, a_i, \widehat{f}_{-i}, s') \\ q(s' | s, a_i, \widehat{f}_{-i}), \text{ for all } a_i, i \end{array} \right\} \tag{13}$$

where, as before,

$$\pi_i(s, \widehat{f}) = \sum_{a_{-i}} \left[ \sum_{a_i} \pi_i(s, a_i, a_{-i}) \widehat{f}_i(a_i) \right] \widehat{f}_{-i}(a_{-i}; s) \tag{14}$$

and

$$q(s' | s, \widehat{f}) = \sum_{a_{-i}} \left[ \sum_{a_i} q(s' | s, a_i, a_{-i}) \widehat{f}_i(a_i) \right] \widehat{f}_{-i}(a_{-i}; s) \tag{15}$$

Finally, let  $V^*$  denote the SPE payoffs correspondence, i. e.,  $V^*(s)$  is the set of SPE payoffs starting from initial state  $s$ . Note that the correspondence is non-empty by virtue of Theorem 1.

**Theorem 2** *Suppose that  $S$  is countable,  $A_i$  are finite sets, and the payoff functions  $\pi_i$  are bounded. Suppose furthermore that  $T$  is infinite. Then a)  $V^*$  is a fixed point of the APS operator, i. e.,  $LV^* = V^*$ . Furthermore, b) consider any other fixed point, i. e., a correspondence  $\tilde{V}$  such that  $L\tilde{V} = \tilde{V}$ . Then it must be the case that  $\tilde{V} \subset V^*$ . Finally, c) there is an algorithm that generates the SPE correspondence,  $V^*$ .*

*Proof of a:* Suppose that  $v^* \in V^*(s)$ , i. e., is a SPE payoff starting from  $s$ . Then, by definition, there is a first-period play,  $f^*$  and a continuation strategy after every one-period history  $h(1)$ ,  $\sigma^*(h(1))$ , such that  $\{f^*, \sigma^*(h(1))\}$  is a SPE. By definition, then, the payoffs associated with each history-dependent strategy,  $\sigma^*(h(1))$ , call them  $w_i(s, f^*, s')$ , satisfy Eq. 13. (Note that  $\pi_i$  bounded implies that the lifetime payoffs  $w_i(s, f^*, s')$  are uniformly bounded. In other words,  $v^* \in LV^*(s)$ . On the other hand, suppose that  $v^* \in LV^*(s)$ . Then, by definition, there is a first-period play,  $f^*$ , and SPE payoffs,  $w(s, f^*, s')$ , that together satisfy Eq. 13. Let the SPE strategy associated with  $w(s, f^*, s')$  be  $\sigma^*(h(1))$ . It is not difficult to see that the concatenated strategy –  $f^*, \sigma^*(h(1))$  – forms a SPE. Since the associated lifetime payoff is  $v^*$ , it follows that  $v^* \in V^*(s)$ .  $\square$

*Proof of b:* Suppose that  $L\tilde{V} = \tilde{V}$ . Let  $v \in L\tilde{V}$ . Then, from Eq. 13, there is  $\tilde{f}$ , and SPE payoffs,  $w(s, \tilde{f}, s')$  that satisfy the equation. In turn, since  $w(s, \tilde{f}, s') \in \tilde{V}(s') = L\tilde{V}(s')$  there is an associated  $\tilde{f}(s')$  and  $w(s', \tilde{f}, s'')$  for which Eq. 13 holds. By repeated application of this idea, we can create a sequence of strategies for periods  $t = 0, 1, 2, \dots$  –  $\tilde{f}, \tilde{f}(s'), \tilde{f}(s, s'), \dots$  such that at each period Eq. 13 holds. Call the strategy so formed,  $\phi$ . This strategy can then not be improved upon by a single-period deviation. A standard argument shows that if a strategy cannot be profitably deviated against in one period then it cannot be profitably deviated against even by deviations in multiple periods. (This idea of “unimprovability” is already present in dynamic programming. Within the context of repeated games, it was articulated by Abreu [1].)  $\square$

*Proof of c:* Note two properties of the APS operator:

**Lemma 1**  *$LW$  is a compact-valued correspondence (whenever  $W$  is compact-valued).*

*Proof* Consider Eq. 13. Suppose that  $v^n \in LW(s)$  for all  $n$ , with associated  $\hat{f}^n$  and  $w^n$ . By diagonalization, there exists a subsequence s.t.  $v^n \rightarrow v^0, \hat{f}^n \rightarrow \hat{f}^0$  and  $w^n \rightarrow w^0$ .

This arguments uses the countability of  $S$  and the finiteness of  $A_i$ . From Eq. 14 evidently  $\pi_i(s, \hat{f}^n) \rightarrow \pi_i(s, \hat{f}^0)$  and similarly from Eq. 15  $\sum_{s'} w_i(s, \hat{f}^n, s')q(s' | s, \hat{f}^n)$  goes to  $\sum_{s'} w_i(s, \hat{f}^0, s')q(s' | s, \hat{f}^0)$ . Hence the inequality in Eq. 13 is preserved and  $v^0 \in LW(s)$ .  $\square$

It is not difficult to see that – on account of the boundedness of  $\pi_i$  – if  $W$  has a uniformly bounded selection, then so does  $LW$ . Note that the operator is also monotone in the set-inclusion sense, i. e., if  $W'(s) \subset W(s)$  for all  $s$  then  $LW' \subset LW$ .

The APS algorithm finds the set of SPE payoffs by starting from a particular starting point, an initial set  $W^0(s)$  that is taken to be the set of all feasible payoffs from initial state  $s$ . (And hence the correspondence  $W^0$  is so defined for every initial state.) Then define,  $W^1 = LW^0$ . More generally,  $W^{n+1} = LW^n, n \geq 0$ . It follows that  $W^1 \subset W^0$ . This is because  $W^1$  requires a payoff that is not only feasible but additionally satisfies the incentive inequality of Eq. 13 as well. From the monotone inclusion property above it then follows that, more generally,  $W^{n+1} \subset W^n, n \geq 0$ . Furthermore,  $W^n(s)$  is a non-empty, compact set for all  $n$  (and  $s$ ). Hence,  $W^\infty(s) = \bigcap_n W^n(s) = \lim_{n \rightarrow \infty} W^n(s)$  is non-empty and compact.

Let us now show that  $W^\infty$  is a fixed point of the APS operator, i. e., that  $LW^\infty = W^\infty$ .

**Lemma 2**  *$LW^\infty = W^\infty$ , or, equivalently,  $L(\lim_{n \rightarrow \infty} W^n) = \lim_{n \rightarrow \infty} LW^n$ .*

*Proof* Clearly, by monotonicity,  $L(\lim_{n \rightarrow \infty} W^n) \subset \lim_{n \rightarrow \infty} LW^n$ . So consider a  $v \in LW^n(s)$ , for all  $n$ . By Eq. 13 there is at each  $n$  an associated first-period play  $f^n$  and a continuation payoff  $w^n(s, f^n, s')$  such that the inequality is satisfied and

$$v_i = \pi_i(s, f^n) + \delta \sum_{s'} w_i^n(s, f^n, s')q(s' | s, f^n).$$

By the diagonalization argument, and using the countability of  $S$ , we can extract a (subsequential) limit  $f^\infty = \lim_{n \rightarrow \infty} f^n$  and  $w^\infty = \lim_{n \rightarrow \infty} w^n$ . Clearly,  $w^\infty \in W^\infty$ . Since equalities and inequalities are maintained in the limit, equally clearly

$$v_i = \pi_i(s, f^\infty) + \delta \sum_{s'} w_i^\infty(s, f^\infty, s')q(s' | s, f^\infty)$$

and

$$v_i \geq \pi_i(s, a_i, f_{-i}^\infty) + \delta \sum_{s'} w_i^\infty(s, a_i, f_{-i}^\infty, s')q(s' | s, a_i, f_{-i}^\infty), \text{ for all } a_i, i$$

thereby proving that  $v \in L(\lim_{n \rightarrow \infty} W^n)(s)$ . The lemma is proved.  $\square$

Since the set of SPE payoffs,  $V^*(s)$ , is a subset of  $W^0(s)$  – and  $LV^*(s) = V^*(s)$  – it further follows  $V^*(s) \subset W^\infty(s)$ , for all  $s$ . From the previous lemma, and part b), it follows that  $V^*(s) \supset W^\infty(s)$ , for all  $s$ . Hence,  $V^* = W^\infty$ . Theorem 2 is proved.  $\square$

A few remarks are in order.

*Remark 1* If the game horizon  $T$  is finite, there is an immediate modification of the above arguments. In the algorithm above, take  $W^0$  to be the set of SPE payoffs in the one-period game (with payoffs  $\pi_i$  for player  $i$ ). Use the APS operator thereafter to define  $W^{n+1} = LW^n$ ,  $n \geq 0$ . It is not too difficult to show that  $W^n$  is the set of SPE payoffs for a game that lasts  $n + 1$  periods (or has  $n$  remaining periods after the first one).

*Remark 2* Of course an immediate corollary of the above theorem is that the set of SPE payoffs  $V^*(s)$  is a compact set for every initial state  $s$ . Indeed one can go further and show that  $V^*$  is in fact an upper hemi-continuous correspondence. The arguments are very similar to those used above – plus the Maximum Theorem.

*Remark 3* Another way to think of Theorem 2 is that it is also an existence theorem. Under the conditions outlined in the result, the SPE equilibrium set has been shown to be non-empty. Of course this is not a generalization of Theorem 1 since Theorem 2 does not assert the existence of a MPE.

*Remark 4* When the state space  $A_i$  is infinite or the state space  $S$  is uncountably infinite we run into technical difficulties. The complications arise from not being able to take limits. Also, as in the discussion of the Integration to the Limit problem, integrals can fail to be continuous thereby rendering void some of the arguments used above.

**Folk Theorem**

The folk theorem for Repeated Games – Fudenberg and Maskin [15] following up on earlier contributions – is very well-known and the most cited result of that theory. It proves that the necessary conditions for a payoff to be a SPE payoff – feasibility and individual rationality – are also (almost) sufficient provided the discount factor  $\delta$  is close enough to 1. This is the result that has become the defining result of Repeated Games. For supporters, the result and its logic of proof are a compelling demonstration of the power of reciprocity, the power of long-term relationships in fostering cooperation through the lurking power of “punishments” when cooperation breaks

down. It is considered equally important and significant that such long-term relationships and behaviors are sustained through implicit promises and threats which therefore do not violate any legal prohibitions against explicit contracts that specify such behavior. For detractors, the “anything goes” implication of the Folk Theorem is a clear sign of its weakness – or the weakness of the SPE concept – in that it robs the theory of all predictive content. Moreover there is a criticism, not entirely correct, that the strategies required to sustain certain behaviors are so complex that no player in a “real-world” setting could be expected to implement them.

Be that as it may, the Folk Theorem question in the context of Dynamic Games then is: is it the case that feasibility and individual rationality are also (almost) enough to guarantee that a payoff is a SPE payoff at high enough  $\delta$ ? Two sets of obstacles arise in settling this question. Both emanate from the same source, the fact that the state does not remain fixed in the play of the games, as it does in the case of Repeated Games. First, one has to think long and hard as to how one should define individual rationality. Relatedly, how does one track feasibility? In both cases, the problem is that what payoff is feasible and individually rational depends on the state and hence changes after every history  $h(t)$ . Moreover, it also changes with the discount factor  $\delta$ . The second set of problems stems from the fact that a deviation play can unalterably change the future in a dynamic game – unlike a repeated game where the basic game environment is identical every period. Consequently one cannot immediately invoke the logic of repeated game folk theorems which basically work because any deviation has only short-term consequences while the punishment of the deviation is long-term. (And so if players are patient they will not deviate.)

Despite all this, there are some positive results that are around. Of these, the most comprehensive is one due to Dutta [9]. To set the stage for that result, we need a few crucial preliminary results. For this sub-section we will assume that  $S$  is finite – in addition to  $A_i$ .

**Feasible Payoffs Role of Markovian Strategies**

– Let  $F(s, \delta)$  denote the set of “average” feasible payoffs from initial state  $s$  and for discount factor  $\delta$ . By that I mean

$$F(s, \delta) = \{v \in \mathbb{R}^I : \exists \text{ strategy } \sigma$$

$$\text{s.t. } v = (1 - \delta) \sum_{t=0}^T \delta^t \pi_i(s(t; \sigma), a(t; \sigma))\}.$$

Let  $\Phi(s, \delta)$  denote the set of “average” feasible payoffs from initial state  $s$  and for discount factor  $\delta$  that are generated by pure stationary Markovian strategies – PSMS. Re-

call that a SMS is given by a map  $f_i$  from  $S$  to the probability distributions over  $A_i$ , so that at state  $s(t)$  player  $i$  chooses the mixed strategy  $f_i(s(t))$ . A pure SMS is one where the map  $f_i$  is from  $S$  to  $A_i$ . In other words,

$$\Phi(s, \delta) = \{v \in \mathbb{R}^I : \exists \text{ PSMS } f \\ \text{s.t. } v = (1 - \delta) \sum_{t=0}^T \delta^t \pi_i(s(t); f), a(t; f)\}.$$

**Lemma 3** *Any feasible payoff in a dynamic game can be generated by averaging over payoffs to stationary Markov strategies, i. e.,  $F(s, \delta) = \text{co}\Phi(s, \delta)$ , for all  $(s, \delta)$ .*

*Proof* Note that  $F(s, \delta) = \text{co}[\text{extreme points } F(s, \delta)]$ . In turn, all extreme points of  $F(s, \delta)$  are generated by an optimization problem of the form:  $\max_{\sigma} \sum_{i=1}^I \alpha_i v_i(s, \delta)$ . That optimization problem is a dynamic programming problem. Standard results in dynamic programming show that the optimum is achieved by some stationary Markovian strategy.  $\square$

Let  $F(s)$  denote the set of feasible payoffs under the long-run average criterion. The next result will show that this is the set to which discounted average payoffs converge:

**Lemma 4**  $F(s, \delta) \rightarrow F(s)$ , as  $\delta \rightarrow 1$ , for all  $s$ .

*Proof* Follows from the fact that a)  $F(s) = \text{co}\Phi(s)$  where  $\Phi(s)$  is the set of feasible long-run average payoffs generated by stationary Markovian strategies, and b)  $\Phi(s, \delta) \rightarrow \Phi(s)$ . Part b) exploits the finiteness of  $S$  (and  $A_i$ ).  $\square$

The lemmas above simplify the answer to the question: What is a feasible payoff in a dynamic game? Note that they also afford a dimensional reduction in the complexity and number of strategies that one needs to keep track of to answer the question. Whilst there are an uncountably infinite number of strategies – even with finite  $S$  and  $A_i$  – including the many that condition on histories in arbitrarily complex ways – the lemmas establish that all we need to track are the finite number of PSMS. Furthermore, whilst payoffs do depend on  $\delta$ , if the discount factor is high enough then the set of feasible payoffs is well-approximated by the set of feasible long-run average payoffs to PSMS.

One further preliminary step is required however. This has to do with the fact that while  $v \in F(s, \delta)$  can be exactly reproduced by a period 0 average over PSMS payoffs, after that period continuation payoffs to the various component strategies may generate payoffs that could be arbitrarily distant from  $v$ . This, in turn, can be problematic since one would need to check for deviations at every one of these (very different) payoffs. The next lemma addresses this problem by showing that there is an averaging

over the component PSMS that is ongoing, i. e., happens periodically and not just at period 0, but which, consequently, generates payoffs that after all histories stays arbitrarily close to  $v$ .

For any two PSMS  $f^1$  and  $f^2$  denote a *time-cycle strategy* as follows: for  $T^1$  periods play proceeds along  $f^1$ , then it moves for  $T^2$  periods to  $f^2$ . After the elapse of the  $T^1 + T^2$  periods play comes back to  $f^1$  for  $T^1$  periods and  $f^2$  for  $T^2$  periods. And so on. Define  $\lambda^1 = T^1/(T^1 + T^2)$ . In the obvious way, denote a general time-cycle strategy to be one that cycles over any finite number of PSMS  $f^k$  where the proportion of time spent at strategy  $f^k$  is  $\lambda^k$  and allows the lengths of time to depend on the initial state at the beginning of the cycle.

**Lemma 5** *Pick any  $v \in \cap_s F(s)$ . Then for all  $\varepsilon > 0$  there is a time cycle strategy such that its long-run average payoff is within  $\varepsilon$  of  $v$  after all histories.*

*Proof* Suppose that  $v = \sum_k \lambda^k(s) v^k(s)$  where  $v^k(s)$  is the long-run average payoff to the  $k$ th PSMS when the initial state is  $s$ . Ensure that  $T^k$  is chosen such that a) the average payoff over those periods under that PSMS –  $1/T^k \sum_{t=0}^{T^k-1} \pi_i(s(t); f^k), a(t; f^k)$  – is within  $\varepsilon$  of  $v^k(s)$  for all  $s$ . And b) that  $T^k(s)/\sum_i T^i(s)$  is arbitrarily close to  $\lambda^k(s)$  for all  $s$ .  $\square$

Since  $\Phi(s, \delta) \rightarrow \Phi(s)$  it further follows that the above result also holds under discounting:

**Lemma 6** *Pick any  $v \in \cap_s F(s)$ . Then for all  $\varepsilon > 0$  there is a time cycle strategy and a discount cut-off  $\delta(\varepsilon) < 1$  such that the discounted average payoffs to that strategy are within  $\varepsilon$  of  $v$  for all  $\delta > \delta(\varepsilon)$  and after all histories.*

*Proof* Follows from the fact that  $(1-\delta)/(1-\delta^T) \sum_{t=0}^{T^k-1} \delta^t \pi_i(s(t); f^k), a(t; f^k)$  goes to  $\frac{1}{T^k} \sum_{t=0}^{T^k-1} \pi_i(s(t); f^k), a(t; f^k)$  as  $\delta \rightarrow 1$ .  $\square$

**Individually Rational Payoffs** Recall that a min-max payoff is a payoff level that a player can guarantee by playing a best response. In a Repeated Game that is defined at the level of the component stage game. Since there is no analog of that in a dynamic game, the min-max needs to be defined over the entire game – and hence is sensitive to initial state and discount factor:

$$m_i(s, \delta) = \min_{\sigma_{-i}} \max_{\sigma_i} R_i(\sigma | s, \delta).$$

Evidently, given  $(s, \delta)$ , in a SPE it cannot be that player  $i$  gets a payoff  $v_i(s, \delta)$  that is less than  $m_i(s, \delta)$ . Indeed that inequality must hold at all states for a strategy to be a SPE, i. e., for all  $s(t)$  it must be the case that

$v_i(s(t), \delta) \geq m_i(s(t), \delta)$ . But, whilst necessary, even that might not be a sufficient condition for the strategy to be a SPE. The reason is that if player  $i$  can deviate and take the game to, say,  $s'$  at  $t + 1$ , rather than  $s(t + 1)$ , he would do so if  $v_i(s(t), \delta) < m_i(s', \delta)$  since continuation payoffs from  $s'$  have to be at least as large as the latter level and this deviation would be worth essentially that continuation when  $\delta$  is close to 1. So sufficiency will require a condition such as  $v_i(s(t), \delta) > \max_s m_i(s, \delta)$  for all  $s(t)$ . Call such a strategy *dynamically Individually Rational*. From the previous lemmas, and the fact that  $m_i(s, \delta) \rightarrow m_i(s)$ , as  $\delta \rightarrow 1$ , where  $m_i(s)$  is the long-run average min-max level for player  $i$  the following result is obvious. The min-max limiting result is due to Mertens and Neyman [21].

**Lemma 7** *Pick any  $v \in \cap_s F(s)$  such that  $v_i > \max_s m_i(s)$  for all  $s$ . Then there is a time-cycle strategy which is dynamically Individually Rational for high  $\delta$ .*

We are now ready to state and prove the main result:

**Theorem 3 (Folk Theorem)** *Suppose that  $S$  and  $A_i$  are finite sets. Suppose furthermore that  $T$  is infinite and that  $\cap_s F(s)$  has dimension  $I$  (where  $I$  is the number of players). Pick any  $v \in \cap_s F(s)$  such that  $v_i > \max_s m_i(s)$  for all  $s$ . Then, for all  $\epsilon > 0$ , there is a discount cut-off  $\delta(\epsilon) < 1$  and a time-cycle strategy that for  $\delta > \delta(\epsilon)$  is a SPE with payoffs that are within  $\epsilon$  of  $v$ .*

*Proof* Without loss of generality, let us set  $\max_s m_i(s) = 0$  for all  $i$ . From the fact that  $\cap_s F(s)$  has dimension  $I$  it follows that we can find  $I$  payoff vectors in that set –  $v^i$ ,  $i = 1, \dots, I$  – such that for all  $i$  a)  $v^i \gg 0$ , b)  $v^j_i > v^i_i$ ,  $j \neq i$ , and c)  $v_i > v^i_i$ . That we can find these vectors such that b) is satisfied follows from the dimensionality of the set. That we can additionally get the vectors to satisfy a) and c) follows from the fact that it is a convex set and hence an appropriate “averaging” with a vector such as  $v$  achieves a) while an “averaging” with  $i$ 's worst payoff achieves c). □

Now consider the following strategy: Norm – Start with a time-cycle strategy that generates payoffs after all histories that are within  $\epsilon$  of  $v$ . Choose a high enough  $\delta$  as required. Continue with that strategy if there are no deviations against it. Punishment – If there is, say if player  $i$  deviates, then min-max  $i$  for  $T$  periods and thereafter proceed to the time-cycle strategy that yields payoffs within  $\epsilon$  of  $v^i$  after all histories. Re-start the punishment whenever there is a deviation.

Choose  $T$  in such a fashion that the payoff to the min-max period plus  $v^i_i$  is strictly less than  $v_i$ . That ensures there is no incentive to deviate against the norm provided the punishment is carried out. That there is incentive for

players  $j \neq i$  to punish player  $i$  follows from the fact that  $v^i_j > v^j_j$  the former payoff being what they get from punishing and the latter from not punishing  $i$ . That there is incentive for player  $i$  not to deviate against his own punishment follows from the fact that re-starting the punishment only lowers his payoffs. The theorem is proved. A few remarks are in order.

*Remark 1* If the game horizon  $T$  is finite, there is likely a Folk Theorem along the lines of the result proved for Repeated Games by Benoit and Krishna [4]. To the best of my knowledge it remains, however, an open question.

*Remark 2* When the state space  $A_i$  is infinite or the state space  $S$  is uncountably infinite we again run into technical difficulties. There is an analog to Lemmas 3 and 4 in this instance and under appropriate richer assumptions the results can be generalized – see Dutta (1993). Lemmas 5–7 and the Folk Theorem itself does use the finiteness of  $S$  to apply uniform bounds to various approximations and those become problematical when the state space is infinite. It is our belief that nevertheless the Folk Theorem can be proved in this setting. It remains, however, to be done.

**Dynamics**

Recall that the fourth question is: what can be said about the dynamics of SPE outcome paths? The analogy that might be made is to the various convergence theorems – sometimes also called “turnpike theorems” – that are known to be true in single-player dynamic programming models. Now even within those models – as has become clear from the literature of the past twenty years in chaos and cycles theory for example – it is not always the case that there are regularities exhibited by the optimal solutions. Matters are worse in dynamic games.

Even within some special models where the single-player optima are well-behaved, the SPE of the corresponding dynamic game need not be. A classic instance is the neo-classical aggregative growth model. In that model, results going back fifty years show that the optimal solutions converge monotonically to a steady-state, the so-called “golden rule”. (For references, see Majumdar, Mitra and Nishimura (2000).) However, examples can be constructed – and may be found in Dutta and Sundaram (1996) and Dockner, Long and Sorger (1998) – where there are SPE in these models that can have arbitrarily complex state dynamics which for some range of discount factor values descend into chaos. And that may happen with Stationary Markov Perfect Equilibrium. (It would be less of a stretch to believe that SPE in general can have

complex dynamics. The Folk Theorem already suggests that it might be so.)

There are, however, many questions that remain including the breadth of SPE that have regular dynamics. One may care less for complex dynamic SPE if it can be shown that the “good ones” have regular dynamics. What also remains to be explored is whether adding some noise in the transition equation can remove most complex dynamics SPE.

## Global Climate Change – Issues, Models

### Issues

The dramatic rise of the world’s population in the last three centuries, coupled with an even more dramatic acceleration of economic development in many parts of the world, has led to a transformation of the natural environment by humans that is unprecedented in scale. In particular, on account of the greenhouse effect, *global warming* has emerged as a central problem, unrivaled in its potential for harm to life as we know it on planet Earth. Seemingly the consequences are everywhere: melting and break-up of the world’s ice-belts whether it be in the Arctic or the Antarctic; heat-waves that set all-time temperature highs whether it be in Western Europe or sub-Saharan Africa; storms increased in frequency and ferocity whether it be Hurricane Katrina or typhoons in Japan or flooding in Mumbai. In addition to Al Gore’s eminently readable book, “An Inconvenient Truth”, two authoritative recent treatments are the Stern Review on the Economics of Climate Change, October, 2006 and the IPCC Synthesis Report, November, 2007. Here are three – additional – facts drawn from the IPCC Report:

1. Eleven of the last twelve years (1995–2006) have been amongst the twelve warmest years in the instrumental record of global surface temperatures (since 1850).
2. If we go on with “Business as Usual”, by 2100 global sea levels will probably have risen by 9 to 88 cm and average temperatures by between 1.5 and 5.5°C.

Various factors contribute to global warming, but the major one is an increase in greenhouse gases (GHGs) – primarily, carbon dioxide – so called because they are transparent to incoming shortwave solar radiation but trap outgoing longwave infrared radiation. Increased carbon emissions due to the burning of fossil fuel is commonly cited as the principal immediate cause of global warming. A third relevant fact is:

3. Before the Industrial Revolution, atmospheric CO<sub>2</sub> concentrations were about 270–280 parts per million

(ppm). They now stand at almost 380 ppm, and have been rising at about 1.5 ppm annually.

The IPCC Synthesis (2007) says “Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level.” (IPCC Synthesis Report [17]).

It is clear that addressing the global warming problem will require the coordinated efforts of the world’s nations. In the absence of an international government, that coordination will have to be achieved by way of an international environmental treaty. For a treaty to be implemented, it will have to align the incentives of the signatories by way of rewards for cutting greenhouse emissions and punishments for not doing so. For an adequate analysis of this problem one needs a dynamic and fully strategic approach. A natural methodology for this then is the theory of Subgame Perfect (Nash) equilibria of dynamic games – which we have discussed at some length in the preceding sections.

Although there is considerable uncertainty about the exact costs of global warming, the two principal sources will be a rise in the sea-level and climate changes. The former may wash away low-lying coastal areas such as Bangladesh and the Netherlands. Climate changes are more difficult to predict; tropical countries will become more arid and less productive agriculturally; there will be an increased likelihood of hurricanes, fires and forest loss; and there will be the unpredictable consequences of damage to the natural habitat of many living organisms. On the other hand, emission abatement imposes its own costs. Higher emissions are typically associated with greater GDP and consumer amenities (via increased energy usage). Reducing emissions will require many or all of the following costly activities: cutbacks in energy production, switches to alternative modes of production, investment in more energy-efficient equipment, investment in R&D to generate alternative sources of energy, etc.

The principal features of the global warming problem are:

- *The Global Common* – although the sources of carbon buildup are localized, it is the total stock of GHGs in the global environment that will determine the amount of warming.
- *Near-irreversibility* – since the stock of greenhouse gases depletes slowly, the effect of current emissions can be felt into the distant future.
- *Asymmetry* – some regions will suffer more than others.

- *Nonlinearity* – the costs can be very nonlinear; a rise in one degree may have little effect but a rise in several degrees may be catastrophic.
- *Strategic Setting* – Although the players (countries) are relatively numerous, there are some very large players, and blocks of like-minded countries, like the US, Western Europe, China, and Japan. That warrants a strategic analysis.

The theoretical framework that accommodates all of these features is an *asymmetric dynamic commons* model with the global stock of greenhouse gases as the (common) state variable. The next sub-section will discuss a few models which have most of the above characteristics.

### Models

Before presenting specific models, let us briefly relate the climate change problem to the general dynamic game model that we have seen so far, and provide a historical outline of its study. GHGs form – as we saw above – a global common. The study of global commons is embedded in dynamic commons game (DCG). In such a game the state space  $S$  is a single-dimensional variable with a “commons” structure meaning that each player is able to change the (common) state. In particular, the transition function is of the form

$$s(t+1) = q \left( s(t) - \sum_{i=1}^I a_i(t) \right).$$

The first analysis of a DCG may be found in [18]. That paper considered the particular functional form in which  $q(s(t) - \sum_{i=1}^I a_i(t)) = [s(t) - \sum_{i=1}^I a_i(t)]^\alpha$  for a fixed fraction  $\alpha$ . (And, additionally, Levhari and Mirman assumed the payoffs  $\pi_i$  to be logarithmic.) Consequently, the paper was able to derive in closed form a (linear) MPE and was able to analyze its characteristics.

Subsequently several authors – Sundaram [31], Sobel [27], Benhabib and Radner [3], Rustichini [25], Dutta and Sundaram (1992, [14]), Sorger [28] – studied this model in great generality, without making the specific functional form assumption of Levhari and Mirman, and established several interesting qualitative properties relating to existence of equilibria, welfare consequences and dynamic paths.

More recently in a series of papers by Dutta and Radner on the one hand and Dockner and his co-authors on the other, the DCG model has been directly applied to environmental problems including the problem of global warming. We shall describe the Dutta and Radner work in detail and also discuss some of the Dockner, Long and

Sorger research. In particular, the transition equation is identical in the two models (and described below). What is different is the payoff functions.

We turn now to a simplified climate change model to illustrate the basic strategic ideas. The model is drawn from Dutta and Radner [12]. In the basic model there is no population growth and no possibility of changing the emissions producing technologies in each country. (Population growth is studied in Dutta and Radner [11] while certain kinds of technological changes are allowed in Dutta and Radner [10]. These models will be discussed later.) However, the countries may differ in their “sizes”, their emissions technologies, and their preferences.

There are  $I$  countries. The emission of (a scalar index of) greenhouse gases during period  $t$  by country  $i$  is denoted by  $a_i(t)$ . [Time is discrete, with  $t = 0, 1, 2, \dots$ , ad inf.] Let  $A(t)$  denote the global (total) emission during period  $t$ ;

$$A(t) = \sum_{i=1}^I a_i(t). \quad (16)$$

The total (global) stock of greenhouse gases (GHGs) at the beginning of period  $t$  is denoted by  $g(t)$ . (Note, for mnemonic purposes we are denoting the state variable – the amount of “gas” –  $g$ .) The law of motion – or transition function  $q$  in the notation above – is

$$g(t+1) = A(t) + \sigma g(t), \quad (17)$$

where  $\sigma$  is a given parameter ( $0 < \sigma < 1$ ). We may interpret  $(1 - \sigma)$  as the fraction of the beginning-of-period stock of GHG that is dissipated from the atmosphere during the period. The “surviving” stock,  $\sigma g(t)$ , is augmented by the quantity of global emissions,  $A(t)$ , during the same period.

Suppose that the payoff of country  $i$  in period  $t$  is

$$\pi_i(t) = h_i[a_i(t)] - c_i g(t). \quad (18)$$

The function  $h_i$  represents, for example, what country  $i$ 's gross national product would be at different levels of its own emissions, holding the global level of GHG constant. This function reflects the costs and benefits of producing and using energy as well as the costs and benefits of other activities that have an impact on the emissions of GHGs, e. g., the extent of forestation. It therefore seems natural to assume that  $h_i$  is a strictly concave  $C^2$  function that reaches a maximum and then decreases thereafter.

The parameter  $c_i > 0$  represents the marginal cost to the country of increasing the global stock of GHG. Of course, it is not the stock of GHG itself that is costly, but

the associated climatic conditions. As discussed below, in a more general model, the cost would be nonlinear.

Histories, strategies – Markovian strategies – and outcomes are defined in exactly the same way as in the general theory above – and will, hence, not be repeated. Thus associated with each strategy vector  $\sigma$  is a total discounted payoff for each player

$$v_i(\sigma, g_0) \equiv \sum_{t=0}^{\infty} \delta^t \pi_i(t; \sigma, g_0).$$

Similarly, SPE and MPE can be defined in exactly the same way as in the general theory.

The linearity of the model is undoubtedly restrictive in several ways. It implies that the model is unable to analyze catastrophes or certain kinds of feedback effects running back from climate change to economic costs. It has, however, two advantages: first, its conclusions are simple, can be derived in closed-form and can be numerically calibrated; hence may have a chance of informing policy-makers. Second, there is little consensus on what is the correct form of non-linearity in costs. Partly the problem stems from the fact that some costs are not going to be felt for another fifty to hundred years and forecasting the nature of costs on that horizon length is at best a hazardous exercise. Hence, instead of postulating one of many possible non-linear cost functions, all of which may turn out to be incorrect for the long-run, one can opt instead to work with a cost function which may be thought of as a linear approximation to any number of actual non-linear specifications.

Dockner, Long and Sorger (1998) impose linearity in the emissions payoff function  $h$  (whereas in Dutta and Radner it is assumed to be strictly concave) while their cost to  $g$  is strictly convex (as opposed to the above specification in which it is linear). The consequent differences in results we will discuss later.

## Global Climate Change – Results

In this section we present two sets of results from the Dutta and Radner [12] paper. The first set of results characterize two benchmarks – the global Pareto optima, and a simple MPE, called “Business As Usual” and compares them. The second set of results then characterizes the entire SPE correspondence and – relatedly – the best and worst equilibria. Readers are referred to that paper for further results from this model and for a numerical calibration of the model. Furthermore, for the results that are presented, the proofs are merely sketched.

## Global Pareto Optima

Let  $x = (x_i)$  be a vector of positive numbers, one for each country. A *Global Pareto Optimum (GPO)* corresponding to  $x$  is a profile of strategies that maximizes the weighted sum of country payoffs,

$$v = \sum_i x_i v_i, \quad (19)$$

which we shall call *global welfare*. Without loss of generality, we may take the weights,  $x_i$ , to sum to  $I$ .

**Theorem 4** *Let  $\hat{V}(g)$  be the maximum attainable global welfare starting with an initial GHG stock equal to  $g$ . That function is linear in  $g$ ;*

$$\begin{aligned} \hat{V}(g) &= \hat{u} - wg, \\ w &= \frac{1}{1 - \delta \sigma} \sum_i x_i c_i, \\ \hat{u} &= \frac{\sum_i x_i h_i(\hat{a}_i) - \delta w \hat{A}}{1 - \delta}. \end{aligned} \quad (20)$$

*The optimal strategy is to pick a constant action – emission – every period and after all histories,  $\hat{a}_i$  where its level is determined by*

$$x_i h'_i(\hat{a}_i) = \delta w. \quad (21)$$

*Proof* We shall show by dynamic programming arguments that the Pareto-optimal value function is of the form  $\hat{V} = \sum_{i=1}^I x_i [\hat{u}_i - w_i g]$ . We need to be able to find the constants  $\hat{u}_i$  to satisfy:

$$\begin{aligned} \sum_{i=1}^I x_i [\hat{u}_i - w_i g] &= \max_{a_1, \dots, a_I} \sum_{i=1}^I x_i \\ &\cdot \left[ h_i(a_i) - c_i g + \delta (\hat{u}_i - w_i (\sigma g + \sum_{j=1}^I a_j)) \right]. \end{aligned} \quad (22)$$

Collecting terms that need maximization we can reduce the equation above to

$$\begin{aligned} &\sum_{i=1}^I x_i \hat{u}_i \\ &= \max_{a_1, \dots, a_I} \sum_{i=1}^I x_i \left[ h_i(a_i) - \delta w_i \sum_{j=1}^I a_j \right] + \delta \sum_{i=1}^I x_i \hat{u}_i. \end{aligned} \quad (23)$$

It is clear that the solution to this system is the same for all  $g$ ; call this (first-best) solution  $\hat{a}_i$ . Elementary algebra

reveals that

$$\hat{u}_i = \frac{h_i(\hat{a}_i) - \delta w_i \sum_{j=1}^I \hat{a}_j}{1 - \delta} \quad \text{and} \quad w_i = \frac{c_i}{1 - \delta \sigma}.$$

It is also obvious that  $x_i h'_i(\hat{a}_i) = \delta w_i$ , where  $w = \sum_{i=1}^I x_i w_i$ .  $\square$

Theorem 4 states that, independently of the level of GHG,  $g$ , each country should emit an amount  $\hat{a}_i$ . The fact that the optimal emission is constant follows from the linearity of the model in  $g$ . Notice that on account of the linearity in the gas buildup equation – Eq. 17 – a unit of emission in period  $t$  can be analyzed in isolation as a surviving unit of size  $\sigma$  in period  $t + 1$ ,  $\sigma^2$  in period  $t + 2$ ,  $\sigma^3$  in period  $t + 3$ , and so on. On account of the linearity in cost, these surviving units add  $(\sum_i x_i c_i) \times \delta \sigma$  in period  $t + 1$ ,  $(\sum_i x_i c_i) \times (\delta \sigma)^2$  in period  $t + 2$ , and so on, i. e., the marginal lifetime cost is

$$\frac{1}{1 - \delta \sigma} \sum_i x_i c_i,$$

or  $w$ , and that marginal cost is independent of  $g$ .

#### A Markov–Perfect Equilibrium: “Business as Usual”

This MPE shares the feature that the equilibrium emission rate of each country is constant in time, and it is the unique MPE with this property. We shall call it the “Business-as-Usual” equilibrium. Note that in this equilibrium each country takes account of the incremental damage to itself caused by an incremental increase in its emission rate, but does not take account of the damage caused to other countries.

**Theorem 5 (Business-as-Usual Equilibrium)** *Let  $g$  be the initial stock of GHG. For each country  $i$ , let  $a_i^*$  be determined by*

$$\begin{aligned} h'_i(a_i^*) &= \delta w_i, \\ w_i &= \frac{c_i}{1 - \delta \sigma}, \end{aligned} \quad (24)$$

and let its strategy be to use a constant emission equal to  $a_i^*$  in each period; then this strategy profile is a MPE, and country  $i$ 's corresponding payoff is

$$\begin{aligned} V_i^*(g) &= u_i^* - w_i g, \\ u_i^* &= \frac{h_i(a_i^*) - \delta w_i A^*}{1 - \delta}. \end{aligned} \quad (25)$$

The intuition for the existence of an MPE with constant emissions is similar to the analogous result for the GPO solution. (And indeed for that reason the proof will be omitted.) As long as other countries do not make their emissions

contingent on the level of GHGs, country  $i$  has a constant marginal lifetime cost to emissions. And that marginal cost is independent of  $g$ .

#### Comparison of the GPO and Business as Usual

The preceding results enable us to compare the emissions in the GPO with those in the Business-as-Usual MPE:

$$\text{GPO: } h'_i(\hat{a}_i) = \frac{\delta \sum_j x_j c_j}{x_i(1 - \delta \sigma)}, \quad (26)$$

$$\text{BAU: } h'_i(a_i^*) = \frac{\delta c_i}{1 - \delta \sigma}.$$

Since

$$x_i c_i < \sum_j x_j c_j,$$

it follows that

$$\frac{\delta c_i}{1 - \delta \sigma} < \frac{\delta \sum_j x_j c_j}{x_i(1 - \delta \sigma)}.$$

Since  $h_i$  is concave, it follows that

$$a_i^* > \hat{a}_i. \quad (27)$$

Note that this inequality holds except in the trivial case in which all welfare weights are zero (except one). This result is known as the tragedy of the commons – whenever there is some externality to emissions, countries tend to over-emit in equilibrium. In turn, all this follows from the fact that in the BAU equilibrium each country only considers its own marginal cost and ignores the cost imposed on other countries on account of its emissions; in the GPO solution that additional cost is, of course, accounted for. It follows that the GPO is strictly Pareto superior to the MPE for an open set of welfare weights  $x_i$  (and leads to a strictly lower steady-state GHG level for all welfare weights).

One can contrast these results with those in Dockner, Long and Sorger (1998) that studies a model in which the benefits are linear in emission – i. e.,  $h_i$  is linear – but convex in costs  $c_i(\cdot)$ . The consequence of linearity in the benefit function  $h$  is that the GPO and BAU solutions have a “most rapid approach” (MRAP) property – if  $(1 - \sigma)g$ , the depreciated stock in the next period, is less than a most preferred  $g^*$ , it is optimal to jump the system to  $g^*$ . Else it is optimal to wait for depreciation to bring the stock down to  $g^*$ . In other words, linearity in benefits implies a “one-shot” move to a desired level of gas  $g^*$ , which is thereafter maintained, while linearity in cost (as in the Dutta and Radner model) implies a constant emission rate. What is unclear in the Dockner, Long and Sorger model is why

the multiple players would have the same target steady-state  $g^*$ . It would appear natural that, with asymmetric payoffs, each player would have a different steady-state. The existence of a MRAP equilibrium would appear problematical consequently. The authors impose a condition that implies that there is not too much asymmetry.

### All SPE

We now turn to the second set of results – a full characterization of SPE in Dutta and Radner [12]. We will show that the SPE payoff correspondence has a surprising simplicity; the set of equilibrium payoffs at a level  $g$  is a simple linear translate of the set of equilibrium payoffs from some benchmark level, say,  $g = 0$ . Consequently, it will be seen that the set of emission levels that can arise in equilibrium from level  $g$  is identical to those that can arise from equilibrium play at a GHG level of 0. Note that the fact that the set of equilibrium possibilities is invariant to the level of  $g$  is perfectly consistent with the possibility that, in a particular equilibrium, emission levels vary with  $g$ . However, the invariance property will make for a particularly simple characterization of the best and worst equilibria.

Let  $\mathcal{E}(g)$  denote the set of equilibrium payoff vectors with initial state  $g$ , i. e., each element of  $\mathcal{E}(g)$  is the payoff to some SPE starting from  $g$ .

**Theorem 6** *The equilibrium payoff correspondence  $\mathcal{E}$  is linear; there is a compact set  $U \subset \mathbb{R}^I$  such that for every initial state  $g$*

$$\mathcal{E}(g) = U - \{w_1g, w_2g, \dots, w_Ig\}$$

where  $w_i = c_i/(1 - \sigma\delta)$ ,  $i = 1, \dots, I$ . In particular, consider any SPE, any period  $t$  and any history of play up until  $t$ . Then the payoff vector for the continuation strategies must necessarily be of the form

$$v - (w_1g_t, w_2g_t, \dots, w_Ig_t).$$

The theorem is proved by way of a bootstrap argument. We presume that a (candidate) payoff set has this invariance and show that the linear structure of the model confirms the conjecture. Consequently, we generate another candidate payoff set – which is also state-invariant. Then we look for a fixed point of that operator. In other words, we employ the APS operator to generate the SPE correspondence. Since that has already been discussed in the previous section, it is skipped here.

We will now use the above result to characterize the best – and the worst – equilibria in the global climate change game. Consider the *second-best problem* (from

initial state  $g$  and for a given vector of welfare weights  $x = (x_i; i = 1, \dots, I)$ ), i. e., the problem of maximizing a weighted sum of *equilibrium payoffs*:

$$\max \sum_{i=1}^I x_i V_i(g), \quad V(g) \in \mathcal{E}(g).$$

Note that we consider all possible equilibria, i. e., we consider equilibria that choose to condition on current and past GHG levels as well as equilibria that do not. The result states that the best equilibrium *need not* condition on GHG levels:

**Theorem 7** *There exists a constant emission level  $\bar{a} \equiv \bar{a}_1, \bar{a}_2, \dots, \bar{a}_I$  – such that no matter what the initial level of GHG, the second-best policy is to emit at the constant rate  $\bar{a}$ . In the event of a deviation from this constant emissions policy by country  $i$ , play proceeds to  $i$ 's worst equilibrium. Furthermore, the second-best emission rate is always strictly lower than the BAU rate, i. e.,  $\bar{a} < a^*$ . Above a critical discount factor (less than 1), the second-best rate coincides with the GPO emission rate  $\hat{a}$ .*

The theorem is attractive for three reasons: first, it says that the best possible equilibrium behavior is no more complicated than BAU behavior; so there is no argument for delaying a treaty (to cut emissions) merely because the status quo is simple. Second, the cut required to implement the second-best policy is an across the board cut – independently of anything else, country  $i$  should cut its emissions by the amount  $a_i^* - \bar{a}_i$ . Third, the second-best is exactly realized at high discount factors, rather than asymptotically approached as the discount factor tends to 1.

Sanctions will be required if countries break with the second-best policy and without loss of generality we can restrict attention to the worst such sanction. We turn now to a characterization of this worst equilibrium (for, say, country  $i$ ). One definition will be useful for this purpose:

**Definition 1** An  $i$ -less second-best equilibrium is the solution to a second-best problem in which the welfare weight of  $i$  is set equal to zero, i. e.,  $x_i = 0$ .

By the previous theorem, every such problem has a solution in which on the equilibrium path, emissions are a constant. Denote that emission level  $a(x_{-i})$ :

**Theorem 8** *There exists a “high” emission level  $\bar{a}(i)$  (with  $\sum_{j \neq i} \bar{a}_j(i) > \sum_{j \neq i} a_j^*$ ) and an  $i$ -less second-best equilibrium  $a(x_{-i})$  such that country  $i$ 's worst equilibrium is:*

1. Each country emits at rate  $\bar{a}_j(i)$  for one period (no matter what  $g$  is),  $j = 1, \dots, I$ .

2. From the second period onwards, each country emits at the constant rate  $a_j(x_{-i})$ ,  $j = 1, \dots, I$ .

And if any country  $k$  deviates at either stages 1 or 2, play switches to  $k$ 's worst equilibrium from the very next period after the deviation.

Put another way, for every country  $i$ , a sanction is made up of two emission rates,  $\bar{a}(i)$  and  $a(x_{-i})$ . The former imposes immediate costs on country  $i$ . The way it does so is by increasing the emission levels of countries  $j \neq i$ . The effect of this is a temporary increase in incremental GHG but due to the irreversibility of gas accumulation, a permanent increase in country  $i$ 's costs, enough of an increase to wipe out any immediate gains that the country might have obtained from the deviation. Of course this additional emission also increases country  $j$ 's costs. For the punishing countries, however, this increase is offset by the subsequent permanent change, the switch to the emission vector  $\mathbf{a}(x_{-i})$ , which permanently increases their quota at the expense of country  $i$ 's.

### Generalizations

The models discussed thus far are base-line models and do not deal with two important issues relating to climate change – technological change and capital accumulation. Technological change is important because that opens access to technologies that do not currently exist, technologies that may have considerably lower “emissions to energy” ratios, i. e., cleaner technologies. Capital accumulation is important because an important question is whether or not curbing GHGs is inimical to growth. The position articulated by both developing countries like Indian and China as well as by developed economies like the United States is that it is: placing curbs on emissions would restrict economic activities and hence restrain the competitiveness of the economy.

In Dutta and Radner [10,13] the following modification was made to the model studied in the previous section. It was presumed that the actual emission level associated with energy usage  $e_i$  is  $f_i e_i$  where  $f_i$  is an index of (un)cleanliness – or *emission factor* – higher values implying larger emissions for the same level of energy usage. It was presumed that the emission factor could be changed at cost but driven no lower than some minimum  $\mu_i$ . In other words,

$$0 \leq e_i(t), \quad (28)$$

$$\mu_i \leq f_i(t+1) \leq f_i(t). \quad (29)$$

Capital accumulation and population growth is also allowed in the model but taken to be exogenous. The dy-

namics of those two variables are governed by:

$$g(t) = \sigma g(t-1) + \sum_{i=1}^I f_i(t) e_i(t), \quad (30)$$

$$K_i(t+1) = H[K_i(t)], \quad K_i(t) \nearrow \text{ and unbounded in } t, \quad (31)$$

$$P_i(t+1) = \psi_i P_i(t) + (1 - \psi_i) \Psi, \quad P_i(t) \leq \Psi. \quad (32)$$

The output (gross-domestic product) of country  $i$  in period  $t$  is

$$h_i[K_i(t), P_i(t), e_i(t)],$$

where the function  $h_i$  has all of the standard properties mentioned above. The damage due to the stock of GHG,  $g(t)$ , is assumed to be (in units of GDP):

$$c_i P_i(t) g(t).$$

The cost of reducing the emission factor from  $f_i(t)$  to  $f_i(t+1)$  is assumed to be:

$$\varphi_i [f_i(t) - f_i(t+1)].$$

Immediately it is clear that the state variable now encompasses not just the common stock  $g$  but, additionally, the emission factor profile as well as the sizes of population and capital stock. In other words,  $s = (g, f, K, P)$ . Whilst this significant increase in dimensionality might suggest that it would be difficult to obtain clean characterizations, the papers show that there is some separability. The MPE “Business as Usual” has a separable structure – energy usage  $e_i(t)$  and emission factor choice  $f_i(t+1)$  – depend solely on country  $i$ 's capital stock and population alone. It varies by period – unlike in the base-line model discussed above – as the exogenous variables vary. Furthermore, the emission factor  $f_i(t+1)$  stays unchanged till the population and capital stock cross a threshold level beyond which the cleanest technology  $\mu_i$  gets picked. (This bang-bang character follows from the linearity of the model.)

The Global Pareto Optimal solution has similar features – the energy usage in country  $i$  is directly driven by the capital stock and population of that country. Furthermore the emission factor choice follows the same bang-bang character as for the MPE. However, there is a tragedy of the common in that in the MPE (versus the Pareto optimum) the energy usage is higher – at every state – and the switch to the cleanest technology happens later.

## Future Directions

Within the general theory of dynamic games there are several open questions and possible directions for future research to take. On the existence question, there needs to be a better resolution of the case where the state space  $S$  is uncountably infinite. This is not just a technical curiosity. In applications, typically, in order to apply calculus techniques, we take the state variable to be a subset of some real space. The problem is difficult but one hopes that ancillary assumptions – such as concavity and monotonicity – will be helpful. These assumptions come “cheaply” because they are routinely invoked in economic applications.

The characterization result via APS techniques has a similar technical difficulty blocking its path, as the existence question. The folk theorem needs to be generalized as well to the  $S$  infinite case. Here it is our belief though that the difficulty is not conceptual but rather one where the appropriate result needs to be systematically worked out. As indicated above, the study of the dynamics of SPE paths is in its infancy and much remains to be done here.

Turning to the global climate change application, this is clearly a question of utmost social importance. The subject here is very much in the public consciousness yet academic study especially within economics is only a few years old. Many questions remain: generalizing the models to account for technological change and endogenous capital accumulation, examination of a carbon tax, of cap and trade systems for emission permits, of an international bank that can selectively foster technological change, ... There are – as should be immediately clear – enough interesting important questions to exhaust many dissertations and research projects!

### Glossary

**Grid** Virtual metacomputer, which uses a network of geographically distributed local networks, computers and computational resources and services. *Grid Computing* focuses on distributed computing technologies, which are not in the traditional dedicated clusters. *Data Grids* – represent controlled sharing and management of large amounts of distributed data.

**Problem solving environment (PSE)** A specialized computer software for solving one class of problems. They use the language of the respective field and often employ modern graphical user interfaces. The goal is to make the software easy to use for specialists in fields other than computer science. PSEs are available for generic problems like data visualization or large systems of equations and for narrow fields of science or engineering.

**Global seismographic network (GSN)** The goal of the GSN is to deploy permanent seismic recording stations uniformly over the earth's surface. The GSN stations continuously record seismic data from very broad band seismometers at 20 samples per second, and to provide for high-frequency (40 sps) and strong-motion (1 and 100 sps) sensors where scientifically warranted. It is also the goal of the GSN to provide for real-time access to its data via Internet or satellite. Over 75% of the over 128 GSN stations meet this goal as of 2003.

**WEB-IS** A software tool that allows remote, interactive visualization and analysis of large-scale 3-D earthquake clusters over the Internet through the interaction between client and server.

**Scientific visualization** is branch of computer graphics and user interface design that are dealing with presenting data to users, by means of patterns and images. The goal of scientific visualization is to improve understanding of the data being presented.

**Interactive visualization** is a branch of graphic visualization that studies how humans interact with computers to create graphic illustrations of information and how this process can be made more efficient. **Remote-visualization** – the tools for interactive visualization of high-resolution images on remote client machine, rendered and preprocessed on the server.

**OpenGL** A standard specification defining a cross-language cross-platform API for writing applications that produce 2D and 3D computer graphics.

**Sumatra-Andaman earthquake** An undersea earthquake that occurred at 00:58:53 UTC (07:58:53 local time) December 26, 2004, with an epicenter off the west coast of Sumatra, Indonesia. The earthquake triggered a series of devastating tsunamis along the coasts of most landmasses bordering the Indian Ocean, killing large numbers of people and inundating coastal communities across South and Southeast Asia, including parts of Indonesia, Sri Lanka, India, and Thailand.

**Earthquake catalog** Data set consisting of earthquake hypocenters, origin times, and magnitudes. Additional information may include phase and amplitude readings, as well as first-motion mechanisms and moment tensors.

**Pattern recognition** The methods, algorithms and tools to analyze [data](#) based on either [statistical](#) information or on a [priori](#) knowledge extracted from the patterns. The patterns for classification are groups of observations, measurements, objects, defining feature vectors in an appropriate multidimensional feature [space](#).

**Data mining** Algorithms, tools, methods and systems used in extraction of knowledge hidden in a large amount of data.

**Features** denoted  $f_i$  or  $F_j$  ( $i, j$  – feature indices) – a set of variables which carry discriminating and characterizing information about the objects under consideration. The features can represent raw measurements (data)  $f_i$  or can be generated in a non-linear way from the data  $F_j$  (features).

**Feature space** The multidimensional space in which the  $F_k$  vectors are defined. Data and feature vectors represent vectors in respective spaces.

**Feature vector** A collection of features ordered in some meaningful way into multi-dimensional feature vectors  $F_l$  ( $F_l$  where  $l$  – feature vector index) that represents the signature of the object to be identified represented by the generated features  $F_l$ .

**Feature extraction** The procedure of mapping source feature space into output feature space of lower dimensionality, retaining the minimal value of error cost function.

**Multidimensional scaling** The nonlinear procedure of feature extraction, which minimizes the value of the “stress” being the function of differences of all the distances between feature vectors in the source space and corresponding distances in the resulting space of lower dimensionality.

**Data space** The multi-dimensional space in which the data vectors  $f_k$  exist.

**Data vector** A collection of features ordered in some meaningful way into multi-dimensional vectors  $f_k$  ( $f_k, k$  – data vector index) and  $f_k = [m_k, z_k, x_k, t_k]$  where  $m_k$  is the magnitude and  $x_k, z_k, t_k$  – its epicentral coordinates, depth and the time of occurrence, respectively.

**Cluster** Isolated set of feature (or data) vectors in data and feature spaces.

**Clustering** The computational procedure extracting clusters in multidimensional feature spaces.

**Agglomerative (hierarchical) clustering algorithm** The clustering algorithm in which at the start the feature vectors represent separate clusters and the larger clusters are built-up in a hierarchical way. The procedure repeats the process of gluing-up the closest clusters up to the stage when a desired number of clusters is achieved.

**k-Means clustering** Non-hierarchical clustering algorithm in which the randomly generated centers of clusters are improved iteratively.

**Multi-resolutional clustering analysis** Due to clustering a hierarchy of clusters can be obtained. The analysis

of the results of clustering in various resolution levels allows for extraction of knowledge hidden in both local (small clusters) and global (large clusters) similarity of multidimensional feature vectors.

**N-body solver** The algorithm exploiting the concept of time evolution of an ensemble of mutually interacting particles.

**Non-hierarchical clustering algorithm** The clustering algorithm in which the clusters are searched for by using global optimization algorithms. The most representative algorithms of this type is **k-means** procedure.

### Definition of the Subject

Earthquakes have a direct societal relevance because of their tremendous impact on human community [59]. The genesis of earthquakes is an unsolved problem in the earth sciences, because of the still unknown underlying physical mechanisms. Unlike the weather, which can be predicted for several days in advance by numerically integrating non-linear partial differential equations on massively parallel systems, earthquake forecasting remains an elusive goal, because of the lack of direct observations and the fact that the governing equations are still unknown. Instead one must employ statistical approaches (e. g., [61,72,82]) and data-assimilation techniques (e. g., [6,53,81]). The nature of the spatio-temporal evolution of earthquakes has to be assessed from the observed seismicity and geodetic measurements. Problems of this nature can be analyzed by recognizing non-linear patterns hidden in the vast amount of seemingly unrelated information. With the proliferation of large-scale computations, data mining [77], which is a time-honored and well-understood process, has come into its own for extracting useful patterns from large incoherent data sets found in diverse fields, such as astronomy, medical imaging, combinatorial chemistry, bio-informatics, seismology, remote sensing and stock markets [75]. Recent advances in information technology, high performance computing, and satellite imagery have led to the availability of extremely large data sets, exceeding Terabytes at each turn, that are coming regularly to physical scientists who need to analyze them quickly. These data sets are non-trivial to analyze without the use of new computer science algorithms that find solutions with a minimal computing complexity. With the imminent arrival of petascale computing by 2011 in USA, we can expect some breakthrough results from clustering analysis. Indeed, clustering has become a widely successful approach for revealing features and patterns in the data-mining process. We describe the method of using clustering as a tool for analyzing complex seismic data sets

and the visualization techniques necessary for interpreting the results. Petascale computing will also spur visualization techniques, which are sorely needed to understand the vast amounts of data compressed in many different kinds of spaces, with spatial, temporal and other types of dimensions [78]. Examples of clusters abound in nature include stars in galaxies, hubs in airline routes and centers of various human relationships [5]. Clustering comes from multi-scale, nonlinear interactions due to the rock rheology and earthquakes.

## Introduction

Earthquake clustering is automatically implicated by the classical Gutenberg–Richter relationship [40], which specifies the frequency of earthquakes between some small magnitude cutoff and a certain large magnitude around 8 [39]. This empirical finding with a broad magnitude range implies that the largest seismic events are surrounded by a large number of smaller events. This clustering may have both spatial and temporal dependences. One of the goals of earthquake clustering studies is to find these special points in a high-dimensional space related to the nature of the dimensional space associated with earthquake dynamics [24,25]. One major goal of this chapter is to introduce the reader to the notion of searching for clustering points in dimensional spaces higher than the 3D physical space we are used to. This concept is crucial to our understanding of the clustering points of earthquakes in these higher-dimensional spaces, which may enable progress in forecasting earthquakes. Information in seismicity data sets can be both relevant and irrelevant from the point of view of deterministic earthquake dynamics. It can be also “entangled” and impossible to be interpreted with normal human perception. The role of data mining is to have a mathematically rigorous algorithm for extracting relevant information from this deluge of data, and make it understandable. Clustering techniques, which are commonly used today in many fields, ranging from biology (e. g., [26]) to astrophysics, allows us to produce specially crafted data models that can be employed for predicting the nature of future events. In more complex cases, these special data models can work in concert with formal mathematical and physical paradigms to give us deeper physical insight.

The concept of clustering has been used for many years in pattern recognition [2,50,78]. The clustering can use more (e. g. [54]) or less mathematically rigorous principles (e. g. [33]). Nowadays clustering and other feature extraction algorithms are recognized as important tools for revealing coherent features in the earth sciences [32,65,66,

67], bioinformatics [51] and in data mining [37,43,44,57]. Depending on the data structures and goals of classification, different clustering schemes must be applied [36,55].

In this chapter we emphasize the role of clustering in the understanding of earthquake dynamics and the way to visualize and interpret the computed results from clustering. All the seismic events occurring over a certain region during a given time period can be viewed as a single cluster of correlated events. The strength of mutual correlations between events, such as correlations in spatial and time positions along with magnitude, cause this single cluster to have very complex internal structure. The correlations – the measures of similarity between events – divide the global cluster into variety of small clusters of multi-scale nature, i. e., small clusters may consist of a cascade of smaller ones. Coming down the scale we record clusters of more and more tightly correlated events. Exploring the nature of events belonging to a single cluster, we can extract common features they possess. Having more information about events belonging to the same cluster we can derive hidden dependences between them. Moreover, we can anticipate the type of an unknown event belonging to a certain cluster from the character of the other events of this cluster.

In the following sections we describe the idea of clustering and the new idea of higher dimensions associated with data sets. We also demonstrate the results of clustering analysis of both synthetic and real data. Long synthetic data were derived by using a model for a segmented strike-slip fault zone in a 3D elastic half-space [7]. The real data represent short time (5 years interval) seismic activities of the Changbaishan volcano (the north-east frontier of the North China craton) and the Japanese Archipelago. Lastly, we also highlight the role of visualization of clusters as an important tool for understanding this type of new data arrangement, and we describe the role played by remote visualization environment specially devised for visualization of earthquake clusters.

## Earthquakes Clustering

### Statistical Laws as Elementary Building Bricks of Earthquake Models

The earthquake prediction problem is of fundamental importance to society and also geosciences. Progress in this field is hampered, mainly because many important dynamic variables – such as stress – are not accessible for direct observations. Moreover, instrumental observations of seismicity are possible only for a fraction of a single large earthquake cycle. Overcoming these difficulties will require combining analyses of model and observed data by

using knowledge extraction instruments. The fundamental process of knowledge extraction is finding dependences between data and/or between model parameters. They can be revealed as patterns (clusters) in time, spatial and feature (parameter) space domains. The most elementary dependences can be expressed in the form of semi-empirical functional laws.

There are a few basic statistical laws which represent the basis for earthquake models development. The frequency-size statistics of regular tectonic earthquakes (excluding swarms and deep focus earthquakes) follow the Gutenberg–Richter relation [39,80,84]:

$$\log N(M) = a - bM \quad (1)$$

where  $N$  is the number of events with magnitude larger than  $M$  and  $a$ ,  $b$  are constants giving, respectively, the overall seismicity rate and relative rates of events in different magnitude ranges. Observed  $b$ -values of regional seismicity typically fall in the range 0.7–1.3.

Aftershock decay rates are usually be described by the Omori–Utsu law [71,79]:

$$\Delta N/\Delta t = K(t + c)^{-p} \quad (2)$$

where  $N$  is the cumulative number of events,  $t$  is the time after the mainshock, and  $K$ ,  $c$ , and  $p$  are empirical constants. The epidemic-type aftershock-sequences (ETAS) model combines the Omori–Utsu law with the Gutenberg–Richter frequency-magnitude relation for a history-dependent occurrence rate of a point process in the form (e. g., [61])

$$\lambda(t|H_t) = \mu + \sum_{t_i < t} \frac{K_0 \exp[\alpha(M_i - M_c)]}{(t - t_i + c)^p} \quad (3)$$

where  $\alpha$  is a constant background rate,  $M_i$  is the magnitude of earthquake at time  $t_i$ ,  $M_c$  is a lower magnitude cut-off,  $H_t$  denotes the history, and the productivity factor  $K_0 \exp[\alpha(M_i - M_c)]$  gives the number of events triggered by a parent earthquake with magnitude  $M_i$ . The ETAS model is used widely in analysis of seismic data, owing to its built-in clustering associated with the incorporation of the Gutenberg–Richter and Omori–Utsu laws. Examples of recent applications can be found in [45,62,68].

These results can be used to derive additional properties such as average recurrence times (e. g., [4,18,19,20,68,89]). It is usually defined as the number of years between occurrences of an earthquake of a given magnitude in a particular area. For example, the probability of a devastating earthquake striking the greater San Francisco Bay Region over the following 25 years (2007–2031)

is 0.62 [68]. Corral [18,19,20] proposed the existence of a universal scaling law for the probability density function  $H(\tau)$  of recurrence times (or interevent times)  $\tau$  between earthquakes in a given region:

$$H(\tau) \cong \lambda \times f(\lambda\tau) . \quad (4)$$

The function  $f(x)$  appears to be similar for many different seismic regions, which suggests some universal properties. The average rate  $\lambda$  represent the region specific constant, whose reciprocal is the only relevant characteristic time for the recurrence times. Molchan [58] showed that under general conditions, the only universal distribution of inter-event times in a stationary point process is exponential. Hainzl et al. [42] and Saichev and Sornette [68] discussed relations between statistics of interevent times, the ETAS model of triggered seismicity, and the Corral [18,19] distribution of Eq. (4).

In the context of earthquake prediction it is important to analyze earthquake cycles with repeating sequences of events such as foreshocks, mainshocks and aftershocks (e. g., [9,74,80]). Apart from qualitative tendencies reflected by statistical laws, the earthquakes exhibit various types of more subtle spatio-temporal clustering, i. e., grouping of events of the same type both in time and in spatial coordinates. The recognition of these patterns followed by the analysis of the reasons of their appearance may lead to the development of improved prediction algorithms.

In the following section we present a closer look of clustering as a knowledge extraction technique and a possible way of its application to earthquake data analysis.

### Basic Concepts of Clustering

Clustering analysis is a mathematical concept whose main useful role is to extract the most similar (or dissimilar) separated sets of objects according to a given similarity (or dissimilarity) measure [2]. Clustering is one of the most fundamental processes generated by nature. For example, people gathering in groups, tribes, demonstrations, parties, cities, produce clusters. Similarly, towns and cities are clusters of buildings while galaxies are clusters of stars. The local computer networks and bacterial colonies are also clusters. The objects forming clusters can be the clusters of smaller objects, which in turn, are clusters of even smaller and smaller building bricks. The complexity of cluster structure reflects the complexity of the real world. The clusters of various shapes, densities and sizes, with additional attributes as colors, transparency etc. built up patterns, which are the fingerprints of all multi-scale pro-

cesses and phenomena. The clusters are the primitives of the patterns.

The same notion of clustering concerns geographical locations and other properties of earthquakes. In Fig. 1a we present a spatial distribution of earthquake epicenters in the western hemisphere of the Earth (data from <http://quake.geo.berkeley.edu/cnss/maps/cnss-map.html>). One can see with the naked eye that their distribution is far from being uniform. We observe both elongated and oblate structures – the earthquake clusters – separated at this resolution by large holes of seismically quiescent area.

Properties of the clusters result from properties of the generating processes. The shape and structure of clusters are visual representation of information on these processes. Therefore, detection of clusters and their analysis is the first step for knowledge extraction from this information. For example, as shown in Fig. 1a, the earthquake clusters on Earth are located in geologically active regions, mainly, on the edges of colliding tectonic plates. The distribution and shape of the earthquake clusters follow the borders between the plates. In Fig. 1b we show the large earthquake cluster from Fig. 1a located at the US western coast. One can distinguish here many smaller clusters of different density separated by geologically inactive area. A similar pattern (see Fig. 1c) is observed by zooming in one of denser clusters from Fig. 1b. This multi-reso-

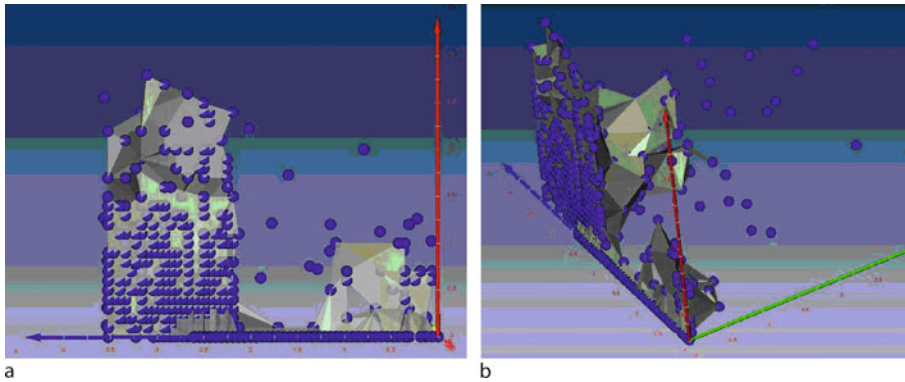

lutional and self-similar system is characteristic for many critical phenomena ▶ *Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of* [3,9,16,74]. The worldwide fault network has a fractal structure (or multifractal) [22,27,79]. Wavelet-based multi-fractal analysis [27] shows clearly several distinct scaling domains in earthquake catalogs revealing rich self-similar multi-scale structure. However, the spatial structure of earthquake clusters alone is inadequate to formulate plausible hypotheses about earthquake dynamics. More information is required.

As shown in Fig. 1, besides the geographical location, earthquakes have additional features such as the time and depth of occurrence and the amount of energy released (proportional to  $10^{\alpha m}$  with  $\alpha \sim 1.5$  and  $m$  the magnitude). These attributes can be used as additional coordinates of, so called, feature space (e. g., [78]). In Fig. 2 we display the earthquake clusters representing the seismic activity nearby the Changbaishan volcano in an abstract 3-D feature space. Apart from geographical location – represented by the distance from the epicenter – other coordinates (features) are employed: the time of occurrence and the magnitude of the earthquake. As shown in Fig. 2, the large cluster of seismic activity is preceded by the small precursory cluster and low activity region. The larger cluster is characterized by the seismic events from broader interval of magnitudes and with satellite earthquakes more

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 1

Multiscale character of the earthquake clusters. The epicenters of earthquakes of various depth and magnitude are displayed. The data come from the CNSS Earthquake Catalog (<http://quake.geo.berkeley.edu/cnss/maps/cnss-map.html>). a the western hemisphere, b the US western coast c California and Nevada

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 2

Seismic activity of the Changbaishan volcano during 5 years time span from 07.1999 to 05.2004 (the north-east frontier of the North China craton) [47]. The plates represent the seismic events in 3-D feature space attributed by eruption time (*blue axis*), magnitude (*red axis*) and distance to the epicenter (*green axis*) coordinates. The clusters are rendered using the *wrap point* technique (the Amira visualization package [www.amiravis.com](http://www.amiravis.com)). Two different positions of coordinates are shown. The *large cluster* representing the earthquake swarm is preceded by the *small precursory cluster* of seismic activity and quiescent time period

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 3

The plot reconstructing seismic activity during 150 years from synthetic data [7] (horizontal distance – *X*, depth – *z*; visualized by using the Amira visualization package [1]). Large events (with magnitude  $m > 6$ ) are shown as distinctly larger dots on the background of the lowest magnitude events ( $m < 4$ ). There are visualized patches of low magnitude events preceding larger events [24]. The separate clusters are marked in colors

distant from the epicenter than in the preceding smaller cluster.

The dynamics of the volcanic earthquakes covers only a period of 5 years. The time is too short to conclude about the long-time earthquake dynamics. To obtain data covering much longer time period we used synthetic data generated by numerical simulations of seismicity on a heterogeneous fault governed by 3-D elastic dislocation theory, power-law creep and boundary conditions corresponding

to the central San Andreas Fault [7,28,29]. In Fig. 3 we represent seismic activity during 150 years. This period contains  $M_f \sim 1 - 3 \times 10^4$  events (represented in Fig. 3 by colored dots) in the magnitude interval [3.3–6.8]. Unlike in the Changbaishan case, the seismic events have one more feature – the earthquake depth. Thus the feature space has now four dimensions. In Fig. 3 we display the data distribution in time-depth-position 3-D space. The fourth dimension – the magnitude – is displayed in Fig. 3 by the size

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 4

The plot reconstructing seismic activity during 1500 years from synthetic data [7]. The largest clusters obtained for events with magnitudes  $4.5 < m < 6$ . Large events ( $m > 6$ ) are shown as distinctly larger plates. The separate clusters are marked in colors

of dot. To make the situation clearer only the large earthquakes with magnitudes  $m > 6$  (large dots) and the smallest ones  $m < 4$  (small dots) are distinguished in Fig. 3. As shown in Fig. 3 and in [24], the synthetic seismic events with magnitudes  $m < 4$  produce stripe-like clusters in the data space. They precede large earthquakes ( $m > 6$ ) and are separated in time by the regions of mixed type of events (i. e., with  $4 < m < 5$ ).

Another system of earthquake clusters are shown in Fig. 4. The synthetic data ( $M_f \sim 10^5$  events) corresponding to the seismic activity during 1500 years were generated by the same model [7] for similar geological and boundary conditions. Only medium size events with  $4.5 < m < 6$  were taken for clustering. In addition to the local strip like clusters of smaller events ( $m < 4$ ) detected for 150-years data, one can observe in Fig. 4a distinct spatio-temporal patchwork structure of clusters of medium sized events ( $4.5 < m < 6$ ). These clusters follow spatio-temporal changes in strength-stress properties of the fault in the region simulated.

In summary, we can highlight very fundamental properties of earthquakes, multi-resolutional clusters are built up by the earthquake epicenters. The clustering is a dynamical process involving many spatio-temporal scales. The dynamic nature of earthquake clusters in a very long time horizon is obvious because everyone can expect that tectonic plates will change dynamically the geo-mechanical properties of the Earth crust. In a long time period covering thousands years, the patterns from Fig. 1 will evolve following the changes in the fault network. More mysterious is the character of earthquake dynamics in spatio-temporal scales allowing for making realistic predictions. We show that in the medium-time period lasting more than

a hundred of years the seismic events may produce periodic system of clusters in approximately equal time intervals with increasing and decreasing seismic activity. The large earthquakes, preceded by the quiescent time periods, appear. The short-time dynamics reveal additionally, that the earthquake swarms are signaled by the smaller precursory cluster of seismic activity. The earthquake attributes such as the magnitude, and the epicenter depth, allow for better interpretation of emerging clusters and exploration of hypotheses space. Therefore, for studying various aspects of earthquake dynamics, including their prediction, we have to analyze the cluster structures in multi-dimensional feature space, to be sure that none of important information will be lost or neglected.

### Multidimensional Feature Space

In Fig. 1 every point  $i$  representing one out of  $M_f$  earthquakes has two dimensions – the geographical coordinates  $\mathbf{x}_i = [x_1, x_2]$  of the epicenter. The point can be treated as 2-D vector  $\mathbf{f}_i$  in the feature space where  $\mathbf{f}_i = \mathbf{x}_i$ . Assuming additional coordinates, at the highest level of resolution, a single seismic event  $i$  can be represented as a five-dimensional data vector  $\mathbf{f}_i = [m_i, z_i, \mathbf{x}_i, t_i]$  where  $m_i$  is the magnitude and  $\mathbf{x}_i, z_i, t_i$  – its epicentral coordinates, depth and the time of occurrence, respectively. The spatio-temporal clusters can be extracted by 3-D visualization similar as those of Figs. 3, 4 distinguishing extra dimension by the size of dots and colors. Only clusters in the three spatially visualized dimensions can be extracted, while the other attributes associated with the earthquake characteristics are used for discriminating among the different types of clusters.

As shown in Figs. 3, 4 and in [24], at the lowest resolution level we can analyze the data locally by looking for clusters with similar events. However, considering a single event on a given area as a feature vector [78] cannot be a good approach from a generalization point of view. The number of events is usually large. There are many noisy background events, which destroy the relevant clusters or produce artificial ones. Moreover, the clustering of raw data neglects the important statistical information, which concerns the entire inspected area. An alternative approach exists in which the entire seismic area can be described as a multidimensional feature vector evolving in time. In the following these features will represent descriptors  $a_k$  (seismicity parameters) corresponding to different statistical properties of all the events measured in a given time interval. The number of descriptors  $N$  defines the dimensionality of the feature vector  $F_i = [a_1, a_2, \dots, a_N]$ ,  $i = 1, 2, \dots, M$ . The vector represents not a single seismic event but it corresponds to seismic situation on the whole controlled area in the subsequent time interval indexed by  $i$ . The number of feature vectors  $M$  is equal to the number of time intervals in which the descriptors are computed. The index  $i$  is a discrete equivalent of time. We expect that the features vectors representing different moments of time also have the tendency to produce clusters in the abstract  $N$ -dimensional feature space. Monitoring changes of these time-series in abstract  $N$ -dimensional space may be used as a proxy for the evolution of stress and a large earthquake cycle on a heterogeneous fault [9].

To explain this approach better, let us assume that we have to analyze the client behaviors in a hypermarket. We can watch every client separately assuming that it can be defined as a feature vector consisting of only two coordinates: the time he entered the shop, money spent. Then we can try to find clusters emerging with time during a shopping day. This cannot be easy due to both a large number of feature vectors (clients) producing statistical noise and lack of correlations between them. Another approach consists in treating as a feature vector not a single client but every subsequent time interval  $t_i = i \times \Delta T$  ( $i = 0, 1, 2, \dots, M_F$ ;  $t_i < t_e$ ;  $M_F = (t_e - t_b)/\Delta T$  and  $t_b$  - beginning of the working day and  $t_e$  - closing time). Let the coordinates of the subsequent feature vector define the following descriptors averaged in  $\Delta t$ : the number of people inside the shop (crowding), the flow, items bought, money spent per person. We note that now the number of feature vectors will be substantially smaller than in the previous approach but the dimensionality of feature space is larger. Let us assume that as a result of clustering we extract two distinct clusters. The first one consists of feature vec-

tors (time intervals) from between 10.00–11.00 and 13.00–14.00. The cluster is characterized by very small values of the first three descriptors (crowding, flow, numbers of items sold) and relatively large expenses. The second cluster consists of time intervals from between 8.00–9.00 and 16.00–18.00 with all descriptors large. We could conclude that the first cluster consists of time intervals from shopping hours that are the favorite for wealthy retired people from the rich village in the neighborhood, while the second cluster is associated with the rush in shopping just before before the beginning and after the end of working hours.

In the same way, the clusters of feature vectors (time intervals) consisting of seismicity parameters should reflect the similarity between seismic activities in various time intervals. As we show before the large seismic events are preceded by precursory events, reflected by an abnormal seismic activity in the whole area. We suppose that these moments of time are similar in the context of the set of seismicity parameters selected. Thus the feature vectors corresponding to precursory events should belong to the same cluster. The idea of predictive system based on clustering consists in detecting the clusters of former foreshocks and signal if the current feature vector – which represents current seismic situation over the area – is or is not the member of this clusters.

The seismicity parameters are computed as time and space averages in a given time and space intervals within a sliding time window with a length  $\Delta T$  and time step  $dt$ . The values of  $a_k$  represents one of the following seismicity parameters: **NS**, **NL**, **CD**, **SR**, **AZ**, **TI**, **MR**. The value of  $dt$  was assumed to be equal to the average time difference between two recorded consecutive events while  $\Delta T$

Earthquake Clusters over Multi-dimensional Space, Visualization of, Table 1

#### Definition of seismicity parameters

<b>NS</b>	Degree of spatial non-randomness at short distances. The differences between distributions of event distances and distances between randomly distributed points.
<b>NL</b>	Degree of spatial non-randomness at short distances.
<b>CD</b>	Spatial correlation dimension calculated on the basis of correlation integrals and on interevent distances.
<b>SR</b>	Degree of spatial repetitiveness represents the tendency of events with similar magnitudes to have nearly the same locations of hypocenters.
<b>AZ</b>	Average depth of the earthquake occurrence.
<b>TI</b>	Inverse of seismicity rate – time interval in which a given (constant) number of events occurs.
<b>MR</b>	Ratio of the numbers of events falling into two different magnitude ranges = $M_r(m \geq M_0)/M_r(m < M_0)$ .

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 5

The exemplary set of seismicity parameters  $\{M, NS, NL, CD, SR, AZ, TI, MR\}$  in time ( $i$  – subsequent number of the feature vector) for a file from the 1500-years synthetic data catalog (from [25]). The green and red strips show the time moments belonging to the two different clusters. The green cluster corresponds to the time intervals of lower while the red cluster of higher seismic activities. The time series represent about  $M_F = 10^3$  feature vectors  $F_i$

is equal to about 1/10 of the average time distance between two successive large events ( $m > 6$  or  $m > 5$ ). By increasing the values of  $dt$  and  $\Delta T$  one can obtain smoother time series due to better statistics. On the other hand, poorer prediction characteristics can be expected then. We define the seismicity parameters as shown in Table 1 [28,29].

The seismicity parameters produces seven time series and create the abstract 7-dimensional feature space of time events  $F_i = (NS_i, NL_i, CD_i, SR_i, AZ_i, TI_i, MR_i)$  where  $i$  are discretized values of time  $t = t_b + i\Delta T$ . In Fig. 5 we display an example set of seismicity parameters (with average magnitude  $M$ ) for synthetic data [25]. The precise location of the clusters and the visualization of the clustering results are significant challenges in clustering over multi-dimensional space. In the following section we present briefly the basics of clustering and algorithms needed in this venture.

### The Detection and Visualization of Clusters in Multi-Dimensional Feature Space

Our main challenge is to devise a clustering scheme which can divide the  $M$  feature vectors  $x_i$ ,  $i = 1, 2, \dots, M$  into  $k$  separate groups (clusters). More formally, assuming that  $X$

$= \{x_i\}_{i=1, \dots, M}$  and  $x \in \mathbf{R}^N$ ;  $x_i = \{x_{i1}, x_{i2}, \dots, x_{iN}\}$  we define as an  $k$ -clustering of  $X$ , i. e., the partition of  $X$  into  $k$  clusters  $C_1, \dots, C_k$  provided three conditions are met:

- $C_i \neq \emptyset$ ,  $i = 1, \dots, k$  – the clusters are non empty sets,
- $\cup_{i=1, \dots, k} C_i = X$  – the sum of elements inside clusters is equal to the total number of feature vectors,
- $C_i \cap C_j = \emptyset$ ,  $i \neq j$ ,  $j = 1, \dots, k$  – each feature vector belongs to only one cluster.

The computational problem with clustering is that the number of possible clustering of  $M$  vectors into  $k$  groups is given by the Stirling numbers (very large numbers) of the second kind:

$$S(M, k) = \frac{1}{k!} \sum_{i=1}^k (-1)^{k-i} \binom{k}{i} \cdot i^M. \quad (5)$$

Some values of  $S(N, k)$  are:  $S(15, 3) \approx 2 \times 10^6$ ,  $S(20, 4) \approx 45 \times 10^9$ ,  $S(25, 8) \approx 7 \times 10^{17}$ ,  $S(100, 5) \approx 2 \times 10^{68}$ . Knowing that the value of  $N$  in typical clustering problems can be  $10^2$  to  $10^9$  and more we see that the clustering problem is intrinsically hard and exhaustive search – looking through all possible clusterings – cannot be considered. The special clustering schemes based on the proximity measures between feature vectors have to be exploited. The basic steps must be followed in order to develop a clustering task are the following:

1. *Feature selection* – Features must be properly selected to encode as much information as possible. Parsimony and minimum redundancy among the features is a major goal.
2. *Proximity measure* – This is the measure how “similar” (or “dissimilar”) two features vectors are.
3. *Clustering criterion*, which depends on the interpretation of the term “sensible”, depending on the type of clusters expected in the data set e. g., oblate, elongated, “bridged”, circular etc.
4. *Clustering algorithms*. Choose a specific algorithmic scheme that unravels the clustering structure of the data set.
5. *Validation and interpretation of results* are the final processes of clustering.

There are two principal types of clustering algorithms: non-hierarchical and agglomerative schemes [2,50,78].

### Clustering Techniques

The non-hierarchical clustering algorithms are used mainly for extracting compact clusters by using global

knowledge about the data structure. The well known *k-means* based schemes [78], consist in finding the global minimum of the following goal function:

$$J(w, z) = \sum_j \sum_{i \in C_j} |x_i - z_j|^2, \quad (6)$$

where:  $z_j$  is the position of the center of mass of the cluster  $j$ , while  $x_i$  are the feature vectors closest to  $z_j$ . To find a global minimum of function  $J()$ , one repeats many times the clustering procedures for different initial conditions [48]. Each new initial configuration is constructed in a special way from the previous results by using the methods from [48,87]. The cluster structure with the lowest  $J(w, z)$  minimum is selected.

Agglomerative clustering schemes consist in the subsequent merging of smaller clusters into the larger clusters, basing on proximity and clustering criteria. Depending on the definition of these criteria, there exist many agglomerative schemes such as: average link, complete link, centroid, median, minimum variance and nearest neighbor algorithm. The hierarchical schemes are very fast for extracting localized clusters with non-spherical shapes. The proper choice of proximity and clustering criteria depend on many aspects such as dimensionality of data. For example, a smart clustering criterion based on linked-list scheme for finding neighbors used for molecules clustering is completely worthless for clustering  $N$ -dimensional data for which it has extremely high computational complexity. All of agglomerative algorithms suffer from the problem of not having properly defined control parameters, which can be matched for the data of interest and hence can be regarded as invariants for other similar data structures.

Majority of the classical clustering algorithms require knowledge on the number of clusters. However this number is usually unknown a priori. Furthermore, these methods do not perform well in the presence of heavy noise or outliers. Recently, new methods have been proposed that can: deal with noisy data, discover non-spherical clusters and allow for automatic assessment of number of clusters. Some important examples are the Chameleon [55], DBSCAN [70] and CURE [38] algorithms. Unfortunately, these methods are suited only for low dimensional data and are rather inefficient limiting their use for data mining of large-scale sets. For clustering of large data sets of multidimensional data other approaches are in great demand. In the innovative work by Frey and Dueck [33] the authors use the concept of “affinity propagation,” which takes as input measures of similarity between pairs of data points. Real-valued messages are exchanged between data points until a high-quality set of exemplars and corresponding

clusters gradually emerges. Affinity propagation promises to find clusters with much lower error than other methods, and it can do this in less than one-hundredth the amount of time.

Clustering schemes do not produce univocal results. For low dimensional 2-3-D spaces human eye can decide whether the clustering result is optimal or not. However, it becomes hopeless for higher dimensions. There exist many techniques for visualization multidimensional clusters. One of them is the multi-dimensional scaling (MDS) (see overview of mapping techniques in [73]) – the most powerful non-linear mapping technique. This method allows for visualization of the multidimensional data in 2-D or 3-D and for interactive extraction of clusters.

### Multidimensional Scaling

Multi-dimensional scaling or MDS is mathematically a non-linear transformation of  $N$ -dimensional data onto  $n$ -dimensional space, where  $n \geq N$  [23,73,78]. The MDS algorithm bases on the “stress function” criterion. The goal is to maintain all the distances between points  $\mathbf{R}_i \in \omega \subset \mathfrak{R}^N$  in the Euclidean 3-D (or 2-D) space with a minimum error. The “stress function” can be written as follows:

$$E(\omega, \omega') = \sum_{j < i} s_{i,j}^{w \cdot m_i} \cdot (s_{i,j} - s'_{i,j})^{m_i} = \min$$

where:  $s'_{i,j} = (\mathbf{y}_i - \mathbf{y}_j) \cdot (\mathbf{y}_i - \mathbf{y}_j)$ ,  $i, j = 1, \dots, M$ , (7)

and  $D_{i,j}$  – is a squared distance between points  $\mathbf{R}_i, \mathbf{R}_j \in \omega \subset \mathfrak{R}^N$  and  $\mathbf{r}_i, \mathbf{r}_j \in \omega' \subset \mathbb{E}^3$  – coordinates of the respective points in 3-D Euclidean space. The values of  $w$  and  $m_i$  are the parameters of transformation.

The result of mapping depends on the quality of the minimum obtained for the “stress function”. Usually the dimensionality of the “stress function” domain is very high and is equal to  $N \cdot M$ , i. e., thousands, in the smallest and billions in large problems. For more than  $M = 10^3$  feature vectors, the high dimensionality of source space and data complexity may cause the resulting low dimensional patterns to be completely illegible. The application of standard numerical algorithms for finding global minimum of this multimodal, non-linear and complex criterion becomes hopeless. Therefore, for visualization of  $M > 10^3$  multidimensional data samples, more reliable minimization techniques extracting global minimum of the “stress function” are required. In [23] we proposed N-body solver

by ODE's as a heuristic means. The algorithm is as follows:

1. The initial configuration of  $M$  interacting "particles" is generated in  $\mathbb{E}^3$ ,
2. Every "particle" corresponds to the respective  $N$ -dimensional point from  $\mathfrak{R}^N$ ,
3. The "particles" interact with each other with  $\Phi_{i,j}$  particle-particle potential:

$$V_{i,j} = \frac{1}{4} \cdot k \left( r_{i,j}^2 - a_{i,j}^2 \right)^2 \quad (8)$$

( $k$  – is the stiffness factor) and the energy produced is dissipated by the friction force proportional to the velocity of the particles.

4. The system of particles evolves according to the Newtonian equations of motion.

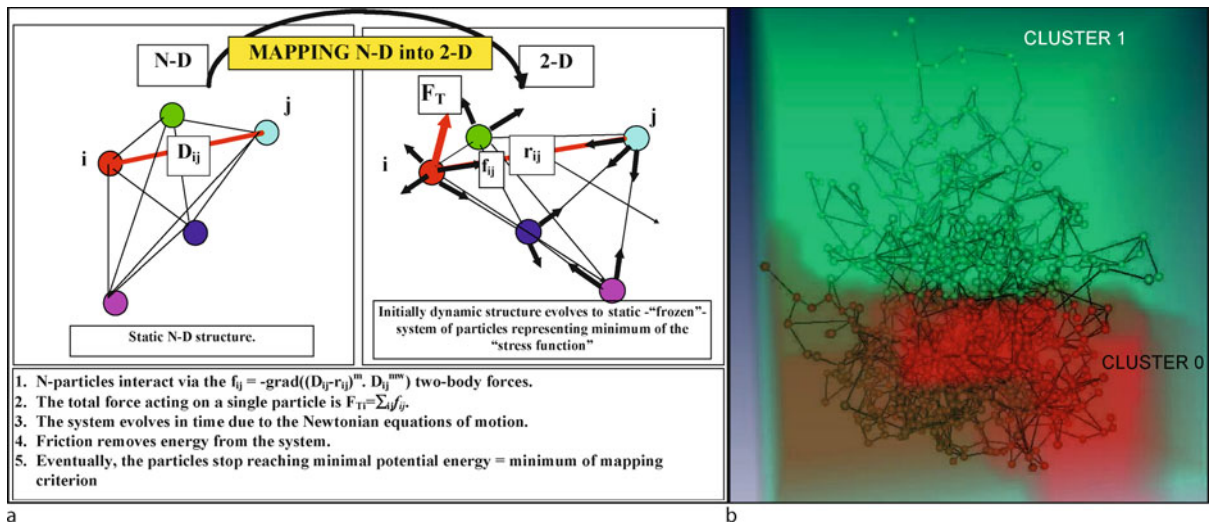

In this way the interactions between each pair of particles are described by various spring like potentials, dependent on the separation distance between particles  $r_{ij}$  and the distance  $D_{ij}$  between respective multidimensional points in  $\mathfrak{R}^N$ . If the distance between particles  $i$  and  $j$  in the output 2(3)-D space is smaller than the distance between respective  $i$  and  $j$  feature vectors in the source  $N$ -D space these points repel one another. Otherwise, i. e. the distance is larger, the particles attract one another. By using the *leap-frog* numerical scheme for time-integration [41] the fol-

lowing formula for velocities and positions of "particles" can be derived from the Newtonian equations:

$$\begin{aligned} \mathbf{v}_i^{n+1/2} &= \frac{(1-\varphi)}{(1+\varphi)} \cdot \mathbf{v}_i^{n-1/2} \\ &+ \frac{\alpha \Delta t}{(1+\varphi)} \left\{ \sum_{j=1}^K (r_{i,j}^n)^2 - a_{i,j}^2 \right\} \mathbf{r}_{i,j}^n + \frac{\mathbf{g}}{\alpha} \mathbf{i}_z \quad (9) \\ \mathbf{r}_i^{n+1} &= \mathbf{r}_i^n + \mathbf{v}_i^{n+1/2} \cdot \Delta t \\ \alpha &= \frac{k}{m}, \quad \varphi = \frac{\lambda}{2m} \cdot \Delta t, \end{aligned}$$

where  $\mathbf{v}_i^n$ , — the particle  $i$ ,  $n$  – the time-step number,  $m = 1$  – particle mass.

As it is common in molecular dynamics [41], the system of "particles" evolves in time until the global (or close to the global) minimum of Eq. (8) (the total potential energy of the particle system) is gained. Two free parameters,  $\lambda$  and  $k$ , have to be fit to obtain the stable state, where the final positions of frozen "particles" reflect the result of  $N$ -D to 3-D mapping. The conceptual scheme of MDS exploiting N-body solver is shown in Fig. 6A. In Fig. 6B we present the feature vectors shown in Fig. 5, using the 7-dimensional feature space which has been transformed by using the MDS procedure and mapping onto the 3-D space. Take a look on the movies (Movie 1 and 2 in Supplementary Materials), which shows how rotation in the 3-D space can help in cluster recognition.

## Description of the Data

### Natural Datasets

We analyze the observed and synthetic earthquake catalogs for three time intervals of 5, 150 and 1500 years respectively. The observed data (Fig. 7) represents seismic activities of the Japanese islands collected by the Japan Meteorological Agency (JMA).

The JMA Catalog consists of 915,829 events detected in Japan Islands between 1923 and January 31, 2003. The original catalog includes also events with magnitudes less than 1.0. The lowest magnitudes were determined by using a detection level, estimated from the Gutenberg–Richter frequency-size distribution. We have assumed that the cutoff magnitude of earthquake is equal to 3 ( $m > 3$ ). We do not use any cutoff depth of hypocenter events. The seismic events shown in Fig. 7, were recorded during the 5 years time interval from October 1, 1997 to January 31, 2003. The data set processed consists of  $M = 42\,370$  seismic events with magnitudes  $m$ , position in space (latitude  $X$ , longitude  $Y$ , depth  $z$ ) and occurrence time  $t$ .

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 7

Seismic activities around the Japanese Archipelago with a time period of 5 years. We use the hypocentral data provided by the Japan Meteorological Agency (JMA). The magnitude of the earthquakes (JMA magnitude) and their depths are represented by differences of the radius of the circle and colors, respectively. The red stars symbolize large events such as: Chi-Chi Taiwan earthquake (21/9/1999 M7.6 latitude 23.8 longitude 121.1), Swarm at Miyakejima (7/2000-8/2000 latitude 34.0 longitude 139.0), Western Tottori earthquake (6/10/2000 M7.3 latitude 35.3 longitude 133.4) (from [25])

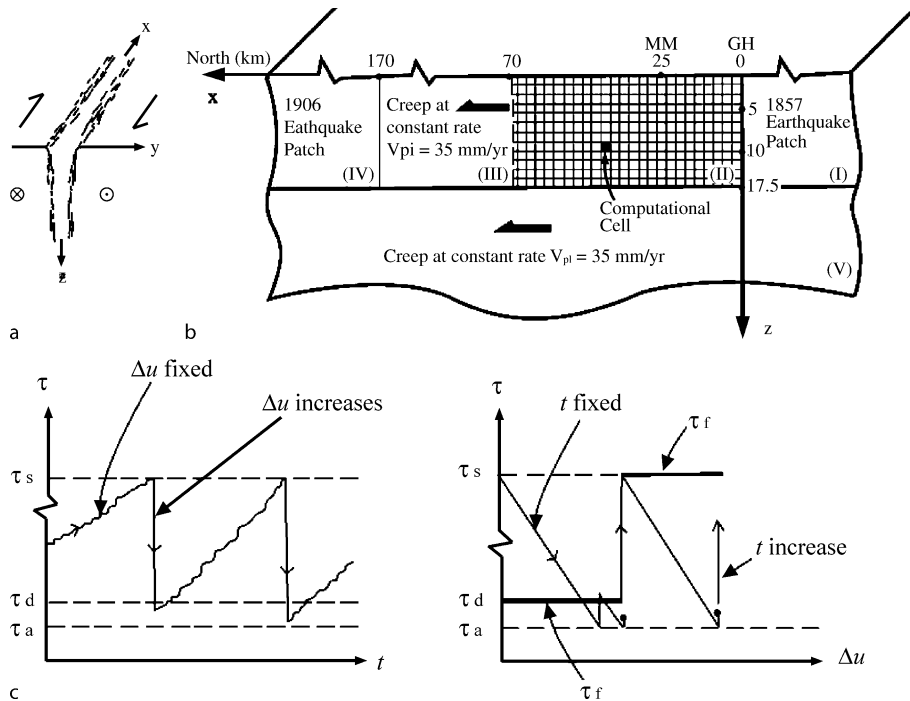

To analyze the seismic activity in longer time periods, we use data from synthetic catalogs generated by numerical earthquake models [7].

### Physical Model of Earthquake Dynamics

The synthetic catalogs are generated by the model of Ben-Zion [7] for a segmented strike-slip fault zone in a 3D elastic half-space, based on earlier developments of Ben-Zion and Rice [10,11]. The model attempts to account for statistical properties of earthquake ruptures on long and narrow fault zones with bends, offsets, etc (Fig. 8a), represented by a cellular structure in a 2D plane with discrete cells and spatial variations of frictional parameters (Fig. 8b). The model contains a computational grid (region II of Fig. 8b) where evolving stress and seismicity are generated in response to ongoing loading imposed as slip boundary conditions on the other fault regions. Regions III and V creep at constant plate velocity of 35 mm/yr, while regions I and IV follow staircase slip histories with recurrence times of 150 yr. The stress transfer due to the imposed boundary conditions and failing grid cells is calculated by using a discretized form of a boundary integral equation and employing the static solution for dislocations in a 3D elastic half-space [10,63].

Deformation at each computational cell is the sum of slip contributions from brittle and creep processes. The brittle process (Fig. 8c) is governed by distributions of static friction  $\tau_s$ , dynamic friction  $\tau_d$ , and arrest stress  $\tau_a$ . The static friction characterizes the brittle strength of a cell until its initial failure in a given model earthquake. When stress  $\tau$  at a cell reaches the static friction, the strength drops to the dynamic friction for the remaining duration of the event. The stress at a failing cell drops to the arrest level  $\tau_a$ , which may be lower than  $\tau_d$  to accommodate dynamic overshoot, producing local slip governed by dislocation theory [17,63]. The static friction, dynamic friction, and arrest stress are connected via a dynamic overshoot coefficient  $D = (\tau_s - \tau_a)/(\tau_s - \tau_d)$ . If the stress transfer from failing regions increases the stress at other cells to their static or dynamic strength thresholds, as appropriate, these cells fail and the event grows. When the stress at all cells is below the brittle failure thresholds, the model earthquake ends and the strength at all failing cells recovers back to  $\tau_s$ . The creep process is governed by a power-law dependence of creep-velocity on the local stress and space-dependent coefficients that increase exponentially with depth and with distance from the southern edge of the computational grid. The chosen parameters produce an overall “pine-tree” stress-depth profile with a “brittle-ductile” transition at a depth of about 12.5

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 8  
The schematics of the model of Ben-Zion [7] for a segmented strike-slip fault zone in a 3D elastic half-space

km, and variable stress-along-strike profiles with a gradual “brittle-creep” transition near the boundary between regions II and III (see Ben-Zion [7] for additional details). The model generates many realistic features of seismicity compatible with observations, including frequency-size and temporal event statistics, hypocenter distribution with depth and along strike, intermittent criticality, accelerated seismic release, scaling of source time functions and more (e. g., [9,29,56,88]).

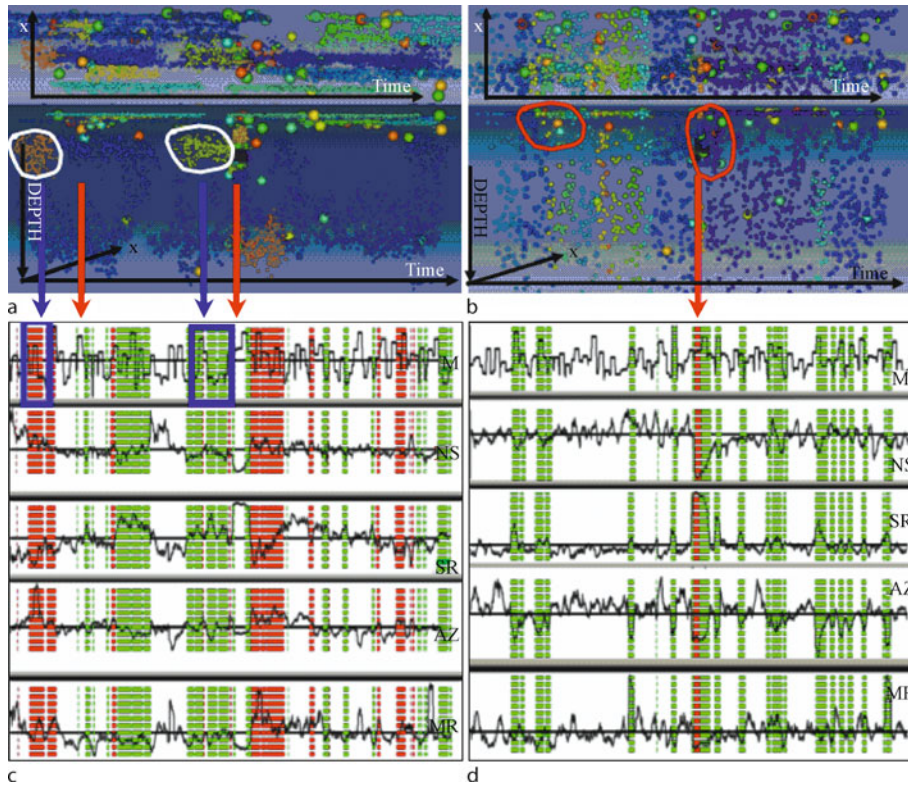

### Synthetic Catalogs

Synthetic data generated by computational models can comprise many events covering large spatial areas and extremely long time spans. Moreover, the synthetic data retain the statistical reliability of the results. The data are free of measurement errors, which occur in estimating earthquake magnitudes and hypocentral locations, and do not suffer from incomplete recording of small events, which exist in natural catalogs. These are significant advantages for our study, which attempts to illustrate clearly the performance of clustering analysis and visualization techniques.

In Sect. “Description of the Data” we analyze synthetic catalogs generated by two model realizations (A and M) of Ben-Zion [7]. The catalogs contain the time, location

and magnitude of earthquakes calculated by the model for 150 and 1500 years. Extensive numerical simulations with several different classes of models, summarized by Ben-Zion [8] and Zöller et al. [9], suggest that the degree of disorder in fault heterogeneities is a tuning parameter of the earthquake dynamics. Catalog A is generated by a model realization tailored to the Parkfield section of the San Andreas fault. Catalog M is generated by a realization of a more-disordered system like the San Jacinto fault or the Eastern California Shear Zone in Southern California. In both data sets the time interval covers all events ( $M \sim 1 - 3 \times 10^4$ ) that have occurred in the last 150 years of simulated fault activity. These simulations were repeated for ten times larger time scale i. e. 1500 year interval (the number of events  $M \sim 10^5$ ) covering hundreds of large earthquakes ( $m > 6$ ) and correspondingly wider time window.

The seismicity parameters were obtained by averaging the data using a sliding time window of constant width  $\Delta T$  and shift  $dt$ . We employ  $\Delta T = 10$  days and  $dt = 2$  days for the Japanese data,  $\Delta T = 10$  months and  $dt = 2$  months for the 150-years synthetic data and  $\Delta T = 30$  months and  $dt = 6$  months for the data covering 1500 years time period. Each parameter in the clustering was normalized with respect to the standard deviation.

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 9

Real seismic data [49] analyzed by using clustering in both the data **a,b** and the feature **(c,d)** spaces. In panels **a** and **b** one can see the results of clustering in the data space (from two different perspectives,  $X$ -Time and Depth-Time) for small ( $3 < m < 4$ ) and medium magnitude ( $4 < m < 6$ ) events, respectively, represented by small dots. The different colors of the dots denote different clusters. Large events are visualized by the larger spheres. Their colors show the difference in magnitudes  $m$  (red – the largest, green – the smallest). The clusters in panels **a,b** encircled in red display the places with the largest seismic activity, while those in white represent the clusters of small precursory events. The red, white and green stripes in panel **c** and **d** representing 4 (out of 7) seismic parameters and maximum magnitude  $M$  show the clusters of similar time events for situations corresponding to panels **a** and **b**, respectively. The Amira visualization package was used (<http://www.amiravis.com>)

## Earthquake Visualization by Using Clustering in Feature Space

### Short-Time Period

Results of clustering of the observed Japanese seismic catalogs (see Fig. 7) both in raw data and in feature spaces are shown in Fig. 9. At the data resolution level a single seismic event  $i$  can be represented as a multi-dimensional data vector  $f_i = [m_i, z_i, X_i, Y_i, t_i]$  where:  $m_i$  is the magnitude,  $X_i$  – the latitude,  $Y_i$  – the longitude,  $z_i$  and  $t_i$  – the depth and the time of occurrence, respectively. The seismic events are visualized with the Amira package in Fig. 9a,b as irregular clouds of colored dots with  $(z, x, t)$  coordinates.

In accordance with the Gutenberg–Richter relationship, we find that the number of events from various ranges of magnitudes differs considerably, and divide the

entire set of data onto three subsets. The first one comprises the small, the second medium and the last one represents the largest earthquakes displayed in Fig. 9a,b as big dots. The deepest earthquakes  $z > 150$  km are not displayed in the Fig. 9. The various shades represent the magnitudes of earthquakes from  $m = 6$  (green) to  $m = 7$  (red). In Fig. 9 we present the clustering results in both the data  $f_i$  and the feature  $F_i$  spaces. We look for clusters of similar seismic events (data space) and time events (feature space). The dots (data vectors), belonging to the same clusters, have the same color. The Fig. 9a,b is very rich in cluster-like forms, some of them hard to interpret. Correspondence of the cluster structure of data  $f_j (j = 1, \dots, M_f)$  with the clusters of averaged events  $F_i (i = 1, \dots, M_F)$  in the feature space can reveal interesting information. As one can see from the panel C, only three clusters are obtained in the feature space consist-

ing of small data events ( $3 < m < 4$ ). The green cluster corresponds to two relatively large time intervals of small events preceding Miyakejima earthquake and many smaller post shock periods. The time events  $F_i$  from this cluster represent averaged data events  $f_j$ , mainly shallow (AZ) of high degree of spatial repetitiveness SR and small diversity of magnitudes (MR). The red cluster consists of deeper events of smaller repetitiveness, and more diversified in magnitudes. The larger time interval of this type of behavior is recognized just after Miyakejima shock. The white cluster is not interesting in this scale of small events and includes all other events (including the earthquake swarm).

In panel D we display the seismicity parameters, which form three clusters of time events obtained for seismic events of larger magnitude  $4 < m < 6$ . Clusters of these events have different structure than in the previous case. They are parallel to X-depth plane. The borders between clusters roughly correspond to the borders of successive showers of the earthquakes. The red cluster comprises only the earthquakes corresponding to the Miyakejima swarm encircled in red in Fig. 9b. As we can see by the MDS visualization displayed in Fig. 10a, this cluster is made up from a needle of time events sprouting away from the two remaining and oval clusters. The green cluster in Fig. 9d represents the deep events, diversified in magnitude of high repetitiveness and rather high degree of spatial non-randomness at short distances (NS). As shown in Fig. 9, these time events represent mainly the post-swarm series of shocks. The white cluster, as before, includes all the other events.

### Time Period of 150 Years

In Fig. 11 we display the time series of seismicity parameters computed for the complete synthetic data catalog A. These time series follow the situation from Fig. 3 where dots represent separate data events. The green, red and white strips in Fig. 11 separate 3 clusters of similar time events represented by 7-dimensional feature vectors. In Fig. 10b these clusters are visualized due to the MDS transformation of 7-dimensional feature space into 3-D space. In Fig. 10b each dot represents a 7-dimensional feature vector mapped into 3-D space by MDS transformation. From the top panel of Fig. 11 displaying the largest events  $M$  in the sliding time window, we may conclude that the white (blue in Fig. 10b) and red clusters from Figs. 10, 11b comprise time events, which correspond to the aftershock effects. The white cluster represents the net aftershock events, while the red one includes the earthquake effects averaged in sliding time window. Conversely, the green cluster (yellow in Fig. 10b) contains the time events preceding the earthquakes.

The selectivity in time of the seismicity parameters depends on the width  $\Delta T$  and shift  $dt$  of the sliding time window. Due to space and time averaging, it is impossible to correlate precisely the appearance of an earthquake with the rest of the seismicity parameters when two earthquakes are too close to each other. Therefore, the sequence of green-red-white cluster events can be broken (Fig. 11) into time domains with many large earthquakes. As shown in Fig. 11 the occurrence of the largest events correlates well with the minima of NS, CD, SR, TI, and maxima of

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 10

The small blue cluster at the bottom represents the events at the end of the time interval, which are averaged within a shrinking time window. b The synthetic seismic data catalog A covering 150 years

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 11  
 The seismicity parameters {*M*,*NS*,*NL*,*CD*,*SR*,*AZ*,*TI*,*MR*} in time for synthetic data catalog A (from [25])

*AZ*, *MR* parameters. This means that the occurrence of large earthquakes is preceded by increasing spatial diffusion of events and increasing seismicity rate. Moreover, the results confirm the some findings from the real data in a shorter time-scale:

1. The events preceding large earthquakes are shallow and have small magnitudes. They have also higher degree of spatial repetitiveness than events from different clusters.
2. The earthquakes accompanying and following the mainshock are rather large in magnitude, deep, have high seismicity rates and low spatial correlation dimension (this drops off rapidly at the onset of large events),

The analysis of synthetic data shows clearly that the clusters in the feature space reflect well the periodicity of increasing and decreasing seismic activity in a given area. For this scale, however, the fine scale characteristics of precursory and after-shock effects become fuzzy.

**Time Period of 1500 Years**

In Figs. 4, 5, 6b and Figs. 12, 13 we visualize the feature vectors for data covering 1500 year period for two models: the A model with a Parkfield-type asperity and the M model with multi-size-heterogeneities. In Fig. 4 and Fig. 12 one can recognize two types of clusters with different sizes. The larger cluster comprises feature vectors forming approximately 150-year long periodic time intervals, which

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 12  
 The seismicity parameters with time for synthetic (catalog M) for seismic data representing time interval of 1500 years. The red and green strips depict the events belonging to red and green clusters from Fig. 7b, respectively

are represented by red strips in Fig. 4 and by green strips in Fig. 12. The second cluster consists of feature vectors from periodic gaps colored in green in Fig. 4 and in white

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 13

The clusters from Fig. 12 mapped by using multidimensional scaling from a 7-dimensional feature space into 3D space for synthetic seismic data catalog M covering 1500 years

in Fig. 12. This anomalous cluster corresponds to the periodic changes in the character of seismic activities. The third cluster (see Fig. 13), marked in red for M type of data in Fig. 12, consists of periodic and short time intervals representing rapid bursts of seismic activity within every 150-year interval.

In both A and M models the gaps between 150-year long intervals are correlated with decrease of: the correlation dimension (CD), degree of spatial repetitiveness (SR) and seismicity rate. These gaps are preceded by large earthquakes. The simulations used for generating the datasets incorporate imposed large earthquakes on regions (I) and (IV) of Fig. 8b that bound the computational grid (region II), as staircase boundary conditions with a step at every 150 years. The analysis detected the effects of these boundary conditions on the seismicity that is calculated in region II.

There are also evident differences between the A and M data in the time intervals belonging to the second cluster. For A environment the gaps between 150-year intervals are greater and the secondary periodicity within them is less clear. Moreover, within time intervals from the second cluster, the degree of spatial non-randomness decreases at long distances (NL) for M model while for A data it decreases at short distances (NS). In addition, the average depth of earthquakes (AZ) is then clearly larger for A model, while for M data it remains on the average level.

In sum, by means of analyzing earthquake clusters in feature space over long time-scale, we can investigate important characteristics of seismic activity such as:

1. The occurrence of hierarchical time-periodicity in seismic activity caused by increase of short-time correlations and their destruction, respectively. Correlations can be broken both due to short-wave and long-wave resonances of the Poincare type (e. g. during largest earthquakes) [Sornette, 2004].
2. The dependence of seismic activities on the ambient rheological and geological properties of the environment, which strongly modify the cluster structure of the feature vectors.

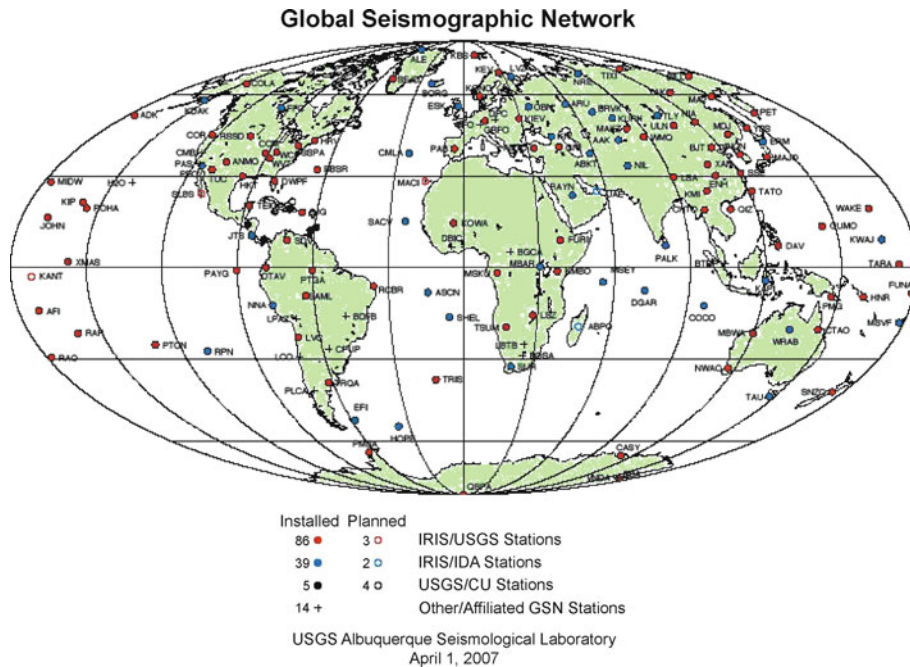

### Remote Problem Solving Environment (PSE) for Analyzing Earthquake Clusters

#### Need for Remote Visualization and Analysis

We need fast access to large databases in order to forecast earthquakes by observation of similarities between thousands and millions of seismic events by visualization of earthquake clusters. The largest earthquake catalogs comprise TBytes of data. Taking into account also the data from tsunami earthquakes and micro-earthquakes in mines, the total amount of data collected by seismic centers spread all over the world is humongous. Moreover, knowledge extraction of earthquake precursors may demand exploration of cross-correlation relationships among many different catalogs. Therefore, both fast communication between data centers and large disk spaces are sorely needed.

As shown in Fig. 14, earthquake seismograph stations, which collect earthquake data from regions with high seismic activity, are distributed worldwide. Therefore, the unprocessed data needs to be stored and then transferred to a dedicated remote server for data processing. After processing, the results must be returned to data acquisition centers and/or other clients. Broadband access to remote facilities dedicated specifically to pattern recognition and visualization allows for scrutinizing local data catalogs by using peer-to-peer connections of data acquisition centers to data preprocessing servers. Clients in the network can automatically compare various types of earthquake catalogs, data measured in distant geological regions, and the results from various theoretical and computational models. By comparing data accessible in the network we have a chance to eliminate the environmental factors and to extract the resultant earthquake precursory effects.

Integration of a variety of hardware, operating systems, and their proper configuration results in many com-

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 14  
Worldwide distribution of earthquake seismographic stations (© USGS)

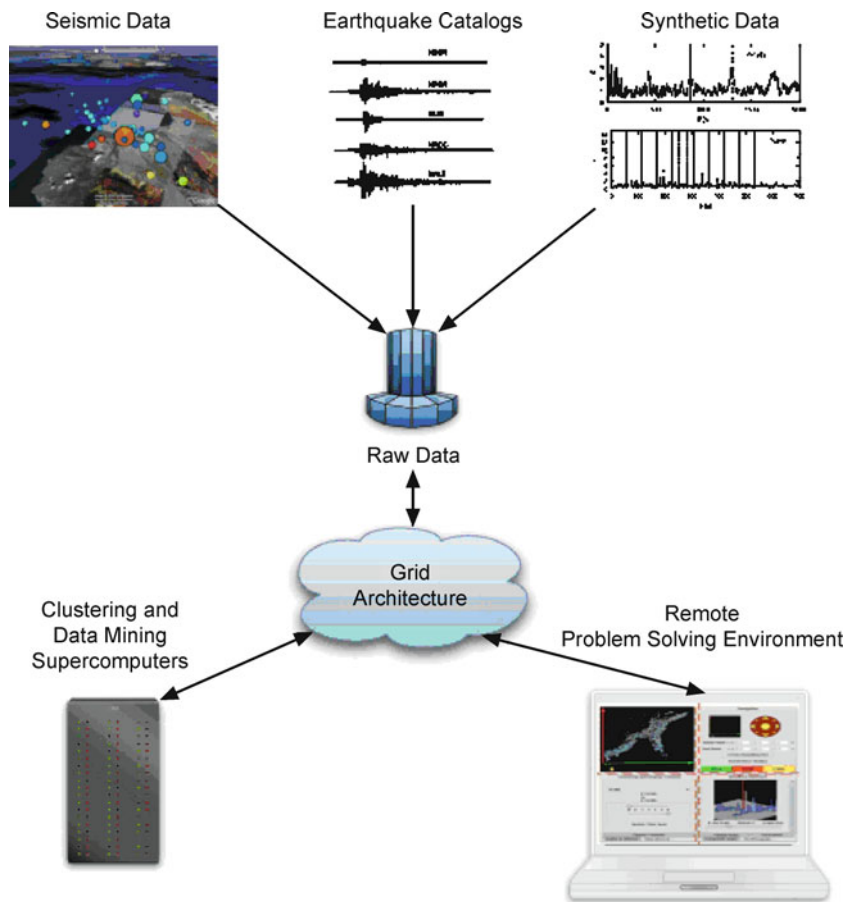

munication problems between data centers. Efficient, reliable, and secure integration of distributed data and software resources, such as pattern recognition and visualization packages, is possible only within the GRID paradigm of computing [13,31]. The GRID mode of computing has flourished rapidly in recent years and has facilitated collaboration and accessibility to many types of resources, such as large data sets, visualization servers and computing engines. Scientific teams have developed easy-to-use, flexible, generic and modular middleware, enabling today's applications to make innovative use of global computing resources. Remote access tools were also produced to visualize huge datasets and monitor performance and data analysis properties, effectively steering the data processing procedures interactively [21]. The TeraGrid project (<http://www.teragrid.org>) is a successful high-performance implementation of such a GRID infrastructure and is being used as an integrated, persistent computational resource at universities and laboratories across the USA. The TeraGrid development impacts also the earthquake science. The National Science Foundation has awarded the Southern California Earthquake Center 15 million service units of computer processing time on supercomputers nationwide [*Grid Today*, August 2007]. These computational resources will be used for simulating thousands of possible earthquakes scenarios in Southern California, includ-

ing the largest breaks on the San Andreas fault ([www.scec.org/cybershake](http://www.scec.org/cybershake)). SCEC will be able to simulate the most disastrous earthquakes ( $M > 7$ ), such as events that could produce Katrina-scale disasters.

We discuss the idea of an integrated problem-solving environment (PSE) intended for the analysis of earthquake clusters for the prediction of earthquakes. A simplified scheme for data acquisition and visualization of earthquake clusters is displayed in Fig. 15. This system promotes portability, dynamic results on-demand, and collaboration among researchers separated by long distances by using a client server paradigm. This is provided through a lightweight front-end interface for users to run locally while the a remote server takes care of intensive processing tasks on large databases, off-screen rendering, and data visualization.

### Grid Environment

In general, large datasets and high-performance computing resources are distributed across the world. When collaboration and sharing of resources are required, a computational GRID infrastructure needs to be in place to connect these servers (see, e.g., [15]). There must exist protocols available to allow clients to tap into these resources and harness their power. The computational grid can be

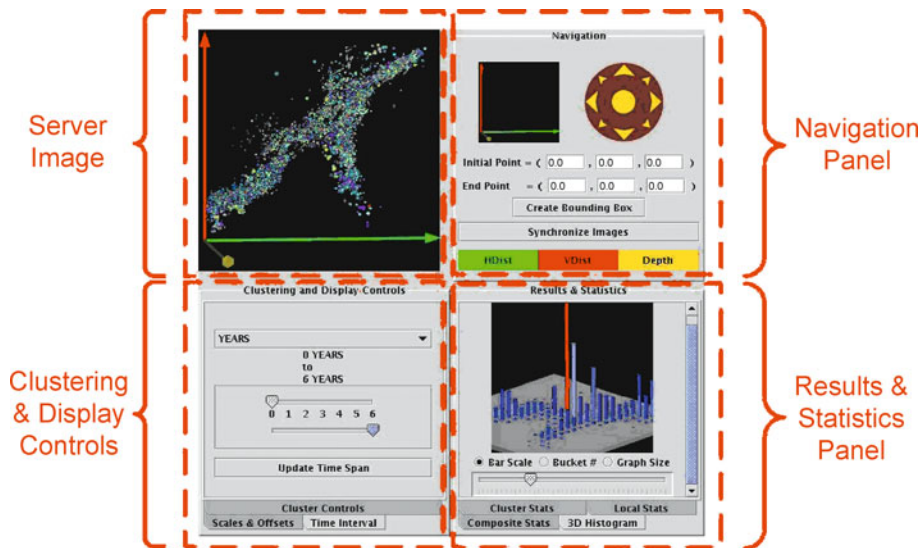

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 15  
Data acquisition, storage, processing, and remote problem solving environments

seen as a distributed system of “clients”, which consists of either “users” or “resources” and proxies. A GRID can be implemented using an event brokering system designed to run on a large network of brokering nodes. Individually, these brokering nodes are competent servers, but when connected to the brokering system, they are able to share the weight of client requests in a powerful and efficient manner. Examples of this include GRID Resource Brokering [30] and NaradaBrokering.

These GRID architectures are well suited to the functionality of a PSE for earthquake cluster analysis and as an integrated computational environment for data exchange and common ventures. The seismic data centers from the networking point of view represent a complex hierarchical cluster structure. They are located geographically in the regions of high seismic activity within heavily populated areas of economic importance. Therefore, the seismic data centers create distant superclusters of various “density” of computational resources corresponding to the

size and importance of the regions. These superclusters are sparse in the sense of computational resources devoted for earthquake detection and data acquisition. However, these same structures contain important computational, scientific and visualization facilities with strong interest in the analysis of earthquake data and earthquake modeling. The efficient interconnection of these sites is of principal interest. Due to the “small world network” structure of GRID architectures it is possible to select the most efficient routing schemes, considerably shortening the average communication path length between brokers. GRID architectures are appropriate to link the clients, both users and resources, together. Construction of efficient and user friendly Problem Solving Environments requires integration of data analysis and visualization software within the GRID environment, in such a way that it can be easily accessed via the Internet. We created an integrated data interrogation toolkit to act as a PSE for visualization and clustering of seismic data, which we call WEB-IS.

Earthquake Clusters over Multi-dimensional Space, Visualization of, Figure 16  
 WEB-IS is an example of a remote earthquake clustering PSE

### Example of Remote PSE

WEB-IS is a software tool that allows remote, interactive visualization and analysis of large-scale 3-D earthquake clusters over the Internet [85] through the interaction between client and server. WEB-IS acts as a PSE through a web portal used to solve problems by visualizing and analyzing geophysical datasets, without requiring a full understanding of the underlying details in software, hardware and communication [34,52]. As shown in Fig. 16, the primary goal of WEB-IS in the geosciences is to provide middleware that sits between the modeling, data analysis tools and the display systems that local or remote users access. In the case of large and physically distributed datasets, it is necessary to perform some preprocessing and then transmit a subset of the data to one or more processes or visualization servers to display. The details of where and how the data migrates should be transparent to the user. WEB-IS makes available to the end users the capability of interactively exploring their data, even though they may not have the necessary resources such as sufficient software, hardware or datasets at their local sites. This method of visualization allows users to navigate through their rendered 3-D data and analyze for statistics or apply earthquake cluster analysis. To the client, the process of accessing and manipulating the data appears simple and robust, while the middleware takes care of the network communication, security and data preparation.

Complete realization of an earthquake clustering PSE consists of:

1. Data analysis tools to implement earthquake clustering techniques;
2. High performance visualization techniques using OpenGL or Amira;
3. The Grid environment;
4. Integration toolkit, such as WEB-IS.

These exist and can work both independently and coupled in a single special purpose system. This system can be developed creating the backbone of the sophisticated computational data acquisition environment, which can be devised specifically for earthquake clustering or for general needs of the geophysical community. Equipped with only PDAs or laptops, and working on location in unreachable desert terrains with remote data acquisition centers or perhaps just analyzing data in one of the many computation facilities located around the globe, geophysicists will be enabled unlimited access to data resources spread all over the world.

We see the principal goal of our work in contributing to the construction of a global warning system, which can be used for prediction of catastrophes such as various types of earthquakes along the circum Pacific belt, where there is a great concentration of people. For example, similar methodology can be used for tsunami earthquake alerting. Theoretical models of faulting and seismic wave propagation used for the computation of radiated seismic energy from broad-band records at teleseismic distances [14] can be adapted to the real-time situation when neither the depth nor the focal geometry of the source

is known accurately. The distance-dependent approximation was used in [60]. By analyzing some singular geophysical parameters such as the energy-to moment ratio  $H$  [60] for regular earthquakes, the results obtained from the theoretical models agree well with values computed from available source parameters (e.g., as published by the National Earthquake Information Center). It appears however that the so called “tsunami earthquakes” – characterized by the significant deficiency of moment release at high frequencies – yield the values of  $H$  considerably different the regular earthquakes. Thus  $H$  value can be used as a suitable criterion for discriminating various types of earthquakes in a short duration of time, like an hour. However, this hypothesis holds only for a few cases. For, so called, “tsunamigenic earthquakes” this difference is not so clear. Moreover, the value of the moment computed on the base of long-period seismic waves can be underestimated. For example, analysis of the longest period normal modes of the Earth, 0S2 and 0S3, excited by the December 26, 2004 Sumatra earthquake [76], yields an earthquake moment of  $1.3 \cdot 10^{30}$  dyn-cm, approximately three times larger than the  $4 \cdot 10^{29}$  dyn-cm measured from long-period surface waves. Therefore, instead of a single-value discrimination we recommend using more parameters (dimensions) for detecting tsunami earthquakes. As shown in [64] and [83], one could employ other T-phase characteristics such as its duration, seismic moment, and spectral strength or even similar features associated with the S-phase. We believe that the lack of success in predicting earthquakes still comes from the lack of communications between researchers and difficulties in free and fast access to the various types of data. Therefore, we hope that globalization of computation, data acquisition and visualization resources, together with fast access through a scale-free network, will provide a triumphant solution to this problem.

### Future Directions

In this chapter we endeavor to bring across the basic concept of clustering and its role in earthquake forecasting. Indeed we find that the clustering of seismic activities reflects both the similarity among them and their correlation properties. As discussed in, e.g., Ben-Zion et al. [9], Saichev and Sornette [68] and Zöller et al. ► [Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space](#), there exists an evolutionary process or memory between successive earthquakes, which impact the distribution of the inter-event times. We believe that by means of earthquake clustering we can capture the essence of this predictive information [27]. Therefore,

in order to carry out real-time earthquake forecasting for short-time scales, it is necessary to derive a thorough understanding of all families of earthquake clusters produced over an earthquake-prone region.

We stress here that in obtaining this type of information one must first be able to detect the precise location of the significant clusters, by filtering out simultaneously the noise and the outliers. While the existence of spatial-temporal clusters is important, they do not reveal the subtle information hidden behind the relations among the data events, such as: spatial-temporal correlation dimensions, correspondence between the numbers of small and large magnitude events, degree of spatial randomness, repetitiveness at different distances and other factors. The features – “descriptors” or seismicity parameters – constructed from the empirical knowledge of the researcher should be largely independent and should represent aptly distinctive features, which are useful for the purpose of pattern recognition. Unlike single events described only by spatio-temporal features (and magnitude), the  $N$ -dimensional feature vectors can represent better the dynamics of the seismically active area in different moments of time. By following the basic rules of learning theory, we may be able to arrive at the number  $N$  and quality of features, which can assure the generalization power of the data and allow us to construct reliable data-models or classifiers.

We have shown that clustering, as a well-honed tool in data mining and pattern recognition, represents the classifier without the teacher, which means that the nature of the clustering is unknown and its exact background must be guessed at from expert knowledge and analysis of the cluster properties. Clustering is a process based on a priori knowledge extraction for constructing the hypothesis space needed for reliable classifiers that can be taught and used for forecasting [25]. However, the quality of these data models depends strongly on the quality of hypothesis space constructed. Consequently, it depends on the quality of clusters extraction. The major problem comes from the lack of a universal clustering scheme, thus making the clustering process somewhat subjective. In this case we must visualize the multidimensional feature space. Visual confirmation gives one a confidence concerning the validity of the clusters and we can then adjust for the optimal clustering procedures by removing the noise and outliers. Among the major goals of earthquake clustering, we can include the following salient points:

- classification of the chaotic properties of seismicity patterns [35], for example to recognize the three main groups of shocks: foreshocks, mainshocks and after-

shocks or to remove the temporary clustering to estimate the background seismicity;

- understanding the correlations between observed properties of earthquakes in different domains (e. g., space, time, number, size);
- understanding the relations between various physical parameters of the models and properties of the generated earthquakes;
- investigating the multi-scale nature of the cluster structure and reconstructing the important and hidden information associated with the stress characteristics.

Classification of type of shocks seems to be an unresolved problem because there are no observable differences between foreshocks, main shocks and aftershocks [68]. Each earthquake is able of triggering other earthquakes according to the basic laws from [46,69]. Despite this difficulty, as shown in [9], it is possible to construct some sort of stochastic classifiers based on theoretical footing. The method proposed here closely related to the epidemic-type aftershock sequence (ETAS) model [61]. It is important that the principal characteristics of ETAS-based models correspond to experimental verifications, i. e., they treat all earthquakes on the same footing and there is not distinction between foreshocks, main shocks and aftershocks. The key points of the method are the probabilities of one event being triggered by a previous event (e. g., [82]). Making use of these probabilities, we can reconstruct the functions associated with the characteristics of earthquake clusters to test a number of plausible hypotheses about the earthquake clustering phenomena.

As shown above by our results on seismicity clustering for the three different time epochs, clustering can be truly regarded as a coarse-graining procedure. We can see details from the smaller scales are erased, thereby exposing the general trends associated with the long correlation length. For large data bases covering long time intervals we can unveil the shorter timescale characteristics by removing the background events, using successive clustering. Eventually, we can build up the strong classifiers. In the case where the long-time data catalogs are missing, we can employ the stochastic classifiers advocated Ben-Zion et al. [9] for prior thresholding of the background data or what is sometimes called “fuzzification” [86]. By this procedure we can construct the hypothesis space for data models by clustering (or fuzzy clustering) procedures.

The results discussed in this paper contribute to the development of improved software infrastructure for analysis of seismicity. A combined clustering analysis of observed and synthetic data, aided by state-of-the-art visualization of multidimensional clusters, undoubtedly lead to

improved earthquake forecasting algorithms with shorter time windows of increased probability of large seismic events.

**Structural health monitoring** Is the process of determining and tracking the structural integrity and assessing the nature of damage in a structure. It is often used interchangeably with *structural damage detection*.

**Inter-story drift** Is the ratio between the relative horizontal displacements at two levels of the structure and the distance between them. It is important to distinguish between drift resulting from *deformation* of the structure, which is directly related to damage, and drift resulting from the deformation of the soil and rocking of the structure as a rigid body. It is also important to estimate reliably the drift due to permanent displacement (its “DC” component), which cannot be done reliably using data from vibrational sensors unless six degrees of freedom of motion (three translations and three rotations) are recorded.

**Soil-structure interaction (SSI)** Is a process occurring during vibration of structures founded on flexible soil, in which the structure and soil interact, and their motions are modified. *Kinematic interaction* refers to the effects of scattering and diffraction of the incident seismic waves from the soil excavation for the foundation. *Dynamic interaction* refers to the effects caused by the inertia forces of the structure and foundation, which lead to deformation of the soil, and results in modification of the *resonant frequencies* and *damping* of the response of the structure, foundation and soil acting as a system.

**Resonant frequencies of vibration** Of a structure on flexible soil are those of the *soil-structure system*, and the energy of the vibrational response is concentrated around these frequencies. They depend on the stiffness of the building and that of the soil. *Fixed-base frequencies of vibration* are the resonant frequencies of the structure on rigid soil, and depend only on the stiffness of the structure. Loss of stiffness of the structure due to damage results in reduction of the fixed-base frequencies, and indirectly of the system frequencies. Monitoring changes in the fixed-base frequencies is most reliable because it eliminates the effects of the soil, which can exhibit (recoverable) nonlinear behavior during strong shaking.

### Definition of the Subject

*Structural health monitoring* and structural damage detection refers to the process of determining and tracking the structural integrity and assessing the nature of damage in a structure. Being able to detect the principal components of damage in structures as they occur during an earthquake or soon after the earthquake, or the absence of it, before physical inspection is possible, is an important and challenging problem. Considering the challenges faced and the potential benefits for safety and for minimizing disruption of productivity, structural health monitoring has the elements of a *grand challenge* problem in civil engineering [12].

*Structural damage* can be described by the following five attributes: existence, location, type, extent, and prognosis for the remaining useful life. Structural damage is a complex state, which can occur on different time scales, suddenly during some catastrophic event such as earthquake or explosion, or gradually over the life of the structure, due to deterioration of the structural materials by aging, service, and exposure to environmental influences. This article is concerned primarily with identification of the most significant components in the space of complex patterns of damage caused by earthquakes. Damage in structures also can be described on different spatial scales, e. g. from small defects and localized damage in a component, to global state of damage of the structural system. Hence the damage detection methods are classified as *local* and *global*. The local methods are those for nondestructive testing (NDT) of materials, which can determine the location of the damage in a structural component. They involve use of actuators (radiating ultrasonic waves into the structural element), and require access to the element. The global methods assess the overall state of damage of the structural system (as it reflects on its overall perfor-

mance during an extreme event). The focus of this review is on the global methods, and intermediate scale methods, which can point to the part of the structure that has been damaged.

Structural damage detection and early warning involve: (1) *recording* some sensory data, (2) *identification* of some structural parameter(s) sensitive to damage (e. g. natural frequencies of vibration, or wave travel times), some characteristic of response (e. g. levels of inter-story drift) that can be correlated with damage, or some other patterns (e. g. abrupt changes in the response detected as novelties), (3) *comparison* of the result of the identification with some knowledge base of correlation of such patterns with levels of damage, and (4) *decision making* (e. g. whether to evacuate or continue occupancy). Because of various uncertainties, the answer can be only expressed probabilistically, and the decision will also depend on the nature of the use of the structure and level of tolerance of the user.

The earliest and most wide-spread methods of structural damage detection are those based on data from vibrational sensors. In fact, the hope to eventually be able to detect hidden damage has been one of the motivations for the development and deployment of seismic sensors in structures. The first strong motion recordings in a building are those during the  $M = 5.4$  Southern California earthquake of October 2, 1933, obtained in the Hollywood Storage Building, the instrumented structure in US with the longest history of recording earthquakes [63]. The earliest identification methods consisted of estimation of the building resonant frequencies and damping, from energy distributions of small amplitude ambient noise and forced vibration tests [3], as well as from earthquake records [63]. These studies identified the resonant frequencies and damping of the soil-structure system, which depend on the properties of the soil, and can change significantly even when there is no damage. Detailed system identification studies from full-scale test vibration data that separate the effects of the soil-structure interaction appeared in the 1970s, following theoretical developments that helped understanding the phenomenon of soil-structure interaction [13,32,33,34,71]. Thirty years later, such studies are still rare, due to a combination of factors, one of which is the inadequate coverage of this topic in the graduate curricula, and the other is the emphasis of earthquake engineering research on laboratory experimentation and numerical simulations, rather than on the full-scale testing of structures [63].

Despite the progress made to date in instrumentation of structures as well as in development of theoretical methods, structural health monitoring systems are deployed in

structures only on an experimental basis. The main obstacles to the routine practical deployment of such systems are: (1) the high cost of sensors and monitoring systems, which limits the number of structures that are instrumented and the detail of the measurements (spatial resolution, e. g.), (2) the low sensitivity and robustness of the methods, and ability to discriminate between changes in the damage sensitive feature caused by damage from changes caused by other factors (e. g. age, level of excitation, and weather), and (3) the paucity of data recorded in damaged structures necessary to calibrate the health monitoring methods. Consequently, the main challenges for future research are: (1) to design low cost but high performance sensors and monitoring systems, making it possible to densely instrument many structures, (2) to develop methods that are robust and sensitive enough to detect also light damage (in particular one that is not visible), and (3) to build a knowledge base that can help reliably relate observed patterns in the data with actual observations of damage.

Recently, structural identification and health monitoring of buildings by detecting changes in wave travel time through the structure has received revived attention and has proven to be very promising [20,24,25,37,39,41,42,53,54,65]. Exploratory applications to data from damaged buildings [53,54] showed that the method (1) is robust when applied to damaging levels of earthquake response data, (2) is not sensitive to the effects of soil-structure interaction, and (3) is local in nature (i. e. gives results consistent with the spatial distribution and degree of the observed damage).

## Introduction

This volume would not be complete without addressing the catastrophic consequences of earthquakes, and damage in soil-structure systems, which is a complex, multidimensional, and highly interrelated set of phenomena.

Since the early days, the mathematical formulation of practical earthquake engineering problems has been dominated by *linear* differential equations [58], which *cannot* lead to chaos. Nevertheless, cost and the increasing needs of society have pushed the design into the nonlinear regimes of large deformations increasing the possibility of encountering chaotic dynamic phenomena in structural response, and have increased the complexity of the possible damage outcomes. However, working with parameters that produce chaotic output reduces the ability to predict the outcome. The chaotic behavior of nonlinear systems does not completely exclude the possibility to predict the response, but introduces an upper bound (prediction

horizons) [30]. Then the remaining question is over what time-scales can the predictions still be reliable. Also, the prediction of response requires a realistic physical *model*, while the practical outcome of most work in engineering remains *empirical*. Consequently, there is a conflict in the classical engineering description of the world. This conflict is in part due to the assumption that nature is moving forward, according to a deterministic law, and in part due to the fact that engineers model the world based on incomplete data, and thus working with unverifiable representation. This leads to the question what models are good for. The problem is further aggravated by the fact that the art of dynamical modeling tends to be neglected in discussions of nonlinear and chaotic systems, in spite of its crucial importance [2]. In the following review of structural health monitoring in earthquake engineering, it is accepted that there is a modeling problem, and the success of a method is gauged by the degree to which its predictions match the observed outcomes.

During the last several decades, stochastic processes have been used to help analyze the irregular behavior of deterministic systems with too many variables to be described in detail. Stochastic processes have been used also to model the deterministic response of structures to earthquake and wind forces, and as an approximate description of deterministic systems sensitive to their initial conditions. In some analyses, random noise is added to the model to account for the differences between the behaviors of model and prototype. This noise represents no more than lack of knowledge of the system structure or inadequacy of the identification procedure [23].

Following a damaging earthquake, buildings, bridges, dams and other structures are physically inspected for damage, and their safety is assessed. To assess the safety of buildings, the city departments of public safety (or their equivalents) dispatch inspectors to the field to “walk through” each building and write a report on the observed damage and safety concerns to its occupants. On the basis of such assessments, a color tag can be assigned to the building: (1) green if the structure is safe, (2) yellow if it has been damaged and needs to be evacuated, but is safe for the occupants to return to retrieve their belongings, and (3) red if it has been damaged to a degree that it is unsafe for the occupants to return to the structure [1]. When the affected area is relatively large, such inspection takes time (several weeks or longer), and the tagging is often first preliminary, to be revised at a later time after a preliminary inspection of all buildings has been completed. Such walk-in inspections can detect only damage that is visible, and there is always considerable subjectivity in the assessments. The major problem with such inspections is

however the timeliness, as aftershocks following the earthquakes can further damage a structure that has survived the main event but is weakened, and endanger the occupants. Another problem is the loss of function of a structure that may be safe, until a more detailed inspection and assessment is possible. This is particularly important for critical facilities, such as hospitals, as well as for major businesses, such as banks, for which interruption of work can cause major financial losses. Without a doubt, the ability to detect damage in structures early, as it occurs or soon after the earthquake, using some structural health monitoring system, and assess the state of safety of the structure before physical inspection is possible, can benefit society immensely. Ideally, based on instrumental data, such systems would be able to detect also hidden damage that is not visible to the naked eye. There would be benefit even when the damage is obvious, if that information is available immediately after the earthquake. To be effective, however, such systems must be sensitive enough to detect at least the significant damage, and also be accurate enough, to avoid false alarms and unnecessary and costly service interruption.

The objective of this article is to review the basic principles on which such systems operate, and to present some illustrative examples of several robust methods applied to full-scale buildings. This is followed by a discussion of remaining critical issues and directions for future research, in the view of the author.

## Literature Review

### Earthquake Damage Detection in Structural Health Monitoring Research

Earthquake damage detection in civil structures, such as buildings and bridges, is closely related to structural health monitoring of structures such as light aerospace structures, rotating machinery and offshore platforms, for example, that are of concern to other disciplines. A review of recent developments in this broader field, as applied to civil and mechanical systems, can be found in Chang et al. [7] and Liu et al. [31]. The earliest, and still the most popular methods for civil structures are those that use data from vibrational sensors, and detect changes in the vibrational characteristics of the structure – frequencies of vibration and mode shapes. Detailed reviews of vibrational methods in the general area of structural health monitoring can be found in a report by Doebling et al. [11], its shorter version as a journal paper [10], and a follow up report by Sohn et al. [40]. Another recent review of the vibrational methods can be found in Carden and Fanning [4].

These detailed reviews conclude that the currently available vibrational methods can determine if the structure has been damaged, but cannot indicate precisely the location of the damage, and are therefore referred to as *global*. Most vibrational methods monitor changes in the *modal* properties of the structures (modal frequencies and mode shapes). The stated difficulties associated with these methods include: (1) the presence of other factors than damage that produce similar effects on the monitored parameters not easy to isolate (e. g. the effects of soil-structure interaction on the measured frequencies of vibration, as well as environmental influences such as temperature and rain; [8,46,47]); (2) the redundancy of the civil engineering structures, which results in low sensitivity of the method (i. e. small change of the overall stiffness and consequently of the measured frequencies) when the damage is localized; and (3) dependence on detailed prior analytical models and/or prior test data for the detection and location of damage (supervised learning), which may not be readily available for a structure, may be outdated, and even when available represent only an idealization of the real structure [7,11]. Further critical issues identified are (4) the scarcity of objective comparisons of different procedures applied to a common data set, and (5) the number and location of sensors (techniques to be seriously considered for implementation in the field should demonstrate that they can perform well for small numbers of measurements). Finally, Doebling et al. [11] conclude that “while sufficient evidence exists to promote the use of measured vibration data for the detection of damage in structures, using both forced-response testing and long-term monitoring of ambient signals, the research needs to be more focused on the specific applications and industries that would benefit from this technology... Additionally, research should be focused more on testing of real structures in their operating environment, rather than laboratory tests of representative structures.”

In the follow up review, Sohn et al. [40] mention as outstanding problems: The reliance on analytical models to obtain the structural parameters from the data, not only in methods involving direct inversion, but also in those that use neural networks; and that the damage sensitive features are also sensitive to changes of the environmental and operational conditions of the structures. They mention as one of the most significant improvements since the previous review [11] the signal processing methods that do not rely on detailed analytic models, such as novelty/outlier analysis, statistical process control charts, and simple hypothesis testing (unsupervised learning), shown to be very effective to identify the onset of damage growth, and the presence of damage but not the damage type. In

this article, one such method – based on detection of novelties using wavelets – is reviewed and illustrated. Another significant advancement is the availability of more affordable MEMS sensors, as well as fiber optics, and piezoceramic sensors, and of wireless data communication technology.

In structural health monitoring literature, the vibrational methods are referred to as *global*, due to the relatively small number of sensors typically installed in structures, and can detect only significant damage [11,40]. The cost of seismic monitoring systems is still high, and trade-offs have to be made between the detail of the instrumentation of a particular structure and the number of structures that are instrumented. The truly *local* methods are those for nondestructive testing (NDT) of materials, which can detect the location of cracks or some other defects in a structural member. These methods typically use: (1) ultrasonic waves, which are attenuated quickly along the wave path, (2) need an actuator to create such waves, and (3) require direct access to the structural member, usually not readily available. Consequently, they are used to detect the location of the damage in a particular structural member, known or suspected to have been damaged, but are too costly and impractical for structural health monitoring of an entire structure [7]. To make a difference for society, structural health monitoring and early warning systems have to be reasonably priced so that they can be installed in many structures.

### Earthquake Damage Detection in Earthquake Engineering Research

In the earthquake engineering research, earthquake damage detection emerges from system identification studies of full-scale structures (typically involving identification of their frequencies of vibration and damping) from ambient and forced vibration test data, or earthquake records. Consequently, it is *data driven*, in contrast to the structural health monitoring research, which focuses on methodologies, validated mostly on “clean” numerically simulated data, and sometimes on laboratory data or small amplitude full-scale data. In the US, the earliest system identification studies from full-scale data follow the first deployment of strong motion instruments in structures [3], and continue through the 1960s [9,19,70]. More sophisticated studies from the system identification point-of-view using earthquake response data appear in the 1970s, following the San Fernando, California earthquake of 1971, which produced strong motion records in many buildings in the Los Angeles metropolitan area [66,67,68,69]. A significant finding of these studies is that the building frequencies of

actual structures vary significantly as a function of the level of the response. The variation is such that the fundamental frequency decreases during the largest shaking, but recovers afterwards during the remaining smaller amplitude shaking, or during subsequent shaking from aftershocks or small amplitude tests. The recovery may be partial or complete, and a large reduction of frequency of vibration during the earthquake is not always associated with visible damage. This is an important fact, as the decrease of the fundamental frequency of vibration is used as one of the global indicators of damage in structural health monitoring research, and also because many sophisticated structural identification methods are based on the assumption of stationarity and time invariance of the response.

Further, system identification studies of structures using earthquake records, considering the effects of the interaction of the structural vibrations with the vibration of the surrounding soil, appear in the 1960 and 1970s. The most detailed such full-scale studies are probably those of the Millikan library in Pasadena [33,34,71]. Understanding and consideration of the effects of soil-structure interaction in system identification and health monitoring of structures is of *fundamental importance* for the development of reliable methodologies, as this phenomenon is an integral part of the seismic response, and affects the estimation of both the frequencies of vibration and the inter-story drift, both used to infer about the state of damage. Nevertheless, these effects are typically ignored in structural health monitoring research. A detailed literature review on full-scale studies of soil-structure interaction can be found in Trifunac et al. [63], and a discussion of critical issues in recording and interpreting earthquake response of full-scale structures can be found in Trifunac and Todorovska [60,61].

### Damage and Damage-Sensitive Features

The damage of a structure can be described by the following five states: (1) no damage, (2) repairable (light and moderate) damage, (3) irreparable damage, (4) extreme damage, and (5) collapse [14].

Damage is associated with large deformations of the structural elements (usually expressed via the inter-story drift), which cause yielding of the structural steel or steel reinforcement and cracking of the structural concrete. Also, damage causes changes of the structural vibrational characteristics (frequencies of vibration), and wave propagation characteristics (wave velocities/travel times). This section presents the rationale for damage detection algorithms based on monitoring such changes. The concepts are illustrated on a simple soil-structure interaction model.

## Structural Models and Identification

### Structure as an Oscillator

From an elementary vibrational viewpoint, a structure responds to earthquake shaking as an oscillator characterized by its frequencies of vibration. The fixed-base frequencies are those of free vibration of the structure on *rigid* ground. They are the eigenvalues of a boundary value problem, and the associated eigenfunctions are referred to as mode shapes in structural engineering. The fixed-base frequencies depend only on the properties of the structure, i. e. on the structural stiffness and mass, while their dependence on the structural damping is small for most structures, which are lightly damped. In the linear range, the response of an n-degree-of-freedom system to earthquake shaking is a superposition of the modal responses. The contribution of the fundamental mode is usually the largest, and in engineering design structures are often represented by an equivalent single degree-of-freedom oscillator. For a single degree-of-freedom oscillator, the natural frequency of vibration is

$$\omega_1 = \sqrt{k/m}, \quad (1)$$

where  $k$  is its stiffness and  $m$  its mass. The frequency of such an oscillator is affected little by typical fluctuations of the mass due to variations in the life load of the structure, and is mostly affected by changes in the stiffness. Damage would cause loss of stiffness, and consequently reduction of the fixed-base frequency of vibration. If  $\omega_{1,\text{ref}}$  is a reference frequency corresponding to reference stiffness  $k_{\text{ref}}$ , then for the damaged structure

$$(\omega_1/\omega_{1,\text{ref}})^2 = k/k_{\text{ref}}. \quad (2)$$

As the fixed-base frequency depends on the *overall* stiffness of the structure, it is by definition a *global* property, and would not change much due to localized damage of civil structures, which are designed to be highly redundant. One advantage of detecting damage by monitoring changes in fixed-base frequency of vibration is that, in the ideal case when the ground is practically rigid (as compared to the structure), and the excitation is relatively broadband, the fixed-base frequency can be determined using only one sensor, on the roof, as the frequency of the peak of the Fourier transform of the roof response. The availability of recorded response at ground level would produce a more accurate estimate, as a transfer-function can be computed between the roof and ground level response motion. Changes in the frequency versus time can be estimated from the Fourier transform in moving windows in time.

Buildings are founded on soil, which is flexible and deforms under the action of forces from the incident waves and from the vibrating structure. Even if rigid, a structure founded on soft soil will vibrate, with the soil acting as a spring. The soil adds both *flexibility* and *dissipation mechanism* to the vibrations of the structure and soil, which act as a coupled system. Two sources of dissipation are (1) scattering of the incident waves from the foundation and (2) radiation of energy into the soil (through vibration of the foundation, which acts as a source of waves radiated in semi-infinite medium). The third source of dissipation is in the structure, and includes a distribution of frictional sources, and hysteretic damping during nonlinear response. The soil-structure system has its own resonant frequencies and “damping”, which is a combination of the contributions from the structure and from the soil. The fundamental frequency of the system is always lower than the fundamental fixed-base frequency of the structure, but the associated system damping can be larger or smaller than the damping of the structure alone, depending on the radiation damping and relative stiffness of the structure with respect to the soil.

In conclusion, the difficulties with Fourier-type analyses for identification of the building frequencies are that these give the resonant frequencies and equivalent damping of the *system*, which depend on the soil, and that they are global properties. Also, there is no knowledge base of changes in such frequencies (for different types of structures and different types of soils) related to different degrees of damage.

### Structure as a Wave Guide

Alternatively, the seismic response can be represented as a superposition of waves that propagate through the structure, reflect from its exterior and interior boundaries and interfere [22,39,41,48,49,50,56,57]. Loss of stiffness due to local damage would cause delays in the wave propagation through the damaged part, which could be detected using seismic response data recorded on each side of the damaged area, along the wave path. A change in wave travel time would depend *only on the changes of the physical properties between the sensors*. Hence, the wave methods are more sensitive to local damage than the modal methods, and should be able to point out the location of damage with a relatively small number of sensors. Additionally, the local changes in travel time are not sensitive to the effects of soil-structure interaction (as demonstrated in [44,45]), which is a major obstacle for the modal methods based on detecting changes in the structural frequencies.

The basic principles of the method are as follows. It is based on D’Alembert’s solution of the wave equation, and representation of the structural response as a superposition of waves traveling through the structure. In contrast, the modal methods are based on representation in the Fourier domain, as superposition of modes of vibration.

The wave travel time between two points

$$\tau = d/V_s, \quad (3)$$

where  $d$  is the distance traveled and  $V_s$  is the equivalent shear wave velocity in the part of the building between the two sensors. The latter is related to the rigidity via

$$V_s = \sqrt{\mu/\rho}, \quad (4)$$

where  $\mu$  is the shear modulus and  $\rho$  is the density. Hence, reduction of rigidity due to damage will produce a reduction of the equivalent shear wave velocity, which will produce an increase in the pulse travel time, relative to the travel time for the undamaged state. Let  $\mu_{\text{ref}}$  be reference rigidity, and  $V_{s,\text{ref}}$  and  $\tau_{\text{ref}}$  be the corresponding shear wave velocity and wave travel time. Then their changes are related as follows

$$\frac{\tau}{\tau_{\text{ref}}} = \frac{1}{V_s/V_{s,\text{ref}}} = \frac{1}{\sqrt{\mu/\mu_{\text{ref}}}}. \quad (5)$$

Global changes can also be detected by monitoring the *total* wave travel time from the base to the roof of a building. Let  $\tau_{\text{tot}}$  be the travel time of seismic waves from the point of fixity (ground level) to the roof. Then the building fundamental fixed-base frequency  $f_1 = 1/(4\tau_{\text{tot}})$  assuming that the building as a whole deforms like a shear beam. Based on this relation,  $f_1$  can be estimated using data from only two horizontal sensors. While the goodness of this approximation of  $f_1$  may vary from one building to another, the changes in  $f_1 = 1/(4\tau_{\text{tot}})$  will still depend *only* on changes in the building itself, and not on changes in the soil, and monitoring of changes in such an estimate of  $f_1$  can be used as a global indicator of damage in a building [44,45].

Figure 1 shows a conceptual model for the analysis, in which the building is a horizontally layered medium, with the interfaces between layers at the floor slabs. For vertically incident waves, or/and a narrow building, the layered medium will be traversed by waves propagating upward and downward. Let the excitation be a pulse. At each interface, an incident pulse will be split into a reflected pulse, and a transmitted pulse, and at the roof total reflection will occur. The transmission and reflection coefficients will depend on the impedance contrast between the layers, in particular on the shear wave velocities, which will change due

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 1  
Layered building model

to loss of stiffness caused by damage. Because of reflections and material damping, an incident wave pulse will attenuate as it propagates through the structure, and will be also modified in a dispersive medium. This is schematically illustrated in Fig. 1. The total wave motion propagating upward in a layer will be a superposition of all the pulses, those from direct incidence and those from different generations of reflections. The same applies for the pulses propagating downward. The downward propagating pulses that are reflected back into the building, from the interface with the soil, will interfere with the newly incident pulses just transmitted into the building. Eventually, constructive interference will occur, and the standing waves will be formed, which are the fixed-base modes of vibration of the building.

The wave travel times can be detected by tracing the propagation of a pulse. Such a pulse can be created by signal processing of recorded earthquake response data, i. e. by deconvolution of the recorded response, which results in the *system impulse response functions*. These can be obtained by computing the transfer-functions between the motion at a particular level and the reference motion, and then computing inverse Fourier transform. The location of

the virtual source would coincide with the location of the sensor that recorded the reference motion. Let  $u_{ref}(t)$  be the reference motion,  $u_i(t)$  be the motion at level  $i$ . Then the impulse response at that level,  $h_i(t)$ , can be computed as

$$h_i(t) = FT^{-1} \left\{ \frac{\hat{u}_i(\omega)\hat{u}_{ref}^*(\omega)}{|\hat{u}_{ref}(\omega)|^2 + \varepsilon} \right\}, \tag{6}$$

where the hat symbol indicates Fourier transform, the bar indicates complex conjugate, and  $\varepsilon$  is a regularization parameter, used to avoid dividing by a very small number [39]. At the reference level, the transfer-function is unity, and its inverse is a Dirac delta function.

Proof-of-concept applications to two buildings damaged by earthquakes, and to an analytical model of a building-foundation-soil system showed that the method (1) is robust when applied to damaging levels of earthquake response data, (2) is not sensitive to the effects of soil-structure interaction, and (3) is local in nature (i. e. gave results consistent with the spatial distribution and degree of the observed damage) [44,45,53,54]. The damaged buildings are the former Imperial County Services Building – a 6-story RC structure in El Centro, California, damaged by the 1979 Imperial County earthquake and later demolished [52,54], and the 7-story RC building in Van Nuys, damaged by both the 1971 San Fernando and the 1994 Northridge earthquakes [53,62]. Another application is to a building in Banja Luka in former Yugoslavia, using records of 20 earthquakes, one of which led to levels of response that might have caused structural damage, but no damage was reported following a detailed inspection [65]. This study was aimed at learning about the *threshold change* in the building fixed-base frequency, estimated from wave travel time, associated with damage.

While this method is local, its spatial resolution is limited by the number of sensors. A minimum of two sensors (at the base and at the roof) are required to determine if the structure has been damaged, and additional sensors at the intermediate floors would help point out the part of the structure that has been damaged. For example, one additional sensor between these two would help identify if the damage has been in the part of the structure above or beyond that sensor.

There have been only a few publications in the literature on wave propagation methods for structural health monitoring and damage detection in civil structures other than the NDT methods [20,35,37,41,53,54,64]. Similar wave travel time analyses (using deconvolution or the NIOM method) of buildings that have not been damaged include Kawakami and Oyunchimeg [24,25], Snieder and

Şafak [39], Kohler et al. [26], and Todorovska [44,45]. These studies show that the wave travel times reflect well the characteristics of the buildings studied. A recent review can be found in [53,54].

In conclusion, the advantages of this wave method are its local nature achieved with a relatively small number of sensors, its insensitivity to the effects of soil-structure interaction, and the ability to estimate the structural fixed-base frequency using data from only two sensors (one at the base and one at the roof), which will extend the usability of old data. An outstanding issue to its implementation is the lack of a knowledge base relating changes in wave travel times (and fixed-base frequency) with different levels of damage for different types of structures.

### Inter-Story Drift

Structural damage of a building under seismic loads occurs primarily due to large *lateral* deformations of its columns and shear walls, as they are by design much stiffer in the vertical direction to carry the static gravity loads. A measure of the lateral deformations is the inter-story drift. The inter-story drift is also a good indicator of the damage to the architectural (nonstructural) components (partition walls, facade, windows, etc.), which can be costly. As the value of the structure is only about 10–25% of the total construction cost of a building, the damage to the nonstructural components represents a significant portion of the total repair cost following an earthquake. For these reasons, the inter-story drift is one of the performance parameters considered in design. It is important to note that the structural and nonstructural damage are related only to the drift caused by *deformation* of the structure, and not by the drift caused by *rigid body motion*.

The level of structural damage (to a particular element and to the structure as a whole) associated with a particular level of inter-story drift varies depending on the type of structure, height and ductility, among other factors, and is still *not a completely resolved issue in structural engineering* [14]. To illustrate this correlation, Table 1 shows some values of drift associated with different levels of damage (simplified from [14]) for ductile and nonductile moment resisting frames (MRF), and based on experimental data, field observations and measurements and theoretical analyses. (Ductile are those structures that can undergo large nonlinear deformations before failure as opposed to the nonductile ones, which experience quick brittle failure soon after exceeding the linear range of response). It can be seen from Table 1 that, roughly, inter-story drift > 1% for ductile and > 0.5% for nonductile moment resisting frames causes damage beyond repair, and drift > 3% and

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Table 1

Drift ratios (in %) associated with various damage levels (based on [14])

State of damage	Ductile MRF	Nonductile MRF
No damage	< 0.2	< 0.1
Repairable damage		
Light	0.4	0.2
Moderate	< 1.0	< 0.5
Irreparable damage	> 1.0	> 0.5
Severe damage, life safe, partial collapse	1.8	0.8
Collapse	> 3.0	> 1.0

> 1% for the same type of frames is significant for life safety.

Drift-based assessment of the state of damage of a building following an earthquake would require: (1) measurement of the drift during the earthquake shaking, and (2) knowledge base of values of drift associated with different states of damage for the particular structure. The accuracy of the assessment would depend on the accuracy of both the measurements and knowledge base, as discussed in the following.

The drift is commonly estimated from the difference of displacements obtained by double integration of recorded velocities in the structure [28]. While in the past these calculations were performed by specialists, after the data had been manually collected, at present, such calculations can be done in near real time either using telemetry or at the site by “client” software supplied by the instrument manufacturer. Such estimates of drift however are limited by: (1) the inability to estimate reliably the *static* component of the drift associated with permanent deformations (i. e. the drift at  $\omega \rightarrow 0$ ), which is not negligible for structures experiencing large deformations in the nonlinear range of response, when damage occurs, and (2) the inability to separate the drift due to deformation of the structure (which is directly related to damage) from the drift due to rigid body rocking because of inadequate instrumentation.

The inability to estimate reliably the static part of the displacement (and drift) is due to the fact that the traditional (translational) sensors are sensitive also to rotational motions of their support [16,59], which produce errors in the recorded translations and the integrated displacements mimicking permanent displacement [16]. This problem can be solved, by deploying sensors recording all six components of motion (three translations and three rotations) and performing appropriate instrument correction. Such future deployments and their assessment are of

interest to and have been advocated by the International Working Group on Rotational Seismology [29].

The *dynamic* (at  $\omega > 0$ ) drift due to deformation of the structure only is not simple to estimate, especially for structures on soft soil, with significant rocking response of their foundation. The rocking motions of the foundation are due to the wave nature of the incident seismic waves, and also due to feedback forces from the structure acting on the soil. The foundation rocking results in relative horizontal displacement between two floors and is not related to damage. Such excessive relative displacements, can affect the stability of the structure, which may collapse before yielding occurs in its members, but that is out of the scope of this article. The *average dynamic* floor rocking can be calculated from the difference of vertical motions recorded by two sensors on that floor, assuming the floor slab is rigid, but such sensor configurations are not routinely installed even in recent denser deployments in buildings. If the building foundation is fairly rigid, the rigid body rocking of the structure can be estimated from two vertical sensors at foundation level. Unfortunately, even such data is lacking for most of the significant earthquake records in buildings, and even in recent dense deployments (e. g. in [6]). It is noted that vertical sensors are also less sensitive to rotation of their support and to cross-axis motion [15,43].

It should be noted here that permanent displacements can be measured directly using GPS (Global Positioning System), and there have been such deployments in long period structures [5]. While GPS measurements are not contaminated by rotation, they are limited by the fact that what is measured are only the roof *absolute* displacements, which makes it impossible to separate the displacement due to deformation of the structure from the rigid body horizontal translation and rocking. The other two limitations in the presently available systems are the small sampling rate (10–20 Hz) and the limited resolution of GPS for civilian applications ( $\pm 1$  cm horizontally and  $\pm 2$  cm vertically; [5]).

Damage estimation algorithms based on published damage versus drift relationships (e. g. in [1]) started to be implemented by manufacturers of strong motion instruments in structural seismic monitoring systems but there is no data yet of their performance. Despite errors in the assessment resulting from the mentioned difficulties, such algorithms are robust when applied to earthquake data and can be useful within a suite of methods.

Matrices like the one in Table 1 [14] can serve as a knowledge base in assessing the class of damage state for a given maximum drift reached. Such matrices are associated with scatter, due to the variability from one struc-

ture to another within the same class. Another source of scatter is the source of the data. Because of the limited amount of full-scale earthquake response data, information for such relationships is complemented by laboratory data (e. g. pushover tests). While the drift in the former is the total drift, which includes the drift due to rigid body motion, the drift in the latter is only due to deformation of the structural elements.

In conclusion, outstanding issues in measuring the drifts are: (1) separation of the drift due to deformation of the structure only, and (2) estimation of the static component of the drift. It may be possible to resolve these issues by deploying six degrees-of-freedom sensors. An outstanding issue in the knowledge base is more accurate drift versus damage state relations for specific buildings.

### System Identification Considering the Effects of Soil-Structure Interaction – Example

As mentioned earlier, both for frequency-based identification and for damage assessment based on drift, the effects of soil-structure interaction have a significant effect on the reliability of the estimation. This section presents a simple soil-structure interaction model, in which the building is represented as a shear beam. It illustrates the different contributions to the inter-story drift, the difference between fixed-base and apparent building frequencies and their relationship, and the relationship between the model fixed-base frequencies and wave travel times. More detailed analysis can be found in [44,45].

The model is shown in Fig. 2. It consists of a shear beam of height  $H$  and fundamental fixed-base frequency of vibration  $f_1$ , representing the building, and a rigid foundation of width  $2a$  embedded in elastic half-space. The excitation, in general, is an incident wave (plane P and SV or a Rayleigh wave). The motion on the surface of the half-space in the absence of any structures and excavations, acting as scatterers, is commonly referred to as “free-field.” The effective motion at the base of the building differs from the free field motion at the half-space surface, because of two phenomena: (1) scattering and diffraction of the incident waves from the excavation for the foundation, (2) differential displacements due to feedback forces from the building and foundation acting on the half-space through the contact with the foundation. The former phenomenon is referred to as kinematic and the latter as dynamic or inertial interaction. For the linear problem and a rigid foundation, the two problems can be solved separately and their effects superimposed. The apparent frequency, which is the one estimated from peaks of energy distributions of the response, is affected mostly by the dy-

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 2  
Soil-structure interaction model

dynamic interaction, while the apparent drift is also affected by the type of incident waves, and the point rotation they produce on the ground surface, and the size of the foundation relative to the wavelength of the incident waves. To consider only the effects of the dynamic interaction, it suffices to take excitation consisting of only horizontal foundation driving motion.

The building foundation has three degrees of freedom: horizontal translation  $\Delta$ , vertical translation  $V$ , and rocking angle  $\phi$ . In the *linear approximation* of the solution, only the horizontal and rocking motions are coupled, while the vertical motions are independent of the other degrees of freedom. Let the excitation be horizontal driving motion  $\Delta_{inp}$ . Then, the foundation response will be

$$\Delta = \Delta_{inp} + \Delta_{fb} \quad (7)$$

$$\phi = \phi_{fb}, \quad \phi_{inp} = 0, \quad (8)$$

where  $\Delta_{fb}$  and  $\phi_{fb}$  are the feedback horizontal displacement and rocking angle, which depend on the stiffness of the foundation and on the forces with which the structure and foundation interact with the soil, and are the solution of the dynamic equilibrium equations of the foundation. The building horizontal displacement  $u(\xi)$ , as a function of the height  $\xi$  measured from ground level, is a sum of

three terms

$$u(\xi) = \Delta + \phi\xi + u^{rel}(\xi), \quad (9)$$

where the first two terms are from the translation and rotation as a rigid body, and the third term is relative displacement from *deformation* during the vibration. The damage in the building will depend only on  $u^{rel}(\xi)$ . It is noted here that including the coupling between horizontal and vertical motions turns a linear elastic system into a nonlinear elastic system [21].

For the shear beam,  $u(\xi)$  can be computed as a solution of the wave equation for moving boundary conditions. It can be represented as a sum of motions  $u_{\Delta}(\xi)$ , which is due to translation of the base only, and  $u_{\phi}(\xi)$ , which is due to rotation of the base only, where

$$u_{\Delta}(\xi) = \Delta \frac{\cos k_S(H - \xi)}{\cos k_S H} \quad (10)$$

$$u_{\phi}(\xi) = \frac{\phi \sin k_S \xi}{k_S \cos k_S H}, \quad (11)$$

where  $k_S = \omega/V_S$  and  $V_S = \sqrt{\mu_b/\rho_b}$  is the shear wave velocity in the building. Equations (10) and (11), reflecting the interference conditions in the building, imply fundamental fixed-base frequency of the structure  $f_1 = V_S/(4H)$  and overtones at  $f_n = (2n - 1)V_S/(4H)$ ,  $n > 1$ . If  $\tau$  is

the time it takes for a wave to propagate from the base (at  $\xi = 0$ ) to the top (at  $\xi = H$ ), the interference conditions in the shear beam imply

$$f_1 = 1/(4\tau). \quad (12)$$

Let us now consider the frequencies of vibration. If the building did not deform, the foundation and the building would oscillate freely as a rigid body with frequency  $f_{RB}$  such that

$$\frac{1}{f_{RB}^2} = \frac{1}{f_H^2} + \frac{1}{f_R^2}, \quad (13)$$

where  $f_H$  and  $f_R$ , referred to as the horizontal and rocking foundation frequency, depend on the stiffness of the foundation and on the system mass [33]. If the building is flexible and would freely vibrate on a fixed base with fundamental frequency  $f_1$ , on flexible soil it would freely vibrate with fundamental frequency  $f_{sys}$ , which is the soil-structure *system* frequency, and is a result of the coupling between the vibration of the building and the vibrations of the foundation. The following relationship holds approximately

$$\frac{1}{f_{sys}^2} = \frac{1}{f_{RB}^2} + \frac{1}{f_1^2}. \quad (14)$$

This relationship implies that  $f_{sys} < \min(f_1, f_{RB})$ , i. e.  $f_{sys}$  is always lower than both  $f_1$  and  $f_{RB}$ , and that if  $f_1$  and  $f_{RB}$  differ significantly, then  $f_{sys}$  would be closer to the smaller one of them. How much  $f_1$  would differ from  $f_{sys}$  would depend on the *relative* stiffness of the soil compared to the building. The energy of the response of vibrating systems is concentrated around their resonant frequencies, which are measured from the frequency of the peaks of the corresponding transfer-functions. The energy of the building roof response (absolute and relative) will be concentrated around  $f = f_{sys}$ .

Of interest is how to estimate the relevant quantities from recorded response during an earthquake. If the building foundation is fairly rigid, and there are at least two appropriately located vertical sensors to compute the foundation rocking  $\varphi$  (average value), then  $u^{rel}(\xi)$  can be computed. To measure  $f_{sys}$ , the driving motion  $\Delta_{inp}$  is also needed, so that the transfer function between the building response and  $\Delta_{inp}$  can be computed. Motion from a nearby free-field site can be used for that purpose, but such sites are often not available, and truly free-field sites practically do not exist in urban areas. Also, for most instrumented buildings, the foundation rocking cannot be estimated because of the lack of two vertical sensors even under the ideal conditions that the foundation behaves as rigid.

Consequently, in reality, for most instrumented buildings, the true relative roof displacement cannot be estimated from the recorded data, but only the *apparent* relative displacement

$$\begin{aligned} u_{app}^{rel}(H) &= u(H) - \Delta \\ &= u^{rel}(H) + \varphi H \end{aligned} \quad (15)$$

which includes the contribution of the roof displacement due to rigid body rotation, and only the transfer-function  $|u_{app}^{rel}(H)/\Delta|$  can be computed, the peak of which gives the *apparent* building frequency  $f_{app}$ , which is different from both the fixed base frequency and the system frequency.

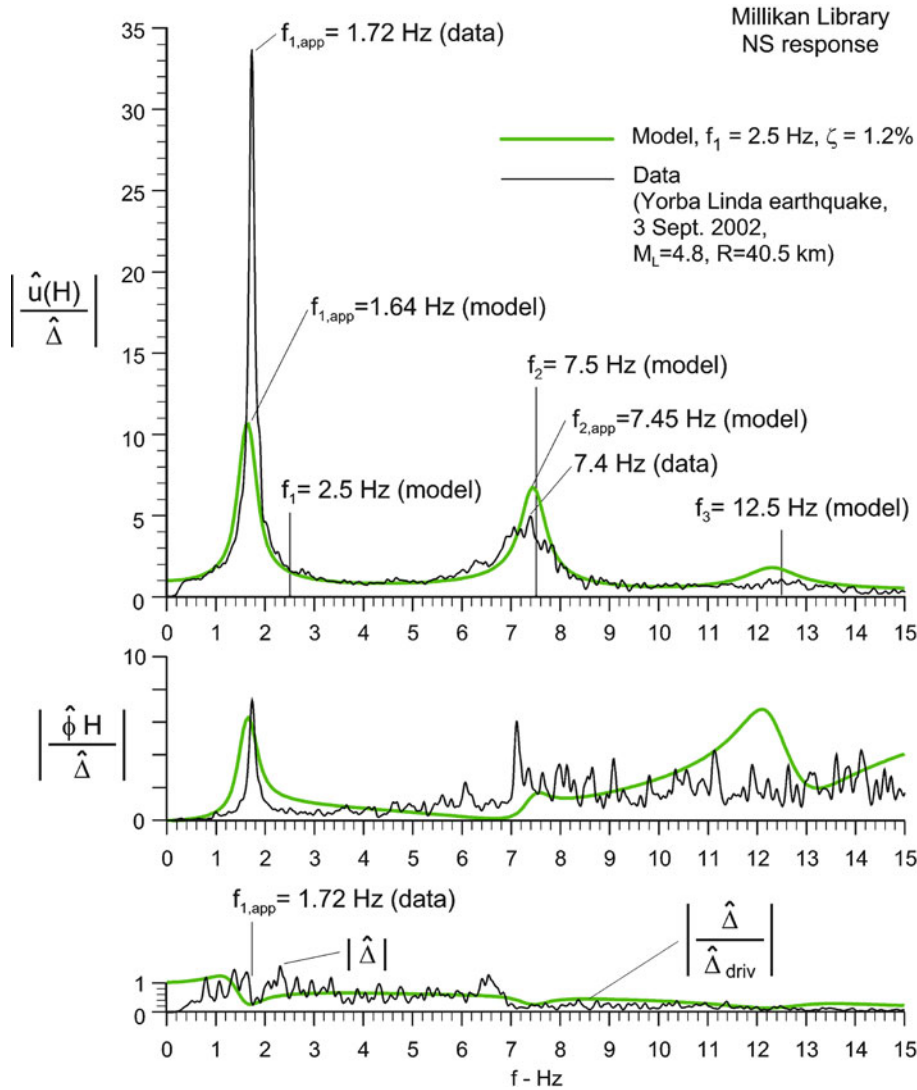

What is of interest for structural health monitoring is that the energy of the roof response will be concentrated around  $f = f_{sys}$ , not around  $f = f_1$ . It is also significant that the damage will depend on  $u^{rel}(\xi)$ , while what is usually measured is  $u^{rel}(\xi) + \varphi H$ .

Figure 3 (redrawn from [45]) shows a comparison of model and measured transfer-functions for a model of the NS response of Millikan library. The model has  $f_1 = 2.5$  Hz, height  $H = 44$  m, shear wave velocity in the soil 300 m/s, and Poisson ratio 0.333, while the data are from the Yorba Linda earthquake of 2002. Figure 4 shows the corresponding impulse response function for a virtual source at the ground floor. It can be seen that there is a very good qualitative agreement despite the model simplicity and roughly chosen parameters.

### Novelty Detection in the Recorded Response

Novelty detection is used in data mining to detect unusual events in data. The unusual events are *outliers* deviating from the *trend*. Within the framework of multi-resolution analysis, the trends and novelties are determined by splitting the signal in two subbands, one smooth (low frequency) and the other one containing the detail (high frequency). By consecutively splitting the smooth subband, trends and detail are obtained at different resolution levels. If  $J$  is the last level, then there will be  $J$  detail subbands  $D_i$ ,  $i = 1, \dots, J$  and one smooth subband  $S_J$ . The last smooth subband can be expanded in a basis of scaling functions  $\varphi_{j,k}(t)$ , and each of the detail subbands – in a basis of wavelet functions  $\psi_{j,k}(t)$ , leading to the representation of a discrete time signal  $s[n]$ ,  $n = 1, \dots, N$

$$\begin{aligned} s[n] &= \sum_{j=1}^J D_j[n] + S_J[n] \\ &= \sum_{j=1}^J \sum_{k=1}^{N/2^j} d_{j,k} \psi_{j,k}[n] + \sum_{k=1}^{N/2^J} s_{J,k} \varphi_{J,k}[n]. \end{aligned} \quad (16)$$

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 3  
 Model (thick line) versus Yorba Linda, 2002, earthquake (thin line) NS response: transfer-functions of roof response (top), and base rocking response (middle) with respect to horizontal response of ground level. The plot in the bottom shows the model horizontal response at ground level for unit driving motion (thick line), and the Fourier spectrum of the earthquake response at ground level (thin line) on a relative scale

The coefficients of the expansion,  $d_{j,k}$  and  $s_{j,k}$ , can be computed using the fast wavelet transform. The pyramid algorithm on which it is based [36] is shown in Fig. 5.

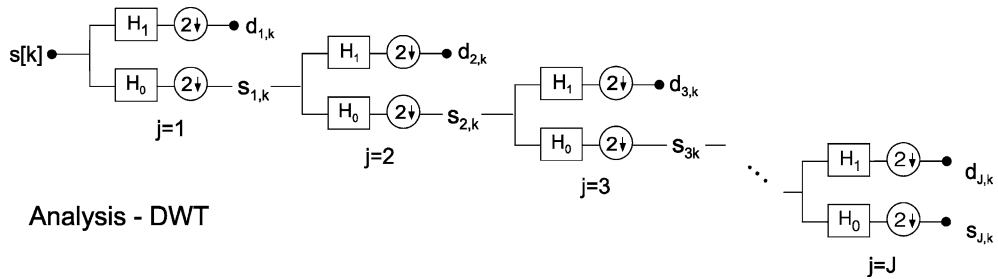

The wavelet functions  $\psi_{j,k}[n]$ , where  $j$  is a level and  $k$  is the time shift, are localized both in frequency and in time, and each wavelet is a projection of the signal onto the corresponding tile of the phase plane. For a wavelet basis that is orthonormal, the square of a wavelet coefficient represents the energy of the signal in the corresponding tile of the phase plane.

The damage detection method is based on the assumption that, when damage occurs and there is a sudden loss of stiffness, there will be some abrupt change in the response that would produce novelties. These would be seen as spikes in the time series of the square of the detail coefficients (e.g.  $d_{1,k}^2$ ,  $k = 1, \dots, N/2$  for the highest detail coefficients) plotted versus the central time of the corresponding wavelet. These spikes indicate high frequency energy in the response. For data with Nyquist frequency 25 Hz, the novelties can be best seen in the highest detail

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 4  
 Model (*thick line*) versus Yorba Linda, 2002, earthquake (*thin line*) NS response: impulse responses of roof (*top*), and base rocking (*middle*) to input impulse at ground level (*bottom*), i. e. roof horizontal motion, foundation rocking and ground level horizontal motions deconvolved with the resultant horizontal motion at ground level

subband (12.5 to 25 Hz), which is away from the frequency of the first few modes of typical buildings, where the response is amplified by the structure.

Applications to numerically simulated response of simple models with postulated damage [17,18] have shown that this method *can point out very precisely the time of damage*, but the changes are detectable only if the spikes in the wavelet coefficients are above the noise. Further, the magnitude of the novelties is larger if the sensor is closer

to the location of the damaged member, and may be difficult to detect if the sensor is far from the location of damage. There have been only few applications to earthquake response records in buildings. Rezaei et al. [38] and Hou et al. [18] have shown that there *are* novelties (spikes) in earthquake records of damaged buildings, but have not discussed and extracted other possible causes. Todorovska and Trifunac [51,55] presented a detailed analysis of the correspondence between the spatial distribution and am-

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 7  
 ICS building: schematic representation of the damage following the 1979 Imperial Valley earthquake (reproduced from [27])

plitudes of the detected novelties and the observed damage for the Imperial County Services building (see illustrations in Sect. “Examples”), and also analyzed the “noise.” Their study shows that: (1) the spatial distribution and magnitudes of the novelties were generally consistent with the spatial distribution and degree of the observed damage, (2) the timing of those suggesting major damage agreed with the time of significant drops in frequency and of large inter-story drifts, and (3) were much larger in the transverse response, in which the building was stiffer.

In summary, the method of novelties is very effective in determining the time of occurrence of damage, and can reveal the spatial distribution and degree of damage if there is sufficiently dense instrumentation. Unresolved issues are how to distinguish novelties that are not caused by damage, and small novelties due to larger damage far from the sensor from those due to small damage close to the sensor.

## Examples

In this section, the methods previously described are illustrated for the former Imperial County Services (ICS) building – a rare example of an instrumented building damaged by an earthquake, for which description of damage and the strong motion data are available. The build-

ing is first described and the strong motion data of the Imperial Valley earthquake, which severely damaged the building.

The ICS building was a 6-story reinforced concrete structure located in El Centro, California (Fig. 6a). It was designed in compliance with the 1967 Uniform Building Code, and its construction was completed in 1969. It had plan dimensions  $41.70 \times 26.02$  m, height 25.48 m, and pile foundation. Up to depth of 9 m, the underlying soil consisted of soft to medium-stiff damp sandy clay with organic materials, with inter-layers of medium dense moist sand, and beneath 9 m it consisted of stiff, moist sandy clay and silty clay [27].

The building was severely damaged by the Imperial Valley earthquake of October 15, 1979 ( $M = 6.6$ ), and was later demolished (Fig. 6b,c). Figure 7 shows a schematic representation of the observed damage. The major failure occurred in the columns of frame F (at the east end of the building) at the ground floor. The vertical reinforcement was exposed and buckled, and the core concrete could not be contained, resulting in sudden failure and shortening of the columns subjected to excessive axial loads. This in turn caused an incipient vertical fall of the eastern end of the building, causing cracking of the floor beams and slabs near column line F on the second, third and higher floors. Columns in lines A, B, D, and E

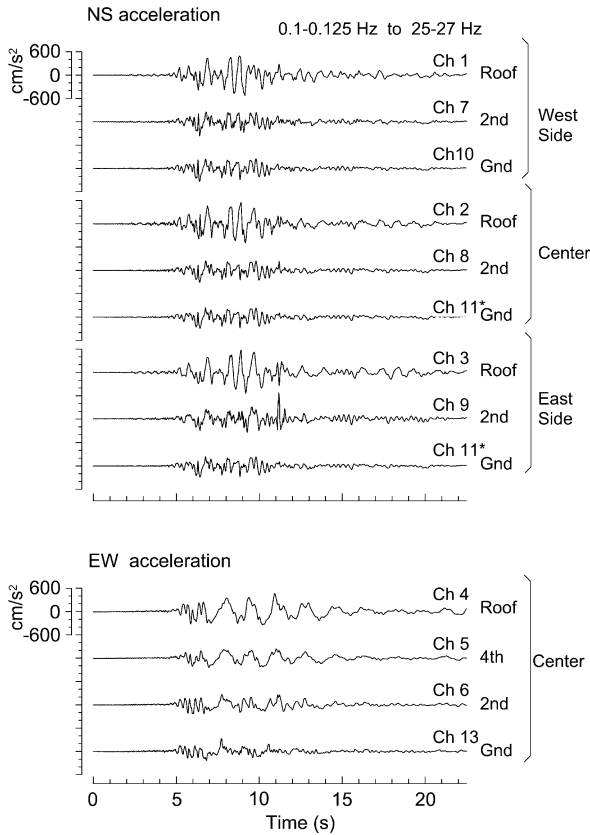

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 8  
 ICS building: layout of the seismic monitoring array

also suffered damage. Columns in frames A and E did not suffer as extensive damage as shortening and buckling of the reinforcement in line F at the east side, but large concrete cracks and exposed reinforcement could be seen near the base. In the columns in interior frames B through E, visible cracks and spalling of the concrete cover were also observed [27].

The building was instrumented by a 16-channel seismic monitoring array (installed by the California Geological Survey, formerly the California Division of Mines and Geology) consisting of a 13-channel structural array of force balance accelerometers (FBA-1), with a central analog recording system, and a tri-axial SMA-1 accelerome-

ter in the “free field,” approximately 104 m east from the northeast corner of the building (Fig. 8). Figure 9 shows the accelerations (corrected) during the Imperial Valley earthquake. The peak accelerations at the roof and ground floor were 571  $\text{cm/s}^2$  and 339  $\text{cm/s}^2$  in the NS direction and 461  $\text{cm/s}^2$  and 331  $\text{cm/s}^2$  in the EW direction.

Figure 10 shows the NS (top) and EW (bottom) inter-story drifts computed from band-pass filtered displacements (between 0.1–0.125 Hz and 25–27 Hz) (redrawn from [52]). Hence, they represent only a limited view of the actual drifts – through a tapered window in the frequency domain, and a combination of the drift due to *rigid body rocking* (one of the effects of soil-structure interac-

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 9

ICS building: accelerations (NS and EW components) recorded during the 1979 Imperial Valley earthquake

tion) and drift due to relative *deformation* of the building. The horizontal lines show 0.5%, 1%, and 1.5% drift levels. The plotted drifts suggest: (1) “soft” first story in both NS and EW directions, (2) larger flexibility in the EW direction, and (3) significant torsional response, probably amplified by the wave passage, and by the asymmetric distribution of stiffness in the NS direction at the soft first story (see Fig. 8). It can be seen that during the most severe shaking, the inter-story drifts exceeded 0.5% for NS and 1.5% for EW motions, consistent with irreparable to severe damage (Table 1).

Figure 11 shows results of time frequency analysis (using Gabor transform) for the EW response (redrawn from [52]). Parts a and b show the ground floor accelerations, and the roof relative displacements (at the center of the building), both included as background information. Part c shows the skeleton (the thicker line), which is a smoothed estimate of the amplitude envelope of the estimated signal, which is the relative roof response near the

first system frequency. The thin line is the actual amplitude envelope (that for the broad-band signal), determined by Hilbert transform. This plot is included to help monitor rapid changes in the amplitude of the signal and artifacts in the estimate of instantaneous frequency caused by violations of the asymptoticity condition. Part d shows the Fourier spectra of the relative roof displacement (the solid line), and of the ground floor acceleration (the dashed line, on a relative scale), both included as background information. Part e shows the variations of the system frequency as a function of amplitude of response (estimated from the ridge and skeleton of the Gabor transform), with the arrows indicating the direction of increasing time. Part f shows the variations of the system frequency versus time, estimated from the ridge of the Gabor transform. The missing segments and the dashed lines in parts e and f correspond to time intervals where the estimates cannot be obtained or are not believed to be reliable, due to rapid variations of the envelope of the amplitude, and/or very weak “signal.” The rectangle in part f with sides  $2\sigma_t = 1.42$  s and  $2\sigma_\nu = 0.22$  Hz illustrates the theoretical uncertainty of the estimates due to the finite resolution of the Gabor transform. In practice, the uncertainty is larger due to violations of the asymptoticity assumption. Finally, the numbered open dots (occurring at different times in parts b, c, e, and f) correspond to some characteristic points in time associated with changes in amplitude or frequency, as well as a few other points in-between. It can be seen that the EW frequency dropped rapidly from  $\nu \approx 0.88$  Hz at  $t \approx 3.5$  s to  $\nu \approx 0.67$  Hz at  $t \approx 7$  s ( $\Delta\nu \approx 0.21$  Hz  $> \sigma_\nu$ ;  $\Delta\nu/\nu \approx 24\%$ ), and then continued to drop gradually to  $\nu \approx 0.53$  Hz at  $t \approx 17$  s ( $\Delta\nu \approx 0.14$  Hz  $\approx \sigma_\nu$ ;  $\Delta\nu/\nu \approx 20.9\%$ ).

Figure 12 shows results of impulse response analysis for the EW response (redrawn from [53]). The different types of lines correspond to different time intervals of the recorded motion, before, during, and after the major damage occurred:  $t < 7$  s,  $7 < t < 13$  s, and  $t > 13$  s (based on novelty analysis, discussed below). The plots on the left correspond to an input impulse at the ground floor, and those on the right – to an input impulse at the top. The latter plots show two waves propagating downwards, one acausal (in negative time, representing the wave going up) and one causal (in positive time). The delays in the pulse arrival during the second and third time interval are obvious, and are consistent with the occurrence of damage, as determined using other methods. The wave travel times suggest, for EW motions initial wave velocities of 201 m/s through the first floor, 183 m/s between the 2nd and 4th floors, and 111 m/s between the 4th floor and roof. The velocity of an equivalent uniform shear beam is 142 m/s.

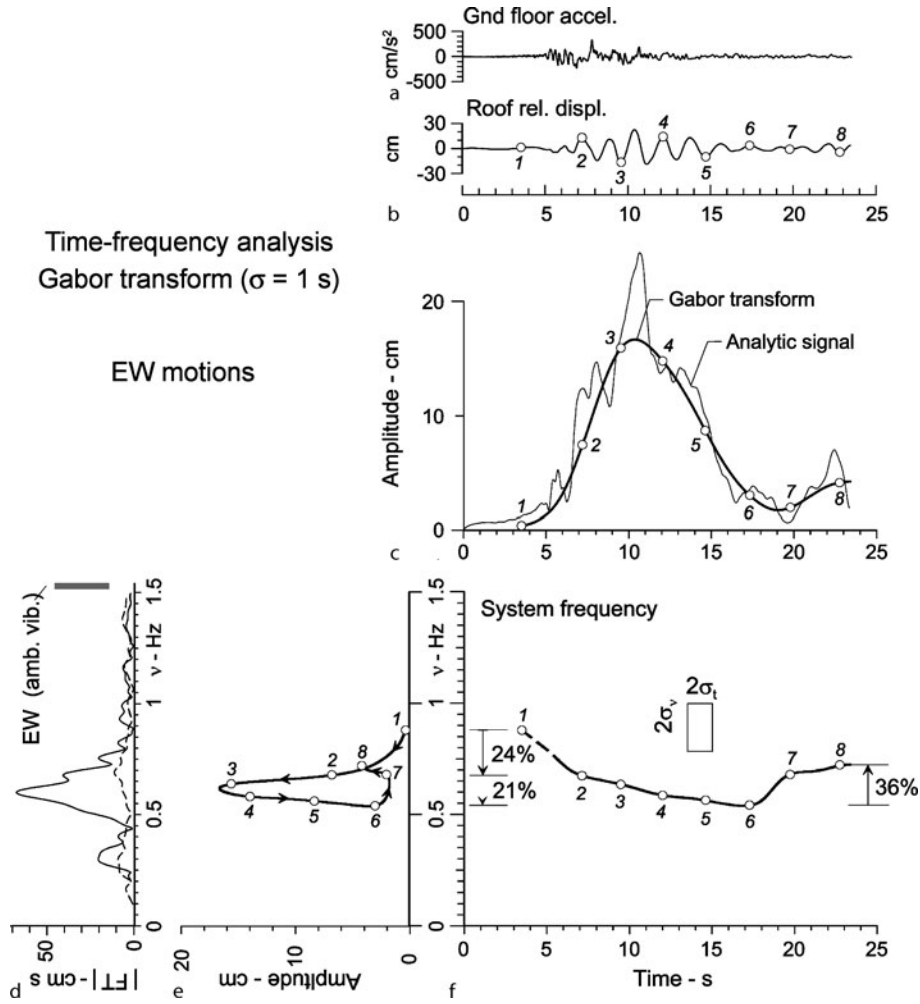

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 10  
 ICS building: inter-story drifts during the Imperial Valley earthquake

Figure 13 shows the corresponding reduction of stiffness. It can be seen that, for EW motions, the reduction was the largest in the first story (80% during the second time window), but was also large in the upper stories (72% between the 2nd and 4th floors, and 60% between the 4th floor and roof). This is consistent with the spatial distribution of the observed damage (Fig. 6), which was the largest in the first story.

Figure 14 shows the results of novelty analysis, for the EW accelerations (part a) and for the NS accelerations at the east side of the building, where the most severe damage occurred (part b) (redrawn from [55]). The inter-story drifts (in %) between the corresponding stories are also shown, by a solid line for NS and by a dashed line for EW motions. Selected novelties are identified by letters. Novelties T1–T3 are believed to be caused by damage, and are seen in all channels. Novelties G1–G3 and g1–g4 originate in the ground motion, and L1–L6 are possibly caused by

local damage close to the sensor, or by other causes. By far the largest novelty is T3, which has amplitude more than an order of magnitude larger than all other novelties in the NS acceleration at the 2nd floor at the east side of the building, where the most severe damage (failure of the first story columns of frame F) occurred. The timing of T3 suggests that the collapse of the columns of the first story occurred at about 11.2 s after trigger. The other two large novelties consistent with the observed damage, T1 and T2, occurring at about 8.2 s and 9.2 s after trigger, indicating damage that weakened the structure, before the collapse of the first story columns.

Figure 15 (redrawn from [54]) shows a comparison of different values of frequency for EW motions:  $f_1$  from wave travel times (the gray line), system frequency  $f_{sys}$  estimated from time-frequency analysis (the red line; [52], and  $f_1$  using ETABS models [27]. T1, T2, and T3 mark the times of occurrence of major damage, as indicated by nov-

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 11  
 ICS building: time frequency analysis for EW response

elties in the response [51,51]. It can be seen that  $f_1$  from wave travel times is consistent with the results of other independent studies.

Finally, Fig. 16 shows results for another building, the Van Nuys 7-story hotel, which has been damaged by earthquakes [53]. It shows a comparison of fixed-base frequency  $f_1$  during 11 earthquakes estimated from wave travel times, and system frequency  $f_{sys}$  during the same earthquakes estimated by time frequency analysis (Gabor transform), as well as estimates of  $f_{sys}$  during ambient vibration tests. The analysis shows that, during the San Fernando earthquake,  $f_1$  decreased by about 40% (relative to its value within the first 5 s from trigger), which corresponds to a decrease in the global rigidity of about 63%. During the Northridge earthquake,  $f_1$  decreased by about

22% (relative to its value within the first 3 s from trigger), which corresponds to a decrease in the global rigidity of about 40%. The analysis also showed that, although  $f_{sys}$  was always smaller than  $f_1$ , their difference varied, contrary to what one could expect from a linear soil-structure interaction model. It also showed that while  $f_{sys}$  was significantly lower during the Landers and Big Bear earthquakes, compared to the previous earthquakes,  $f_1$  did not change much, with is consistent with the fact that these earthquakes (which occurred about 200 km away from the building) did not cause any damage. The study concluded that monitoring changes in  $f_{sys}$  can lead to false alarms about the occurrence of damage, and that  $f_1$ , as estimated from wave travel times by the proposed method, is a much more reliable estimator of damage.

**Future Directions**

A successful system for earthquake damage detection and early warning would involve applications of technologies in fields other than structural mechanics and engineering, such as sensing, data communication, signal processing, artificial intelligence, and decision analysis. The end of the 20th and the beginning of the 21st centuries have been marked by a revolution in the development and af-

fordability of the technologies in these other fields. Much research in structural health monitoring for civil structures has been directed towards *adaptation* of these technologies to civil structures. The remaining challenge is to develop a system that is robust, redundant and well calibrated, which will neither miss significant damage nor produce many false alarms. Achieving this would require focusing the efforts and resources to further develop those methodologies that are robust when applied to real structures and data, and to calibrate them using documented full-scale data. Further enhancement of the spatial resolution of such methods would benefit from inexpensive and reliable new sensors.

All this will have to be accomplished by continuously expanding our experience in dealing with the complexities of metastable damage states of engineering structures, which will gradually become more feasible with the formulation of realistic physical models. Nevertheless, the practical outcome of most approaches in engineering will probably remain empirical. Also, the art of dynamical modeling will have to be further developed, especially for the assessment of the damaged states of engineering structures that are highly nonlinear and chaotic. In the end, in structural health monitoring, and in design of earthquake resistant structures, the fact that some modeling problems

will remain will have to be accepted. However, considerable progress will be achieved if the success is gauged by the degree to which the predictions match observations in the full-scale structures, contributing towards safety and minimization of disruption and productivity of society in seismically active regions.

## Van Nuys Hotel

**Data: 11 earthquakes and 5 ambient vibration tests in 24 years**

**$f_{sys}$**  – form time-freq. energy distribution,  **$f_1$**  – from wave travel times.

**$f_1$  decrease:** 1971 San Fernando - by ~40%. 1994 Northridge - by ~22%.

Difference between  $f_1$  and  $f_{sys}$  is not constant (see Landers and Big Bear).

Earthquake Damage: Detection and Early Warning in Man-Made Structures, Figure 16

Variations of  $f_1$  and  $f_{sys}$  in the Van Nuys building during the 11 earthquakes, between February of 1971 and December of 1994. Measured values of  $f_{sys}$  during five ambient vibration tests: (1) in 1967, following construction, (2) in 1971, after San Fernando earthquake and before repairs, (3) in 1971 after the repairs, (4) in January of 1994, 18 days after the Northridge earthquake, and (5) in April of 1994, after the building was restrained by wooden braces

### Glossary

**Data transmission system** A multi-component device aimed at the transmission of seismic signals over a distance, also denoted as a telecommunication system. Each data transmission system consists of two basic elements: a transmitter that takes information and converts it to an electromagnetic signal and a receiver that receives the signal and converts it back into usable information.

Modern telecommunication systems are two-way and a single device, a transceiver, acts as both a transmitter and receiver. Transmitted signals can either be analogue or digital. In an analogue signal, the signal is varied continuously with respect to the information. In a digital signal, the information is encoded as a set of discrete, binary values. During transmission, the in-

formation contained in analogue signals will be degraded by noise, while, unless the noise exceeds a certain threshold, the information contained in digital signals will remain intact. This represents a key advantage of digital signals over analogue signals. A collection of transmitters, receivers or transceivers that communicate with each other is a telecommunication network. Digital networks may consist of one or more routers that route data to the correct user.

### Earthquake early warning system (EEWS)

A real-time, modern information system that is able to provide rapid notification of the potential damaging effects of an impending earthquake, through rapid telemetry and processing of data from dense instrument arrays deployed in the source region of the event of concern (regional EEWS) or surrounding the target infrastructure (site-specific EEWS). A “regional” EEWS is based on a dense sensor network covering a portion or the entirety of an area that is threatened by earthquakes. The relevant source parameters (event location and magnitude) are estimated from the early portion of recorded signals and are used to predict, with a quantified confidence, a ground motion intensity measure at a distant site where a target structure of interest is located. On the other hand, a “site-specific” EEWS consists of a single sensor or an array of sensors deployed in the proximity of the target structure that is to be alerted, and whose measurements of amplitude and predominant period on the initial *P*-wave motion are used to predict the ensuing peak ground motion (mainly related to the arrival of *S* and surface waves) at the same site.

**Earthquake location** An earthquake location specifies the spatial position and time of occurrence for an earthquake. The location may refer to the earthquake hypocenter and corresponding origin time, a mean or centroid of some spatial or temporal characteristic of the earthquake, or another property of the earthquake that can be spatially and temporally localized.

**Earthquake magnitude** The magnitude is a parameter used by seismologists to quantify the earthquake size. The Richter magnitude scale, or more correctly, local magnitude *ML* scale, assigns a single number to quantify the amount of seismic energy released by an earthquake. It is a base-10 logarithmic scale obtained by calculating the logarithm of the combined horizontal amplitude of the largest displacement from zero on a seismometer output. Measurements have no limits and can be either positive or negative.

Introduced by the Japanese seismologist Aki in 1962, the seismic moment is the present-day physical pa-

parameter used to characterize the earthquake strength. It represents the scalar moment of one of the couples of forces producing the dislocation at an earthquake fault and it is measured from the asymptotic DC level on displacement Fourier spectra of recorded seismic signals.

**Probability density function – PDF** A function in one or more dimensional space  $\mathbf{X}$  that (i) when integrated over some interval  $\Delta x$  in  $\mathbf{X}$  gives a probability of occurrence of any event within  $\Delta x$ , and (ii) has unit integral over space  $\mathbf{X}$ , where  $\mathbf{X}$  represents a space of possible events.

**Seismic data-logger** A core element of a digital seismic station, whose aim is to record the analogue signals from seismic sensors and convert them in digital form with an assigned sampling frequency. Ground motion signals acquired by seismic sensors are pre-amplified and anti-aliasing filtered in a data-logger before they are digitalized through an AD (analog-to-digital) converter. The main technical features of a modern data-logger are the number of available channels, the allowed sampling frequencies, the dynamic range, the digitizer clock type, the storage capacity (PCMCIA, internal flash and/or hard disk, USB, ...), network interfaces (ethernet, wireless lan, or ppp) and power consumption.

**Seismic hazard** The probability that at a given site, a strong motion parameter (generally the peak ground acceleration) exceeds an assigned value in a fixed time period. When the seismic hazard is computed for an extended region it is generally represented as a map. The hazard map is commonly computed for a constant probability level (10%, 5% or 2%) and a given time window (50 years). It represents the spatial variation of the peak ground acceleration (expressed in percentage of gravity  $g$ ) to be exceeded in the given period with the chosen probability level.

Earthquake early warning systems can provide a mean for the evaluation of real-time hazard maps which evolve with time, as new information about source location, magnitude and predicted peak ground motion parameters are available soon after the earthquake occurrence.

**Seismic sensors** Instruments used to record the ground vibration produced by natural and artificial sources, generally denoted as seismometers. A seismometer measures the relative motion between its frame and a suspended mass. Early seismometers used optics, or motion-amplifying mechanical linkages. The motion was recorded as scratches on smoked glass, or exposures of light beams on photographic paper. In modern

instruments the proof mass is held motionless by an electronic negative feedback loop that drives a coil. The distance moved, speed and acceleration of the mass are directly measured. Most modern seismometers are broadband, working on a wide range of frequencies (0.01–100 Hz). Another type of seismometer is a digital strong-motion seismometer, or accelerometer, which measures soil acceleration. Due to its relatively high dynamic range, the accelerometer can record unsaturated strong amplitude signals at close distances from a large earthquake. This data is essential to understand how an earthquake affects human structures.

### Definition of the Subject

The origin of the term “early warning” probably goes back to the first decades of the last century. However, the first practical use of an “early warning” strategy was military and it was developed during the “cold war” years as a countermeasure to the potential threat from inter-continental ballistic missiles. The objective of these systems was to give an alert to target areas as soon as a missile was detected by a radar system or a launch was detected by a satellite system. In this context the term “lead time” was defined as the time elapsing between the detection of the missile and the estimated impact on the target.

In the last decades the use of the term “early warning” greatly expanded. It is used with small, but significant, variations in various types of risks, from epidemiological, to economic, social, and of course all the types of natural and environmental risks.

In fact, in these contexts, including some natural risks such as hydro-geological and volcanic, the warning is not given at the onset of the catastrophic phenomenon, but after the occurrence of some precursory phenomena which can trigger a catastrophic event (for instance intensive rainfall for hydrological risk, earthquakes and/or ground deformation for volcanic risk). The main consequence of this difference is an increase in the probability of issuing false alarms.

The case of earthquake early warning is similar to missile early warning. The alert is given after an earthquake is detected by a network of seismometers. An earthquake early warning is based on the fact that most of the radiated energy is contained in the slower traveling phases (S- and surface waves traveling at about 3.5 km/s or less) which arrive at any location with a delay with respect to small amplitude higher velocity phases (P-waves, travelling at about 6–7 km/s) or to an electromagnetically transmitted (EM) signal giving the warning.

## Introduction

Many regions in the world are affected by natural hazards such as earthquakes, tsunamis, volcanoes, floods, storms, landslides, etc., each of which can have devastating socio-economic impacts. Among these natural events, earthquakes, have been among the most recurrent and damaging hazards during last few decades, resulting in large numbers of casualties, and massive economic losses [30].

The problem of earthquake risk mitigation is faced using different approaches, depending upon the time scale being considered. Whilst over time scales of decades it is of utmost importance that land use regulations and building/infrastructure codes are continuously updated and improved, for time scales of a few years, the main risk mitigation actions are at the level of information and education in order to increase individual and social community awareness about potentially damaging hazards. Over shorter time scales (months to hours), it would naturally be of great benefit to society as a whole if the capability to accurately predict the time, location and size of a potentially catastrophic natural event were available. However, due to the great complexity of the natural processes of concern, such predictions are currently not possible.

On the other hand, on very short time scales (seconds to minutes), new strategies for earthquake risk mitigation are being conceived and are under development worldwide, based on real-time information about natural events that is provided by advanced monitoring infrastructures, denoted as “early warning systems”.

## Regional and On-site Early Warning Systems

Earthquake Early Warning Systems (EWS) are modern, real-time information systems that are able to provide rapid notification of the potential damaging effects of an impending earthquake through the rapid telemetry and processing of data from dense instrument arrays deployed in the source region of the event of concern. Such systems allow mitigating actions to be taken before strong shaking and can significantly shorten the time necessary for emergency response and the recovery of critical facilities such as roads and communication lines.

Advances have been made towards the implementation of operational systems in Japan, Taiwan, and Mexico using two different approaches, i. e., “regional warning” and “onsite warning” [25]. A regional warning system is based on a dense sensor network covering a portion or the entire area that is threatened by earthquakes. The relevant source parameters (earthquake location and magnitude) are estimated from the early portion of recorded signals and are used to predict, with a quantified confidence,

a ground motion intensity measure at a distant site where a target structure of interest is located. Alternatively, “onsite warning” systems consist of a single sensor or an array of sensors deployed in the proximity of the target structure that is to be alerted, and whose measurements on the initial *P*-wave motion are used to predict the ensuing peak ground motion (mainly related to the arrival of *S* and surface waves) at the same site.

## Implementation of Early Warning Systems Worldwide

In Japan, since the 1965, the JNR (Japanese National Railway) has developed and operated the Urgent Earthquake Detection and Alarm System (UrEDAS), which is an onsite warning system along the Shinkansen (bullet train) railway. UrEDAS is based on seismic stations deployed along the Japanese Railway with an average distance of 20 km. An alert is issued if the horizontal ground acceleration exceeds 40 cm/s<sup>2</sup>. In the 1996, the UrEDAS was combined with a new seismometer called “compact UrEDAS” [31,32,33].

On the other hand, for about one decade the Japanese Meteorological Agency (JMA) has been developing and experimenting with a mixed single station and network based early warning system to generate immediate alerts after earthquakes with JMA Intensity greater than “lower 5” (approximately  $M > 6$ ) [24]. During a testing period from February 2004 to July 2006, the JMA sent out 855 earthquake early warnings, only 26 of which were recognized as false alarms [40]. On October 1, 2007 the broadcast early warning system developed by the Japanese Meteorological Agency (JMA) became operative. In this system, the first warning is issued 2 s after the first *P* phase detection, if the maximum acceleration amplitude exceeds the threshold of 100 cm/s<sup>2</sup>.

In the United States the first prototype of an early warning system was proposed by Bakun et al. [4] and developed for mitigating earthquake effects in California. It was designed to rapidly detect the Loma Prieta aftershocks and send an alert when the estimated magnitude was greater than 3.7, in order to reduce the risk of the crews working in the damaged area. The system is composed of four components: ground motion sensors deployed in the epicentral area, a central receiver, radio repeaters and radio receivers. The prototypical system worked for 6 months, during which time 19 events with  $M > 3.5$  occurred, 12 alerts were issued with only 2 missed triggers and 1 false alarm.

Based on pioneering work by Allen and Kanamori [2] seismologists across California are currently planning real-time testing of earthquake early warning across the

state using the ElarmS (Earthquake Alarms Systems) methodology [1]. The approach uses a network of seismic instruments to detect the first-arriving energy at the surface, the *P*-waves, and translate the information contained in these low amplitude waves into a prediction of the peak ground shaking that follows. Wurman et al. [47] illustrated the first implementation of ElarmS in an automated, non-interactive setting, and the results of 8 months of non-interactive operation in northern California.

Since 1989, in Mexico, the civil association CIRES (Centro de Instrumentacion y REgistro Sismico) with the support of Mexico City Government Authorities, developed and implemented the Mexican Seismic Alert System (SAS) [15]. The SAS is composed of (a) a seismic detection network, 12 digital strong motion stations deployed along 300 km of the Guerrero coast, (b) a dual communication system: a VHF central radio relay station and three UHF radio relay stations, (c) a central control system which continuously controls the operational status of the seismic detection and communication system and, when an event is detected, automatically determines the magnitude and issues the alarm, and (d) a radio warning system for broadcast dissemination of the alarm to end users. After 11 years, the SAS system recorded 1373 events in the Guerrero coast, it issued 12 alerts in Mexico city, with only one false alarm.

In Taiwan, the Taiwan Central Weather Bureau (CWB) developed an early warning system based on a seismic network consisting of 79 strong motion stations installed across Taiwan and covering an area of  $100 \times 300 \text{ km}^2$  [44]. Since 1995 the network has been able to report event information (location, size, strong motion map) within 1 min after an earthquake occurrence [39]. To reduce the report time, Wu and Teng [44] introduced the concept of a virtual sub-network: as soon as an event is triggered by at least seven stations, the signals coming from the stations less distant than 60 km from the estimated epicenter are used to characterize the event. This system successfully characterized all the 54 events occurred during a test period of 7 months (December 2000 – June 2001), with an average reporting time of 22 s.

In Europe, the development and testing of EEWS is being carried out in several active seismic regions. Europe is covered by numerous high-quality seismic networks, managed by national and European agencies, including some local networks specifically designed for seismic early warning around, for example, Bucharest, Cairo, Istanbul and Naples.

In Turkey, an EEWS is operative, called PreSEIS (pre-seismic shaking), to provide rapid alert for Istanbul and surrounding areas. It consists of 10 strong motion sta-

tions located along the border of the Marmara sea along an arc of about 100 km, close to the seismogenetic zone of the Great Marmara Fault Zone with real time data transmission to Kandilli-Observatory [7,14]. An alarm is issued when a threshold amplitude level is exceeded.

In Romania, the EEWS is based on three tri-axial strong motion sensors deployed in the Vrancea area with a satellite communication link to the Romanian Data Center at NIEP in Bucharest [7,42]. The system is based on first *P* wave detection and prediction of the peak horizontal acceleration recorded in Bucharest, allowing for a warning time of about 25 s.

On 2006 the European Union launched the 3-year project SAFER (Seismic Early Warning for Europe), which is a cooperative scientific program aimed at developing technological and methodological tools that exploit the possibilities offered by real-time analysis of signals coming from these networks for a wide range of actions, performed over time intervals of a few seconds to some tens of minutes. The project includes the participation of 23 research groups from several countries of Europe. The primary aim of SAFER is to develop tools that can be used by disaster management authorities for effective earthquake early warning in Europe and, in particular, its densely populated cities.

### **The Development of an Early Warning System in Campania Region, Southern Italy**

The present article is focused on the description of technologies and methodologies developed for the EEWS under construction in southern Italy.

With about 6 million inhabitants, and a large number of industrial plants, the Campania region (southern Italy), is a zone of high seismic risk, due to a moderate to large magnitude earthquake on active fault systems in the Apenninic belt. The 1980,  $M = 6.9$  Irpinia earthquake, the most recent destructive earthquake to occur in the region, caused more than 3000 casualties and major, widespread damage to buildings and infrastructure throughout the region.

In the framework of an ongoing project financed by the Regional Department of Civil Protection, a prototype system for seismic early and post-event warning is being developed and tested, based on a dense, wide dynamic seismic network under installation in the Apenninic belt region (ISNet, Irpinia Seismic Network).

Considering an earthquake warning window ranging from tens of seconds before to hundred of seconds after an earthquake, many public infrastructures and buildings of strategic relevance (hospitals, gas pipelines, railways,

railroads, ...) in the Campania region can be considered as potential EEWS target-sites for experimenting with innovative technologies for data acquisition, processing and transmission based on ISNet. The expected time delay to these targets for the first energetic *S* wave train is around 30 s at about 100 km from a crustal earthquake occurring in the source region. The latter is the typical time window available for mitigating earthquake effects through early warning in the city of Naples (about 2 million inhabitants, including suburbs).

This article illustrates the system architecture and operating principles of the EEWS in the Campania region, focusing on its innovative technological and methodological aspects. These are relevant for a reliable real-time estimation of earthquake location and magnitude which are used to predict, with quantified confidence, ground motion intensity at a distant target site.

The system that we describe in this article uses an integrated approach from real time determination of source parameters to estimation of expected losses.

This problem must be dealt in an evolutionary (i. e., time-dependent) and probabilistic framework where probability density functions (PDFs) for earthquake location, magnitude and attenuation parameters are combined to perform a real-time probabilistic seismic hazard analysis.

### Earthquake Potential and Seismic Risk in the Campania Region

The southern Apennines are an active tectonic region of Italy that accommodates the differential motions between the Adria and Tyrrhenian microplates [23]. The majority of the seismicity in this region can be ascribed to this motion. These earthquakes mainly occur in a narrow belt along the Apennine chain and are associated with young faults, with lengths ranging from 30 to 50 km, and mainly confined to the upper 20 km of the crust [28,41].

Recent stress and seismic data analyzed by [29] using earthquake locations and fault mechanisms show that the southern Apennines are characterized by an extensional stress regime and normal-fault earthquakes. However, the occurrence of recent (e. g., 5 May, 1990, Potenza,  $M$  5.4; 31 October – 1 November, 2002, Molise,  $M$  5.4) and historic (e. g., 5 December, 1456,  $M$  6.5) earthquakes do not exclude other mechanisms such as strike-slip faulting.

There have been numerous large and disastrous events in the southern Apennines, including those which occurred in 1694, 1851, 1857 and 1930. The location of historical earthquakes retrieved from the CFTI (Catalogo dei Forti Terremoti in Italia, Catalogue of Strong Earthquakes

in Italy) database [6] is shown in Fig. 1. The most recent and well documented event is the complex normal-faulting  $M$  6.9 Irpinia earthquake of 23 November, 1980 [5,43].

As recently indicated in the study by Cinti et al. [9], the southern Apennines has a high earthquake potential with an increasing probability of occurrence for  $M \geq 5.5$  earthquakes in the next decade. The new national hazard map (Gruppo di lavoro MPS, 2004), indicates that the main towns of the region fall in a high seismic hazard area, where it is expected that a peak ground acceleration value ranging between 0.15 and 0.25 g will be exceeded in 475 years.

These aspects make the Campania region a suitable experimental site for the implementation and testing of an early warning system. A potential application of an early warning system in the Campania region should consider an expected time delay to the first energetic *S* wave train varying between 14–20 s at 40–60 km distance to 26–30 s at about 80–100 km, from a crustal earthquake occurring along the Apenninic fault system. Based on those delay times, a large number of civil and strategic infrastructures located in the Campania region are eligible for early warning applications, as shown in Fig. 2.

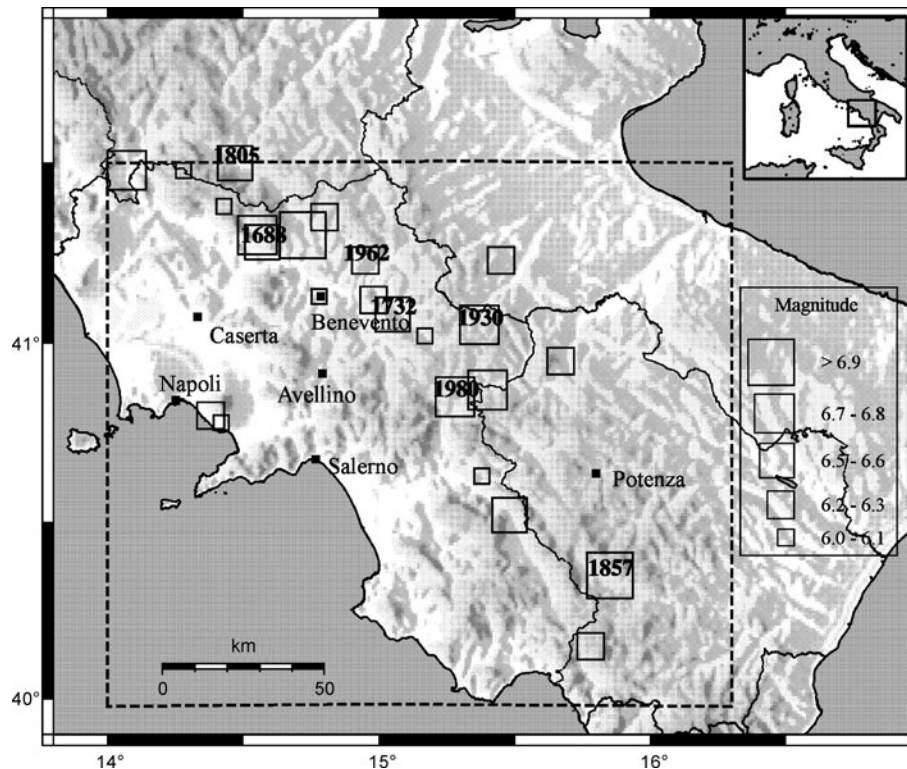

### Seismic Network Architecture and Components

The Irpinia Seismic Network (ISNet) is a local network of strong motion, short period and broadband seismic stations deployed along the southern Apenninic chain covering the seismogenic areas of the main earthquakes that occurred in the region in the last centuries, including the  $M_s = 6.9$ , 23 November 1980 event.

The seismic network is composed of 29 stations organized in six sub-nets, each of them composed of a maximum of 6–7 stations (Fig. 3). The stations of a given sub-net are connected with real-time communications to a central data-collector site called the Local Control Center (LCC).

The different LCCs are linked to each other and to a Network Control Center (NCC) with different types of transmission systems. The whole data transmission system is fully digital over TCP/IP, from the data-loggers, through the LCC, to the NCC, located in the city of Naples, 100 km away from the network center.

To ensure a high dynamic recording range, each seismic station is equipped with a strong-motion accelerometer and a three-component velocity meter (natural period = 1 s). In five station locations the seismometers are replaced by broadband (0.025–50 Hz) sensors to guarantee good-quality recording of teleseismic events. Data acquisition at the seismic stations is performed by the inno-

Earthquake Early Warning System in Southern Italy, Figure 1

Location of the main historic earthquakes retrieved from the CFTI database using as region of interest that defined by the external rectangle. The box dimensions are proportional to magnitude. The best constrained historic earthquakes are reported along with their date of occurrence

vative data-logger Osiris-6, produced by Agecodagis sarl. The hardware/software characteristics of the system allow it to install self-developed routines to perform real time specific analysis.

The data-loggers are remotely controlled through a configuration tool accessible via TCP/IP, managing sampling rate, gain, application of calibration signal to the resets of disks, GPS, etc. Furthermore, a complete station health status is available, which helps in the diagnosis of component failure or data-logger malfunction. The data-loggers store the data locally or send it to each LCC where the real-time data management system Earthworm (developed at USGS-United State Geological Survey) is operating.

A calibration unit is installed at each seismic station to automatically provide a periodic calibration signal to seismic sensors in order to verify the correct response curve of the overall acquisition chain.

The power supply of the seismic station is provided by two solar panels (120 W peak, with 480 Wh/day), two 130 Ah gel cell batteries, and a custom switching circuit board between the batteries. With this configura-

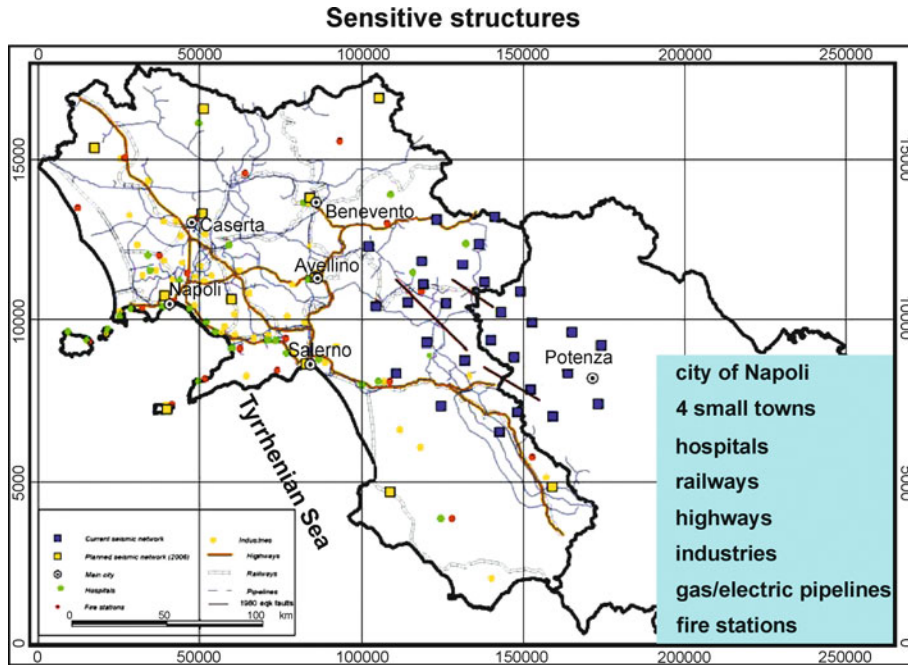

tion, 72-h autonomy is ensured for the seismic and radio communication equipment. Each site is also equipped with a GSM/GPRS programmable control/alarm system connected to several environmental sensors and through which the site status is known in real time. With SMS (Short Message Service) and through the programmable GSM controller, the seismic equipment can be completely reset remotely with a power shutdown/restart. The GSM also controls the device start/stop release procedure when the battery goes over/under a predefined voltage level.

Unlike the seismic stations, LCCs, which host the data server and transmission system instruments, are AC power supplied with back-up gel batteries guaranteeing 72-h stand-by power.

### Real-Time Data Transmission System

ISNet has a distributed star topology that uses different types of data transmission systems.

The seismic stations are connected via spread-spectrum radio bridges to the LCCs. Data transmission between LCCs from the local control center to the network

Earthquake Early Warning System in Southern Italy, Figure 2

Symbols explanation: green squares – seismic stations; blue squares – Local Control Centres (LCC); yellow lines – WLAN radio linkconnecting seismic stations and LCC; white segments – SDH carrier-class radio; red triangles – radio link repeaters; red circle – Network Control Centre RISS in Naples; yellow squares – main cities

control center in Naples is performed through different technologies and media types as shown in Table 1.

To transmit waveforms in real time from the seismic stations to the LCCs, a pair of outdoor Wireless LAN

bridges operating in the 2.4 GHz ISM band are used. Our tests have shown that these instruments operate continuously without any radio link failure due to adverse weather conditions (snow, heavy rain).

Earthquake Early Warning System in Southern Italy, Table 1  
Specification of the ISNet data communication links

Type	Frequency (GHz)	Bandwidth (Mbps)	# Number of		Comments
			Stations	LCCs	
Spread spectrum Radio	2.45	54	27 <sup>3</sup>	–	Throughput around 20–24 Mbps for links between 10–15 km (based on ethernet packets with an average size of 512 bytes).
Ethernet	–	100	2 <sup>3</sup>		Stations connected with ethernet cable to LCC infrastructure.
Wireline SHDSL over Frame Relay	–	2.048	–	2	At the central site (RISSC) the CIR <sup>1</sup> is maximum 1.6 Mbps depending upon number of PVCs <sup>2</sup> . At the remote (LCC) site the bandwidth is 640/256 kbps with CIR of 64 kbps in up and download, over ADSL with ATM ABR service class.
Microwave Radio SDH	7	155	–	6	Carrier-class microwave link. Connect six LCC with 155 Mbps (STM-1) truly full bandwidth available. First link constructed for early warning applications.
Microwave Radio HyperLAN/2	5.7	54	–	2	The true usable maximum throughput of HyperLAN/2 is 42 Mbps.

<sup>1</sup> CIR Committed Information Rate.

<sup>2</sup> PVC permanent virtual circuit.

<sup>3</sup> Not included stations hosted by LCCs.

The two primary backbone data communication systems of the central site use Symmetrical High-speed Digital Subscriber Line (SHDSL) technology over a frame-relay protocol. Frame relay offers a number of significant benefits over analogue and digital point-to-point leased lines. With the latter, each LCC requires a dedicated circuit between the LCCs and NCC. Instead, the SHDSL frame relay is a packet-switched network, which allows a site to use a single frame-relay phone circuit to communicate with multiple remote sites through the use of permanent virtual circuits. With virtual circuits, each remote site is seen as part of a single private LAN, simplifying IP address scheme maintenance and station monitoring.

Each seismic site has a real-time data flow of 18.0 kbps (at 125 Hz sampling rate for each physical channel), and the overall data communication bandwidth that is needed is around 540 kbps for 30 stations. ISNet supports this throughput under the worst conditions seen and it has been designed to guarantee further developments, such as the addition of further seismic or environmental sensors, without the need for larger economic and technological investment.

## Network Management and Data Archiving

### The Network Manager Application and Implementation Overview

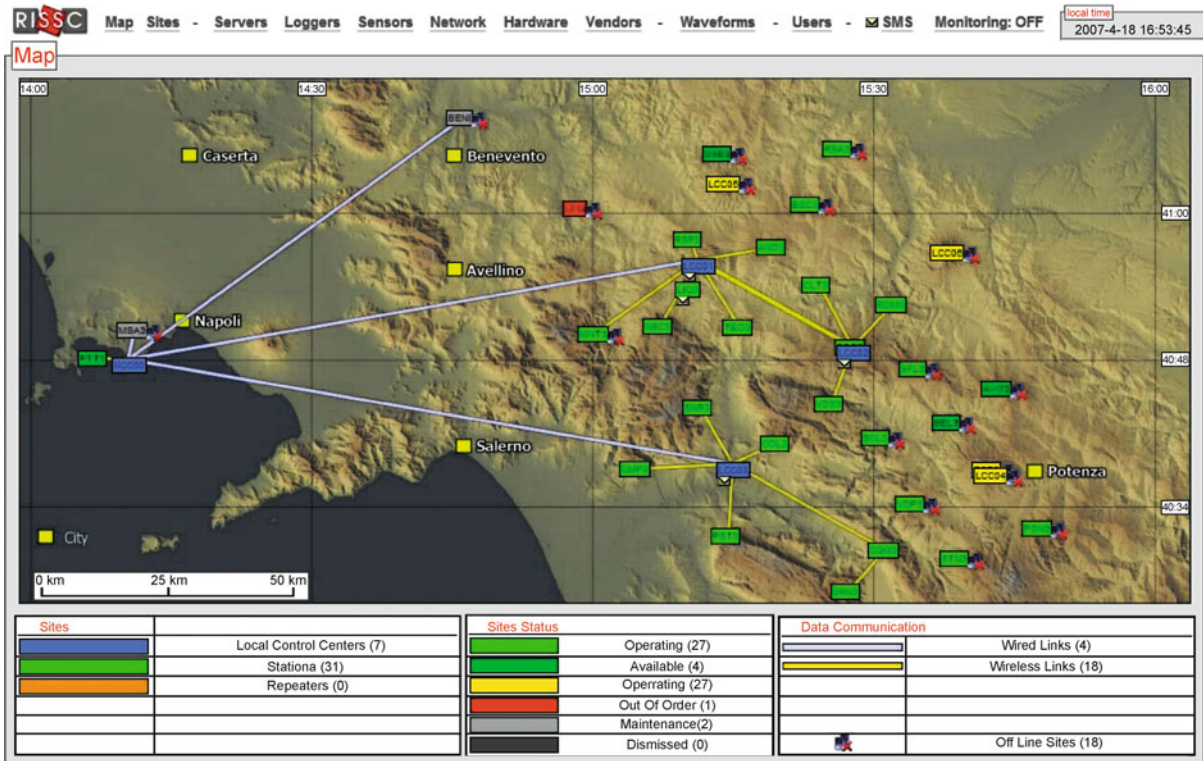

As seen in the previous paragraphs, ISNet is a complex infrastructure, and thus needs a suitable software application

in order to be effectively managed: a front-end to users and administrators with an interface that is simple to use. To this aim we developed a server-client database-driven application, dubbed *SeismNet Manager*, to keep track of the several components that comprise or are produced by the network, such as stations, devices and recorded data. This application, whose front page is shown in Fig. 4, lets the administrators manage (insert, edit, view and search) the details of (a) seismic stations and Local Control Centers (sites), (b) data communication links between sites (wired or wireless), instruments and devices (sensors, loggers, network hardware), and (c) recorded and computed data (waveforms, events). *SeismNet Manager* also keeps an historical record of the installations and configurations of the above elements.

All of the mentioned components are handled by leveraging an instrumental database, a flexible repository of information that was implemented by using PostgreSQL, a robust and feature-rich Database Management System available as open source.

### The Instrumental Database

The instrumental database is a web-oriented application tool where, at the top level, the network is modeled as a set of sites, with installed loggers, sensors, data acquisition servers, network hardware and generic hardware, in a given configuration. Each of the mentioned entities is mirrored by a different class of objects in the database,

Earthquake Early Warning System in Southern Italy, Figure 4

The front page of SeismNet Devices Manager. This page is meant to convey the state of the whole network at a glance. Each node (station or LCCs) is shown along with its operating state, data links of different types to nearby nodes, whether it's currently on-line or not, along with eventual alarms still pending

where the relevant details are stored and then presented to the users as interactive web pages. As an example, see the page for a typical seismic station in Fig. 5.

The instrumental database was implemented with a layer of abstraction that lets one easily perform complex queries and hides the actual implementation details of the underlying structure to a possible client. There are both *stored procedures*, i. e., functions that perform complex tasks given simple inputs, and *views*, i. e., virtual database tables that collect the most important pieces of information about an object, physically scattered in many tables, in a single place and make it possible to easily query, for example, for all the details of the correctly operating sensors installed one year ago at stations with a working wireless link to a given LCC server.

This abstract interface makes the devices database a central repository for effectively cross-correlating the seismic data recorded at any given place and time with the details of the instrument(s) that recorded them, and the configuration details of the systems that ultimately made them available. The interface approach also makes

it easier to change the implementation details without the need to update the web application, or any external client procedures that need to interact with the instrumental database.

### Automatic Monitoring of the Devices and Automatic Data Retrieval

All of the details about the network described so far are provided by the administrators of the system and are manually updated every time the configuration of something in the network changes, e. g., after installing a new sensor or replacing some faulty hardware at a station. This manual input is needed for “dumb” devices, such as sensors. “Smart” devices, i. e., computers with an IP address (loggers, bridges and Earthworm servers), on the other hand, can be queried about their actual configuration from time to time. The web application can plot the temporal evolution of some selected parameters as graphs, spanning a period ranging from hours to years (Fig. 6). This is useful to correlate issues spotted on the recorded seis-

Earthquake Early Warning System in Southern Italy, Figure 5

The page relative to a seismic station. This page is a collection of all the pieces of information linked to a particular site: location details and map; some pictures and notes; recently received warning messages; currently installed devices and their configurations and mutual connections; data links to other stations; most recent waveforms recorded. Every device at a site also has an associated installation object, that records the configuration parameters and the physical connections to other nearby devices, valid over a period of time. Some elements, such as the data storage servers and the loggers, also need some further configuration parameters, that are independent of their actual physical installation, for things like firmware release and versions of the software packages run

mic data (typically, "holes" in the stream of data) to hardware problems. It is possible to inspect the whole chain of data transfers to pinpoint the source of the problem (e. g., low batteries on a logger due to a faulty inverter, low signal of a wireless connection due to harsh weather conditions).

There are both automatic and manual procedures to insert new events and data files in the system. The automatic procedures make use of several sources of events to process, such as: INGV (Istituto Nazionale di Geofisica e Vulcanologia, Italy) bi-weekly bulletins; INGV real time alerts; our early warning system. Likewise, they exploit several sources of recorded seismic data in order to provide a SAC file (SAC – seismic analysis code from

Lawrence Livermore National Laboratory) spanning the period from just before the arrival time, up to the end of the event.

Sensor data are retrieved from: (1) a repository of files from the internal mass storage of the loggers; (2) a local Earthworm Wave Server that caches older data collected from all the LCCs; (3) the most recent real time recording from the remote Wave Servers. The instrumental database is used to determine which sites/sensors/configurations recorded each event and to fill the headers of the files using the standard SAC format. The waveforms and events database, on the other end, is used by the automatic procedures to know which pieces of data are still missing for already recorded events (due to e. g., the temporary un-

Earthquake Early Warning System in Southern Italy, Figure 6

Health graphs of the devices. A device can be marked for monitoring and its internal state, or “health”, gets polled at regular intervals. Several of its internal variables are then retrieved and stored into the database, and their temporal evolution can be plotted as a graph. In this case both the internal temperature and CPU load of an OSISRIS data logger are shown, over periods ranging from one hour to one year

availability of one or more seismic data sources) and need to be collected.

**The Waveforms and Events Database: Searching and Visualizing the Seismic Data**

We also built a waveform and event database, the natural complement to the instrumental database. It keeps track of the events detected by the network and the relative waveforms recorded by the sensors. This database stores objects for events, origin estimations (time and location), magnitude estimations and waveforms. Several origins can be attached to a single event, as different algorithms and different institutions provide different estimations. Likewise, several magnitude types and estimations are attached to each origin. A waveform object for each sensor that recorded the earthquake is also linked to the event object, and stores a pointer to a SAC file, and its source (site and channel). The latter records are then used to gather, from the instrumental database, the actual details of the instruments that recorded the data.

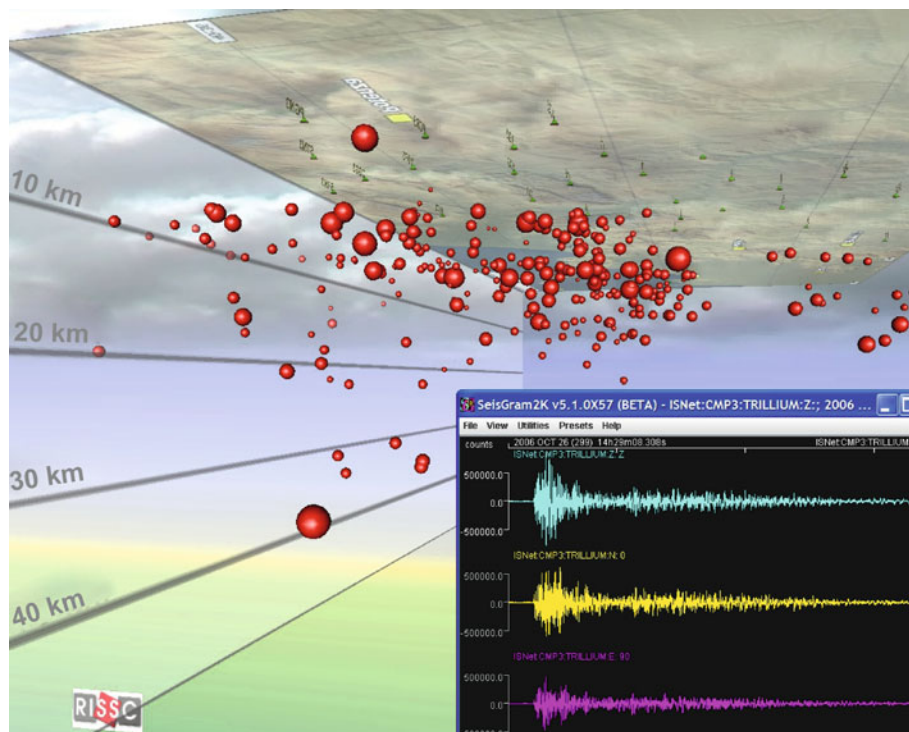

An interface for searching both events and waveforms is provided, as pictured in Fig. 7. Events can be filtered on origin time and location, magnitude, and distance to the stations. Waveforms can be filtered on station, component, instrument and quality.

**Real-Time Earthquake Location and Magnitude Estimation**

**Real-Time Earthquake Location**

**Previous Related Studies** There are many methodologies for standard earthquake location, performed when most or all the phase arrival times for an event are available. Standard analysis techniques are generally not suited for early warning applications, since they typically need the seismic event to be fully recorded at several stations, leaving little or no lead time for the warning [25]. For this reason, a different strategy is required, where the computation starts when a few seconds of data and a small number of recording stations are available, and the results are updated with time.

Earthquake Early Warning System in Southern Italy, Figure 7

Visualization of the seismic data. This is the graphical presentation of data recorded by ISNet. The waveforms matching the user's search criteria can be viewed on-line via Seisgram2K (where they can also be processed), while the events are rendered via VRML as a fully interactive 3D scene in the browser itself

Previous work on earthquake location for early warning includes several approaches to gain constraints on the location at an earlier time and with fewer observations than for standard earthquake location.

In the ElarmS methodology [47], when the first station triggers, the event is temporarily located beneath that station; after a second station trigger the location moves to a point between the two stations, based on the timing of the arrivals; with three or more triggered arrivals, the event location and origin time is estimated using trilateration and a grid search algorithm.

Horiuchi et al. [18] combine standard L2-norm event location, equal differential-time (EDT) location on quasi-hyperbolic surfaces, and the information from not-yet arrived data to constrain the event location beginning when there are triggered arrivals from two stations. The two arrival times define a hyperbolic surface, which contains the event location. This solution is further constrained by EDT surfaces constructed using the current time ( $t_{\text{now}}$ ) as a substitute for future, unknown arrival times at the stations, which have not yet recorded arrivals. The constraint increases as  $t_{\text{now}}$  progresses, even if no further stations record an arrival.

Rydelek and Pujol [36], applying the approach of Horiuchi et al. [18], show that useful constraints on an event location can be obtained with only two triggered stations. Cua and Heaton [12], generalized the approach by Rydelek and Pujol in order to start the location with one single triggering station.

The real-time location technique described in this paper is based on the equal differential-time (EDT) formulation [16,27] for standard earthquake location. The EDT location is given by the point traversed by the maximum number of quasi-hyperbolic surfaces, on each of which the difference in calculated travel-time to a pair of stations is equal to the difference in observed arrival times for the two stations. The EDT location determination is independent of origin time and reduces to a 3D search over latitude, longitude and depth. Furthermore, EDT is highly robust in the presence of outliers in the data [27]. This robustness is critical for the problem of earthquake location for seismic early warning, since we will often work with small numbers of data and may have outlier data such as false triggers, picks from other events, and misidentified picks from energetic, secondary phases.

Assuming that a dense seismic network is deployed around the fault zone, we define as the “*evolutionary approach*” a type of analysis where the estimates of earthquake location and size, and their associated uncertainty, evolve with time as a function of the number of recording stations and of the length of the portion of signal recorded at each station.

A direct implication of the evolutionary strategy is that each algorithm must be capable of *real-time* operation, i. e., its computational time must be smaller than the rate at which data enters the system.

Furthermore, since each algorithm starts processing a limited amount of information, the estimated earthquake parameter must be provided, at each time step, as a *probability density function* (PDF) which incorporates in its definition the uncertainties related both to the model employed and to the available data.

**The Real-Time Earthquake Location Method** The methodology is related to that of Horiuchi et al. [18], which has been extended and generalized by (a) starting the location procedure after only one station has triggered, (b) using the equal differential-time approach proposed by Font [16] to incorporate the triggered arrivals and the not-yet-triggered stations, (c) estimating the hypocenter probabilistically as a PDF instead of as a point, and (d) applying a full, non-linearized, global-search for each update of the location estimate.

We assume that a seismic network has known sets of operational and non-operational stations (Fig. 8a), that when an earthquake occurs, triggers (first *P*-wave arrival picks) will become available from some of the operational stations, and that there may be outlier triggers which are not due to *P* arrivals from the earthquake of interest.

Let's denote the operational stations as  $(S_0, \dots, S_N)$ , and consider a gridded search volume  $V$  containing the network and target earthquake source regions, and the travel times from each station to each grid point  $(i, j, k)$  in  $V$  computed for a given velocity model.

The standard EDT approach states that, if the hypocenter  $(i, j, k)$  is exactly determined, then the difference between the observed arrival times  $t_n$  and  $t_m$  at two stations  $S_n$  and  $S_m$  is equal to the difference between calculated travel times  $tt_n$  and  $tt_m$  at the hypocentral position, since the observed arrival times share the common earthquake origin time. In other words, the hypocenter must satisfy the equality:

$$(tt_m - tt_n)_{i,j,k} = t_m - t_n; \quad m \neq n \quad (1)$$

for each pair of triggering stations  $S_n$  and  $S_m$ . For a constant velocity model, this equation defines a 3D hyperbolic

surface whose symmetry axis goes through the two stations. Given  $N$  triggering stations,  $N(N-1)/2$  surfaces can be drawn; the hypocenter is defined as the point crossed by the maximum number of EDT surfaces.

Following an evolutionary approach, the method evaluates, at each time step, the EDT equations considering not only each pair of triggered stations, but also those pairs where only one station has triggered.

Therefore, when the first station,  $S_n$ , triggers with an arrival at  $t_n = t_{\text{now}}$  ( $t_{\text{now}}$  is the current clock time), we can already place some limit on the hypocenter position (Fig. 8b). These limits are given by EDT surfaces defined by the condition that each operational but not-yet-triggered station  $S_l$  will trigger in the next time instant,  $t_l \geq t_n$ . That is:

$$(tt_l - tt_n)_{i,j,k} = t_l - t_n \geq 0; \quad l \neq n. \quad (2)$$

On these conditional EDT surfaces, the *P* travel time to the first triggering station  $tt_n$  is equal to the travel-time to each of the not-yet-triggered stations,  $tt_l$ ,  $l \neq n$ . These surfaces bound a volume (defined by the system of inequalities) which must contain the hypocenter. In the case of a homogeneous medium with constant *P*-wave speed, this hypocentral volume is the Voronoi cell around the first recording station, defined by the perpendicular bisector surfaces with each of the immediate neighboring stations.

As the current time  $t_{\text{now}}$  progresses, we gain the additional information that the not-yet-triggered stations can only trigger with  $t_l > t_{\text{now}}$ . Thus the hypocentral volume is bounded by conditional EDT surfaces that satisfy the inequality:

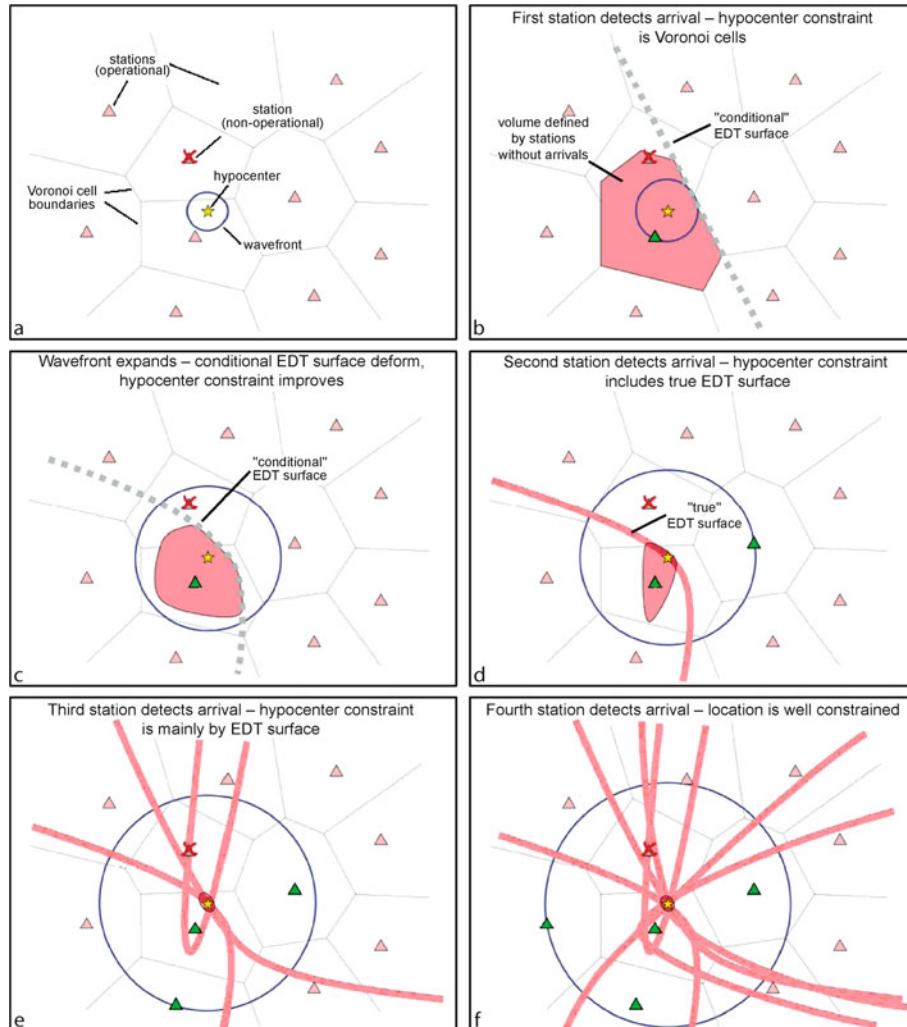

$$(tt_l - tt_n)_{i,j,k} \geq \delta t_{n,l}; \quad l \neq n. \quad (3)$$

$\delta t$  is the time interval between the arrival time at station  $S_n$  and the latest time for which we have information from station  $S_l$ ,

$$\delta t_{n,l} = t_{\text{now}} - t_n, \quad (4)$$

where  $t_n$  is the observed arrival time at station  $S_n$ .

The system (3) defines the volume, bounded by the conditional EDT surfaces, in which the hypocenter may be located given that, at current time  $t_{\text{now}}$ , only the station  $S_n$  has triggered. When  $\delta t = 0$  the system (3) reduces to the system (2); for  $\delta t > 0$ , the hypocentral volume will be smaller than the previous one, since the updated, conditional EDT surfaces tend to fold towards and around the first triggered station (Fig. 8c).

Earthquake Early Warning System in Southern Italy, Figure 8

Schematic illustration of the evolutionary earthquake location algorithm. For clarity, only a map view with the epicentral location is represented. **a** Given a seismic network with known sets of operational and non-operational stations, we can define a priori the Voronoi cell associated to each station. **b** When the first station triggers, we can define a volume that is likely to contain the location, this volume is limited by conditional EDT surfaces on which the  $P$  travel time to the first triggering station is equal to the travel-time to each of the operational but not-yet-triggered stations. **c** As time progresses, we gain additional information from the stations that have not yet triggered, the EDT surfaces move towards and bend around the first triggering station, and the likely-location volume decreases in size. **d** When the second station triggers, we can define a true EDT surface; the hypocenter is on the intersection between this surface and the volume defined by the conditional EDT surfaces, which continues decreasing in size. **e** When a third station triggers, we can define two more true EDT surfaces, further increasing the constraint on hypocenter position. **f** As more stations trigger, the location converges to the standard EDT location composed entirely of true EDT surfaces

We interpret the hypocentral volume in a probabilistic way by defining, for each inequality in (3), a value  $p_{n,l}(i, j, k)$  which is 1 if the inequality is satisfied and 0 if not. Then we sum the  $p_{n,l}(i, j, k)$  over stations  $l$  at each grid point, obtaining a non-normalized probability density  $P(i, j, k)$ , where  $P(i, j, k) = N - 1$  for grid points where

all the inequalities are satisfied and a value less than  $N - 1$  elsewhere.

When the second and later stations trigger, we first re-evaluate the system (3) for all pairs of triggered stations  $S_n$  and all not-yet-triggered stations  $S_l$ . Secondly, we construct standard, true EDT surfaces (see Eq. 2) between

each pair  $S_n, S_m$  of the triggered stations, by evaluating for each grid point the quantity:

$$q_{n,m}(i, j, k) = \exp \left\{ -\frac{[(tt_n - tt_m)_{i,j,k} - (t_n - t_m)]^2}{2\sigma^2} \right\};$$

$$n \neq m. \quad (5)$$

The expression between square brackets at the exponent is the standard EDT Eq. 2 whose solutions are quasi-hyperbolic surfaces; in practice all true EDT surfaces are given a finite width by including the uncertainty  $\sigma$  in the arrival time picking and the travel-time calculation.

The quantity  $q_{n,m}(i, j, k)$  has values between 0 and 1. We sum the  $q_{n,m}(i, j, k)$  with the  $p_{n,l}(i, j, k)$  obtained from the re-evaluation of (4) to obtain a new  $P(i, j, k)$ .

Starting from  $P$ , we define a value:

$$Q(i, j, k) = \left( \frac{P(i, j, k)}{P_{\max}} \right)^N, \quad (6)$$

which forms a relative probability density function (PDF, with values between 0 and 1) for the hypocenter location within the grid cell  $(i, j, k)$ . The function  $Q(i, j, k)$  may be arbitrarily irregular and may have multiple maxima.

At predetermined time intervals, we evaluate (3) and (5) to obtain  $Q(i, j, k)$  in the search volume, using the Oct-tree importance sampling algorithm ([13,27], <http://www.alomax.net/nlloc/octtree>). This algorithm uses recursive subdivision and sampling of rectangular cells in 3D space to generate a cascade structure of sampled cells, such that the spatial density of sampled cells follows the target function values. The Oct-tree search is much faster than a simple or nested grid search (factor 10–100 faster) and more global and complete than stochastic search methods algorithms such as simulated annealing and genetic algorithms [13]. For each grid point, an origin time estimate can be obtained from the observed arrival times and the calculated travel times.

As more stations trigger, the number of not-yet-triggered stations becomes small, and the location converges towards the hypocentral volume that is obtained with standard EDT location using the full set of data from all operational stations (Fig. 8d–f).

If there are uncorrelated outlier data (i.e., triggers that are not compatible with  $P$  arrivals from a hypocenter within or near the network), then the final hypocentral volume will usually give an unbiased estimate of the hypocentral location, as with standard EDT location. However, if one or more of the first arrival times is an outlier, then the earliest estimates of the hypocentral volume

may be biased. Synthetic tests have shown that, if  $N_{\text{out}}$  is the number of outlier data, the bias reduces significantly after about  $4 + N_{\text{out}}$  arrivals have been obtained, and then decreases further with further arrivals, as the solution converges towards a standard EDT location [37].

We performed several synthetic tests using the geometry of the ISNet network. For each simulated event, we computed theoretical arrival picks using travel times obtained by the finite difference solution of the eikonal equation [35] for a 1D,  $P$ -wave velocity model. To reproduce uncertainties introduced by the picking algorithm, we add to each arrival time a random error following a Gaussian distribution with a variance of 0.02 s.

Here we use only  $P$  picks since currently most networks have poor capability to perform real-time  $S$  picking. Our tests consider an earthquake occurring at the center of the network at a depth of 10 km (Fig. 9) and an earthquake occurring outside the network at a depth of 10 km (Fig. 10). Each panel in Figs. 9 and 10 is a snapshot at a given time showing the marginal map (i.e., summed over  $i, j$  or  $k$ ) for  $Q(i, j, k)$  along the horizontal ( $x, y$ ) and the two vertical ( $x, z$  and  $y, z$ ) planes. The star shows the known, synthetic hypocentral location. In the first case, two seconds after the first trigger (5.03 s from the event origin), 9 stations have triggered and the location is already well constrained for early warning purposes.

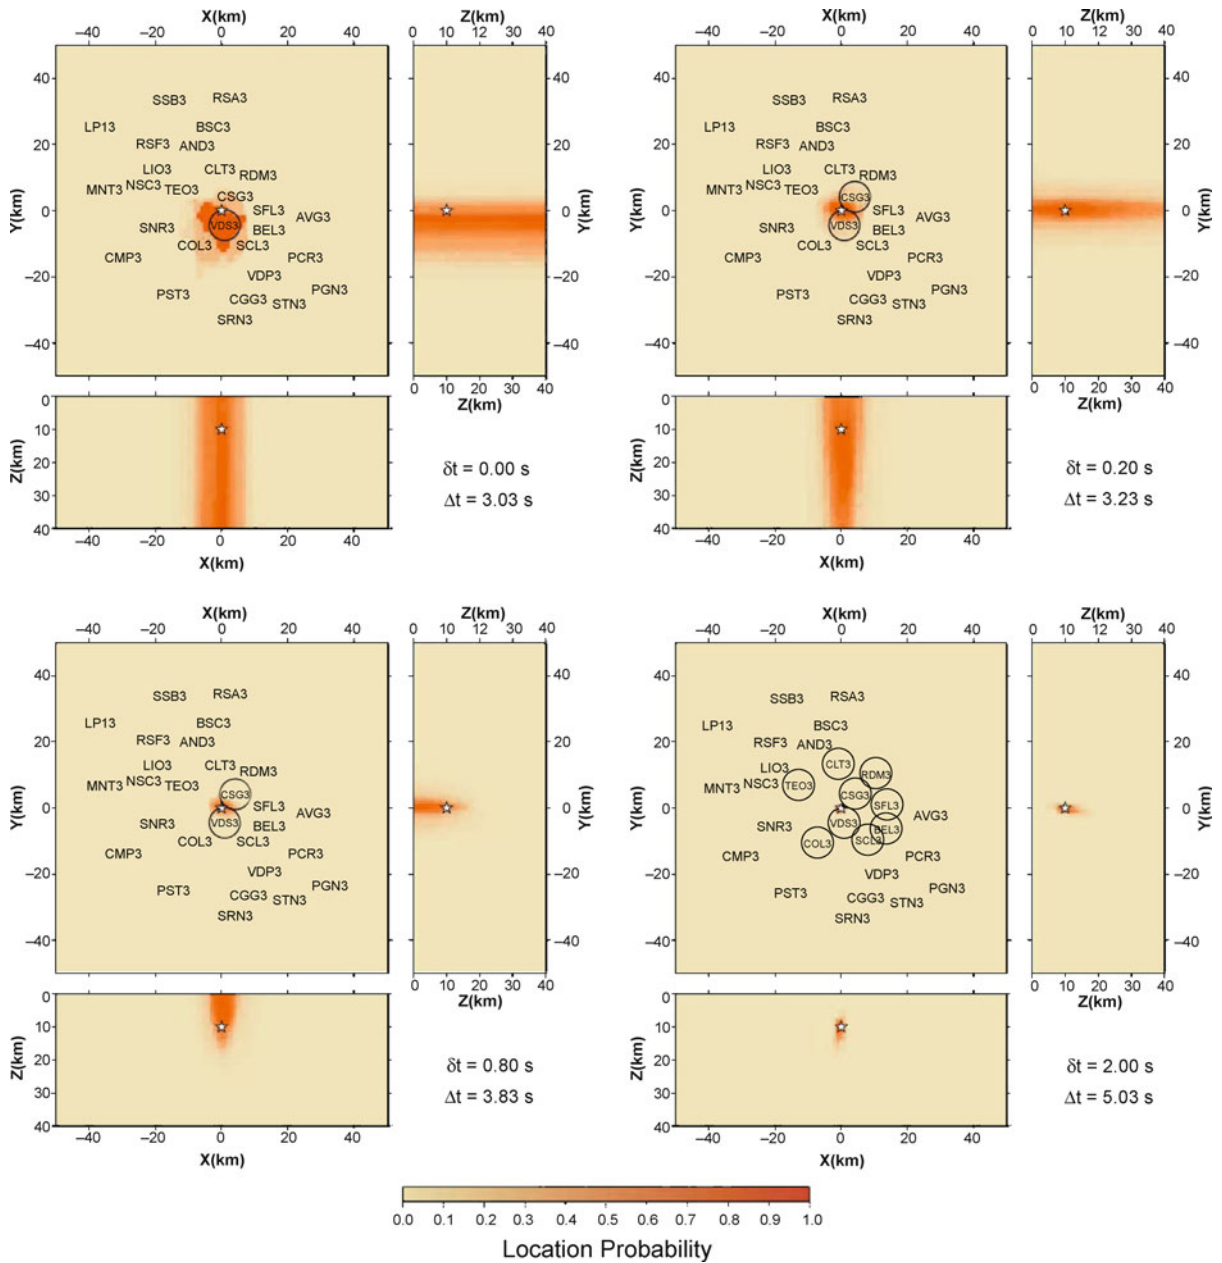

In the second case, at  $\Delta t = 11.76$  s, 2 s after the first event detection, the constraint on the location PDF improves further, but the PDF retains an elongated shape because of the poor azimuthal coverage of the network for this event. The event depth is only constrained by an upper bound, but the depth range includes the true value.

### Real-Time Magnitude Estimation Using a Bayesian, Evolutionary Approach

**Previous Related Studies** The problem of magnitude estimation from early seismic signal has been previously approached and analyzed by different authors.

Nakamura [31] first proposed the correlation between the event magnitude and the characteristic period of  $P$ -phase defined as the ratio between the energy of the signal and its first derivative.

Allen and Kanamori [2] modified the original Nakamura method and described the correlation between the predominant period and the event magnitude for Southern California events. Lockman and Allen (2007) studied the predominant period – magnitude relations for the Pacific Northwest and Japan. They also investigated the sensitivity of such relations using different frequency bands.

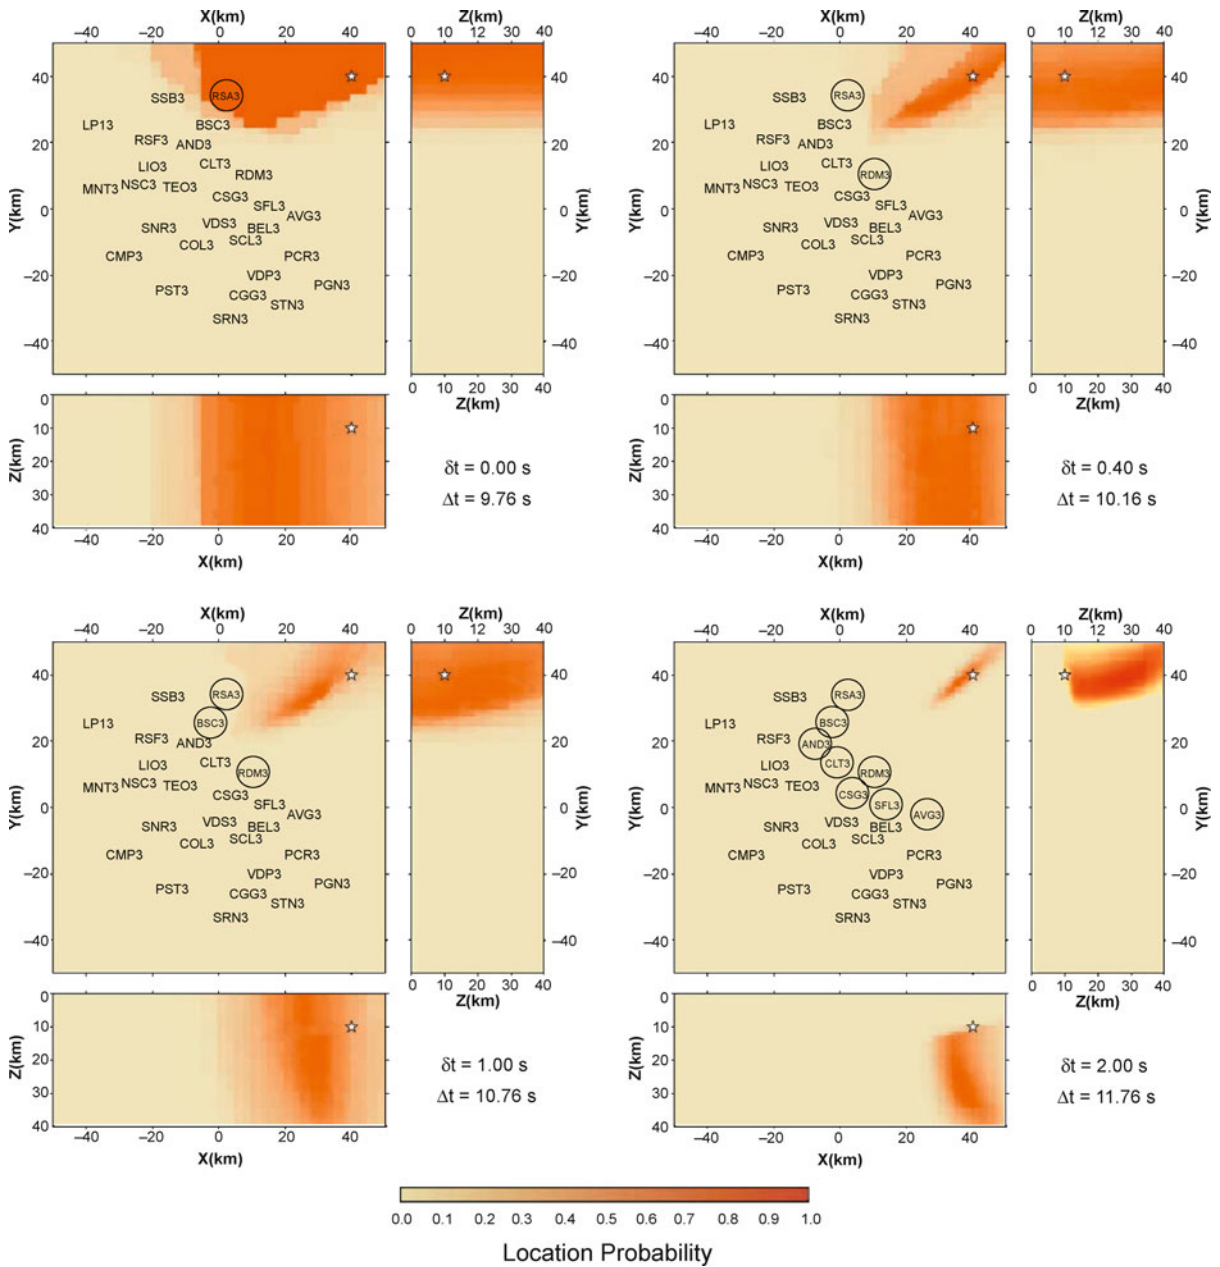

Earthquake Early Warning System in Southern Italy, Figure 9

Location test for a synthetic event occurring at the center of the Irpinia Seismic Network (ISNet). The three orthogonal views show marginal values of the probability function  $Q(i, j, k)$ . The true hypocenter is identified by a star.  $\delta t$  is the time from the first trigger,  $\Delta t$  is the time from event origin. For each snapshot, stations that have triggered are marked with a circle

Using a complementary approach, Wu and Kanamori [45] investigated the feasibility of an on-site EEWs for Taiwan region based on prediction of earthquake damage, based on measurements of the predominant period and peak displacement on early  $P$ -wave signals detected at the network.

Odaka et al. (2003) proposed a single station approach for the real-time magnitude estimation. The authors fit the initial part of waveform envelope and showed a relation between the final event magnitude, the envelope shape coefficient and the maximum  $P$  amplitude measured in a 3 s time window.

Earthquake Early Warning System in Southern Italy, Figure 10  
 Location test for a synthetic event occurring outside the ISNet network (see Fig. 9 for explanation)

Wu and Zhao [46] and Zollo et al. [49] (Fig. 11) demonstrated the existence of a correlation between the event magnitude and the peak displacement measured a few seconds after the *P* arrival based on massive analysis of Southern Californian and Euro-Mediterranean earthquake records. In particular, Zollo et al. showed that

both *P* and *S* wave early phases have the potential for real time estimation of magnitude up to about *M* 7. Zollo et al. [50] and Lancieri and Zollo [26] extended this observation to Japanese earthquake records, showing that a possible saturation effect may exist at about *M* 6.5 for *P* measurements in 2 s windows while it vanishes when a larger,

Earthquake Early Warning System in Southern Italy, Figure 11

Correlation between low-pass filtered peak ground motion value and moment-magnitude for earthquakes occurred in the Euro-Mediterranean region (after [49]). The panels show the logarithm of peak ground displacement normalized at a reference distance of 10 km as a function of Mw in time windows of (left) 2 s length from the first *P*-arrival and (middle) 1- and (right) 2-s from the first *S*-arrivals. *P*- and *S*-data are measured on vertical and root-squared sum of horizontal components, respectively. Each panel shows the best fit regression line (solid line) along with 1-WSE limits (dashed lines)

4 s window is considered. The scaling of displacement peak with magnitude, instead, appears at even shorter (1 s) time lapses after the first *S*-arrival.

Using an alternative method, Simmons [38] proposed a new algorithm based on discrete wavelet transforms able to detect first *P* arrival and to estimate final magnitude analyzing first seconds of *P*-wave.

**The Real-Time Magnitude Estimation Method** The real time and evolutionary algorithm for magnitude estimation presented in this paper is based on a magnitude predictive model and a Bayesian formulation. It is aimed at evaluating the conditional probability density function of magnitude as a function of ground motion quantities measured on the early part of the acquired signals [19].

The predictive models are empirical relationships which correlate the final event magnitude with the logarithm of quantities measured on first 2–4 s of record.

The first prediction model, based on the predominant period of *P*-phase ( $\tau_P$ ), has been introduced by Allen and Kanamori [2]. Recently, Wu and Zhao [46] showed the existence of a correlation between magnitude, distance and peak displacement measured in a 2–4 s window after *P*-phase.

Zollo et al. [49,50] refined this correlation and extended the observation on the peaks measured in 2 s after the *S*-phase arrival through the analysis of the European and Japanese strong motion data-bases (Ambraseys et al. [3], K-NET www service of NIED – National Research Institute for Earth Science and Disaster Prevention, Japan).

The method therefore assumes that the linear relationship between the logarithm of the observed quantity and

magnitude is known, along with standard errors of the predictive models.

At each time step  $t$  from the first station trigger, the conditional PDF of magnitude  $M$  given the observed data vector  $\underline{d} = \{d_1, d_2, \dots, d_n\}$  is expressed via the Bayes theorem as:

$$f(m|\underline{d}) = \frac{f(\underline{d}|m)f(m)}{\int_{M_{\text{MIN}}}^{M_{\text{MAX}}} f(\underline{d}|m)f(m)dM}, \quad (7)$$

where  $f(m)$  is the a priori distribution which incorporates the information available before the experimental data are collected through a truncated exponential functional form, derived by the Gutenberg–Richter recurrence relationship,

$$f(m) : \begin{cases} \frac{\beta e^{-\beta m}}{e^{-\beta M_{\text{min}}} - e^{-\beta M_{\text{max}}}} & M_{\text{min}} \leq m \leq M_{\text{max}} \\ 0 & m \notin [M_{\text{min}}, M_{\text{max}}] \end{cases}, \quad (8)$$

where  $\{\beta, M_{\text{min}}, M_{\text{max}}\}$  depend on the seismic features and on the detection threshold of the seismic network of the considered region.

The conditional probability  $f(\underline{d}|m)$  contains all the information concerning the magnitude as retrievable from the data acquired at time  $t$ .

Assuming that components of the observed data vector  $\underline{d}$  have a lognormal distribution, and that they are stochastically independent and identically distributed random variables of parameters  $\mu_{\log(d)}$  and  $\sigma_{\log(d)}$ , then the likelihood is written as:

$$f(\underline{d}|m) = \prod_{i=1}^v \frac{1}{\sqrt{2\pi}\sigma_{\log(d)}d_i} e^{-\frac{1}{2}\left(\frac{\log(d_i) - \mu_{\log(d)}}{\sigma_{\log(d)}}\right)^2}, \quad (9)$$

where  $\nu$  is the number of stations acquiring at the instant  $t$ ;  $\mu_{\log(d)}$  and  $\sigma_{\log(d)}$  are the mean and the standard deviation of the logs of  $d_i$ , respectively.

Substituting Eq. 8 and Eq. 9 into Eq. 7,  $f(m|d)$  results as in Eq. 10 where it depends on data only through  $\sum_{i=1}^{\nu} \log(d_i)$  and  $\nu$ , which therefore are jointly sufficient statistics for the estimation of magnitude [21]:

$$f(m|d) = f\left(m \mid \sum_{i=1}^{\nu} \log(d_i)\right) = \frac{e^{\left(2\mu_{\log(d)}\left(\sum_{i=1}^{\nu} \log(d_i)\right) - \nu\mu_{\log(d)}^2\right) / 2\sigma_{\log(d)}^2} e^{-\beta m}}{\int_{M_{\text{MIN}}}^{M_{\text{MAX}}} e^{\left(2\mu_{\log(d)}\left(\sum_{i=1}^{\nu} \log(d_i)\right) - \nu\mu_{\log(d)}^2\right) / 2\sigma_{\log(d)}^2} e^{-\beta m} dm} \quad (10)$$

As just outlined,  $f(m|d)$  depends on  $\sum_{i=1}^{\nu} \log(d_i)$  and on the number of stations triggered,  $\nu$ , at the time of the estimation and, consequently, on the amount of information available. As more stations are triggered, and provide more measures of  $d$ , the estimation improves.

The described technique is evolutionary in the sense that  $f(m|d)$  depends on time, i. e., as time passes, additional stations provide new observations (predominant period and/or  $P$ -,  $S$ -peaks), which are used to refine the probabilistic estimation of magnitude.

### Magnitude Estimation from Peak Displacement Measurements

The empirical relationships between low-pass filtered, initial  $P$ - and  $S$ -peak displacement amplitudes and moment magnitude (e. g. [49]) can be used as predictive models for the real-time estimation of magnitude using the Bayesian approach described above.

While the  $P$ -wave onset is identified by an automatic picking procedure, the  $S$ -onset can be estimated from an automatic  $S$ -picking or from a theoretical prediction based on the hypocentral distance given by the actual earthquake location. At a given time step after the first  $P$ -wave detection at the network, progressively refined estimates of magnitude are obtained from  $P$ - and  $S$ -peak displacement data. These are preliminarily corrected for distance amplitude effects through an empirical attenuation relationship obtained from available strong motion records [46,49]:

$$f(M, R) = A_{\text{phase}} + B_{\text{phase}}M + C_{\text{phase}} \log(R), \quad (11)$$

where the constants  $A_{\text{phase}}$ ,  $B_{\text{phase}}$  and  $C_{\text{phase}}$  are determined through a best-fit regression with a retrieved standard error of  $SE_{\text{phase}}^{\text{PMR}}$  and  $R$  is the hypocentral distance.

Following the procedure described in [49], the relationship (11) is used to correct observed peaks for the distance effect, by normalizing them to a reference distance (e. g.,  $R = 10$  km) and to determine a new best fit regression between the distance corrected peak value  $(PD_{\text{phase}})^{10 \text{ km}}$  and the final magnitude:

$$\log\left(PD_{\text{phase}}^{10 \text{ km}}\right) = \log\left(PD_{\text{phase}}^R\right) - C_{\text{phase}} \log\left(\frac{R}{10}\right) \quad (12)$$

$$\log\left(PD_{\text{phase}}^{10 \text{ km}}\right) = A'_{\text{phase}} + B'_{\text{phase}}M. \quad (13)$$

Assuming a standard error of  $SE_{\text{phase}}^{\text{PM}}$  on peak displacements retrieved from (13) and combining the Eqs. (11) and (13), the mean values and standard deviation of quantity  $\log(PD_{\text{phase}})$ , can be written as:

$$\begin{aligned} \mu_{\log(PD_{\text{phase}})} &= B'_{\text{phase}}M + A'_{\text{phase}} + C_{\text{phase}} \log\left(\frac{R}{10}\right) \\ \sigma_{\log(PD_{\text{phase}})} &= SE_{\text{phase}}^{\text{PM}} + \log\left(\frac{R}{10}\right) \Delta C_{\text{phase}} \\ &\quad + C_{\text{phase}} \frac{1}{R} \Delta R, \end{aligned} \quad (14)$$

where  $R$  is estimated with an error of  $\Delta R$  and  $\Delta C_{\text{phase}}$  is the error on the  $C_{\text{phase}}$  coefficient in Eq. (12).

The values of coefficients in (14) used for real time magnitude estimates at ISNet are obtained from the regression analysis based on records from the European Strong Motion Database [49] and given in Table 2.

Figure 12 illustrates an example of real time magnitude estimation on a simulated event with  $M = 7.0$ , whose epicenter is located along the 1980 Irpinia earthquake faulting system. Synthetic seismograms have been computed by using the discrete wave-number method of Bouchon [8] and Coutant (1989) for a extended source model in a flat-layered velocity model.

Figure 13a shows the probability density function defined in Eq. (8) evaluated at each time step. Time zero is assigned to the first  $P$  detection at the network. As time evolves the PDF tightens around the predicted magnitude value, indicating a more refined, probabilistic estimate of magnitude.

Earthquake Early Warning System in Southern Italy, Table 2  
Coefficients of the empirical regression relationships between low-pass filtered  $P$  and  $S$  displacement peaks and magnitude

Phase	$A'_{\text{phase}}$	$B'_{\text{phase}}$	$C_{\text{phase}}$	$SE_{\text{phase}}^{\text{PM}}$	$\Delta C_{\text{phase}}$
2P	-6.31	0.70	-1.05	0.22	0.30
2S	-5.77	0.71	-0.71	0.13	0.16

Earthquake Early Warning System in Southern Italy, Figure 12

Synthetic seismograms for a  $M 7.0$  earthquake at the center of the network (see Fig. 9). The seismograms are computed using a line source, rupture model (constant rupture velocity) while complete wavefield green's functions in a flat-layered model are computed by using the discrete wavenumber summation method of Bouchon [8]. Each vertical line indicates the 1 s signal packets examined at each time step. This plot allows us to understand seconds after seconds which stations are acquiring and what sort of input ( $P$  or  $S$  peak) they are giving to the real time system. For example after three seconds to the first  $P$  phase picking thirteen stations are acquiring, the 2 s  $S$ -phase peak is available at the nearest stations. This observation motivates the use of the  $S$  phase information in a real time information. If a dense network is deployed in the epicentral area the nearest station will record the  $S$ -phase before the  $P$  phase arrives to the far ones, as seen in previous example, and this is perfectly compatible with the real time analysis

By defining  $F_t(m)$  as the cumulative PDF at time  $t$ , it is possible to estimate a magnitude range of variation  $[M_{\min}; M_{\max}]$  whose limits are defined based on the shape of the  $F_t(m)$  function:

$$\begin{aligned} M_{\min} &: \int_{-\infty}^{M_{\min}} f_t(m|\underline{d}) dm = \alpha, \\ M_{\max} &: \int_{-\infty}^{M_{\max}} f_t(m|\underline{d}) dm = 1 - \alpha. \end{aligned} \quad (15)$$

For example, if we assume  $\alpha = 1\%$ , then  $M_{\min}$  and  $M_{\max}$  will be, respectively, the  $F_t(m)$  evaluated at 0.01 and 0.99.

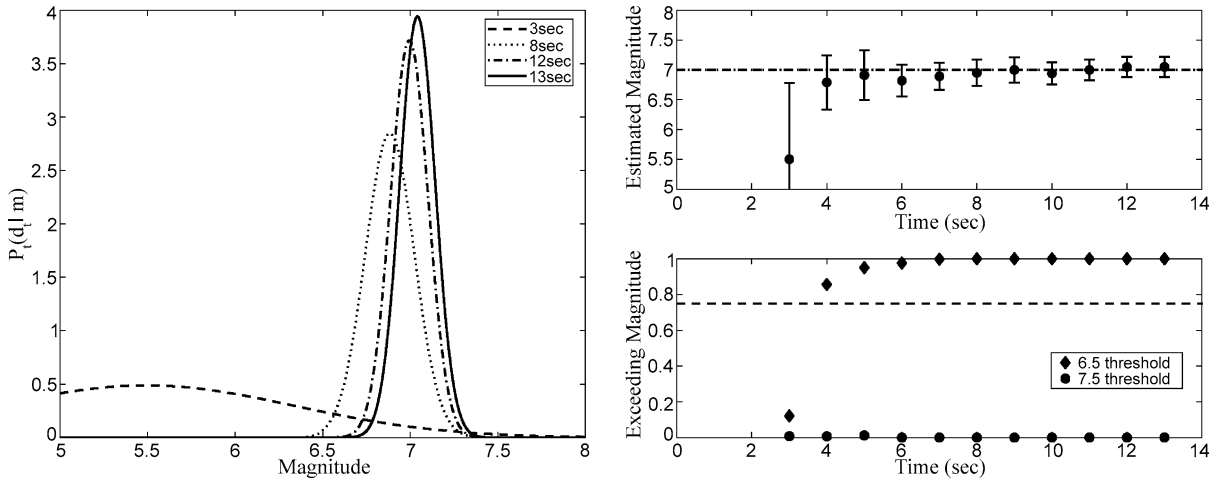

In Fig. 13b the estimates of magnitude uncertainty bounds are reported as a function of time. After three iterations (corresponding to a time of 9 s from the event origin time and 4 s after the first  $P$ -phase arrival at the network) the magnitude estimation converges to the true magnitude

value. In fact, due to the high density of seismic station in the epicentral area, at that time most of seismic station contributes to the magnitude estimation with peaks read on  $P$ -phase windows (Fig. 14), while a further refinement of magnitude estimate is due to the near source  $S$ -wave arrivals.

### Real-Time Hazard Analysis for Earthquake Early Warning

#### The Real-Time Hazard Determination

Using the methods previously described for estimating in real-time the event magnitude and location, it is possible to perform a real-time hazard analysis [19]. This analysis is based on the extension of classical Probabilistic Seismic Hazard Analysis (PSHA) proposed by Cornell [11] that is generally used for long-term probabilistic hazard

Earthquake Early Warning System in Southern Italy, Figure 13  
 Application of the method for real time magnitude estimate to a  $M 7$  simulated event occurring within the area covered by the ISNet network. *Left panel.* PDF distribution at several time steps measured from the first  $P$ -phase picking. *Right top,* magnitude estimation with uncertainties as a function of time. The *dashed line* refers to the actual magnitude value, the errors represent the 95% of confidence bound evaluated as cumulative PDF integral in the 5–95% range. *Right bottom,* probability to exceed magnitude 6.5 and magnitude 7.5 thresholds in function of time. The *dashed line* is the 75% probability level

assessment. Classical PSHA integrates data from existing seismic catalogs both in terms of magnitude, location and recorded strong ground motion values in addition to the information concerning seismogenic areas of interest (expected maximum magnitude,  $b$ -value of the Gutenberg Richter relationship, etc.) to provide the hazard curve as the final outcome. Each point on that curve corresponds to the value of a ground motion intensity measure (IM) (e. g., peak ground acceleration, PGA, peak ground velocity, PGV or the spectral acceleration,  $S_a$ ), having a given probability or frequency of exceedance in a fixed period of time for a site of interest.

The probabilistic framework of the PSHA, specifically the hazard integral, can be used for real-time hazard if the PDFs of magnitude and source-to-site distance are replaced with those depending on the data gathered by the EEWs during the occurrence of a specific earthquake.

This is the case, for example, of the PDF on the source-to-site distance whose statistical moments evolve with real-time earthquake location. As a consequence, this PDF does not depend on the seismic potential of the area of interest (as in the case of the classical PSHA, which accounts for the occurrence of all the earthquake in a fixed range of magnitude), but rather depends on the time evolving event location provided by the EEWs. The same considerations apply to the PDF on the magnitude as described in the following sections whose statistical moment, at a given

time, depends on the number of triggered stations at that time.

In this theoretical framework the real-time hazard integral can be written as:

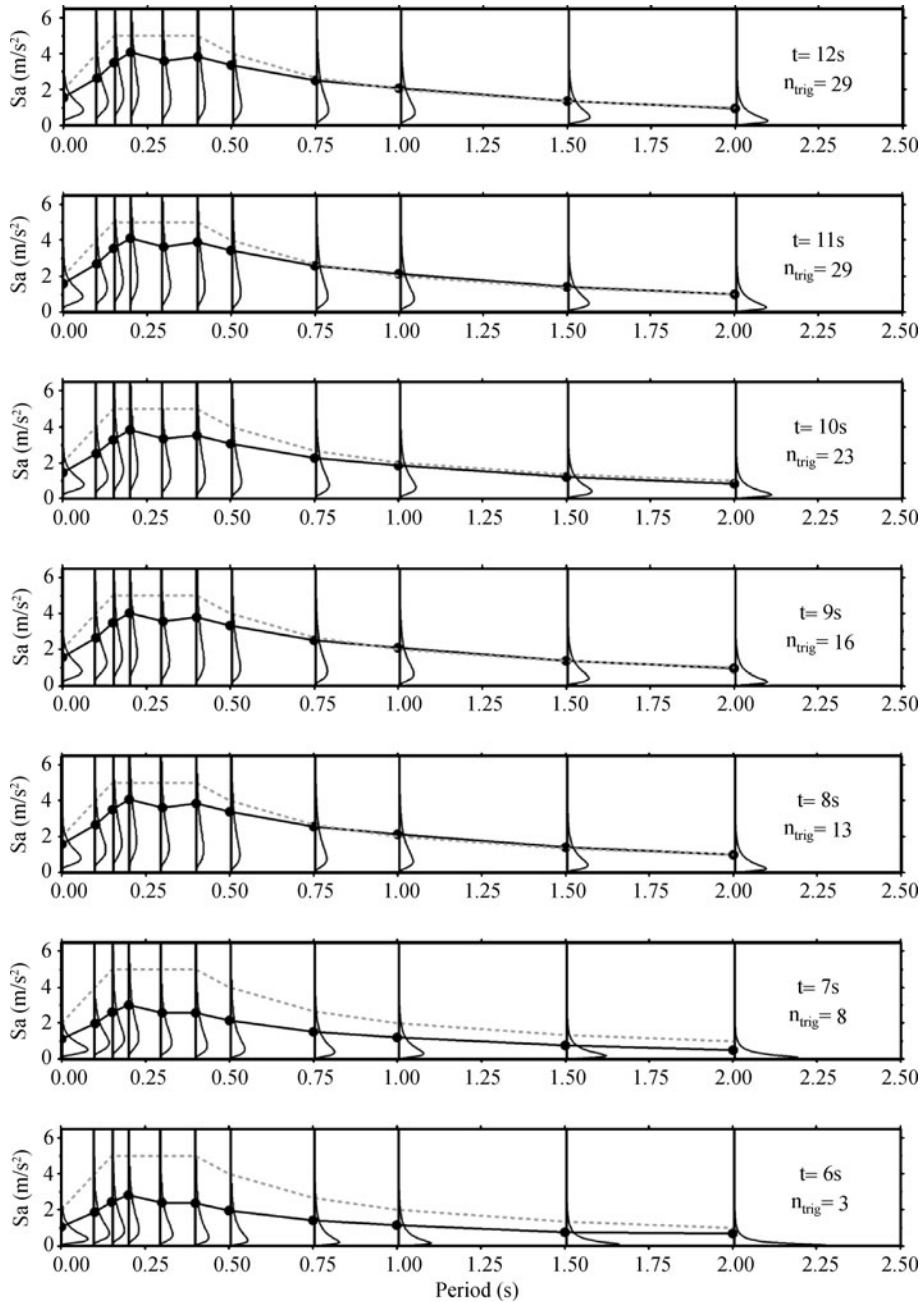

$$f(\text{IM}|\underline{d}, \underline{s}) = \int_M \int_R f(\text{IM}|m, r) f(m|\underline{d}) f(r|\underline{s}) dM dR, \quad (16)$$

where  $f(r|\underline{s})$  is the PDF of distance  $r$ , which eventually depends only on the triggering sequence of the stations in the network, where  $\underline{s} = \{s_1, \dots, s_N\}$  is such a sequence. This renders also the PDF of  $r$  time dependent.

Given that for each point in a volume containing the earthquake hypocenter, the probability of that point being coincident with the true hypocenter is calculated via a rapid location technique, a simple geometrical transformation allows one to obtain the probabilistic distribution of the source-to-site distance.

The PDF  $f(\text{IM}|m, r)$ , is given, for example, by an ordinary attenuation relationship. It is worth to recall that the computed hazard refers to a particular set of triggered stations and, consequently, it depends on the information available at time  $t$  from the first detection of the event.

Figure 14 illustrates, as an example, the estimation of spectral acceleration ordinates for different periods, for a  $M 7.0$  event located at an epicentral distance of 50 km from the early warning target site [10].

Earthquake Early Warning System in Southern Italy, Figure 14

Real-time estimation of spectral ordinates' distributions as function of the number of stations triggered for a  $M$  7.0 event with an epicentral distance of 50 km from the early warning target site. The parameter  $n_{trig}$  in the figure is equivalent to the number of stations  $\nu$  in the text. The acceleration spectrum (*black curve*) was obtained by choosing at each period the spectral value with 20% exceedance probability according to the corresponding distribution, so it is analogous to a uniform hazard spectrum with the exception that it is computed in real-time. The *grey dashed line* is the Italian code spectrum assigned for building design in the target location at the town of Avellino, 40 km distant from the earthquake epicenter, and is reported for comparison purposes (after [10])

We note the evolution of Sa predictions via the corresponding PDFs. The different panels correspond to increasing times from the earthquake origin and, therefore, to different numbers of stations triggered.

### The False Alarm Issue

Once the EEWS provides a probability distribution of the ground motion intensity measure (IM) at the target site (e. g., peak ground acceleration or velocity), a decisional condition has to be checked in order to decide whether to alert or not.

Several options are available to formulate a decisional rule, for example the alarm may be issued if the probability of the predicted IM exceeding a critical threshold ( $IM_C$ ) is greater than a reference value ( $P_c$ ):

$$\text{Alarm if: } \int_0^{IM_C} f(IM|\underline{d}, \underline{s})d(IM) = P[IM > IM_C] > P_c. \quad (17)$$

The efficiency of the decisional rule may be evaluated in terms of false and missed alarms probabilities (known as the “cry wolf” issue, e. g., [20]). The false alarm occurs when, on the basis of the information processed by the EEWS, the alarm is issued while the intensity measure at the site  $IM_T$  (T subscript means “true”, indicating the realization of the IM to be distinguished from the prediction  $IM_C$ ) is smaller than the threshold  $IM_C$ . A missed alarm corresponds to not launching the alarm if needed,

$$\begin{aligned} \text{Missed Alarm: } & \{\text{No Alarm} \cap IM_T > IM_C\} \\ \text{False Alarm: } & \{\text{Alarm} \cap IM_T \leq IM_C\}. \end{aligned} \quad (18)$$

It has been discussed above how the information and the uncertainties on earthquake location and magnitude are dependent on the number of stations triggered at a certain time.

Therefore, in principle, the decisional rule may be checked at any time after the first station has triggered and, consequently, the false and missed alarm probabilities are also time dependent.

Using the decisional rule of (18) and considering PGA as IM, the time evolution of false/missed alarm probabilities has been simulated for the Campania EEWS, given the occurrence of a  $M 7$  earthquake, and a target site at an epicentral distance of 110 km.

Figure 15 reports the missed and false alarm probabilities as a function of time from the first trigger at the ISNet network.

Earthquake Early Warning System in Southern Italy, Figure 15 Example of estimation of false and missed alarm probabilities as function of the time from the first trigger for a  $M 7.0$  event with an epicentral distance of 110 km from the early warning target site. For the decisional rule adopted in this case the threshold is  $PGAc = 0.3 \text{ m/s}^2$  and the limit probability is  $P_c = 0.2$  (after [19])

### A Loss Estimation Approach to Early Warning

Magnitude and distance distributions conditioned to the measurements of the seismic network can also be used for a real-time estimation of risk, which includes losses produced by the earthquake [21]. Based on the real-time risk assessment, a security action aimed at risk mitigation is undertaken if the alarm is issued.

For example, some critical system could shut down or people in buildings may shelter themselves if the warning time is not sufficient to evacuate the dangerous buildings. More complex security measures may be related to the semi-active control of buildings [22].

Therefore, if an EEWS exists, it may trigger a security procedure in case of warning. The estimation of the expected losses for a specific building may be computed, for the case of warning issued and not issued respectively:

$$\begin{aligned} E^W[L|\underline{d}, \underline{s}] = & \int_L \int_{DM} \int_{EDP} \int_{IM} l f^W(l|dm) f(dm|edp) \\ & \times f(edp|im) f(im|\underline{d}, \underline{s}) dL dDM dEDP dIM, \end{aligned} \quad (19)$$

where  $f^W(l|dm)$  is the PDF of the loss ( $L$ ) given the structural and non-structural damage vector ( $DM$ ) reflecting the risk reduction in the case of warning; and  $f^W(l|dm)$  is the loss function if no alarm is issued (no security action is undertaken);  $f(dm|edp)$  is the joint PDF of damages given the Engineering Demand Parameters (EDP), proxy for the structural response;  $f(edp|im)$  is the joint PDF of

the EDPs conditioned to a vector of ground motion intensity measures (IM);  $f(im|\underline{d}, \underline{s})$  is the real-time hazard expressed by (16) in the case of a scalar IM.

Being able to compute, before the ground motion hits the site, the expected losses in case of warning ( $W$ ) or not ( $\bar{W}$ ), is relevant for taking the optimal decision, i. e., to alarm if this reduces the expected losses and to not issue any warning otherwise:

$$\text{to alarm if } E^W[L|\underline{d}, \underline{s}] \leq E^{\bar{W}}[L|\underline{d}, \underline{s}]$$

Optimal decision: (20)

$$\text{to not alarm if } E^W[L|\underline{d}, \underline{s}] > E^{\bar{W}}[L|\underline{d}, \underline{s}]$$

which is a better decisional rule in respect to that of (18).

Computing and comparing expected losses, conditioned to the real-time information coming from the EEWS, in the case of alarming or not, allows the determination of the alarm threshold above which it is convenient to issue the warning according to the optimally maximum criterion.

Assessment of average loss reduction determined by issuing an Early Warning provides a quantitative tool to evaluate the efficiency and feasibility of an EEWS.

Other potential advantages given by this approach are that: (a) the threshold may be set on a statistic (i. e., the summation of the logs) inferred from seismic network measurements, dramatically reducing the required computational effort for real-time decision making; (b) it minimizes the cry wolf issue reducing the probability of false and missed alarms thanks to threshold optimization. In fact, although the number of MA and FA depend on the decisional rule adopted to issued the alarm, the approach developed in Iervolino et al. [20,21,22] avoids explicitly considering the missed and false alarm rates associated with the decision, as the choice to alarm or not is taken based on the expected economic loss (not on the estimation of peak ground motion). In other words, if in computing the expected loss one accounts for the costs of false and missed alarms, there is no need to optimize the *cry wolf* issue, and MA and FA rates are at their values determined by the respective costs, and in this sense are optimal.

### Future Directions

We have analyzed and illustrated the main scientific and technological issues related to the implementation and management of an earthquake early warning system under development in the Campania region of southern Italy.

The system is designed for early warning alert notification at distant coastal targets based on a dense, wide-dynamic seismic network (accelerometers, seismometers

and broadband sensors) deployed in the Apenninic belt region (ISNet – Irpinia Seismic Network). It can therefore be classified as a regional Early Warning System consisting of a wide seismic sensor network covering a portion or the entire area which is threatened by a quake's strike.

According to [25], real-time estimates of earthquake location and magnitude are needed for regional warning systems (EEWS), i. e., dense seismic networks covering all or a portion of an area of interest. However the alarm decision in an early warning system is based, rather, on the prediction, with quantified confidence, of a ground motion intensity at a distant target site (where a sensitive structure is located). This problem needs an evolutionary (i. e., time-dependent) and probabilistic frame where pdfs for earthquake location, magnitude and attenuation parameters are combined to perform a real-time probabilistic seismic hazard analysis (e. g., [19]).

Considering the peak displacement amplitude and/or predominant frequency measured in the early portion of  $P$ -waves, we have shown that suitable probability density functions for the earthquake location and magnitude parameters can be constructed and used for real-time probabilistic assessment of false alarms and loss estimation, which are the key elements based on which automatic actions can be undertaken to mitigate earthquake effects.

Based on the analysis of acceleration records of Euro-Mediterranean and Japanese earthquakes, Zollo et al. [49,50] have shown the advantages of using near source strong motion records for real time estimation of earthquake magnitude. In fact they provide unsaturated recordings of moderate to large earthquakes and, in case of dense station coverage of the source area, the combination of both  $P$ - and  $S$ -wave amplitude information can be used to get fast and robust earthquake location and magnitude estimates.

We support the use of  $S$ -waves recorded in the near-source of an impending earthquake for earthquake early warning, especially in view of the excellent correlation that  $S$ -peaks show with magnitude up to about  $M = 7$  for Euro-Mediterranean and Japanese earthquakes [49,50]. Dense accelerometric networks now operating in Europe, USA, Taiwan, Japan and other seismic regions in the world can provide a sufficient number of records at distances smaller than 20–30 km from potentially damaging crustal earthquakes so that  $S$ - $P$  times are expected to be smaller than 2–3 s. A magnitude estimation using  $S$ -waves could be therefore available 4–5 s after the first  $P$ -wave is recorded, which is still useful for sending an alert to distant target sites.

Although relatively few magnitude 7 and larger earthquakes have hit the Apenninic belt, and generally the

Mediterranean region, during the last century, there have been many instances of damaging quakes in the magnitude 6 range.

Earthquake early warning systems have the potential to mitigate the effects of moderate size earthquakes ( $M = 6-7$ ), which can produce severe damage in densely urbanized areas and places where old structures were not built to current standards. This has been the case for a significant number of earthquakes occurred in the Mediterranean basin during last decades: the 1976 Friuli ( $M = 6-6.5$ ) and 1997 Colfiorito ( $M = 6$ ) in Italy, 1999 Athens ( $M = 5.9$ ) in Greece, 2002 Nahrin, in Afghanistan ( $M = 6.1$ ), 2003 in Algeria ( $M = 6.7$ ), 2003 Bam ( $M = 6.3$ ) in Iran, 2004 in Morocco ( $M = 6.4$ ).

An earthquake early warning system can be effective for mitigating the effects of moderate earthquakes. For moderate size events, early warning systems could also mitigate earthquake effects in terms of infrastructure operability (e.g., hospitals, firehouses, telecommunication hubs, ...) during the post-event emergency phase and rescue operations. For instance, in tall buildings, the higher floors generally sway much more than those near ground level, so that even a moderate earthquake could cause severe damage to a high rise. Therefore, even at 70–80 km distance from its epicenter, a magnitude 6 quake could affect hospital operating rooms and other critical installations.

Installations as close as 50 km from the epicenter could receive an earthquake warning 10 s prior to the arrival of the more energetic waves ( $S$  and surface waves) of an earthquake. To take advantage of this brief warning period, automated systems would have to be created that respond instantly to notification alert signals, and they would have to be carefully calibrated to avoid false or missed alarms. Closer to the epicenter, a magnitude 6 or higher earthquake can damage critical infrastructures, such as telephone lines, gas pipelines, highways, and railroads, as well as airport runways and navigation systems. These disruptions would have a domino effect in more distant areas, which could be mitigated by an early warning alert system, based on the earliest primary wave data to arrive at recording stations close to the epicenter.

Finally, we note that earthquake early warning systems can also help mitigate the effects of such earthquake-induced disasters as fires, explosions, landslides, and tsunamis, which can in many cases be more devastating than the earthquake itself. Systems could be installed at relatively low cost in developing countries, where moderate sized earthquakes can cause damage comparable to that caused by much larger earthquakes in developed countries.

### Glossary

**Meta-stability of man-made structures** is the consequence of their upright construction above ground. For excessive dynamic (earthquake) loads, when the lateral deflection exceeds some critical value (this is normally accompanied by softening nonlinear behavior of the structural members), the overturning moment of the gravity forces becomes larger than the restoring moment, and the structure becomes unstable and moves exponentially toward collapse.

**Complex and evolving structural systems** are structures with a large number of degrees of freedom and many structural members, which for given loads experience softening nonlinear deformations. During strong excitation, continuous changes (typically decreases) in effective stiffness and time-dependent changes in boundary conditions result in a system whose properties are changing with time.

**Soil–structure interaction** is a process in which the soil and the structure contribute to mutual deformations while undergoing dynamic response. In time, with continuously changing contact area between the foundation and the soil (opening and closing of gaps), when the deformations are large, soil–structure interaction is characterized by nonlinear geometry and nonlinear material properties in both the soil and in the structure.

### Definition of the Subject

Nonlinear problems in structural earthquake engineering deal with the dynamic response of meta-stable, man-

made buildings subjected to strong earthquake shaking. During earthquakes, structures constructed on soft sediments and soils deform together with the underlying soil in the dynamic process called soil–structure interaction. Strong shaking forces the soil–structure systems to evolve through different levels of nonlinear response, with continuously changing properties that depend upon the time history of excitation and on the progression and degree of damage. Thus far, the analyses of this response have used the vibrational approach and lumped mass discrete models to represent real structures. Loss of life and property, however, continue to be high during strong shaking in the vicinity of the faults responsible for earthquakes. This calls for new, more physically refined methods of analysis, which can be based on nonlinear wave propagation, and for balancing of the structural capacities with the power carried by the earthquake waves.

After a brief discussion of the literature on the complex and chaotic dynamics of simple mechanical oscillators, the dynamic characteristics and governing equations in the meta-stable structural dynamics of earthquake engineering are introduced. The nature of the solutions of the governing equations in terms of both the vibrational and the wave representations is discussed, and the dynamic instability, material and geometric nonlinearities, and complexities of the governing equations associated with nonlinear soil–structure interaction are described. Collectively, the examples presented reflect the complex physical nature of meta-stable structural systems that experience nonlinear dynamic response, the characteristics of which change and evolve during earthquake excitation.

### Introduction

Earthquake engineering, through a cooperation of structural and geotechnical engineers with seismologists and geologists, aims to develop methods for safer design of man-made structures to withstand shaking near intermediate and large earthquakes. This requires addressing the problems of predictability of the response of complicated nonlinear systems, which is one of the important subjects of modern nonlinear science. Through the studies of the dynamic response, earthquake engineers address complex physical problems and issues with important social implications.

The completeness and beauty of the linear differential equations appear to have led to their dominance in the mathematical training of engineers and scientists during most of the 20th century. The recognition that chaotic dynamics is inherent in all nonlinear physical phenomena, which has created a sense of revolution in applied me-

chanics and physics today, so far has had little if any effect on the research and design of earthquake-resistant structures. In the past, the designs in structural engineering and control systems were kept within the realm of linear system dynamics. However, the needs of modern technology have pushed the design into the nonlinear regimes of large deformations, which has increased the possibility of encountering chaotic dynamic phenomena in structural response. Even a cursory review of papers on chaotic vibrations in mechanical systems leads to the conclusion that chaotic dynamics is not a small, insignificant class of motions and that chaotic oscillations occur in many nonlinear systems and for a wide range of values of the parameters.

If an engineer chooses parameters that produce chaotic output, then he or she loses predictability. However, the chaotic behavior of nonlinear systems does not exclude predictability of the response but rather introduces upper bounds (prediction horizons) [31] and renders the predictions probabilistic. The important question is then over what time-scale are the forecasts reliable, given the current state and knowledge of the system. Another key ingredient for prediction is an adequate physical model. At present, because of the multitude of interacting phenomena and the absence of physically complete equations of motion, there exists no adequate general model of the complete earthquake response process. While the practical outcome of most work in earthquake engineering remains empirically based, the nonlinear methods are gaining popularity, aiming to decipher the governing phenomena and to assess the reliability of the models. It appears now that the broad-based revolution in the worldview of science that begun in the twentieth century will be associated with chaotic dynamics [43]. This revolution should eventually also contribute to better understanding and more complete representation of the response analyses in earthquake engineering.

It has been argued that major changes in science occur not so much when new theories are advanced but when the simple models with which scientists conceptualize a theory are changed [24]. In vibrations, such a conceptual model that embodies the major features of a whole class of problems is the spring-mass system. Lessons emerging from studies of the spring-mass model and several other relevant models can serve as conceptual starting points for generalizations and also as a guide to further studies of more complex models in earthquake engineering and structural dynamics.

Studies of forced vibrations of a pendulum have revealed complex dynamics and chaotic vibrations [14,15]. A simply supported beam with sub-buckling axial com-

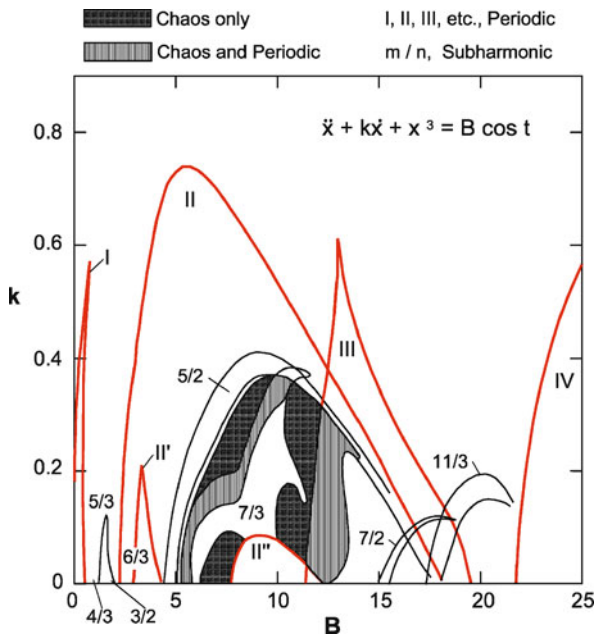

pression modeled by a single mode approximation yields a Mathieu type equation and for certain values of the parameters leads to unstable solutions. When nonlinearities are added, these vibrations result in a limit cycle. A related problem is a classical pendulum with a vibrating pivot support, which also leads to chaotic vibrations [29,34]. Chaotic motions in a double pendulum have been studied by Richter and Scholz [45], and the complex dynamics and chaotic solutions for a spherical pendulum with two degrees of freedom have been described by Miles [35].

Impact-type problems result in explicit difference equations or maps, which can yield chaotic vibrations for certain values of the governing parameters [30]. A mass vibrating in a gap between two stiff springs on either side [17,46,47] is a simple related model, which suggests a starting point for research in nonlinear vibration of piles, and for impact-type interaction of adjacent buildings, excited by strong earthquake ground motion. The reader can find examples of such problems in the description of damage in Mexico City, for example, during several earthquakes [32].

Chaotic motions of an elasto-plastic arch have been studied by Poddar et al. [42]. Forced vibrations of a buckled beam, modeled by the Duffing equation, showed that chaotic vibrations are possible [16]. Forced vibrations described by a Duffing equation with viscous damping and nonlinear (cubic) elastic (stiffening) spring were studied by Ueda [67]. Figure 1 summarizes his results and describes the regions of chaotic, periodic (I, II, etc.), and subharmonic (m/n) motions as functions of the damping and forcing amplitudes. This simple equation, representing a hardening spring system, has direct analogues in the dynamics of piles and in the rocking of buildings, both following the strong-motion phase of earthquake shaking after horizontal gaps have been created between the pile (foundation walls) and the soil [63].

A mechanical system with a nonlinear restoring force and with a control force added to move the system according to some prescribed signal has been studied by Holmes and Moon [19] and Holmes [18]. It was shown that such a system exhibits both periodic limit-cycle oscillation and chaotic motions. Chaotic vibrations in continuous beams have been studied for nonlinear body forces and nonlinear boundary conditions (that depend on the motion), and for motions large enough for the nonlinear terms in the equations of motion to be significant [37,38,39,40,41]. Forced planar vibrations of nonlinear elastica [35,36], were shown to become unstable and exhibit chaotic motions under certain conditions.

The above-mentioned studies imply that there is a conflict in the classical engineering description of the world.

Earthquake Engineering, Non-linear Problems in, Figure 1  
Chaos diagram showing regions of chaotic, chaotic and periodic, periodic (I, II, III, etc.), and sub-harmonic ( $4/3$ ,  $3/2$ ,  $5/3$ , etc.) motions for a nonlinear equation as functions of non-dimensionalized damping and forcing amplitude (from [67])

One aspect of this conflict is the assumption that nature is a deductive system, moving forward in time according to deterministic laws. Another aspect is that a scientist attempting to model portions of the world from finite data projects unverifiable structure onto the local environment. The conflict is that these two views do not match, leaving us with a question: what are models good for? There are many systems in nature that are observed to be chaotic, and for which no adequate physical model exists. Whether a model is adequate or not depends, of course, on the questions asked [7]. Unfortunately, the art of dynamical modeling is often neglected in discussions of nonlinear and chaotic systems, in spite of its crucial importance [1]. In the following, the modeling problem in earthquake engineering will be illustrated using two common approaches to the solution, one based on an equivalent oscillator and the other one using wave representation.

Stochastic processes have been developed to describe irregular phenomena in deterministic systems that are too complicated or have too many variables to be fully described in detail. For example, stochastic processes have been used to model the response of structures to earthquake and wind forces, which are deterministic, and in principle could be completely described. In practice, the

stochastic modeling has been used also as an approximate description of a deterministic system that has unknown initial conditions and may be highly sensitive to the initial conditions. In trying to model real systems, as a result of the modeling process, we sometimes obtain a model that shows very regular behavior, while the real system has very irregular behavior. In that case, random noise is added to the model, but this represents no more than our lack of knowledge of the system structure or the inadequacy of the identification procedure [22].

In earthquake engineering, the complexity of the multi-dimensional real world is reduced to a sub-space, which is defined by (1) the dimensions and properties of the adopted mathematical models, (2) the nature of the adopted boundary conditions, and (3) the method of solution. A linear mechanical system cannot exhibit chaotic vibrations, and for periodic inputs it produces periodic outputs. The chaotic system must have nonlinear elements or properties, which can include, for example, (1) nonlinear elastic or spring elements; (2) nonlinear damping (such as stick-slip friction); (3) backlash, play, or bilinear springs; and (4) nonlinear boundary conditions. The nonlinear effects can be associated with the material properties, with the geometric effects, or both. In the following, the consequences of unorthodox boundary conditions and nonlinear waves in a building will be used to illustrate the extensions and complexities associated with evolving systems. The utility of this complexity can be viewed as the arbiter of the order and randomness.

### Vibrational Representation of Response

The first modern uses of mechanics in problems of earthquake engineering appeared during the early 1900s, following the earthquake disasters in San Francisco (1906), Messina-Reggio (1908), and Tokyo (1923) and the realization that something needed to be done to prevent such losses of life and property during future events. The first practical steps consisted of introducing the *seismic coefficient* (*shindo* in Japan, and *rapporto sismico* in Italy). This was followed by earthquake-resistant design codes, first adopted in Japan in 1923, and then in California in 1934 [44]. During the same period, there also appeared the first studies of the effects of earthquake shaking on structures in terms of simple mechanical oscillators [48], and in the early 1930s the modern theory based on the response spectrum method was introduced [2,3,4]. These early developments follow the deterministic formulations of Newtonian mechanics and employ linear models and equations of motion.

### Elementary Vibrational Representation of Response

The basic model employed to describe the response of a simple structure to only horizontal earthquake ground acceleration,  $\ddot{\Delta}_x$ , is a single-degree-of-freedom system (SDOF) that experiences rocking  $\psi_r$  relative to the normal to the ground surface. The model also assumes that the ground does not deform in the vicinity of the foundation—that is, it neglects the soil–structure interaction (Fig. 2). The rotation  $\psi_r$  is restrained by a spring with stiffness  $K_r$  and by a dashpot with rocking damping constant  $C_r$ , providing the fraction of critical damping  $\zeta_r$ . The natural frequency of this system is  $\omega_r = (K_r/h^2 m_b)^{1/2}$ , and for small rocking angles it is governed by the linear ordinary differential equation

$$\ddot{\psi}_r + 2\omega_r \zeta_r \dot{\psi}_r + \omega_r^2 \psi_r = -\ddot{\Delta}_x/h. \quad (1)$$

For any initial conditions, and for arbitrary excitation, this system always leads to a deterministic and predictable response. Equation (1) was used originally to develop the concept of relative response spectrum and continues to this day as the main vehicle in formulation of most earthquake engineering analyses of response [56]. If the gravity force is considered,  $\omega_r$  in Eq. (1) has to be reduced [5]. The system described by Eq. (1) is meta-stable for  $\psi_r$  smaller than its critical value. At the critical value of  $\psi_r$ , the over-

turning moment of the gravity force is just balanced by the elastic moment in the restraining spring, and for values greater than the critical value the system becomes unstable.

### Advanced Vibrational Representation of Response

In more advanced vibrational representations of the response, additional components of the earthquake excitation, structural dynamic instability, soil–structure interaction, spatial and temporal variations of the excitation, differential motions at different support points, and non-linear behavior of the stiffness  $K_r$  can be considered, but the structure usually continues to be modeled by mass-less columns, springs, and dashpots, and with a rigid mass  $m_b$ . In the following, we illustrate some of the above-mentioned cases.

**Dynamic Instability** An example of a simple model that includes instability is shown in Fig. 3. It experiences horizontal, vertical, and rocking excitations, which can result, for example, from incident P and SV waves. The structure

Earthquake Engineering, Non-linear Problems in, Figure 2  
Single-degree-of-freedom system (SDOF) representation of a building (inverted pendulum) with equivalent mass  $m_b$  and mass-less column of height  $h$ , experiencing rocking  $\psi_r$  due to horizontal motion of its base  $\Delta_x$

Earthquake Engineering, Non-linear Problems in, Figure 3  
Single-degree-of-freedom system (SDOF) representation of a building (inverted pendulum), with equivalent mass  $m_b$ , moment of inertia (about  $O$ )  $I_b$ , and a mass-less column of height  $h$ , experiencing relative rocking  $\psi_r$  due to horizontal, vertical, and rocking motions of its foundation ( $\Delta_x$ ,  $\Delta_z$ , and  $\phi_y$ ), which result from soil–structure interaction when excited by incident wave motion

is represented by an equivalent single-degree-of-freedom system, with a concentrated mass  $m_b$  at height  $h$  above the foundation. It has a radius of gyration  $r_b$  and a moment of inertia  $I_b = m_b r_b^2$  about point O. The degree-of-freedom in the model is chosen to correspond to the relative rocking angle  $\psi_r$ . This rotation is restrained by a spring with rocking stiffness  $K_r$  and by a dashpot with rocking damping  $C_r$  (both not shown in Fig. 3), and the gravitational force  $m_b g$  is considered. Taking moments about B results in the equation of motion

$$\ddot{\phi}_y + \ddot{\psi}_r + 2\omega_r \zeta_r \dot{\psi}_r + \omega_r^2 \psi_r = \{- (\ddot{\Delta}_x/a) \cos(\phi_y + \psi_r) + (\omega_r^2 \varepsilon_g + \ddot{\Delta}_z/a) \sin(\phi_y + \psi_r)\} / \varepsilon, \quad (2)$$

where  $\varepsilon = h(1 + (r_b/h)^2)/a$ ,  $\omega_r^2 = K_r/[m(h^2 + r_b^2)]$ ,  $\omega_r$  is the natural frequency of rocking,  $\zeta_r$  is a fraction of critical damping in  $2\omega_r \zeta_r = C_r/[m(h^2 + r_b^2)]$ , and  $\varepsilon_g = 2/\omega_r^2 a$ . Equation (2) is a differential equation coupling the rocking of the foundation,  $\phi_y$ , and of the structure,  $\psi_r$ , with the horizontal and vertical motions of the foundation. It is a nonlinear equation the solution to which requires numerical analysis. In this example, we will discuss only the case in which  $\phi_y + \psi_r$  is small. Then,

$$\ddot{\psi}_r + 2\omega_r \zeta_r \dot{\psi}_r + \{\omega_r^2(1 - \varepsilon_g/\varepsilon) - \ddot{\Delta}_z/\varepsilon a\} \psi_r = -\ddot{\phi}_y + \{-\ddot{\Delta}_x/a + (\omega_r^2 \varepsilon_g + \ddot{\Delta}_z/a) \phi_y\} / \varepsilon. \quad (3)$$

For steady-state excitation by incident P and SV waves with frequency  $\omega$ ,  $\Delta_x$ ,  $\phi_y$ , and  $\Delta_z$ , and therefore the forcing function of Eq. (3), will be periodic. Equation (3) is then a special form of the Hill's equation. Analysis of the stability of this equation can be found in the work of Lee [25]. For general earthquake excitation,  $\Delta_x$ ,  $\phi_y$ , and  $\Delta_z$  will be determined by the recorded components of motion, and in predictive analyses by simulated ground motions [27,28,70].

In Eq. (3),  $\phi_y$  describes rocking of the foundation to which the structure is attached. In analyses that do not consider soil-structure interaction,  $\phi_y$  will be determined directly by the rocking component of strong ground motion [21,28], and in studies that consider soil-structure interaction  $\phi_y$  will be one of the variables to be determined by the analysis [25].

**Soil-Structure Interaction** The problem of linear soil-structure interaction embodies the phenomena that result from (1) the presence of an inclusion (foundation, Fig. 4) in the soil [26], and (2) the vibration of the structure supported by the foundation, which exerts dynamic forces on the foundation [25]. Examples and a discussion of the non-

Earthquake Engineering, Non-linear Problems in, Figure 4 Six components of motion (three translations and three rotations)  $\{\Delta_x, \Delta_y, \Delta_z, \phi_x, \phi_y, \phi_z\}$  of point B, and six components of force (three forces and three moments)  $\{F_{ext}\} = \{F_{bx}, F_{by}, F_{bz}, M_{bx}, M_{by}, M_{bz}\}$ , that the structure exerts on the foundation at B

linear aspects of soil-structure interaction can be found in Gicev [9] and in a review of observations of response to earthquake shaking in full-scale structures in Trifunac et al. [63,64,65].

The dynamic response of a rigid, embedded foundation to seismic waves can be separated into two parts. The first part corresponds to the determination of the restraining forces due to the motion of the inclusion, usually assumed to be a rigid body. The second part deals with the evaluation of the driving forces due to scattering of the incident waves by the inclusion, which is presumed to be immobile. This can be illustrated by considering a foundation embedded in an elastic medium and supporting an elastic superstructure. The steady-state harmonic motion of the foundation having frequency  $\omega$  can be described by a vector  $\{\Delta_x, \Delta_y, \Delta_z, \phi_x, \phi_y, \phi_z\}^T$  (Fig. 4), where  $\Delta_x$  and  $\Delta_y$  are horizontal translations,  $\Delta_z$  is vertical translation,  $\phi_x$  and  $\phi_y$  are rotations about horizontal axes, and  $\phi_z$  is torsion about the vertical axis. Using superposition, displacement of the foundation is the sum of two displacements:

$$\{U\} = \{U^*\} + \{U_0\}, \quad (4)$$

where  $\{U^*\}$  is the foundation input motion corresponding to the displacement of the foundation under the action of the incident waves in the absence of external forces, and  $\{U_0\}$  is the relative displacement corresponding to the dis-

placement of the foundation under the action of the external forces in the absence of incident wave excitation.

The interaction force  $\{F_s\}$  generates the relative displacement  $\{U_0\}$ , which corresponds to the force that the foundation exerts on the soil and that is related to  $\{U_0\}$  by  $\{F_s\} = [K_s(\omega)]\{U_0\}$ , where  $[K_s(\omega)]$  is the  $6 \times 6$  complex stiffness matrix of the embedded foundation. It depends upon the material properties of the soil medium, the characteristics and shape of the foundation, and the frequency of the harmonic motion, and it describes the force-displacement relationship between the rigid foundation and the soil medium.

The driving force of the incident waves is equal to  $\{F_s^*\} = [K_s]\{U^*\}$ , where the input motion  $\{U^*\}$  is measured relative to an inertial frame. The “driving force” is the force that the ground exerts on the foundation when the rigid foundation is kept fixed under the action of the incident waves. It depends upon the properties of the foundation and the soil and on the nature of excitation.

The displacement  $\{U\}$  is related to the interaction and driving forces via  $[K_s]\{U\} = \{F_s\} + \{F_s^*\}$ . For a rigid foundation having a mass matrix  $[M_0]$  and subjected to a periodic external force,  $\{F_{ext}\}$ , the dynamic equilibrium equation is

$$[M_0]\{\ddot{U}\} = -\{F_s\} + \{F_{ext}\}, \tag{5}$$

where  $\{F_{ext}\} = \{F_{bx}, F_{by}, F_{bz}, M_{bx}, M_{by}, M_{bz}\}$  is the force the structure exerts on the foundation (Fig. 4). Then, Eq. (5) becomes

$$[M_0]\{\ddot{U}\} + [K_s]\{U\} = \{F_s^*\} + \{F_{ext}\}. \tag{6}$$

The solution of  $\{U\}$  requires the determination of the mass matrix, the impedance matrix, the driving forces, and the external forces [25].

After the mass matrix  $[M_0]$ , the stiffness matrix  $[K_s]$ , and the force  $\{F_s^*\}$  have all been evaluated, they can be used to determine the foundation displacement  $\{U\}$ . For in-plane response excited by P and SV waves, for example, the relative response  $\psi_r$  is then given by Eq. (3).

**Differential Motions** Common use of the response spectrum method [56] and many dynamic analyses in earthquake engineering implicitly assume that all points of building foundations move synchronously and with the same amplitudes. This, in effect, implies that the wave propagation in the soil is neglected. Unless the structure is long (e. g., a bridge with long spans, a dam, a tunnel) or “stiff” relative to the underlying soil, these simplifications are justified and can lead to a selection of approximate design forces if the effects of soil-foundation interaction in the presence of differential ground motions can be

Earthquake Engineering, Non-linear Problems in, Figure 5 Schematic representation of the deformation of columns accompanying differential wave excitation of long structures for out-of-plane response (top) and in-plane response (bottom) when SH or Love waves (top) or Rayleigh waves (bottom) propagate along the longitudinal axis of a structure

neglected [6]. Simple analyses of two-dimensional models of long buildings suggest that when  $a/\lambda < 10^{-4}$ , where  $a$  is wave amplitude and  $\lambda$  is the corresponding wavelength, the wave propagation effects on the response of simple structures can be neglected [50].

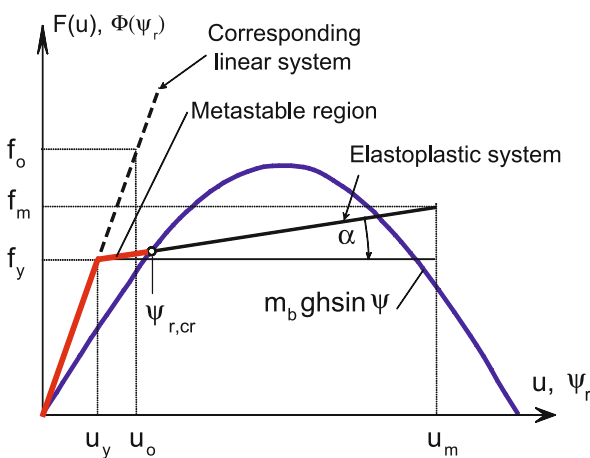

Figure 5 illustrates the “short” waves propagating along the longitudinal axis of a long building or a multiple-span bridge. For simplicity, the incident wave motion has been separated into out-of-plane motion (Fig. 5, top), consisting of SH and Love waves, and in-plane motion (Fig. 5, bottom) consisting of P, SV, and Rayleigh waves. The in-plane motion can further be separated into horizontal (longitudinal), vertical, and rocking components, while out-of-plane motion consists of horizontal motion in the transverse direction and torsion along the vertical axis. Trifunac and Todorovska [61] analyzed the effects of the horizontal in-plane components of differential motion

for buildings with models that are analogous to the sketch in Fig. 5 (bottom), and they showed how the response spectrum method can be modified to include the first-order effects of differential motions. Trifunac and Gicev [59] showed how to modify the spectra of translational motions, into a spectrum that approximates the total (translational and torsional) responses, and how this approximation is valid for strong motion waves an order of magnitude longer than the structure ( $\lambda \gg L$ ).

As can be seen from the above examples the differential motions lead to complex excitation and deformation of the structural members (columns, shear walls, beams, braces), increase the dimensions of the governing differential equations, lead to three-dimensional dynamic instability problems, and can lead to nonlinear boundary conditions. These are all conditions that create an environment in which, even with the most detailed numerical simulations, it is difficult to predict all of the complexities of the possible responses.

### Nonlinear Vibrational Analyses of Response

For engineering estimation of the maximum nonlinear response of a SDOF system,  $u_m$ , in terms of the maximum linear response,  $u_0$ , it is customary to specify a relation between  $u_m$  and  $u_0$  (Fig. 6). By defining the yield-strength reduction factor as  $R_y = u_0/u_y$ , where  $u_y$  is the yielding displacement of the SDOF system equivalent spring, and ductility as  $\mu = u_m/u_y$ , for the same ground motion the ratio  $u_m/u_0$  is then equal to  $\mu/R_y$ . Veletsos and

Earthquake Engineering, Non-linear Problems in, Figure 6 Bi-linear representation of stiffness (yielding at  $(u_y, f_y)$ ), overturning moment of gravity force ( $m_b g h \sin \psi$ ), critical rocking angle  $\psi_{r,cr}$ , and meta-stable region ( $0 < \psi_r < \psi_{r,cr}$ ) for an SDOF system

Newmark [68,69] showed that (1) for a long-period SDOF system when its natural period  $T_n = 2\pi/\omega_n$  becomes very long,  $u_m / u_0$  tends toward 1 and  $R_y$  approaches  $\mu$  (equal deformation rule); (2) for the response amplitudes governed mainly by the peak excitation velocities,  $u_m / u_0$  can be approximated by  $\mu/\sqrt{2\mu - 1}$  and  $R_y$  by  $\sqrt{2\mu - 1}$  (equal strain energy rule); and (3) for a high-frequency (stiff) system when  $T_n \sim 0$ ,  $R_y \sim 1$ .

**Complexities of Simultaneous Action of Dynamic Instability, Nonlinearity, and Kinematic Boundary Conditions – Example** The model we illustrate next is an SDOF when it is excited by synchronous horizontal ground motion at its two supports (1 and 2 in Fig. 7), but it behaves like a three-degree-of-freedom (3DOF) system when excited by propagating horizontal, vertical, and rocking ground motions. For such a system, the above classical equal energy and equal displacement rules for SDOF system will not apply.

The goals here are to describe the effects of differential motion on strength-reduction factors  $R_y$  of the simple structure shown in Fig. 7 when it is subjected to all of the components of near-source ground motions, and to illustrate the resulting complexities of nonlinear response. Analyses of the consequences of the differences in ground motion at structural supports, caused by non-uniform soil properties, soil-structure interaction, and lateral spreading, for example, will further contribute to the complexities of the response, but these factors will not be discussed here.

The original response spectrum method was formulated using a vibrational solution of the differential equation of an SDOF system excited by synchronous, and only horizontal (one component), ground motion. The consequences of simultaneous action of all six components of ground motion (three translations and three rotations) on the relative response of an SDOF system are still rarely considered in modern engineering design [58], even though it has been 75 years since the original response spectrum method was formulated and about 40 years since it became the principal tool in engineering design [56]. Because the response spectrum method has become an essential part of the design process and of the description of how strong motion should be specified for a broad range of design applications [52], we hope that the present examples will help to further understanding of the complexities of response in more realistic models of structures.

The nature of the relative motion of individual column foundations or of the entire foundation system will depend upon the type of foundation, the characteristics of the soil surrounding the foundation, the type of incident

Earthquake Engineering, Non-linear Problems in, Figure 7  
**The structure deformed by the wave, propagating from left to right, with phase velocity  $C_x$ , for the case of  $+v_{g_i}$  ("up" motion). Different column rotations  $\psi_1$  and  $\psi_2$  result from different translations and rotations at supports 1 and 2 (from [21])**

waves, and the direction of wave arrival, with the motion at the base of each column having six degrees of freedom. In the following example, we assume that the effects of soil–structure interaction are negligible; consider only the in-plane horizontal, vertical, and rocking components of the motion of column foundations; and show selected results of the analysis for a structure on only two separate foundations. We assume that the structure is near the fault and that the longitudinal axis of the structure ( $X$  axis) coincides with the radial direction ( $r$  axis) of the propagation of waves from the earthquake source, so that the displacements at the base of columns are different as a result of the wave passage alone. We suppose that the excitations at the piers have the same amplitude but different phases and that the phase difference (or time delay) will depend upon the distance between the piers and the horizontal phase velocity of the incident waves.

The simple model we consider, which is described in Fig. 7, represents a one-story structure consisting of a rigid mass,  $m$ , with length  $L$ , supported by two rigid, mass-less columns with height  $h$ , which are connected at the top to the mass and at the bottom to the ground by rotational springs (not shown in Fig. 7). The stiffness of the springs,  $k_\phi$ , is assumed to be elastic-plastic, as in Fig. 6, without hardening ( $\alpha = 0$ ). The mass-less columns are connected to the ground and to the rigid mass by rotational dashpots,  $c_\phi$ , providing a fraction of critical damping equal to 5 percent. Rotation of the columns,  $\phi_i = \theta_{g_i} + \psi_i$  for  $i = 1, 2$ , which is assumed to be not small, leads us to consider the geometric nonlinearity. The mass is acted upon by the acceleration of gravity,  $g$ , and is excited by differential hori-

zontal, vertical, and rocking ground motions,  $u_{g_i}$ ,  $v_{g_i}$ , and  $\theta_{g_i}$ ,  $i = 1, 2$  (Fig. 7) at the two bases, so that

$$u_{g_2}(t) = u_{g_1}(t - \tau); \quad v_{g_2}(t) = v_{g_1}(t - \tau);$$

$$\theta_{g_2}(t) = \theta_{g_1}(t - \tau); \quad \tau = L/C_x,$$

with  $\tau$  being the time delay between the motions at the two piers and  $C_x$  the horizontal phase velocity of the incident waves. The functional forms of  $u_{g_i}$ ,  $v_{g_i}$ , and  $\theta_{g_i}$  are defined by the near-source ground motions [21], and the rocking component of the ground motion is approximated by [28]  $\theta_{g_i}(t) = -\dot{v}_{g_i}(t)/C_x$ , where  $\dot{v}_{g_i}(t)$  is the vertical velocity of the ground motion at the  $i$ th column. Of course, in a more accurate modeling, the ratio of the  $v_{g_i}$  to  $u_{g_i}$  amplitudes will depend upon the incident angle and the character of incident waves, while the associated rocking  $\theta_{g_i}$  will be described by a superposition of the rocking angles associated with incident body and dispersed surface waves [28].

The yield-strength reduction factor for the system subjected to synchronous ground motion is  $R_y = f_0/f_y = u_0/u_y$ , where all of the quantities are defined in Fig. 6. In this example, for the assumed model and because of the differential ground motions and rotation of the beams, the relative rotation for the two columns at their top and bottom will be different. Therefore, it is necessary to define the  $R$ -factor and ductility for each corner of the system, instead of one factor for the entire system. In all calculations here, we consider the actions of the horizontal, vertical, and rocking components of the ground motion, the effects of gravity force, dynamic instability, and geometric nonlinearity. For the structure in Fig. 7, we calculate maximum linear and nonlinear relative rotations at four corners of the system under downward ( $-v_{g_i}$ ), radial, and rocking, and upward ( $+v_{g_i}$ ), radial and rocking near-source differential ground motions corresponding to a given earthquake magnitude, ductility  $\mu$ , and for different time delays,  $\tau$ . Then we plot  $R_y$  versus  $T_n$  for the four corners of the system.

Figure 8 illustrates typical results for  $R_y$  versus the oscillator period for near-source, fault-parallel displacement  $d_N(t) = A_N(1 - e^{-t/\tau_N})/2$  [21], with downward vertical ground displacement, magnitude  $M = 8$ , for a ductility ratio of 8 and a time delay of  $\tau = 0.05$  s. It shows the results for the top-left, top-right, bottom-left, and bottom-right corners of the system, assuming wave propagation from left to right (see Fig. 7). For reference and easier comparison with the previously published results, we also plot one of the oldest estimates of  $R_y$  versus period, using piecewise straight lines [21]. The curve  $(R_y)_{\min}$  shows the minimum values of  $R_y$  for  $d_N(t)$  motion with  $-v_{g_i}$ , and for  $M = 8$ ,  $\mu = 8$ , and  $\tau = 0.05$  s.

Earthquake Engineering, Non-linear Problems in, Figure 8  
 Example of the effects of the differential ground motion on the strength-reduction factors  $R_y$  at the four corners of the structure in Fig. 7, subjected to horizontal, vertical, and rocking components of the fault-parallel displacement, for downward vertical motion ( $-v_{gj}$ ) for earthquake magnitude  $M = 8$ , ductility  $\mu = 8$ , and delay at the right support  $\tau = 0.05$  s. The amplitudes of the piecewise straight representation of the classical  $R_y$  are shown for comparison [21].  $(R_y)_{min}$  shows the smallest values of the  $R$ -factors, which for the set of conditions in this example are determined by the response at the top left corner (for periods shorter than 0.1 s), at the bottom right corner (for periods between 0.1 and 0.35 s), and at the top right corner (for periods longer than 0.35 s)

For periods longer than 5 to 10 s,  $R_y$  curves approach “collapse boundaries” [21]. This is implied in Fig. 8 by the rapid decrease of  $R_y$  versus period for periods longer than about 7 s. At or beyond these boundaries, the nonlinear system collapses due to the action of gravity loads and dynamic instability.

The complex results illustrated in Fig. 8 can be simplified by keeping only  $(R_y)_{min}$ , since it is only the minimum value of  $R_y$  that is needed for engineering design. By mapping  $(R_y)_{min}$  versus period of the oscillator for different earthquake magnitudes,  $M$ , different ductilities,  $\mu$ , and different delay times,  $\tau$ , design criteria can be formulated

for design of simple structures to withstand near-fault differential ground motions [21]. Nevertheless, the above shows how complicated the response becomes even for as simple a structure as the one shown by the model in Fig. 7, when differential ground motion with all of the components of motion is considered. In this example, this complexity results from simultaneous consideration of material and geometric nonlinearities, dynamic instability, and kinematic boundary conditions.

**Response in Terms of Wave Propagation – An Example**

The vibrational representation of the solution of response of a multi-degree-of-freedom system subjected to earthquake shaking is frequently simplified by considering only the fundamental and, occasionally, a few of the lowest frequencies of the system. Doing so is analogous to low-pass filtering of the complete solution [56,57], but it can work well when the excitation amplitudes are small and the motions are associated with long waves. However, during strong earthquakes, the ground motion contains large displacement pulses, the duration of which can be shorter than the fundamental period of the structure. For this type of excitation, the vibrational representation of response and the response spectrum superposition method cease to be suitable and should be replaced by a solution in terms of propagating waves. For short impulsive ground motions, the damage can occur before the wave entering the structure completes its travel up and down the structure, and well before the wave interference can occur—that is, well before the physical conditions can lead to the interference of waves and creation of the mode shapes.

To illustrate the phenomena that can occur during nonlinear wave propagation in a building, we describe horizontal motions,  $u$ , in a one-dimensional shear beam, supported by one-dimensional half space and excited by a vertically propagating shear wave described by a half-sine-pulse (Fig. 9). A finite-difference scheme for solution of this problem with accuracy,  $O(\Delta t^2, \Delta x^2)$ , where  $\Delta x$  and  $\Delta t$  are the space and time increments, leads to the exact solution for  $\beta \Delta t / \Delta x = 1$ , where  $\beta$  is the velocity of shear waves. For simplicity, the incident displacement in the soil is chosen to be a sinusoidal pulse with the characteristics shown on Fig. 9.

A mesh with different spatial intervals in the soil and in the building will be used. The equation of motion is

$$v_t = (\sigma)_x / \rho, \tag{7a}$$

and the relation between the derivative of the strain and the velocity is

Earthquake Engineering, Non-linear Problems in, Figure 9  
Shear beam (building) (left) and incoming strong-motion displacement pulse (right) in the soil

$$\varepsilon_t = v_x, \quad (7b)$$

where  $v$ ,  $\rho$ ,  $\sigma$ , and  $\varepsilon$  are particle velocity, density, shear stress, and shear strain, respectively, and the subscripts  $t$  and  $x$  represent derivatives with regard to time and space.

The domain consists of two materials (Fig. 9): (1)  $-2\Delta x_s \leq x < 0$  with physical properties  $\rho_s$  and  $\mu_s$ , representing foundation soil, and (2)  $0 < x \leq H_b$  with physical properties  $\rho_b$  and  $\mu_b$  for linear response, where  $\rho_i$  is the density and  $\mu_i$  is the shear modulus in the soil ( $i = s$ ) or in the building ( $i = b$ ).  $v = \partial u / \partial t$  and  $\varepsilon = \partial u / \partial x$  are the velocity and the strain of a particle, and  $u$  is out-of-plane displacement of a particle perpendicular to the propagation ray.

It is assumed that the incoming wave is known and that its displacement as a function of time is prescribed at the point 1 in the soil ( $x = -2\Delta x_s$ ). Also, it is assumed that the soil is always in the linear elastic state. The finite difference method for a set of simultaneous equations is used to solve the problem, and spatial intervals are defined by  $\Delta x_i = \beta_i \cdot \Delta t$ , where  $\beta_i$  is the velocity of shear waves in the soil ( $i = s$ ) or in the building ( $i = b$ ) and  $\Delta t$  is the time step. The transparent boundary adopted for this study, which is described in Fujino and

Hakuno [8], is a perfect, transparent boundary for one-dimensional waves when  $\beta \Delta x / \Delta t = 1$ . Point 1 is where the prescribed displacement is applied, and we assume that this displacement travels upward in each time step. Point 2 is the boundary point of the model, where the quantities of motion are updated in each time step, and point 3 is the first spatial point, where the motion is computed using finite differences.

For the linear case at the contact (see point 3 in Fig. 9), one part of the incoming wave is transmitted into the other medium and one is reflected back into the same medium. The corresponding coefficients are obtained from the boundary conditions of continuity of the displacements and stresses at the contact. For a transmitted wave from medium B to medium A, the transmission coefficient is equal to  $k_{trB \rightarrow A} = 2 / [1 + \rho_a \beta_a / (\rho_b \beta_b)]$ . For a reflected wave from medium A back into medium B, this coefficient is  $k_{refB \rightarrow B} = [1 - \rho_a \beta_a / (\rho_b \beta_b)] / [1 + \rho_a \beta_a / (\rho_b \beta_b)]$ . For the opposite direction of propagation, the numerators and the denominators in these fractions exchange places.

### Numerical Examples

We consider a shear beam supported by elastic soil, as shown in Fig. 9. The densities of the soil and of the beam are assumed to be the same:  $\rho_b = \rho_s = \rho = 2000 \text{ kg/m}^3$ . The velocity of the shear waves in the soil is taken as  $\beta_s = 250 \text{ m/s}$ , and in the building as  $\beta_b = 100 \text{ m/s}$ .

To describe nonlinear response and the development of permanent deformations in the beam, we introduce two dimensionless parameters: (1) dimensionless amplitude  $\alpha = A / (H_b \varepsilon_{yb})$ , where  $A$  is the amplitude of the pulse (Fig. 9),  $H_b$  is the height of the building, and  $\varepsilon_{yb}$  is the yielding strain in the building, and (2) dimensionless frequency  $\eta = H_b / (\beta_b t_d)$ , where  $\beta_b t_d$  is one half of the wavelength of the wave in the building,  $\beta_b$  is the shear-wave velocity in the building, and  $t_d$  is the duration of the half-sine pulse.

To understand the development of the permanent strain in the nonlinear beam, we describe first the solution for the linear beam. The displacement and the strain for the linear beam are:

$$\begin{aligned} u(x, t) &= A \sum_{j=1}^{\infty} k_j \left\{ \sin \frac{\pi}{t_d} \left( t - t_{j-1} - \frac{x}{\beta_b} \right) \left[ H \left( t - t_{j-1} - \frac{x}{\beta_b} \right) \right. \right. \\ &\quad \left. \left. - H \left( t - t_{j-1} - \frac{x}{\beta_b} - t_d \right) \right] + \sin \frac{\pi}{t_d} \left( t - t_j + \frac{x}{\beta_b} \right) \right. \\ &\quad \left. \cdot \left[ H \left( t - t_j + \frac{x}{\beta_b} \right) - H \left( t - t_j + \frac{x}{\beta_b} - t_d \right) \right] \right\} \end{aligned} \quad (8)$$

and

$$\begin{aligned} \varepsilon(x, t) = & A \frac{\pi}{\beta_b t_d} \sum_{j=1}^{\infty} k_j \left\{ -\cos \frac{\pi}{t_d} \left( t - t_{j-1} - \frac{x}{\beta_b} \right) \right. \\ & \cdot \left[ H \left( t - t_{j-1} - \frac{x}{\beta_b} \right) - H \left( t - t_{j-1} - \frac{x}{\beta_b} - t_d \right) \right] \\ & + \cos \frac{\pi}{t_d} \left( t - t_j + \frac{x}{\beta_b} \right) \\ & \cdot \left. \left[ H \left( t - t_j + \frac{x}{\beta_b} \right) - H \left( t - t_j + \frac{x}{\beta_b} - t_d \right) \right] \right\} \quad (9) \end{aligned}$$

where  $j$  is the order number of the passage of the wave on the path bottom-top-bottom in the building,  $t_j = 2jH_b/\beta_b$  ( $j = 0, 1, 2, 3, \dots$ ), is the time required for the wave to pass  $j$  times over the path bottom-top-bottom (two heights),  $k_j = k_t k_r^{j-1}$  is the amplitude factor of the pulse in the soil in its  $j$ th passage along the path bottom-top-bottom through the building, and  $k_t$  and  $k_r$  are coefficients defined by  $k_{trB \rightarrow A}$  and  $k_{refB \rightarrow B}$  above.

The odd terms in Eq. (8) and Eq. (9) describe the response to the pulse coming from below, while the even terms describe the response to the pulse arriving from above. For the shear-wave velocities in our example,  $k_t = 10/7$  and  $k_r = -3/7$ . In Eq. (8) the displacement is positive for odd passages and negative for even passages. The displacement and velocity change sign after reflection from the soil-building interface and do not change sign after reflection from the top of the building. The strain changes sign after reflection from the top of the building and does not change sign after reflection from the building-soil interface. The constant that multiplies the series in Eq. (8) in terms of dimensionless amplitude and dimensionless frequency is  $A\pi/(\beta_b t_d) = A_\varepsilon = \pi\alpha\eta\varepsilon_{yb}$ .

To describe the occurrence of permanent strain, we consider two characteristic points in the building: (1) Point B ( $x = 0$ ) at the soil-building interface (point 3 in the grid, see Fig. 9), and (2) point T ( $x = H_b - \beta_b t_b/2$ ), where the amplitudes of the strain with the same sign meet after reflection from the top of the building. The location of this point is dependent upon the duration (wavelength) of the pulse. The first term in Eq. (8) is one if the argument of the cosine function is equal to  $t_d(t - t_0 - x/\beta_b = t_d)$ , and the second term is one if the argument of the second cosine function is equal to 0 ( $t - t_1 + x/\beta_b = 0$ ). The position of point T, where the strain amplitude is two times larger than the strain entering the beam, is at  $x = H_b - \beta_b t_d/2$ , and the time when this occurs is  $t = H_b/\beta_b + t_d/2$ . From Eq. (9) in the first passage of the pulse,  $t < 2H_b/\beta_b$ , and only the first term in the series exists. The strain at point B

reaches its absolute maximum at the very beginning, during the entrance of the pulse into the building, and its value is  $|\varepsilon_{B\max}^1| = \pi\alpha\eta\varepsilon_{yb}k_t$ . If this strain is greater than the yielding strain in the building,  $\varepsilon_{yb}$ , a permanent strain at the interface will develop, and the condition for occurrence of permanent strain at this point is  $|\varepsilon_{B\max}^1| > \varepsilon_{yb}$ , or, in terms of the dimensionless parameters,

$$\alpha\eta > (\pi k_t)^{-1} = (\beta_b + \beta_s)/(2\pi\beta_s) = C_B. \quad (10B)$$

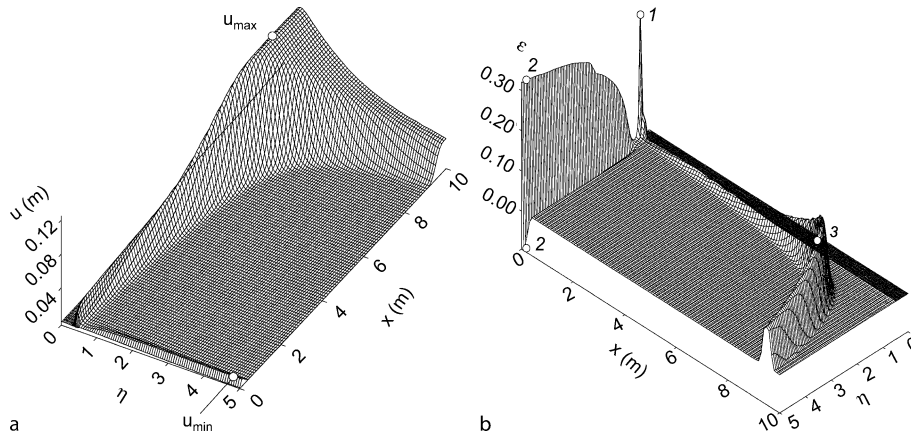

At point T (this point does not exist if  $t_d > 2H_b/\beta_b$ , and it coincides with point B if  $t_d = 2H_b/\beta_b$ ), from Eq. (9), the maximum strain during the first passage occurs at  $t = H_b/\beta_b + t_d/2$ , and its amplitude is  $2A_\varepsilon \cdot k_t$ . The condition for occurrence of the permanent strain is

$$\alpha\eta > (2\pi k_t)^{-1} = (\beta_b + \beta_s)/(4\pi\beta_s) = C_B/2 = C_T. \quad (10T)$$

For the shear-wave velocities in our example  $C_B = 0.2228$  and  $C_T = 0.1114$ .

For the above simple model, the occurrence, development, and amplitudes of permanent strains and displacements have been studied by Gicev and Trifunac [10,11]. They found that for large ground-displacement pulses (large  $\alpha$ ) the maximum permanent strains occur mainly at the interface of the building with the soil, while for smaller amplitudes of pulses permanent strains occur closer to the top of the building. They distinguished three zones of the permanently deformed beam: (1) a permanently deformed zone at the bottom; (2) an intermediate zone, which is not deformed at its bottom part and is deformed in the top part; and (3) a non-deformed zone at the top of the beam. The occurrence and development of these zones depends upon the dimensionless excitation amplitudes and the dimensionless frequencies, and in particular on the conditions that lead to the occurrence of the first permanent strain (see Eqs. (10B) and (10T)). For large and long strong-motion pulses ( $\eta \leq 0.5$ ; first, the condition in Eq. (10B) is relevant), only zones 1 and 3 are present in the beam. For large amplitudes and short strong-motion pulses, all three zones develop and are present. For smaller excitation amplitudes (when the condition in Eq. (10B) cannot be satisfied for long pulses, and when the condition in Eq. (10T) is satisfied), only zones 2 and 3 exist in the beam. For larger values of  $\eta$  (when the condition in Eq. (10B) is satisfied) all three zones exist.

Gicev and Trifunac [10,11] found a similar situation for the occurrence of the maximum strains. For large and long pulses, maximum strain is located at the bottom of the building, and, as the pulses become shorter, peak strains occur at higher positions in the building. For some high frequencies of excitation, the maximum strain again appears at the bottom of the building because the loss of

Earthquake Engineering, Non-linear Problems in, Figure 10

Permanent displacements ( $u_{\max} = 0.126$  m) (left), and permanent strains ( $\epsilon_1 = 0.31$ ,  $\epsilon_2 = 0.32$ ,  $\epsilon_3 = 0.20$ ) (right), along the building versus dimensionless frequency  $\eta$  and for dimensionless amplitude  $\alpha = 0.3$

Earthquake Engineering, Non-linear Problems in, Figure 11

Linear displacements along the normalized length of the beam,  $\chi = x/H_b$ , versus normalized time  $\tau = \beta_b t / 2H_b$ , for dimensionless pulse amplitude  $\alpha = 0.03$  and dimensionless frequency  $\eta = 3$

energy due to the development of the permanent strain at the bottom overcomes the effects of the wave reflections from the top of the building (Fig. 10).

Creation of large permanent deformation zones in the building by the incident waves absorbs some or most of the incident wave energy and can reduce or eliminate further wave propagation and the associated energy transport (Figs. 11 and 12). To the extent that the locations of the plastic deformation zones can be controlled by the design process, absorption of the incident-wave energy by structural members may become a new and powerful tool for performance-based design. To take advantage of such possibilities, the governing differential equations must be solved by the wave-propagation method.

Examples illustrated here show that for excitation of structures by large, near-field displacement pulses failure

can occur anywhere in the building before the incident wave has completed its first travel from the foundation to the top of the building and back to the foundation ( $2H_b/\beta_b$ ). Because this travel time is shorter (by 1/2) than the natural period of the structure on the fixed base, it is seen that the common response spectrum method of analysis (based on the vibrational formulation of the solution) cannot provide the required details for the design of structures for such excitation. The complexity of the outcome increases with amplitudes of excitation and depends upon the pulse duration. Because actual strong ground motion in the near field has at least several strong pulses, it can be seen that the complexity in real structures responding to strong earthquake motions will be even greater. In engineering approximation based on the vibrational solution of the problem and on the SDOF models, where the location of ductile response is predetermined by the simple modeling assumptions, this complexity cannot be included because of the modeling constraints. The outcome is that it is virtually impossible for simplified models to identify or to predict the location of damage. In contrast, for properly chosen wave propagation models, prediction and identification of damage is a natural and logical outcome of interaction between excitation and model properties. A good example of this can be found in Gicev and Trifunac [12], who showed how a simple wave-propagation model can predict the actually observed location of damage.

### Observations of Nonlinear Response

Invaluable for understanding and proper treatment of the actual nonlinear response, and for validation of vibration

Earthquake Engineering, Non-linear Problems in, Figure 12  
 Nonlinear displacements along the normalized length of the beam,  $\chi = x/H_b$ , versus normalized time  $\tau = \beta_b t/2H_b$  for dimensionless pulse amplitude  $\alpha = 0.3$  and dimensionless frequencies  $\eta = 3$  (left) and  $\eta = 0.41$  (right)

Earthquake Engineering, Non-linear Problems in, Figure 13  
 Layout of the seismic monitoring array in the ICS building (dots, without arrows, show the NS recording channels)

monitoring and analysis methods for real-life problems, are earthquake response data from well-instrumented, full-scale structures that have been damaged by an earthquake. Such data are rare and are not always freely available. An example of an instrumented building that has been damaged by an earthquake, and for which information about the damage and strong-motion data on the causative earthquake are available, is the former Imperial County Services Building in El Centro, California, which was severely damaged by the magnitude 6.6 Imperial Valley earthquake of October 15, 1979, and later demolished [23,51]. Its transverse (NS) response was recorded by three vertical arrays (recording channels 1, 3, 7, 9, 10, and 11; see Fig. 13), and its longitudinal (EW) response was recorded by one vertical array (recording channels 4, 5, 6, and 13, also shown in Fig. 13).

For a simplified soil-structure interaction model of a building supported by a rigid foundation, the difference

between the roof and base horizontal displacements during earthquake shaking is the sum of the horizontal displacements due to (1) horizontal deformation of the soil, (2) rigid-body rocking of the foundation, and (3) deformation of the structure. The estimated frequency from such data is referred to as system or “apparent” frequency, which differs from the fixed-base frequency of the building. While the fixed-base frequency depends only upon the properties of the structure, the apparent frequency depends also upon the stiffness of the foundation soil. The following relationship holds:

$$\frac{1}{\omega_{sys}^2} = \frac{1}{\omega_1^2} + \frac{1}{\omega_H^2} + \frac{1}{\omega_R^2}, \tag{13}$$

where  $\omega_{sys} = 2\pi\nu_{sys}$  is the soil-structure system frequency,  $\omega_1$  is the fundamental fixed-base frequency of the structure, and  $\omega_H$  and  $\omega_R$  are the horizontal and rocking

Earthquake Engineering, Non-linear Problems in, Figure 14  
**Time-frequency analysis for the NS response of the ICS building: a ground acceleration, b relative roof response, and c system frequency versus time**

frequencies, respectively, of a rigid structure on flexible soil [33].

Figure 14c shows that during earthquake shaking (Fig. 14a) the NS frequency of relative system response (Fig. 14b) dropped from  $\nu \approx 2.12$  Hz in the early stage of response (at  $t \approx 2$  s) to  $\nu \approx 1.52$  Hz at  $t \approx 6.8$  s ( $\Delta\nu \approx 0.6$  Hz,  $\Delta\nu/\nu \approx 28\%$ ), that it was constant during the interval  $t \approx 6.8 - 8.5$  s, and that it dropped further to  $\nu \approx 0.85$  Hz at  $t \approx 12$  s ( $\Delta\nu \approx 0.67$  Hz,  $\Delta\nu/\nu \approx 44\%$ ). Then, toward the end of the recorded shaking, the frequency increased to  $\nu \approx 1.15$  Hz ( $\Delta\nu \approx 0.3$  Hz;  $\Delta\nu/\nu \approx 35\%$ ). Early in the response ( $t < 7$  s), the amplitudes of the first story drifts in the building were relatively small ( $< 0.5\%$ ), and the observed decrease of system frequency is believed to be due to changes in the soil and bonding between the soil and foundation. This was followed by a further decrease in the system frequency of about 44% (between 8 and 12 s). The first-story drifts in the building were large when this occurred ( $> 0.5\%$  for NS), and the principal cause for this change is believed to be the damage, with the most severe damage occurring between 8 and 12 s after

trigger. Near the end of the shaking, a 35% increase in system frequency was observed, suggesting system hardening, which is believed to be due to changes in the soil [51].

Changes similar to what is shown in Fig. 14c were first observed following the San Fernando earthquake in California in 1971 [66] and then during many subsequent earthquakes. It is known at present that many different factors can contribute to fluctuations of the system frequency, including rainfall, temperature fluctuations, changes in occupancy, remodeling and strengthening of buildings, wind, and earthquakes [49]. The simultaneous action of some of these factors and the associated time-dependent changes in the physical model contribute to complex and evolving system changes that make predictions of the dynamic response difficult.

### Future Directions

Well-designed structures are expected to have ductile behavior during the largest credible shaking, and a large energy reserve to at least delay failure if it cannot be avoided. As the structure finally enters large nonlinear levels of response, it absorbs the excess of the input energy through ductile deformation of its components. Thus, it is logical to formulate future earthquake-resistant design procedures in terms of the energy driving this process. From the mechanics point of view, this introduces nothing new, because the energy equations can be derived directly from the dynamic equilibrium equations. The advantage of using energy is that the duration of strong motion, the number of cycles to failure, and dynamic instability all can be addressed directly and explicitly. This, of course, requires scaling of the earthquake source and of the attenuation of strong motion described in terms of its wave energy. Trifunac et al. [65] reviewed the seismological aspects of empirical scaling of seismic wave energy,  $E_s$ , and showed how the radiated energy can be represented by the functionals of strong ground motion [53,54,55]. They described the energy propagation and attenuation with distance and illustrated it for the three-dimensional geological structure of the Los Angeles basin during the 1994 Northridge, CA earthquake, then they described the seismic energy flow through the response of soil-foundation-structure systems, analyzed the energy available to excite the structure, and finally examined the relative response of the structure.

### Power Design

Figure 15 illustrates the cumulative wave energies recorded at a building site during two hypothetical earthquakes, E1 and E2, and presents a conceptual framework

Earthquake Engineering, Non-linear Problems in, Figure 15  
**Schematic comparison of strong-motion power demands E1 and E2 with an envelope of structural power capacity**

that can be used for development of the power design method. E1 results in a larger total shaking energy at the site and has a long duration of shaking, leading to relatively small average power, P1. E2 leads to smaller total shaking energy at the site but has short duration and thus greater power, P2. The power capacity of a structure cannot be described by one unique cumulative curve, as this depends upon the time history of shaking. For the purposes of this illustration, the line labeled “capacity envelope of the structure” can be thought of as an envelope of all possible cumulative energy paths for the response of this structure. Figure 15 implies that E1 will not damage this structure, but E2 will. Hence, *for a given structure, it is not the total energy of an earthquake event (and the equivalent energy-compatible relative velocity spectrum) but the rate with which this energy arrives and shakes the structure that is essential for the design of the required power capacity of the structure to withstand this shaking and to control the level of damage.*

Trifunac [57] outlined the elementary aspects of such design based on the power of the incident wave pulses. He showed how this power can be compared with the capacity of the structure to absorb the incident wave energy and described the advantages of using the computed power of incident strong motion for design. Power (amplitude and duration) of the strong near-field pulses will determine whether the wave entering the structure will continue to propagate through the structure as a linear wave or will begin to create nonlinear zones (at first near the top and/or near the base of the structure; Gicev and Tri-

funac [10,11,12]). For high-frequency pulses, the nonlinear zone, with permanent strains, can be created before the wave motion reaches the top of the structure—that is, before the interference of waves has even started to occur and lead to formation of mode shapes. Overall duration of strong motion [60] will determine the number of times the structure may be able to complete full cycles of response and the associated number of “minor” excursions into the nonlinear response range when the response is weakly non-linear [13], while the presence of powerful pulses of strong motion will determine the extent to which the one-directional quarter period responses [57] may lead to excessive ductility demand, leading to dynamic instability and failure, precipitated by the gravity loads [20]. All of these possibilities can be examined and quantified deterministically by computation of the associated power capacities and power demands for different scenarios, for given recorded or synthesized strong-motion accelerograms, or probabilistically by using the methods developed for Uniform Hazard Analysis [52].

### Glossary

**Binary forecast** A type of forecast where earthquakes are forecast to occur in certain regions and forecast not to occur in other regions.

**Continuum forecast** A type of forecast where the likelihood of an earthquake throughout an entire region is specified.

**Failure to predict** Earthquake event that occurs where no earthquake are forecasted to occur.

**False alarm** Earthquake event that is forecasted to occur at a specific location at a specific time but does not occur.

**PDF** Probability Density Function – A probability density function is any function  $f(x)$  that describes the probability density in terms of the input variable  $x$  such that  $f(x)$  is greater than or equal to zero for all values of  $x$  and the total area of the function is 1.

### Definition of the Subject

Forecasts of likely future events are used in almost every field: from forecasting tomorrow's weather to modeling the rise and fall of financial indices to predicting the growth of cancerous cells in human tissue. Generally, these forecasts are created under the belief that having a forecast – regardless of the level of complexity of the underlying models – is more desirable than not having a forecast. That is, human nature prefers the foreseeable over the unexpected. It is therefore important to verify the forecast and measure its skill, or “goodness”, and its value, or “usefulness”. The process of testing a given forecast with past trend data is the study of forecast verification. Forecast verification allows for a precise and repeatable (as op-

posed to relative or subjective) judgment of a forecasting model.

### Introduction

Earthquakes are the most feared of natural hazards because they generally occur without warning. Hurricanes can be tracked, floods develop gradually, tornados are caused by measurable atmospheric conditions, and volcanic eruptions are preceded by a variety of precursory phenomena. Earthquakes, however, occur suddenly and often without precursory indicators. There have been a wide variety of approaches applied to the forecasting of earthquakes [30,31,37,40,56,65]. These approaches can be divided into two general classes. The first approach is based on empirical observations of precursory changes. Examples include precursory seismic activity, precursory ground motions, and many others. The second approach is based on statistical patterns of seismicity. Neither approach has been able to provide reliable short-term forecasts (days to months) on a consistent basis.

Although short-term predictions are not available (see Table 1), long-term seismic-hazard assessments can be made. It is also possible to assess the long-term probability of having an earthquake of a given magnitude in a given region. These assessments are primarily based on the hypothesis that future earthquakes will occur in regions where past earthquakes have occurred [14,35]. Specifically, the rate of occurrence of small earthquakes in a region can be analyzed to assess the probability of occurrence of much larger earthquakes. While some earthquakes occur in plate interiors – a specific example is the three large (magnitude  $\sim 7.7$ ) earthquakes that occurred near New Madrid, Missouri in 1810 and 1811 – the large majority of all earthquakes occur in the vicinity of plate boundaries. A number of large cities are located very close to plate boundaries. Examples include Tokyo, Los Angeles, San Francisco, Seattle, Lima, Jakarta, and Santiago. Much of China is a diffuse plate boundary, and major earthquakes have caused devastating losses of life throughout this region. A recent example was in the 1976 Tangshan earthquake with some 500,000 deaths.

A major goal for earthquake forecasting is to quantify the risk of occurrence of an earthquake of a specified magnitude, in a specified area, and in a specified time window. This is routinely done and results in the creation of hazard maps. Another goal is to specifically forecast or predict earthquakes. The fundamental question is whether forecasts of the time and location of future earthquakes can be accurately made. It is accepted that long term hazard maps of the expected rate of occurrence of earthquakes are rea-

Earthquake Forecasting and Verification, Table 1

Warning times, scientific bases, and scientific feasibility for various types of earthquake predictions and estimates of long-term potential [62]

Term	Warning Time	Scientific Basis	Feasibility
Immediate alert	0 to 20 seconds	Speed of electro -magnetic waves $\gg$ speed of seismic waves	Good
Short-term prediction	Hours to weeks	Accelerating aseismic slip, foreshocks for some events	Unknown
Mid-term prediction	1 month to 10 years	Changes in seismicity, strain, chemistry, and fluid pressure	Fair
Long-term prediction	10 to 30 years	Time remaining in cycle of large shocks, increase in regional shocks	Good
Long-term potential	> 30 years	Long-term rate of activity, plate tectonic setting	Very good

sonably accurate. But is it possible to do better? Are there precursory phenomena that will allow earthquakes to be forecast?

### Earthquake Forecasting

#### Chaos and Forecasting

One of the reasons earthquakes are difficult to accurately forecast is the underlying complexity of the fault system. Earthquakes are caused by displacements on preexisting faults. Most earthquakes occur at or near the boundaries between the near-rigid plates of plate tectonics. Earthquakes in California are associated with the relative motion between the Pacific plate and the North American plate. Much of this motion is taken up by displacements on the San Andreas fault, but deformation and earthquakes extend from the Rocky Mountains on the east into the Pacific Ocean on the west. Clearly this deformation and the associated earthquakes are extremely complex.

It is now generally accepted that earthquakes are examples of deterministic chaos [66]. Some authors [16,17] have argued that this chaotic behavior precludes the prediction of earthquakes. Weather systems, however, are also chaotic, yet short-term forecasts are routinely made. Weather forecasts are probabilistic in the sense that weather cannot be predicted exactly. One such example is the track of a hurricane. Probabilistic forecasts of hurricane tracks are made every year; sometimes they are extremely accurate while at other times they are not. Another example of weather forecasting is the forecast of El Niño events. Forecasting techniques based on pattern recognition and principle components of the sea surface temperature fluctuation time series have been developed that are quite successful in forecasting future El Niños, but again they are probabilistic in nature [11]. It has also been argued [62] that chaotic behavior does not preclude the probabilistic forecasting of future earthquakes. The belief is that the chaos and nonlinearity in earthquakes arise mainly during unstable sliding in large events. Thus, predictions are possible before large earthquakes, but take a fi-

nite amount of time for the system to recover after large earthquakes.

#### Unobservable Dynamics

Another reason earthquakes are difficult to accurately forecast is that the true dynamics driving the system are simply unobservable and unmeasurable. As discussed above, earthquake faults occur in topologically complex, multi-scale networks that are driven to failure by external forces arising from plate tectonic motions [66]. The basic problem is that the details of the true space-time, force-displacement dynamics are in general unobservable, except in a few selected locations such as deep drill holes [52] or in a very crude, time-averaged sense such as the World Stress Map [81]. In order to completely describe the system, the true dynamics would have to be observable for all space and at all times. In fault systems these unobservable dynamics are usually encoded [59] in the time evolution of the Coulomb failure function,  $CFF(x, t)$ :

$$CFF(x, t) = \tau(x, t) - \mu_s \sigma_N(x, t), \tag{1}$$

where  $\tau(x, t)$  is the shear stress at point  $x$  and at time  $t$ ,  $\mu_s$  is the coefficient of static friction, and  $\sigma_N(x, t)$  is normal stress at point  $x$  and at time  $t$ . The space-time patterns associated with the time, location, and magnitude of the earthquakes, however, are observable. This leads to a focus on understanding the observable, multi-scale, apparent dynamics [52] of earthquakes in an attempt to infer the underlying dynamics.

#### Empirical Approaches

Empirical approaches to earthquake prediction rely on local observations of precursory phenomena in the vicinity of the earthquake to be predicted. It has been suggested that one or more of the following phenomena may indicate a future earthquake [30,31,37,40,56,65]:

1. precursory increase or decrease in seismicity in the vicinity of the origin of a future earthquake rupture,

2. precursory fault slip that leads to surface tilt and/or displacements,
3. electromagnetic signals,
4. chemical emissions, and
5. changes in animal behavior.

Examples of successful near-term predictions of future earthquakes based solely on empirical observations have been rare. A notable exception was the prediction of the  $M = 7.3$  Haicheng earthquake in northeast China that occurred on 4 February 1975. This prediction led to the evacuation of the city which undoubtedly saved many lives. The Chinese reported that the successful prediction was based on foreshocks, groundwater anomalies, and animal behavior. Unfortunately, a similar prediction was not made prior to the magnitude  $M = 7.8$  Tangshan earthquake that occurred on 28 July 1976 [68]. Official reports placed the death toll in this earthquake at 242,000, although unofficial reports placed it as high as 655,000.

In order to thoroughly test for the occurrence of direct precursors the United States Geological Survey (USGS) initiated the Parkfield (California) Earthquake Prediction Experiment in 1985 [1,30]. Earthquakes on this section of the San Andreas had occurred in 1857, 1881, 1901, 1922, 1934, and 1966. It was expected that the next earthquake in this sequence would occur by the early 1990s, and an extensive range of instrumentation was installed. The next earthquake in the sequence finally occurred on 28 September 2004. No precursory phenomena were observed that were significantly above the background noise level. Although the use of empirical precursors cannot be ruled out, the future of those approaches does not appear to be promising at this time.

### Statistical Approaches

A variety of studies have utilized variations in seismicity over relatively large distances to forecast future earthquakes. The distances are large relative to the rupture dimension of the subsequent earthquake. These approaches are based on the concept that the earth's crust is an activated, or driven, thermodynamic system [52]. Among the evidence for this behavior is the continuous level of background seismicity in all seismographic areas. About a million magnitude two earthquakes occur each year on our planet. In southern California about a thousand magnitude two earthquakes occur each year. Except for the aftershocks of large earthquakes, such as the 1992  $M = 7.3$  Landers earthquake, this seismic activity is essentially constant over time. If the level of background seismicity varied systematically with the occurrence of large earth-

quakes, earthquake forecasting would be relatively easy. This, however, is not the case.

While there is yet no indication of a universal earthquake indicator, there is increasing evidence that there are systematic precursory variations in some aspects of regional seismicity at least some of the time. For example, it has been observed that there is a systematic variation in the number of magnitude  $M = 3$  and larger earthquakes prior to at least some magnitude  $M = 5$  and larger earthquakes, and a systematic variation in the number of magnitude  $M = 5$  and larger earthquakes prior to some magnitude  $M = 7$  and larger earthquakes. The spatial regions associated with this phenomena tend to be relatively large, suggesting that an earthquake may resemble a phase change with an increase in the "correlation length" prior to an earthquake [5,26]. A specific example is the sequence of earthquakes that preceded the 1906 San Francisco earthquake [61]. This seismic activation has been quantified as a power law increase in seismicity prior to earthquakes [4,5,6,7,8,9,10,26,34,38,46,55,79]. There have also been reports of anomalous quiescence in the source region prior to a large earthquake, a pattern that is often called a "Mogi Donut" [30,40,76,77]. Unfortunately, these studies have all been performed retrospectively and their successes have depended on knowing the location of the subsequent earthquake.

There are two fundamentally different approaches to assessing the probabilistic risk of earthquake occurrence using statistical methods. The first of these is fault based, where the statistical occurrence of earthquakes is determined for mapped faults. The applicable models are known as renewal models and a tectonic loading of faults is included. The second approach is seismicity based, where the risk of future earthquakes is based on the past seismicity in the region. These are also known as cluster models and include the epidemic type aftershock sequence (ETAS) model and the branching aftershock sequence (BASS) model.

**Fault Based Models** Fault based models consider the earthquakes that occur on recognized (i. e., previously known) active faults. These models are also known as renewal models. Renewal models assume that the stress on an individual fault is "renewed" by the tectonic drive of plate tectonics. The simplest renewal model would be that of a single planar strike-slip fault subjected to a uniform rate of strain accumulation (plate motion). In this case, "characteristic" earthquakes would occur periodically. Clearly the earth's crust is much more complex with faults present at all scales and orientations. This complexity leads to chaotic behavior and statistical variability.

An important question is whether the concept of quasi-periodic “characteristic” earthquakes is applicable to tectonically active areas. There is extensive evidence that characteristic earthquakes do occur quasi-periodically on major faults. Many studies have been carried out to quantify the recurrence time statistics of these characteristic earthquakes [43,45,67]. Recurrence time statistics can be characterized by a mean value,  $\mu$ , and a coefficient of variation,  $C_v$ . The coefficient of variation is the ratio of the standard deviation to the mean. Mathematically,  $C_v = 0$  for periodic characteristic earthquakes and  $C_v = 1$  for a random distribution of recurrence times. Ellsworth et al. [13] reviewed many examples of recurrence time statistics and concluded that  $C_v \approx 0.5$  for characteristic earthquakes. Many probability distribution functions have been proposed for recurrence times, including the Weibull, lognormal, Brownian passage time, and gamma distributions.

Two major renewal simulation models have been developed. The first is “Virtual California” [49,50,53]. This is a geometrically realistic numerical simulation of earthquakes occurring on the San Andreas fault system and includes all major strike-slip faults in California. The second model is the “Standard Physical Earth Model” (SPEM) developed by Ward [69] and applied to characteristic earthquakes associated with subduction at the Middle American trench. This model was further developed and applied to the entire San Andreas fault system by Goes and Ward [18], to the San Andreas system in southern California by Ward [70], and to the San Andreas system in northern California by Ward [71].

Both simulation models utilize backslip, with the accumulation of a slip deficit on each fault segment prescribed using available data. The backslip represents the tectonic drive. Both models “tune” the prescribed static friction to give recurrence times that are consistent with available data. In both models fault segments are treated as dislocations when characteristic earthquakes occur, and all fault segments interact with each other elastically utilizing dislocation theory. These chaotic interactions result in statistical distributions of recurrence times on each fault. The resulting coefficients of variation are measures of this interaction.

Yakovlev et al. [78] utilized the Virtual California model to test alternative distributions of recurrence times. They concluded that the Weibull distribution is preferable and based its use on its scale invariance. The hazard rate is the probability that a characteristic earthquake will occur at a given time after the last characteristic earthquake. The Weibull distribution is the only distribution that has a power-law (scale-invariant) hazard function. In

the same study, Yakovlev et al. [78] found that the coefficient of variation of the recurrence times of 4606 simulated great earthquakes on the northern San Andreas fault is  $C_v = 0.528$ . Goes and Ward [18] using the SPEM simulator found that  $C_v = 0.50 - 0.55$  on this fault. The two simulations are quite different, so the statistical variability appears to be a robust feature of characteristic earthquakes. A similar simulation model for New Zealand has been given by Robinson and Benites [47,48].

Renewal models have also formed the basis for three formal assessments of future earthquake probabilities in California. These assessments were carried out by the United States Geological Survey [72,73,74,75]. A major problem with renewal models is that large earthquakes in nature often occur on faults that were not previously recognized. Recent examples in California include the 1952 Kern County earthquake, the 1971 San Fernando Valley earthquake, the 1992 Landers earthquake, the 1994 Northridge earthquake, and the 1999 Hector Mine earthquake. At the times when these earthquakes occurred, the associated faults were either not mapped or were considered too small to have such large earthquakes. To compensate for this problem, renewal models often include a random level of background seismicity unrelated to recognized faults.

**Seismicity Based Models** An alternative approach to probabilistic seismic hazard assessment and earthquake forecasting is to use observed seismicity. The universal applicability of Gutenberg–Richter frequency-magnitude scaling allows the rate of occurrence of small earthquakes to be extrapolated to estimate the rate of occurrence and location of large earthquakes. This type of extrapolation played an important role in creating the national seismic hazard map for the United States [15].

A more formalistic application of this extrapolation methodology is known as a relative intensity (RI) forecast. This type of forecast was made on a world wide basis by Kossobokov et al. [35] and to California by Holliday et al. [23]. A related forecasting methodology is the pattern informatics (PI) method [22,24,25,51,63,64]. This method was used by Rundle et al. [51] to forecast  $m = 5$  and larger earthquakes in California for the time period 2000–2010. This forecast successfully predicted the locations of 16 of the 18 large earthquakes that have subsequently occurred.

Keilis-Borok [31,33] and colleagues utilized patterns of seismicity to make formal intermediate term earthquake predictions. The most widely used algorithm, M8, has been moderately successful in predicting the times and locations of large earthquakes. More recently, this group has used chains of premonitory earthquakes to make interme-

mediate term predictions [32,58]. Again, moderate success was achieved.

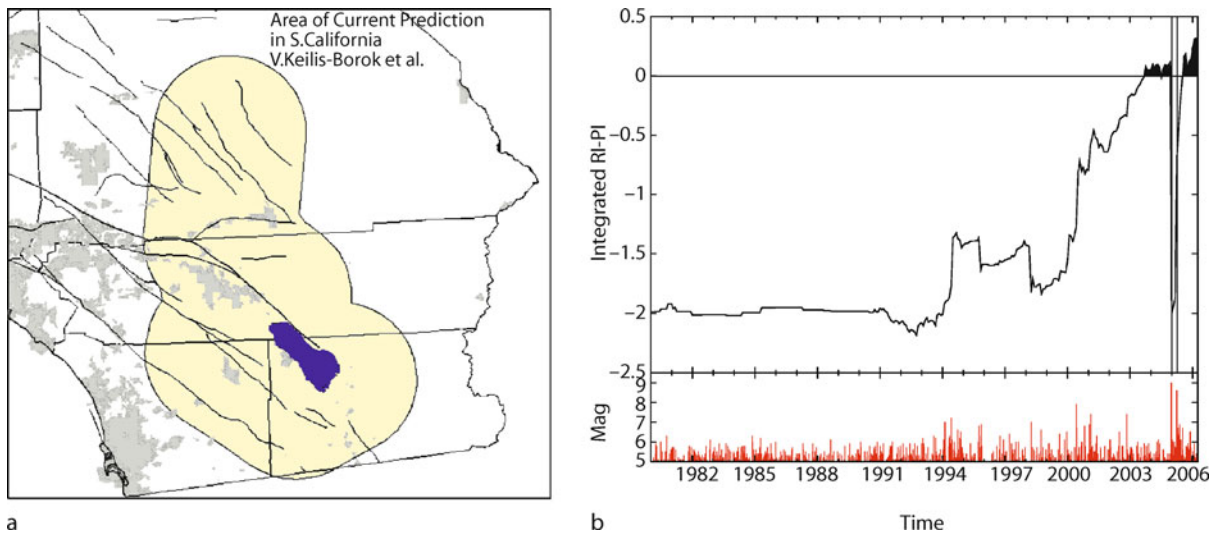

It has also been proposed that there is an increase in the number of intermediate sized earthquakes prior to a large earthquake [26]. This phenomenon is known as accelerating moment release (AMR) and is due primarily to an increase in the number of intermediate-size events that occur within a characteristic distance of the main shock and that scale with magnitude. AMR is characterized by a decrease in the rate of regional seismicity followed by a rapid rebound back to historic levels. Sammis and Bowman [54] have proposed a number of physical models to explain AMR. These include:

1. an analogy with critical phase transitions where the correlation length of the stress field rapidly increases as the system nears the critical point,
2. an erosion of a stress shadow from some previous, large event, and
3. a slow, silent earthquake propagating upward on a ductile extension loading the seismogenic crust above.

The existence of such a seismicity pattern does, however, appear to require a certain regional fault system structure

and density. Simulation models using a hierarchical distribution of fault sizes match this pattern well, but other types of fault distributions may also support AMR [26]. Conversely, some real-world fault distributions may not support AMR as a predictive tool. The AMR approach has shown considerable success retrospectively [5,10,55] but has not evolved into a successful prediction algorithm as of yet.

Seismicity based models are often referred to as clustering models. That is, clusters of small earthquakes indicate the future occurrence of larger earthquakes. The RI, PI, and AMR models clearly belong to this class. Other approaches in this class are the epidemic type aftershock sequence (ETAS) model [21,29,42,44] and the branching aftershock sequence (BASS) model. These are statistical models based on applicable scaling laws: Gutenberg–Richter scaling relation and the modified Båth’s law for the scaling relation of magnitudes, Omori’s law for the distribution of earthquake times, and a modified form of Omori’s law for the distribution of earthquake locations. Clustering by definition is not a random process. A rationale for the application of clustering models is that the clustering is related to families of foreshocks, main shocks, and aftershocks.

Earthquake Forecasting and Verification, Figure 1

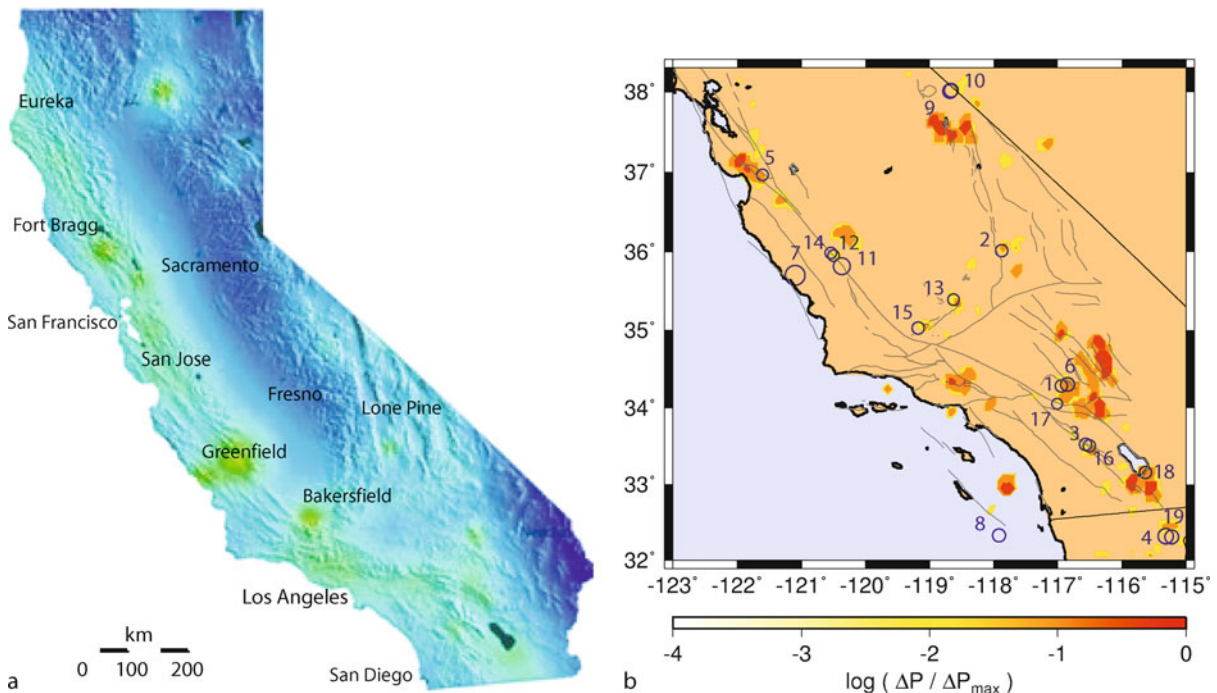

Plots of sample binary earthquake forecasts. **a** Prediction for a magnitude 6.4 or greater earthquake to occur between 5 January 2004 and 4 September 2004, within a 12,440 sq. miles area of southern California using the M8 algorithm (image courtesy Dr. Vladimir Keilis-Borok). This is a binary forecast since it forecasts an earthquake to occur within the *shaded* area during the time period and not to occur in the *non-shaded* region. Ultimately no magnitude 6.4 or greater earthquake occurred in the test region during the forecast interval. **b** Retrospective prediction for a magnitude 8.0 or greater earthquake to occur in the Sumatra region between 1 June 2003 and 1 June 2005 (image courtesy Dr. James Holliday). This is a time-dependent binary forecast since large earthquakes are forecasted to occur in the test region within a two year window once the time series becomes positive. Note that the magnitude 9.0 Sumatra-Andaman earthquake occurred 18 months after the time series became positive

## Types of Forecasts

**Binary Forecasts** The simplest type of earthquake forecast is a binary forecast. An earthquake is forecast to occur in a certain regions and forecast not to occur in other regions. This is analogous to the issuance of tornado warnings. Examples of two binary forecast maps are presented in Fig. 1. The plot on the left is for a prediction for a magnitude 6.4 or greater earthquake to occur between 5 January 2004 and 4 September 2004, within a 12,440 sq. miles area of southern California using the M8 algorithm. This map is a binary forecast since it forecasts an earthquake to occur within the shaded area during the time period and not to occur in the non-shaded region. The plot on the right is a retrospective prediction for a magnitude 8.0 or greater earthquake to occur in the Sumatra region between 1 June 2003 and 1 June 2005. This is a time-dependent binary forecast since large earthquakes are forecasted to occur in the test region within a two year window once the time series becomes positive and not to occur when the time series is negative.

**Continuum Forecasts** The alternative to binary forecasts is a continuum forecast. The likelihood of an earthquake throughout the entire region is specified. This would be analogous to temperature forecasts in the atmospheric sciences. Examples of two continuum forecast maps are presented in Fig. 2. The plot on the left is a time-dependent map produced in real time by the USGS Earthquake Hazards Program giving the probability of strong shaking at any location in California within a given 24-hour period. The plot on the right is a forecast map giving the probability for large (magnitude greater than 5.0) earthquakes in southern California using the Pattern Informatics method.

Any continuum forecast can be converted into a binary forecast through the use of a hard threshold. Spatial regions where the likelihood value is greater than the threshold are taken to be regions where earthquakes are forecasted to occur. Spatial regions where the likelihood value is less than the threshold value are taken to be regions where earthquakes are forecasted not to occur.

Earthquake Forecasting and Verification, Figure 2

Plots of sample continuum earthquake forecasts. **a** Time-dependent map giving the probability of strong shaking at any location in California within a given 24-hour period (image courtesy USGS Earthquake Hazards Program). **b** Forecast map giving the probability for large ( $m > 5$ ) earthquakes in southern California using the Pattern Informatics method (image courtesy Dr. Kristy Tiampo). Circles mark the locations of large earthquakes which occurred after the forecast creation. Both of these are continuum forecasts since they present a continuous likelihood for earthquakes to occur throughout the entire test region

## Forecast Verification

### Continuum Forecasts

**Likelihood Tests** The standard approach for testing the hypothesis that a probability measure can forecast future earthquakes is the maximum likelihood test [2,19,24,28,51,57,63]. The likelihood  $\mathbf{L}$  is a probability measure that can be used to assess the quality of one forecast measure over another. Typically, one computes the log-likelihood  $\mathcal{L} \equiv \log(\mathbf{L})$  for the proposed forecast measure  $\mathbf{L}$ . Models with higher (less negative) log-likelihood values are said to perform better than models with lower (more negative) log-likelihood values. In these types of likelihood tests, a probability density function (PDF) is required. Two different PDFs are commonly used: a global, Gaussian model and a local, Poissonian model.

Tiampo et al. [63] calculated likelihood values by defining  $P[\mathbf{x}]$  to be the union of a set of  $N$  Gaussian density functions  $p_G(|\mathbf{x} - \mathbf{x}_i|)$  [2] centered at each location  $\mathbf{x}_i$ . Each individual Gaussian density has a standard deviation  $\sigma$  equal to the width of their coarse-grained lattice cell and a peak value equal to the calculated probability divided by  $\sigma^2$ .  $P[\mathbf{x}(e_j)]$  was then interpreted as a probability measure that a future large event  $e_j$  would occur at location  $\mathbf{x}(e_j)$ :

$$P[\mathbf{x}(e_j)] = \sum_i \frac{P_i}{\sigma^2} e^{-\frac{|\mathbf{x}(e_j) - \mathbf{x}_i|^2}{\sigma^2}}. \quad (2)$$

If there are  $J$  future events, the normalized likelihood  $\mathbf{L}$  that all  $J$  events are forecast is

$$\mathbf{L} = \prod_j \frac{P[\mathbf{x}(e_j)]}{\sum_i P[\mathbf{x}_i]}. \quad (3)$$

Furthermore, the log-likelihood value  $\mathcal{L}$  for a given calculation can be calculated and used in ratio comparison tests:

$$\mathcal{L} = \sum_j \log \frac{P[\mathbf{x}(e_j)]}{\sum_i P[\mathbf{x}_i]}. \quad (4)$$

The second model commonly used is based on work performed by the Regional Earthquake Likelihood Models (RELM) group [57]. For each coarse-grained lattice cell  $i$  an expectation value  $\lambda_i$  is calculated by scaling the local probability value  $P_i$  by the number of earthquakes that occurred over all space during the forecasted time period:

$$\lambda_i = n \cdot P_i, \quad (5)$$

where  $n$  is the number of future events. Note that for any future time interval  $(t_2, t_3)$ ,  $n$  could in principle be estimated by using the Gutenberg–Richter relation. For each

bin an observation value  $\omega_i$  is also calculated such that  $\omega_i$  contains the number of future earthquakes that actually occurred in cell  $i$ . Note that  $\sum_i \omega_i = n$ . For the RELM model, it is assumed that earthquakes are independent of each other. Thus, the probability of observing  $\omega_i$  events in cell  $i$  with expectation  $\lambda_i$  is the Poissonian probability

$$p_i(\omega_i|\lambda_i) = \frac{\lambda_i^{\omega_i}}{\omega_i!} e^{-\lambda_i}. \quad (6)$$

The log-likelihood  $\mathcal{L}$  for observing  $\omega$  earthquakes at a given expectation  $\lambda$  is defined as the logarithm of the probability  $p(\omega|\lambda)$ , thus

$$\mathcal{L}(\omega|\lambda) = \log p(\omega|\lambda) = -\lambda + \omega \log \lambda - \log(\omega!). \quad (7)$$

Since the joint probability is the product of the individual cell probabilities, the log-likelihood value for a given calculation is the sum of  $\mathcal{L}(\omega_i|\lambda_i)$  over all cells  $i$ :

$$\mathcal{L} = \sum_i \mathcal{L}(\omega_i|\lambda_i) = \sum_i (-\lambda_i + \omega_i \log \lambda_i - \log(\omega_i!)). \quad (8)$$

Most tests of earthquake forecasts have emphasized the likelihood test [24,28,51,64]. These tests have the significant disadvantage that they are overly sensitive to the least probable events. For example, consider two forecasts. The first perfectly forecasts 99 out of 100 events but assigns zero probability to the last event. The second assigns zero probability to all 100 events. Under a log-likelihood test, both forecasts will have the same skill score of  $-\infty$ . Furthermore, a naive forecast that assigns uniform probability to all possible sites will always score higher than a forecast that misses only a single event but is otherwise superior. For this reason, likelihood tests are more subject to unconscious bias. Other methods of evaluating earthquake forecasts are suggested by Vere-Jones [20] and Holliday et al. [25].

**Information Metrics** One such alternative is the use of information metrics. Using methods from information theory [12], it is possible to calculate the entropy,  $H$ , of a forecast map. Entropy can be considered a measure of disorder (e.g. randomness) or “surprise”, hence maps with lower entropy contain more useful information than maps with higher entropy. We define entropy as

$$H(z) = - \sum_{i=1}^N p(\mathbf{x}_i; z) \log p(\mathbf{x}_i; z), \quad (9)$$

where

$$p(\mathbf{x}_i; z) = \begin{cases} P(\mathbf{x}_i) & P(\mathbf{x}_i) \geq z \\ 0 & P(\mathbf{x}_i) < z \end{cases}, \quad (10)$$

and the probabilities are scaled such that  $\sum_{i=1}^N p(x_i) = 1$ . This definition allows a measurement of entropy as a function of some lower threshold  $z$ . A small, non-zero value for  $z$  allows for the measurement of the entropy above and relative to background noise.

## Binary Forecasts

**ROC Analysis** The standard approach to the evaluation of a binary forecast is the use of a relative operating characteristic (ROC) diagram [39,60]. This method evaluates the performance of the forecast method relative to random guessing by constructing a plot of the fraction of failures to predict (events that occur where no event is forecast) against the fraction of false alarms (events that are forecast to occur at a location but do not occur) for an ensemble of forecasts. Molchan [41] has used a modification of this method to evaluate the success of intermediate term earthquake forecasts.

The binary approach has a long history, over 100 years, in the verification of tornado forecasts [39]. These forecasts take the form of a tornado forecast for a specific location and time interval, each forecast having a binary set of possible outcomes. For example, during a given time window of several hours duration, a forecast is issued in which a list of counties is given with a statement that one or more tornadoes will or will not occur. A  $2 \times 2$  contingency table is then constructed, the top row contains the counties in which tornadoes are forecast to occur and the bottom row contains counties in which tornadoes are forecast to not occur. Similarly, the left column represents counties in which tornadoes were actually observed, and the right column represents counties in which no tornadoes were observed.

With respect to earthquakes, binary forecasts take exactly this form. A time window is proposed during which the forecast of large earthquakes having a magnitude above some minimum threshold is considered valid. An example might be a forecast of earthquakes larger than  $M = 5$  during a period of five or ten years duration. A map of the seismically active region is then completely covered ("tiled") with boxes of two types: boxes in which the epicenters of at least one large earthquake are forecast to occur and boxes in which large earthquakes are forecast to not occur. In other types of forecasts, large earthquakes are given some continuous probability of occurrence from 0% to 100% in each box [28]. These forecasts can be converted to the binary type by the application of a threshold value. Boxes having a probability below the threshold are assigned a forecast rating of non-occurrence during the time window, while boxes having a probability above

Earthquake Forecasting and Verification, Table 2  
Schematic contingency table for categorical forecasts of a binary event

Forecast	Observed		
	Yes	No	Total
Yes	$a$	$b$	$a + b$
No	$c$	$d$	$c + d$
Total	$a + c$	$b + d$	$a + b + c + d = N$

the threshold are assigned a forecast rating of occurrence. A high threshold value may lead to many failures to predict, but few false alarms. The level at which the threshold is set is then a matter of public policy specified by emergency planners, representing a balance between the prevalence of failures to predict and false alarms.

**Contingency Tables** An extensive review on forecast verification in the atmospheric sciences has been given by Jolliffe and Stephenson [27]. The wide variety of approaches that they consider are directly applicable to earthquake forecasts as well. Verification of earthquake forecasts proceeds in exactly the same way as for, say, tornado forecasts when using these approaches. For a given forecast, the contingency table (see Table 2) is constructed. Values for the table elements  $a$  (Forecast=yes, Observed=yes),  $b$  (Forecast=yes, Observed=no),  $c$  (Forecast=no, Observed=yes), and  $d$  (Forecast=no, Observed=no) are obtained from the forecast map. The fraction of alarm space, also called the probability of forecast of occurrence, is  $r = (a + b)/N$ , where the total number of boxes is  $N = a + b + c + d$ . The hit rate is  $H = a/(a + c)$  and the false alarm rate is  $F = b/(b + d)$ . From these quantities a number of descriptive, performance, and skill measures can be constructed [27]. Table 3 lists a few possible measures.

**ROC Curves** The standard ROC diagram [23,27] is a plot of the points  $\{H, F\}$  calculated for a binary forecast (see Fig. 3). If the forecast was converted from continuum map,  $H$  and  $F$  are plotted as the lower (conversion) threshold is varied. A perfect forecast of occurrence (perfect order, no fluctuations) would consist of two line segments, the first connecting the points  $(H, F) = (0, 0)$  to  $(H, F) = (1, 0)$ , and the second connecting  $(H, F) = (1, 0)$  to  $(H, F) = (1, 1)$ . A curve of this type can be described as maximum possible hits ( $H = 1$ ) with minimum possible false alarms ( $F = 0$ ). Another type of perfect forecast consists of two lines connecting the points  $(0, 0)$  to  $(0, 1)$  and  $(0, 1)$  to  $(1, 1)$ , a perfect forecast of non-occurrence.

Earthquake Forecasting and Verification, Table 3

Table of various descriptive and performance measures that can be calculated from the binary contingency table for an earthquake forecast

Name	Definition	Definition ( $H, F,$ and $\tau$ )	Range
Fraction of alarm space $\tau$	$\tau = (a + c)/N$	$\tau$	[0, 1]
Hit rate $H$	$H = a/(a + c)$	$H$	[0, 1]
False alarm rate $F$	$F = b/(b + d)$	$F$	[0, 1]
False alarm ratio $FAR$	$FAR = b/(a + b)$	$FAR = (1 + \frac{\tau}{1-\tau} \frac{H}{F})^{-1}$	[0, 1]
Miss rate $\nu$	$\nu = c/(a + c)$	$\nu = 1 - H$	[0, 1]
Peirce's skill score $PSS$	$PSS = \frac{ad-bc}{(b+d)(a+c)}$	$PSS = H - F$	[-1, 1]
Yule's $Q$	$Q = \frac{ad-bc}{ad+bc}$	$Q = \frac{H-F}{H(1-F)+F(1-H)}$	[-1, 1]
Peirce Area $A$	$A = \int PSS$	$A = \int HdF - \frac{1}{2}$	$[-\frac{1}{2}, \frac{1}{2}]$

Earthquake Forecasting and Verification, Figure 3

Sample relative operating characteristic (ROC) diagram. Shown is a plot of hit rates,  $H$ , as a function of false alarm rates,  $F$ , for a sample earthquake forecast (blue) and random guessing (black). Confidence intervals for the one-, two- and three- $\sigma$  levels are shown as well [23,80]

The line  $H = F$  occupies a special status, and corresponds to a completely random forecast [23,27] (maximum disorder, maximum fluctuations) where the false alarm rate is the same as the hit rate and no information is produced by the forecast. Points above this line are said to have performed better than simple random guessing. If competing forecasts are plotted on the same graph, the forecast whose  $H-F$  curves lies the highest is said to outperform the others. Often, however, competing forecasts will have intersecting curves. In this case, forecasts

are said outperform each other only in specific ranges and only for specific choices of the lower (conversion) threshold value.

**$\nu$ - $\tau$  Curves** An alternative diagram [41] is a plot of the points  $\{\nu, \tau\}$  for a binary forecast map. In this case a perfect forecast of occurrence would consist of two line segments, the first connecting the points  $(\nu, \tau) = (0, 0)$  to  $(\nu, \tau) = (0, 1)$ , and the second connecting  $(\nu, \tau) = (0, 1)$  to  $(\nu, \tau) = (1, 1)$ . A curve of this type can be described as

minimum possible missed events ( $\nu = 0$ ) with minimum possible alarm space ( $\tau = 0$ ).

As with the  $H$ - $F$  curve, the line  $\nu = \tau$  corresponds to a completely random forecast. Points below this line are said to have performed better than simple random guessing. If competing forecasts are plotted on the same graph, the forecast whose  $\nu$ - $\tau$  curves lies the lowest is said to outperform the others. As can be verified from Table 3,  $\nu$ - $\tau$  curves offer the same information as  $H$ - $F$  curves and are identical in the range  $a \ll d$ .

### Future Directions

It is actually quite surprising that immediate local precursory phenomena are not seen. Prior to a volcanic eruption, increases in regional seismicity and surface movements are generally observed. For a fault system, the stress gradually increases until it reaches the frictional strength of the fault and a rupture is initiated. It is certainly reasonable to hypothesize that the stress increase would cause increases in background seismicity and aseismic slip. In order to test this hypothesis the Parkfield Earthquake Prediction Experiment was initiated in 1985. The expected Parkfield earthquake occurred beneath the heavily instrumented region on 28 September 2004. No local precursory changes were observed [3,36]. In the absence of local precursory signals, the next question is whether broader anomalies develop, and in particular whether there is anomalous seismic activity.

Assuming precursors do exist and can be exploited to create earthquake forecasts, testing and verification of the usefulness of the forecasts is the necessary next step. A forecast method that predicts all earthquakes but carries a high false alarm rate is likely to be useless as a public warning tool. Similarly, a forecast method that issues warnings for only a small fraction of actual earthquakes but never issues false alarms is likely to be a poor tool for catastrophe preparation. Forecast verification techniques can be used to find the middle ground that is most useful.

As a final warning, researchers must be careful not to create artificial skill in their forecasts. Since nature provides us only with one earthquake record (the actual history of a given test region), the quality of a new forecast system is often assessed on the same data set used to create it. This can potentially lead to an optimistic bias in any skill scores. This is a particular problem if the score itself is used to calibrate the method, either directly or indirectly. Development of realistic earthquake simulators and cross-testing against test regions with similar fault structures can help protect against this.

### Glossary

**Arrival time** The time of the first measurable energy of a seismic phase on a seismogram.

**Centroid** The coordinates of the spatial or temporal average of some characteristic of an earthquake, such as surface shaking intensity or moment release.

**Data space** If the data are described by a vector  $\mathbf{d}$ , then the data space  $D$  is the set of all possible values of  $\mathbf{d}$ .

**Direct search** A search or inversion technique that does not explicitly use derivatives.

**Earthquake early-warning** The goal of earthquake early-warning is to estimate the shaking hazard of a large earthquake at a nearby population center or other critical site before destructive  $S$  and surface waves have reached the site. This requires that useful, probabilistic constraint on the location and size of an earthquake is obtained very rapidly.

**Earthquake location** An earthquake location specifies a spatial position and time of occurrence for an earthquake. The location may refer to the earthquake hypocenter and corresponding origin time, a mean or centroid of some spatial or temporal characteristic of the earthquake, or another property of the earthquake that can be spatially and temporally localized. This term also refers to the process of locating an earthquake.

**Epicenter** The point on the Earth's surface directly above a hypocenter.

**Error** A specified variation in the value assumed by a variable. See also *uncertainty*.

**Global search** A search or inversion that samples throughout the prior *pdf* of the unknown parameters.

**Hypocenter** The point in three-dimensional space of initial energy release of an earthquake rupture or other seismic event.

**Importance sampling** A sampling procedure that draws samples following the posterior *pdf* of an inverse, optimization or other search problem. Since these problems involve initially unknown, posterior *pdf* functions, importance sampling can only be performed approximately, usually through some adaptive or learning procedure as sampling progresses.

**Inverse problem, inversion** The problem of determining the parameters of a physical system given some data. The solution of an inverse problem requires measurements of observable quantities of the physical system, and the mathematical expression (the forward problem) that relates the parameters defining the physical system (model space) to the data (data space). In inverse problems, estimates of the unknown parameters in the model space and of their uncertainties are sought from the combination of the available information on the model parameters (prior *pdf*), the data and the forward problem.

**Likelihood function** A non-normalized *pdf*.

**Misfit function** A function that quantifies the disagreement between observed and calculated values of one or more quantities. See *objective function*.

**Model space** If the model parameters are described by a vector  $\mathbf{m}$ , then model space  $M$  is the set of all possible values of  $\mathbf{m}$ .

**Objective function** A function expressing the quality of any point in the model space. Inversion and optimization procedures use an objective function to rank and select models. Usually objective functions are defined in terms of misfit functions, and for probabilistic inversion the objective function must be a *pdf* or likelihood function.

**Origin time** The time of occurrence of initial energy release of an earthquake rupture or other seismic event.

**Prior pdf** A *pdf* that expresses the information on the unknown parameters available before an inverse problem is solved. For an earthquake location, the prior *pdf* is often a simple function (e. g., boxcar) of three spatial dimensions and time. See also *Inverse problem*.

**Probability density function – pdf** A function in one or more dimensional space  $X$  that (i) when integrated

over some interval  $\Delta \mathbf{x}$  in  $X$  gives a probability of occurrence of any event within  $\Delta \mathbf{x}$ , and (ii) has unit integral over space  $X$ , where  $X$  represents a space of possible events. An earthquake location *pdf* is often a 3-dimensional probability density function over all possible spatial locations or a 4-dimensional probability density function over all possible spatial locations and times of occurrence.

**Posterior pdf** A *pdf* that expresses the information about the unknown parameters available after inversion. The posterior *pdf* for an earthquake location is often a function of the three spatial dimensions and the origin time of the hypocenter parameters; this function may be complicated. See also *Inverse problem*.

**Ray path** A local minimum-time path between a source and receiver of idealized, infinite frequency wave energy of a specified wave type (e. g.,  $P$  or  $S$ ).

**Receiver or station** Synonyms for an observation point where ground motion is detected and a seismogram recorded.

**Seismic phase** A distinct packet of energy from a seismic source. Usually refers to a specified wave type (e. g.  $P$  or  $S$ ) satisfying a particular physics of wave propagation.

**Seismicity** The distribution in space and time of seismic event locations.

**Seismogram** An analogue or digital recording of the ground motion at a point (receiver or station) in the Earth. Also called a waveform.

**Source** A general term referring to an earthquake, explosion or other release of seismic energy as a physical phenomenon localized in space and time.

**Station** See *receiver*.

**Travel time** The time that a signal, e. g. elastic wave energy of a seismic phase, takes to propagate along a ray path between two points in a medium.

**Uncertainty** Random variation in the values assumed by a variable. See also *error*.

## Definition of the Subject

An earthquake location specifies the place and time of occurrence of energy release from a seismic event. A location together with a measure of size forms a concise description of the most important characteristics of an earthquake. The location may refer to the earthquake's epicenter, hypocenter, or centroid, or to another observed or calculated property of the earthquake that can be spatially and temporally localized. A location is called *absolute* if it is determined or specified within a fixed, geographic coordinate system and a fixed time base (e. g., Coordinated

Universal Time, UTC); a location is called *relative* if it is determined or specified with respect to another spatio-temporal object (e. g., an earthquake or explosion) which may have unknown or uncertain absolute location.

For rapid hazard assessment and emergency response, an earthquake location provides information such as the locality of potential damage or the source region of a possible tsunami, and a location is required to calculate most measures of the size of an earthquake, such as magnitude or moment. Locations are required for further analysis and characterization of the event, for studies of general patterns of seismicity, to calculate distributions of stress and strain changes around the earthquake, for assessing future earthquake hazard, and for basic and applied seismological research.

Since earthquakes occur deep in the Earth, their source locations must be inferred indirectly from distant observations, and earthquake location is thus a remote-sensing problem. Most commonly an earthquake location is determined by the match or misfit between observed arrival times of seismic wave-energy at seismic stations, and predictions of these arrival times for different source locations using a given elastic-wave speed model; this is an inverse problem. Essentially, many potential locations (place and time) are examined and those for which some measure of misfit between predicted and measured arrival times is smallest are retained as best estimates of the true location.

Many numerical location methods involve linearization of the equations relating the predicted arrival times to the location through Taylor expansion involving partial derivatives; these are called *linearized* methods. Methods that do not involve linearization are called *nonlinearized* or *direct-search* methods. The term *nonlinear* is used ambiguously in geophysics to refer to linearized-iterated and to nonlinearized methods. In this chapter we focus on nonlinearized, direct-search methods, and to avoid ambiguity we identify them with the term *direct-search*.

Direct-search location can be performed through graphical analysis, regular or stochastic searches over a space of possible locations, and other algorithms. Direct-search earthquake location is important because, relative to linearized methods, it is easy to apply with realistic earth models which may have abrupt and complicated velocity variations in three-dimensions, it places little restriction on the form of the measure of misfit, it is stable (i. e., does not suffer numerical convergence problems) when the observations are insufficient to fully constrain the spatial location or origin time, and it can produce comprehensive, probabilistic solutions which indicate the full location uncertainty, often a complex function of space and time.

Conversely, the primary advantage of linearized location methods is that they are much less demanding computationally than direct-search methods.

## Introduction

Most commonly, an earthquake location is determined using observed seismic-phase arrival-times and associated uncertainties, and predicted travel times in a given wave-speed model. Ideally, the location procedure will determine a 4-dimensional, posterior probability density function, or location *pdf*, over all possible solutions (spatial locations and origin times). This location *pdf* quantifies the agreement between predicted and observed arrival times in relation to all uncertainties, and forms a complete, probabilistic solution. In practice, however, an earthquake location is often specified as some optimal solution (a point in space and time) with associated uncertainties.

The earliest, formal earthquake locations using seismic-phase arrival-time observations employed direct-search procedures such as graphical methods (e. g., [37]) or simple grid searches (e. g., [52]). The advent of digital computers in the 1960's lead to the use of iterated linearized approaches based mainly on Geiger's method [17]. Since the 1980's, the increasing power of digital computers has made large-scale, grid and stochastic direct searches practical for routine earthquake location. Direct-search methods are now used routinely in research and earthquake monitoring (e. g., [22,23,31,32,46,48,61]).

In principle, direct-search methods can be applied to locate the relative positions of ensembles of events, and for joint epicentral determination (e. g., [47]) to simultaneously determine multiple earthquake locations and station corrections related to errors in the velocity model. However, the high-dimensionality of such problems makes direct-search solution difficult and computationally demanding; at the present time these problems are usually performed through large scale, linearized procedures. For these reasons, we mainly consider here absolute location of individual events.

In this article we describe the earthquake location problem and direct-search methods used to perform this location, and we present a number of examples of direct-search location. We do not compare different direct-search location methods or compare direct-search to linearized algorithms, but instead focus on illustrating important features and complexity in earthquake location results. For this reason we emphasize direct, global-search, probabilistic location, which produces general and complete solutions that best illuminate these features and complexity.

## The Earthquake Location Problem

### An Inherently Nonlinear Problem

In a homogeneous medium with wave speed  $v$  and *slowness* defined to be  $u = 1/v$ , the arrival time,  $t_{\text{obs}}$ , at an observation point  $x_{\text{obs}}, y_{\text{obs}}, z_{\text{obs}}$  of a signal emitted at origin time  $t_0$  from a source location at  $x_0, y_0, z_0$  is,

$$t_{\text{obs}} = t_0 + u \left[ (x_{\text{obs}} - x_0)^2 + (y_{\text{obs}} - y_0)^2 + (z_{\text{obs}} - z_0)^2 \right]^{1/2}, \quad (1)$$

This expression shows that a change in the spatial position of the source introduces a nonlinear change in  $t_{\text{obs}}$ , even in the simplest possible medium. When the speed  $v$  and hence slowness  $u$  are inhomogeneous in space, the arrival time at the observation point becomes,

$$t_{\text{obs}} = t_0 + \int_{\mathbf{r}_0(s)} u(\mathbf{r}_0) ds, \quad (2)$$

where  $\mathbf{r}_0(s)$  denotes a point at distance  $s$  along ray path  $\mathbf{r}_0$  between source and receiver locations. Equation (1) is a special case of (2) that has straight source-receiver ray paths. Equation (2) is nonlinear since a change in the source location changes the ray path over which the integral is calculated. Thus, earthquake location, which maps arrival times into spatial location and origin time, is inherently a nonlinear problem.

### The Observed Data

Data used to constrain earthquake locations are usually derived from seismograms recorded at seismic stations distributed around the earthquake source area, usually at or near the surface of the Earth. The derived data for earthquake location include arrival times, polarization angles, or array slownesses and azimuths. For earthquake location there are three important aspects of this data determination:

- 1) choosing locations for the stations (before data have been collected),
- 2) deriving data and associated uncertainties from the seismograms, and
- 3) association of the derived data into subsets of data corresponding to unique events.

The first important aspect of data determination is choosing station locations with the goal of constraining as tightly as possible event locations for a given source area; this is classified as a problem of "experimental design" in the field of statistics. The design problem must be resolved prior to

data collection and so is posed in terms of *expected* data, and *expected* location results. We describe experimental design techniques in more detail later, after introducing and discussing the location solution on which such designs depend.

Once stations are installed and have recorded seismograms from earthquakes of interest, a data set must be extracted that is sensitive to the event source location, and which we can associate with some physics (e.g., of  $P$  or  $S$  waves) and paths of wave propagation. Most commonly for earthquake location the data set will be phase arrival times and associated uncertainties picked manually or automatically from seismograms (Fig. 1). It is often easy to detect and pick arrivals manually since the human eye can identify a change in amplitude or frequency in the signal even in the presence of significant noise. The picking of the  $S$  phase is sometimes more difficult because it arrives in the  $P$  coda and can be preceded by  $S$  to  $P$  or other converted phases; this is a common problem with recordings at local (e.g., up to about 100 km) and near-regional (e.g., up to about 300 km) distances, especially if horizontal component seismograms are not available. The automatic detection, identification and picking of  $P$  and  $S$  arrivals is much more difficult, especially in the presence of high noise levels. However, automatic detection and picking is faster and, for the case of initial  $P$  phases or other phases with characteristic forms, can produce a more con-

sistent data set than manual processing. Automatic arrival detection relies on identifying temporal variations in energy, frequency content, polarization or other characteristics of the signal which are anomalous relative to their background or noise level. Often the detection and picking algorithms are applied to filtered and processed time-series in order either to reduce noise, or to augment the signal in pre-set or dynamically-determined frequency bands or polarization directions. See [18] for an approach that exploits neural networks for phase identification and picking, and [82] for a review and systematic comparison of several approaches to automatic detection and picking.

The data used for earthquake location (e.g., arrival times) must have associated uncertainty estimates otherwise the location uncertainty and a probabilistic solution (i.e., location *pdf*) can not be calculated. Most generally, a vector  $\mathbf{d}$  that describes the data takes values from a data space  $\mathbf{D}$ , and  $p(\mathbf{d})$  denotes the *pdf* representing uncertainty in  $\mathbf{d}$ . The uncertainty in arrival time data should include not only an estimate of the uncertainty in the picked phase arrival time, but also uncertainty in which phase (e.g.,  $P$  or  $S$ ) is associated with the pick. If there are multiple expected phase arrivals close to the picked arrival time of a phase, then ideally these should all be taken as candidate phase types for the arrival. Also, the pick uncertainty of each phase may be best described by a *pdf* that is asymmetric in time, since usually a latest-possible time

Earthquake Location, Direct, Global-Search Methods, Figure 1

A short waveform segment ( $\sim 5$  sec) showing the first  $P$  wave arrivals from a small earthquake in Northern Italy recorded on a vertical component seismogram at a nearby station. Automatic arrival pick times (vertical blue lines) and uncertainty estimates (blue error bars) are shown for two phases, a first arriving  $P$  phase ( $P_0$ ) and secondary  $P$  arrival ( $P_1$ ). The red curves show the data *pdf* functions representing these arrival pick times and uncertainties for an event location procedure where the data  $P(\mathbf{d})$  is approximated by a normal distribution. The green curves show irregular, asymmetric *pdf* functions that may more accurately represent the uncertainty in the phase arrival times; if such *pdf* functions were routinely estimated during arrival picking, they could be used for direct-search location without major difficulty

for a pick is much easier to define than the earliest time (Fig. 1). True data uncertainty *pdf*'s are therefore generally multi-modal, and can be quite complex to calculate and parametrize. In practice, an enumerated quality indication or, at best, a simple normal distribution (Gaussian uncertainty) is used to describe the picking error, and the phase association is usually fixed (e. g. to *P* or *S*) so corresponding uncertainties are ignored. In many cases these simplified data uncertainty estimates will lead to bias or increased error in the resulting event locations.

The third important aspect of data determination is the association of the derived data into sets of data for unique events. For example, this association may entail the assignment of each observed arrival time within a specified time window to a unique event, forming the minimum possible number of events and corresponding arrival time sets required to explain observed data. This association procedure can be very difficult, especially with automatic systems and when there are signals from multiple seismic events that are close or overlapping in time (e. g., [24]), and we do not address this issue further here. In the following, except for an examination of outlier data, we implicitly assume that location is performed with a data set that is already associated to a unique event.

### The Velocity or Slowness Model

The velocity or slowness model specifies seismic wave-speeds in the region of the Earth containing the sources, the receivers and the ray paths between the sources and receivers. Equation (2) is nonlinear with respect to source location, but also with respect to slowness since a change in the slowness distribution of the medium changes the ray path. The velocity structure is sometimes estimated through coupled, simultaneous inversions for velocity structure and event locations (commonly called seismic tomography), but these are very large inverse problems solved mainly with linearized methods. Usually for earthquake location the velocity model is taken as known and fixed.

Often, for computational convenience or due to lack of information, the velocity model is parametrized with velocity varying only with depth. This is commonly called a laterally homogeneous or 1-dimensional (1D) model. Such a model may consist of one or more layers of constant or vertical-gradient wave-speeds. For work at a local or near-regional scale the layers may be horizontal and flat; for larger, regional or global scale problems the layers should be spherically symmetric shells to represent the curvature of the Earth. When more information on the velocity structure is available, a 3D model may be used

in order to increase the accuracy of the ray paths and travel times, and hence of the locations, relative to a 1D model. All models, whether 1D or 3D, are described by a limited number of parameters and include some form of spatial averaging or interpolation with respect to the true Earth. Although 3D models can potentially represent velocity variations in the Earth more accurately than 1D models, in practice the velocities in 3D models can locally be poorly constrained and have large errors. It is therefore often important to consider several different possible 1D and 3D velocity structures in a location study, either to test the sensitivity of the locations to errors in velocity, or to better estimate the travel-time uncertainties and produce a more meaningful location *pdf*. In principle the use of diverse velocity models poses no difficulties with direct-search location methods.

### The Travel-Time Calculation

The theoretical seismic wave travel-times through a given velocity model between any particular source and receiver locations are required by most location algorithms. The calculation of travel times is commonly referred to as forward modeling, because inverse theory need not be invoked. There are three basic classes of methods to calculate the travel times: full-waveform methods, ray methods, and Huygens wavefront or eikonal methods.

Full-waveform methods (e. g., [1]) produce complete synthetic seismograms from which predicted travel times can be extracted. These methods include frequency-wavenumber or modal-summation techniques which are valid for a broad range of frequencies and can produce exact waveforms, but which are only applicable for relatively simple velocity structures. Numerical techniques such as finite elements and finite differences can accurately model full wave phenomena in complicated structures, but these methods typically require large computing resources and computing time. Currently, full-waveform methods are rarely used to determine predicted travel times for earthquake location because these times can be obtained directly and more efficiently with ray and eikonal methods.

Ray methods (e. g., [1,7,75]) provide travel times and the path, or ray, traveled by high-frequency waves, and can be applied to complicated and 3D velocity structures. With simple model parametrizations such as flat layers with constant or gradient velocity, ray paths and travel times can be determined very rapidly with analytical or semi-numerical algorithms. For these and more complicated models, shooting, or ray tracing techniques generate rays by iteratively solving of a set of ray-tracing equations starting in a specified direction at the source or receiver lo-

cation. The ray that passes through a specified end point is found by a search over the direction at the starting point; this search can be time consuming or unstable. In addition, shooting methods do not produce diffracted arrivals (e. g., “head waves” from the Mohorovičić discontinuity) which are often the first arriving signal at near-regional distances and are thus critical for earthquake location. Two-point, ray bending and perturbation techniques rely on Fermat’s principle of least time: an initial guess at the ray between two points is perturbed repeatedly to attain a minimum travel time and corresponding ray between the points. These techniques perform best with smooth models, but do produce diffracted arrivals. In general, except for analytical or semi-numerical algorithms in simple models, ray methods are too computationally expensive for direct-search location, which usually requires evaluation of travel times between a very large number of source and receiver positions. However, some ray bending methods (e. g., [39,77]) are efficient enough to be used in direct-search location when a relatively small number of source and receiver positions need to be examined.

Wavefront, eikonal and graph-based methods [75] provide travel-times of the first arriving, high frequency waves including diffracted arrivals, and are efficient and applicable with complicated, 3D velocity structures. In effect, these methods propagate wavefronts through a velocity model with repeated application of Huygen’s principle, by considering a large number of virtual sources (*Huygens sources*) along each wavefront. At time  $t$  these sources emit circular wavelets which expand for a small time  $\Delta t$  through the (constant) local, medium velocity. The locus of the first arriving circular wavelets defines the new wavefront location at time  $t + \Delta t$ . The synthetic travel time of the first-arriving energy at the receiver is the time at which a wavefront first touches the receiver. In practice, this problem is solved on a computer either by replicating this “wavefront marching” process (e. g., [50,66]), or by finding a numerical solution to the eikonal equation (e. g., [44,79]), or by graphical analysis (e. g., [38]). Though wavefront, eikonal and graph-based methods produce directly only the travel time of the first-arriving signal, information about the path traveled by the signal can be derived numerically from the travel-time field or from ray-tracing, and travel-times of secondary arrivals can be obtained through multi-stage calculations (e. g., [44,51]).

Wavefront, eikonal and graph-based methods can efficiently generate the travel-times from one point in a gridded velocity model to all other points in the model. This makes these methods particularly useful for direct-search location, which may test a large number of possible source positions widely distributed in space. For this purpose, the

travel times from each seismic station to all points in the model can be pre-calculated and stored in computer disk files or in memory; obtaining the travel time from a station to any other point then reduces to a simple lookup (e. g., [35,38]).

### A Complete Solution – Probabilistic Location

Consider a vector  $\mathbf{d}_{\text{obs}}$  of observed data (e. g., arrival times) that takes values in a data space  $\mathbf{D}$ , and let  $p(\mathbf{d})$  be the *pdf* over  $\mathbf{D}$  describing the data uncertainty in  $\mathbf{d}_{\text{obs}}$  due to measurement and processing uncertainties. Similarly, let  $\mathbf{m}$  denote the vector of source location parameters (spatial coordinates and origin time) which take values from parameter space  $\mathbf{M}$ . Let  $p(\mathbf{m})$  be the prior *pdf* representing all information available about the location before (prior to) using the data  $\mathbf{d}_{\text{obs}}$ ;  $p(\mathbf{m})$  might include knowledge of the known, active fault zones in the area, or might specify the bounds of a region within which we know the event occurred from damage reports, or of a region containing the network of stations that recorded the event. Also consider the forward problem (e. g., travel time calculation) relating  $\mathbf{m}$  to a vector of predicted data (e. g., arrival times),  $\mathbf{d}_{\text{calc}}$ . In general the forward problem may also be uncertain, for example due to uncertainties in velocity structure, so we use  $F(\mathbf{d}, \mathbf{m})$  to denote the *pdf* of the relationship between  $\mathbf{d}_{\text{calc}}$  and  $\mathbf{m}$  as constrained by the forward problem.

As an example of  $F$ , it is commonly assumed that for each particular  $\mathbf{m}$ , the corresponding predicted data  $\mathbf{d}_{\text{calc}}$  are given by a function  $\mathbf{f}(\mathbf{m})$  with negligible errors. Then the conditional *pdf*  $F(\mathbf{d}|\mathbf{m})$  (the probability distribution of  $\mathbf{d}$  when  $\mathbf{m}$  is fixed at a particular value) is described by  $F(\mathbf{d}|\mathbf{m}) = \delta[\mathbf{d} - \mathbf{f}(\mathbf{m})]$  where  $\delta$  is the Dirac delta-function. Also, the forward problem is often assumed to place minimum possible constraint on parameters  $\mathbf{m}$ ; the *pdf* describing this state of information about  $\mathbf{m}$  is called the homogeneous distribution, represented by  $\mu(\mathbf{m})$ . No *pdf* exists that describes zero information, but *some* information about  $\mathbf{m}$  always exists in practice (the positivity of parameter values, for example);  $\mu(\mathbf{m})$  describes that minimum state of information. In that case the forward problem is given by [73,74],

$$F(\mathbf{d}, \mathbf{m}) = \delta[\mathbf{d} - \mathbf{f}(\mathbf{m})] \mu(\mathbf{m}) . \quad (3)$$

A solution to the earthquake location problem is found by combining the information in the observed data,  $p(\mathbf{d})$ , the prior *pdf*,  $p(\mathbf{m})$ , and the ability of the forward problem to predict the observed data,  $F(\mathbf{d}, \mathbf{m})$  [73,74]. This is achieved in a probabilistic framework by constructing a *pdf*  $Q$  describing the state of posterior (post-experimental) infor-

mation by:

$$Q(\mathbf{d}, \mathbf{m}) = k \frac{p(\mathbf{d})F(\mathbf{d}, \mathbf{m})p(\mathbf{m})}{\mu(\mathbf{d}, \mathbf{m})}, \quad (4)$$

where the constant  $k$  normalizes  $Q$  to unit integral over  $\mathbf{D} \times \mathbf{M}$  and  $\mu(\mathbf{d}, \mathbf{m})$  is the homogeneous distribution over data  $\mathbf{d}$  and parameters  $\mathbf{m}$ . Equation (4) contains all information (from the prior knowledge, data and physics) that could have a bearing on location  $\mathbf{m}$ , and defines a joint *pdf* between parameters  $\mathbf{m}$  and data  $\mathbf{d}$ . The final, posterior state of information about location parameters  $\mathbf{m}$  is given by integrating over the data  $\mathbf{d}$  to obtain the marginal posterior *pdf*,

$$Q(\mathbf{m}) = k p(\mathbf{m}) \int_{\mathbf{D}} \frac{p(\mathbf{d})F(\mathbf{d}, \mathbf{m})}{\mu(\mathbf{d}, \mathbf{m})} d\mathbf{d}. \quad (5)$$

Equation (5) is the general, probabilistic solution to the inverse problem of event location from the available data since it describes the uncertainty in event location  $\mathbf{m}$  given all available information. It is usual to call the integral in (5) the *likelihood* function  $L(\mathbf{m})$ , which gives a (non-normalized) measure of how good any model  $\mathbf{m}$  is in explaining the observed data  $p(\mathbf{d})$ .

As mentioned earlier it is often the case that  $p(\mathbf{d})$  for the observed data is approximated by a Gaussian distribution, described by mean  $\mathbf{d}_0$  and covariance matrix  $\mathbf{C}_d$ . Assuming that the uncertainties in the forward problem  $F$  relating  $\mathbf{d}$  and  $\mathbf{m}$  are negligible results in the form of  $F$  in Eq. (3). It is also usually assumed that  $\mathbf{d}$  and  $\mathbf{m}$  are independent and hence that  $\mu(\mathbf{d}, \mathbf{m})$  can be written  $\mu(\mathbf{d})\mu(\mathbf{m})$ ;  $\mu(\mathbf{d})$  is usually taken to be constant. With these simplifications, used by many current direct-search location procedures, the (non-normalized) likelihood function is given by,

$$L(\mathbf{m}) = \exp \left\{ -\frac{1}{2} [\mathbf{d}_0 - \mathbf{f}(\mathbf{m})]^T \mathbf{C}_d^{-1} [\mathbf{d}_0 - \mathbf{f}(\mathbf{m})] \right\}. \quad (6)$$

With the above simplifications a maximum likelihood origin time,  $t_0$ , can be determined analytically from weighted means of the observed arrival times and the predicted travel times (e. g., [74]), and if the observed and predicted times are uncorrelated we arrive at a likelihood function,

$$L(\mathbf{x}) = \exp \left\{ -\frac{1}{2} \sum_i \frac{[T_i^o - T_i^c(\mathbf{x})]^2}{\sigma_i^2} \right\}, \quad (7)$$

where  $\mathbf{x}$  is the spatial part of  $\mathbf{m}$ ,  $T_i^o$  are observed travel times,  $T_i^c$  are the calculated travel times for observation  $i$  (i. e.,  $T_i^c$  represents the travel time, rather than arrival time,

part of  $\mathbf{f}(\mathbf{m})$ ), and  $\sigma_i$  summarizes the associated standard deviation of uncertainty in  $T_i^o$  and  $T_i^c$ .

Though not normalized,  $L(\mathbf{x})$  is sufficient to provide the *relative* probability of any location  $\mathbf{m}$  being the best estimate of the event location given the available data measurements. Since in practice integrating over all of  $\mathbf{D} \times \mathbf{M}$  to find normalizing constant  $k$  in Eq. (5) is often computationally intractable, the product of the prior, spatial location information  $p(\mathbf{x})$  (i. e., the spatial part of  $p(\mathbf{m})$ ) and the non-normalized likelihood  $L(\mathbf{x})$  is usually taken as the objective function for inversion and searching in direct-search location algorithms. If  $L(\mathbf{x})$  is determined through-out the prior *pdf*  $p(\mathbf{x})$  through a global-search, then Eq. (5) can be normalized approximately after location. In the following text and examples, we refer to such an approximately normalized function,  $p(\mathbf{x})L(\mathbf{x})$ , as a location *pdf*.

The likelihood function in Eq. (5) is entirely defined by the probabilistic error processes involved. However, often it is desirable to change the approximations employed in deriving Eqs. (6) and (7) from Eq. (5), in order to remove biases or instability in the solution. The approximation in Eq. (6) uses the exponential of an L2-norm misfit function (the term in braces  $\{\}$  in Eq. (6) or (7)) to represent the *pdf* of the data error variation, but because data used for location often contain outliers it is often considered that an L1 norm or other  $L_p$  norm ( $p < 2.0$ ) is more appropriate (e. g., [69]), where  $L_p$ -norm  $|\mathbf{x}| = \sqrt[p]{\sum |x_i|^p}$ . Earthquake location problems formulated with an  $L_p$  norm (or indeed other kinds of likelihood functions – see Eq. (8) below), can be solved relatively easily with direct-search methods, which, unlike linearized methods, do not require determination of partial derivatives of the likelihood or objective function with respect to event location.

An alternative to  $L_p$ -likelihood functions that is very robust in the presence of outliers is given by the equal differential-time (EDT) formulation [16,31,84]. For the EDT case, the location likelihood is given by,

$$L(\mathbf{x}) = \left[ \sum_{a,b} \frac{1}{\sqrt{\sigma_a^2 + \sigma_b^2}} \cdot \exp \left( -\frac{\{ [T_a^o - T_b^o] - [TT_a^c(\mathbf{x}) - TT_b^c(\mathbf{x})] \}^2}{\sigma_a^2 + \sigma_b^2} \right) \right]^N, \quad (8)$$

where  $\mathbf{x}$  is the spatial part of  $\mathbf{m}$ ,  $T_a^o$  and  $T_b^o$  are the observed arrival times and  $TT_a^c$  and  $TT_b^c$  are the calculated travel times for two observations  $a$  and  $b$ ; the sum is taken over all pairs of observations, and  $N$  is the total number of observations. Standard deviations  $\sigma_a$  and  $\sigma_b$  summarize the

assigned uncertainties on the observed arrival times and calculated travel times, where it is assumed that the observed and the calculated times are uncorrelated.

In Eq. (8), the first and second terms in brackets in the exponent are, respectively, the differences between the observed arrival times and the differences between the calculated travel times. The exponent is the difference between these two terms, and thus the exponential has a maximum value of 1 which occurs at points  $\mathbf{x}$  where the two differences are equal (hence, the name “equal differential time”). Such points  $\mathbf{x}$  best satisfy the two observations  $a$  and  $b$  together, and, in general, the set of  $\mathbf{x}$  where the exponential is nonzero forms a “fat,” curved surface in 3D space. Because the summation over observations is outside the exponential, the EDT location *pdf* has its largest values for those points  $\mathbf{x}$  where the most pairs of observations are satisfied and thus is far less sensitive to outlier data than  $Lp$  norms which seek to best satisfy all of the observations simultaneously. Note that the EDT likelihood function  $L(\mathbf{x})$  does not require calculation of an origin time  $t_0$ ; this reduces the hypocenter search to a purely 3-parameter problem and contributes to the robustness of the EDT method. Nevertheless, a compatible estimate of  $t_0$  can be calculated for any hypocenter point  $\mathbf{x}$ .

Ultimately, the full solution to the probabilistic location problem is a posterior *pdf* which includes as comprehensive as possible uncertainty information over parameters  $\mathbf{m}$ . This may include multiple “locally-optimal” solutions, e. g.,  $Q(\mathbf{m})$  or  $p(\mathbf{x})L(\mathbf{x})$  may have multiple maxima, and may have a highly irregular form. Some studies of seismicity and seismotectonics make explicit use of a probabilistic representation of seismic event locations (e. g., [22,31,46]).

### Experimental Design Methods – Choosing Receiver Locations

As noted earlier, it is important to position stations so as to constrain as tightly as possible the event locations for a given source area. The location inverse problem solution in Eqs. (5), (7) or (8) is constrained by prior information on location  $p(\mathbf{m})$ , by observed data  $p(\mathbf{d})$ , and by forward-problem physics relating  $\mathbf{d}$  and  $\mathbf{m}$ . One way to significantly influence the form of this inverse problem, and hence uncertainty in its solution, is to change the data we record. Thus, we alter both  $p(\mathbf{d})$  and the forward-problem physics,  $F(\mathbf{d}, \mathbf{m})$ .

For seismic location problems we may change the data by employing experimental design methods to choose or change the locations of seismic receivers. The goal of the design procedure is to place receivers such that the loca-

tion information described by solution  $Q(\mathbf{m})$  is expected to be maximized. This is a “macro-optimization” problem where, prior to the occurrence of an earthquake, we optimize the design of the inverse problem that we expect to solve after an earthquake has occurred.

The design is varied such that it maximizes an objective function. This is usually taken to be the expected value of some approximation to the unique measure of information that was discovered by Shannon [67],

$$J(\mathbf{R}) = E_{\mathbf{m}_t} \{I[Q(\mathbf{m}); \mathbf{R}, \mathbf{m}_t]\} \quad (9)$$

where  $\mathbf{R}$  is a vector describing the design (e. g., receiver locations),  $I[Q(\mathbf{m}); \mathbf{R}, \mathbf{m}_t]$  is the information contained in the resulting posterior *pdf*  $Q(\mathbf{m})$  for design  $\mathbf{R}$  when the true parameters (e. g., event location) is  $\mathbf{m}_t$ , and the statistical expectation  $E_{\mathbf{m}_t}$  is taken over all possible  $\mathbf{m}_t$  which (according to our prior knowledge) are expected to be distributed according to the prior distribution  $p(\mathbf{m})$ .  $J(\mathbf{R})$  should be maximized.

Within the expectation in Eq. (9), the design criterion  $J(\mathbf{R})$  takes account of all possible potential true event locations  $\mathbf{m}_t$ , their prior probability of occurrence  $p(\mathbf{m})$ , and the corresponding data (including their uncertainties) that are expected to be recorded for each location (the latter are included within  $Q(\mathbf{m})$ ). To calculate the expectation usually requires integration over a far greater proportion of the model and data spaces,  $\mathbf{M}$  and  $\mathbf{D}$  respectively, than need be considered when solving the inverse problem after a particular event has occurred (since then  $p(\mathbf{d})$  and hence  $Q(\mathbf{m})$  are fixed, and  $p(\mathbf{m})$  is more tightly constrained). Consequently, experimental design is generally far more computationally costly than solving any particular inverse problem post-event.

For this reason, design methods invoking linearized approximations to the model-data relationship  $F(\mathbf{m}, \mathbf{d})$  (e. g., Eq. (10) below) have been employed by necessity in the past [11,13,49,70], or indeed non-probabilistic methods have been employed (e. g., [9,10,36,71]). Truly non-linearized design methods have been developed for location problems only relatively recently [12,78,80]. Historically, however, station network geometry has been defined more by heuristics (rules of thumb) and geographical, logistical and financial constraints, with design theory only recently being deployed.

### Location Methods

Once data have been recorded and prior *pdf*'s defined, a solution such as that of Eqs. (5), (7) or (8) must be evaluated throughout the prior *pdf*,  $p(\mathbf{x})$ , to identify one or more “locally-optimal” solutions, or, preferably, to obtain

a full probabilistic location *pdf*. This evaluation generally requires direct-search optimization and search techniques, which we discuss below. We first digress and summarize linearized location procedures, which typically determine a single optimal hypocenter along with a simplified and approximate representation of the location *pdf* (e. g., a confidence ellipsoidal centered on the estimated hypocenter and origin time).

### Linearized Location Methods

With linearized methods the arrival time expression (2), which is nonlinear with respect to the spatial location  $\mathbf{m} = (x, y, z)$ , is approximated by a Taylor series expansion around some prior estimate  $\mathbf{m}_0 = (x_0, y_0, z_0)$  of the spatial location:

$$f(\mathbf{m}) = f(\mathbf{m}_0) + (\mathbf{m} - \mathbf{m}_0)f'(\mathbf{m}_0) + \frac{(\mathbf{m} - \mathbf{m}_0)^2}{2}f''(\mathbf{m}_0) + O[(\mathbf{m} - \mathbf{m}_0)^3] \quad (10)$$

where  $f(\mathbf{m})$  is the forward problem that calculates an arrival time  $d_{\text{calc}}$  given a location  $\mathbf{m}$  (e. g.,  $f(\mathbf{m})$  might represent the right hand side of Eq. (2) directly). A linear vector-matrix inverse problem is obtained if we approximate the forward problem for all  $d_{\text{calc}}$  by using only the first two terms of the Taylor series. The resulting vector-matrix equation may be solved using linear algebraic methods. This process is called *linearized inversion*.

Usually, this linearized inversion is iterated: the prior estimate  $\mathbf{m}_0$  is set equal to the newly-found, best-fit location, the problem is re-linearized around this new estimate using Eq. (10), and the new linear problem solved again. This method may be repeated (iterated) many times, as needed to attain some convergence criteria.

Linearized methods produce a single, best-fit (e. g., maximum likelihood) hypocenter and origin time location, and associated, linearly-estimated uncertainties, such as a multi-dimensional, normal-distribution centered on the best-fit hypocenter and origin time. However, this linearized solution is often a poor representation of the complete solution *pdf* (Fig. 2 and see examples), and it may be unstable when the *pdf* is irregular or has multiple peaks due to insufficient or outlier data, velocity model complexities, and other causes (e. g., [5,34]).

### Direct-Search Location Methods

The earliest, formal earthquake locations from phase arrival time observations used nonlinearized procedures. Milne [37] describes and applies several graphical and algebraic methods to determine earthquake locations. These

Earthquake Location, Direct, Global-Search Methods, Figure 2 Schematic diagram comparing linearized and direct-search locations for the case where the complete location *pdf* is moderately complicated, with two maxima. This example arises from the case of a location at the limits of the recording network and near a sharp, horizontal interface in the velocity model between lower velocities above and higher velocities below. The colored, contoured form shows the true location *pdf*, as should be determined by a complete, probabilistic, direct-search location procedure. A linearized location that iterates from an initial trial location below the sharp interface will find an optimal hypocenter near the secondary, local maximum of the location *pdf*, below the interface. The linearized error ellipsoid, based on the curvature of the misfit function at this optimal hypocenter, reflects the form of this secondary maximum only. The linearized location procedure never identifies or explores the primary maximum of the *pdf* above the sharp interface, and produces incorrect error information above this interface (i. e. the uppermost part of the error ellipsoid). A probabilistic, direct, global-search procedure can determine the complete location *pdf* and identify correctly the maximum likelihood hypocenter located above the sharp interface

include a perpendicular bisector method for the case of 3 or more simultaneous arrival time observations (related to the modern arrival order or bisector method), a method of hyperbolae based on the differences in arrival times at pairs of stations (related to the modern EDT method) and a method using the differences in arrival times of different wave types at individual stations. The latter is a generalization of the method of circles using *S-P* times, in which the distance from a station to the source is, for given *P* and *S* velocity models, a function of the difference of the *S* and *P* arrival times; an epicenter can be constrained with such *S-P* based distances from 3 stations. Reid [52] determined a hypocenter location for the great 1906 California earthquake through a coarse, systematic grid search over velocity, position along the causative fault and depth, solving for the origin time and wave velocity by least-squares at each grid point.

The arrival order or bisector method [2,42] is a non-linear, geometrical approach that uses the constraint that if a phase arrival is earlier at station A than at station B, then the event is closer to A than to B (assuming the velocity model is such that arrival order implies distance order). Applying this constraint to all pairs of stations defines a convex region containing the event location. This method is useful for obtaining some constraint on the location of events far outside of an observing station network, and for rapidly and robustly obtaining starting locations for linearized methods.

Most other modern, direct-search earthquake location methods (excluding graphical methods that are now mainly used for illustrative and educational purposes) are based on deterministic or stochastic searches which may be exhaustive or directed and evolutionary. These searches are used to explore or map likelihood functions such as those given in Eqs. (5), (7) or (8). When these searches gather and retain information globally, throughout the prior *pdf*  $p(\mathbf{x})$ , they can produce a complete, probabilistic location *pdf*. Otherwise, searches may determine a global or local maximum of the location *pdf*, or may explore the neighborhood around these optimal points to locally estimate the *pdf* and obtain uncertainty information.

**Regular, Deterministic Search** Regular and deterministic searches, such as grid-searches, nested grid-searches and stochastic, “crude” Monte-Carlo searches (e. g., [20,62]) use global and well-distributed sampling of the model space and thus can estimate the complete location *pdf*. All of these approaches are computationally demanding for problems with many unknown parameters, large parameter spaces, or time consuming forward calculations, because the number of models that must be tested can be very large. These methods have been successfully applied to the determination of optimal hypocenters (i. e., [14,26,61,69]), and to probabilistic location (i. e., [6,34,38,83]), but their inefficiency may impose unacceptable limitations on the number of events that can be considered, or on the size of the search volume.

**Directed Search** Directed, stochastic search techniques include evolutionary, adaptive global search methods such as the genetic algorithm [19,59] and simulated annealing [28,53,72]. The simplex method is a directed, deterministic search technique that is nonlinearized and can be used for earthquake location (e. g., [48]). Most of these methods were developed for optimization or the identification of some very good solutions, which is equivalent to identifying a global or local maximum of the location *pdf*. In general, these methods do not explore the prior

*pdf*  $p(\mathbf{x})$  in a manner that can produce complete, probabilistic solutions to inverse problems. For example, the genetic algorithm performs global searching and may be one of the most efficient stochastic methods for optimization, but it does not use well distributed sampling (the sampling tends to converge rapidly to the region of a locally optimum solution). Similarly, in the simulated annealing, random-walk method the interaction of its variable “temperature” parameter and step size with the local structure of the misfit function can lead to convergence and stalling near a locally optimum solution, and a sample distribution that is neither well nor globally distributed. Both the genetic algorithm and simulated annealing can be tuned to sample more broadly and in the limit become crude Monte Carlo searches, but this removes the main advantage of these methods – that of rapid stochastic optimization.

Though not directly applicable to complete, probabilistic location, directed search algorithms are useful for direct-search, earthquake hypocenter estimation because of their efficiency (e. g., [4,48,60,61]).

**Importance sampling** The efficiency of a Monte Carlo algorithm used to estimate properties of a target (misfit or likelihood) function can be increased by choosing a sampling density which follows the target function as closely as possible [20,30,45]. Techniques that follow this rule are referred to as importance sampling methods, and were originally developed in physics for fast and accurate numerical integration of multi-dimensional functions. The target function is unknown, however, and consequently the optimum importance sampling distribution cannot be determined a priori. Instead, improved efficiency is attained by adjusting (or adapting or evolving) the sampling by using information gained from previous samples so that the sampling density tends towards the target function as the search progresses [30,40,45,65]. For example, importance sampling to determine an earthquake location *pdf* or likelihood function (e. g., Eqs. (5), (7) or (8)), can be obtained by beginning with a sampling that follows the prior *pdf*,  $p(\mathbf{m})$ , and then adjusting the sampling as the search progresses so that the sampling density approaches the posterior, location *pdf*.

Importance sampling techniques that can be used to find complete, probabilistic solutions to inverse problem include the VEGAS algorithm [30], the Metropolis algorithm [40], the neighborhood algorithm [55] and, for three-dimensional problems, oct-tree [33]. Other importance sampling methods are discussed in Hammersley and Handscomb [20] and in Press et al. [45] in the context of numerical integration.

The VEGAS algorithm [30,45] performs importance sampling by accumulating appropriate sampling distributions independently for each parameter as the sampling proceeds. This method can give very good estimates of an individual or a joint marginal *pdf*, but it loses efficiency if the target function includes strong correlation between parameters or if it is independent of some parameters [45]. In addition, the VEGAS algorithm may be difficult or impossible to implement with prior information, such as smoothness constraints, that introduces correlation between parameters. Consequently, this algorithm may not be appropriate for some geophysical problems, including earthquake location, when the location parameters are often correlated or poorly resolved.

The Metropolis or Metropolis-Hastings algorithm (e. g., [40]) is similar to simulated annealing but with a constant temperature parameter. The Metropolis algorithm performs a random walk in the model space, testing at each step nearby trial samples which are accepted or rejected after evaluation of the forward problem according to a likelihood  $L(\mathbf{m})$ . In [40] it is shown that this algorithm samples from the posterior *pdf* of the problem and is therefore an importance sampling method. They show that, in the limit of a very large number of trials, it will not become permanently “trapped” near local maxima and consequently will produce global sampling. Also, because it is a random walk technique, the Metropolis algorithm can perform well even if the volume of the significant regions of the posterior *pdf* is small relative to the volume of the prior *pdf*. However in practical application, with a finite number of samples, this algorithm can become trapped in strong local maxima of the posterior *pdf* if this function is complicated. The Metropolis algorithm has been applied to earthquake location in 3D structures [34,35].

Another recently developed importance sampling technique used in geophysics is the neighborhood algorithm [55,56,57], applicable to high dimensional model spaces. Given an existing set of samples of the objective function, the neighborhood algorithm forms a conditional *pdf* using an approximate Voronoi cell partition of the space around each sample. The algorithm generates new samples through a uniform random walk within the Voronoi cells of the best fitting models determined so far. This algorithm is applied to the 4D hypocenter location problem in [27,58].

The oct-tree importance-sampling method [33] uses recursive subdivision and sampling of rectangular cells in three-dimensional space to generate a cascade structure of sampled cells, such that the spatial density of sampled cells follows the target *pdf* values. The relative probability

that an earthquake location lies within any given cell  $i$  is approximately,

$$P_i = V_i L(\mathbf{x}_i) , \quad (11)$$

where  $V_i$  is the cell volume and  $\mathbf{x}_i$  is the vector of coordinates of the cell center. Oct-tree importance-sampling is used to determine a location *pdf* by first taking a set of samples on a coarse, regular grid of cells throughout the search volume. This is followed by a recursive process which takes the cell  $k$  that has the highest probability  $P_k$  of containing the event location, and subdividing this cell into 8 child cells (hence the name oct-tree), from which 8 new samples of the *pdf* are obtained. These samples are added to a list of all previous samples, from which the highest probability cell is again identified according to Eq. (11). This recursive process is continued until a predetermined number of samples are obtained, or until another termination criterion is reached.

For most location problems, including those with a complicated location *pdf*, the oct-tree recursive subdivision procedure converges rapidly and robustly, producing an oct-tree structure of cells specifying location *pdf* values in 3D space. This oct-tree structure will have a larger number of smaller cells in areas of higher probability (lower misfit) relative to areas of lower *pdf* value and thus the oct-tree method produces approximate importance-sampling without the need for complex geometrical constructs such as Voronoi cells. Oct-tree sampling can be used with the L2-norm likelihood function in Eq. (7) or the EDT likelihood function in Eq. (8), since both require searching over three-dimensional spatial locations only. Oct-tree sampling has been applied to earthquake location in 3D structures [22,23,31,32]; we use this sampling method to determine locations in the examples presented below. Though limited to determination of the 3D, spatial location, this recursive sampling procedure can be extended to 4D to allow determination of the origin time.

### Illustrative Examples

We illustrate the concepts described in the previous sections using an M3.3 earthquake that occurred in the Garfagnana area of Northern Tuscany, Italy, on March 5, 2007 at 20:16 GMT. The earthquake was recorded by stations of the Italian National Seismic Network (INSN) at distances from less than 10 km to more than 300 km. We use manually picked  $P$  and  $S$  phase arrival times from the INSN bulletin with Gaussian uncertainties (standard deviations from 0.01 to 0.1 s), and a 1-D velocity model similar to the standard model used by INSN for routine

earthquake location in Italy. We perform all event locations with the probabilistic location program NonLin-Loc [31,34,35] (<http://www.alomax.net/nlloc>; NLL hereafter), using the oct-tree sampling algorithm (Sect. “**Location Methods**”) to perform a global-search within a parameter space  $\mathcal{M}$  formed by a rectangular volume 360 km on each side and from the Earth’s surface to 35 km depth (except as noted in figure captions). We use the L2-norm (Eq. (7)) or EDT (Eq. (8)) likelihood functions to obtain location *pdf*’s in 3D space and corresponding maximum likelihood origin times.

In order to describe the location problem and the solution quality for each of the examples presented below we focus on geometrical properties of the location *pdf*, which represents most completely the results of probabilistic, direct, global-search methodologies. We also consider the maximum likelihood hypocenter, defined as the point in space of the maximum value of the location *pdf*, and the corresponding origin time. We examine statistics of the quality of the solutions using the half-lengths of three principal axes of a 68% confidence error ellipsoid approximation to the location *pdf*,  $l_{\text{ell}}$ , the weighted, root-mean-square of the arrival residual (observed – calculated) times, *rms*, and a relative measure of the volume of the high likelihood region of the location *pdf*,  $V_{\text{pdf}}$ , given by,

$$V_{\text{pdf}} = \int_{\mathcal{M}} \frac{\text{pdf}(\mathbf{x})}{\text{pdf}^{\text{max}}} dV, \quad (12)$$

where  $\text{pdf}^{\text{max}}$  is the maximum value of the location *pdf* in  $\mathcal{M}$ . We also make use of standard measures of the experimental design quality (i.e, stations coverage) including the *gap* – the largest angle between the epicenter and two azimuthally adjacent stations used for location, and the distance  $\Delta_0$  from the hypocenter to the closest station. These indicators are summarized in Table 1 for the examples presented here.

These examples are meant to show important features and complexity in earthquake location results, not to compare different direct-search location methods or to compare direct-search to linearized algorithms. However, because linearized earthquake location has been and remains an important and widely used tool, we indicate for each example the location results obtained with a linearized algorithm, Hypoellipse [29]. Hypoellipse uses a least-squares, L2-norm and produces a 68% confidence ellipsoid for the hypocenter location. For well constrained locations this ellipsoid should closely match the *pdf* of our probabilistic, L2-norm locations; we plot the Hypoellipse ellipsoid for cases where it differs notably from the probabilistic location, L2-norm *pdf*.

### Example 1: An Ideal Location

To construct an ideal, reference location and synthetic data set for the 2007 Italian earthquake we first locate the event using the earliest 20 observed *P* or *S* arrival times (Fig. 3; Table 1; Example 1a). Next, we subtract the arrival residuals for this location from the corresponding times for all observations and relocate the event with the earliest 50 of these “corrected” times (Fig. 3; Table 1; Example 1b). This procedure results in an ideal, synthetic data set and a location problem that are equivalent to the case of no “a posteriori” picking error and no travel-time error (i. e., no velocity model error). For this problem the quality of the solution and the shape of the resulting location *pdf* reflect primarily the station geometry and corresponding ray take-off angles about the source.

The reference location (Fig. 3; Table 1; Example 1b) has  $\text{rms} = 0$  s,  $\text{gap} = 63^\circ$ ,  $\Delta_0 \sim 9$  km,  $V_{\text{pdf}} \sim 7.0 \text{ km}^3$  and  $l_{\text{ell}} = 1.05, 1.32$  and  $2.05$  km. The *rms* is necessarily zero because we used residuals as time corrections, while the other indicators and the near-ellipsoidal form of the location *pdf* show a well constrained location. The location is well constrained by the data because stations are available at a wide range of distances and azimuths. In particular, the presence of a station nearly above the event, and of both *P* and *S*-wave arrival times for the closer stations, give good depth constraint.

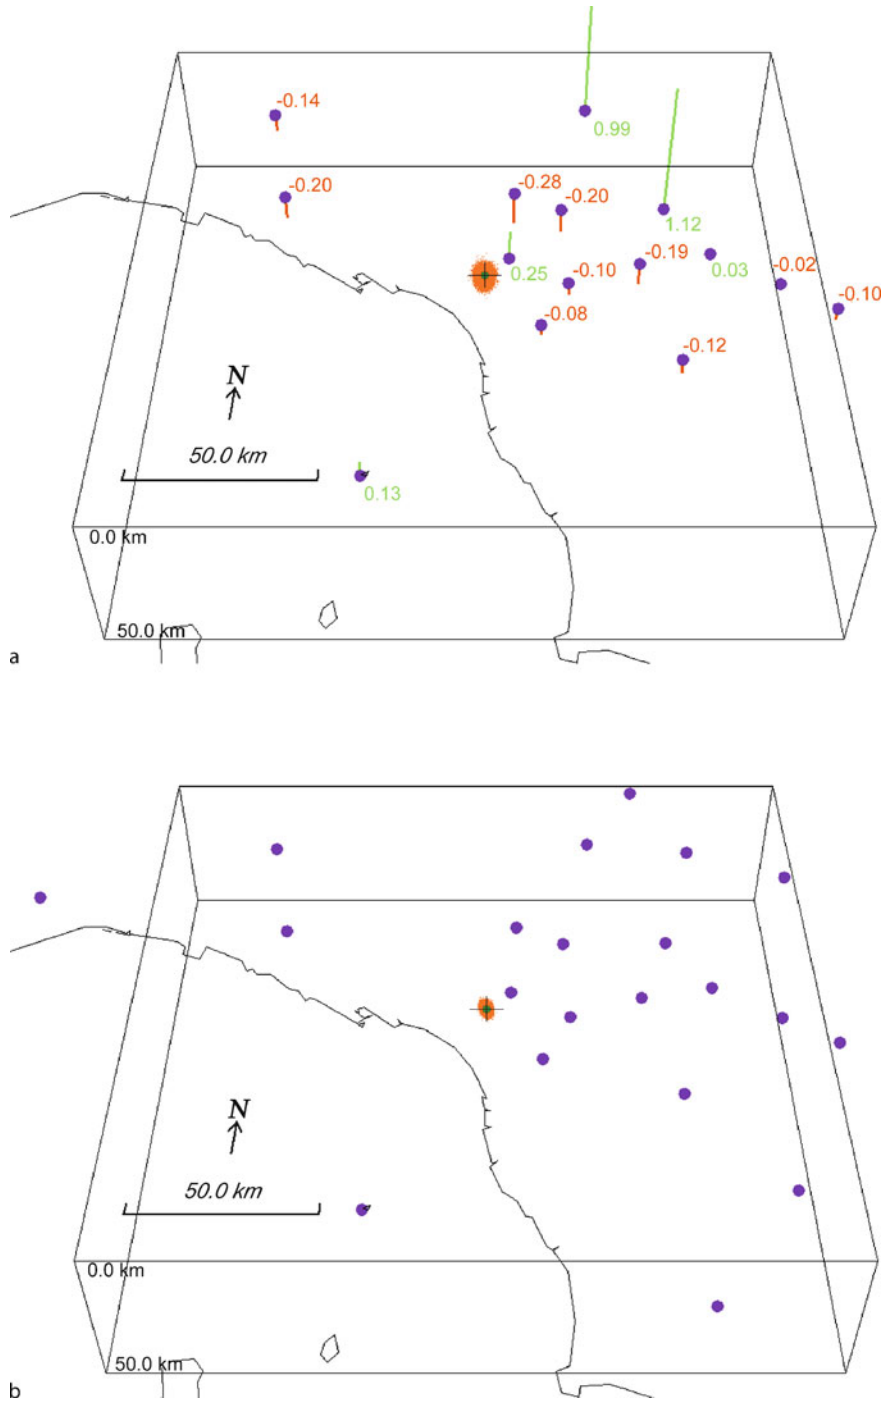

### Examples 2–5: Station Distribution

In the next examples we show locations for three cases with poor station distribution about the source:

- 1) few available stations;
- 2) stations all to one side of the event; and
- 3) no data for stations near or above the source. In addition we illustrate the application of experimental design techniques to improve the station distribution.

**Example 2: Few Available Stations** We first examine relocations of the 2007 Italian earthquake obtained with different numbers of *P* and *S* arrival times selected from the ideal, synthetic data set (Fig. 4; Table 1; Example 2a–d). With only two stations and 2 arrivals (2 *P* phases) the location *pdf* is a fat, near-vertical, planar surface with an elongated, boomerang shape trending perpendicular to the line connecting the two receivers (Fig. 4a). With the addition of *S* arrivals from the same stations (4 arrivals – 2 *P* and 2 *S* phases) the location *pdf* is greatly reduced in volume, and has the form of an annulus oriented roughly perpendicular to the line connecting the two receivers (Fig. 4b). The annular form of this *pdf* results from the intersection

Earthquake Location, Direct, Global-Search Methods, Figure 3

**Example 1: An ideal location.** a Location obtained using the first 20, observed *P* or *S* arrival times; b location obtained using the first 50, *P* or *S* corrected arrival times from the ideal, synthetic data set. The elements shown in these and the following figures are: stations used for location (blue dots, in some cases stations fall outside the plotted region); location pdf (red cloud of points showing an importance sample drawn from the pdf); maximum likelihood hypocenter (green dot); ideal, synthetic location (black cross); *P* arrival residuals at each station: positive (green, up-going bars) and negative (red, down-going bars), numbers indicate residual value in sec. The Hypoellipse linearized locations and ellipsoids do not differ significantly from the direct-search locations shown in this figure

of the boomerang shape *pdf* produced by the 2 *P* phases (Fig. 4a) and two hemispherical *pdf*'s centered on each station. Each of these hemispherical *pdf*'s would be produced by location using only the *P* and the *S* reading from either station; this is the probabilistic analogue to the method of circles using *S-P* times.

With three stations (3 arrivals – 3*P* phases) the location *pdf* forms one mass and its volume is further reduced. This location *pdf* retains an irregular, curved shape resulting from poor constraint of one spatial dimension that trades off with origin time (Fig. 4c). For all of these locations the problem is effectively underdetermined – the data cannot constrain all three hypocentral coordinates and origin time. In these cases a linearized location algorithm may not converge and would be unable to represent properly the effective location uncertainties. As more data are added, the location *pdf* progressively reduces in size and complexity, and with the addition of a station close to and above the source (8 arrivals – 5 *P* and 3 *S* phases), the location *pdf* has a compact, near ellipsoidal form indicating some constraint on all hypocentral coordinates and

origin time (Fig. 4d). This location is similar to that obtained with the complete, ideal data set (Fig. 3b), though the location *pdf* remains much larger than that of the ideal case which has arrival times from many more stations.

**Example 3: Stations to One Side of the Event – Large Gap**

Next, we examine the case of earthquakes occurring outside of the recording network with an example using *P* arrival times from stations only to the southeast of the earthquake (Fig. 5; Table 1; Example 3). The location *pdf* is large and elongated in a northwest-southeast direction oriented towards the centroid of the available stations because the lack of stations to the northwest (and use of *P* times only) allows a strong trade-off between potential hypocenter locations along this direction and origin time. In contrast, there is some constraint of the *pdf* to the northeast and southwest due to the aperture of the available stations. The poor station distribution and potential lack of constraint is clearly indicated by the large gap value for this location, gap = 251°. One or more good quality *S* readings can reduce the elongation of the *pdf*.

Earthquake Location, Direct, Global-Search Methods, Figure 4

**Example 2: Few available stations.** Locations obtained using progressively (a–d) a larger number of arrival observations. a 2P phases (2 stations); b 2P and 2 S phases (2 stations); c 3P phases (3 stations); d 5P and 3S phases (5 stations). For the locations in a and b the oct-tree search is performed to 100 km depth. In this and the following figures the 68% Hypoellipse ellipsoid is shown with *green lines*. Hypoellipse linearized location: does not converge for the location in panel a; ellipsoid differs markedly from the direct-search location *pdf* in panels b and c; and does not differ markedly from the direct-search location in panel d

**Example 4: Stations Far From the Event – Vertically Elongated PDF** We next show an example where the nearest recording stations are far from the earthquake, relative to its depth, and either *P* arrival times only or both *P* and *S* arrival times are available (Fig. 6; Table 1; Examples 4a–b). With this station geometry the seismic rays leave the source region with approximately the same dip-direction to all stations. Consequently a change in source depth gives about the same change in predicted travel times to all stations. This change in travel time is indistinguishable from a change in origin time (c.f., Eqs. (1) or (2), leading to a strong trade-off between origin time and depth. Consequently the location *pdf* has a vertically elongated shape which, for the case of *P* arrivals only (Fig. 6a),

extends throughout the entire search range in depth indicating no depth constraint. For a linearized location algorithm this location problem can be effectively underdetermined, though most linearized algorithms can fix the hypocenter depth artificially in order to obtain a stable epicentral location. The addition of *S* arrival times (Fig. 6b) improves the depth constraint to some extent, although the location *pdf* remains highly elongated in the vertical direction. The lack of close stations and potential lack of constraint is clearly indicated by the large  $\Delta_0$  value for this location,  $\Delta_0 \approx 106$  km.

This case is common with sparse networks and with shallow sources. Reducing the vertical extent of the *pdf* requires stations at distances of the order of the source depth

Earthquake Location, Direct, Global-Search Methods, Figure 5

**Example 3: Stations to one side of the event.** A location example with  $P$ -wave arrival times at 7 stations only to the southeast of the event. The Hypoellipse ellipsoid differs markedly from the direct-search location  $pdf$  in this figure

or less. The addition of one or more good quality  $S$  readings, especially at the closest stations, would further improve the depth constraint.

#### Example 5: Stations Selection with Experimental Design

Next, we illustrate the application of experimental design techniques to station selection (Fig. 7; Table 1; Example 5). Considering a case similar to Example 3, which has 6 stations to one side of the event giving poor constraint on the location, we determine an optimal set of 6 stations to best constrain the location. To do this we apply a linearized design method [13] to select an optimal subset of 6 of the available INSN stations to best constrain an event at the (known) location produced by the ideal, synthetic data (Example 1b).

The design procedure does not simply select the 6 closest receivers to the source (i.e. first 6 available arrival times, Fig. 7a), but instead selects receivers distributed around, and to a large distance away from the source (Fig. 7b). This choice can be understood as balancing the distribution of directions (azimuth and inclination) that the rays leave the source to the selected receivers, a direct result of the use of the linearized approximations to the model-data relationship Eq. (10) in the linearized design method [13]. This method is based on selecting sta-

tions based on the similarity between the rows of the location kernel matrix of the linearized problem; the approach does not differ significantly from that of Uhrhammer [76] based on the condition number of the same matrix. The improvement in station distribution in azimuth is indicated by the small gap value for this location,  $\text{gap} = 89^\circ$ . The resulting location  $pdf$  (Fig. 7b) is compact and symmetric relative to the location  $pdf$  obtained from the first 6 stations recording the  $P$  phases (Fig. 7a), and the maximum likelihood hypocenter is close to the ideal location hypocenter.

#### Example 6: Incorrect Picks and Phase Identification – Outlier Data

For a given hypocenter location, an outlier arrival time has a residual that is much greater than its nominal error. Data outliers are common with automatic phase arrival picking algorithms, with  $S$  arrival picks, for small events, distant stations, or other cases where the signal to noise ratio is low, and for early instrumental data where large timing errors are common. In many cases, such as automatic earthquake monitoring and early warning systems, it is important to have robust location procedures that are influenced as little as possible by the presence of outliers. One way to

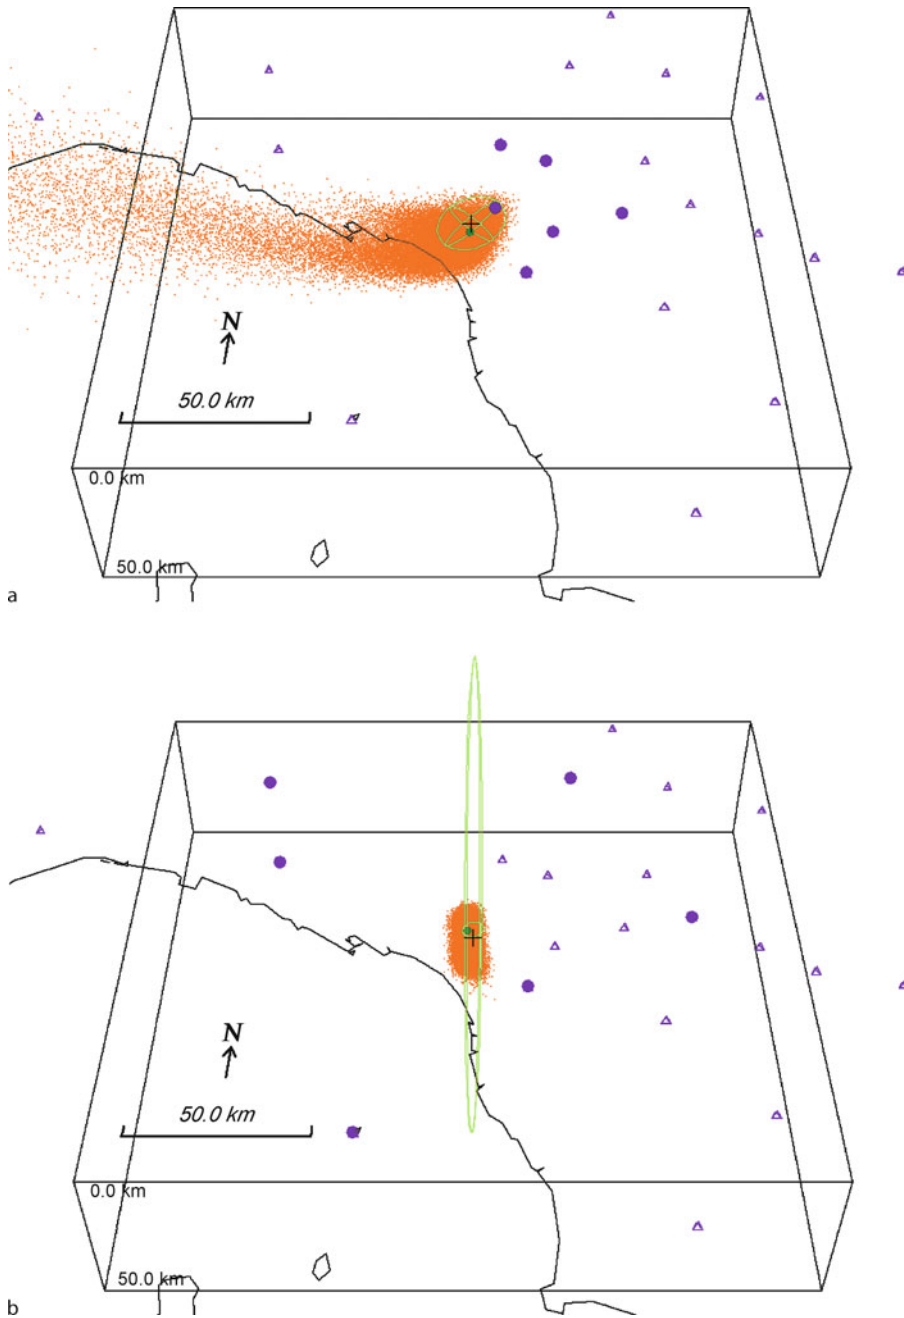

Earthquake Location, Direct, Global-Search Methods, Figure 6

**Example 4: Stations far from the event.** A location example using stations far from the epicenter, with **a**  $P$  arrival times only, **b** both  $P$  and  $S$  arrival times. Hypoellipse linearized location: ellipsoid differs markedly from the direct-search location  $pdf$  in panel **a**; and does not differ markedly from the direct-search location in panel **b**

achieve this is to use robust likelihood functions such as EDT Eq. (8). In the example below, we compare the performance of EDT and the more commonly used L2-norm likelihood functions.

This example uses only stations near the source, and arrival times from ideal, synthetic data sets for both the L2-norm and the EDT likelihood functions. We add 3 s to the  $P$  arrival time at two stations to generate outlier

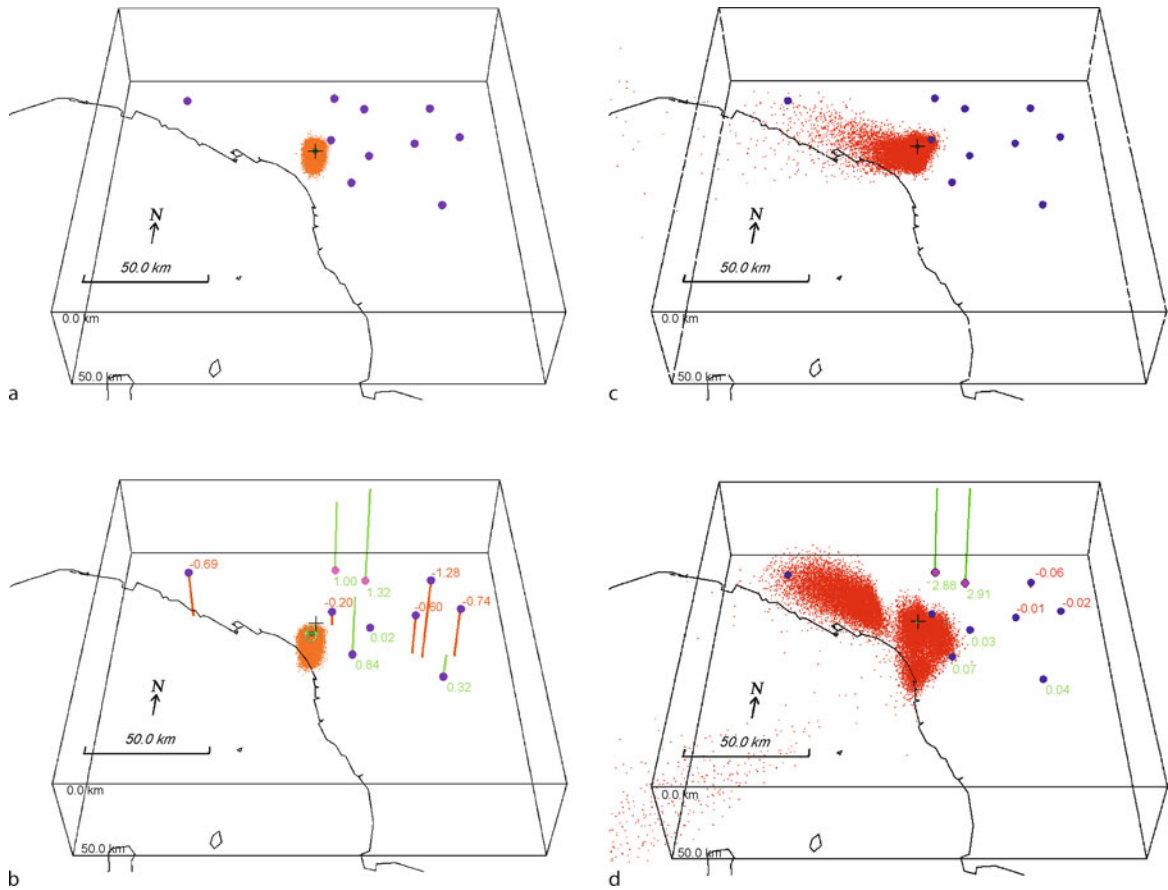

Earthquake Location, Direct, Global-Search Methods, Figure 7

**Example 5: Stations selection with experimental design.** A location example showing a Location using the stations with the first 6 available arrival times, **b** location using an optimal set of 6 stations as determined with a linearized experimental-design method. Available stations not used or selected are shown with *open triangle symbols*. Hypoellipse linearized location: ellipsoids differ markedly from the direct-search location *pdf's* in panels **a** and **b**

data, and examine L2-norm and EDT locations without and with the outlier data (Fig. 8; Table 1; Examples 6a–d). The L2-norm location with the outlier data (Fig. 8b)

does not identify and isolate the two outlier *P*-arrivals but instead mixes information from these arrivals with the other data resulting in relatively large, non-zero residu-

Earthquake Location, Direct, Global-Search Methods, Figure 8

**Example 6: Incorrect picks and phase identification – outlier data.** Locations using ten  $P$ -wave arrival times with L2-norm and a no outliers, **b** two arrival-time outliers, and with EDT and **c** no outliers, **d** two arrival-time outliers. The stations with outlier arrivals are shown with *violet dots*. Note the small  $pdf$  of L2-norm regardless of the outliers and, in contrast, the ability of EDT to detect the outliers (see text). The Hypoellipse ellipsoid differs markedly from the direct-search location  $pdf$  in panel **b**. Hypoellipse not compared to EDT locations in panels **c** and **d**

als for all arrivals. This results in a bias of about 10 km in the maximum likelihood hypocenter location relative to the ideal location hypocenter, while the location  $pdf$  for the L2-norm locations with and without outlier data have about the same size and form, but have little overlap (Figs. 8a and 8b). Thus the L2-norm solution gives no clear indication of the presence of outlier data, or that the solution may be biased. In contrast, the EDT location for the data set containing the outliers (Fig. 8d) correctly identifies the two outlier arrivals (the EDT residuals for these two outlier data are both about 2.9 s) and strongly downweights them (from 1.2 to 0.17 posterior weight), while producing small residuals ( $< 0.08$  s) for the remaining arrival, as would be the case without outlier data. The maximum likelihood hypocenters for the EDT locations with

and without outlier data are almost identical, but the location  $pdf$ 's are very different (Fig. 8c and 8d). With outlier data, the  $pdf$  has an irregular shape and several distinct parts, reflecting the inconsistency of the data set to constrain a unique event location. For the outlier locations, a potential problem with the data set is indicated by the large  $rms$  values with both L2-norm and EDT, and with EDT alone, by the asymmetry in residuals, the irregular  $pdf$  shape, and the large  $V_{pdf}$  and  $I_{ell}$  values.

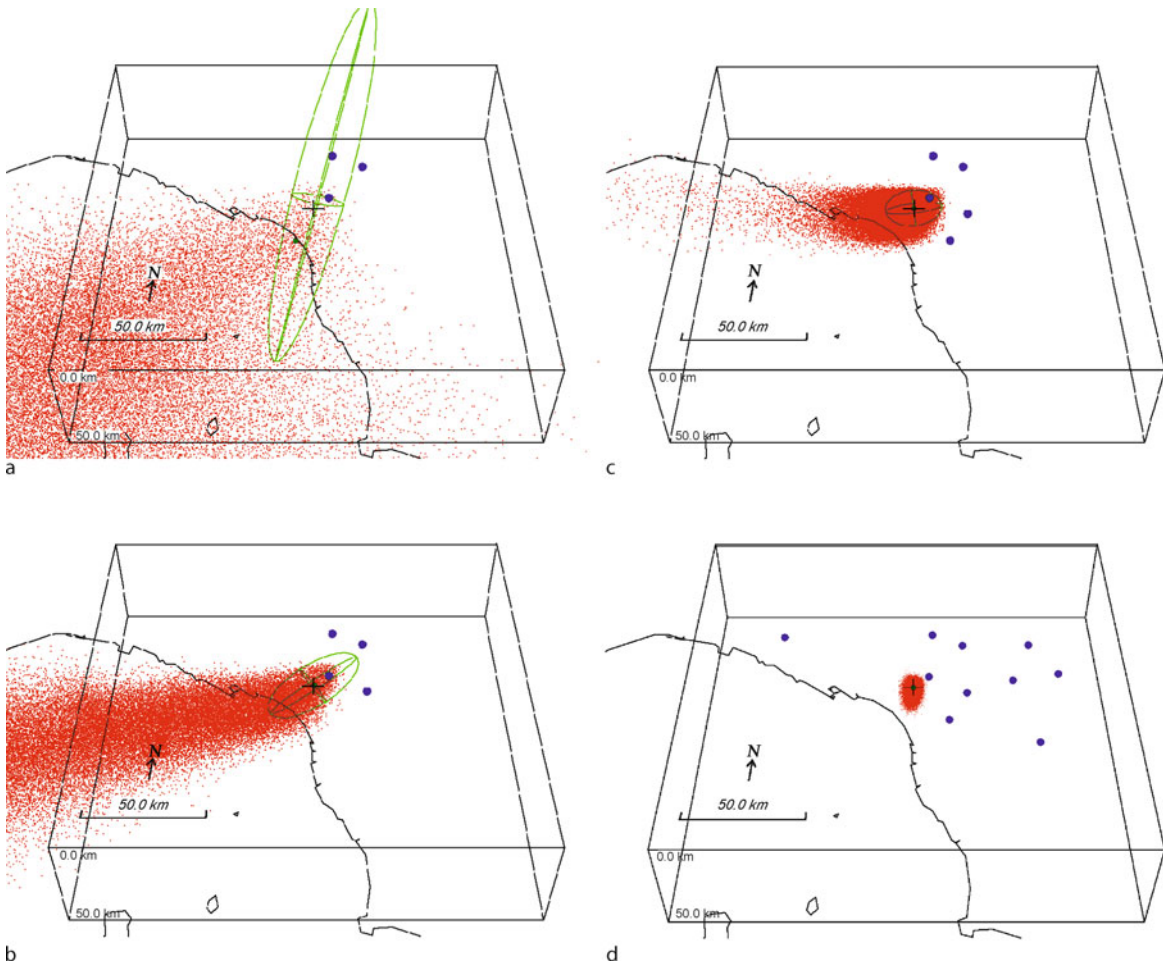

This result shows that location in the presence of outlier data can be remarkably stable with the EDT likelihood function, which is easy to implement with direct-search location techniques. In contrast, the same location with the commonly used, L2-norm likelihood function is biased, while presenting few indicators of this bias.

**Example 7: Earthquake Early-Warning Scenario**

Location for earthquake early-warning must be performed rapidly and in an evolutionary manner starting with the first available phase arrivals. In this example we examine the ability of direct-search location to obtain robust and useful location information using *P* arrivals from the first stations that record the Northern Italian event (Fig. 9; Table 1; Examples 7a–d).

Within about 6 seconds after the origin time,  $t_0$ , three *P* readings are available. Location with these readings produces an extensive location *pdf* that fills the southwest quadrant of the search region (Fig. 9a); this *pdf* does not provide useful constraint on the location, but is robust in that it includes the true location. Progressive addition of

more arrival time data (Fig. 9b and 9c) reduces the size of the location *pdf*. With 5 arrivals, at about 7 s after  $t_0$  (Fig. 9c), the maximum likelihood location is close to that of the ideal, synthetic location and the location *pdf* is well delimited, although elongated towards the west because no arrivals are yet available from stations in that direction. By 13 s after  $t_0$  (Fig. 9d), 10 *P* arrivals are available and the location *pdf* is now compact and symmetrical, primarily because a station to the northwest is included. This *pdf* has small enough  $V_{pdf}$  and  $I_{ell}$  values to provide useful, probabilistic constraint on the location for early-warning purposes at a regional scale, while the maximum likelihood hypocenter is effectively the same as that of the ideal location. In practical application, direct-search location results similar to those illustrated here can be obtained within

Earthquake Location, Direct, Global-Search Methods, Figure 9

**Example 7: Earthquake early-warning scenario.** Progressive location using a 3, b 4, c 5 and d 10 stations. Hypoellipse linearized location: ellipsoid differs markedly from the direct-search location *pdf*'s in panel a, b and c; and does not differ markedly from the direct-search location in panel d

a delay of less than 1 sec after the readings are available (e. g. [64]).

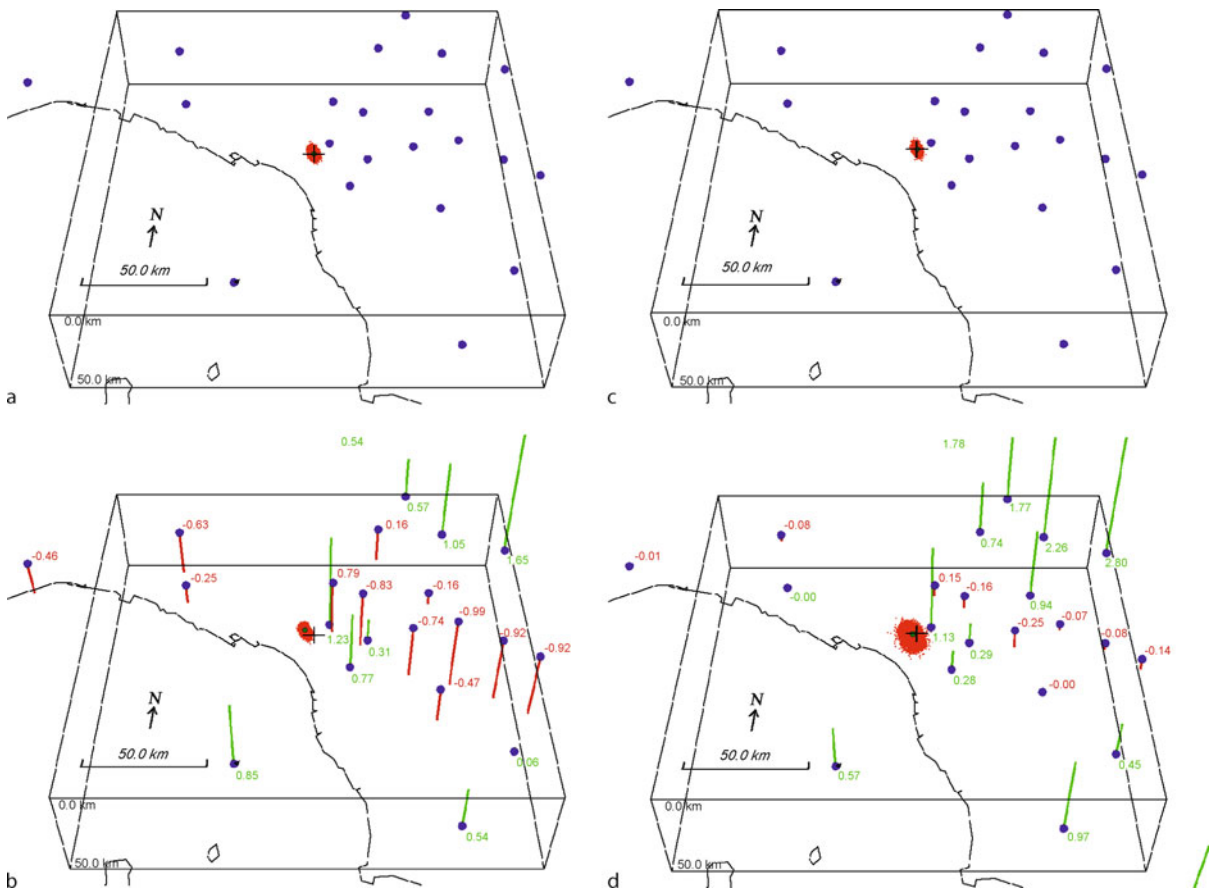

### Example 8: Incorrect Velocity Model

Any velocity model used for earthquake location is an approximation to the true Earth and thus will in general produce erroneous predicted travel times. The magnitude of error in the travel times depends on many factors, but will in general be larger for more distant stations and with increased complexity in the true Earth structure. We examine the effect of an incorrect velocity models by repeating the ideal location (Example 1a and b) with and without the “corrected” times, and using 50  $P$  arrivals (the ideal location was determined using the first 20  $P$  or  $S$  arrivals). We

examine locations using the L2-norm and EDT likelihood functions (Fig. 10; Table 1; Examples 8a–d).

The locations with time corrections (Fig. 10a and 10c) simulate the unrealizable case of perfect knowledge of the velocity structure. With both the L2-norm and EDT the location results show zero residuals, compact location  $pdf$ 's and a maximum likelihood hypocenter that necessarily matches exactly the corresponding ideal location. We note, however, that the L2-norm and EDT “ideal” locations differ slightly because they are derived from noisy, real data, and they use different likelihood functions.

The locations without time corrections (Fig. 10b and 10d) use the true observed data (i. e., travel times through the true Earth) and thus show the effect of an incorrect velocity model (i. e., the 1-D velocity model used

Earthquake Location, Direct, Global-Search Methods, Figure 10

**Example 8: Incorrect velocity model.** Locations using 50  $P$  arrivals with the L2-norm and a time corrections, **b** no time corrections, and with EDT and **c** time corrections, **d** no time corrections. The locations without the ideal time corrections show the effect of an incorrect velocity model. The Hypoellipse linearized locations and ellipsoids do not differ markedly from the direct-search locations shown in this figure

for location). This is shown by the pattern of positive and negative residuals obtained with both the L2-norm and EDT. The L2-norm location without time corrections has a balanced distribution of positive and negative residuals and, relative to the L2-norm location with corrections, a similar size location *pdf* and a biased maximum likelihood hypocenter. In contrast, the EDT location without corrections has more positive than negative residuals and, relative to the EDT location with corrections, a larger location *pdf* and nearly identical, unbiased maximum likelihood hypocenter. For these locations, a potential problem with the velocity model is indicated by the large residuals and *rms* values with both L2-norm and EDT, and, with EDT, by the asymmetry in residuals, the irregular *pdf* shape, and the large  $V_{pdf}$  and  $I_{ell}$  values, as with the outlier data example (Example 6).

In effect, locations with an incorrect velocity model and with outlier data are mathematically similar, though in the former case all or most residuals may be large while in the latter case only a few will be large. It is difficult to distinguish between the two cases with the L2-norm because this algorithm seeks to best satisfy *all* of the observations simultaneously (cf., Eq. (7)) by balancing the distribution of positive and negative residual (cf., Fig. 8b and Fig. 10b). Thus, relative to the residuals corresponding to the correct location, the L2-norm solution damps and hides larger residuals at the expense of increasing small residuals. In contrast, EDT seeks to best satisfy the *most* pairs of observations (cf., Eq. (8)) and imposes no inherent constraint on the distribution of residuals. Thus with EDT the difference in number, magnitude and distribution of large residuals – few and large for the outlier case, many of similar magnitude and spatially correlated for the incorrect velocity model case – allows one, in principle, to distinguish between the two cases (cf., Fig. 8d and Fig. 10d). In addition, the size and complexity of the location *pdf*'s generally increases more rapidly with EDT than with the L2-norm as the solution quality decreases. Thus, with both the outlier and incorrect velocity model cases, the location results with the EDT likelihood function are more informative than with the L2-norm. However, location with the EDT likelihood function can become unstable (e. g. define only a local maximum of the *pdf*) for cases where the outlier data or velocity model errors lead to extreme complexity in the topology of the EDT location *pdf*.

### Future Directions

There are various ways that direct, global-search location methodologies may evolve in the future. For example, the stability and completeness of the location and location *pdf*

could be improved with the use of more complete data uncertainties, expressed as a *pdf*. These *pdf*'s may typically be irregular and asymmetric, and difficult to determine and parametrize. Currently, enumerated quality indications or, at best, simple normal distributions (describing Gaussian uncertainty) are used to describe the picking error.

Similarly, we have shown that earthquake location depends inherently on the velocity model adopted, but that no realistic uncertainties are associated with this model. Differences between the velocity model and the true Earth can result in complicated differences in ray-paths and travel-times, which will depend strongly on the source and receiver positions. These complications, combined with the lack of knowledge about the true Earth, makes estimating true travel time uncertainties effectively impossible. However, it can be assumed that changes become progressively larger with increasing ray-path length. This effect could be accounted for approximately by travel-time uncertainties that increase with the ray-length or travel time. Instead of using a velocity model to generate travel times, another approach is to derive the required times from tables of empirically determined or corrected travel times (e. g. [41,43]). With this approach the travel-time uncertainties are estimated from timing information, with little or no direct use of velocity structures or ray paths.

We have described and illustrated the importance of the source-receiver geometry for locating earthquakes, notably with regards to constraining a compact and symmetric location *pdf*. Thus, improved constraint on event locations can be achieved through prior use of survey design techniques to select station sites. In a related manner, after an event occurs, these techniques could be employed dynamically to weight the available arrival times used for location with respect to the geometry of the available stations around the likely source region.

The demand for rapid, real-time location and earthquake early warning requires improvements in the integration, speed, quality and robustness of the phase arrival picking, phase association and event location procedures. Currently, development is progressing on integrated procedures which are evolutionary and probabilistic, using, for example, robust likelihood functions such as EDT and information from not-yet-triggered stations (e. g., [8,21,54,63,64]).

A current problem in direct-search location is how to describe in a standardized and compact way the sometimes topologically-complex location *pdf*. For example, such a description is needed if the *pdf* is to be included in standard earthquake catalogs and for rapid dissemination

of probabilistic location information for earthquake early-warning. More generally, making full use of the extensive information in direct-search location solutions will require new methods and procedures to store, distribute and analyze the location *pdf*, maximum likelihood hypocenter, arrival residuals and weights, and other statistics and quality indicators of the solutions.

The continuing increase in computer speed will allow application of direct-search inversion methods to relative location of ensembles of events and for joint epicentral determination in the near future. The use of these methods will be important to explore more completely the vast solution space and better determine the error and resolution for such high-dimensional inverse problems.

The continuing increase in computer speed will also make practical earthquake location techniques using waveform recordings directly, without the intermediate stage of extracting phase arrival times. In these techniques, continuous waveform data streams are matched to synthetic Green's functions within a global-search over possible source locations and source parameters. This type of approach is used to locate previously unidentified earthquakes using low amplitude surface waves on off-line, continuous, broadband waveforms [15,68], and for automatic, real-time estimation of moment tensors and location from continuous broadband data streams (e.g., [25]). Waveform methods will likely be applied to earthquake location on local and regional scales as faster computers and more accurate 3D velocity models become available [81]; related applications using simple ray or acoustic theories to generate the Green's functions show promising results (e.g., [3]).

### Glossary

Technical terms that are written in the text in italics are explained in the Glossary.

**Corner frequency** The frequency  $f_c$  at which the curve that represents the Fourier amplitude spectrum of a recorded seismic signal abruptly changes its slope (see Fig. 5). For earthquakes, this frequency is related to the fault size, rupture velocity, rupture duration and stress drop at the source. Also the frequency at which the magnification curve of a recording system (e.g., Fig. 3) changes its slope.

**Dispersion** Frequency-dependence of the wave propagation velocity. Whereas seismic body-waves show virtually no dispersion, it is pronounced for seismic surface waves. It causes a significant stretching of the length of the surface-wave record and the rather late arrival of its largest amplitudes (Airy phases) from which the surface-wave magnitude  $M_S$  and the mantle magnitude  $M_m$ , respectively, are determined.

**Earthquake size** A frequently used, but not uniquely defined term. It may be related – more or less directly – to either the geometric-kinematic size of an earthquake in terms of area and slip of the fault or to the *seismic energy* radiated from a seismic source and its potential to cause damage and casualty (moment or energy *magnitude*).

**Earthquake source** In general terms, the whole area or volume of an *earthquake* rupture where seismic body waves are generated and radiated outwards. More specifically, one speaks either of the *source mechanism*

or the source location. The latter is commonly given as earthquake hypocenter (i. e. the location at the source depth  $h$  from where the seismic rupture, collapse or explosion begins) or as the point on the Earth's surface vertically above the hypocenter, called the epicenter. Earthquakes at  $h < 70$  km are shallow, those at larger depth either intermediate (up to  $h = 300$  km) or deep earthquakes ( $h = 300$ – $700$  km). The determination of the geographical coordinates latitude  $\varphi$ , longitude  $\lambda$ , and focal depth  $h$ , is the prime task of seismic source location. However, for extended seismic sources, fault ruptures of great earthquakes in particular, the hypocenter is generally not the location of largest fault slip and/or seismic moment/energy release and the epicenter is then also not the location where the strongest ground shaking is felt. The locations of largest effects may be dozens of kilometers in space and many seconds to minutes in time away from the hypocenter or epicenter, respectively.

**Fundamental modes** The longest period oscillations of the whole Earth with periods of about 20 min (spheroidal mode), 44 min. (toroidal mode) and some 54 min (“rugby” mode), excited by great earthquakes.

**Magnitude** A number that characterizes the relative *earthquake size*. It is usually based on measurement of the maximum motion recorded by a seismograph (sometimes for waves of a particular type and frequency) and corrected for the decay of amplitudes with epicenter distance and source depth due to geometric spreading and attenuation during wave propagation. Several magnitude scales have been defined. Some of them show *saturation*. In contrast, the moment magnitude ( $M_w$ ), based on the concept of *seismic moment*, is uniformly applicable to all earthquake sizes but is more difficult to compute than the other types, similarly the energy magnitude,  $M_e$ , which is based on direct calculation of the *seismic energy*  $E_s$  from broadband seismic records.

**Saturation** (of magnitudes) Underestimation of *magnitude* when the duration of the earthquake rupture significantly exceeds the seismic wave period at which the magnitude is measured. The shorter this period, the earlier respective magnitudes will saturate (see relation (13) and Figs. 4 and 5).

**Seismic energy** Elastic energy  $E_s$  (in joule) generated by, and radiated from, a seismic source in the form of seismic waves. The amount of  $E_s$  is generally much smaller than the energy associated with the non-elastic deformation in the seismic source (see *seismic moment*  $M_o$ ). The ratio  $E_s/M_o = (\Delta\sigma/2\mu) = \tau_a/\mu$ , i. e., the seismic energy released per unit of  $M_o$ , varies for earthquakes

in a very wide range between some  $10^{-6}$  and  $10^{-3}$ , depending on the geologic-tectonic environment, type of *source mechanism* and related stress drop  $\Delta\sigma$  or apparent stress  $\tau_a$ .

**Seismic moment  $M_o$**  A special measure of earthquake size. The moment tensor of a shear rupture (see *earthquake source*) has two non-zero eigenvalues of the amount  $M_o = \mu \bar{D} F_a$  with  $\mu$ -shear modulus of the ruptured medium,  $\bar{D}$ -average source dislocation and  $F_a$ -area of the ruptured fault plane.  $M_o$  is called the scalar seismic moment. It has the dimension of Newton meter (Nm) and describes the total non-elastic (i. e., ruptural and plastic) deformation in the seismic source volume. Knowing  $M_o$ , the moment *magnitude*  $M_w$  can be determined via Eq. (11).

**Source mechanism** Depending on the orientation of the earthquake fault plane and slip direction in space, one discerns different source mechanisms. Strike-slip faults are vertical (or nearly vertical) fractures along which rock masses have mostly shifted horizontally. Dip-slip faults are inclined fractures. If the rock mass above an inclined fault moves down (due to lateral extension) the fault is termed normal, whereas, if the rock above the fault moves up (due to lateral compression), the fault is termed reverse (or thrust). Oblique-slip faults have significant components of both slip styles (i. e., strike-slip and dip-slip). The greatest earthquakes with the largest release of seismic moment and the greatest potential for generating tsunamis are thrust faults in subduction zones where two of Earth's lithosphere plates (e. g., ocean-continent or continent-continent) collide and one of the two plates is subducted underneath the overriding plate down into the Earth's mantle. Different source mechanisms are characterized by different radiation patterns of seismic wave energy.

**Transfer function** The transfer function of a seismic sensor-recorder system (or of the Earth medium through which seismic waves propagate) describes the frequency-dependent amplification, damping and phase distortion of seismic signals by a specific sensor-recorder (or medium). The modulus (absolute value) of the transfer function is termed the amplitude-frequency response or, in the case of seismographs, also magnification curve (see Fig. 3).

### Definition of the Subject

Besides earthquake location (i. e., the determination of the geographical coordinates of the epicenter, the hypocenter depth and the origin time; for definition of these terms see

*earthquake source* in the Glossary), the *magnitude* is the most frequently determined and commonly used parameter to characterize an earthquake. Despite its various imperfections, it provides important information concerning the earthquake source spectrum at the period where the magnitude is measured and current source theories (cf. [3]) allow one to understand differences in the source spectra of different earthquakes in terms of source dimension and stress drop, i. e., the difference between the stress level before and after the earthquake. Via various empirical relations, magnitudes enable estimates of the *seismic moment* and the *seismic energy* released by the earthquake. These parameters are important in the discussion of various global problems such as the seismic slip rates between lithosphere plates and the excitation of Chandler Wobble [25]. Besides these more academic issues, magnitude values have an immense practical value in providing:

- Rapid simple parameter estimates of the strength of an earthquake that can help to realistically assess the related ground shaking or tsunami potential and thus assist efficient disaster management response;
- Mass data in earthquake catalogs and data banks, covering long time periods over many decades – and hopefully centuries in future, which allows one to assess the seismic activity and related hazards of Earth's regions and their possible variability in space and time. This is not only of high scientific interest, but also the very basis for realistic long-term disaster preparedness and risk mitigation efforts.

The term magnitude and the basic method of its determination were introduced by Charles F. Richter in 1935 [71]. He intended to compare the relative *earthquake size* in southern California in terms of differences in the maximum amplitudes  $A$  recorded at a network of seismic stations that were equipped with standard short-period Wood-Anderson (WA) torsion seismometers.

The WA seismometer response is depicted in Fig. 3 and Fig. 1 shows a WA record and magnitude measurement example. In order to make amplitudes recorded by stations at different epicentral distances  $D$  from the earthquake comparable, Richter had to compensate for the amplitude decay with  $D$  using an appropriate correction term  $-A_0(D)$ . Since the strength and thus the radiated amplitudes of earthquakes vary in a wide range Richter defined his local magnitude scale  $M_L$ , determined from records at source distances up to 600 km, as follows:

*“The magnitude of any shock is taken as the logarithm of the maximum trace amplitude, expressed in microns, with which the standard short-period tor-*

Earthquake Magnitude, Figure 1

Record of a short-period Wood-Anderson seismograph (frequency-magnification curve see Fig. 3) of a local earthquake. *P* marks the onset of the first arriving longitudinal *P* wave, and *S* the onset of the much stronger secondary, transverse polarized shear wave. Note the long tail of coda-waves following *S*. From the time difference  $S - P = 24$  s follows a hypocentral distance  $R = 190$  km. The maximum record amplitude is  $A_{\max} = 23$  mm. Applying the amplitude-distance correction  $-\log A_o(190 \text{ km}) = 3.45$  according to Richter [72] results in a magnitude  $M_L = 4.8$

*sion seismometer ... would register that shock at an epicentral distance of 100 km."*

Thus:

$$M_L = \log A_{\max} - \log A_o(D). \quad (1)$$

According to the above definition, an amplitude of  $1 \mu\text{m}$  in a WA record at a distance  $D = 100$  km from the epicenter would correspond to  $M_L = 0$ . Amplitude means in (1) and the following text either the center-to-peak or half of the peak-to-trough amplitude.

Wood-Anderson (WA) seismographs record horizontal short-period ground motions with an amplification of only about 2080 times [82]. Modern electronic seismographs may achieve magnifications larger than  $10^6$  and thus are able to record local earthquakes with even negative magnitudes, down to about  $-2$ . The largest values determined with the  $M_L$  scale are around seven. Later it was found that all magnitudes derived from short-period waves (typically with periods  $T < 3$  s) show *saturation* (see Glossary, Fig. 4 and Sect. "Magnitude Saturation and Biases Due to Earthquake Complexity"). Therefore, it was necessary to develop complementary magnitude scales that use medium to long-period ( $T \approx 5$  s – 30 s) as well as very long-period waves ( $T \approx 50$  s – 3000 s) in order to enable less or non-saturating magnitude estimates (see Sect. "Introduction to Common Magnitude Scales: Potential and Limitations"). For the so far strongest instrumentally recorded earthquake (Chile 1960) a value of  $M = 9.5$  was determined that way. Accordingly, instrumental seismic monitoring currently covers the magnitude range of

about  $-2 \leq M < 10$ . This roughly corresponds to ruptures of some millimeters to more than 1000 km long. They radiate approximately the same amount of seismic wave energy  $E_s$  as well-contained underground explosions with yields ranging from a few milligrams ( $10^{-9}$  t) to several 10 to 100 Gt ( $1 \text{ Gt} = 10^9$  t) Trinitrotoluol (TNT) equivalent, thus covering about 20 orders in energy. Earthquakes with magnitudes around four may cause only minor local damage, those with magnitudes  $> 6$  heavy damage, and those with magnitudes  $> 7$  already widespread devastating damage. Shallow submarine earthquakes with magnitudes  $> 7$  may generate significant local tsunamis with damage potential to nearby shores whereas those with magnitudes  $> 8.5$  may stimulate ocean-wide tsunamis causing destruction and casualties even at shores thousands of kilometers away from such earthquakes.

In order to measure and classify *earthquake size* in the wide range of magnitudes from about  $-2$  to  $< 10$  and satisfy specific requirements in research and application which are based on magnitude data, it was indispensable to develop different magnitude scales that are complementary, but properly scaled to the original Richter  $M_L$ . Thus, there exists today a host of magnitude scales applicable in a wide range of source distances from less than 1 km up to more than 10,000 km. These scales, their specifics, potential and limitations are discussed in detail (with many reference given) in Chapter 3 of the IASPEI New Manual of Seismological Observatory Practice [6]. The early pioneers of magnitude scales, Beno Gutenberg and Charles Richter, had hoped that different magnitude scales could be cross-calibrated to yield a unique value for any given

earthquake (cf. [25,30]). In their joint book [29] “Seismicity of the Earth” (1954; first edition 1949) and later in Richter’s [72] famous text book “Elementary Seismology” as well as in Duda [22] only one magnitude value  $M$  was given per earthquake. However, this approach proved only partially realistic under certain conditions and within limited magnitude ranges because of the often significant differences in measurement procedures as well as period and bandwidth ranges used in later magnitudes scales. Decades later it took significant efforts (cf. [1,2,25]) to reconvert these  $M$  values, which turned out to be not even compatible (cf. [25]) into their original body or surface wave magnitudes in order to get values that agree with the original definition of these specific magnitude scales and can be compared with current data of the same type.

In general, such magnitude conversion relations strongly depend on initial data errors and the type of least-square regression procedure applied [11,14]. Moreover, the latter have often not been interpreted and used in a correct way. This may result in the case of noisy magnitude data for events at the upper and lower end of the investigated magnitude range, in conversion errors of more than 0.5 magnitude units (m.u.) with serious consequences on seismic hazard estimates based on such converted magnitudes (cf. [7,11,14,15]). Moreover, magnitude values determined within the *saturation* range of a given scale cannot reliably be converted via empirical regression relations into the equivalent magnitude values of another less or non-saturating magnitude scale (see Fig. 4 and [44]). Furthermore, some magnitudes relate best to the released *seismic energy* while others are scaled to the static *seismic moment*, i. e., they measure equally important but fundamentally different physical aspects of the source and the radiated seismic waves and may differ by sometimes more than 1 m.u. Thus there is no way to characterize *earthquake size* in all its different aspects by just a single magnitude value. Proper interpretation and use of different types of magnitude data, however, requires one to understand the physics behind such values and how these may be affected by the complexity and duration of the earthquake rupture process. Further, this necessitates one to discriminate unambiguously the different types of magnitude values by using a unique nomenclature and to assure that magnitude values published with a given nomenclature have been determined with an internationally agreed standard procedure. With this in mind, the most important magnitude scales and related problems are summarized in Sects. “**Introduction to Common Magnitude Scales: Potential and Limitations**” and “**Common Magnitude Estimates for the Sumatra 2004  $M_w$  9.3 Earthquake**”.

## Introduction to Common Magnitude Scales: Potential and Limitations

### Magnitude Scales Used in the Local and Regional Distance Range ( $D < 2000$ km)

The original Richter local magnitude scale for Southern California [71] has been further developed since its invention [38]. In its expanded form (with the nomenclature  $M_L$  common in the United States), the following relation now holds:

$$M_L = \log_{10}(A_{\max}) + 1.11 \log_{10} R + 0.00189 R - 2.09 \quad (2)$$

with  $R$  = distance from the station to the hypocenter in kilometers and  $A_{\max}$  = maximum trace amplitude in nanometers (instead of  $\mu\text{m}$  in a WA record). This amplitude is measured on the output from a horizontal-component seismograph that is filtered so that the response of the seismograph/filter system replicates that of a WA standard seismograph but with a static magnification of one. The underlying procedure of  $M_L$  determination according to relation (2) was adopted by the International Association of Seismology and Physics of the Earth’s Interior (IASPEI) in 2004 as the standard procedure for determining local magnitudes in the distance range up to typically less than 1000 km [42]. For earthquakes in the Earth’s crust of regions with attenuation properties that differ from those of coastal California, and for measuring  $M_L$  with vertical component seismographs, the standard equation takes the form:

$$M_L = \log_{10}(A_{\max}) + F(R) + G \quad (3)$$

where  $F(R)$  is an  $R$ -dependent calibration function and  $G$  a constant which have to compensate for different regional attenuation and/or for any systematic biases of amplitudes measured on vertical instead on horizontal seismographs. Examples of regional  $M_L$  calibration functions developed for different parts of the world have been compiled by Borrmann (Chap. 3, p. 26, and DS 3.1 in [6]).

A few decades ago, analog seismic records prevailed. They had a rather limited dynamic range of only some 40 dB. This caused record traces often to go off-scale when stronger seismic events were recorded at local or regional distances. Then  $A_{\max}$  could not be measured. Yet, it was found that the duration  $\mathbf{d}$  of the coda that follows  $A_{\max}$  with exponentially decaying amplitudes (see Fig. 1) increases with magnitude and distance  $D$ . On this basis, local duration magnitude formulas of the following general form

$$M_d = a + b \log \mathbf{d} + cD \quad (4)$$

have been developed with  $a$ ,  $b$  and  $c$  being coefficients to be determined locally. When using only recordings at distances  $D < 100$  km the distance term  $cD$  is not even needed. However, crustal structure, scattering and attenuation conditions vary from region to region. Moreover, the resulting specific equations will also depend on the chosen definition for  $\mathbf{d}$ , the local signal-to-noise (SNR) conditions and the sensor sensitivity at the considered seismic station(s) of a network. Therefore,  $M_d$  scales have to be determined locally for a given source-network configuration and scaled to the best available amplitude-based  $M_L$  scale.

Nowadays digital recorders with large usable dynamic range of about 140 dB are common. Thus even sensitive modern broadband seismographs remain on scale when recording local or regional earthquakes up to  $M \approx 7$ . This reduces the need for  $M_d$  scales. Moreover, the increasing availability of modern strong-motion (SM) recorders with comparably large dynamic range, which will not clip even in the case of very strong nearby earthquakes, have led to the development of (partially) frequency-dependent  $M_L^{SM}$  scales. They are usually based on the calculation of synthetic WA seismograph outputs from strong-motion accelerograms [35,54].

Also, amplitudes of short-period  $L_g$  waves with periods around 1 s are sometimes used to determine magnitudes, termed  $m_b(L_g)$ .  $L_g$  waves travel with group velocities of 3.6 to 3.2 km/s and arrive after the (secondary, shear) S wave onset (Fig. 1). They propagate well in continental platform areas. Recently, the IASPEI [42] adopted a measurement procedure for  $m_b(L_g)$  as international standard, which had been developed for eastern North America [62] with the aim to improve yield estimates of Nevada Test Site explosions. However, as for all other local or regional magnitude scales, the calibration term is strongly influenced by the local/regional geologic-tectonic conditions in the Earth's crust and requires a proper scaling to this standard, when applied to other areas than eastern North America.

Tsuboi developed for the Japan Meteorological Agency (JMA) in 1954 [79] a magnitude formula for shallow earthquakes (depth  $h < 60$  km) that have been recorded at epicentral distances  $D$  up to 2000 km:

$$M_{JMA} = \log_{10} A_{\max} + 1.73 \log_{10} D - 0.83. \quad (5)$$

$A_{\max}$  is the largest ground motion amplitude (in  $\mu\text{m}$ ) in the total event record of a seismograph with an eigenperiod of 5 s. If horizontal seismographs are used then  $A_{\max} = (A_{NS}^2 + A_{EW}^2)^{1/2}$  with  $A_{NS}$  and  $A_{EW}$  being half the maximum peak-to-trough amplitudes measured in the two horizontal components. This formula was devised to be equivalent to the medium to long-period Gutenberg–

Richter [29] magnitude  $M$ . Therefore,  $M_{JMA}$  agrees rather well with the seismic moment magnitude  $M_w$ . The average difference is less than 0.1 in the magnitude range between 4.5 and 7.5 but becomes  $> 0.5$  for  $M_w > 8.5$  (see Fig. 4). Katsumata [49,50] has later modified the  $M_{JMA}$  formula for earthquakes deeper than 60 km.

Another, more long-period regional moment magnitude scale, termed  $M_{wp}$ , has been developed in Japan as well [80]. It provides quick and less saturating magnitude estimates for tsunami early warning. Velocity-proportional records are twice integrated and approximately corrected for geometrical spreading and an average  $P$ -wave radiation pattern (see *source mechanism*) to obtain estimates of the scalar seismic moment  $M_o$  at each station. Usually the first maximum in the integrated displacement trace, called “moment history”  $M_o(t)$ , is assumed to represent  $M_o$ . From these  $M_o$  values moment magnitudes  $M_w$  are then calculated for each station according to Eq. (11) and averaged.  $M_{wp}$  results from adding an empirically derived correction of 0.2 m.u. to the averaged station  $M_w$  [80]. Finally, a magnitude-dependent correction is applied to  $M_{wp}$  [86] in order to get an even better estimate of the recognized “authoritative” Global Centroid Moment Tensor magnitude  $M_w$  (GCMT) which is calculated according to the Harvard procedure [23] and now published under [41].

The  $M_{wp}$  concept was originally developed for earthquakes at  $5^\circ \leq D^\circ \leq 15^\circ$ , but can be applied for  $M_w < 7.5$  (down to about  $M_w \approx 5$ ) even to shorter local distances as long as this distance is significantly larger than the rupture length. Later the  $M_{wp}$  procedure has been adopted for application to records of deep and teleseismic earthquakes as well [81].  $M_{wp}$  estimates are standard routine in Japan, at the Alaska and the Pacific Tsunami Warning Centers (ATWC and PTWC), and the National Earthquake Information Center (NEIC) of the United States Geological Survey (USGS). However, each of these centers use slightly different procedures. Values for most strong earthquakes are usually available some 10 to 15 min after the origin time (OT). On average  $M_{wp}$  data scale well with  $M_w$ . Exceptions, however, are extremely slow or very large complex earthquakes. Then  $M_{wp}$  is usually too small, up to about 1 m.u.

In recent years great attention is paid to the development of even more rapid earthquake early warning systems (EWS). They aim at event location and magnitude estimates from the very first few seconds of broadband acceleration, velocity or displacement records and within about 10 to 30 s after origin time (OT) of strong damaging earthquakes on land. These data are to be used for instantaneous public alarms and/or automatically triggered risk

mitigation actions after strong earthquakes with damage potential. The goal is to minimize the area of “blind zones” which are left without advanced warning before the arrival of the  $S$  waves which have usually the largest strong-motion amplitudes (see Fig. 1). This necessitates very dense and robust local seismic sensor networks within a few tens of kilometers from potentially strong earthquake sources. Such networks are at present available only in very few countries, e. g. in Japan, Taiwan, Turkey, and Italy.

Their principles of rapid magnitude estimates differ from those mentioned above and below and the data analysis from such systems is largely based on still much debated concepts such as the hypothesis of the deterministic nature of earthquake rupture [66,73]. Data presented in [66] seem to suggest that in the range  $3.0 < M$  (not specified)  $< 8.4$  the magnitude can be estimated with an average absolute deviation of 0.54 m.u. from the maximum period within the initial 4 s of the first arriving (primary, longitudinal)  $P$  wave when many low-pass filtered velocity records within 100 km from the epicenter are available. However, for  $M > 6$  the systematic increase of these greatly scattering periods becomes rather questionable. When analyzing waveforms of the Japanese Hinet seismic network [73], it could not be confirmed that such a dominant frequency scaling with magnitude exists. Also Kanamori [46], together with Nakamura [60,61], one of the fathers of this idea, expressed much more caution about the prospects of this method after he had run, together with Wu [89], an experiment with the Taiwan EWS. For each event they analyzed the first 3 s of at least eight  $P$ -wave records at epicentral distances  $< 30$  km. They knew that: “... the slip motion is in general complex and even a large event often begins with a small short-period motion, followed by a long-period motion. Consequently, it is important to define the average period during the first motion.” (termed  $\tau_c$  in [46,89]). However, after applying the  $\tau_c$  concept to the Taiwan EWS they concluded: “For EWS applications, if  $\tau_c < 1$  s, the event has already ended or is not likely to grow beyond  $M > 6$ . If  $\tau_c > 1$  s, it is likely to grow, but how large it will eventually become, cannot be determined. In this sense, the method provides a threshold warning”. Thus it seems that these new concepts work reasonably well only for earthquakes with  $M < 6.5$  and thus total rupture durations that are according to Eq. (13) on average not more than about 2–3 times the measurement time windows of 3 s or 4 s used in [46,66,89]. Nakamura and Saita [61] reported data from a much smaller set of events ( $N = 26$ ) recorded at local distances in the range  $4.6 < M < 6.9$ . We calculated the average absolute deviation of their rapid UrEDAS system magnitudes (0.47 m.u.) from the official magnitudes  $M_{JMA}$

published later by the Japan Meteorological Agency. This error decreases to 0.32 m.u. when only earthquakes with magnitudes up to  $M_{JMA} = 6.0$  are considered. This seems to support our assessment that the reliability of real-time EMS magnitudes decreases rapidly if the analyzed time window is much shorter than the rupture duration.

### Magnitude Scales Used in the Teleseismic Distance Range ( $D > 2000$ km)

Ten years after the introduction of the local magnitude  $M_L$ , Beno Gutenberg [26,27,28] extended the concept of magnitude determination to teleseismic distances larger than about 1000–2000 km. He used both records of seismic waves that propagate along the Earth’s surface (or near to it with a period-dependent penetration depth) and waves which travel through the Earth. Accordingly, the former are termed surface waves and the latter body waves. For the surface-wave magnitude Gutenberg [28] gave the following relation:

$$M_S = \log_{10} A_{Hmax} + 1.656 \log D^\circ + 1.818 \quad (6)$$

with  $A_{Hmax}$  = maximum “total” horizontal displacement amplitude of surface-waves in  $\mu\text{m}$  for periods around  $20 \pm 2$  s measured in the distance range  $15^\circ < D^\circ < 130^\circ$  ( $1^\circ = 111,195$  km).

While the original Richter  $M_L$  and Gutenberg  $M_S$  magnitudes were calculated from the maximum ground displacement amplitudes, Gutenberg [26,27,30] proposed to determine the body-wave magnitudes  $m_B$  from the relation:

$$m_B = \log_{10} (A/T)_{max} + Q(D^\circ, h), \quad (7)$$

i. e., by measuring the maximum ratio of ground displacement amplitude  $A$  (in  $\mu\text{m}$ ) divided by the related period  $T$  (in s).  $A/T$  is equivalent to measuring the maximum ground motion velocity  $A_{vmax}/2\pi$  which is proportional to the square root of seismic energy, i. e.  $\sqrt{E_s}$ . Thus the magnitude becomes a measure of the elastic kinetic wave energy radiated by an earthquake. Only in this way comparable magnitude data could be obtained for different types of body waves and measurements at different sites. Another great advantage of  $m_B$  is that it permits magnitude estimates also from intermediate and deep earthquake sources, which produce only weak or no surface waves at all. Empirical relationships permit estimating  $E_s$  (in units of Joule) from body-wave magnitude  $m_B$  [30]

$$\log_{10} E_s = 2.4 m_B - 1.2 \quad (8)$$

or surface-wave magnitude  $M_S$  [72]

$$\log_{10} E_s = 1.5 M_S + 4.8. \quad (9)$$

Earthquake Magnitude, Figure 2  
 Calibration values  $Q(D^\circ, h)$  for vertical (Z) component P-wave amplitudes depending on epicentral distance  $D^\circ = \Delta$  and source depth  $h$  as used in the calculation of body-wave magnitudes  $m_b$  and  $m_B$  according to Gutenberg and Richter, 1956 [30]

Accordingly, an increase by 1 m.u. in  $m_B$  and  $M_S$  corresponds to an increase of radiated seismic energy by about 250 and 30 times, respectively.

Revised empirical distance-depth corrections for the calibration of body-wave magnitudes, so-called Q-functions, were published in 1956 by Gutenberg and Richter [30]. They are given as separate tables and charts for the body-wave phases P, PP (a P wave reflected at the surface of the Earth about the half way between source and station) and S. They are still in use, especially  $Q_{PV}$  for calibrating amplitude measurements made on vertical component P-wave records (Fig. 2). However, for epicenter distances between 5° and 20° these calibration values are not reliable enough for global application. In this range the wave propagation is strongly affected by regional variations of the structure and properties of the Earth’s crust and upper mantle. And for  $D > 100^\circ$  the P-wave amplitudes decay rapidly because of the propagation of P waves is influenced by the Earth’s core (so-called core shadow). Therefore, in agreement with current IASPEI recommendations [42],  $m_B$  and its short-period complement  $m_b$  (see below), should be determined by using  $Q_{PV}$  only between  $21^\circ \leq D \leq 100^\circ$ .

These body-wave magnitude calibration functions had been derived from amplitude measurements made mostly on medium-period broadband displacement records which dominated during the first half of the 20th Century at seismological stations. Their period-dependent magnification curve resembled more or less that of the classical standard seismograph type C shown in Fig. 3, although for some of these instruments the roll-off of the amplification occurred already at periods  $T > 10$  s.

Another, so-called Prague–Moscow formula for surface-wave magnitudes was proposed in 1962 by Vaněk et al. [84]. It is based on the measurement of  $(A/T)_{\max}$  in records of shallow earthquakes ( $h < 60$  km) in wide period and distance ranges ( $3 \text{ s} < T < 30 \text{ s}$ ;  $2^\circ \leq D^\circ \leq 160^\circ$ ):

$$M_S = \log_{10}(A/T)_{\max} + 1.66 \log_{10} D^\circ + 3.3 . \quad (10)$$

This relationship, which is – as Eq. (7) – more directly related to  $E_s$ , was adopted by the IASPEI in 1967 as international standard.

The NEIC adopted Eq. (10), but continues to limit the range of application to distances between  $20^\circ \leq D^\circ \leq$

$160^\circ$  and displacement amplitudes in the very limited period range as in formula (6) although Soloviev [74] had shown already in 1955 that  $(A/T)_{\max}$  is a stable quantitative feature of surface waves whatever the period of their maximum at all epicentral distances. Also theory has confirmed [63] that using the ratio  $(A/T)$  is a partial and ad hoc compensation for a large number of frequency-dependent terms ignored in (10). In fact, the periods at the surface-wave maximum used for  $M_S$  determination vary in a wide range between some 3 s and 25 s and show – despite large scatter – a clear distance dependence [84,87]. Therefore, several authors [36,70] showed that using Eq. (10) only for amplitude readings around 20 s results in systematic distance-dependent biases. However, their proposed revised calibration functions for 20 s waves are not yet used in routine practice at international seismological data centers.

The formulas (6) and (10) had originally been developed for horizontal component amplitude readings. Be-

Earthquake Magnitude, Figure 4

**Average relationships between different common types of magnitudes and the moment magnitude  $M_w$ .** Modified from Fig. 1 in [83]

ginning in the 1960s, however, more and more long-period and broadband vertical component instruments became available and are now commonly used for magnitude determination from surface waves. This procedure is easier and better defined than measuring and combining the amplitude measurements made in two horizontal components, yields on average values that are largely comparable with the Gutenberg  $M_S$  [25] and has recently been adopted as IASPEI [42] standard. Herak et al. [37] published theoretical and observed depth corrections for  $M_S(20)$  when determined according to (10). These corrections allow determination of more reliable surface-wave magnitudes for earthquakes in all depth ranges and improve significantly the relationship between  $M_S$  and the seismic moment  $M_0$ .

In the 1960s, the United States deployed a World-Wide Standard Seismograph Network (WWSSN) equipped with short-period (SP) and long-period (LP) seismographs of limited bandwidth (cf. Fig. 3). This network had two priority tasks. Firstly, to significantly increase the signal-to-noise ratio of the seismic records by narrow-band short-period filtering, thus improving the global detection threshold for teleseismic events down to magnitudes around 4–4.5 and the location accuracy for seismic events. Secondly, to realize an effective discriminator between underground nuclear explosions (UNE) and natural earthquakes based on the ratio of a short-period body-wave and a long-period surface-wave magnitude. Natural earthquakes have a much longer source duration (seconds to minutes) than explosions of comparable size (typically milliseconds). Also, at comparable seismic moment magnitude, UNEs radiate significantly more high-frequency energy (see dotted curve in Fig. 5) than earthquakes. Therefore, a better discrimination of the two types of events was

achieved by measuring the  $P$ -wave amplitude only at periods  $< 3$  s (typically around 1 s) and calculating a short-period  $P$ -wave magnitude termed  $m_b$ . In contrast, the Gutenberg  $m_B$  is based on measuring  $A_{\max}$  at periods  $T$  usually between 2 s and 30 s. Further, during the first two decades of the WWSSN, the  $P$ -wave amplitude was not – as required by Gutenberg’s procedure for  $m_B$  determination – always measured at the maximum of the whole  $P$ -wave train (whose length depends on the source duration and thus on the magnitude itself) but initially within the first five half-cycles only and later by USGS requirement in the first 5 s of the record.

Because of the short source duration of explosions, their  $P$ -waves will always reach maximum amplitudes within such a short time-interval. However,  $P$  waves radiated by large earthquakes of much longer source duration will reach their maximum amplitude usually much later in the rupture process. For magnitude 6 the average rupture duration is on average already 6 s, and may increase to about 600 s for the strongest earthquakes (cf. relation (13)). Both effects together, plus the fact, that  $m_b$  was still computed using the  $Q_{PV}$  function derived for mainly medium-period  $P$  waves, which are much less affected by frequency-dependent attenuation than 1 Hz  $P$  waves, resulted in a systematic underestimation of the earthquake size for magnitudes larger than 5 and a *saturation* of  $m_b$  at around 6.5.

In the late 1970s, the NEIC switched back to a longer time window of about 15 s and more recently, with an automatic procedure, to a window covering the first 10 cycles of short-period teleseismic  $P$  waves. In the case of strong earthquakes this window may later be extended interactively up to 60 s. This mitigates to some extent the saturation of  $m_b$ . However, no  $m_b$ -values larger than 7.2 have ever been measured with this procedure. On the other hand  $m_b$  yields rather reliable values for magnitudes  $< 5$  when the corner frequency of the average source spectra falls within the passband of the short-period seismograph or is even more high frequency (cf. Figs. 3, 4, 5). For magnitudes  $< 5$   $m_B$  can usually no longer be determined because of too small signal-to-noise ratio (SNR) in broadband records. Then  $m_b$  is often the only available teleseismic estimator of earthquake size for small earthquakes.

Most seismic stations and networks worldwide adopted the US procedure for  $m_b$  measurement and – with the exception of Russia, China and their former allies – completely abandoned measuring  $m_B$  as originally defined. This change in attitude was stimulated by the fact that the NEIC, which serves in fact as one of the leading international data centers for seismology, did not accept reported  $P$ -wave amplitudes other than those obtained

from short-period measurements. Some stations, national and global data centers continue (at least up to 2008) to measure for  $m_b$  the maximum amplitude of  $P$  exclusively within the first 5 s after the  $P$ -wave *first arrival*, such as the China Earthquake Network Center and the International Data Center (IDC) of the Comprehensive Test-Ban Treaty Organization (CTBTO) in Vienna.

Because of these inconsistencies in  $m_b$  and  $M_S$  determination and the proven merits of both broadband  $m_B$  and  $M_S$  (see also [11]) the IASPEI Working Group on Magnitude Measurements recommended that in future:

- $m_b$  is always determined from  $A_{\max}$  at periods  $T < 3$  s within the whole  $P$ -wave train;
- The band-limited magnitudes  $m_b$  and  $M_S(20)$  be complemented by true broadband magnitudes  $m_B$  and  $M_S(BB)$ . The latter two will be obtained by measuring  $A_{v\max}$  on unfiltered velocity broadband records and thus always include the maximum velocity amplitudes of the source spectrum in the magnitude range of interest (cf. Fig. 5). This will link these two broadband magnitudes to the seismic energy released by an earthquake, more closely than the common band-limited magnitudes.

These recommendations have been adopted by the IASPEI Commission on Seismic Observation and Interpretation (CoSOI) in 2005 as new magnitude measurement standards. More details about the new measurement procedures for  $m_b$ ,  $m_B$ ,  $M_S(20)$  and  $M_S(BB)$  are given on the CoSOI web site [42]. Beginning in 2007 they are gradually implemented at the main seismological data centers and networks.

Since all magnitudes discussed so far show more or less pronounced *saturation* for large earthquakes (cf. Fig. 4 and [44]) a non-saturating magnitude, termed  $M_w$ , has been proposed [31,43,69]. The moment magnitude  $M_w$  is derived from the scalar *seismic moment*  $M_o$  via the relation

$$M_w = (2/3)(\log_{10} M_o - 9.1). \quad (11)$$

$M_o$  has the dimension of Newton meter (Nm) and expresses the total inelastic “work” required for rupturing and displacing the considered earthquake fault. It can be determined either by waveform analysis and inversion in the time domain or by measuring the spectral amplitude  $u_{0p,s}$  of the low-frequency level (plateau) of the displacement spectrum of  $P$  or  $S$  waves (cf. Fig. 5) via the relationship

$$M_o = 4\pi r \rho v_{p,s}^3 u_{0p,s} / R_{\theta,\phi}^{p,s} \quad (12)$$

with  $r$  = hypocenter distance,  $\rho$  = average density of rocks in the source and receiver area,  $v_{p,s}$  = average velocity of the  $P$  or  $S$  waves from the source to the receiver area and  $R_{\theta,\phi}^{p,s}$  = a factor correcting the observed seismic amplitudes for the influence of the radiation pattern of the given *source mechanism*, which is different for  $P$  and  $S$  waves.

$M_0$  is expected to show no *saturation*, provided that the amplitude level is measured only at periods significantly larger than the magnitude-dependent *corner period* of the seismic source spectrum (cf. Fig. 5). In Sects. “**Common Magnitude Estimates for the Sumatra 2004  $M_w$  9.3 Earthquake**” and “**Magnitude Saturation and Biases Due to Earthquake Complexity**” we will show, however, that incorrect determination of  $M_0$  may still result in an underestimation of the earthquake size. Since  $M_w$  is derived from  $M_0$  it is related to the tectonic effect of earthquakes, i. e., to the product of rupture area and average fault slip and thus also relevant to assess the tsunami potential of strong shallow marine earthquakes. An example is the off-shore Nicaragua earthquake of 2 September 1992. Its  $m_b = 5.3$  was too weak to alert the people ashore, some 70–120 km away from the source area. However, its  $M_w = 7.6$  was much larger and caused a damaging local tsunami with almost 200 casualties.

Yet,  $M_0$  and thus  $M_w$  do not carry any direct information about the dominant frequency content and thus of the seismic energy released by the earthquake (cf. Sect. “**Magnitude Saturation and Biases Due to Earthquake Complexity**”). In fact, relation (11) was derived by assuming constant stress drop and an average ratio of  $E_s/M_0 = 5 \times 10^{-5}$  on the basis of elastostatic considerations and empirical data [43] and then replacing in Eq. (9)  $M_S$  by  $M_w$ .

As source theory has advanced and broadband digital data have become readily available, the radiated *seismic energy*  $E_s$  could be computed explicitly rather than from an empirical formula. Boatwright and Choy (cf. [5,16]) developed such an algorithm for computing  $E_s$  as well as a related energy magnitude  $M_e$  which agrees with  $M_w$  for  $E_s/M_0 = 2 \times 10^{-5}$ .  $E_s$  is computed by integrating squared velocity-proportional broadband records over the duration of the  $P$ -wave train, corrected for effects of geometrical spreading, frequency-dependent attenuation during wave propagation and source radiation pattern. According to [16], the radiated seismic energy may vary for a given seismic moment by two to three orders of magnitude. Further, it was found that a list of the largest events is dominated by earthquakes with thrust mechanisms when size is ranked by moment, but dominated by strike-slip earthquakes when ranked by radiated seismic energy. Choy and Kirby [18] gave a striking example for differences between

$M_e$  and  $M_w$  for two Chile earthquakes in 1997 which occurred in the same area but with different *source mechanisms*. One was interplate-thrust with  $M_w = 6.9$  and relatively low  $M_e = 6.1$ , whereas the other was intraslab-normal with  $M_w = 7.1$  and rather large  $M_e = 7.6$ . The first earthquake had a low potential to cause shaking damage and was felt only weakly in a few towns. In contrast, the second one caused widespread damage, land- and rock-slides, killed 300 people and injured 5000. Thus,  $M_w$ , although it theoretically does not saturate, may strongly underestimate or overestimate the size of an earthquake in terms of its potential to cause damage and casualties. Shaking damage is mainly controlled by the relative amount of released high-frequency energy at  $f > 0.1$  Hz which is better measured by  $M_e$ .

The quantity  $\tau_a = \mu E_s/M_0$  is termed apparent stress [90]. It represents the dynamic component of stress acting on the fault during slip, which is responsible for the generation of radiated kinetic seismic wave energy  $E_s$ . On average it holds that  $\tau_a \approx 2\Delta\sigma$  (with  $\Delta\sigma$  = stress drop = difference between the stress in the source area before and after the earthquake rupture). Both  $\tau_a$  and  $\Delta\sigma$  depend strongly on the seismotectonic environment, i. e., the geologic-tectonic conditions, fault maturity and type of earthquake *source mechanisms* prevailing in seismically active regions [16,17,18,19]. However,  $M_e \approx M_w$  holds only for  $\tau_a \approx 0.6$  MPa.

Another important teleseismic magnitude is called mantle magnitude  $M_m$ . It uses surface waves with periods between about 60 s and 410 s that penetrate into the Earth’s mantle. The concept has been introduced by Brune and Engen [13] and further developed by Okal and Talandier [64,65].  $M_m$  is firmly related to the seismic moment  $M_0$ . Best results are achieved for  $M_w > 6$  at distances  $> 15\text{--}20^\circ$  although the  $M_m$  procedure has been tested down to distances of  $1.5^\circ$  [77]. However, at  $D < 3^\circ$  the seismic sensors may be saturated in the case of big events. Also, at short distances one may not record the very long periods required for unsaturated magnitude estimates of very strong earthquakes, and for  $M_w < 6$ , the records may become too noisy at very long-periods. A signal-to-noise ratio larger than 3 is recommended for reliable magnitude estimates.  $M_m$  determinations have been automated at the PTWC and the CPPT [39,85] so that estimates are available in near real-time within about 10 min after OT from near stations, however typically within about half an hour, plus another few minutes for great earthquakes measured at the longest periods. Since  $M_m$  is determined at variable very long periods this magnitude does not – or only marginally – saturate even for very great, slow or complex earthquakes.

### Common Magnitude Estimates for the Sumatra 2004 $M_w$ 9.3 Earthquake

On 26 December 2004, the great Sumatra–Andaman Island earthquake with a rupture length of more than 1000 km occurred. It caused extensive damage in Northern Sumatra due to strong earthquake shaking. Moreover, it generated an Indian Ocean-wide tsunami with maximum run-up heights of more than 10 m. In total, this event claimed more than 200,000 victims and caused widespread damage on the shores of Sumatra, Thailand, India and Sri Lanka that were reached by the tsunami wave within some 15 min to about two hour’s time. This earthquake put the current procedures for magnitude determination to a hard test both in terms of the reliability and compatibility of calculated values and the timeliness of their availability to guide early warning and disaster management activities. Here we address only seismological aspects, not the additional major problems of inadequate global monitoring and insufficient regional communication and disaster response infrastructure. The earliest magnitudes reported by or made available to the Pacific Tsunami Warning Center (PTWC) were:

- $m_b > 7$ , about 8 min after origin time (OT);
- $M_{wp} = 8.0$ , available after some 12 minutes at the PTWC (including a magnitude-dependent correction [86]);
- somewhat later in Japan  $M_{wp} = 8.2$  after magnitude-dependent correction [48];
- $M_m \geq 8.5$  at the PTWC about 45 min after OT, hours later upgraded to  $M_m = 8.9$  by using mantle surface waves with longer periods ( $T \approx 410$  s);
- a first surface-wave magnitude estimate  $M_S = 8.5$ , some 65 min after OT;
- $M_w = 8.9$  (later revised to 9.0) released by Harvard Seismology more than 6 h after OT.

Other available measurements were:  $m_b = 5.7$  and  $M_S = 8.3$  by the IDC of the CTBTO,  $m_b = 7.0$ ,  $M_S = 8.8$ ,  $M_e = 8.5$  and another long-period  $P$ -wave based  $M_w = 8.2$  by the NEIC. All these values were too small and mostly available only after several hours or days (e. g., IDC data). Weeks later, after the analysis of Earth’s *fundamental modes* with periods up to 54 min and wavelength of several 1000 km, the now generally accepted value  $M_w = 9.3$  was published [76]. Why were the other magnitude values all too low and/or too late?:

- $m_b$  NEIC suffers from the combined effect of both spectral and time-window dependent saturation that we will discuss in more detail in Sect. “Magnitude Saturation and Biases Due to Earthquake Complexity”;

- $m_b$  IDC is even more affected by these saturation effects, because of the very short measurement time window of only 5 s after the first  $P$ -wave onset. In the case of the Sumatra 2004 earthquake, the first  $P$ -wave maximum occurred after some 80 s and another, with comparable amplitude, after about 330 s (cf. Fig. 8). Further, prior to  $m_b$  measurement, the IDC broadband data are filtered with a more narrow-band response peaked at even higher frequencies (3–4 Hz) than at NEIC ( $\approx 2.5$  Hz) [11];
- The reported surface-wave magnitudes ranged between  $M_S = 8.3$  (IDC), 8.8 (NEIC and Japan Meteorological Agency) and 8.9 (Beijing), i. e., some of them are close to the moment magnitudes. However, because of the late arrival of long-period teleseismic surface waves, good estimates are usually not available within 1–2 h after OT. This leaves a sufficient tsunami warning lead time only for shores more than 1000–2000 km away from the source.
- The NEIC  $P$ -wave moment magnitude  $M_w = 8.2$  was too small because its procedure is, similar as for  $M_{wp}$  determinations, based on relatively short-period (typically  $T < 25$  s)  $P$ -wave recordings and a single-source model (cf. Sect. “Magnitude Saturation and Biases Due to Earthquake Complexity”).
- The preliminary  $M_e = 8.5$ , computed a few hours after the December 2004 earthquake agreed with the final  $M_e$  computed later using a more robust method [20]. Another algorithm simulating a near-real-time computation would have yielded  $M_e = 8.3$ . Yet  $M_e$ , by its very nature as an energy magnitude and because of the relation  $E_s = \Delta\sigma/2\mu M_e$ , will generally be smaller than  $M_w$  for slow, long duration earthquakes with low stress drop. This is often the case for shallow thrust earthquakes in subduction zones. Extreme examples are four well-known slow tsunami earthquakes of 1992 (Nicaragua;  $M_w = 7.6$ ,  $\Delta M_e = -0.9$ ), 1994 (Java;  $M_w = 7.8$ ,  $\Delta M_e = -1.3$ ), 2000 (New Britain Region;  $\Delta M_w = 7.8$ ,  $\Delta M_e = -1.0$ ) and 2006 (Java;  $M_w = 7.7$ ,  $\Delta M_e = -0.9$ ) [40].

### Magnitude Saturation and Biases Due to Earthquake Complexity

Currently, the most common magnitude scales, especially those based on band-limited short-period data, still suffer *saturation*, e. g., the magnitudes  $m_b$ ,  $M_L$ ,  $m_B$  and  $M_S$ , which are typically measured at periods around 1 s, 2 s, 5–15 s and 20 s, respectively begin to saturate for moment magnitudes  $M_w$  larger than about 5.5, 6.5, 7.5 and 8.0. Earthquakes with  $m_b > 6.5$ ,  $M_L > 7.0$ ,  $m_B > 8.0$  and

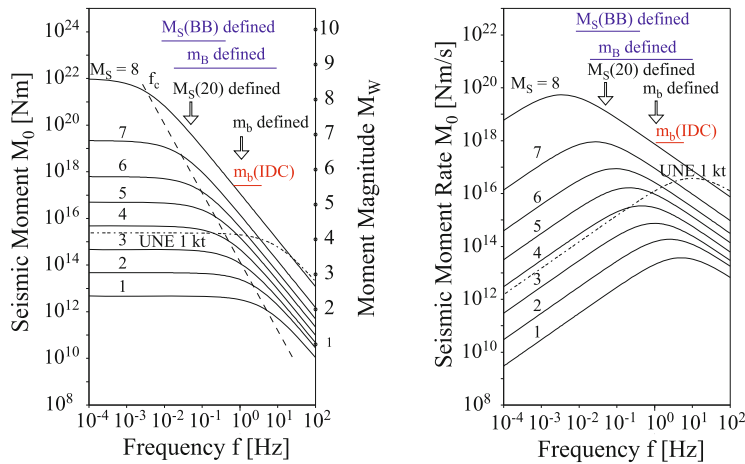

$M_S > 8.5$  are rare been found due to saturation (cf. Fig. 4 and [44]). Magnitude saturation has two causes: spectral saturation and saturation due to insufficient time-window length for the amplitude measurements. Source complexity may cause additional biases between different magnitude scales.

**Spectral Saturation of Magnitudes**

Spectral saturation occurs when the magnitude-dependent *corner frequency*  $f_c$  (for energy-related magnitudes) or the low-frequency plateau of displacement amplitudes (for moment magnitude) fall outside of the passband range of the seismographs *transfer function* or magnification curve (Fig. 3) of the recording seismograph or of the filter applied to broadband data before magnitude measurements are made. The reason for spectral saturation can best be explained by way of idealized average “source spectra” of ground displacement  $u(f)$  and ground velocity  $v(f)$  that have been corrected for the instrument response, for the decay of the wave amplitudes due to attenuation that is caused by internal friction and scattering of the seismic

waves at heterogeneities of the Earth and for amplification effects at the surface of the receiver site. For better understanding such source spectra have been multiplied in Fig. 5 by the factor  $4\pi r \rho v_{p,s}^3 / R_{\theta,\phi}^{p,s}$  given in Eq. (12) in order to get for the displacement amplitudes  $u_0 = \text{constant}$  at  $f < f_c$  the related scalar seismic moment  $M_0$  (Fig. 5, left) and its time-derivative, the so-called moment rate (Fig. 5, right).

The shape of the source spectrum can be interpreted as follows: The critical wavelength, which corresponds to  $f_c$ , is  $\lambda_c = v_{p,s} / f_c = c_{m1} \pi R = c_{m2} (L \times W)^{1/2}$  with  $v_{p,s}$  - velocity of the P or S waves in the source region, depending on whether  $f_c$  relates to a P-wave or an S-wave spectrum, R-radius of a circular fault rupture model, L- length and W- width of a rectangular fault rupture model;  $c_{m1}$  and  $c_{m2}$  are model dependent constants. For very long fault ruptures, i. e.,  $L \gg W$ , one can even write  $\lambda_c = c_{m3} L$ . Thus,  $\lambda_c$  is proportional to the linear dimension of the fault. For  $f < f_c$ ,  $\lambda_c$  becomes larger than the fault. Rupture details along the fault can then no longer be resolved and the fault is “seen” by these long wavelengths just as a point source. Therefore, all frequencies  $f < f_c$  have the

Earthquake Magnitude, Figure 5

“Source spectra” of ground displacement (left) and velocity (right) for an average single rupture seismic shear source, scaled on the left ordinates to seismic moment  $M_0$  (left diagram) and moment rate (right diagram), respectively. The black spectral lines have been scaled according to Aki [3] to integer surface-wave magnitudes  $M_S$  between 1 and 8. For reference the respective integer moment magnitude values  $M_w$  between 1 and 10, calculated according to Eq. (11), have been marked with equidistant dots on the right-side ordinate of the left diagram. The broken line shows the increase of the corner frequency  $f_c$  with decreasing seismic moment of the event, the dotted curve gives the approximate “source spectrum” for a well contained underground nuclear explosion (UNE) of an equivalent yield of 1 kt TNT. Note the plateau in the displacement spectrum towards low frequencies (corresponding to  $u_0 = \text{constant}$  for  $f < f_c$ ), from which  $M_0$  is determined according to Eq. (11) when using the frequency-domain approach. For  $f > f_c$  the amplitudes decay  $\sim f^{-2}$ . The open arrows point to the center frequencies on the abscissa at which the 1 Hz body-wave magnitude  $m_b$  and the 20 s surface-wave magnitude  $M_S(20)$ , respectively, are determined and the blue horizontal interval bars mark the range of frequencies within which the maximum P-wave and Rayleigh-wave amplitudes for  $m_b$  and  $M_S(BB)$  should be measured according to the new IASPEI standards [37]. In contrast, the red bar marks the frequency range of maximum velocity-proportional magnification of the bandpass filter between 1 Hz and 4 Hz which is used for  $m_b$  determination at the IDC.

same displacement amplitudes. Accordingly,  $M_0$ , which is proportional to the fault area and the average slip over the fault, has to be determined either in the spectral domain from the low-frequency asymptote  $u_0$  to the displacement spectrum or in the time domain by fitting synthetic long-period waves with  $f < f_c$  to observed ones that have been low-pass filtered in the same frequency range.

For radiated frequencies  $f > f_c$  with  $\lambda < \lambda_c$ , the shape of the spectrum changes drastically. Related displacement amplitudes are then excited by successively smaller patches of the rupture plane. The area of the rupture elements decreases with the second order of their linear dimension. Accordingly, the generated displacement amplitudes are  $A_d \sim f^{-2}$ , while the related velocity amplitudes  $A_v = A_d 2\pi f$  decay only  $\sim f^{-1}$ . In the seismological literature this is usually called the  $\omega^{-2}$  rupture model [3], based on the concept of similarity, which implies a constant stress drop independent of source size. More complicated rupture models yield a high-frequency amplitude decay  $\sim \omega^{-3}$  [33,34] and even more rapid decays have sometimes been found in empirical data (up to 5th order). Steeper than  $\omega^{-2}$  amplitude decay would further amplify the spectral saturation of magnitude data discussed below.

The Harvard standard procedure for  $M_0$  determination assumes a single point source model with a prescribed, triangular moment-rate function in the time domain (as an approximation to moment-rate curves such the ones shown in Fig. 7) as well a minimum period of 200 s for strong earthquakes with magnitudes  $> 8$ . Assuming an average rupture velocity of 2.5 km/s, this period would correspond to a wavelength of 500 km. This is much shorter than the total rupture length of more than 1100 km for the great Sumatra 2004 earthquake and explains why  $M_w(\text{HRV}) = 9.0$  was smaller than the moment magnitude  $M_w = 9.3$  determined by using fundamental Earth's modes with periods of 1000 s and more [76].

The relationship between the two currently most common magnitudes,  $m_b$  and  $M_S(20)$ , can be understood with reference to Fig. 5.  $m_b$  is measured in the period range  $0.5 < T < 3$  s, typically around 1 s. This corresponds approximately to the *corner frequencies* of earthquakes with  $M_S \approx 3$  to 4.5. According to Utsu [83] this is equivalent to an  $m_b$  between about 3.5 and 5.0. For  $M_S < 4.5$  or  $m_b < 5$ ,  $m_b$  is thus likely to be determined from amplitude measurements near or below the *corner frequency* of the source spectrum. In that case  $m_b$  is a good measure of seismic moment. However, for larger magnitudes  $m_b$  samples spectral amplitudes well above  $f_c$ , resulting in systematically too small  $m_b$  values as compared to  $M_S$  and  $M_w$ . For great earthquakes this difference may reach 2 m.u. (Fig. 4).

In contrast,  $M_S(20)$  is measured at periods around 20 s and thus saturates much later at values between about 8.5 to 9.

However, these arguments only hold on average. The stress drop  $\Delta\sigma$  of individual events may vary by about 2 to 3 orders, as apparent stress  $\tau_a$ , especially for earthquakes with  $M_w < 7.5$  [16,17]. According to the relation  $M_0 = (16/7)\Delta\sigma R^3$  given by Keilis-Borok [52] this may change source radii  $R$  and associated  $f_c$  by about one order. As an example, the dotted curve in Fig. 5 shows the approximate seismic source spectrum for a well contained underground nuclear explosion (UNE) of an equivalent yield of 1 kt TNT which corresponds to a magnitude  $m_b \approx 4$ . Its source volume is much smaller than that of an earthquake with same seismic moment. Hence the *corner frequency* of its source spectrum is not around 1 Hz but around 10 Hz. This is the reason why  $m_b$  determined from UNE records does not saturate, even for the strongest UNE ever tested with  $m_b \approx 7$ . Moreover, Fig. 5 also illustrates that an earthquake and an UNE with seismic moment around  $4 \times 10^{15}$  Nm and  $M_w \approx 4$  have different maximum seismic moment-rate release at about  $4 \times 10^{15}$  and  $4 \times 10^{16}$  Nm/s, respectively. The latter corresponds to 100 times higher seismic energy release or to an energy magnitude  $M_e$  that is 1.3 m.u. larger. Large differences have also been observed amongst earthquakes, e. g., the Balleny Island earthquake of 25.03.1998 had  $M_w(\text{HRV}) = 8.1$  and  $M_e(\text{NEIC}) = 8.8$ . The opposite will happen in the case of low stress drop earthquakes propagating with very low rupture velocity [38]. The Java tsunami earthquake of 17 July 2006 was a striking example with  $M_e = 6.8$ ,  $m_B = 7.0$  and  $M_w = 7.7$ .

Similar observations had already been made in the 1970s when comparing  $m_b$  and  $M_S$  values of identical events. This prompted the Russian scientist Prozorov to propose a “creepex” parameter  $c = M_S - a \times m_b$  (with  $a = \text{constant}$  to be determined empirically for different source types and stress drop conditions). It aims at discriminating between normal, very slow (creeping) and explosion-like (fast rupture, high stress drop) earthquakes. World-wide determination of this parameter for earthquakes in different regions revealed interesting relations of  $c$  to source-geometry and tectonic origin [51]. Similar systematic regional differences were also reported for  $M_S - M_w$  [24,67] and  $M_e - M_w$  [16,19], suggesting systematic regional differences in stress drop.

### Magnitude Saturation Due to Insufficient Time-Window Length for Amplitude Measurement

The second reason for magnitude saturation is insufficient time-window length for measuring  $(A/T)_{\text{max}}$  in seismic

records. It is most relevant when determining body-wave magnitudes, but it has been a subject of controversy, misconceptions and disregard of earlier recommendations for decades. The reason is that in teleseismic seismograms the  $P$ -wave group does not always appear sufficiently well separated in time from later phase arrivals such as the depth phases  $pP$  and  $sP$ . These do not directly travel from the seismic source at depth  $h$  to the recording station but travel first to the Earth's surface above the source and from there, after reflection or conversion from  $S$  to  $P$ , propagate back into the Earth. Depending on  $h$ , which may vary from a few kilometers up to 700 km, and the type of depth phase recorded, they may arrive from a few seconds up to about 4.5 min after the onset of direct  $P$ . Depending on the radiation pattern of the *source mechanism*, some stations may even record the depth phases with larger amplitudes than the direct  $P$  wave. This is one of the concerns that led many researchers to propose measuring the  $P$ -wave amplitudes for magnitude measurements within a short time window after the  $P$  onset. On average, however, the depth phases have smaller amplitudes than  $P$  and will not bias  $m_b$  estimates at all. If, however, a seismic station is situated near to the nodal line of the so-called focal sphere, corresponding to strongly reduced  $P$ -wave radiation in these directions, the amplitude of the depth phase is a better estimator for the body-wave energy radiated by this seismic source and thus of its corresponding magnitude.

Two or three more phases of longitudinal waves may arrive close to the direct  $P$  at teleseismic distances between  $20^\circ$  and  $100^\circ$ . These include  $PcP$ , which results from  $P$ -wave energy reflected back from the surface of the Earth's core at 2900 km depth, and the phases  $PP$  and  $PPP$ , which are  $P$  waves that have been reflected back from the Earth's surface once at half-way or twice at 1/3- and 2/3-way between the seismic source and the recording station, respectively. However, in short-period records the amplitudes of  $PP$  and  $PPP$  are generally smaller and those of  $PcP$  even much smaller than the amplitudes of direct  $P$  waves. These later arrivals will therefore, never bias  $m_b$  estimates. Yet on broadband records  $PP$  may sometimes have equal or even slightly larger amplitudes than primary  $P$ . However,  $P$  and  $PP$  phases are usually well separated by more than 1 min (up to 4 min) and not likely misinterpreted. Only for rare large earthquakes with  $M > 7.5$  the rupture duration and related  $P$ -wave radiation may extend into the time window where  $PP$  should arrive. But even then, wrongly taking  $PP_{\max}$  for  $P_{\max}$ , the bias in  $m_b$  estimate will not exceed 0.2 m.u. and usually be much smaller.

This experience from extensive seismogram analysis practice led Bormann and Khalturin [7] to state in 1974:

... "that the extension of the time interval for the measurement of  $(A/T)_{\max}$  up to 15 or 25 sec., as proposed ... in the Report of the first meeting of the IASPEI Commission on Practice (1972) ... is not sufficient in all practical cases, especially not for the strongest earthquakes with  $M > 7.5$  ...".

This was taken into account in the Manual of Seismological Observatory Practice edited by Willmore [87]. It includes the recommendation to extend the measurement time window for  $P$ -wave magnitudes up to 60 s for very large earthquakes. But still, this has not yet become common practice (see Sect. "Introduction to Common Magnitude Scales: Potential and Limitations") although even a limit of 60 s may not be sufficient for extreme events such as the Sumatra  $M_w$  9.3 earthquake when the first  $P1_{\max}$  appeared around 80 s and a second  $P2_{\max}$  of comparable amplitude at about 330 s after the first  $P$ -wave onset (cf. Fig. 8).

To allow a quick rough estimate of earthquake rupture duration  $\tau_d$  as a function of magnitude we derived from extrapolation of data published in [66] the average relation

$$\log \tau_d \approx 0.6M - 2.8. \quad (13)$$

It yields for  $M = 6, 7, 8$  and  $9$   $\tau_d \approx 6$  s, 25 s, 100 s and 400 s, respectively. Measurement time windows of 5 s, 25 s or 60 s may therefore underestimate the magnitude of earthquakes with  $M_w > 6, > 7$  or  $> 8$ , respectively. We call this effect the time-window component of magnitude saturation. It aggravates the pure spectral saturation component. To avoid this in future, the new IASPEI standards of amplitude measurements for  $m_b$  and  $m_B$  (cf. [42]) recommend to measure  $(A/T)_{\max} = A_{v\max}/2\pi$  in the entire  $P$ -phase train (time span including  $P$ ,  $pP$ ,  $sP$ , and possibly  $PcP$  and their codas but ending preferably before  $PP$ ).

In fact the pioneers of the magnitude scales, Richter and Gutenberg, knew this, because they were still very familiar with the daily analysis of real seismic records and their complexity. Regrettably, they never wrote this down, with respect to magnitude measurements, in detail for easy reference. In the current era of automation and scientific depreciation of alleged "routine processes" the younger generation of seismologists usually had no chance to gather this experience themselves and occasionally introduced technologically comfortable but seismologically questionable practices. In an interview given in 1980 [75] Prof. Richter remembered that Gutenberg favored the body-wave scale in preference to the surface-wave scale because it is theoretically better founded. However, he said:

“... it gives results comparable with Gutenberg’s only if his procedure is closely followed. Experience has shown that misunderstanding and oversimplified misapplications can occur. For instance, magnitude is sometimes assigned on the first few waves of the  $P$  group rather than the largest  $P$  waves as Gutenberg did.”

In order to avoid too-short measurement time windows when searching for the largest  $P$  amplitude one can estimate the rupture duration independently from the duration of large  $P$ -wave amplitudes in high-frequency filtered BB records because the generation of high-frequency waves is directly related to the propagation of the rupture front. Thus one may find  $P_{\max}$  for great earthquakes even beyond the theoretically expected  $PP$  arrival (cf. Fig. 8).

### Magnitude Biases Due to Neglecting Multiple Source Complexity

Realizing that strong earthquakes usually consist of multiple ruptures Bormann and Khalturin [7] also wrote:

*“In such cases we should determine the onset times and magnitudes of all clear successive  $P$ -wave onsets separately, as they give a first rough impression of the temporal and energetic development of the complex rupture process. ... The magnitude  $MP = \log \sum_n (A_i/T_i) + Q(D, h)$  ( $n$  is the number of successive  $P$ -wave onsets) could be considered as a more realistic measure of the  $P$ -wave energy released by such a multiple seismic event than the  $m_b$ -values from ... (single amplitude)  $(A/T)_{\max}$  within the first five half cycles or within the whole  $P$ -wave group.”*

This magnitude, which is based on summed amplitudes in broadband records, is now called  $m_{bc}$  [10], which stands for cumulative body-wave magnitude.

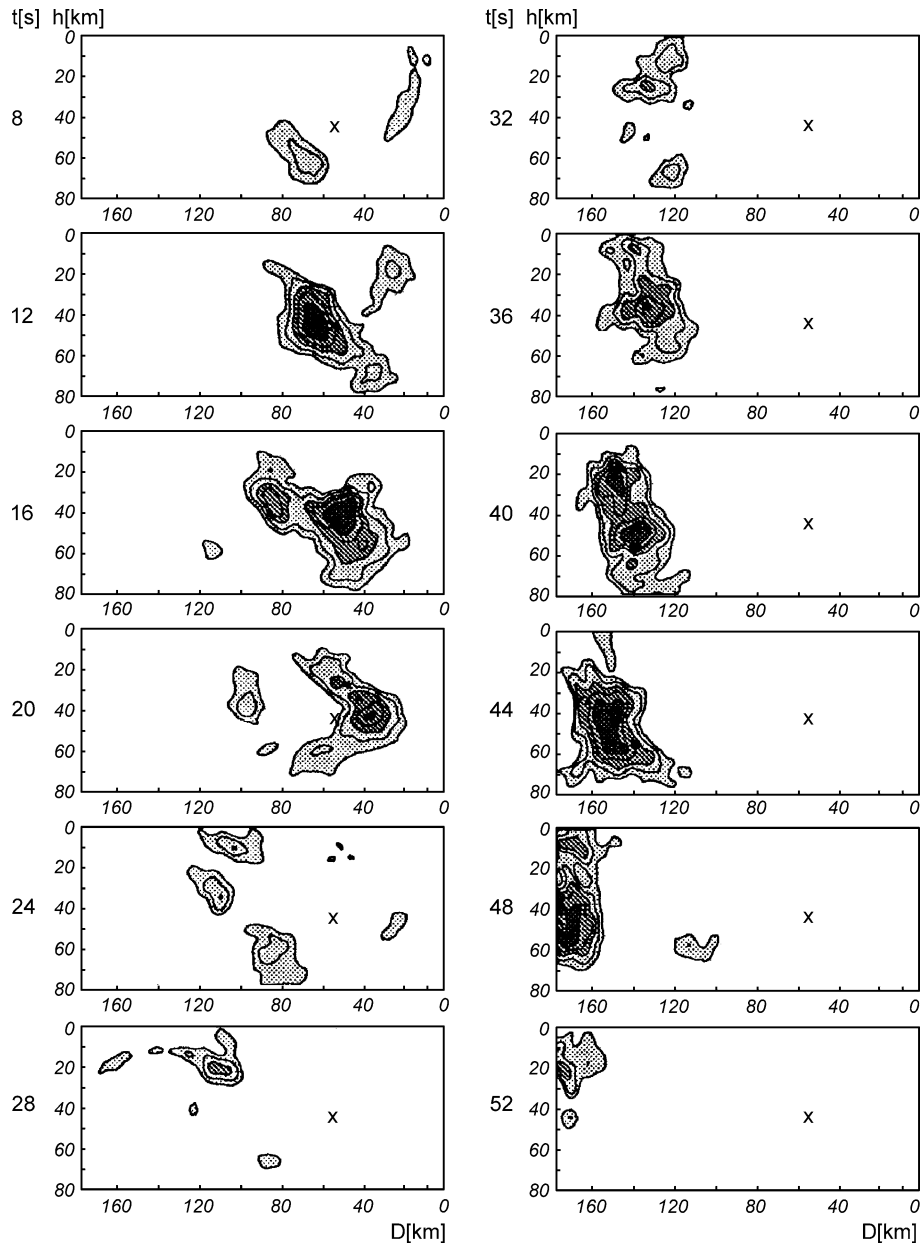

The 1985  $M_w = 8.1$  Mexico earthquake was a striking example for the development of such a multiple rupture process in space and time ([58], Fig. 6). A dense network of high-frequency strong-motion recordings near to the source revealed that the earthquake had a total rupture duration of about 60 s and consisted of two main sub-ruptures with significantly increased slip-velocities (12–32 cm/s). These two fault segments were separated in space by roughly 100 km in strike direction and ruptured between 10–22 s and 34–50 s after rupture start. Such a complicated rupture is not well represented by calculating the average slip and rupture velocity for a single point-source model. Also the *corner frequencies* related to these smaller sub-ruptures will be higher and not correspond to  $(L \times W)^{-1/2}$  of the total rupture area.

Such multiple ruptures are not an exception but rather the rule for earthquakes with magnitudes above 7.5 (and often also for smaller ones, even down to events with magnitudes around 5.0). The detailed patterns of the respective moment-rate curves differ from event to event (Fig. 7). Often they can not be approximated by a single-source triangular moment-rate function, as commonly assumed in the standard procedure for moment tensor solutions practiced at Harvard [78] and other centers.

Therefore, the Harvard group [78] re-analyzed the data of the great Sumatra 2004 earthquake for which  $M_w = 9.0$  had been calculated with the standard procedure. Interactively fitting synthetic records for five successive point sources to the observed mantle surface-wave data in the 200–500 s period range yielded the same value of  $M_w = 9.3$  as derived by [76] for a single-source model but using much longer periods between 20 min and 54 min. In fact, the multiple Centroid Moment Tensor (CMT) source analysis applied in [78] resembles the concept proposed in [7] for  $P$ -wave magnitudes of strong earthquakes, but applied to long-period surface waves. Presently, a multiple CMT source analysis still requires human interaction and takes too much time for early warning applications. Possible alternative procedures such as the automatic line source inversion [21] have been developed but demonstrated so far only for earthquakes with magnitudes  $< 7$  for which classical  $m_b$ ,  $M_S$  or  $M_w$  do not saturate due to source complexity.

### Proposals for Faster Magnitude Estimates of Strong Earthquakes

Soon after the great Sumatra earthquake of 2004 several authors suggested improvements to obtain more reliable and faster magnitude estimates of strong earthquakes. Menke and Levin [59] proposed to use a representative selection of 25 globally distributed high quality stations of the IRIS (Incorporated Research Institutions for Seismology) Global Seismic Network as a reference data base of available strong long-period master-event records with known  $M_w$ . In case of a new strong earthquake, a search for the nearest (within a few hundred kilometers) reference event in the data base is performed and waveforms are compared for a time window of about 30 min. By adding the  $\log_{10}$  of the average amplitude ratio of the two events to the  $M_w$  of the master event, a moment magnitude estimate of the actual event is obtained. This procedure is based on the assumption of similarity of *source mechanisms* and radiation patterns, slip rates and stress drops, at least within the reference regions. The authors expect reasonably good magnitude estimates, with only small un-

Earthquake Magnitude, Figure 6

Snapshots of the development in space and time of the inferred rupture process of the 1985 Michoacán, Mexico earthquake. The cross denotes the NEIC hypocenter position, the shading of the patches (from the outer part inwards *dotted*, *hatched* and *black*) relate to areas with velocities of dip slip (see *source mechanism*) in the ranges between 12 and 22 cm/s, 22 and 32 cm/s and greater than 32 cm/s. Redrawn and modified from Fig. 6 in [58]; taken from Fig. 3.8 in Vol. 1 of [6], © Seismological Society of America and IASPEI; with permission of the authors

derestimation for events with  $M_w > 8.6$ . Thus warnings could be issued within about 40 min after OT (measurement time window plus travel-time to stations of a global network). This would still be relevant for distant coasts that might be affected by a tsunami. However, no data have

been published until now that demonstrate the near-real-time operational capability of this procedure for a representative set of strong events.

Another approach by Lomax et al. [55,56,57] uses high-frequency seismograms ( $f \geq 1$  Hz) that contain pre-

Earthquake Magnitude, Figure 7

Moment-rate functions for the largest earthquakes in the 1960 and 1970s (modified from Fig. 9, p. 1868 in [53]), taken from Fig. 3.7 in Vol. 1 of [6], © Seismological Society of America and IASPEI; with permission of the authors

dominantly  $P$  signals radiated directly from the propagating rupture front and show little interference with later secondary waves such as  $PP$  or  $S$ , thus providing a direct estimate of the rupture duration. Such recordings are available at teleseismic distances ( $30^\circ$ – $90^\circ$ ) within about 20 min after OT, even after strong events with long durations and provide an early picture of the total rupture process. When assuming constant rupture velocity and mean slip for stronger and weaker earthquakes, the seismic moment  $M_0$  and thus moment magnitude  $M_w$  could be esti-

mated by comparing the actual rupture duration (averaged from observations at several seismic stations) with that of a reference event with known  $M_0$  and rupture duration. This is conceptually similar to the approach in [59] but with high-frequency observations and the ratio of rupture duration instead of amplitudes.

However, Hara [32] demonstrated with a large data set of strong earthquakes that it is difficult to estimate earthquake size reliably only from durations  $t$  of high-frequency radiation. Therefore, he measured duration  $t$  in combi-

nation with the maximum displacement amplitude  $A_{dmax}$  within this time interval and derived the following empirical relation:

$$M = 0.79 \log A_{dmax} + 0.83 \log D + 0.69 \log t + 6.47 \quad (14)$$

with  $A_{dmax}$ ,  $D$  and  $t$  in units of m, km and s, respectively. He applied Eq. (14) to 69 shallow earthquakes in the magnitude range  $7.2 \leq M_w(\text{HRV}) \leq 9.0$  at distances between  $30^\circ$  and  $85^\circ$  and on average got a 1:1 relation between  $M_w(\text{HRV})$  and his magnitude with a standard deviation of 0.18 m.u. All event estimates were within  $\pm 0.5$  m.u. of  $M_w(\text{HRV})$ , with the exception of the heavily underestimated Denali/Alaska earthquake of 3 November 2002 (7.1 instead of 7.8). This is a promising and simple procedure.

Bormann and Wylegalla [9] applied the earlier proposal in [7] to recordings with a velocity passband between 40 Hz and 125 s. They interactively summed up the maximum amplitudes of all visually discernible sub-ruptures in the recordings of several recent great earthquakes with  $M_w \geq 8.3$ , amongst them the tsunamigenic  $M_w = 9.3$  Sumatra earthquake of 2004. For the latter they obtained a cumulative broadband body-wave magnitude  $m_{Bc} = 9.3$  in records of just a single German station (RUE;  $D = 82.5^\circ$ ) at the time of the second major amplitude maximum, some 330 s after the first  $P$  onset and 18 min after OT. For three more events with magnitudes  $M_w$  8.3, 8.4 and 8.6 they calculated  $m_{Bc}$  values of 8.4,

8.4 and 8.6, respectively, i. e., excellent agreement. Subsequently, 50 more earthquakes in the magnitude range 6 to 9 were analyzed interactively [10] with the following results:

- Average difference  $m_B - M_w(\text{HRV}) = 0.00 \pm 0.27$  in the range  $6.0 \leq M_w(\text{HRV}) < 8$ . For magnitudes  $> 7.8$ –8, however,  $m_B$  tends to underestimate  $M_w$ , e. g.,  $m_B = 8.3$  for the Sumatra earthquake of 26 December 2004 based on the BB record of station RUE. Remarkably this  $m_B$  value is still very close to  $M_w$ ,  $M_{wp}$  and  $M_e$  of the NEIC, which ranged between 8.2 and 8.5.
- The average difference  $m_{Bc} - M_w(\text{HRV}) = +0.18 \pm 0.26$  in the range  $6.0 \leq M_w(\text{HRV}) \leq 9.0$ , i. e.,  $m_{Bc}$  has a tendency to slightly overestimate  $M_w(\text{HRV})$  on average, but not for  $M_w > 8$  (see the four values above).

In [10] also first results of a fully automatic determination of  $m_B$  and  $m_{Bc}$  have been presented. The algorithm has been improved by incorporating automatic estimates of the rupture duration calculated from the envelope of the high-frequency  $P$ -wave radiation from filtered broadband records of globally distributed stations in a wide range of azimuths and source distances. In the case of strong earthquakes with long rupture duration this justifies the search for broadband  $P_{max}$  even beyond the onset of  $PP$  and to sum-up the amplitudes of major sub-ruptures over the whole rupture duration as defined above. Figure 8 gives an

Earthquake Magnitude, Figure 8

Velocity broadband record at the Berlin station RUE in  $D^\circ = 82.6^\circ$  epicentral distance of the great  $M_w 9.3$  tsunamigenic Sumatra earthquake of Dec. 26, 2004. The record is projected into a time-magnitude diagram as plotted by the automatic  $m_B - m_{Bc}$  algorithm. The red inverted triangles mark the times and give the values of  $m_B$  for the three largest sub-ruptures. The red step curve shows the development of the cumulative magnitude  $m_{Bc}$  as a function of time. The inverted red triangles on this curve give the  $m_{Bc}$  before the onset of  $PP$  and at the end of the rupture process, about 530 s after the first  $P$ -wave onset, as estimated from the decay of the amplitude envelope of short-period filtered  $P$ -waves (see text)

example for a BB record of the Sumatra earthquake of 26 December 2004. The largest  $P$ -wave amplitudes at about 80 s, 280 s and 330 s after the  $P$  onset each yield a single amplitude  $m_B = 8.2$ , whereas the cumulative magnitude  $m_{BC} = 9.3$  is in perfect agreement with the best moment magnitude estimates for this event.

The automatic algorithm for  $m_B$  and  $m_{BC}$  determination has been in use since spring 2007 in the operational Indonesian prototype tsunami early warning system and yields online estimates of  $m_B$ . Before the implementation it had been tested whether the automatic procedure produces results that are comparable with those determined earlier interactively by two experienced seismogram analysts. Identical broadband records of 54 earthquakes in the magnitude range  $6 \leq M_w(\text{HRV}) \leq 9$  were used for this comparison based on 138  $m_B$  and 134  $m_{BC}$  values. The average difference between the interactively and automatically determined magnitudes was 0.03 and 0.02 m.u. with standard deviations of  $\pm 0.13$  and  $\pm 0.19$  m.u., respectively. This is in the range of other high-quality magnitude measurements. Even single station  $m_B$  and  $m_{BC}$  estimates differed on average  $< 0.08$  m.u. from average global network estimates based on up to hundreds of stations. Their standard deviations were  $< \pm 0.25$  m.u. and decreased to  $\pm 0.10$  m.u. for  $m_B$  and  $\pm 0.14$  m.u. for  $m_{BC}$  when just a few stations (between two and seven) were used to estimate the  $m_B$  and  $m_{BC}$  event magnitudes. This documents both the reliability of the automatic procedure as well as the reliability of  $m_B$  and  $m_{BC}$  estimates, even if derived from a few records of globally distributed high-fidelity stations. Thus, the automatic procedure is suitable for reproducibly determining the IASPEI recommended standard magnitude  $m_B$  and its proposed non-saturating extension  $m_{BC}$  in near real-time. When using only observations in the distance range  $21^\circ \leq D^\circ \leq 100^\circ$  saturation-free teleseismic magnitude estimates of earthquakes with potential for strong shaking damage and tsunami generation could be made available in near real-time within about 4 to 18 min after OT, depending on epicentral distance and rupture duration.

Compared to other more theoretically based methods such as  $M_{wp}$  and  $M_w$ , the empirical  $m_B - m_{BC}$  method is free of any hypothesis or model assumptions about the rupture process (single or multiple source), type of rupture mechanism, rupture velocity, average slip and/or stress drop, complexity or simplicity of the moment-release function, etc. It just measures velocity amplitudes on the unfiltered broadband record, complex or not, sums them up over the duration of the rupture process and calibrates them with the classical empirical broadband  $Q_{pV}$  function (Fig. 2 and [30]). However, one has to consider

that – in contrast to all types of moment magnitudes –  $m_B$  and  $m_{BC}$  are not determined from the maximum long-period displacement amplitudes, but from the maximum velocity amplitudes. Therefore,  $m_B$  (for earthquakes with  $M_w < 8.0$ ) and  $m_{BC}$  (for earthquakes with  $M_w > 7.8$ ) are better estimators than  $M_w$  for the seismic energy released by the earthquake and thus of its shaking-damage potential. Figure 9 compares  $m_B$  and  $m_{BC}$  with  $M_w(\text{HRV})$  for 76 earthquakes in the range  $6 \leq M_w \leq 9.3$ . The respective standard regression relations are:

$$M_w(\text{HRV}) = 1.22 m_B - 1.54 \pm 0.29 \quad (15)$$

and

$$M_w(\text{HRV}) = 1.16 m_{BC} - 1.59 \pm 0.25 \quad (16)$$

These scaling relations allow much faster estimates of  $M_w$  than current routine standard  $M_w$  procedures. The rough moment estimates derived from  $m_B$  and  $m_{BC}$  data,  $M_w(m_B)$  or  $M_w(m_{BC})$ , are sufficiently reliable for initial earthquake and tsunami alarms with standard deviations of the  $M_w$  estimates of about  $\pm 0.29$  and  $\pm 0.25$  m.u., respectively. However, looking into details of the somewhat irregular data scatter one realizes how *seismic source* complexity may “spoil” such regression relations. The five data points marked red in Fig. 9(left and right) are distinct outliers in the left diagram, i. e., the respective  $m_B$  values are 0.5 to 0.75 m.u. smaller than  $M_w(\text{HRV})$  although usually  $m_B$  scales rather well with  $M_w(\text{HRV})$  between  $6.5 < m_B < 8.0$ . These points correspond to slow earthquakes, one in Peru (1996) and four are tsunami earthquakes as mentioned at the end of Sect. “Common Magnitude Estimates for the Sumatra 2004  $M_w$  9.3 Earthquake”. Their rupture durations ranged from about 100 s to 200 s, i.e, according to relationship (13) about 2–3 times longer than expected on average for their  $M_w$  value. Both  $m_B$  and  $M_e$  are usually much smaller than  $M_w$  for such events. In contrast, when calculating  $m_{BC}$ , then these five data points all move close to the (not marked) 1:1 line in the  $m_{BC}-M_w(\text{HRV})$  diagram Fig. 9(right). Thus  $m_{BC}$  becomes a good direct estimator of  $M_w$  for typical slow earthquakes, much better than via relation (16), which compensates for the usually too large  $m_{BC}$  values of shallow depth and “normal” rupture earthquakes with  $M_w < 8$ . Thus, by determining rupture duration independently and treating very slow events separately, the standard deviation in relations (15) and (16) can be reduced. Moreover, the blue dots in Fig. 9 belong to very deep earthquakes with  $h = 525$  km, 583 km and 631 km, respectively. Such deep earthquakes are “explosion-like” with comparably short rupture durations. Both  $m_B$  (for  $M_w < 8$ ) and  $m_{BC}$  yield values very close to

Earthquake Magnitude, Figure 9

Standard regression relationships of  $M_w(\text{HRV})$  over  $m_B$  (left) and  $m_{Bc}$  (right). Red dots correspond to very slow earthquakes (Nicaragua 1992, Java 1994, New Britain Region 2000, Peru 2001 and Java 2006) and the blue dots belong to very deep earthquakes (Bolivia 1994, Philippines 2005 and Fiji Island 2006) with source depths  $h = 631$  km, 525 km and 583 km, respectively. The gray band and the two white bands around the average straight line correspond to the width of one and two standard deviations in  $y$ -direction

Earthquake Magnitude, Figure 10

Standard regression of  $M_{wp}(\text{PTWC})$  over  $m_B$ . The standard deviations in  $y$ -direction are marked as in Fig. 9. The  $M_{wp}$  data have been kindly provided by the PTWC (courtesy of B. Hirshorn)

$M_w$ . In the  $m_{Bc}-M_w$  diagram, which is dominated by shallow and normal rupture earthquakes, such deep events ap-

pear as outliers. However, rapid event locations with good depth estimates allow one to identify such events and  $m_{Bc}$  (or  $m_B$ ) should then be taken directly as estimator of  $M_w$  and not via relation (16).

$M_{wp}$  has so far been the fastest operationally determined estimator of  $M_w$ . Comparably fast automatic  $m_B$  determination is now implemented, complementary to  $M_{wp}$ , in the German Indonesian Tsunami Early Warning System (GITEWS). Figure 10 compares the relation between  $m_B$  and  $M_{wp}$  for our test data set. These two magnitudes scale almost 1:1, following the standard regression relation:

$$M_{wp} = 1.08 m_B - 0.638 \pm 0.24. \quad (17)$$

### Future Requirements and Developments

Few national seismological data centers and stations report amplitude, period and/or magnitude data to the international data centers. The main reason is usually the lack of manpower to make competent measurements of these parameters interactively for the large amount of data recorded nowadays. Instrument responses of the seismographs used are sometimes not known accurately enough. There is, however, a growing practical and research need for such parameter data that have been determined ac-

ording to international standards. Therefore, the most urgent requirements in the field of magnitudes are:

- Training of station and network operators to understand and practice proper magnitude measurements, instrument calibration and control;
- Implementation of the IASPEI magnitude standards [42];
- Making the tested and calibrated automatic algorithms available worldwide to data producers so that lack of manpower is no longer a hindrance to mass-produce such data;
- Use of such standardized mass data with significantly reduced procedure-dependent errors for improved research into the attenuation properties of the Earth and deriving better magnitude calibration functions for all distance ranges;
- Comparison of magnitude data derived from identical record sets by applying both traditional and new standard measurement procedures and to derive standardized conversion relationships. This is a precondition for assuring long-term compatibility of magnitude data in national and international data catalogs and their usefulness for seismic hazard assessment and research;
- Improvement of current procedures for direct determination of seismic moment and energy in a wider magnitude range than currently possible, down to small magnitudes that are at present well covered only by  $M_L$  and  $m_b$ ;
- Development of regional calibration functions for  $m_b$  and  $m_B$ , which will permit more reliable and much faster body-wave magnitude estimates from records at distances down to about  $5^\circ$
- Development and consequent use of standard procedures for  $M_o$  and  $E_s$  measurements that assure non-saturating and globally compatible estimates of seismic moment and energy and of their related magnitude scales  $M_w$  and  $M_c$ ;
- Use of these data for in-depth studies in the regional variability of apparent stress conditions and their relevance for improving (time-variable) regional earthquake and tsunami hazard and risk assessment;
- Comprehensive testing of speed and reliability of the various methods recently proposed for more rapid (near) real-time magnitude estimates (e. g. [9,10,32,46,55,56,57,59,61,66]) under operational EWS conditions;
- Development of faster automated procedures for direct non-saturating  $M_w$  and  $M_c$  determination for improving quick and realistic disaster response;
- Development of alternative automatic (near) real-time procedures of magnitude determination such as the

rapid finite-source analysis [21], their scaling to both seismic energy and moment and operational testing also for very large earthquakes.

### Glossary

**Active fault** A *fault* (q.v.) that has moved in historic (e. g., past 10,000 years) or recent geological time (e. g., past 500,000 years).

**Body waves** Waves which propagate through the interior of a body. For the Earth, there are two types of seismic body waves: (1) compressional or longitudinal (*P* wave), and (2) shear or transverse (*S* wave).

**Coda waves** Waves which are recorded on a *seismogram* (q.v.) after the passage of *body waves* (q.v.) and *surface waves* (q.v.). They are thought to be back-scattered waves due to the Earth's inhomogeneities.

**Earthquake early warning system (EEWS)** An earthquake monitoring system that is capable of issuing warning message after an earthquake occurred and before strong ground shaking begins.

**Earthquake precursor** Anomalous phenomenon preceding an earthquake.

**Earthquake prediction** A statement, in advance of the event, of the time, location, and *magnitude* (q.v.) of a future earthquake.

**Epicenter** The point on the Earth's surface vertically above the *hypocenter* (q.v.).

**Far-field** Observations made at large distances from the *hypocenter* (q.v.), compared to the wave-length and/or the source dimension.

**Fault** A fracture or fracture zone in the Earth along which the two sides have been displaced relative to one another parallel to the fracture.

**Fault slip** The relative displacement of points on opposite sides of a *fault* (q.v.), measured on the fault surface.

**Focal mechanism** A description of the orientation and sense of slip on the causative fault plane derived from analysis of *seismic waves* (q.v.).

**Hypocenter** Point in the Earth where the rupture of the rocks originates during an earthquake and *seismic waves* (q.v.) begin to radiate. Its position is usually determined from arrival times of *seismic waves* (q.v.) recorded by *seismographs* (q.v.).

**Intensity, earthquake** Rating of the effects of earthquake vibrations at a specific place. Intensity can be estimated from instrumental measurements, however, it is formally a rating assigned by an observer of these effects using a descriptive scale. Intensity grades are commonly given in Roman numerals (in the case of the Modified Mercalli Intensity Scale, from I for "not perceptible" to XII for "total destruction").

**Magnitude, earthquake** Quantity intended to measure the size of earthquake at its source, independent of the place of observation. *Richter magnitude* ( $M_L$ ) was originally defined in 1935 as the logarithm of the maximum amplitude of seismic waves in a seismogram written by a Wood–Anderson seismograph (corrected to) a distance of 100 km from the epicenter. Many types of magnitudes exist, such as *body-wave magnitude* ( $m_b$ ), *surface-wave magnitude* ( $M_S$ ), and *moment magnitude* ( $M_W$ ).

**Moment tensor** A symmetric second-order tensor that characterizes an internal seismic point source completely. For a finite source, it represents a point source approximation and can be determined from the analysis of *seismic waves* (q.v.) whose wavelengths are much greater than the source dimensions.

**Near-field** A term for the area near the causative rupture of an earthquake, often taken as extending a distance from the rupture equal to its length. It is also used to specify a distance to a seismic source comparable or shorter than the wavelength concerned. In engineering applications, near-field is often defined as the area within 25 km of the fault rupture.

**Plate tectonics** A theory of global *tectonics* (q.v.) in which the Earth's lithosphere is divided into a number of essentially rigid plates. These plates are in relative motion, causing earthquakes and deformation along the plate boundaries and adjacent regions.

**Probabilistic seismic hazard analysis** Available information on earthquake sources in a given region is

combined with theoretical and empirical relations among earthquake *magnitude* (q.v.), distance from the source, and local site conditions to evaluate the exceedance probability of a certain ground motion parameter, such as the peak ground acceleration, at a given site during a prescribed time period.

**Seismic hazard** Any physical phenomena associated with an earthquake (e.g., ground motion, ground failure, liquefaction, and tsunami) and their effects on land use, man-made structure, and socio-economic systems that have the potential to produce a loss.

**Seismic hazard analysis** The calculation of the *seismic hazard* (q.v.), expressed in probabilistic terms (See *probabilistic seismic hazard analysis*, q.v.). The result is usually displayed in a *seismic hazard map* (q.v.).

**Seismic hazard map** A map showing contours of a specified ground-motion parameter or response spectrum ordinate for a given *probabilistic seismic hazard analysis* (q.v.) or return period.

**Seismic moment** The magnitude of the component couple of the double couple that is the point force system equivalent to a *fault slip* (q.v.) in an isotropic elastic body. It is equal to rigidity times the fault slip integrated over the fault plane. It can be estimated from the far-field seismic spectrum at wave lengths much longer than the source size. It can also be estimated from the near-field seismic, geologic and geodetic data. Also called “scalar seismic moment” to distinguish it from *moment tensor* (q.v.).

**Seismic risk** The risk to life and property from earthquakes.

**Seismic wave** A general term for waves generated by earthquakes or explosions. There are many types of seismic waves. The principle ones are *body waves* (q.v.), *surface waves* (q.v.), and *coda waves* (q.v.).

**Seismograph** Instrument which detects and records ground motion (and especially vibrations due to earthquakes) along with timing information. It consists of a *seismometer* (q.v.) a precise timing device, and a recording unit (often including telemetry).

**Seismogram** Record of ground motions made by a *seismograph* (q.v.).

**Seismometer** Inertial sensor which responds to ground motions and produces a signal that can be recorded.

**Source parameters of an earthquake** The parameters specified for an earthquake source depends on the assumed earthquake model. They are origin time, *hypo-center* (q.v.), *magnitude* (q.v.), *focal mechanism* (q.v.), and *moment tensor* (q.v.) for a point source model. They include fault geometry, rupture velocity, stress drop, slip distribution, etc. for a finite fault model.

**Surface waves** Waves which propagate along the surface of a body or along a subsurface interface. For the Earth, there are two common types of seismic surface waves: Rayleigh waves and Love waves (both named after their discoverers).

**Tectonics** Branch of Earth science which deals with the structure, evolution, and relative motion of the outer part of the Earth, the lithosphere. The lithosphere includes the Earth’s crust and part of the Earth’s upper mantle and averages about 100 km thick. See *plate tectonics* (q.v.).

**Teleseism** An earthquake at an epicentral distance greater than about 20° or 2000 km from the place of observation.

### Definition of the Subject

When a sudden rupture occurs in the Earth, elastic (seismic) waves are generated. When these waves reach the Earth’s surface, we may feel them as a series of vibrations, which we call an earthquake. *Seismology* is derived from the Greek word *σεισμός* (seismos or earthquake) and *λόγος* (logos or discourse); thus, it is the science of earthquakes and related phenomena. Seismic waves can be generated naturally by earthquakes or artificially by explosions or other means. We define earthquake monitoring as a branch of seismology, which systematically observes earthquakes with instruments over a long period of time.

Instrumental recordings of earthquakes have been made since the later part of the 19th century by seismographic stations and networks of various sizes from local to global scales. The observed data have been used, for example, (1) to compute the source parameters of earthquakes, (2) to determine the physical properties of the Earth’s interior, (3) to test the theory of plate tectonics, (4) to map active faults, (5) to infer the nature of damaging ground shaking, and (6) to carry out seismic hazard analyzes. Constructing a satisfactory theory of the complex earthquake process has not yet been achieved within the context of physical laws, e.g., realistic equations for modeling earthquakes do not exist at present. Good progress, however, has been made in building a physical foundation for the earthquake source process [62], partly as a result of research directed toward earthquake prediction.

Earthquakes release large amounts of energy that potentially can cause significant damage and human deaths. During an earthquake, potential energy (mainly elastic strain energy and some gravitational energy) that has accumulated in the hypocentral region over decades to centuries or longer is released suddenly [63]. This energy is partitioned into (1) radiated energy in the form of prop-

agating seismic waves, (2) energy consumed in overcoming fault friction, (3) the energy which expands the rupture surface area or changes its properties (e.g., by pulverizing rock), and (4) heat. The radiated seismic energy is a small fraction (about 7%) of the total energy budget, and it can be estimated using the recorded seismograms. Take, for example, the 1971 San Fernando earthquake ( $M_W = 6.6$ ) in southern California. Its radiated energy was about  $5 \times 10^{21}$  ergs, or about 120 kilotons of TNT explosives, or the energy released by six atomic bombs of the size used in World War II. The largest earthquake recorded instrumentally (so far) is the 1960 Chilean earthquake ( $M_W = 9.5$ ). Its radiated energy was about  $1.1 \times 10^{26}$  ergs, an equivalent of about 2,600 megatons of TNT explosives, the energy released by about 130,000 atomic bombs. It is, therefore, no surprise that an earthquake can cause up to hundreds of thousands of human deaths, and produce economic losses of up to hundreds of billions of dollars.

Monitoring earthquakes is essential for providing scientific data to investigate complex earthquake phenomena, and to mitigate seismic hazards. The present article is a brief overview of earthquake monitoring and early warning systems; it is intended for a general scientific audience, and technical details can be found in the cited references. Earthquakes are complex natural phenomena and their monitoring requires an interdisciplinary approach, including using tools from computer science, electrical and electronic engineering, mathematics, physics, and others. Earthquake early warning systems (which are based on earthquake monitoring) offer practical information for reducing seismic hazards in earthquake-prone regions.

After the “Introduction”, we will present a summary of earthquake monitoring, a description of the products derived from the analysis of seismograms, and a discussion of the limitations of these products. Earthquake early warning systems are then presented briefly, and we conclude with a section on future directions, including a progress report on rotational seismology (Appendix). We present overviews of most topics in earthquake monitoring, and an extensive bibliography is provided for additional reading and technical details.

## Introduction

Earthquakes, both directly and indirectly, have caused much suffering to mankind. During the 20th century alone about two million people were killed as a result of earthquakes. A list of deadly earthquakes (death tolls  $\geq 25$ ) of the world during the past five centuries was compiled by Utsu [115]. It shows that earthquakes of magnitude  $\geq 6$

( $\sim 150$  per year worldwide) can be damaging and deadly if they occur in populated areas, and if their focal depths are shallow ( $< 50$  km). Seismic risk can be illustrated by plotting the most deadly earthquakes of the past five centuries (1500–2000) over a map of current population density. This approach was used by Utsu [115], and his result is shown in Fig. 1. Most of these deadly earthquakes are concentrated (1) along the coasts of Central America, the Caribbean, western South America, and Indonesia, and (2) along a belt that extends from southern Europe, the Middle East, Iran, Pakistan and India, to China and Japan.

Table 1 lists the most deadly earthquakes (death toll  $> 20,000$ ) of the past 110 years based on official estimates (often under-estimated for political reasons, or lack of accurate census data in many areas of the world). In the first 5 years of the 21st century, four disastrous earthquakes occurred in India, Indonesia, Iran, and Pakistan. In the 20th century, the average death toll caused by earthquakes (and tsunamis they triggered) was about 16,000 per year. For the past seven years the yearly death toll was about 60,000 – four times higher than the average in the previous century. In Fig. 2 we extracted a portion of Fig. 1 to illustrate the relationship between past earthquakes and population in India, Pakistan, northern Indonesia, and adjoining regions. We numbered the four most recent disastrous earthquakes in Fig. 2. It is obvious that the large populations in India, Indonesia, Iran, Pakistan, and their adjoining regions (over 1.5 billion people) has been and will continue to be adversely affected by earthquakes. Fatalities depend largely on resistance of building construction to shaking, in addition to population density and earthquake occurrence.

In recent decades, population increases, accelerated urbanization, and population concentration along coastal areas prone to earthquakes suggest that many more earthquake-related fatalities will occur unless effective steps are taken to minimize earthquake and tsunami hazards.

## Earthquake Monitoring: Instrumentation

Besides geodetic data [28], the primary instrumental data for the quantitative study of earthquakes are *seismograms*, records of ground motion caused by the passage of seismic waves. Seismograms are written by *seismographs*, instruments which detect and record ground motion along with timing information. A seismograph consists of three basic components: (1) a seismometer, which responds to ground motion and produces a signal proportional to acceleration, velocity, or displacement over a range of amplitudes and frequencies; (2) a timing device; (3) either a local recording unit which writes seismograms on paper, film, or elec-

"+" denotes a minimum value.

tronic storage media, or more recently, a telemetry system for delivering the seismograms to a central laboratory for recording. Technical discussions of seismometry may be found, for example, in Wielandt [122], and of seismic instruments in Havskov and Alguacil [48]. An overview of challenges in observational earthquake seismology is given by Lee [71], and a useful manual of seismological observatory practice is provided by Bormann [12].

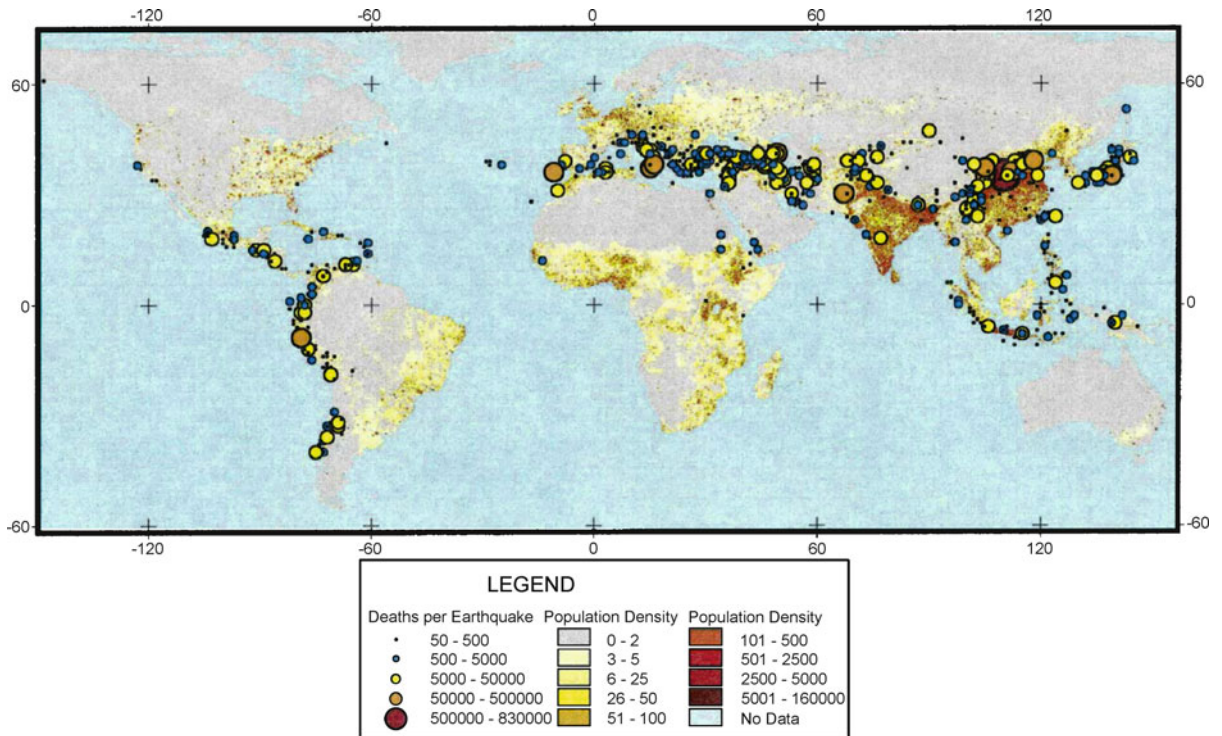

An *accelerograph* is a seismograph designed to record, on scale, the acceleration time history of strong ground motions. Measuring acceleration is important for studying response of buildings to strong ground motions close to earthquakes. Many modern sensitive seismographs are *velocigraphs* recording the time history of ground velocity. They are designed to measure seismic waves of small amplitudes (because seismic waves attenuate quickly from their sources) either from small earthquakes nearby, or from large earthquakes that are far away.

A seismic network (or an "array") is a group of seismographs "linked" to a central headquarters. Nowadays the

link is by various methods of telemetry, but in early days the links were by mail or telegrams, or simply by manual collection of the records. When we speak of a seismic *station*, we may mean an observatory with multiple instruments in special vaults or a small instrument package at a remote site.

Seismographs were first developed in the late 19th century, and individual seismographic observatories (often a part of astronomical or meteorological observatories) began earthquake monitoring by issuing earthquake information in their station bulletins and other publications. However, in order to accurately locate an earthquake, data from several seismographic stations are necessary. It was then natural for many governments to assume responsibility for monitoring earthquakes within their territories. However, because seismic waves from earthquakes do not recognize national boundaries, the need for international cooperation became clear. In the following subsections, we present an overview of the history and results of earthquake monitoring.

Earthquake Monitoring and Early Warning Systems, Figure 1

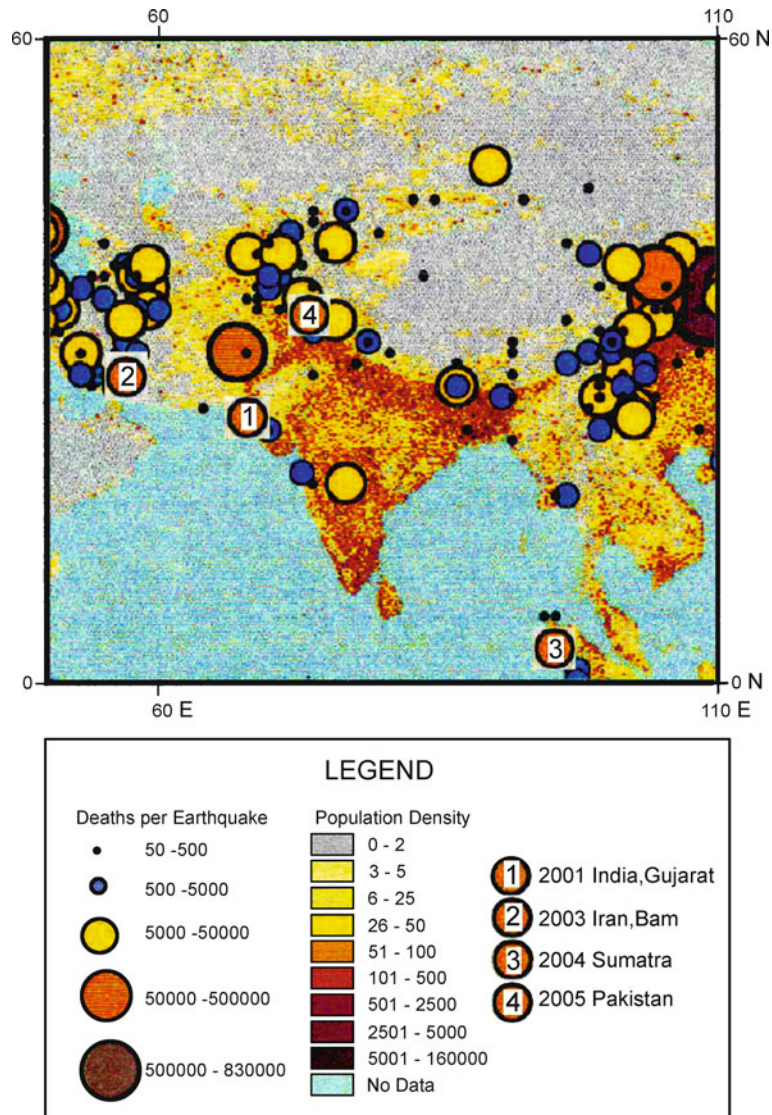

Location of deadly earthquakes around the world, 1500–2000. Population density is shown by the *background colors*. See [115] for details

## Historical Developments

In 1897, John Milne designed the first inexpensive seismograph, which was capable of recording very large earthquakes anywhere in the world. With a small grant from the British Association for the Advancement of Science (BAAS), a few other donations, and his own money, Milne managed to deploy about 30 of his instruments around the world, forming the first worldwide seismographic network. At the same time, seismogram readings were reported voluntarily to Milne's observatory at Shide on the Isle of Wight, England. A global earthquake summary with these seismogram readings was issued by Milne beginning in 1899. These summaries are now known as the "Shide Circulars". Milne also published progress and results in the "Reports of the BAAS Seismological Committee" from 1895 to 1913. A review of Milne's work and a reproduction of his publications as computer readable files were given by Schweitzer and Lee [101] and its attached CD-ROM. After Milne's death in 1913, Herbert H. Turner continued Milne's efforts, and in 1918 established publication of the International Seismological Summary (ISS).

The shortcomings of the Milne seismograph (low magnification, no damping, and poor time resolution) were soon recognized. Several improved seismographs (notably the Omori, Bosch–Omori, Wiechert, Galitzin, and Milne–Shaw) were developed and deployed in the first three decades of the 20th century. Figure 3 shows several of these classical seismographs (see Schweitzer and Lee [101] for further explanation). Although the ISS provided an authoritative compilation arrival-time data of seismic waves and determinations of earthquake hypocenters beginning in 1918, its shortcomings were also evident. These include difficulties in collecting the available arrival-time data around the world (which were submitted on a voluntary basis), and in the processing and analysis of data from many different types of seismographs. Revolutions and wars during the first half of the 20th century frequently disrupted progress, particularly impacting collection and distribution earthquake information.

In the late 1950s, attempts to negotiate a comprehensive nuclear test ban treaty failed, in part because of perceptions that seismic methods were inadequate for monitoring underground nuclear tests [95]. The influ-

Earthquake Monitoring and Early Warning Systems, Figure 2

Location of the 4 most deadly earthquakes of the 21st century (up to the end of 2007) on a map showing the location of the deadly earthquakes from 16th to 20th centuries (after [115] and Table 1)

ential Berkner report of 1959 therefore advocated major support for seismology [66]. As a result, the Worldwide Standardized Seismograph Network (WWSSN) was created in the early 1960s with about 120 continuously recording stations located across much of the world, except China and the USSR [91]. Each WWSSN station was equipped with *identical* sets of short-period and long-period three-component seismographs and accurate chronometers. Figure 4 shows some of the equipment at a WWSSN station, including three-components of long-period seismometers, long-period recording and

test instruments, and the time and power console. A similar set of three-component short-period seismometers and recording and test instruments, nearly identical in appearance, was also deployed at each station. Seismograms from the WWSSN were sent to the United States to be photographed on 70 mm film chips for distribution (about US\$ 1 per chip as then sold to any interested person).

The WWSSN network is credited with making possible rapid progress in global seismology, and with helping to spark the plate tectonics revolution of the late

Earthquake Monitoring and Early Warning Systems, Figure 3  
Some classical seismographs: a Milne, b Bosch-Omori, c Wiechert, and d Galitzin (after [101])

1960s [117]. At about the same time, the Unified System of Seismic Observations (ESSN) of the former USSR and its allied countries was established, consisting of almost 100 stations equipped with Kirnos short-period, 1–20 s displacement sensors, and long-period seismographs.

Samples of seismograms recorded on smoked paper and photographic paper or film by analog seismographs

are shown in Figs. 5 and 6. Two efforts to preserve and make such records available online are now underway: the *SeismoArchives* ([www.iris.edu/seismo/](http://www.iris.edu/seismo/) [72]), and *Sismos* ([sismos.rm.ingv.it](http://sismos.rm.ingv.it) [82]).

With the establishment of the WWSSN, the United States also assumed the task of monitoring earthquakes on a global scale beginning in the early 1960s. The mis-

sion of the US National Earthquake Information Center (NEIC, now part of the US, Geological Survey) is “to determine rapidly the location and size of all destructive earthquakes worldwide and to immediately disseminate this information to concerned national and international agencies, scientists, and the general public” (<http://earthquake.usgs.gov/regional/neic/>).

In 1964, the ISS was reorganized as the International Seismological Centre (ISC). Since then, the ISC (<http://www.isc.ac.uk/>) has issued annual global earthquake catalogs with a time lag of about two years [123].

### Technical Considerations

To record seismic waves, we must consider both the available technology for designing seismographs, and the nature of the Earth’s background noise [121]. The Earth is constantly in motion. This “background” noise is usually classified as either (1) *microseisms*, which typically have frequencies below about 1 Hz, are often the largest background signals, and are usually caused by natural disturbances (largely caused by ocean waves near shorelines); or (2) *microtremors*, which have frequencies higher

Earthquake Monitoring and Early Warning Systems, Figure 5  
Some sample analog seismograms recorded on smoked paper

than about 1 Hz, and are due to human activities (such as traffic and machinery) and local natural sources (such as wind and moving vegetation). Ground motions from earthquakes vary more than ten orders of magnitude in amplitude and six orders of magnitude in frequency, depending on the size of the earthquake and the distance at which it is recorded. Figure 7 illustrates the relative dynamic range of some common seismometers for global earthquake monitoring. A “low Earth noise” model [10,92] is the lower limit of Earth’s natural noise in its quietest locations – it is desirable to have instruments that are sensitive enough to detect this minimal background Earth

signal. In the analog instrument era (i. e., prior to about 1980), short-period and long-period seismometers were designed separately to avoid microseisms, which have predominant periods of about 6 s. Short-period seismometers were designed to detect tiny ground motions from smaller, nearby earthquakes, while long-period instruments were designed to recover the motions of distant, larger earthquakes (“teleseisms”). Additionally, strong-motion accelerometers, generally recording directly onto 70 mm-wide film strips, were used to measure large motions from nearby earthquakes. In today’s much more capable digital instrumentation, two major types of instru-

ments are deployed: (1) “broadband” seismometers, which replace and improve upon both short-period and long-period seismometers, and (2) strong-motion accelerometers for high-amplitude, high-frequency, seismic waves from local earthquakes, which often drive broadband seismometers off scale. While rare examples of the old ana-

log instruments are still in use, the vast majority of instruments presently operating are digital.

In addition to having large variations in amplitudes and frequencies, seismic waves from earthquakes also attenuate rapidly with distance, that is, they lose energy as they travel, particularly at higher frequencies. We must

Earthquake Monitoring and Early Warning Systems, Figure 7

Relative dynamic range of some common seismometers for global earthquake monitoring (modified from Fig. 1 in [54]). The Y-axis is marked in decibel (dB) where  $\text{dB} = 20 \log(A/A_0)$ ;  $A$  is the signal amplitude, and  $A_0$  is the reference signal amplitude

consider these effects in order to monitor seismic waves effectively.

In 1935, C.F. Richter introduced the concept of *magnitude* to classify local earthquakes by their “size”, effectively the amount of energy radiated at the actual rupture surface within the Earth. See the entry by Bormann and Saul ► [Earthquake Magnitude](#) for a discussion of the various magnitude scales in use. While every effort is made to make these different scales overlap cleanly, each has strengths and weaknesses that make one or another preferable in a given situation. Probably the most general and robust of these methods is called a “moment magnitude”, symbolized as  $M_W$ . Existing instruments and environments are such that the smallest natural earthquakes we routinely observe close by are about magnitude = 1. The largest earthquake so far recorded by instrumentals is the  $M_W = 9.5$  Chilean earthquake in 1960. In 1941, B. Gutenberg and C.F. Richter discovered that over large

geographic regions the rate of earthquake occurrence is empirically related to their magnitudes by:

$$\log N = a - bM \quad (1)$$

where  $N$  is the number of earthquakes of magnitude  $M$  or greater, and  $a$  and  $b$  are numerical constants. It turns out that  $b$  is usually about 1, which implies that  $M = 6$  earthquakes are about ten times more frequent than  $M = 7$  earthquakes. Engdahl and Villasenor [24] show that there has been an *average* of about 15 major ( $M \geq 7$ ) earthquakes per year over the past 100 years, and about 150 large ( $M \geq 6$ ) earthquakes per year during this same time interval. Strong ground motions (above 0.1 g in acceleration) over sizeable areas are generated by  $M \geq 6$  earthquakes; these are potentially damaging levels of ground shaking.

Earthquakes are classified by magnitude ( $M$ ) as *major* if  $M \geq 7$ , as *moderate to large* if  $M$  ranges from 5 to 7, as

*small* if  $M$  ranges from 3 to 5, as *micro* if  $M < 3$ , and as *nano* if  $M < 0$ . An earthquake with  $M \geq 7\ 3/4$  is often called *great*, and if  $M \geq 9$ , *mega*.

### Earthquake Monitoring in the Digital Era

Figure 8 shows the expected amplitudes of seismic waves by earthquake magnitude. The top frame is a plot of the equivalent peak ground acceleration versus frequency. The two heavy curves denote the “minimum Earth noise”, and the “maximum Earth noise” (i. e., for seismographic station located in the continental interior versus near the coast).

The two domains of the WWSSN equipment, short-period long-period seismometers are shown as gray shading. The domains for two other instruments, SRO (Seismic Research Observatories Seismograph) and IDA (International Deployment of Accelerometers), are also shown; these were the early models of the current instruments now in operation in the *Global Seismographic Network* (GSN). The bottom two frames indicate expected amplitudes of seismic waves from earthquakes of a range of magnitudes (we use the moment magnitude,  $M_W$ ). For simplicity, we consider two cases: (bottom left) global earthquakes recorded at a large distance with a seismographic network spaced at intervals of about 1000 km, and (bottom right) local earthquakes recorded at short distances with a seismic array spaced at intervals of about 50 km. In the bottom left plot, the global-scale network, the expected amplitudes of  $P$ -wave and surface wave at 3000 km from the earthquake source are shown; for the bottom right plot, a local seismic array, the expected amplitudes of  $S$ -wave at 10 km and 100 km from the earthquake source are shown. Seismologists use this and similar figures in planning seismographic networks. Local noise surveys are usually conducted as well when designing specific seismographic networks.

With advances in digital technology, earthquake monitoring entered the digital era in the 1980s. Older analog equipment was gradually phased out as modern digital equipment replaced it [54]. The WWSSN was replaced by the *Global Seismographic Network* (GSN), a collaboration of several institutions under the IRIS consortium (<http://www.iris.edu/>). The goal of the GSN (<http://www.iris.edu/about/GSN/index.htm>) is “to deploy over 128 permanent seismic recording stations uniformly over the Earth’s surface”. The GSN project provides funding for two network operators: (1) the IRIS/ASL Network Operations Center, in Albuquerque, New Mexico (operated by the US Geological Survey), and (2) the IRIS/IDA Network Operations Center in La Jolla, California (operated by personnel from

the Scripps Institution of Oceanography). Components of a modern IRIS GSN seismograph system, which include broadband seismometers, accelerometers, and recording equipment, are shown in Fig. 9.

Figure 10 shows the station map of the Global Seismographic Network as of 2007. IRIS GSN stations continuously record seismic data from very broad band seismometers at 20 samples per second (sps), and also include high-frequency (40 sps) and strong-motion (1 and 100 sps) sensors where scientifically warranted. It is the goal of the GSN project to provide real-time access to its data via Internet or satellite. Since 1991, the IRIS Data Management Center has been providing easy access to comprehensive seismic data from the GSN and elsewhere [1].

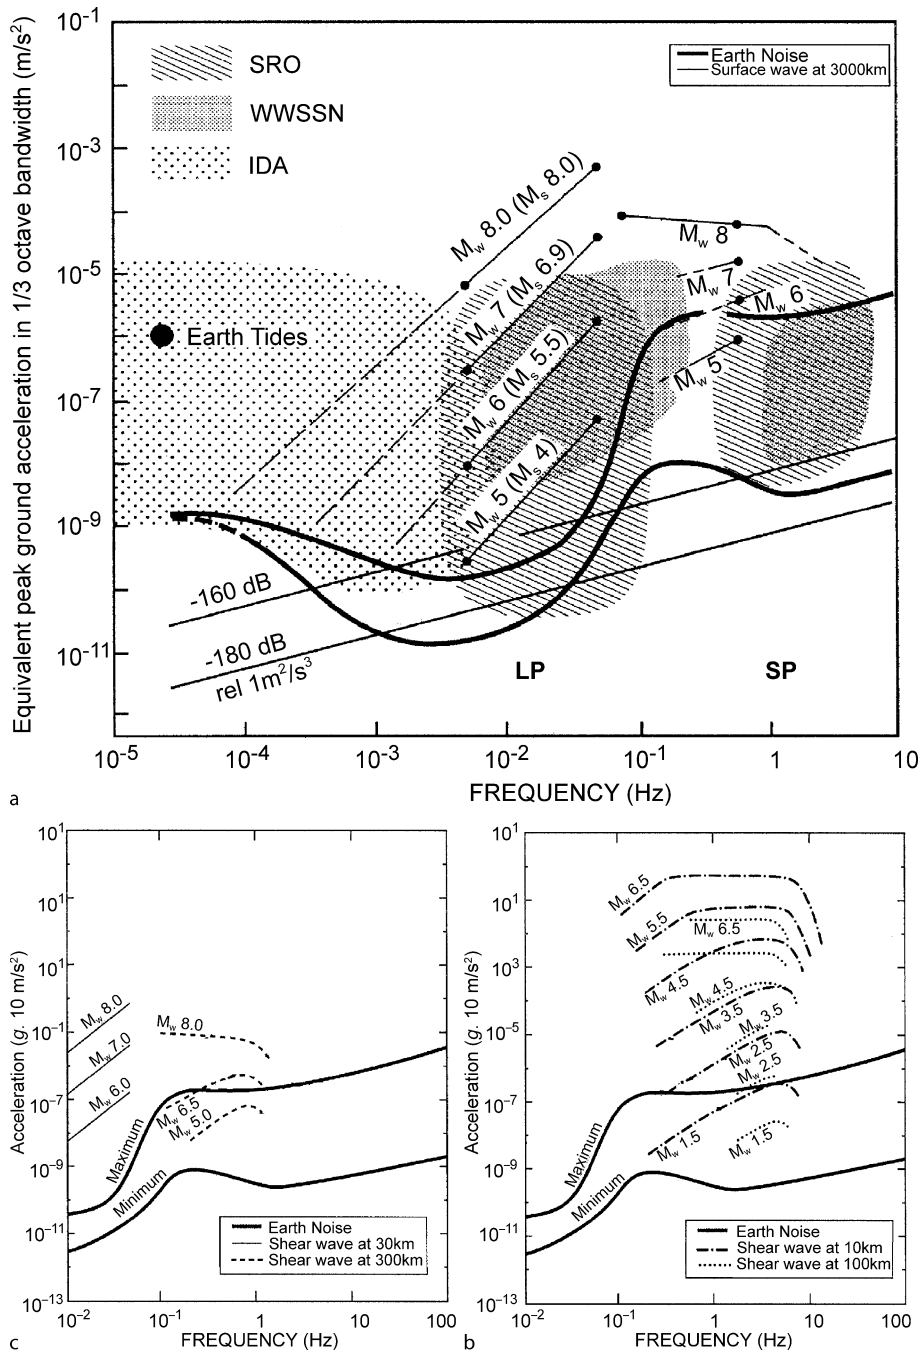

### Earthquake Monitoring: Regional and Local Networks

A major development in earthquake monitoring was the establishment of seismographic networks optimized to record the many *frequent* but *smaller* regional and local earthquakes occurring in many locations. To observe as many of these nearby earthquakes as possible, inexpensive seismographs with high magnifications and low dynamic-range telemetry are used to record the smallest earthquakes feasible with current technology and local background noise. As a result, the recorded amplitudes often overdrive the instruments for earthquakes with  $M \gtrsim 3$  within about 50 km of such seismographs. This is not a serious defect, since the emphasis for these networks is to obtain as many first arrival times as possible, and to detect and to locate the maximum number of earthquakes. Because seismic waves from small earthquakes are quickly attenuated with increasing distance, it is also necessary to deploy many instruments at small station spacing (generally from a few to a few tens of kilometers), and to cover as large a territory as possible in order to record at least a few earthquakes every week. Since funding often is limited, these local and regional seismic networks are commonly optimized for the largest number of stations rather than for the highest quality data.

### A Brief History

In the 1910s, the Carnegie Institution of Washington D.C. (CIW) was spending a great deal of money building the world’s then largest telescope (100 inch) at Mount Wilson Observatory, southern California [38]. Since astronomers were concerned about earthquakes that might disturb their telescopes, Harry O. Wood was able to persuade CIW to support earthquake investigations, and as a result, a regional network of about a dozen Wood–Anderson seis-

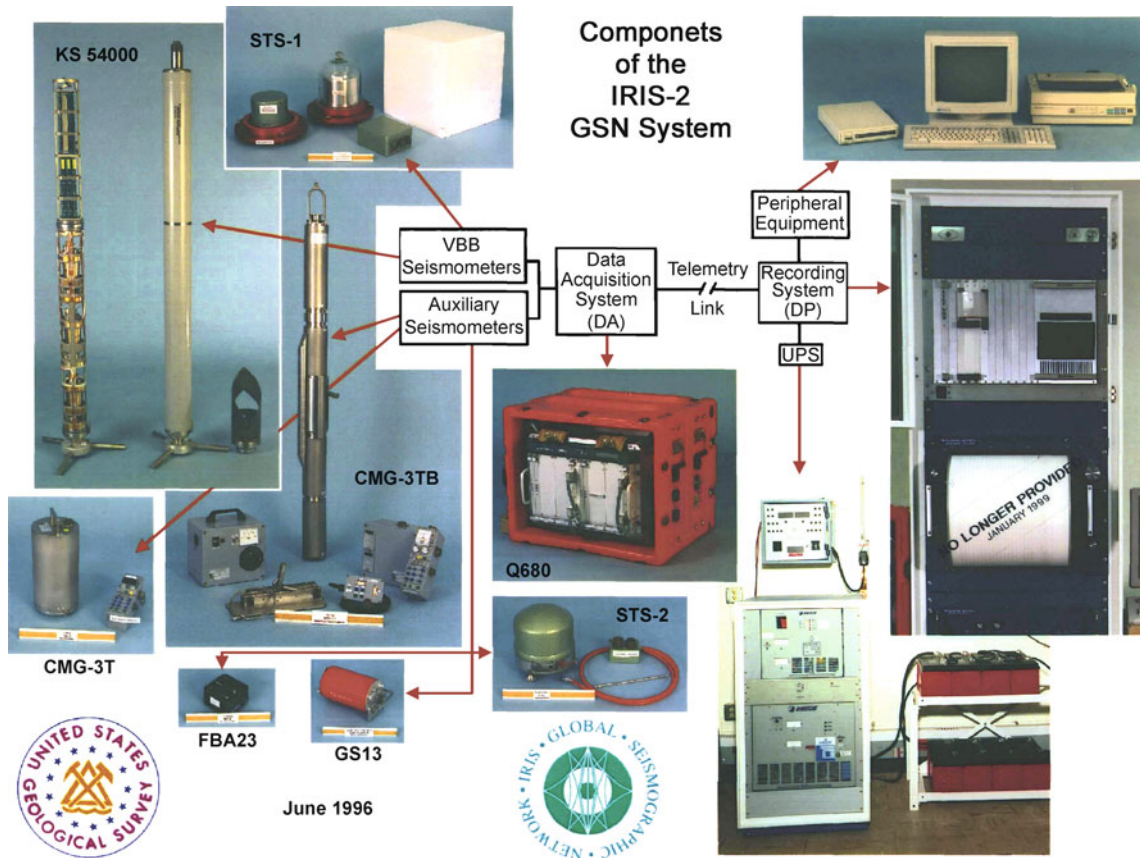

Earthquake Monitoring and Early Warning Systems, Figure 8

mographs was established in southern California in the 1920s. See Goodstein [38] for the early history leading to the establishment of the California Institute of Technology (Caltech) and its Seismological Laboratory. Astronomers

played important roles in getting seismic monitoring established in various other regions of the world as well.

Regional networks using different types of seismographs were established in many countries about this time,

Earthquake Monitoring and Early Warning Systems, Figure 9  
 Components of the IRIS-2 GSN System: broadband seismometers, accelerometers and recording equipment

such as in Japan, New Zealand, and the USSR and its allies. In the 1960s, high-gain, short-period, telemetered networks were developed to study microearthquakes. To support detailed studies of local earthquakes and especially for the purpose of earthquake prediction, over 100 microearthquake networks were established in various parts of the world by the end of the 1970s [74]. These microearthquake networks comprised from tens to hundreds of short-period seismometers, generally with their signals telemetered into central recording sites for processing and analysis. High magnification was achieved through electronic amplification, permitting recording of very small earthquakes (down to  $M = 0$ ), though this came at the expense of saturated records for earthquakes of  $M \gtrsim 3$  within about 50 km. Unfortunately, the hope of discovering some sort of earthquake precursor from the data obtained by these microearthquake networks did not work out. For a review of the earthquake prediction efforts, please read Kanamori [60].

### Some Recent Advances

Because of recent advances in electronics, communications, and microcomputers, it is now possible to deploy sophisticated digital seismograph stations at global, national, regional, and local scales for *real-time* seismology [64]. Many such networks, including temporary portable networks, have been implemented in many countries. In particular, various real-time and near real-time seismic systems began operation in the 1990s: for example, in Mexico [25], California [32,47], and Taiwan [110]. The Real-Time Data (RTD) system operated by the Central Weather Bureau (CWB) of Taiwan is based on a network of telemetered digital accelerographs [102]; since 1995, this system has used pagers, e-mail, and other techniques to automatically and rapidly disseminate information about the hypocenter, magnitude, and shaking amplitude of felt earthquakes ( $M \gtrsim 4$ ) in the Taiwan region. The disastrous Chi-Chi earthquake ( $M_W = 7.6$ ) of 20

### Global Seismographic Network

Earthquake Monitoring and Early Warning Systems, Figure 10  
Station map of the Global Seismographic Network (GSN) as of 2007

September 1999 caused 2,471 deaths and total economic losses of US\$ 11.5 billion. For this earthquake sequence, the RTD system delivered accurate information to government officials 102 seconds after the origin time of the main shock (about 50 seconds for most aftershocks), and proved to be useful in the emergency response of the Taiwan government [37,131].

#### Recording Damaging Ground Shaking

Observing teleseisms on a global scale with station spacing of several hundreds of kilometers does not yield critical information about near-source strong ground shaking required for earthquake structural engineering purposes and seismic hazard reduction. Broadband seismometers, which are optimized to record earthquakes at great distances, do not perform well in the near-field of a major

earthquake. For example, during the 1999 Chi-Chi earthquake the nearest broadband station in Taiwan (epicentral distance of about 20 km) was badly overdriven, recorded no useful data beyond the arrival time of the initial *P*-wave, and finally failed about one minute into the shock.

A regional seismic network with station spacing of a few tens of kilometers cannot do the job either: the station spacing is still too large and the records are typically overdriven for earthquakes of  $M \gtrsim 3$  (any large earthquake would certainly overdrive these sensitive instruments in the entire network). In his account of early earthquake engineering, Housner [51] credited John R. Freeman, an eminent engineer, with persuading the then US Secretary of Commerce to authorize a strong-motion program, and, in 1930, the design of an accelerograph for engineering purposes. In a letter to R.R. Martel, Housner's professor at Caltech, Freeman wrote:

*I stated that the data which had been given to structural engineers on acceleration and limits of motion in earthquakes as a basis for their designs were all based on guesswork, that there had never yet been a precise measurement of acceleration made. That of the five seismographs around San Francisco Bay which tried to record the earthquake of 1906 not one was able to tell the truth.*

Strong-motion recordings useful to engineers must be on-scale for damaging earthquakes and, in particular, from instruments located on or near built structures in densely urbanized environments, within about 25 km of the earthquake-rupture zone for sites on rock, or within about 100 km for sites on soft soils. Recordings of motions sufficient to cause damage at sites at greater distances are also of interest for earthquake engineering in areas likely to be affected by major subduction-zone earthquakes and in areas with exceptionally low attenuation rates [11]. In addition, densely-spaced networks of strong-motion recorders are needed to study the large variations in these motions over short distances [26,29].

Although several interesting accelerograms were recorded in southern California in the 1930s and 1940s, most seismologists did not pursue strong-motion monitoring until much later. The 1971 San Fernando earthquake emphatically demonstrated the need for more strong-motion data [9]. Two important programs emerged in the United States – the National Strong-Motion Program (<http://nsmp.wr.usgs.gov/>), and the California Strong Motion Instrumentation Program (<http://docinet3.consrv.ca.gov/csmip/>). However, the budgets for these programs were and continue to be small in comparison to other earthquake programs. High levels of funding for strong-motion monitoring, comparable to that of the GSN and the regional seismic networks, became available in Taiwan in the early 1990s, and in Japan in the mid-1990s. The Consortium of Organizations for Strong-Motion Observation Systems (<http://www.cosmos-eq.org/>) was established recently to promote the acquisition and application of strong-motion data.

### Seismograms and Derived Products

Even before instruments were developed to record seismic waves from earthquakes, many scholars compiled catalogs of earthquake events noted in historical and other documents. Robert Mallet in 1852–1854 published the first extensive earthquake catalog of the world (1606 B.C.–A.D. 1842) totaling 6831 events [79]. Based on this compilation, Mallet prepared the first significant seismicity map of the Earth in 1858. Mallet's map is remarkable in that

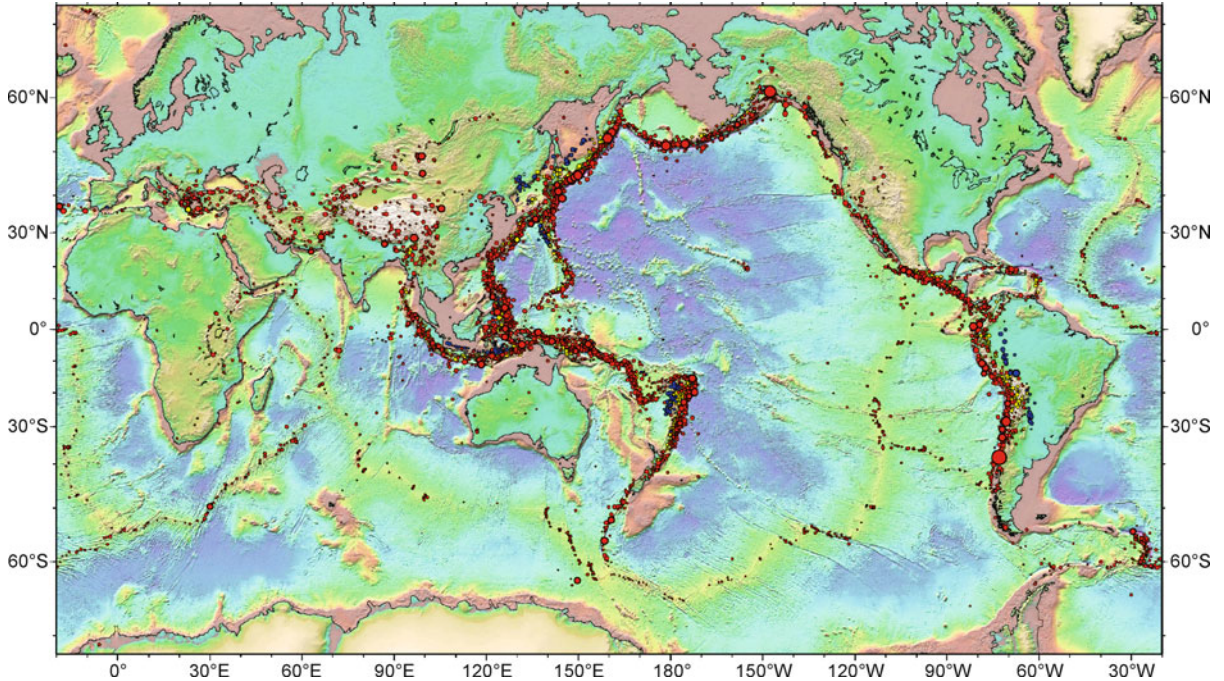

it correctly identifies the major earthquake zones of the Earth excepting for parts of the oceans. Although Mallet's earthquake catalog and similar compilations contain a wealth of information about earthquakes, they were made without the aid of instruments, and thus were subject to the biases of the observers as well as to population distributions. These non-instrumental earthquake catalogs also contain errors because the source materials were commonly incomplete and inconsistent regarding date, time, place names, and reported damage. Ambraseys et al. [8] discusses these difficulties for a regional case and Guidoboni [42] addresses the matter in general.

Today, seismograms are the fundamental data produced by earthquake monitoring. An analyst's first task is to find out when and where the earthquakes occurred, its size, and other characteristics. The accuracy of determining earthquake parameters, as well as the number of parameters used to characterize an earthquake, has progressed along with the availability of seismograms and computers, as well as advances in seismology. In the analog era, earthquake parameters were primarily the origin time, geographical location (epicenter), focal depth, and magnitude. A list of these parameters for earthquakes occurring over some time interval is called an *earthquake catalog*. A useful and common illustration of such results is a map showing the locations of earthquakes by magnitude (a seismicity map). Figure 11 is such a seismicity map for 1900–1999 as prepared by Engdahl and Villaseñor [24]. The map shows that moderate and large earthquakes are concentrated in tectonic active areas while most areas of the Earth are aseismic.

### Earthquake Location

Several methods have been developed to locate earthquakes (i.e., determine origin time, latitude and longitude of the epicenter, and focal depth). Common to most of these methods is the use of arrivals times of initial *P*- and *S*-waves. In particular, Geiger [33] applied the Gauss–Newton method to solve for earthquake location, which is a nonlinear problem, by formulating it as an inverse problem. However, since Geiger's method is computational intensive, it was not practical to apply it for the routine determinations of earthquake hypocenters until the advance of modern computers in the early 1960s.

Before computers became widely available starting in the 1960s, earthquakes were usually located by a manual, graphical method. In any location method, we assume that an earthquake is a point source and its sole parameters are origin time (time of occurrence,  $t_o$ ) and hypocenter position ( $x_o, y_o, z_o$ ). If both *P*- and *S*-arrival

Earthquake Monitoring and Early Warning Systems, Figure 11  
Seismicity of the Earth: 1900–1999 (see [24] for details)

times are available, one may use the time intervals between  $P$ - and  $S$ -waves at each station ( $S$ - $P$  times) and estimates of seismic wave velocities in the Earth to obtain a rough estimate of the epicentral distance,  $D$ , from that station:

$$D = [V_P V_S / (V_P - V_S)](T_S - T_P) \quad (2)$$

where  $V_P$  is the  $P$ -wave velocity,  $V_S$  the  $S$ -wave velocity,  $T_S$  the  $S$ -wave arrival time, and  $T_P$  the  $P$ -wave arrival time. For a typical crustal  $P$ -wave velocity of 6 km/s, and  $V_P/V_S \approx 1.8$ , the distance  $D$  in kilometers is about 7.5 times the  $S$ - $P$  interval measured in seconds. If three or more epicentral distances are available, the epicenter may be placed at the intersection of circles with the stations as centers and the appropriate  $D$  as radii. The intersection will seldom be a point, and its areal extent gives a rough estimate of the uncertainty of the epicenter and hypocentral (focal) depth. In the early days, the focal depth was usually assumed or occasionally determined using a “depth phase” (generally, a ray that travels upward from the hypocenter and reflects back from the Earth’s surface, then arcs through the Earth to reach a distant seismograph).

Although Geiger [33] presented a method for determining the origin time and epicenter, the method can be extended easily to include focal depth. To locate an earth-

quake using a set of arrival times,  $\tau_k$ , from stations at positions  $(x_k, y_k, z_k)$ ,  $k = 1, 2, \dots, m$ , we must assume a model of seismic velocities from which theoretical travel times,  $T_k$  for a trial hypocenter at  $(x^*, y^*, z^*)$  to the stations can be computed. Let us consider a given trial origin time and hypocenter as the trial vector  $\chi^*$  in a four-dimensional Euclidean space:

$$\chi^* = (t^*, x^*, y^*, z^*)^T \quad (3)$$

where the superscript  $T$  ( $^T$ ) denotes the vector transpose. Theoretical arrival time,  $t_k$ , from  $\chi^*$  to the  $k$ -th station is the theoretical travel time,  $T_k$ , plus the trial origin time,  $t^*$ . We now define the arrival time residual at the  $k$ -th station,  $r_k$ , as the difference between the observed and the theoretical arrival times. We may consider this set of station residuals as a vector in an  $m$ -dimensional Euclidean space and write:

$$\mathbf{r} = (r_1(\chi^*), r_2(\chi^*), \dots, r_m(\chi^*))^T. \quad (4)$$

We now apply the least squares method to obtain a set of linear equations solving for an adjustment vector,  $\delta\chi$ :

$$\mathbf{A}^T \mathbf{A} \delta\chi = -\mathbf{A}^T \mathbf{r}, \quad (5)$$

where  $A$  is the Jacobian matrix consisting of partial derivatives of travel time with respect to  $t$ ,  $x$ ,  $y$ , and  $z$ . A detailed derivation of the Geiger method is given by Lee and

Stewart (see, pp 132–134 in [74]). There are many practical difficulties in implementing Geiger’s method for locating earthquakes, as discussed by Lee and Stewart (see, pp 134–139 in [74]). Although standard errors for these earthquake locations can be computed, they are often not meaningful because errors in the measurement of arrival times usually do not obey a Gaussian probability distribution. In recent years, many authors applied various nonlinear methods to locate earthquakes; a review of these methods is given by Lomax et al. ► **Earthquake Location, Direct, Global-Search Methods.**

### Earthquake Magnitude

After an earthquake is located, the next question is: how big was it? The Richter magnitude scale was originally devised to measure the “size” of an earthquake in southern California. Richter [96] defined the local (earthquake) magnitude,  $M_L$ , of an earthquake observed at any particular station to be:

$$M_L = \log A - \log A_0(\Delta) \quad (6)$$

where  $A$  is the maximum amplitude in millimeters as recorded by a Wood–Anderson seismograph for an earthquake at epicentral distance of  $\Delta$  km. The correction factor,  $\log A_0(\Delta)$ , is the maximum amplitude at  $\Delta$  km for a “standard” earthquake. Thus, three arbitrary choices enter into the definition of local magnitude: (1) the use of the Wood–Anderson seismographs, (2) the use of the common logarithm (i. e., the logarithm to the base 10), and (3) the selection of the standard earthquake, whose amplitudes as a function of distance  $\Delta$  are represented by  $A_0(\Delta)$ .

In the 1940s, B. Gutenberg and C.F. Richter extended the local magnitude scale to include more distant earthquakes. Gutenberg [43] defined the surface-wave magnitude,  $M_S$ , as

$$M_S = \log(A/T) - \log A_0(\Delta^\circ) \quad (7)$$

where  $A$  is the maximum combined horizontal ground displacement in micrometers ( $\mu\text{m}$ ) for surface waves with a period of 20 s, and  $-\log A_0$  is tabulated as a function of epicentral distance  $\Delta$  in degrees, in a similar manner to that for the local magnitude’s  $A_0(\Delta)$ . Specifically, surface-wave magnitude is calculated from

$$M_S = \log A + 1.656 \log \Delta + 1.818 \quad (8)$$

using the prominent 20 s period surface waves commonly observed on the two horizontal-component seismograms from earthquakes of shallow focal depth.

Both magnitude scales were derived empirically and have scale-saturation problems, e. g., for very large earthquakes above a certain size the computed magnitudes of a particular type are all about the same. After the pioneering work of Charles F. Richter and Beno Gutenberg, numerous authors have developed alternative magnitude scales, as reviewed recently by Utsu [116] and by Bormann and Saul ► **Earthquake Magnitude.** A current magnitude scale widely accepted as “best” (as having the least saturation problem and being a close match to an earthquake’s total release of stress and strain) is the “moment magnitude”,  $M_W$ , computed from an earthquake’s “moment tensor”.

### Quantification of the Earthquake Source

As pointed out by Kanamori [59], it is not a simple matter to find a single measure of the “size” of an earthquake, simply because earthquakes result from complex physical processes. The elastic rebound theory of Harry F. Reid suggests that earthquakes originate from spontaneous slippage on active faults after a long period of elastic strain accumulation [94]. Faults may be considered the slip surfaces across which discontinuous displacement occurs in the Earth, while the faulting process may be modeled mathematically as a shear dislocation in an elastic medium (see [100], for a review). A shear dislocation (or slip) is equivalent to a double-couple body force [15,81]. The scaling parameter of each component couple of a double-couple body force is its *moment*. Using the equivalence between slip and body forces, Aki [2] introduced the *seismic moment*,  $M_0$ , as:

$$M_0 = \mu \int D(A) dA = \mu s A \quad (9)$$

where  $\mu$  is the shear modulus of the medium,  $A$  is the area of the slipped surface or source area, and  $s$  is the slip  $D(A)$  averaged over the area  $A$ . If an earthquake produces surface faulting, we may estimate its rupture length,  $L$ , and its average slip,  $s$ , from measurement of that faulting. The area  $A$  may be approximated by  $Lh$ , where  $h$  is the focal depth (it is often, but not always, found that the hypocenter is near the bottom of the rupture surface). A reasonable estimate for  $\mu$  is  $3 \times 10^{11}$  dynes/cm<sup>2</sup>. With these quantities, we can estimate the seismic moment from Eq. (9).

Seismic moment also can be estimated independently from seismograms. From dislocation theory, the seismic moment can be related to the far-field seismic displacement recorded by seismographs. For example, Hanks and Wyss [46] showed that

$$M_0 = (\Omega_0/\psi_{\theta\phi}) 4\pi\rho Rv^3 \quad (10)$$

where  $\Omega_0$  is the long-period limit of the displacement spectrum of either  $P$  or  $S$  waves,  $\psi_{\theta\phi}$  is a function accounting for the body-wave radiation pattern,  $\rho$  is the density of the medium,  $R$  is a function accounting for the geometric spreading of body waves, and  $v$  is the body-wave velocity. Similarly, seismic moment can be determined from surface waves or coda waves [2,3].

In 1977, Hiroo Kanamori recognized that a new magnitude scale can be developed using seismic moment ( $M_0$ ) by comparing the earthquake energy and seismic moment relation

$$E_S = (\Delta\sigma/2\mu)M_0, \quad (11)$$

where  $\Delta\sigma$  is the stress drop and  $\mu$  is the shear modulus, with the surface-wave magnitude and energy relation [45]

$$\log E_S = 1.5M_S + 11.8, \quad (12)$$

where  $E_S$  and  $M_0$  are expressed in ergs and dyne-cm, respectively. The average value of  $(\Delta\sigma/2\mu)$  is approximately equal to  $1.0 \times 10^{-4}$ . If we use this value in Eq. (11), we obtain

$$\log M_0 = 1.5M_S + 16.1. \quad (13)$$

It is known that  $M_S$  values saturate for great earthquakes ( $M_0$  about  $10^{29}$  dyne-cm or more) and, therefore, that Eqs. (12) and (13) do not hold for such great earthquakes. If a new moment-magnitude scale using the notation  $M_W$  is defined by

$$\log M_0 = 1.5M_W + 16.1 \quad (14)$$

then  $M_W$  is equivalent to  $M_S$  below saturation and provides a reasonable estimate for great earthquakes without the saturation problem [58]. The subscript letter  $W$  stands for the work at an earthquake fault, but soon  $M_W$  became known as the *moment magnitude*. Determining earthquake magnitude using seismic moment is clearly a better approach because it has a physical basis.

The concept of seismic moment led to the development of moment tensor solutions for quantifying the earthquake source, including its focal mechanism [35,36]; the seismic moment is just the scalar value of the moment tensor. Since the 1980s, Centroid-Moment-Tensor (CMT) solutions have been produced routinely for events with moment magnitudes ( $M_W$ ) greater than about 5.5. The CMT methodology is described by Dziewonski et al. [22] and Dziewonski and Woodhouse [20]; a comprehensive review is given in Dziewonski and Woodhouse [21]. These CMT solutions are published yearly

in the journal *Physics of the Earth and Planetary Interiors*, and the entire database is accessible online. This useful service is now performed by the Global CMT Project (<http://www.globalcmt.org/>), and more than 25,000 moment tensors have been determined for large earthquakes from 1976 to 2007. In the most recent decade, Quick CMT solutions [23] determined in near-real time have been added and are distributed widely via e-mail (<http://www.seismology.harvard.edu/projects/CMT/QuickCMTs/>).

### Limitations of Earthquake Catalogs

In addition to international efforts to catalog earthquakes on a global scale, observatories and government agencies issue more-detailed earthquake catalogs at local, regional, and national scales. However, earthquake catalogs from local to global scales vary greatly in spatial and temporal coverage and in quality, with respect to completeness and accuracy, because of the ongoing evolution of instrumentation, data processing procedures, and agency staff. An earthquake catalog, to be used for research, should have at least the following source parameters: origin time, epicenter (latitude and longitude), focal depth, and magnitude.

The International Seismological Summary and its predecessors provided compilations of arrival times and locations of earthquakes determined manually from about 1900 to 1963. Despite their limitations (notably the lack of magnitude estimates), these materials remain valuable. The first global earthquake catalog that contains both locations and magnitudes was published by Gutenberg and Richter in 1949, and was followed by a second edition in 1954 [44]. This catalog contains over 4,000 earthquakes from 1904 to 1951. Unfortunately, its temporal and spatial coverage is uneven as a result of rapid changes in seismic instrumentation, and of the interference of both World Wars. Nevertheless, the procedures used for earthquake location and magnitude estimation were the same throughout, using the arrival-time and amplitude data available to Gutenberg and Richter during the 1940s and early 1950s.

Since 1964, the International Seismological Centre has performed systematic cataloging of earthquakes worldwide by using computers and more modern seismograph networks. The spatial coverage of this catalog is not complete for some areas of the Earth (especially the oceans) because of the paucity of seismographic stations in such areas. By plotting the cumulative numbers of earthquakes above a certain magnitude versus magnitude, and using Eq. (1), the lower limit of completeness of an earthquake catalog may be estimated – it is the magnitude below which the data deviate below a linear fit to Eq. (1).

A *Centennial Earthquake Catalog* covering ISS- and ISC-reported global earthquakes from 1900–1999 was generated using an improved Earth model that takes into account regional variations in seismic wave velocities in the Earth’s crust and upper mantle [24,118]. Engdahl and Villasenor [24] also compiled existing magnitude data from various authors and suggested preferred values. However, these “preferred magnitudes” were not determined by the same procedures. At present, the Global CMT Project (<http://www.globalcmt.org/>) provides the most complete online source parameters for global earthquakes (with  $M_W > 5.5$ ), including Centroid-Moment-Tensor solutions. Although the CMT catalog starts in 1976, the improved global coverage of modern broadband digital seismographs began only in about 1990.

In summary, earthquake catalogs have been used extensively for earthquake prediction research and seismic hazard assessment since the first such catalog was produced. Reservations have been expressed about the reliability of the results and interpretations from these studies because the catalogs cover too little time and have limitations in completeness and accuracy (both random and systematic). Nevertheless, advances have been made in using earthquake catalogs to (1) study the nature of seismicity (e. g., ► [Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space](#)), (2) investigate earthquake statistics (e. g., ► [Earthquake Occurrence and Mechanisms, Stochastic Models for](#)), (3) forecast earthquakes (e. g., ► [Earthquake Forecasting and Verification](#)), (4) predict earthquakes (e. g., ► [Geo-complexity and Earthquake Prediction](#)), (5) assess seismic hazards and risk, and so forth.

### Earthquake Early Warning (EEW) Systems

With increasing urbanization worldwide, earthquake hazards pose ever greater threats to lives, property, and livelihoods in populated areas near major active faults on land or near offshore subduction zones. Earthquake early-warning systems can be useful tools for reducing the impact of earthquakes, provided that cities are favorably located with respect to earthquake sources and their citizens are properly trained to respond to the warning messages. Recent reviews of earthquake early warning systems may be found in Lee and Espinosa-Aranda [73], Kanamori [61], and Allen [6], as well as a monograph on the subject by Gasparini et al. [31].

Under favorable conditions, an EEW system can forewarn an urban area of impending strong shaking with lead times that range from a few seconds to a few tens of seconds. A lead time is the time interval between issuing

a warning and the arrival of the S-waves, which are the most destructive seismic waves. Even a few seconds of advanced warning is useful for pre-programmed emergency measures at various critical facilities, such as the deceleration of rapid-transit vehicles and high-speed trains, the orderly shutoff of gas pipelines, the controlled shutdown of some high-technological manufacturing operations, the safe-guarding of computer facilities (e. g., disk-head parking), and bringing elevators to a stop at the nearest floor.

### Physical Basis and Limitations of EEW Systems

The physical basis for earthquake early warning is simple: damaging strong ground shaking is caused primarily by shear (S) and subsequent surface waves, both of which travel more slowly than the primary (P) waves, and seismic waves travel much more slowly than electromagnetic signals transmitted by telephone or radio. However, certain physical limitations must be considered, as shown by Fig. 12.

Figure 12 is a plot of the travel time for the P-wave and S-wave as a function of distance from an earthquake. We make the following assumptions about a typical destructive earthquake: (1) focal depth at  $\sim 20$  km, (2) P-wave velocity  $\sim 8$  km/s, and (3) S-wave velocity  $\sim 4.5$  km/s. If an earthquake is located 100 km from

Earthquake Monitoring and Early Warning Systems, Figure 12  
Travel time of P-waves and of S-waves versus distance for a typical earthquake

a city, the *P*-wave arrives at the city after about 13 s, and the *S*-waves in about 22 s (Fig. 12). If we deploy a dense seismic network near the earthquake source area (capable of locating and determining the size of the event in about 10 s), we will have about 3 s to issue the warning before the *P*-wave arrives, and about 12 s before the more destructive *S*-waves and surface waves arrive at the city. We have assumed that it takes negligible time to send a signal from the seismic network to the city via electromagnetic waves, which travel at about one-third the velocity of light or faster (between about 100,000 and 300,000 km/s depending on the method of transmission).

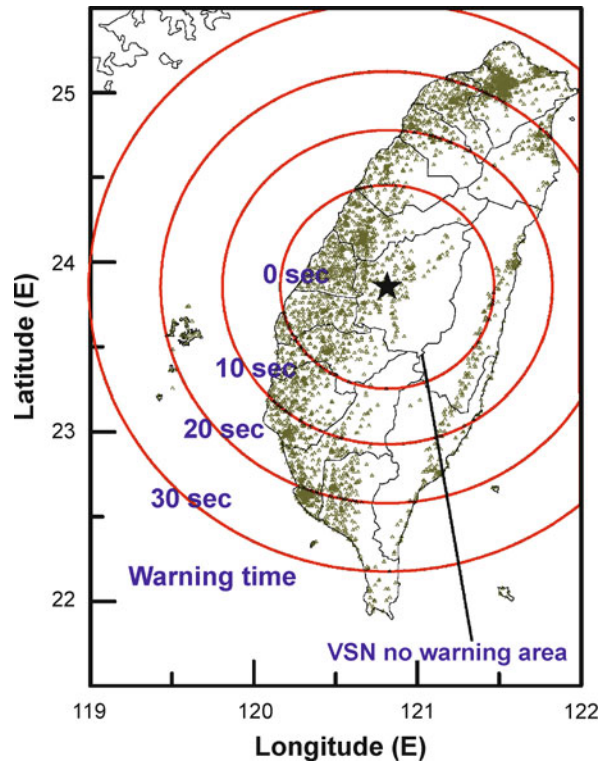

From Fig. 12 it is clear that this strategy may work for earthquakes located at least about 60 km from the urban area. For earthquakes at shorter distances ( $\sim 20$  to  $\sim 60$  km), we must reduce the time needed to detect the event and issue a warning to well under 10 s. This requirement implies that we must deploy a very dense seismic network very close to the fault and estimate the necessary parameters very fast. However, such dense networks are not economical to deploy using existing seismic instruments.

For earthquakes within 20 km of a city, there is little one can do other than installing motion-sensitive automatic shut-off devices at critical facilities (natural gas, for example) and hope that they are either very quick when responding to *S*-waves or are triggered by the onset of the *P*-wave. Normally an earthquake rupture more than  $\sim 100$  km from an urban area does not commonly pose a large threat (seismic waves would be attenuated and spread out farther). There are exceptions caused either by unusual local site conditions, such as Mexico City, or by earthquakes with large rupture zones which therefore radiate efficiently to greater distances.

### Design Considerations for EEW Systems

In the above discussion, we have assumed that one implements an earthquake early warning system with a traditional seismic network. Such EEW systems have limitation as illustrated by Fig. 13, which shows the expected early warning times for a repeat of the 1999 Chi-Chi earthquake. However, Nakamura and his colleagues have been successful in applying a single-station approach [84,99], where seismic signals are recorded and processed locally by the seismograph and an earthquake warning is issued whenever ground motions there exceed some trigger threshold. We will next discuss these two basic approaches, regional versus on-site in designing an earthquake early warning system.

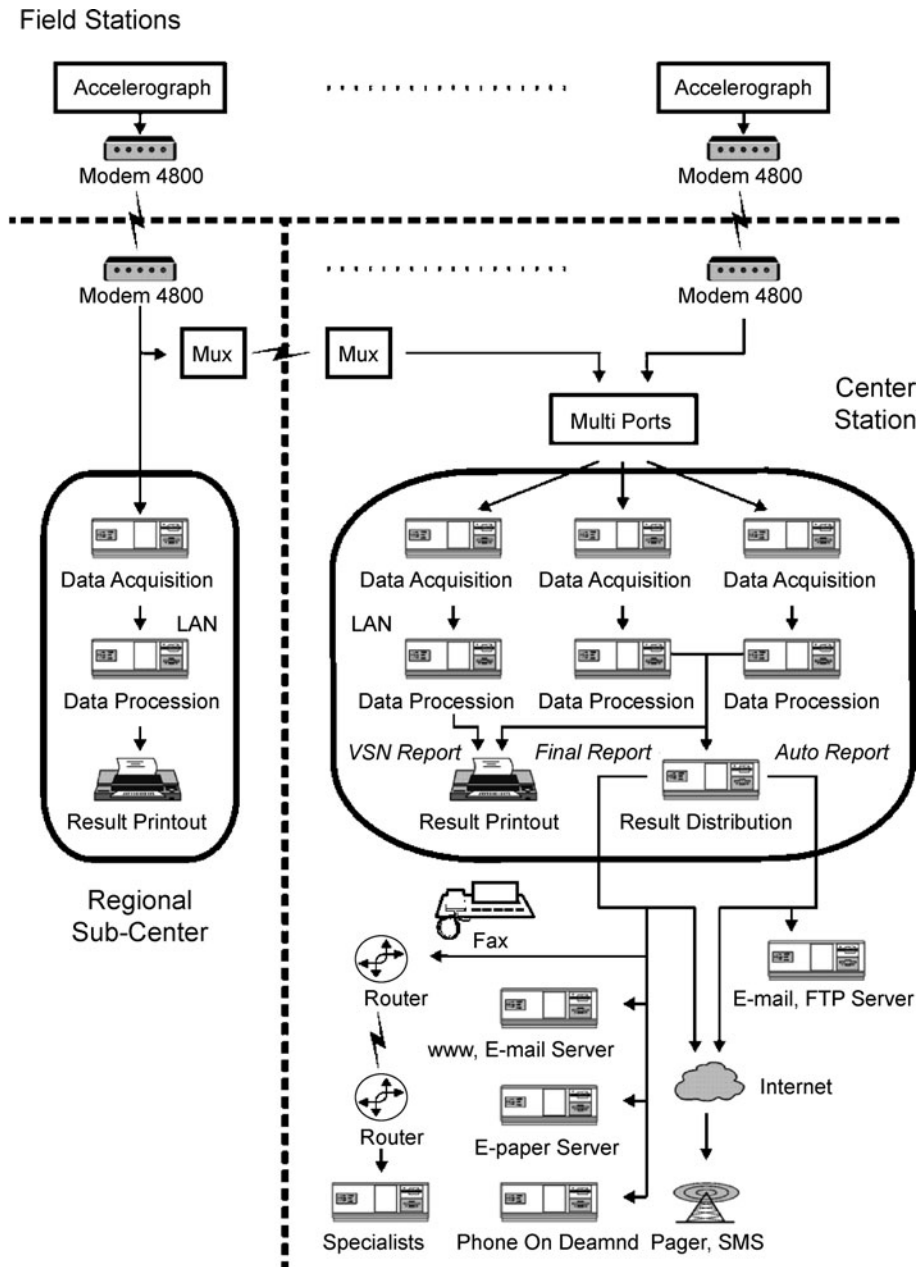

Earthquake early warning capability can be implemented through a rapid reporting system (RRS) from

Earthquake Monitoring and Early Warning Systems, Figure 13 Expected EWS early warning times (indicated by circles) in Taiwan with respect to the occurrence of an event similar to the Chi-Chi earthquake of 20 September 1999. Triangles are locations of elementary schools, which can be regarded as a good indicator for the population density of Taiwan

a traditional network, assuming real-time telemetry into the network's central laboratory. This type of system provides, to populated areas and other sensitive locations, primary event information (hypocenter, magnitude, ground shaking intensities, and potential damage) about one minute after the earthquake begins. The RRS transmits this critical information electronically to emergency response agencies and other interested organizations and to individuals. Each recipient can then take action (some of which may be pre-programmed) shortly after the earthquake begins. Response measures can include the timely dispatch of rescue equipment and emergency supplies to the likely areas of damage.

California's ShakeMap [119,120], Taiwan's CWB, and Japan's JMA systems are typical examples of RSS. In the case of the Taiwan RRS, the CWB has, since 1995, provided intensity maps, hypocenters, and magnitudes within one minute of the occurrence of  $M > 4$  earthquakes [110,128]. This system's reliability, documented by electronic messages to government agencies and scientists,

Earthquake Monitoring and Early Warning Systems, Figure 14  
 A block diagram showing the hardware of the Taiwan Earthquake Rapid Reporting System

has been close to perfect, particularly for large, damaging earthquakes. Figure 14 shows a block diagram of the Taiwan RRS, and details may be found in [128].

Using a set of empirical relationships derived from the large data set collected during the 1999 Chi-Chi earthquake, CWB now releases, within a few minutes of an event, the estimated distributions of PGA and PGV, refined magnitudes, and damage estimates [129]. This near-

real-time damage assessment is useful for rapid post-disaster emergency response and rescue missions.

### Regional Warning Versus Onsite Warning

Two approaches have been adopted for earthquake early warning systems: (1) regional warning, and (2) on-site warning. The first approach relies on traditional seismo-

logical methods in which data from a seismic network are used to locate an earthquake, determine the magnitude, and estimate the ground motion in the region involved. In the second approach, the initial ground motions (mainly *P* wave) observed at a site are used to predict the ensuing ground motions (mainly *S* and surface waves) at the same site.

The regional approach is more comprehensive, but takes a longer time to issue an earthquake warning. An advantage of this approach is that estimates of the timing of expected strong motions throughout the affected region can be predicted more reliably. The early warning system in Taiwan is a typical example and it uses a regional warning system called virtual sub-network approach (VSN) that requires an average of 22 s to determine earthquake parameters with magnitude uncertainties of  $\pm 0.25$ . It provides a warning for areas beyond about 70 km from the epicenter (Fig. 13). This system has been in operation since 2002 with almost no false alarms [129]. With the advancement of new methodology and more dense seismic networks, regional systems are beginning to be able to provide early warnings to areas closer to the earthquake epicenter.

The regional approach has also been used in other areas. The method used in Mexico [25] is slightly different from the traditional seismological method. It is a special case of EEW system due to the relatively large distance (about 300 km in this case) between the earthquake source region (west coast of Central America) and the warning site (Mexico City). However, the warning is conceptually “regional”.

In Japan, various EEW techniques have been developed and deployed by the National Research Institute for Earth Science and Disaster Prevention (NIED) and Japan Meteorological Agency (JMA) since 2000 [49,57,89], **► Tsunami Forecasting and Warning**. In particular, JMA has started sending early warning messages to potential users responsible for emergency responses [50]. The potential users include railway systems, construction companies, and others; and they are familiar with the implications of early warning messages, as well as the technical limitations of EEW [57].

**Some Recent EEW Advances**

Allen and Kanamori [7] proposed the Earthquake Alarm System (ElarmS) to issue an earthquake warning based on information determined from the *P*-wave arrival only. Kanamori [61] extended the method of Nakamura [84] and Allen and Kanamori [7] to determine a period parameter,  $\tau_c$ , from the initial 3 s of the *P* wave.  $\tau_c$  is defined as

Earthquake Monitoring and Early Warning Systems, Figure 15  $\tau_c$  estimates from 20 events using the nearest 6 stations of the K-NET. Small open circles show single-record results, and large circles show event-average values with one standard deviation bars. Solid line shows the least squares fit to the event-average values, and the two dashed lines show the range of one standard deviation

$$\tau_c = 2\pi / \sqrt{r} \tag{15}$$

where

$$r = \frac{\int_0^{\tau_0} \dot{u}^2(t) dt}{\int_0^{\tau_0} u^2(t) dt} \tag{16}$$

$u(t)$  is the ground-motion displacement;  $\tau_0$  is the duration of record used (usually 3 s), and  $\tau_c$ , which represents the size of an earthquake, can be computed from the incoming data sequentially.

The  $\tau_c$  method was used for earthquake early warning in southern California, Taiwan, and Japan by Wu and Kanamori [124,125,126] and Wu et al. [130]. At a given site, the magnitude of an event is estimated from  $\tau_c$  and the peak ground-motion velocity (PGV) from  $P_d$  (the peak amplitude of displacement in the first 3 s after the arrival of the *P* wave). The incoming 3-component signals are recursively converted to ground acceleration, velocity and displacement. The displacements are recursively filtered using an accusal Butterworth high-pass filter with a cut-off frequency of 0.075 Hz, and a *P*-wave threshold trigger is constantly monitored. When a trigger occurs,  $\tau_c$  and  $P_d$  are computed. The relationships between  $\tau_c$  and magnitude ( $M$ ), and  $P_d$  and peak ground velocity (PGV) for

Earthquake Monitoring and Early Warning Systems, Figure 16 Relationship between peak initial displacement amplitude ( $P_d$ ) measurements and peak ground velocity (PGV) for the records with epicentral distances less than 30 km from the epicenter in Southern California (red solid circles), Taiwan (blue diamonds) and Japan (black solid triangles). Solid line shows the least squares fit and the two dashed lines show the range of one standard deviation

southern California, Taiwan, and Japan were investigated. Figure 15 shows a good correlation between  $\tau_c$  and  $M_W$  from the K-NET records in Japan, and Fig. 16 shows the  $P_d$  versus PGV plot for southern California, Taiwan, and Japan. These relationships may be used to detect the occurrence of a large earthquake and provide onsite warning in the area immediately around the station where the onset of strong ground motion is expected within a few seconds after the arrival of the  $P$ -wave. When the station density is high, the onsite warning methods may be applied to data from multiple stations to increase the robustness of an onsite early warning, and to complement the regional warning approach. In an ideal situation, such warnings would be available within 10 s of the origin time of a large earthquake whose subsequent ground motion may last for tens of seconds.

Wu and Zhao [127] investigated the attenuation of  $P_d$  with the hypocentral distance  $R$  in southern California as a function of magnitude  $M$ , and obtained the following relationships:

$$M_{P_d} = 4.748 + 1.371 \times \log(P_d) + 1.883 \times \log(R) \quad (17)$$

and

$$\log(P_d) = -3.463 + 0.729 \times M - 1.374 \times \log(R). \quad (18)$$

For the regional warning approach, when an earthquake location is determined by the  $P$ -wave arrival times at stations close to the epicenter, this relationship can be used to estimate the earthquake magnitude. Their result shows that for earthquakes in southern California the  $P_d$  magnitudes agree with the catalog magnitudes with a standard deviation of 0.18 for events less than magnitude 6.5. They concluded that  $P_d$  is a robust measurement for estimating the magnitudes of earthquakes for regional early warning purposes in southern California. This method has also applied to Italian region by Zollo et al. [132] with a very good performance.

Because the on-site approach is faster than the regional approach, it can provide useful early warning to sites at short distances from the earthquake epicenter where early warning is most needed. Onsite early warning can be generated by either a single station or by a dense array. For a single station operation, signals from  $P$ -waves are used for magnitude and hypocenter determination to predict strong ground shaking. Nakamura [83] first proposed this concept, developed the Urgent Earthquake Detection and Alarm System or UrEDAS [86], and introduced a simple strong-motion index for onsite EEW [85]. However, the reliability of on-site earthquake information is generally less than that obtained with the regional warning system. There currently is a trade-off between warning time and the reliability of the earthquake information. Generally, an information updating procedure is necessary for any EEW system. On-site warning methods can be especially useful in regions where a dense seismic network is deployed.

The Japan Meteorological Agency (JMA) began distribution of earthquake early warning information to the public in October 1, 2007 through several means, such as TV and radio [50] (<http://www.jma.go.jp/jma/en/Activities/eeew.html>). The JMA system was successfully activated during the recent Noto Hanto and Niigata Chuetsu–Oki earthquakes in 2007, and provided accurate information of hypocenter, magnitude, and intensity about 3.8 s after the arrival of  $P$ -waves at nearby stations. The warning message reached sites further than about 30 km from the epicenter as an early warning alert (i. e., information arrived before shaking started at the site). This is a remarkable performance of the system for damaging earthquakes and gives promise of an early warning system as a practical means for earthquake damage mitigation. Although warning alert is most needed within 30 km of the epicenter, it is not feasible with the current density and configuration of the JMA network.

Lawrence and Cochran [68] proposed a collaborative project for rapid earthquake response and early warning by using the accelerometers that are already installed in-

side many laptop computers. Their Quake-Catcher Network (QCN) will employ existing laptops, which have accelerometers already installed, and desktops outfitted with inexpensive (under \$ 50) USB accelerometers to form the world's largest high-density, distributed computing seismic network for monitoring strong ground motions (<http://qcn.stanford.edu/>). By freely distributing the necessary software, anyone having a computer with an Internet connection can join the project as a collaborative member. The Quake-Catcher Network also has the potential to provide better understanding of earthquakes, and the client-based software is also intended to be educational, with instructive material displaying the current seismic signal and/or recent earthquakes in the region. It is an effective way to bring earthquake awareness to students and the general public.

### Future Directions

To be successful, monitoring earthquakes requires large, stable funding over a long period of time. The most direct argument for governments to support long-term earthquake monitoring is to collect scientific data for hazard mitigation. In the past two decades about half a million of

human lives have been lost due to earthquakes, and economic losses from earthquake damage total about \$ 200 billion. Future losses will be even greater as rapid urbanization is taking place worldwide. For example, the recent Japanese Fundamental Seismic Survey and Observation Plan (costing several hundred million US dollars) is a direct response to the economic losses of about \$ 100 billion due to the 1995 Kobe earthquake. In addition to scientific and technological challenges in monitoring earthquakes, seismologists must pay attention to achieve (1) stable long-term funding, (2) effective management and execution, and (3) delivery of useful products to the users.

Seismologists benefit greatly from scientific and technological advances in other fields. For example, Global Positioning Systems (GPS) open a new window for monitoring crustal deformation which is important to understand the driving forces that generate earthquakes (► [GPS: Applications in Crustal Deformation Monitoring](#), ► [Crustal Deformation During the Seismic Cycle, Interpreting Geodetic Observations of](#)). Under the US Earth Scope Program (<http://www.earthscope.org/>) the Plate Boundary Observatory (PBO) is covering the western Northern America and Alaska with a network of high precision GPS and strain-meter stations in order to mea-

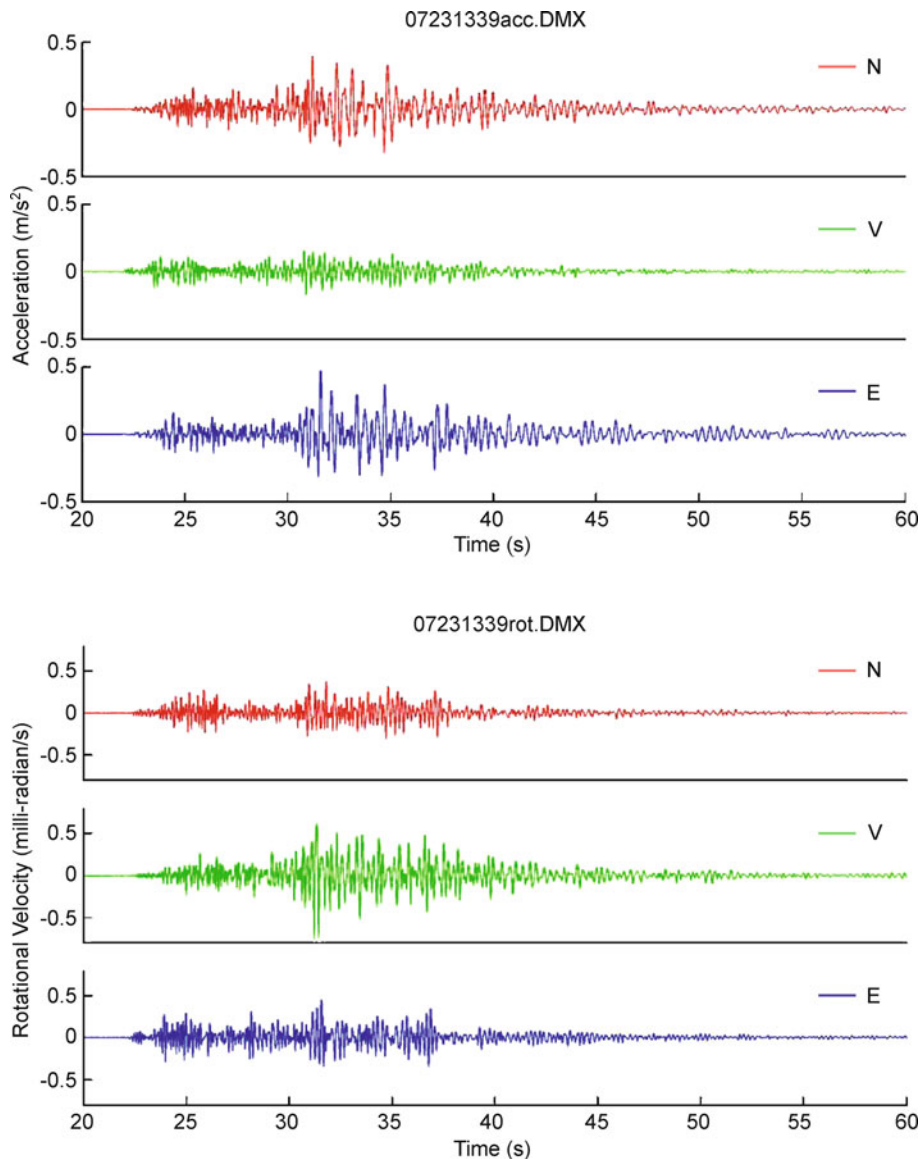

Earthquake Monitoring and Early Warning Systems, Figure 17

Instruments deployed at the HGSD station in eastern Taiwan. Clockwise from the top: (1) A broadband seismometer (Model CMG-3TB) installed at a depth of 100 m), (2) A continuous GPS instrument, (3) A strain-meter installed at a depth of 210 m), (4) A Model Q330 6-channel recorder with an accelerometer (Model EpiSensor) and a short-period seismometer (Model L2), and (5) A Model K2 6-channel accelerometer with an internal accelerometer and a rotational sensor (Model R-1)

sure deformation across the active boundary between the Pacific and North America plates (<http://www.earthscope.org/observatories/pbo>). As the sampling rate of GPS data increases, they can provide time histories of displacement during an earthquake. Monitoring earthquakes with multiple types of instruments and sensors is now increasingly popular, and “integrated” or “super” stations are increasingly common. Figure 17 shows an example of an integrated station (HGSD) in eastern Taiwan. Instruments de-

ployed at the HGSD station in eastern Taiwan include: a broadband seismometer, a continuous GPS instrument, a strain-meter, and a 6-channel accelerograph (Model K2 by Kinemetrics) with an internal accelerometer and a rotational sensor (Model R-1 by eentec). A digital seismogram recorded at the HGSD station from an earthquake ( $M_W = 5.1$ ) of July 23, 2007 at a distance of 34 km is shown in Fig. 18. The importance of rotational seismology and its current status are given in the [Appendix](#).

Earthquake Monitoring and Early Warning Systems, Figure 18

A digital seismogram recorded at the HGSD station from an earthquake ( $M_W = 5.1$ ) of July 23, 2007 at a distance of 34 km. *Top frame:* 3-component translational accelerations. *Bottom frame:* 3-component rotation velocity motions. N = North-South; V = Vertical, and E = East-West

A radically different design of seismographic networks (and earthquake early warning system in particular) is now possible using the “Sensor Network” developed by Intel Research. Intel is working with the academic community and industry collaborators to actively explore the potential of wireless sensor networks. This research is already demonstrating the potential for this new technology to enhance public safety, reduce the cost of doing business, and bring a host of other benefits to business and society ([http://www.intel.com/research/exploratory/wireless\\_sensors.htm](http://www.intel.com/research/exploratory/wireless_sensors.htm)).

It has been very difficult historically to obtain adequate and stable funding for long-term earthquake monitoring, largely because disastrous earthquakes occur infrequently. Since there are many pressing problems facing modern societies, almost all governments react to earthquake (and tsunami) disasters only after the fact, and even then for relatively short periods of time. To advance earthquake prediction research and to develop effective earthquake warning systems will require continuous earthquake monitoring with extensive instrumentations in the near-field for decades and even centuries. Therefore, innovative approaches must be developed and perseverance is needed.

### Acknowledgments

We thank John Evans, Fred Klein, Woody Savage, and Chris Stephens for reviewing the manuscript, their comments and suggestions greatly improved it. We are grateful to Lind Gee and Bob Hutt for information about the Global Seismographic Network (GSN) and for providing a high-resolution graphic file of an up-to-date GSN station map.

### Appendix:

#### A Progress Report on Rotational Seismology

Seismology is based primarily on the observation and modeling of three orthogonal components of translational ground motions. Although effects of rotational motions due to earthquakes have long been observed (e. g., [80]), Richter (see, p. 213 in [97]) stated that:

*Perfectly general motion would also involve rotations about three perpendicular axes, and three more instruments for these. Theory indicates, and observation confirms, that such rotations are negligible.*

However, Richter provided no references for this claim, and the available instruments at that time did not have the sensitivity to measure the very small rotation motions that the classical elasticity theory predicts.

Some theoretical seismologists (e. g., [4,5]) and earthquake engineers have argued for decades that the rotational part of ground motions should also be recorded. It is well known that standard seismometers and accelerometers are profoundly sensitive to rotations, particularly tilt, and therefore subject to rotation-induced errors (see e. g., [39,40,41,93]). The paucity of instrumental observations of rotational ground motions is mainly the result of the fact that, until recently, the rotational sensors did not have sufficient resolution to measure small rotational motions due to earthquakes.

Measurement of rotational motions has implications for: (1) recovering the complete ground-displacement history from seismometer recordings; (2) further constraining earthquake rupture properties; (3) extracting information about subsurface properties; and (4) providing additional ground motion information to engineers for seismic design.

In this Appendix, we will first briefly review elastic wave propagation that is based on the linear elasticity theory of simple homogeneous materials under infinitesimal strain. This theory was developed mostly in the early nineteenth century: the differential equations of the linear elastic theory were first derived by Louis Navier in 1821, and Augustin Cauchy gave his formulation in 1822 that remains virtually unchanged to the present day [103]. From this theory, Simeon Poisson demonstrated in 1828 the existence of longitudinal and transverse elastic waves, and in 1885, Lord Rayleigh confirmed the existence of elastic surface waves. George Green put this theory on a physical basis by introducing the concept of strain energy, and, in 1837, derived the basic equations of elasticity from the principle of energy conservation. In 1897, Richard Oldham first identified these three types of waves in seismograms, and linear elasticity theory has been embedded in seismology ever since.

In the following we summarize recent progress in rotational seismology and the need to include measurements of rotational ground motions in earthquake monitoring. The monograph by Teisseyre et al. [109] provides a useful summary of rotational seismology.

#### Elastic Wave Propagation

The equations of motion for a homogeneous, isotropic, and initially unstressed elastic body may be obtained using the conservation principles of continuum mechanics (e. g., [30]) as

$$\rho \frac{\partial^2 u_i}{\partial t^2} = (\lambda + \mu) \frac{\partial \theta}{\partial x_i} + \mu \nabla^2 u_i, \quad i = 1, 2, 3 \quad (A1)$$

and

$$\theta = \sum_j \partial u_j / \partial x_j \quad (\text{A2})$$

where  $\theta$  is the dilatation,  $\rho$  is the density,  $u_i$  is the  $i$ th component of the displacement vector  $\vec{u}$ ,  $t$  is the time, and  $\lambda$  and  $\mu$  are the elastic constants of the media. Eq. (A1) may be rewritten in vector form as

$$\rho(\partial^2 \vec{u} / \partial t^2) = (\lambda + \mu) \nabla(\nabla \cdot \vec{u}) + \mu \nabla^2 \vec{u}. \quad (\text{A3})$$

If we differentiate both sides of Eq. (A1) with respect to  $x_i$ , sum over the three components, and bring  $\rho$  to the right-hand side, we obtain

$$\partial^2 \theta / \partial t^2 = [(\lambda + 2\mu) / \rho] \nabla^2 \theta. \quad (\text{A4})$$

If we apply the curl operator ( $\nabla \times$ ) to both sides of Eq. (A3), and note that

$$\nabla \cdot (\nabla \times \vec{u}) = 0 \quad (\text{A5})$$

we obtain

$$\partial^2 (\nabla \times \vec{u}) / \partial t^2 = (\mu / \rho) \nabla^2 (\nabla \times \vec{u}). \quad (\text{A6})$$

Now Eqs. (A4) and (A6) are in the form of the classical wave equation

$$\partial^2 \Psi / \partial t^2 = v^2 \nabla^2 \Psi, \quad (\text{A7})$$

where  $\Psi$  is the wave potential, and  $v$  is the wave-propagation velocity (a pseudovector; wave slowness is a proper vector). Thus a dilatational disturbance  $\theta$  (or a compressional wave) may be transmitted through a homogenous elastic body with a velocity  $V_p$  where

$$V_p = \sqrt{[(\lambda + 2\mu) / \rho]} \quad (\text{A8})$$

according to Eq. (A4), and a rotational disturbance  $\nabla \times \vec{u}$  (or a shear wave) may be transmitted with a wave velocity  $V_s$  where

$$V_s = \sqrt{\mu / \rho} \quad (\text{A9})$$

according to Eq. (A6). In seismology, and for historical reasons, these two types of waves are called the primary ( $P$ ) and the secondary ( $S$ ) waves, respectively.

For a heterogeneous, isotropic, and elastic medium, the equation of motion is more complex than Eq. (A3), and is given by Karal and Keller [65] as

$$\begin{aligned} \rho(\partial^2 \vec{u} / \partial t^2) &= (\lambda + \mu) \nabla(\nabla \cdot \vec{u}) + \mu \nabla^2 \vec{u} \\ &+ \nabla \lambda (\nabla \cdot \vec{u}) + \nabla \mu \times (\nabla \times \vec{u}) + 2(\nabla \mu \cdot \nabla) \vec{u}. \end{aligned} \quad (\text{A10})$$

Furthermore, the compressional wave motion is no longer purely longitudinal, and the shear wave motion is no longer purely transverse. A review of seismic wave propagation and imaging in complex media may be found in the entry by Igel et al. ► [Seismic Wave Propagation in Media with Complex Geometries, Simulation of.](#)

A significant portion of seismological research is based on the solution of the elastic wave equations with the appropriate initial and boundary conditions. However, explicit and unique solutions are rare, except for a few simple problems. One approach is to transform the wave equation to the eikonal equation and seek solutions in terms of wave fronts and rays that are valid at high frequencies. Another approach is to develop through specific boundary conditions a solution in terms of normal modes [77]. Although ray theory is only an approximation [17], the classic work of Jeffreys and Bullen, and Gutenberg used it to determine Earth structure and locate earthquakes that occurred in the first half of the 20th century. It remains a principal tool used by seismologists even today. Impressive developments in normal mode and surface wave studies (in both theory and observation) started in the second half of the 20th century, leading to realistic quantification of earthquakes using moment tensor methodology [21].

### Rotational Ground Motions

Rotations in ground motion and in structural responses have been deduced indirectly from accelerometer arrays, but such estimates are valid only for long wavelengths compared to the distances between sensors (e.g., [16,34,52,88,90,104]). The rotational components of ground motion have also been estimated theoretically using kinematic source models and linear elastodynamic theory of wave propagation in elastic solids [14,69,70,111].

In the past decade, rotational motions from teleseismic and small local earthquakes were also successfully recorded by sensitive rotational sensors, in Japan, Poland, Germany, New Zealand, and Taiwan (e.g., [53,55,56,105,106,107,108]). The observations in Japan and Taiwan show that the amplitudes of rotations can be *one to two orders of magnitude greater than expected* from the classical linear theory. Theoretical work has also suggested that, in granular materials or cracked continua, asymmetries of the stress and strain fields can create rotations in addition to those predicted by the classical elastodynamic theory for a perfect continuum (► [Earthquake Source: Asymmetry and Rotation Effects](#)).

Because of lack of instrumentation, rotational motions have not yet been recorded in the near-field (within ~ 25 km of fault ruptures) of strong earthquakes (magnitude

> 6.5), where the discrepancy between observations and theoretical predictions may be the largest. Recording such ground motions will require extensive seismic instrumentation along some well-chosen active faults and luck. To this end, several seismologists have been advocating such measurements, and a current deployment in southwestern Taiwan by its Central Weather Bureau is designed to “capture” a repeat of the 1906 Meishan earthquake (magnitude 7.1) with both translational and rotational instruments.

Rotations in structural response, and the contributions to the response from the rotational components of the ground motion, have also been of interest for many decades (e.g., [78,87,98]). Recent reviews on rotational motions in seismology and on the effects of the rotational components of ground motion on structures can be found, for examples, in Cochard et al. [18] and Pillet and Virieux [93], and Trifunac [112], respectively.

### Growing Interest – The IWGoRS

Various factors have led to spontaneous organization within the scientific and engineering communities interested in rotational motions. Such factors include: the growing number of successful direct measurements of rotational ground motions (e.g., by ring laser gyros, fiber optic gyros, and sensors based on electro-chemical technology); increasing awareness about the usefulness of the information they provide (e.g., in constraining the earthquake rupture properties, extracting information about subsurface properties, and about deformation of structures during seismic and other excitation); and a greater appreciation for the limitations on information that can be extracted from the translational sensors due to their sensitivity to rotational motions e.g., computation of permanent displacements from accelerograms (e.g., [13,39,40,41,93,113]).

A small workshop on Rotational Seismology was organized by W.H.K. Lee, K. Hudnut, and J.R. Evans of the USGS on 16 February 2006 in response to grassroots interest. It was held at the USGS offices in Menlo Park and in Pasadena, California, with about 30 participants from about a dozen institutions participating via teleconferencing and telephone [27]. This event led to the formation of the *International Working Group on Rotational Seismology* in 2006, inaugurated at a luncheon during the AGU 2006 Fall Meeting in San Francisco.

The *International Working Group on Rotational Seismology* (IWGoRS) aims to promote investigations of rotational motions and their implications, and the sharing of experience, data, software and results in an open web-based environment (<http://www.rotational-seismology.org>).

It consists of volunteers and has no official status. H. Igel and W.H.K. Lee currently serve as “co-organizers”. Its charter is accessible on the IWGoRS web site. The Working Group has a number of active members leading task groups that focus on the organization of workshops and scientific projects, including: testing and verifying rotational sensors, broadband observations with ring laser systems, and developing a field laboratory for rotational motions. The IWGoRS web site also contains the presentations and posters from related meetings, and eventually will provide access to rotational data from many sources.

The IWGoRS organized a special session on *Rotational Motions in Seismology*, convened by H. Igel, W.H.K. Lee, and M. Todorovska during the 2006 AGU Fall Meeting [76]. The goal of that session was to discuss rotational sensors, observations, modeling, theoretical aspects, and potential applications of rotational ground motions. A total of 21 papers were submitted for this session, and over 100 individuals attended the oral session.

The large attendance at this session reflected common interests in rotational motions from a wide range of geophysical disciplines, including strong-motion seismology, exploration geophysics, broadband seismology, earthquake engineering, earthquake physics, seismic instrumentation, seismic hazards, geodesy, and astrophysics, thus confirming the timeliness of IWGoRS. It became apparent that to establish an effective international collaboration within the IWGoRS, a larger workshop was needed to allow sufficient time to discuss the many issues of interest, and to draft research plans for rotational seismology and engineering applications.

### First International Workshop

The *First International Workshop on Rotational Seismology and Engineering Applications* was held in Menlo Park, California, on 18–19 September 2007. This workshop was hosted by the US Geological Survey (USGS), which recognized this topic as a new research frontier for enabling a better understanding of the earthquake process and for the reduction of seismic hazards. The technical program consisted of three presentation sessions: plenary (4 papers) and oral (6 papers) held during the first day, and poster (30 papers) held during the morning of the second day. A post-workshop session was held on the morning of September 20, in which scientists of the Laser Interferometer Gravitational-wave Observatory (LIGO) presented their work on seismic isolation of their ultra-high precision facility, which requires very accurate recording of translational and rotational components of ground motions (3 papers). Proceedings of this Workshop were re-

leased in Lee et al. [75] with a DVD disc that contains all the presentation files and supplementary information.

One afternoon of the workshop was devoted to in-depth discussions on the key outstanding issues and future directions. The participants could join one of five panels on the following topics: (1) theoretical studies of rotational motions (chaired by L. Knopoff), (2) measuring far-field rotational motions (chaired by H. Igel), (3) measuring near-field rotational motions (chaired by T.L. Teng), (4) engineering applications of rotational motions (chaired by M.D. Trifunac), and (5) instrument design and testing (chaired by J.R. Evans). The panel reports on key issues and unsolved problems, and on research strategies and plans, can be found in Appendices 2.1 through 2.5 in Lee et al. [75]. Following the in-depth group discussions, the panel chairs reported on the group discussions in a common session, with further discussions among all the participants.

## Discussions

Since rotational ground motions may play a significant role in the near-field of earthquakes, rotational seismology has emerged as a new frontier of research. During the Workshop discussions, L. Knopoff asked: Is there a quadratic rotation-energy relation, in the spirit of Green's strain-energy relation, coupled to it or independent of it? Can we write a rotation-torque formula analogous to Hooke's law for linear elasticity in the form

$$L_{ij} = d_{ijkl}\omega_{kl} \quad (\text{A11})$$

where  $\omega_{kl}$  is the rotation,

$$\omega_{kl} = \frac{1}{2}(u_{k,l} - u_{l,k}). \quad (\text{A12})$$

$L_{ij}$  is the torque density; and  $d_{ijkl}$  are the coefficients of rotational elasticity? How are the  $d$ 's related to the usual  $c$ 's of elasticity? If we define the rotation vector as

$$\vec{\Omega} = \frac{1}{2}(\nabla \times \vec{u}) \quad (\text{A13})$$

we obtain

$$-\nabla_s^2 \nabla \times (\nabla \times \vec{\Omega}) = \partial^2 \vec{\Omega} / \partial t^2 - \frac{1}{2} \rho^{-1} (\nabla \times \vec{f}) \quad (\text{A14})$$

where the torque density is  $\nabla \times \vec{f}$ ,  $\vec{f}$  is the body force density, and  $\rho$  is density of the medium. This shows that rotational waves propagate with S-wave velocity and that it may be possible to store torques. Eq. (15) is essentially an extension using the classical elasticity theory.

Lakes [67] pointed out that the behavior of solids can be represented by a variety of continuum theories. In particular, the elasticity theory of the Cosserat brothers [19]

incorporates (1) a local rotation of points as well as the translation motion assumed in the classical theory, and (2) a couple stress (a torque per unit area) as well as the force stress (force per unit area). In the constitutive equation for the classical elasticity theory, there are two independent elastic constants, whereas for the Cosserat elastic theory there are six. Lakes (personal communication, 2007) advocates that there is substantial potential for using generalized continuum theories in geo-mechanics, and any theory must have a strong link with experiment (to determine the constants in the constitutive equation) and with physical reality.

Indeed some steps towards better understandings of rotational motions have taken place. For example, Twiss et al. [114] argued that brittle deformation of the Earth's crust (► **Brittle Tectonics: A Non-linear Dynamical System**) involving block rotations is comparable to the deformation of a granular material, with fault blocks acting like the grains. They realized the inadequacy of classical continuum mechanics and applied the Cosserat or micropolar continuum theory to take into account two separate scales of motions: macro-motion (large-scale average motion composed of macrostrain rate and macrospin), and micro-motion (local motion composed of microspin). A theoretical link is then established between the kinematics of crustal deformation involving block rotations and the effects on the seismic moment tensor and focal mechanism solutions.

Recognizing that rotational seismology is an emerging field, the *Bulletin of Seismological Society of America* will be publishing in 2009 a special issue under the guest editorship of W.H.K. Lee, M. Çelebi, M.I. Todorovska, and H. Igel.

**Network or graph** A network (or a graph) [28] consists of vertices (or nodes) and edges (or links) connecting them. In general, a network contains loops (i. e., edges with both ends attached to the same vertices) and multiple edges (i. e., edges more than one that connect two different vertices). If edges have their directions, such a network is called directed. A simple graph is a network, in which loops are removed and each multiple edge is replaced by a single edge. In a stochastic network, each connection is inherently probabilistic. A classical random graph is a simple example, in which each two vertices are connected by an edge with probability  $p$  and unconnected with probability  $1 - p$  ( $0 < p < 1$ ).

**Connectivity distribution or degree distribution** The connectivity distribution (or the degree distribution),  $P(k)$ , is the probability of finding vertices with  $k$  edges in a stochastic network. In a directed network, the number of incoming/outgoing edges is called the in-degree/out-degree. Connectivity of a classical random graph obeys the Poissonian distribution in the limit of the large number of vertex [11,14,20],  $P(k) = e^{-\lambda} \lambda^k / k!$  ( $\lambda$ : a positive parameter,  $k = 0, 1, 2, \dots$ ), whereas a scale-free network [11,12,14,20]

has a power-law shape,  $P(k) \sim k^{-\gamma}$  ( $\gamma$ : a positive exponent), for large  $k$ .

**Preferential attachment rule** This is a concept relevant to a growing network, in which the number of vertices increases. Preferential attachment [11,12,14,20] implies that a newly created vertex tends to link to pre-existing vertices with the probability  $\Pi(k_i) = k_i / \sum_j k_j$ , where  $k_i$  stands for the connectivity of the  $i$ th vertex. That is, the larger the connectivity of a vertex is, the higher the probability of getting linked to a new vertex is.

**Clustering coefficient** The clustering coefficient [27] is a quantity characterizing an undirected simple graph. It quantifies the adjacency of two neighboring vertices of a given vertex, i. e., the tendency of two neighboring vertices of a given vertex to be connected to each other. Mathematically, it is defined as follows. Assume the  $i$ th vertex to have  $k_i$  neighboring vertices. There can exist at most  $k_i(k_i - 1)/2$  edges between the neighbors. Define  $c_i$  as the ratio

$$c_i = \frac{\text{actual number of edges between the neighbors of the } i\text{th vertex}}{k_i(k_i - 1)/2} . \quad (1)$$

Then, the clustering coefficient is given by the average of this quantity over the network:

$$C = \frac{1}{N} \sum_{i=1}^N c_i , \quad (2)$$

where  $N$  is the total number of vertices contained in the network. The value of the clustering coefficient of a random graph,  $C_{\text{random}}$ , is much smaller than unity, whereas a small-world network has a large value of  $C$  which is much larger than  $C_{\text{random}}$ .

**Hierarchical organization** Many complex networks are structurally modular, that is, they are composed of groups of vertices that are highly interconnected to each other but weakly connected to outside groups. This hierarchical structure [22] can conveniently be characterized by the clustering coefficient at each value of connectivity,  $c(k)$ , which is defined by

$$c(k) = \frac{1}{NP_{SG}(k)} \sum_{i=1}^N c_i \delta_{k_i, k} , \quad (3)$$

where  $c_i$  is given by (1),  $N$  the total number of vertices, and  $P_{SG}(k)$  the connectivity distribution of an undirected simple graph. Its average is the clustering coefficient in (2):  $C = \sum_k c(k)P_{SG}(k)$ . A network is said to

be hierarchically organized if  $c(k)$  varies with respect to  $k$ , typically due to a power law,  $c(k) \sim k^{-\beta}$ , with a positive exponent  $\beta$ .

**Assortative mixing and disassortative mixing** Consider the conditional probability,  $P(k'|k)$ , of finding a vertex with connectivity  $k'$  linked to a given vertex with connectivity  $k$ . Then, the nearest-neighbor average connectivity of vertices with connectivity  $k$  is defined by [20,21,26]

$$\bar{k}_{nn}(k) = \sum_{k'} k' P(k'|k). \quad (4)$$

If  $\bar{k}_{nn}(k)$  increases/decreases with respect to  $k$ , mixing is termed assortative/disassortative. A simple model of growth with preferential attachment is known to possess no mixing. That is,  $\bar{k}_{nn}(k)$  does not depend on  $k$ . The above-mentioned linking tendency can be quantified by the correlation coefficient [17] defined as follows. Let  $e_{kl}(= e_{lk})$  be the joint probability distribution for an edge to link with a vertex with connectivity  $k$  at one end and a vertex with connectivity  $l$  at the other. Calculate its marginal,  $q_k = \sum_l e_{kl}$ . Then, the correlation coefficient is given by

$$r = \frac{1}{\sigma_q^2} \sum_{k,l} kl (e_{kl} - q_k q_l), \quad (5)$$

where  $\sigma_q^2 = \sum_k k^2 q_k - (\sum_k k q_k)^2$  stands for the variance of  $q_k$ .  $r \in [-1, 1]$ , and if  $r$  is positive/negative, mixing is assortative/disassortative [17,20].

### Definition of the Subject

Complexity is an emergent collective property, which is hardly understood by the traditional approach in natural science based on reductionism. Correlation between elements in a complex system is strong, no matter how largely they are separated both spatially and temporally, therefore it is essential to treat such a system in a holistic manner, in general.

Although it is generally assumed that seismicity is an example of complex phenomena, it is actually nontrivial to see how and in what sense it is complex. This point may also be related to the question of primary importance of why it is so difficult to predict earthquakes.

Development of the theory of complex networks turns out to offer a peculiar perspective on this point. Construction of a complex earthquake network proposed here consists of mapping seismic data to a growing stochastic graph. This graph, or network, turns out to exhibit a number of remarkable behaviors both physically and mathematically, which are in common with many other complex

systems. The scale-free and small-world natures are typical examples. In this way, one will be able to obtain a novel viewpoint of seismicity.

### Introduction

Seismicity is a field-theoretical phenomenon. Released energy of each earthquake may be regarded as a field amplitude defined at a discrete spacetime point. However, in contrast to a familiar field theory such as the electromagnetic theory, both amplitudes and locations are intrinsically probabilistic. The fault distribution may geometrically be fractal [18], and the stress distribution superposed upon it often has a complex landscape. Accordingly, seismicity is characterized by extremely rich phenomenology, which attracts physicists' attention from the viewpoint of science of complex systems.

There are at least two celebrated empirical laws known in seismology. One is the Gutenberg–Richter law [16], which states that the frequency of earthquakes obeys a power law with respect to released energy. This power-law nature makes it difficult or even meaningless to statistically distinguish earthquakes by their values of magnitude because of the absence of typical energy scales. The other is the Omori law [19], which states that the rate of the frequency of aftershocks following a main shock algebraically decays with respect to time elapsed from the main shock. This slow relaxation reminds one of complex glassy dynamics [13]. Such a viewpoint is supported by the discovery of the aging phenomenon and the scaling law for aftershocks [2].

Another point, which seems less noticed, is that correlation of two successive events is strong, no matter how large their spatial separation is. There is, in fact, an observation [23] that an earthquake can be triggered by a fore-going one more than 1000 km away. The reason why two successive events are indivisibly related can also be found in another observation [3,6] that both spatial distance and time interval between two successive events obey the  $q$ -exponential distributions in nonextensive statistics [1,15,24], which offers a statistical-mechanical framework for describing complex systems. Thus, the correlation length can be enormously large and long-wave-length modes of seismic waves play an important role. This has a strong similarity to phase transitions and critical phenomena. Accordingly, it may not be appropriate to use spatial windows in analysis of seismicity. Furthermore, all of the data in a relevant area (ideally the whole globe, though still not satisfactorily available) should be treated based on the nonreductionistic standpoint.

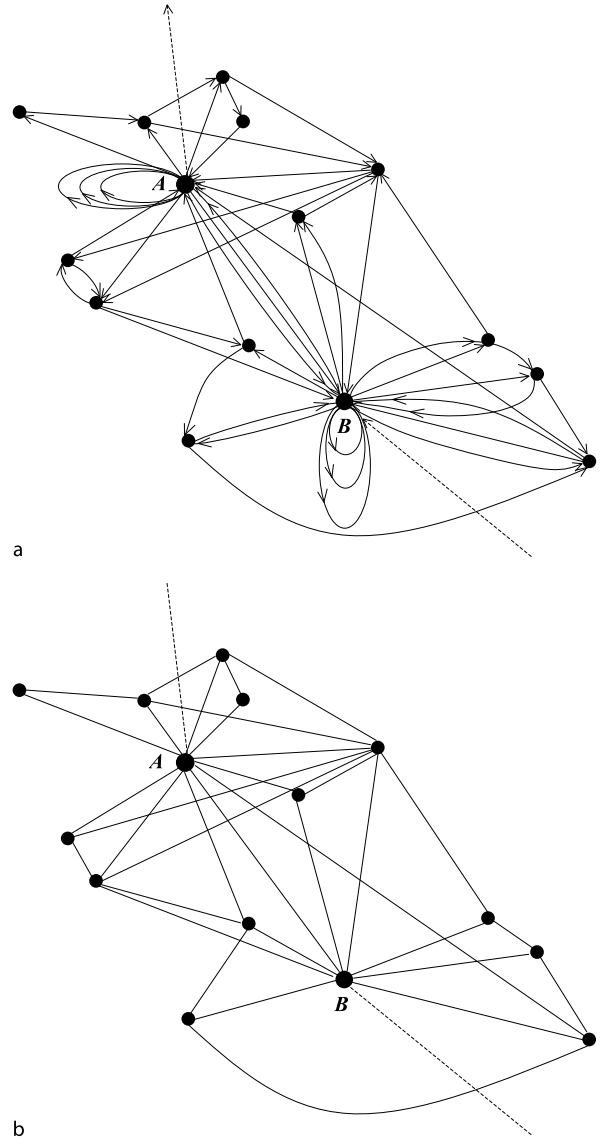

The network approach is a powerful tool for analyzing kinematical and dynamical structures of complex systems in a holistic manner. Such a concept was introduced to seismology by the present authors in 2004 [4] in order to represent complexity of seismicity. The procedure described in Sect. “Construction of an Earthquake Network” allows one to map a seismic time series to a growing stochastic network in an unambiguous way. Vertices and edges of such a network correspond to coarse-grained events and event-event correlations, respectively. Yet unknown microscopic dynamics governing event-event correlations and fault-fault interactions are replaced by these edges. Global physical properties of seismicity can then be explored by examining its geometric (e. g., topological etc.) and dynamical features. It turns out that earthquake networks have a number of intriguing properties, some of which are shared by many other natural as well as artificial systems including metabolic networks, food webs, the Internet, the world-wide web, and so on [11,14,20]. This, in turn, enables seismologists to study seismicity in analogy with such relatively better understood complex systems. Thus, the network approach offers a novel way of analyzing seismic time series and casts fresh light on the physics of earthquakes.

In this article, only the data taken from California is utilized. However, it has been ascertained that the laws and trends discussed here are universal and hold also in other geographical regions including Japan.

### Construction of an Earthquake Network

An earthquake network is constructed as follows [4]. A geographical region under consideration is divided into small cubic cells. A cell is regarded as a vertex if earthquakes with any values of magnitude above a certain detection threshold occurred therein. Two successive events define an edge between two vertices. If they occur in the same cell, a loop is attached to that vertex. This procedure enables one to map a given interval of the seismic data to a growing probabilistic graph, which is referred to as an earthquake network (see Fig. 1a).

Several comments are in order. Firstly, this construction contains a single parameter: cell size, which is a scale of coarse graining. Once cell size is fixed, an earthquake network is unambiguously defined. However, since there exist no a priori operational rule to determine cell size, it is important to notice how the properties of an earthquake network depend on this parameter. Secondly, as mentioned in Sect. “Introduction”, edges and loops efficiently represent event-event correlation. Thirdly, an earthquake network is a directed graph in its nature. Directedness does

Earthquake Networks, Complex, Figure 1

**a** A schematic description of earthquake network. The *dashed lines* correspond to the initial and final events. The vertices, *A* and *B*, contain main shocks and play roles of hubs of the network. **b** The undirected simple graph reduced from the network in **a**.

not bring any difficulties to statistical analysis of connectivity (degree, i. e., the number of edges attached to the vertex under consideration) since, by construction, the in-degree and out-degree are identical for each vertex except the initial and final vertices in analysis. Therefore, the in-degree and out-degree are not distinguished from each other in the analysis of the connectivity distribution (see Sections “Scale-free Nature of Earthquake Network”

and “Mixing Property”). However, directedness becomes essential when the path length (i. e., the number of edges) between a pair of connected vertices, i. e., the degree of separation between the pair, is considered. This point is explicitly discussed in the analysis of the period distribution in Sect. “Period Distribution”. Finally, a full directed earthquake network has to be reduced to a simple undirected graph, when its small-worldness and hierarchical structure are examined (see Sections “Small-World Nature of Earthquake Network” and “Hierarchical Structure”). There, loops are removed and each multiple edge is replaced by a single edge (see Fig. 1b). The path length in this case is the smallest value among the possible numbers of edges connecting a pair of vertices.

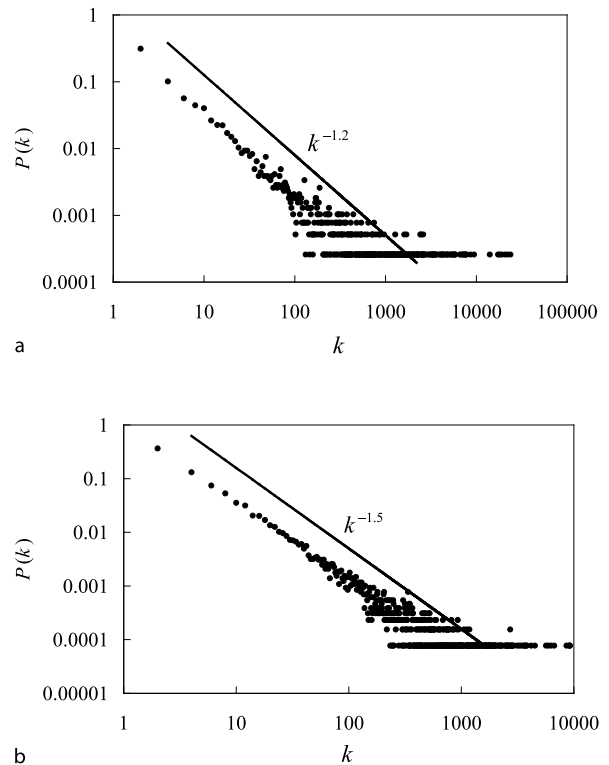

**Scale-free Nature of Earthquake Network**

An earthquake network contains some special vertices which have large values of connectivity. Such “hubs” turn out to correspond to cells with main shocks. This is due to a striking fact discovered from real data analysis that aftershocks associated with a main shock tend to return to the locus of the main shock, geographically. This is the primary reason why a vertex containing a main shock becomes a hub. The situation is analogous to the preferential attachment rule for a growing network [11,14,20]. According to this rule, a newly created vertex tends to be connected to the (already existing)  $i$ th vertex with connectivity  $k_i$  with probability,  $\Pi(k_i) = k_i / \sum_j k_j$ . It can generate a scale-free network characterized by the power-law connectivity distribution [11,12]:

$$P(k) \sim k^{-\gamma}, \tag{6}$$

where  $\gamma$  is a positive exponent.

In Fig. 2, the connectivity distribution of the full earthquake network with loops and multiple edges is presented [4]. From it, one appreciates that the earthquake network in fact possesses connectivity of the form in (6) and is therefore scale-free. The smaller the cell size is, the larger the exponent,  $\gamma$ , is, since the number of vertices with large values of connectivity decreases as cell size becomes smaller. The scale-free nature may be interpreted as follows. As mentioned above, aftershocks associated with a main shock tend to be connected to the vertex of the main shock, satisfying the preferential attachment rule. On the other hand, the Gutenberg–Richter law states that frequency of earthquakes decays slowly as a power law with respect to released energy. This implies that there appear to be quite a few giant components, and accordingly the network becomes highly inhomogeneous.

Earthquake Networks, Complex, Figure 2  
 The log-log plots of the connectivity distributions of the earthquake network constructed from the seismic data taken in California [the Southern California Earthquake Data Center (<http://www.data.scec.org/>)]. The time interval analyzed is between 00:25:8.58 on January 1, 1984 and 22:21:52.09 on December 31, 2003. The region covered is 29°06.00’N–38°59.76’N latitude and 113°06.00’W–122°55.59’W longitude with the maximum depth 175.99 km. The total number of events is 367 613. The data contains no threshold for magnitude (but “quarry blasts” are excluded from the analysis). Two different values of cell size are examined: a 10 km × 10 km × 10 km and b 5 km × 5 km × 5 km. All quantities are dimensionless.

**Small-World Nature of Earthquake Network**

The small-world nature is an important aspect of complex networks. It shows how a complex network is different from both regular and classical random graphs [27]. A small-world network resides in-between regularity and randomness, analogous to the edge of chaos in nonlinear dynamics.

To study the small-world nature of an earthquake network, a full network has to be reduced to a simple undirected graph: that is, loops are removed and each multiple edge is replaced by a single edge (see Fig. 1b). This is because in the small-world picture one is concerned only with simple linking pattern of vertices.

Earthquake Networks, Complex, Table 1

The small-world properties of the undirected simple earthquake network. The values of the number of vertices,  $N$ , the clustering coefficient,  $C$ , (compared with those of the classical random graphs,  $C_{\text{random}}$ ) and the average path length,  $L$  are presented. The data employed is the same as that in Fig. 2.

Cell size	10 km × 10 km × 10 km	5 km × 5 km × 5 km
Number of vertices	$N = 3869$	$N = 12913$
Clustering coefficient	$C = 0.630$ ( $C_{\text{random}} = 0.014$ )	$C = 0.317$ ( $C_{\text{random}} = 0.003$ )
Average path length	$L = 2.526$	$L = 2.905$

A small-world network is characterized by a large value of the clustering coefficient in (2) and a small value of the average path length [27]. The clustering coefficient quantifies the tendency of two neighboring vertices of a given vertex to be connected to each other. A small-world network has a large value of the clustering coefficient, whereas the value for the classical random graph is very small [11,14,20,27]:  $C_{\text{random}} = \langle k \rangle / N \ll 1$ , where  $N$  and  $\langle k \rangle$  are the total number of vertices and the average value of connectivity, respectively.

In Table 1, the results are presented for the clustering coefficient and the average path length [5,9]. One finds that the values of the clustering coefficient are in fact much larger than those of the classical random graphs and the average path length is short. Thus, the earthquake network sportant features of small-world network.

### Hierarchical Structure

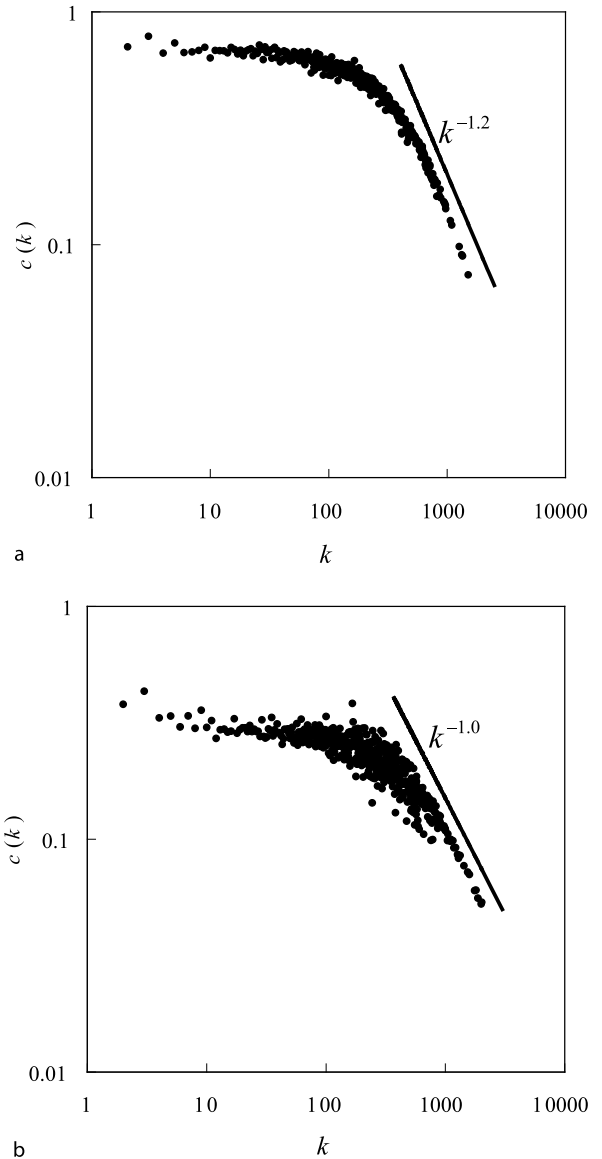

As seen above, seismicity generates a scale-freeexity of an earthquake network further, one may examine if it is hierarchically organized [8]. The hierarchical structure can be revealed by analyzing the clustering coefficient as a function of connectivity. The connectivity-dependent clustering coefficient,  $c(k)$ , is defined in (3). This quantifies the adjacency of two vertices connected to a vertex with connectivity,  $k$ , and gives information on hierarchical organization of a network.

In Fig. 3, the plots of  $c(k)$  are presented [8]. As can be clearly seen, the clustering coefficient of the undirected simple earthquake network asymptotically follows the scaling law

$$c(k) \sim k^{-\beta} \quad (7)$$

with a positive exponent  $\beta$ . This highlights hierarchical organization of the earthquake network.

Existence of the hierarchical structure is of physical importance. The earthquake networkment [11,12,14,20].

Earthquake Networks, Complex, Figure 3

The log-log plots of the connectivity-dependent clustering coefficient for two different values of cell size: a 10 km × 10 km × 10 km and b 5 km × 5 km × 5 km. The analyzed period is between 00:25:8.58 on January 1, 1984 and 22:50:49.29 on December 31, 2004, which is taken from the same catalog as in Fig. 2. The region covered is 28°36.00'N–38°59.76'N latitude and 112°42.00'W–123°37.41'W longitude with the maximal depth 175.99 km. The total number of the events is 379728. All quantities are dimensionless.

However, the standard preferential-attachment-model is known to fail at generating hierarchical organization [22]. To mediate between growth with preferential attachment and the presence of hierarchical organization, the concept

of vertex deactivation has been introduced in the literature [25]. According to this concept, in the process of network growth, some vertices deactivate and cannot acquire new edges any more. This has a natural physical implication for an earthquake network: active faults may be deactivated through the process of stress release. In addition, the fitness model [26] is also known to generate hierarchical organization. This model generalizes the preferential attachment rule in such a way that not only connectivity but also “charm” of vertices (i. e., attracting a lot of edges) are taken into account. Seismologically, fitness is considered to describe intrinsic properties of faults such as geometric configuration and stiffness. Both of these two mechanisms can explain a possible origin of the complex hierarchical structure, by which relatively new vertices have chances to become hubs of the network. In the case of an earthquake network, it seems plausible to suppose that the hierarchical structure may be due to both deactivation and fitness.

A point of particular interest is that the hierarchical structure disappears if weak earthquakes are removed. For example, setting a lower threshold for earthquake magnitude, say  $M_{th} = 3$ , makes it difficult to observe the power-law decay of the clustering coefficient hierarchical structure of an earthquake network is largely supported by weak shocks.

**Mixing Property**

The scale-free nature, small-worldness, growth with preferential attachment, and hierarchical organization all indicate that earthquake networks are very similar to other known networks, for example, the Internet. However, there is at least one point which shows an essential difference between the two. It is concerned with the mixing property, which is relevant to the concept of the nearest-neighbor average connectivity  $\bar{k}_{nn}(k)$  [in (4)], of a full network with loops and multiple edges.

The plots of this quantity are presented in Fig. 4. There, the feature of assortative mixing [8] is observed, since  $\bar{k}_{nn}(k)$  increases with respect to connectivity  $k$ . Therefore, vertices with large values of connectivity tend to be linked to each other. That is, vertices containing stronger shocks tend to be connected among themselves with higher probabilities.

To quantify this property, the correlation coefficient in (5) is evaluated [8]. The result is summarized in Table 2. The value of the correlation coefficient is in fact positive, confirming that the earthquake network has assortative mixing. On the other hand, the Internet is of disassortative mixing [17,20,21,26]. That is, the mixing properties

**Earthquake Networks, Complex, Figure 4**  
 The log-log plots of the nearest-neighbor average connectivity for two different values of cell size: **a** 10 km × 10 km × 10 km and **b** 5 km × 5 km × 5 km. The data employed is the same as that in Fig. 3. The solid lines show the trends depicted by the exponentially increasing functions. All quantities are dimensionless.

10 km × 10 km × 10 km	5 km × 5 km × 5 km
$r = 0.285$	$r = 0.268$

of the earthquake network and the Internet are opposite to each other. It is noticed however that the loops and multiple edges play essential roles for the assortative mixing: an undirected simple graph obtained by reducing a full earthquake network turns out to exhibit disassortative mixing. These are purely the phenomenological results, and their physical origins still have yet to be clarified.

**Period Distribution**

So far, directedness of an earthquake network has been ignored. The full directed network picture is radically different from the small-world picture for a simple undirected graph. It enables one to consider interesting dynamical

Earthquake Networks, Complex, Figure 5  
 A full directed network:  $\dots \rightarrow v_1 \rightarrow v_2 \rightarrow v_3 \rightarrow v_2 \rightarrow v_2 \rightarrow v_4 \rightarrow v_3 \rightarrow v_2 \rightarrow \dots$ . The period associated with  $v_3$  is 4, whereas  $v_2$  has 1, 2 and 3.

features of an earthquake network. As an example, here the concept of period [7] is discussed. This is relevant to the question “after how many earthquakes does an event return to the initial cell, statistically?” It is therefore of obvious interest for earthquake prediction.

Period in a directed network is defined as follow. Given a vertex of a network, there are various closed routes starting from and ending at this vertex. The period,  $L_p$ , of a chosen closed route is simply the number of edges forming the route (see Fig. 5).

The period distribution,  $P(L_p)$ , is defined as the number of closed routes. The result is presented in Fig. 6 [7]. As can be seen there,  $P(L_p)$  obeys a power law

$$P(L_p) \sim (L_p)^{-\alpha}, \tag{8}$$

where  $\alpha$  is a positive exponent. This implies that there exist a number of closed routes with significantly long periods in the network. This fact makes it highly nontrivial to statistically estimate the value of period.

Earthquake Networks, Complex, Figure 6  
 The log-log plots of the period distribution for two different values of cell size: a  $10 \text{ km} \times 10 \text{ km} \times 10 \text{ km}$  and b  $5 \text{ km} \times 5 \text{ km} \times 5 \text{ km}$ . The data employed is the same as that in Fig. 2. All quantities are dimensionless.

### Future Directions

In the above, the long-time statistical properties of an earthquake network have mainly been considered. On the other hand, given the cell size, an earthquake network represents all the dynamical information contained in a seismic time series, and therefore the study of its time evolution may give a new insight into seismicity. This, in turn, implies that it may offer a novel way of monitoring seismicity.

For example, it is of interest to investigate how the clustering coefficient changes in time as earthquake network dynamically evolves. According to the work in [10], the clustering coefficient remains stationary before a main shock, suddenly jumps up at the main shock, and then slowly decays to become stationary again following the power-law relaxation. In this way, the clustering coefficient successfully characterizes aftershocks in association with main shocks.

A question of extreme importance is if precursors of a main shock can be detected through monitoring dynamical evolution of earthquake network. Clearly, further de-

velopments are needed in science of complex networks to address to this question.

### Addendum

Some authors (e.g., Sornette and Werner) raised questions about the applicability of complex earthquake network using online accessible earthquake catalog data and on the validity of our results. A preprint of an article by the authors discussing these questions can be found in the e-print available at <http://arxiv.org/abs/0708.2203>.

### Glossary

**Nucleation process** The process in which rupture velocity accelerates from quasi-static to dynamic. The dynamic rupture velocity almost equals the shear wave velocity.

**Nucleation zone** The portion of the fault where rupture velocity accelerates from quasi-static to dynamic.

**Initial rupture process** The rupture process that precedes the largest slip. This term is used when the acceleration of rupture velocity is not clear. This is a wider concept that includes the earthquake nucleation process. The area where the initial rupture process occurs is called the initial rupture fault.

**Slip velocity** The dislocation velocity at a point on the fault. The rupture velocity is the velocity at which the rupture front is expanding.

**Preslip model** An earthquake source model having a detectable size nucleation zone.

**Cascade model** An earthquake source model in which smaller sub-events successively trigger larger sub-events. A sub-event is the same as a small earthquake if it does not trigger a successive sub-event.

**Stress drop (static stress drop)** The amount of shear stress change at a point on the fault before and after an earthquake. It is proportional to the strain released on the fault.

**Dynamic stress drop** The difference between the initial shear stress and the minimum frictional stress at a point on the fault during fault slip.

**Fault strength** The shear stress level necessary to initiate slip at a point on the fault.

**$M$**  Magnitude. Earthquake size computed basically from waveform amplitudes and focal distances.

**Seismic moment** The most reliable measure of earthquake size which is determined from the products of the rigidity near the fault, the amount of slip, and the area of the fault surface.

**$M_w$**  Moment magnitude. Earthquake magnitude derived from the seismic moment.

### Definition of the Subject

Earthquake prediction in the long, intermediate, and short terms is essential for the reduction of earthquake disasters. However, it is not practical at present, in particular, for the intermediate and short time scales of a few days to years. This is mainly because we do not know exactly how and why earthquakes begin and grow larger or stop. Theoretical and laboratory studies have confirmed that earthquakes do not begin abruptly with dynamic rupture propagation. They show that a quasi-static rupture growth precedes dynamic rupture. Thus, if we can detect the quasi-static rupture growth, we could forecast the following dynamic rupture. A key issue is how natural earthquakes initiate. To solve this issue, a first approach would be to investigate the very beginning parts of observed waveforms of earthquakes, since they can reflect the earthquake nucleation process from a quasi-static to a dynamic rupture. This paper reviews the studies analyzing the beginning parts of observed waveforms, and shows what we presently understand about the earthquake nucleation process.

### Introduction

Earthquakes initiate at a small portion on a fault. Then, their rupture fronts expand outward until they stop. Some large earthquakes have a rupture extent greater than 1000 km (e. g., the 2004 Sumatra Earthquake), while fault lengths of very small microearthquakes ( $M = 0$ ) are estimated to be a few meters [13]. Fault lengths of earthquakes range at least over 6 orders of magnitude. Surprisingly, the concept that earthquakes are self-similar is widely accepted in spite of the difference in fault length (e. g., [40]). One example of the similarity is that the average fault slip is proportional to the fault length. In other words, the static stress drop is constant independent of earthquake size.

The similarity law raises fundamental questions: Why do large earthquakes grow larger? What is the difference between large and small earthquakes? An end member model represents earthquakes as ruptures that grow randomly, and terminate in an earlier stage for smaller earthquakes while continuing longer for larger earthquakes.

This type of model has been proposed mainly to explain the frequency–size distribution of earthquakes (e. g., [8]) and implies that it is impossible to forecast the final size of earthquakes at the time of the rupture initiations. However, another end member model predicts that larger earthquakes have a larger “seed” than smaller earthquakes and that large and small earthquakes are different even at their beginnings (e. g., [66]).

The key issue is how earthquakes initiate and grow larger.

All the theoretical models of earthquake sources predict that earthquake shear failures begin with a quasi-static rupture growth on a small portion on the fault (e. g., [5]). The shear failures become unstable and the rupture growth begins to accelerate after the energy released by the rupture growth equals to or becomes larger than the work necessary for producing new fracture surfaces. Finally, the rupture velocity, the velocity at which the rupture front is expanding, reaches a constant value comparable to the shear wave velocity. We call the process from the rupture initiation to rupture growth acceleration the earthquake nucleation process, and the portion of the fault where the rupture growth accelerates the nucleation zone. The important point is that the rupture velocity (and slip velocity) accelerates during the nucleation process, since it is a transient process from quasi-static to dynamic. One of the major differences between various models is whether the size of the nucleation zone is much smaller than the final fault length and is not detected by observations, and whether the size of the nucleation zone is different between large and small earthquakes.

If the size of the nucleation zone is extremely small and can be approximated as a point, the waveforms radiated from the earthquake are shown in Fig. 1a. Figure 1a displays the initial rise of the P-wave velocity pulse at a far-field (distant relative to the fault length) station, when the waveform propagates in a purely elastic homogenous medium with no attenuation and scattering under the following assumption: the rupture initiates at a point, the circular rupture front expands at a constant velocity, the stress on the fault abruptly drops from an initial level to a final level, and the stress drop is constant over the fault, as modeled by Sato and Hirasawa [60]. In this case, the initial portion of the P-wave velocity pulse is characterized by a linear rise (and the initial rise of the displacement pulse is quadratic with time, due to increasing circular fault area with time). The tangent of the linear rise is proportional to the stress drop and rupture velocity.

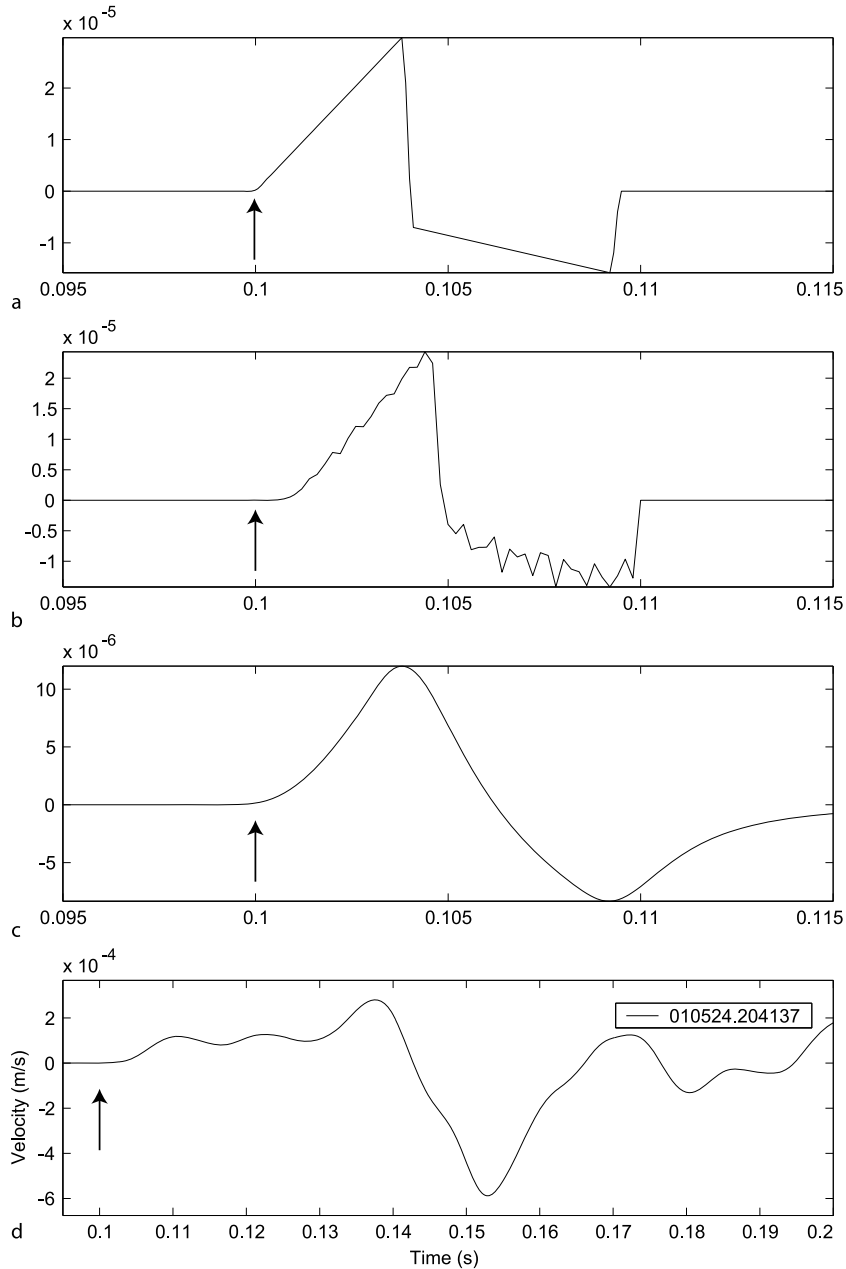

On the other hand, if the size of the nucleation zone is relatively large, the velocity pulse can be approximated as

shown in Fig. 1b. It is seen that the linear rise is delayed and the slope of the initial portion gradually increases. Theoretical models explain such a slow rise as follows. Shibazaki and Matsu’ura [64] demonstrated that the slow rise could be explained by gradually accelerating rupture and slip velocities in a relatively large nucleation zone. The size of the nucleation zone is controlled by the critical slip distance,  $D_c$ , that is the amount of slip necessary to drop the peak shear strength down to the dynamic frictional level (e. g., [19]). This frictional behavior is called slip-weakening, which is theoretically predicted (e. g., [15]) and is observed in laboratory experiments (e. g., [52,56]). According to their theory, since large slips are necessary to decrease the friction on faults with a large  $D_c$ , the rupture and slip velocities are not accelerated in the beginning on the faults. Sato and Kanamori [61] modeled the slow rise by Griffith’s fracture criterion based on the energy balance indicated above, as the rupture velocity gradually increases under the assumptions of a large pre-existing fault and small trigger factor (instantaneous small stress increment) on the fault. The pre-existing fault is often called the initial crack. In this model, large initial cracks result from large fracture energies on the fault and the rupture and slip velocities are not accelerated right after the rupture onset owing to the large fracture energies. In this paper, the model having a detectable size of the nucleation zone is called the preslip model, following Beroza and Ellsworth [9].

It is important to examine whether initial rises of observed velocity pulses are linear or gradually increasing, since the above two models predict different initial rises. Although the examination seems to be very easy at first glance, it is actually very difficult. The path effect is an inevitable obstacle to the examination, in particular for small earthquakes. The effects of anelastic attenuation and/or scattering contaminate observed waveforms and can reproduce a slow rise of observed waveforms even though the waveforms show a linear rise at the source. Figure 1c shows the initial rise of velocity pulses calculated by considering anelastic attenuation by a convolution of a Q operator [7]. It is found that the linear rise is delayed as shown in Fig. 1b.

Another serious obstacle is the complexity of observed waveforms. They are not often as simple and smooth as those shown in Figs. 1b and c, but complicated as shown in Fig. 1d. If several small patches in a relatively large nucleation zone break during the nucleation process [9,65] as shown in Fig. 2a, it is difficult to detect an acceleration of the rupture velocity from the complicated waveforms that include several small phases radiated from the breaks of the small patches. In other words, it is difficult to infer

Earthquake Nucleation Process, Figure 1

Examples of P-wave velocity pulses. Arrows indicate onsets of P-waves. **a** Source pulse from the circular fault model [60]. Stress drop: 1 MPa, fault radius: 17 m, rupture velocity:  $0.8 V_s$ , take-off angle: 61 degrees. **b** Source pulse from a circular fault model with a rupture velocity accelerating with time for first 20% of the total duration time. The other parameters are the same as a. **c** Q convolved velocity pulse at a distance of 3.58 km from the source. Q is set as 300. The other parameters are the same as a. **d** Velocity waveform of a complicated shape observed in the Western Nagano Prefecture region

the nucleation process from the complicated waveforms. On the other hand, the model with small nucleation zones claims that the complicated waveforms are radiated only from successive breaks of small sub-events and a delayed

break of the largest sub-event, as shown in Fig. 2b. This concept is known as the cascade model (e. g., [1,9,23,78]). In this model, a former sub-event triggers successive larger sub-events and the final event is the largest among de-

Earthquake Nucleation Process, Figure 2

Schematic source models in which small amplitude phases are generated by breaking of small fault patches within the nucleation zone (*shaded portion*) **a**, and as successive small subevents **b**. *Large and small circles* are the mainshock fault and small subevent fault patches, respectively

tectable sub-events. Although it is not always clear how larger sub-events are delayed from former smaller sub-events, the growth of the rupture can raise the possibility that larger sub-events are generated. For small earthquakes also, it is possible that very small sub-events trigger successive sub-events. In this case, their waveforms produced by the source are complicated, but the observed waveforms are likely to show a smooth initial rise as shown in Figs. 2b and c, due to the path effects. Thus, in this paper, both smooth initial rises of small earthquakes and complicated initial portions of large earthquakes are discussed in the same manner.

By the way, if the size of the nucleation zone is relatively large, it could be possible to detect a quasi-static rupture growth at the very beginning of the earthquake nucleation process by near-field broadband instruments, such as strain meters. However, it has not, to present, succeeded except for a few very large earthquakes, such as the 1964 Chile earthquake (e. g., [41]). This fact suggests the possibility that the size of the nucleation zone is too small to be recorded by strain meters or the duration of the quasi-static rupture process is much longer than a practical frequency range of strain meters. Furthermore, the observations for very large earthquakes were not explained by the nucleation process that occurs near the hypocenter but by slow slips on the downward extension of the seismogenic faults (e. g., [33,41]). Thus, we will examine data obtained by seismometers.

It is very important to carefully analyze observed waveforms recorded at a short focal distance by a wide-dynamic range and frequency range. This paper reviews various studies related to the earthquake nucleation process, indicates the problems about these studies, and summarizes the current observations. First, in Sect. “**Introduction**”, contributions from earthquake early-warning systems are

reviewed, since they are directly influenced by the problems cited above. In Sect. “**Contribution from the Development of Earthquake Early-Warning Systems**”, important studies about the initial rupture process are reviewed basically in the order in which they were published. In Sect. “**Observations of Initial Rupture Processes**”, a probable model for the process will be proposed based on the reviews in the former sections.

### Contribution from the Development of Earthquake Early-Warning Systems

To solve the problem of how earthquakes initiate and grow larger, the most straightforward approach is a comparison between initial rises of observed waveforms of large and small earthquakes. Important studies were done for the development of earthquake early-warning systems which hope to forecast, as early as possible, the final size of earthquakes from observed waveforms, from the very beginning parts of seismograms. Olson and Allen [57] applied the method by Allen and Kanamori [3] to a new dataset including many large earthquakes ( $M_w > 6$ ) and claimed that the final size of earthquakes ( $3 < M_w < 8$ ) can be estimated from waveforms of the first several seconds. The method is based on the scaling relationship between the predominant period of waveforms and the final size of earthquakes, which was first derived by Aki [2]. To implement the scaling relationship in earthquake early-warning systems, Allen and Kanamori [3] adopted an algorithm to estimate the period from a short waveform, computing regressively the ratio of velocity and displacement amplitudes (modified after Nakamura [49]).

For smaller earthquakes, it is quite natural to be able to estimate the final size from the first several seconds of the waveforms, since the waveforms cover the entire source duration. The problem is estimating large earthquakes ( $M_w > 5.5$ ). Rydelek and Horiuchi [58] evaluated the statistical significance of the results by Olson and Allen [57] and reported that the results are not clear. Rydelek and Horiuchi [58] analyzed waveforms observed by Hi-net, a nation-wide high gain seismometer network operated by NIED in Japan, and found no trend between the period and earthquake size for larger earthquakes. On the other hand, Wu et al. [77] analyzed many waveforms recorded at the southern California Seismic Network stations and showed that the period increases with magnitude ( $4 < M < 7.5$ ). For earthquake early-warning system applications, where a quick response is essential, a precise waveform analysis is not required. A more careful analysis is needed to answer the question raised by Rydelek and Horiuchi [58].

## Observations of Initial Rupture Processes

### Measurements of Initial Parts of Observed Seismograms

#### How are Initial Portions of the Waveforms Measured?

Observed waveforms of large to small earthquakes are measured in various manners in the studies reviewed in the following sections. Sometimes special names are given to a characteristic phase of the waveforms. First, the problems concerning the measurement of observed waveforms will be discussed.

Many studies try to find which phase is radiated from the source process with a constant rupture velocity and slip velocity, since the nucleation process is basically an accelerating rupture process. Since the nucleation process is a beginning rupture process, it is likely that the rupture front just after the nucleation process expands nearly circularly. Consequently, the phase following the nucleation phase is thought to show a linear rise in velocity waveforms. For this reason, the first linear rise in velocity waveforms is extensively investigated in various studies.

Various studies also measure a pulse of the largest amplitude or a group of pulses including the largest amplitude, which is called the main phase in this paper. Amplitudes of waveforms are thought to show the maximum value after they reach terminal velocity, which is the maximum rupture velocity determined by the shear wave velocity. However, the largest amplitude does not necessarily occur just after rupture velocities reach the terminal velocity; all the waveforms preceding the maximum phase do not necessarily reflect the nucleation phase.

The problem is determining which phase is radiated just after rupture velocities reach terminal velocity. Furthermore, since slip velocities can cover a wide range of magnitude, it is important to investigate whether slip velocities are similar to the average values of earthquakes. In the following, when it is necessary to explicitly indicate the phase generated by faulting with a nearly constant rupture velocity and dynamic stress drop that are representative of average values for earthquakes, the phase is called the ordinary phase.

As schematically shown in Fig. 3, for large earthquakes, the first linear rise is not always a part of the main phase, which has the largest amplitude. For small earthquakes, the main phase often shows a linear rise. However, it is possible that the main phase is not the ordinary phase, as we discuss in a later section.

**Large Earthquakes** One of the first studies that indicated the importance of small amplitude waveforms preceding the main pulse is Furumoto and Nakanishi [24],

Earthquake Nucleation Process, Figure 3  
Schematic illustration of large and small earthquakes to show the first linear rise and the main phase

which analyzed long-period waveforms from a worldwide network; this was followed by many similar studies (e. g., [4,14,68]). Umeda [72,73] analyzed broadband seismograms at local, regional and teleseismic distances and found that small amplitude waveforms preceded large amplitude waveforms, as shown in Fig. 3. Umeda [72] called the onsets of the P-waves and large amplitude waveforms P1 and P2, respectively. He originally thought that the large amplitude waveforms were generated by somewhat special processes that characterized large earthquakes, e. g., breaks of many small faults triggered by both static and dynamic stress concentrations due to the preceding fault motion and/or a dynamic connection of separated faults [74], while the smaller waveforms were radiated from ordinary smooth rupture propagation. His important result is the relationship between the duration of P2-P1 and magnitude ( $3 < M < 7$ ), suggesting earthquake sizes are scaled with P2-P1, the duration of small amplitude waveforms.

The determinations of P2 seem to be reasonable from his figures. However, the criterion of P2 determination is not necessarily clear and quantitative compared to the studies cited in the following sections. In many cases it seems that P2 is the onset of the main phase that includes the largest amplitude, in particular for smaller earthquakes, but this point is not clearly shown in his papers. Furthermore, it is seen that absolute velocity amplitudes after P1 do not show an accelerating increase with time, although both the preslip model and the cascade model basically indicate that velocity amplitudes should have a growth that is faster than linear with time.

One of the important problems raised by Umeda [72, 73] is identification of the ordinary phase, the main phase or preceding smaller amplitude waveforms. The ordinary

Earthquake Nucleation Process, Figure 4

Initial parts of observed waveforms of large earthquakes [73]. P1 and P2 indicate the onsets of P-waves and the large amplitude phases, respectively. Velocity waveforms are shown in a and the lower panel of b. Figure 7 in [73], copyright 1992 by Elsevier Science Publishers B.V.

Earthquake Nucleation Process, Figure 5

Slow initial phase of the velocity pulse observed in the Western Nagano Prefecture region and the measurement of the duration of the slow initial phase relative to the main phase that shows a linear increase of velocity amplitudes. The vertical arrow indicates the onset of P-waves, determined by their amplitudes. The portion indicated by the horizontal arrow is defined as the slow initial phase. The inclined line is the tangent at the maximum slope. The same pulse is shown in Fig. 7 by the black line

phase is the phase generated by faulting with a nearly constant rupture velocity and a dynamic stress drop, which are representative of average values for earthquakes. Furumoto and Nakanishi [24] regarded the main phase as the ordinary phase with a special rupture process occurring before the main phase, while in Umeda [72,73] the opposite is the case.

**Small Earthquakes** Iio [30,31] analyzed waveforms of microearthquakes recorded at very short focal distances

(down to a few hundreds of meters) using instruments with a wide-frequency response and found that the initial rises of velocity pulses did not show a linear increase but, rather, a convex downward (or upward) shape as approximated by  $t^n$  ( $t$  is the time measured from the onset and  $2 < n < 4$ ). He termed the initial rise “the slow initial phase”, and measured the duration of the slow initial phase relative to the main phase that shows a linear increase, as shown in Fig. 5. He found that the duration of the slow initial phase is proportional to the earthquake size. Al-

though the slow initial phase of microearthquakes could be the effect of anelastic attenuation as shown in Sect. “**Introduction**”, Iio et al. [32] analyzed velocity pulses recorded at a 10 kHz sampling frequency at numerous stations at short focal distances using an instrument with a wide dynamic range and frequency range, and concluded that the slow initial phase mainly reflects the source process for M2 events.

These observations are unique and important, but their interpretations and implications contain several fundamental problems and might cause some misunderstandings. First, it was intuitively regarded that the main phase showing the linear rise was the ordinary phase radiated from a circular fault with constant rupture and slip velocities of ordinary magnitudes. This was derived from the interpretation that the slow initial phase reflected the nucleation process in which the rupture and/or slip velocities gradually accelerated. However, the interpretation has not been thoroughly examined. As emphasized by Ellsworth and Beroza [21] and Beroza and Ellsworth [9], waveforms recorded by seismometers basically reflect slips on the fault that have accelerated above a certain level.

The second problem is the meaning of the scaling relationship indicating that larger earthquakes have a longer slow initial phase. Although the possibility was suggested from this relationship that larger earthquakes had a larger nucleation zone, this is true only if the main phase is the ordinary phase and the slow initial phase reflects the nucleation process. The relationship could be also misunderstood as larger earthquakes begin more slowly. The observational results mean only that the portion of velocity pulse approximated by  $t^n$  ( $2 < n < 4$ ) is longer for larger earthquakes. Furthermore, Iio [30,31] mentioned nothing about the difference between the slopes right after the onsets of larger and smaller earthquakes. Thus, another possible explanation is that for larger earthquakes, the slope of the velocity pulse increases with time for a longer period and the maximum slope becomes larger, even though the initial slope is the same as that for smaller earthquakes. This possibility implies that the final size of earthquakes is not estimated only from the initial part of velocity pulses, as pointed by Mori and Kanamori [48], although larger earthquakes have a greater dynamic stress drop. Several studies have indicated that the initial rises of large earthquakes ( $M > 6$ ) are similar to small events occurring in the vicinity of their hypocenters (e. g., [12]), while other studies have indicated that larger earthquakes display a larger initial rise (e. g., [35,50]). However, it is possible that the initial parts of these waveforms mainly reflect the initial rise radiated from a small patch within the initial rupture fault, as shown in Sect. “**Introduction**”.

In that case, the results did not negate the existence of an observable earthquake nucleation process for large events. Further, these results were obtained only for a few earthquake sequences and need to be systematically examined for a greater data set.

The third problem is the propagation effects from the source to the observation stations. Iio [30,31] thought that observed waveforms basically reflect the characteristics of the source process in which the rupture and slip velocities gradually increase during the slow initial phase, assuming that source pulses of small earthquakes are simple and consist of a single event. However, it is possible that anelastic attenuation modifies two connected linear trends of small and large slopes from two subevents, creating a smoothed waveform of convex downward shape. This point is qualitatively examined in a later section. Furthermore, it might be possible that waveforms near the source are complex; several very short duration small pulses may precede the main phase, since short duration pulses can be smoothed by the path effect to produce a slow initial phase.

### Estimate of Source Time Functions

Ellsworth and Beroza [21] and Beroza and Ellsworth [9] focused on initial parts of seismograms of a very wide range of earthquake sizes ( $1 < M_w < 8$ ) and estimated source time functions. They paid attention to the first large linear rise of velocity pulses and deduced that the signal before the linear rise reflected the earthquake nucleation process, since a linear rise of velocity pulses is characteristic of the waveforms radiated from an ordinary circular fault model. They termed the linear rise “the breakaway phase” and the portion before “the seismic nucleation phase”. The term “seismic” is added, since waveforms detected by seismometers are radiated from dynamic slip on the fault. The criterion for the detection of the breakaway phase is not necessarily quantitative, but it seems from their figures that their classifications are reasonable. As shown above, they regarded the breakaway phase as the ordinary phase, since they roughly estimated that dynamic stress drops of the breakaway phases were several or several tens of MPa, that is comparable to average values of earthquakes. However, it is possible that the seismic nucleation phase is the ordinary phase, since the rupture velocity and slip velocity during the seismic nucleation phase is not quantitatively estimated.

Kilb and Gomberg [43] analyzed initial portions of the waveforms of the Northridge earthquake, which were also used in Ellsworth and Beroza [21] as a typical example, and claimed that the initial portions are very similar to those from nearby small earthquakes. They inferred from these

Earthquake Nucleation Process, Figure 6

Relationship between the duration of the seismic nucleation phase and the seismic moment, together with the data of the slow initial phases by Iio [30,31] and P2-P1 by Umeda [72,73] (Beroza and Ellsworth [9])

results that the cascade model is plausible. However, their results did not exclude the preslip model in which the rupture and slip velocities are accelerating in the nucleation zone, since they analyzed only the very beginning portions and not the following portions that might result from slow slips in the nucleation zone. Shibazaki et al. [67] discussed the possibility that large earthquakes begin by a breaking of a small patch in the nucleation zone. As discussed in the Introduction, the breaking of small patches can mask the nucleation process.

Ellsworth and Beroza [21] demonstrated the relationship between the duration of the seismic nucleation phase and the seismic moment, together with the data of the slow initial phases by Iio [30,31] and P2-P1 by Umeda [72,73], as shown in Fig. 6, and concluded that the duration of the seismic nucleation phase scaled with the seismic moment. However, it is seen in Fig. 6 that the data of Iio [30,31]

and Umeda [72,73] are shifted upward from the regression line. It seems that their data for small earthquakes also shifted upward from the regression line. The offsets of these shifts are about 1 order of magnitude. For larger earthquakes, this may be because Umeda [72,73] determined P2 as the onset of the main phase, while Ellsworth and Beroza [21] determined onsets of the first large linear rises. For smaller earthquakes, Iio [30,31] also detected the onsets of the main phases. They regarded the phases as the first large linear rises, but it is possible that the onsets of the first large linear rises are earlier than the main phases, as discussed in the following section.

### Estimate of Source Processes

**Small Earthquakes** In order to solve the problems cited in the previous sections, several studies tried to estimate

the source process that produces the initial phases. Hiramatsu et al. [26] analyzed rising parts of seismograms using the model of Sato and Kanamori [61], in which larger initial cracks generate a slower initial phase under a small triggering factor.

It was inferred from deep borehole (1800 m) seismograms by Hiramatsu et al. [26] that initial rises of velocity pulses of 5 events were explained by the ordinary circular fault model [60], namely the initial crack is too small to be detected, while the other 7 events needed a large initial crack. They first estimated source processes of the beginning of such small earthquakes; however, some basic problems remained. The first is that they modeled the first half cycle of velocity pulses. Since even portions of the first half cycle of the waveform can be affected by rupture arrest, it is not reasonable to fit the first half cycle of the waveform by using a model that does not include a reasonable rupture stopping process. Furthermore, a closer inspection of their results (Fig. 5 of [26]) reveals that some of the waveforms modeled with an initial crack do not display a smooth increase of the rising slope but appear to consist of two linear phases with different slopes. It is possible that these earthquakes result from a cascade rupture of a first and second sub-events with smaller and larger dynamic stress drops, respectively. For the data analyzed by Iio [30,31], waveforms with a predominantly longer slow initial phase appear to show a similar feature. Furthermore, it is not clear which is the ordinary phase, the first or second linear phase.

The problem of identifying the “ordinary phase”, the initial or main phase, is again pointed out. Recently, Iio et al. [34] analyzed the 10 kHz sampling data [32,36] and obtained results that suggest the initial rise is the ordinary phase.

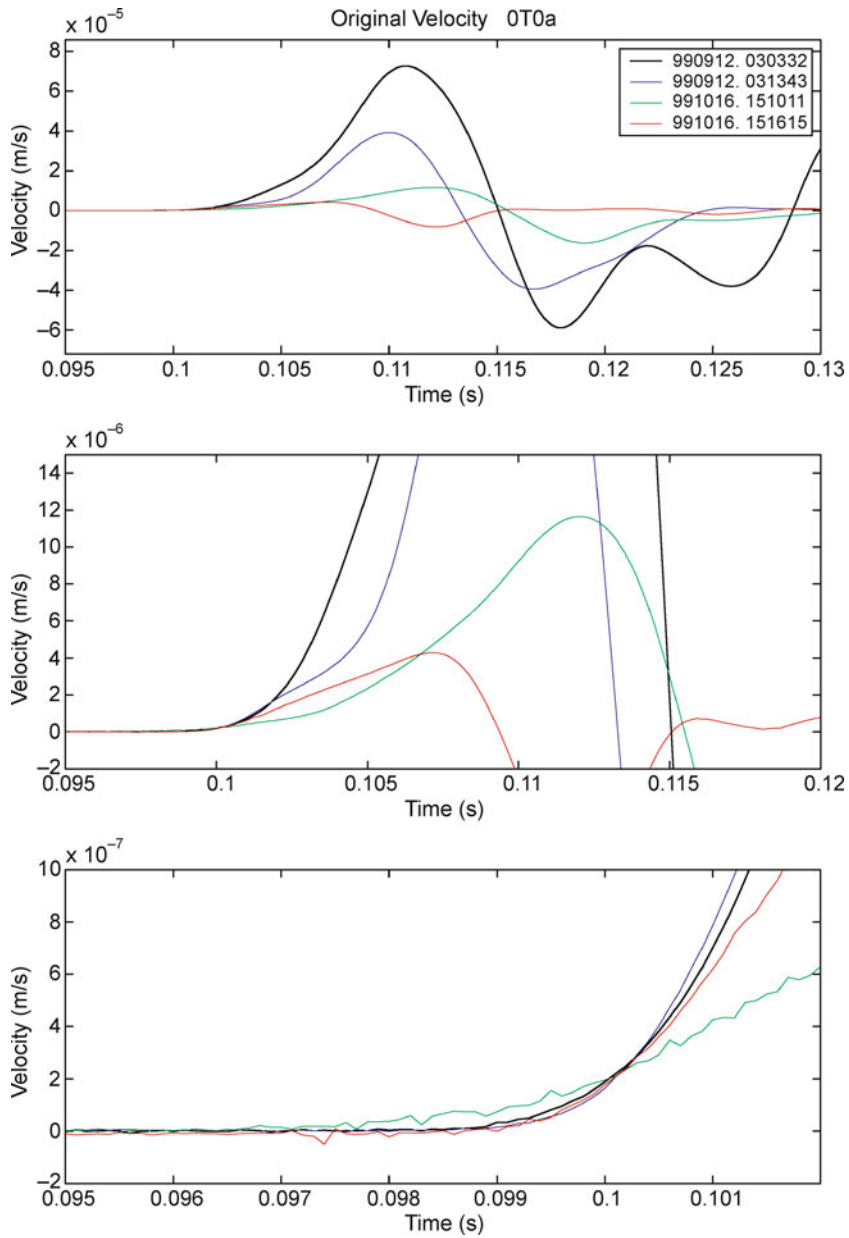

Figure 7 shows velocity pulses of microearthquakes ( $0.5 < M < 2.0$ ) for which relative locations are estimated within 100 m and fault plane solutions are similar [34]. These pulses were recorded at a borehole station at a depth of 800 m in the Western Nagano prefecture region [37,76]. The focal distances are about 3.6 km. It is seen that the smallest event (shown in red) shows a linear rise except for the first 1 ms, while slopes of the other events increase with time. Thus, if the linear rise is explained by a circular fault model of the Sato and Hirasawa type with an ordinary rupture velocity and stress drop, the increasing slopes reflect increasing slip velocities accelerated beyond ordinary values.

The linear rise of the waveforms was modeled by various kinematic fault models. Figure 8 displays the comparison of synthesized and observed velocity pulses for three borehole stations at depths of 800, 150, and 100 m [37].

The fault plane was determined from focal mechanisms and hypocentral distributions around these events. Since all three waveforms were not explained simultaneously by a Sato and Hirasawa type of circular fault model, they used a fan fault of various angles. Further, they did not assume that the slip terminated simultaneously over the fault, but that it begins to stop at a point on the fault edge and the stopping phase propagates circularly at a constant velocity. The stress drop, rupture and stopping phase expanding velocities, fault radius, fan angle and fan fault geometry were determined by a grid search technique.  $Q$  values are set as 300 by trial and error, to fit the very beginning initial rises with duration of about 1 ms.

It is seen that the observed waveforms in the first half cycle are well explained by the fan fault model, except for the middle trace, which might be contaminated by a surface reflection. The rupture velocity was estimated as  $0.8 V_s$  (the shear wave velocity), which is similar to that for large earthquakes. The stress drop was estimated as about 5 MPa by the formula for the circular fault of the equivalent fault area. Although they modeled only two events, they found that a few percent of events that occurred within about 5 km from the 800 m borehole station also showed such a linear rise. Furthermore, the other events generally show a steeper initial rise than the linear rise events. Consequently, it is likely that small earthquakes occurring in the Western Nagano prefecture region have a rupture velocity equivalent to those of large earthquakes even in the initial rupture process. This suggests that the slow initial phase of small earthquakes does not reflect the nucleation process that is characterized by accelerating rupture velocity, since the rupture velocity has already accelerated to a shear wave velocity in an early stage of rupture growth.

What do steeper main phases of larger earthquakes in the Western Nagano region reflect? In order to clarify this problem, Miura et al. [46] analyzed waveforms of earthquakes ( $0.0 < M < 4.0$ ) occurring from 1996 to 2003 in the Western Nagano prefecture region. They selected M3 events ( $3.0 < M < 4.0$ ) and identified 21 earthquake clusters that consist of M3 events and earthquakes occurring within 500 m of the hypocenters of M3 events. They investigated P-wave velocity pulses observed at three borehole stations for each cluster, in particular the difference in pulse shapes of large and small earthquakes. They found that waveforms of half of the clusters displayed complicated shapes, as shown in Fig. 1d, which are characterized by more inflection points than simple pulses [63]. The other half showed simple waveforms that enabled them to clarify the difference between large and small earthquakes. One example of waveforms is shown in Fig. 9. The ob-

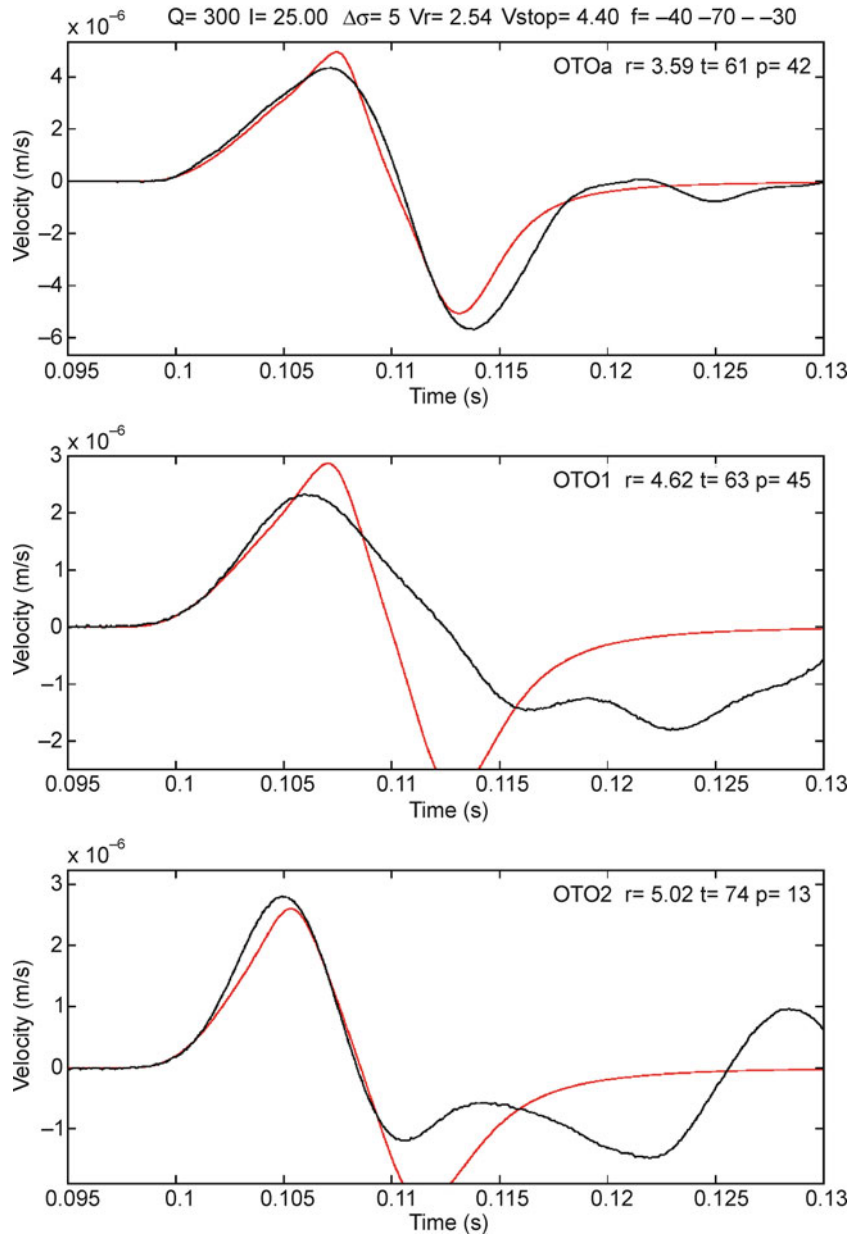

Earthquake Nucleation Process, Figure 7

Comparison of velocity pulses of microearthquakes ( $0.5 < M < 2.0$ ) of which relative locations are estimated within 100 m and fault plane solutions are similar, recorded at a borehole station at a depth of 800 m in the Western Nagano prefecture region [34]. Focal distances are about 3.6 km

served P-wave velocity pulses of  $0.5 < M < 3.1$  are displayed in different magnifications. It is seen that initial rises are similar for the first 1 ms but that slopes of larger events increase with time. The theoretical pulses from the circular fault model [60] are synthesized at the same focal distances for a similar magnitude range in Fig. 9b, assum-

ing a constant stress drop independent of earthquake size, and a  $Q$  value of 230, which was obtained by modeling the waveform of the smallest event. Responses of seismometers are also included. The synthesized pulse shapes of larger events do not display a linear rise but a slight convex upward shape. It is found that a distinct difference between

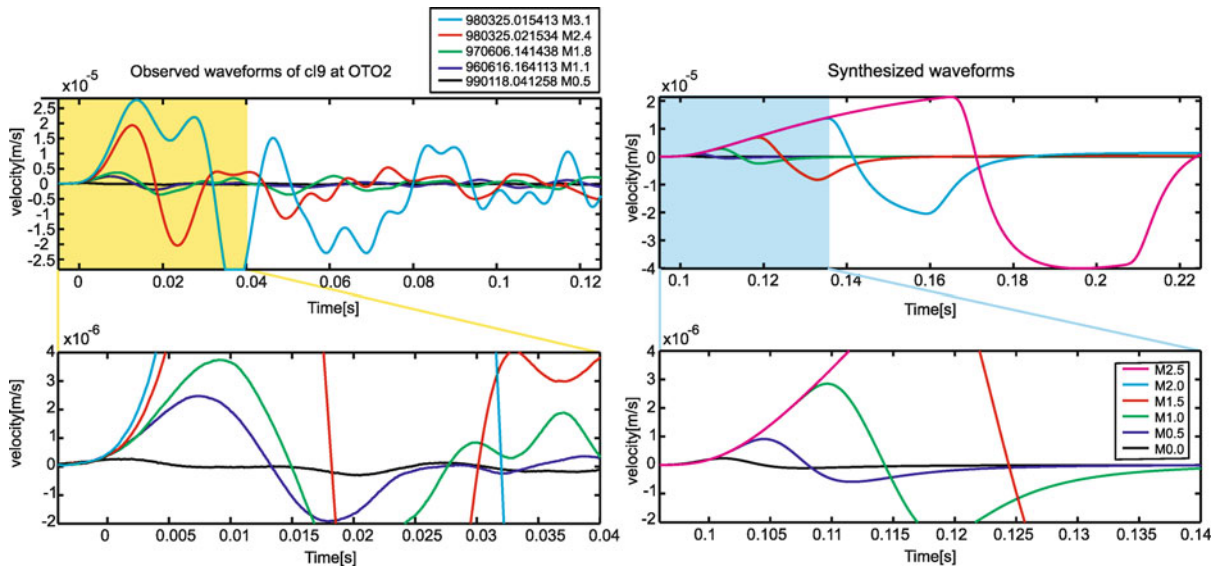

Earthquake Nucleation Process, Figure 8

Comparison of observed and synthesized waveforms for an event that displays a linear rise, shown in Fig. 7 by the red line [34]. Waveforms observed at three borehole stations of depths of 800, 150, and 100 m are shown in the top, middle and bottom panels, respectively. The synthesized waveforms are calculated by a fan fault model in the homogenous half space using the following parameters: The stress drop is estimated as about 5 MPa. The rupture and stopping phase expanding velocities are  $0.8 V_s$  and  $0.8 V_p$  (the P-wave velocity), respectively. Fault radius: 25 m, fan angle: 40. A Q value is 300

theoretical and observed waveforms is seen in the maximum slope of larger events. This figure clearly demonstrates that larger earthquakes have larger dynamic stress drops than smaller events. Similar features are also seen in the other clusters that show simple waveforms. These re-

sults imply that the similarity law does not hold for a small range of magnitudes in the Western Nagano prefecture region, as indicated by Venkataraman et al. [58]. The similarity law predicts pulses as shown in the right hand side of the figure.

Earthquake Nucleation Process, Figure 9

Comparison of observed (*left*) and synthesized (*right*) waveforms for events of an earthquake cluster that shows smooth waveform shapes [46]. The cluster consists of the M3 class events and earthquakes occurring within 500 m from their hypocenters. The synthesized waveforms are calculated by an ordinary circular fault model [60] at the same focal distance. A  $Q$  value of 230 was obtained by modeling the waveform of the smallest event. Responses of the instruments are also convolved

**Large Earthquakes** Sato and Mori [62] used the same method as Hiramatsu et al. [26] and analyzed the very beginnings of waveforms for a very wide range of magnitudes ( $3 < M < 8$ ) recorded by high gain short-period seismometers at local distances. They showed that large initial cracks (a few tens of meters) are necessary to explain the initial rises and that initial crack lengths are almost constant, independent of the eventual earthquake size. Although they might have analyzed only the beginning of the first sub-event in the nucleation zone, it is important that they found that very beginning portions of large earthquakes show an accelerating rise over the first 0.1 s.

For large earthquakes, initial rupture processes can be estimated by near-source broadband seismograms. Shibazaki et al. [67] determined a P2 phase 0.5 s after the P-wave onset (P1) for the Kobe earthquake and performed a waveform inversion using the initial portion of seismograms. They estimated that the slip velocity slowly accelerated for 0.5 s. The average rupture velocity within 0.5 s after the onset of dynamic rupture was about 2 km/s, which is not very low. However, their results possibly detect the earthquake nucleation process, since it is difficult to estimate accelerating rupture velocity in the small nucleation zone of about 500 m, which was inferred from the waveform inversion. It is noted that their estimate of P2-P1 of 0.5 s is consistent with the scaling relationship of Ellsworth and Beroza [21], but is not consistent with that

of Umeda [72,73]. The initial phase of the Kobe earthquake shows an accelerated increase of velocity amplitude with time [67], while a significant part of the data analyzed by the other studies do not show the accelerated increase. These results suggest the possibility that a major part of the initial rises analyzed in the other studies do not reflect the earthquake nucleation process.

Recently, longer durations of P2-P1 were observed for two intraplate earthquakes in Japan, the 2000 Western Tottori Prefecture earthquake (M7.3) and the 2004 West-off Fukuoka earthquake (M7.0). The initial phases of long durations are suitable for analyzing the rupture processes. For the Western Tottori Prefecture earthquake, Hirata [27] measured a duration of 2.5 s for P2-P1, determined the location of the P2 source and estimated the initial rupture process by a waveform inversion. They estimated that during the first 2.5 s, a small slip occurred within the limited area around the hypocenter and later, a large slip began near the location of P2 about 5 km south-east of the hypocenter. The average rupture velocity during the first 2.5 s was estimated to be 1.8 km/s from the waveform inversion of the initial phase. The stress drop in the limited portion was estimated to be small compared with the large slip area.

Since the duration of P2-P1 is long, the above features are also obtained in ordinary waveform inversions. Iwata and Sekiguchi [39] estimated the slip distribution

Earthquake Nucleation Process, Figure 10  
 Source time functions for the initial part of the 2004 West-Off Fukuoka earthquake (M7.0). The waveforms after the onsets are shown. The mainshock (*top*), a M4.5 aftershock (*middle*), and a M5.4 aftershock (*bottom*) estimated by an empirical green function method [75]. Zisin, 59:250, Figure 11, copyright 2007 by the Seismological Society of Japan

using strong ground motion seismograms and geodetic data, and found a large slip area located about 5 km southeast of the hypocenter. They regarded the large slip area as an “asperity” on the fault. It has been well known that slip distributions of large earthquakes are heterogeneous and large slips occur within a limited portion on the fault (e. g., [44]). Although the origin of large slip areas has not yet been clarified, one interpretation is that fault strength is higher in the areas of large slip than in the surrounding areas. This concept is called the asperity model. The observations about P1 and P2 shown above can be explained by the asperity model: The earthquake rupture begins at the weakest portion on the fault, then propagates to stronger portions where large slips occur.

For the 2004 West-off Fukuoka earthquake (M7.0), similar results were obtained. A P2 phase was detected by Yamaguchi et al. [75] and the duration of P2-P1 was long, estimated as 3.38 s. They determined the location of the P2 source as 3.44 km southeast of the hypocenter. The average rupture velocity during the 3.38 s period was computed to be about 1.02 km/s from the distance between the locations of P1 and P2. These results are consistent with those from ordinary waveform inversion studies (e. g., [6]). They also estimated the source time functions of the mainshock and a few large aftershocks by an empirical Green function method, as shown in Fig. 10. It was found that the source time function of the mainshock is not impulsive but has a gradual onset and long duration, while those of the aftershocks are impulsive. Only one aftershock shows a small initial phase, as shown in Fig. 10c. The seismic moment released before the P2 phase is comparable for those of M4 aftershocks. These results clearly show that the initial rise of the West-off Fukuoka Prefecture earthquake is different from those of the small aftershocks and is characterized by a small stress drop. It is suggested that large earthquakes do not accidentally grow larger.

For these two earthquakes with long initial phases, the average rupture velocities and stress drops on the initial rupture faults are small; however, the initial phases do not show a accelerating increase of velocity amplitude with time. These facts suggest the possibility that long initial phases do not reflect the nucleation process.

## Discussion

### Summary of the Observations

The reviews in the previous sections have revealed several important characteristics concerning the initial phases that are commonly seen in many studies. In this section, first, these characteristics are summarized, and then, an inferred initial rupture process will be discussed.

The almost linear initial rises were observed in the Western Nagano region and were well explained by a fan fault model with a constant rupture velocity comparable to the shear wave velocity. On the other hand, nearby larger earthquakes showed an initial rise in which the slope is of the same order of magnitude as that of the linear rise, plus increasing slopes with times of a few to several ms after the onset [34]. Thus, it is thought that the rupture velocity of these larger earthquakes is also comparable to the shear wave velocity during the initial phase. Furthermore, observed waveforms do not necessarily display a gradual increase of rising slope but sometimes show a discrete change in the slope, suggesting that the initial rise of the velocity pulse at the source is not smooth. Consequently, successive sub-events with larger dynamic stress drops possibly produce larger earthquakes for these events occurring in the Western Nagano Prefecture. These inferences are consistent with the results obtained by Hiramatsu et al. [26] that about half of their data are explained by an ordinary circular fault model and longer initial phases are not always smooth. For small earthquakes ( $M < 4$ ), the slow initial phase probably does not reflect the earthquake nucleation process. The nucleation size of small earthquakes is probably small and thus, the very beginning of observed waveforms should be analyzed very carefully considering path effects. This matter is beyond the scope of this paper and is left to future studies.

Larger earthquakes showed a variety of initial phases, as pointed out by Ellsworth and Beroza [21]. It is likely that the observed initial phase of the Kobe earthquakes reflects the earthquake nucleation process [67]. Also, that of the Northridge earthquake probably reflects the earthquake nucleation process, since the very weak initial phase shows an accelerated increase of velocity amplitudes with time [21], although the very beginning part of the initial phase is similar to the waveform of nearby small aftershocks [43]. Further, several data of Ellsworth and Beroza [21], in particular, those shifted downward from the regression line shown in Fig. 6 possibly reflect the earthquake nucleation process. However, it is likely that those of the other large earthquakes do not reflect the earthquake nucleation process, since they do not show an accelerated increase with time but rather are roughly flat. These facts are clear for the two intraplate earthquakes that have a relatively long initial phase (e. g., [27,75]). For these two earthquakes, the average rupture velocity during the initial phases are estimated as 1.02 to 1.8 km/s, slightly smaller than ordinary values, and the stress drops on these large initial rupture faults are estimated to be small (e. g., [27,75]). Ordinary wave-

form inversions for these earthquakes showed that the main phases were generated by the breaking of asperities (e. g., [6,28,39]).

As summarized above, a major part of the initial phases of large earthquakes do not show an accelerating increase of velocity amplitudes with time and it is thought that the rupture and slip velocities of these earthquakes are not accelerating during this time period. Consequently, it is thought that the initial portions of the observed waveforms of these large earthquakes do not reflect the nucleation process that is characterized by the transition from a quasi-static to a dynamic state; instead they represent a part of the dynamic rupture process characterized by a smaller stress drop, before the breaking of large asperities. Small earthquakes possibly show similar characteristics with an initial rupture process that is characterized by an ordinary rupture velocity and much smaller dynamic stress drop than the main phase. Although the nucleation process is probably seen in the very beginning stage of the large earthquakes analyzed by Sato and Mori [62] and Shibasaki et al. [67], it is likely that the scaling relationships between the duration of the initial phases and the rupture size shown by Umeda [72,73], Iio [30,31], and a major part of the data Ellsworth and Beroza [21] do not reflect the nucleation process but a part of the dynamic rupture process before the breaks of relatively large asperities.

### A Possible Model

As summarized in the previous section, since a major part of the observed data do not reflect the earthquake nucleation process, in particular the data from small earthquakes, we cannot examine the preslip model here.

The observed data do not match the cascade model, since the cascade model basically predicts self-similar fault breaks for successive events, not increasing dynamic stress drop events. A variation on the cascade model, the hierarchy fault model explains increasing slopes of initial rises by the abrupt increase of the moment rate function due to a longer fault edge at a higher hierarchy level [23]. However, as shown in Fig. 6, the difference between the slopes of larger and smaller earthquakes can be greater than one order of magnitude, so it is difficult to explain the observed data only by the change in rupture front geometry. It may be necessary to consider differences in dynamic fault parameters.

So the questions to be answered are, why do larger earthquakes have a longer slow initial rupture process? In the first place, why do earthquakes need an initial rupture process to break a stronger portion on the fault? Why don't

earthquakes initiate as a breaking of an asperity without the initial phase?

The key to solving these problems may lie in the studies of the two intraplate earthquakes with longer initial phases. The important observations about these earthquakes are the geometries of the initial rupture fault and mainshock fault. For the 2000 Tottori earthquake, it is found that azimuths of the initial rupture fault and mainshock fault are estimated as  $N135^\circ E$  and  $N150^\circ E$ , respectively [51]. Since the direction of the maximum compressional stress is estimated as  $N90^\circ-100^\circ E$  [42], it is found that the initial rupture fault is favorably oriented, while the mainshock fault is unfavorably oriented. For the 2004 West-off Fukuoka prefecture earthquake, the azimuth of the initial rupture fault is different from that of the mainshock fault by 20 degrees (e. g., [38,69,71]). A more obvious example is obtained for the Landers earthquake, where the Emerson fault with the largest slip is unfavorably oriented, compared with the faults that had broken before (e. g., [25]). These observations indicate that a larger slip occurred on an unfavorably oriented fault. It is possible that the mainshock fault, which generates the main phase, generally has a higher strength than the initial rupture fault. This may be the reason why larger dynamic stress drops occurred on faults of successive larger events.

If this proposed strength profile on the initial and mainshock faults holds for all the earthquakes, the above questions can be re-written: Why is a larger weak initial rupture fault necessary to break a larger strong mainshock fault?

A similar problem has been discussed by Ohnaka [55]. He derived the relationship between the critical slip distance  $D_c$  and the asperity size from laboratory experiments and the physics of contacts on faults. Since  $D_c$  is related to the size of the nucleation zone (e. g., [52]) and it is inferred from the results of waveform inversions that the asperity size is proportional to the total fault length (e. g., [47]), his relationship might be regarded as the relationship between the lengths of initial rupture fault and the mainshock fault. However, the  $D_c$  used in his relationship is that of the asperity, not of the initial rupture fault. Further, it is inferred from the above discussion that a major part of observed initial phases probably do not reflect the nucleation process (namely,  $D_c$ ).

It is important to clarify strength profiles along faults; however, we do not presently have enough information. In the following, we will assume the fault strength is controlled by the geometry of the fault surface, as estimated for the Tottori earthquake. More concretely, it is assumed that the angle between the tangent of the local fault surface and the direction of the uniform principal stresses

Earthquake Nucleation Process, Figure 11  
Schematic illustration of the strength profile along the fault deduced from a fractal geometry of fault surface. The rupture initiates at the weakest portion on the initial rupture fault and then propagates to a portion of higher strengths

controls the fault strength at each point. In this case, it is deduced that the fault strength shows a fractal-like distribution along the fault as shown in Fig. 11, since the geometry of fault surface is thought to be fractal [45]). The fault strength profile should include various wavelengths, but here we will consider the longest wavelength to investigate the interaction between the asperity and initial rupture fault, since amplitudes of a longer wavelength are thought to be larger on fractal fault surfaces (e. g., [11]).

Under the above assumptions, the asperity and initial rupture fault are attributed to the portions of higher and lower strengths on the strength profile, respectively. Strength profiles of faults of larger earthquakes are thought to have a longer wavelength. Actually, it is empirically derived that the asperity size is proportional to the total fault length [47]. Consequently, it is inferred from these results that larger earthquakes have larger initial rupture faults. On initial rupture faults, the fault strength increases with distance from the hypocenter, since the hypocenter is the weakest point on the fault. In other words, the strength at a rupture front increases with rupture growth. Thus, it is thought that the initial rupture does not expand smoothly and the slip velocity does not significantly accelerate, but a large asperity can break after a breaking of the initial rupture fault. This is only a possible qualitative model for the initial rupture process and it suggests a possibility for explaining the observed data. It should be examined by extensive studies.

We do not presently have any clear answers to the subtitle question, 'Does the initiation of earthquake rupture knows about its termination?'. Even if the above model is correct, we also have to know the geometry of the fault surface and the time, slip and slip velocity dependent stress on

the fault for large and small earthquakes, in order to simulate the rupture propagation and must understand the factors that control the earthquake size.

### Future Directions

This paper reviewed studies analyzing the very beginning portions of observed waveforms of earthquakes and showed what we have presently clarified about the earthquake nucleation process. To make further progress, the most straightforward path is to investigate the initial rupture process by precise waveform inversions for large earthquakes. In this case, new inversion methods, as proposed by Uchide and Ide [70], are useful. Furthermore, it is necessary to use broadband near field data, since it is possible that very slow slips occur on the initial rupture fault in association with the initial rupture process or for a very long time before the initial rupture process. For smaller earthquakes, high resolution data, as those in the Western Nagano Prefecture region, are necessary for investigating their rupture processes. These extensive studies about the initial rupture process can clarify the true feature of the earthquake nucleation process.

### Acknowledgments

The project in the Western Nagano Prefecture is a co-operative study with Shigeki Horiuchi, Shiro Ohmi, Hisao Ito, Yasuto Kuwahara, Eiji Yamamoto, Kentaro Omura, Koichi Miura, Bun'ichiro Shibazaki, and Haruo Sato. We thank James Mori and Masumi Yamada for their critical reviews of the manuscript. This work is partly supported by JSPS.KAKENHI (19204043), Japan. We are grateful for two anonymous reviewers for their critical and thoughtful comments.

## Glossary

**Stochastic** occurring by chance;

**Stochastic process** physical or other process evolving in time governed in part by chance.

**Earthquake mechanism** physical processes causing the occurrence of an earthquake.

**Independent events** events not affecting each other's probability of occurrence.

**Branching process** process of ancestors and offspring, as in the model of nuclear fission.

**Point process** stochastic process of point-events in time or space.

**Probability forecast** prediction of the probability distribution of the time and other features of some future event, as distinct from a forecast for the time (etc.) of the event itself.

**Model test** a statistical test for the extent to which a stochastic model is supported by the relevant data.

**Precursory signal** observed quantity which affects the occurrence probability of a future event (earthquake).

## Definition of the Subject

Stochastic models for earthquake mechanism and occurrence combine a model for the physical processes generating the observable data (catalog data) with a model for the errors, or uncertainties, in our ability to predict those observables. Such models are essential to properly quantify

the uncertainties in the model, and to develop probability forecasts. They also help to isolate those features of earthquake mechanism and occurrence which can be attributed to mass action effects of a statistical mechanical character. We do not consider in this paper applications of the models to earthquake engineering and insurance.

## Introduction

The complexity of earthquake phenomena, the difficulty of understanding and monitoring the processes involved in their occurrence, and the consequent difficulty of accurately predicting them, are now widely accepted points of view. What are stochastic models, and what role do they play in aiding our understanding of such phenomena?

The present article is an attempt to address these questions. We start from the beginnings, the distinction between stochastic and deterministic models, and the first attempts to model earthquake phenomena in stochastic or statistical terms. We then follow through with a systematic account of some of the main classes of stochastic models that are currently in use, discussing in turn earthquake mechanisms, historical earthquakes, regional catalogs, descriptive patterns, and earthquake precursors.

The focus throughout is on the stochastic modeling aspects, rather than on statistical procedures or associated algorithms. As a result we have given only brief mention to pattern-recognition techniques, or to descriptive procedures such as the estimation of fractal dimensions or of second order properties, which do not lead to fully defined models. Again, although a primary use of stochastic models is in developing probability forecasts, we have limited ourselves to the briefest account of how such forecasts can be produced and assessed. Nor do we directly consider applications to engineering and insurance problems.

The fundamental difference between a physical model and a stochastic model, in broad terms, is that while the physical model attempts to fully describe and predict the process under study, the stochastic model treats some aspects of the physical process as out of range of exact modeling, at least for the time being, and replaces it by some unpredictable and hence random process. The resulting stochastic model should reproduce those aspects of the physical phenomenon which are important and accessible to measurement, but may relegate the rest to dice-tossing or one of its more contemporary avatars such as Brownian motion or the Poisson process.

Across their many different fields of application, two broad roles for stochastic models may be distinguished. The first is epitomized by statistical mechanics. Here the stochastic model plays an integral role in understanding

the physical processes themselves. The macroscopic phenomena that we are able to observe directly – temperature, pressure and the like – are shown to be a consequence, not of the details of the collision processes at the microscopic level, but of their mass interactions, which are governed largely by laws of an essentially statistical character such as the law of large numbers or the central limit theorem. For predicting the macroscopic behavior, it is not necessary to know the details of the complex interactions between individual molecules; it is sufficient to replace them by a simple random process that nonetheless preserves the crucial physical aspects such as mean velocities and angular distributions.

Within seismology such a role is implicit when the fracture processes within the earth's crust are compared to 'frozen turbulence', or in applications of branching process or percolation theory to explain energy distributions, or in discussions of the fracture strength of materials as functions of the density and size distribution of microcracks, or in the use of cellular automata and similar models to explain the appearance of long-range correlations and power-law distributions in the approach to criticality of certain types of complex systems.

In the other, by far more common, type of application, the stochastic model is used as a basis for planning and prediction. In such situations it is vital to know, not just a forecast value, but also something about the reliability of that value. It is also vitally important that the models can be fully fitted to the observable data. Most branches of applied statistics have evolved in response to such requirements. Within seismology, applied models of this type are needed in discussions of earthquake risk for insurance or building codes, in many parts of engineering seismology, and in the development of decision rules for earthquake response and emergency planning. Probability forecasts of any kind, including all forecasts with some associated estimate of precision, necessarily rely on stochastic models of this kind.

Many decades ago, the famous geophysicist and seismologist Sir Harold Jeffreys, who is also regarded as a pioneer in inferential statistics, argued that, to be worthy of its name, every physical theory should contain within itself the means not only of predicting the relevant quantities, but also of predicting their uncertainties [45]. In our terminology, he was arguing that every physical theory should be based on a stochastic model. In the classical studies of physics and astronomy, the uncertainties in the model are assumed to be due to nothing deeper than observational errors. In a subject such as seismology, however, the uncertainties are much more fundamental.

While general patterns of earthquake behavior may

be predicted from physical theories, the predictions do not extend to the times and locations of individual earthquakes. Moreover, the available observational data are rarely more than indirectly relevant to the physical processes controlling the details of earthquake occurrence, as these usually take place many kilometers beneath the surface of the earth, and out of range of direct observation.

Stochastic models of earthquake occurrence that can be used for earthquake prediction must somehow marry the limited physical theory to the limited available data. Attempts to grapple with this central problem have intensified in recent years. They form one factor in the emergence of 'Statistical Seismology' as a new sub-discipline. Another, perhaps dominating, factor, is the enormous improvement in both the quantity and quality of the data that are available, whether from earthquake catalogs, from GPS measurements of ground deformation, or, less commonly, from data on auxiliary quantities such as well levels, electrical signals, ionospheric depression and others thought to have a potential bearing on earthquake occurrence. The high quality data demand a comparable quality in the statistical modeling and analysis.

## Historical Overview

The forerunner of any serious statistical modeling is the availability of reliable and relevant data. For models of earthquake occurrence this means the availability of good quality earthquake catalogs. Broadly speaking, such catalogs had to wait, not only until around the turn of the 20th century, when the first instrumental records became available, but until the development of modern instrumentation and the extensive station networks which came into being after the second World War. Before then, the lack of any consistent measure of the size of an earthquake, and the general unevenness of network coverage, made the records of limited value for statistical purposes.

A turning point was the appearance of the first edition of the classic text [28] by Gutenberg and Richter (1949). For the first time it gave a comprehensive overview of the major features of the seismicity of the earth, and of the key empirical relations governing earthquake occurrence. From that time onwards, the way was open for serious statistical analysis, although recent data is far more comprehensive and detailed. Modern instrumental catalogs, prepared from digital records telemetered to a local center from a dense network of stations, may contain hundreds of thousands of events down to very small magnitudes. Typically such catalogs list for each event the origin time (initiation of rupture), epicenter (latitude

and longitude of place of first motion), depth, magnitude or seismic moment (alternative measures of earthquake size), and often other parameters relating to the fault mechanism (orientation of the fault and direction of first motion).

The availability of these high-quality catalogs, alongside the increasing availability of data from GPS measurements and other earthquake-related phenomena, is a key reason for the recent upsurge of interest and research in statistical seismology. The broad aims of this emerging field may be described as finding statistical models to describe and make use of such data, and to marry it with the existing physical theory.

Even preinstrumental catalogs inspired the investigation of two statistical issues at least: does the occurrence of major earthquakes exhibit some form of periodicity in time? do the numbers of events in time intervals of fixed length follow a Poisson distribution? We comment briefly on these two questions before looking at statistical models more generally.

### Periodicity of Earthquakes

Periodicity of earthquakes, in some more or less regular sense, was the earliest issue to be investigated, and inspired many early studies, including one of Schuster's classic papers on the periodogram [112]. Until the 1930s, however, neither the data nor the statistical techniques were sufficiently developed to allow the question to be properly resolved. On the statistical side, for instance, the periodogram was a new concept, and statistical tests based on it were still in development. Schuster's paper, applied to a special case, contains within itself all the basic elements of point process spectral theory, starting from the finite Fourier transform, calculating the equivalent of rough significance levels using Rayleigh's random flights, and briefly treating the problems caused by binning the data and by clustering. Jeffreys [44] was one of the first to use a modern statistical approach to tackle the question, while Davison [21] reviewed many of the earlier studies and came to the conclusion that most of those studies were inconclusive.

The topic remains controversial, although it is now clear that no obvious periodicities exist. The most important current contenders for small-scale periodicities are in relation to earth tides. It is suggested that the small fluctuations in crustal stress due to the relative movements of the moon and sun around the earth may be large enough to trigger earthquake activity under favorable conditions, for example in regions already under high stress. A careful recent study of lunar tides on microearthquakes, with fur-

ther references, is given in [40]. The possibility of using the response of small-scale seismicity to lunar tides as a possible indicator of regions in some near-critical state, and hence as a precursor for larger events, has been suggested in [139]; a statistical analysis is given in [142].

The possibility of long-term periodicities, of the order of decades or centuries, is unclear because of the shortage of data; substantial fluctuations certainly exist. The problem is still full of potential traps. In testing for periodic effects, for example, it is essential to take into account earthquake clustering, and whether or not the period being tested for is preassigned (as for the lunar cycle) or suggested by the data. Both of these issues are illustrated in the discussion in [134] of Kawasumi's historical data for large earthquakes in the Kanto region of Japan.

### The Poisson Distribution and Process

The distribution

$$p_n = (\mu^n/n!)e^{-\mu}, \quad \mu > 0, \quad n \geq 0,$$

was introduced by Poisson as an approximation to the binomial distribution when the number of trials  $N$  becomes very large but the probability  $p$  of success becomes very small, the two balancing in such a way in such a way that the expected number  $\mu = Np$  of successes remains moderate in size.

Earthquakes were included among the examples studied by von Bortkiewicz [136] in his 1898 compilation of phenomena to which he could apply 'the law of small numbers', the name he gave to the Poisson approximation to the binomial. The question was studied in greater depth by later writers, including Gutenberg and Richter [28], and several important qualifications were noted. In the first instance, the disturbing effect of aftershocks was pointed out, and so the Poisson distribution was supposed to apply just to main shocks. Then other disturbing effects, such as trends and longer-term fluctuations in activity, were noted. In fact almost no catalog fits the Poisson description exactly, and for research purposes its role as a base-line model for 'standard seismicity' has been replaced by the ETAS model (see Sect. "The ETAS Model"), which provides a much better approximation to the clustering properties of smaller earthquakes.

Nevertheless the simple Poisson form is still the principal basis for determining earthquake risk and for earthquake insurance practices. Underlying its continued relevance is the same idea underlying Poisson's original approximation to the binomial: when the data under examination consists of rare 'successes' from many different

and essentially unrelated sources, the Poisson distribution generally emerges as a good approximation.

It is necessary to distinguish between the *Poisson distribution* and the *Poisson process*. The Poisson process refers to an evolutionary model for the occurrence of events in time or space or both. Its principal characteristics, at least in the stationary case, are

1. The number of events within any bounded region (interval in time; area or volume in space) follows a Poisson distribution with parameter  $\mu$  proportional to the size (length, area etc) of the region selected for study;
2. The numbers of events in disjoint regions are independent random variables.

The second condition embodies the famous ‘lack of memory’ property of the Poisson process: the temporal version asserts that the occurrence of one or more events before a certain time has no effect on the occurrence probabilities of subsequent events. It dictates the exponential form of the distribution of the time interval between events, and under simple conditions even dictates the form of the Poisson distribution itself; see, for example, the discussion in Chap. 2 of [20].

### The Empirical Laws of Seismology

The advent of more complete and reliable catalogs saw the recognition of a number of statistical regularities in the occurrence of earthquakes. Two of these are central features of seismicity studies today.

**Omori’s Law** Already by the end of the 19th century, the Japanese pioneer seismologist Omori had made detailed studies of some large Japanese aftershock sequences [92], and suggested that the frequency of aftershock occurrence, say  $\lambda(\tau)$ , decayed approximately hyperbolically with the time  $\tau$  after the main event:

$$\lambda(\tau) \approx A/\tau$$

where  $A$  is a constant characteristic of the particular mainshock and associated with its size. His own and subsequent studies suggested the need for refinements, and the most widely accepted form today is the the Omori–Utsu formula

$$\lambda(\tau) = A/(c + \tau)^p \quad (1)$$

where the parameters  $A$ ,  $c$ ,  $p$  are again peculiar to the individual aftershock sequence,  $c$  is generally small (of the order of seconds to days) and  $p$  is close to 1. A detailed study of the history and other issues associated with the Omori law over the 100 years 1894–1994 is given in [124].

The simplest stochastic model for aftershocks is that suggested by Jeffreys in [44], namely an inhomogeneous Poisson process in which  $\lambda(\tau)$  is interpreted as the current value of the time-varying Poisson intensity; the independence property (2) of the Poisson process of Sect. “**The Poisson Distribution and Process**” is retained, but the mean parameter for the number of events in  $(s, t)$  is now  $\mu = \int_s^t \lambda(\tau) d\tau$ .

**The Gutenberg–Richter (GR) Law** The law was formulated after the definition of earthquake magnitude gave an objective method of quantifying the size of an earthquake. It is a basic component of [28], although a similar relationship, based on the more qualitative maximum intensity concept, had been formulated somewhat earlier by Ishimoto and Iida for Japanese earthquakes [39].

The GR law provides a summary of the magnitude data in a catalog of earthquakes with magnitudes complete above a certain threshold, say  $M_0$ . It is commonly written in the form

$$\begin{aligned} \{\text{Number of events above magnitude } M\} \\ \approx 10^{a-b(M-M_0)} \quad (2) \end{aligned}$$

or equivalently

$$\begin{aligned} \{\text{Proportion of events above Magnitude } M\} \\ = 10^{-b(M-M_0)}. \quad (3) \end{aligned}$$

It is a pity in our view that the former rather than the latter of these two forms has become traditional. The danger then is that  $a$  becomes treated as a separate parameter instead of as a normalizing constant,  $a = \log_{10} N$ , where  $N$  is the total number of events under consideration. One reason for this tradition may have been the common (and incorrect) use of ordinary least squares methods to compute the line of best fit from a graph of the binned numbers. Such an approach will certainly produce a slope as one of the parameters, but the estimate is unstable and distorts the interpretation unless it is especially modified to fit the distribution function context.

The second form makes it clear that what we are looking at is an empirical probability distribution, and that the right hand side could equally and more appropriately be written in the form

$$10^{-b(M-M_0)} = e^{-\beta(M-M_0)}$$

where  $\beta = b \log_e 10 \approx 2.3b$ . Then it is clear that the GR law asserts that, under suitable conditions, the empirical distribution of magnitudes is approximately exponential.

In principle,  $a$  could be regarded as a parameter in an extended model for the space-time-magnitude distribution of events in a given space-time window, but such an interpretation is rarely given.

How valid the exponential distribution remains when examined in greater detail, and whether, and if so by what, it should be replaced for general modeling purposes, is still a subject of debate. The main reservation relates to the possibility of extremely large events, which is physically unreasonable and can lead to misleading conclusions if used in simulation studies of long-term behavior.

Of the many alternatives offered, which include truncated and multi-parameter versions (see [123] for a listing and software), perhaps the most plausible is the ‘tapered Pareto distribution’, or ‘Kagan distribution’ (e.g. [48, 135]), with distribution function written out in terms of seismic moments or energies as (4) below. This distribution arises in branching and similar models for crack propagation (see [123]), and is derived from maximum-entropy considerations in [73]; a further derivation from a critical phase transition in a finite elastic solid is given in [26].

The use of magnitude itself as a basic variable is also open to question. It is not a uniquely or tightly defined quantity. In terms of quantities such as energies or seismic moments with a more direct physical interpretation, the exponential distribution for magnitudes becomes a Pareto (inverse power-law) distribution,

$$\Pr\{E > x\} = (x/x_0)^{-\alpha}, \quad (x > x_0)$$

through a transformation of the form

$$\log_{10}(E) \approx 1.5M + \text{const } n,$$

where  $E$  is the energy. This illustrates the fact that the magnitude scale is essentially a decibel scale, ultimately a consequence of its initial definition in terms of the logarithm of the maximum amplitude of the trace on a seismograph. The tapered Pareto form mentioned earlier is

$$\Pr\{X > x\} \approx Cx^{-\alpha}e^{-\gamma x}, \quad (x \geq x_0), \quad (4)$$

where  $C$  is a normalizing constant, or the variant with a similar form for the density.

**Båth’s Law** The so-called Båth’s Law asserts, loosely, that in an aftershock sequence, the difference between the magnitude of the mainshock and that of the largest aftershock is around 1.2 magnitude units.

Although noted by Båth in 1965, and even earlier by Utsu, this regularity has never enjoyed quite the same status as the other two laws. The question, still an active topic

of debate, is whether it represents a physical phenomenon in its own right, or is merely a consequence of the more general properties of earthquake clustering. It was suggested in [125] (see also the reviews and more extensive studies in [17,63]) that it might be simply a consequence of the statistical properties of the largest and second largest in a sequence of events following the G-R law. More recently, it has been linked to the ‘productivity function’ of earthquake clustering: the expected number of aftershocks increases typically as an exponential function  $Ke^{\alpha M}$  of the magnitude of the main shock, with Båth’s Law resulting when the exponent  $\alpha$  equals the exponent  $\beta$  in the GR law (see [25]). This suggestion is supported by the appearance of a Båth’s law phenomenon in the ETAS model, where there is certainly no explicit model feature relating to Båth’s law, but there is an exponential productivity function [38].

## Stochastic Models for Earthquake Mechanisms

### General Considerations

The earliest model for earthquake mechanism is Reid’s elastic rebound model [98]. It was inspired by studies of large-scale earthquakes, in particular the famous San Francisco earthquake of 1906. The upper part of the crust is deformed elastically by large scale tectonic motions, then ruptures and rebounds when its breaking strength is reached, resulting in an earthquake.

The many attempts to marry this physical picture with simple stochastic ideas lead typically to models based broadly on the renewal process, and will be picked up in the discussion in Sect. “[Background and Data](#)”.

In this section we look rather at models which describe the behavior at the microscopic level, the evolution of the fracture itself, and can be used to explain the basic empirical laws, among other features.

There are strong links with theories on the strength of materials, starting from the classic studies of Griffiths (e.g. [27]) on crack extension in brittle materials, and the role of microfractures in controlling the fracture strength of glass. Griffiths’ crack theory is basic to models of fracture in brittle materials, whether at the scale of rock fracture in laboratory specimens or fault propagation in the earth’s crust (see e.g. [42,82,109,110]).

Griffiths’ ideas were later developed by Weibull [136] into a model explaining the variations in strength of otherwise similar specimens of rock and many other substances. Weibull supposed that the underlying cause was the random distribution of microfracture lengths in the specimen, and used an argument based on the distribution of the length of the largest such microfracture to deduce a form

for the distribution of strengths. Indeed it is from these studies that the ‘Weibull distribution’ takes its name.

The branching process, percolation, and cellular automata interpretations of the earthquake process start from similar general premises. The underlying idea is that, instead of progressing smoothly, as might a fault or fracture in a homogeneous elastic medium, the progress of the fault in a medium containing many weaknesses is controlled by the essentially random locations of these weaknesses. The various models which have been proposed differ mainly in the assumptions governing these random locations.

In Otsuka’s original ‘go-game’ model [93], points were laid down on a lattice in much the same way as in the game of ‘Go’, but at random, using a simulation technique, with the interpretation that the enclosed pieces determined a rupture area. In [108] this was idealized into a model linking weaknesses located on a Bethe lattice, where every node has one input link and the same fixed number of outward links, and each node may or may not be a point of weakness.

Otsuka’s model has both branching process and percolation model interpretations, with a considerable literature surrounding extensions of both. There also links to other, apparently more deterministic, approaches to the generation of the empirical laws, for example through block slider models or in the general class of complex systems. Although the models differ in approach and detail, the size distributions and the like often turn out to be very similar to those derived from the branching models. As in statistical mechanics, the properties have their origin in the mass interactions of many small components, and are relatively insensitive to the details at the microscopic level. The simpler statistical models, such as the branching models, allow these distributions to be explored directly by analytical means. In complex system theory the aim is rather to show how similar results arise from approximating the deterministic equations governing large families of interacting bodies.

### Branching Models

The conceptual framework here is that the crack initiates from an initial weakness (dislocation or microfracture) and spreads to one or more others, or terminates, the ‘others’ being interpreted as ‘offspring’ and the initial weakness as the ‘ancestor’. Each ‘other’ then acts as an ancestor in its own right, and the process continues until either all branches have died out (subcritical and critical cases) or the process explodes (supercritical state). The behavior is controlled by a ‘criticality parameter’  $\rho$ , effectively the

mean number of offspring per ancestor. The subcritical, critical, and supercritical cases correspond respectively to  $\rho < 1$ ,  $\rho = 1$  and  $\rho > 1$ .

This model was developed in general form in [123], following [109] and the earlier work on the ‘go-game’ model in Japan. Related ideas occur in many places papers by Kagan and Kagan and Knopoff, see especially the extended branching model described in [54].

The distribution of the size or energy release of the rupture is then obtained by counting the total number of offspring before the process dies out (critical or subcritical cases). The remarkable feature here is that even when the individual offspring distributions are very regular, the total size distribution approaches a power-law (Pareto) form whose basic parameters are independent of the details of the offspring distribution. In the limiting critical case, the power-law distribution for sizes has  $\Pr\{N > n\} \sim Cn^{-1/2}$ , corresponding roughly, assuming equal energies/event on average, to a G-R law with  $b \approx 0.75$ .

When the process is just subcritical the Pareto distribution becomes a tapered Pareto distribution, with power-law behavior for moderate to large events, and an exponential tail-off at high magnitudes which cuts in at a point determined by the distance from criticality,  $\delta = 1 - \rho$ . Again the behavior is otherwise largely independent of the details of the offspring distribution.

Many further developments and ramifications of this underlying model have been proposed. One of the deepest is the simulation model for earthquakes developed in [54], starting from the scale of dislocations or other defects in the rock fabric, and incorporating temporal, directional, and distance factors into the model evolution to develop an impressive array of properties akin to those of real earthquakes. The model still awaits a full analytical treatment.

It is also remarkable that a branching model underlies one of the most successful models for earthquake occurrence at the regional level, namely the ETAS model described in Sect. “[The ETAS Model](#)”. The fact that the same mechanism seems implicated at both levels lends plausibility to Kagan’s conjecture that the physical process is one and the same at all scales, and that our attempts to decompose it into elements at the fracture formation and inter-fracture stages are more a result of our perceptions and measuring instruments than they are of the underlying physical processes.

### Percolation Models

The classical percolation model starts from a two- or three-dimensional lattice, the sites (or alternatively the

bonds between lattice points) being randomly and independently labeled ‘open’ or ‘closed’ with a fixed probability  $p$  and its complement  $1 - p$ . A crack initiated at an open site links up all contiguous open sites until it can spread no further. In both cases, a critical regime, characterized by a critical value of the probability  $p$ , marks the transition between subcritical (small finite events only) and supercritical (infinite or explosive events) regimes. As with the branching models, it is assumed that the crust is generally in or just below the critical state.

An underlying difficulty is that the available observational data are insufficient to provide any easy control over the best interpretation. As with the branching process model again, the percolation models lead to forms of the G-R law, and with additional features can often be extended to cover aftershock phenomena. [15], and [65,66,67] are among the many papers which discuss and develop these ideas. [5] highlights some of the difficulties of interpretation.

Percolation processes are extensively used in statistical physics to model phase transitions, and their appearance here invites an interpretation of fracture as a phenomenon analogous in some ways to a phase transition. Ideas from the phase transition context that have been transferred to both earthquakes and fracture mechanics include especially features characteristic of the approach to the critical conditions required for the occurrence of a phase transition: the development of long-range correlations, the appearance of power-law or fractal distributions, and approximate self-similarity. Many authors have sought to develop these analogies, often using analogue or simulation models, and attempted to use the appearance of different interaction ranges to identify the approach to near-critical stress conditions in the crust. See [9,10,26,121], as well as the papers cited above, for further references and discussion of such ideas.

### Cellular Automata and Self-Organizing Criticality

A third type of model with a similar general role is the cellular automaton, with the distinction that the application here is not to a single faulting or fracture episode, but to a whole network of interacting faults. The simple basic form, first applied to the earthquake context by Bak and Tang [3], again relates to a two-dimensional lattice model. With each point of the lattice is associated a certain integer stress or force, say  $Z_{ij}$  for points on a 2-dimensional lattice  $\{i, j\}$ . The external force (the ‘immigrants’ in this context) is manifested through the addition of unit force to a site chosen at random through the lattice or on its boundary. When the force exceeds a certain critical value

$Z_c$  on a given site, a ‘microfracture’ occurs, and single units of force are transferred to each of the four directly adjacent sites, while four units are subtracted from the force at the original site. Such transfers may overload one or more of the adjacent sites, which then in turn transfer units of stress to their neighbors (including possibly the initial site), and so on until the system is at rest. Then another unit is added in and a further redistribution of stress takes place. The whole episode is interpreted as an earthquake, and the total number of steps in the episode is taken as proportional to the energy of the earthquake.

The process as a whole is said to exhibit ‘self-organizing (or ‘self-organized’) criticality’. Even if the process is started from a situation where the forces are set to zero at all sites, they will gradually build up, first to the stage where small individual episodes take place, then, as more and more sites approach the the critical value of stress, the episodes become larger, until a stochastically stationary state is reached where the input of stress units is just balanced by the loss of stress units from points on the boundary of the region. So long as the region under consideration is sufficiently large, a process reaching the critical regime exhibits many of the features already indicated as characteristic of the approach to a phase-change: a G-R relation, long-range correlation effects, and (with some elaborations) an Omori-type phenomenon for aftershock sequences.

## Models for Paleoseismological and Historical Earthquakes

### Background and Data

We move now to models designed for use with data on earthquake occurrences. These generally belong to the second class of stochastic models referred to in the introduction. They should be able to be fitted to real catalog data; simulations from them should mimic real catalogs; and they should be useful in real applications, capable in particular of generating probability forecasts.

We have grouped the models into two main types, those developed to model large earthquakes on historical or even geological time scales, and those developed for use with modern instrumental catalogs, where smaller events are included. The main difference between the two types of model is their treatment of clustering; this is largely ignored in models of the first type, but plays a central role for models of the second type. Models of the first type are considered in the present section, models of the second type in Sect. “[Point Process Models for Regional Catalogs](#)”.

The distinction between the groups is associated with one of the longest and still unresolved debates over earth-

quake mechanism, namely the validity of the *characteristic earthquake hypothesis*. Crudely stated, this asserts that, for any given fault or fault segment, there exists an earthquake of approximately fixed magnitude, which is determined by the physical attributes of the fault, and repeats itself after time intervals of approximately fixed length. Since faults occur over a very wide range of sizes (themselves having a power law or Pareto distribution), this does not contradict, but rather suggests a different origin for, the GR distribution.

The empirical evidence for such a hypothesis is equivocal. Its main support comes from the paleoseismological studies on repeated events along a single fault (e. g. [113]), but the data from such studies is usually so limited that it is hard to accept the evidence as conclusive. Other supporting evidence, again observed sometimes but not always, is the occurrence of a hump, corresponding to repeating earthquakes with similar magnitudes, in the frequency-magnitude distribution for selected regions. For large regions (scale of major faults), this may occur around magnitudes 6–7, suggesting that the larger events from that region occur more regularly (with higher relative frequency) than would be expected from the GR model. One difficulty with the hypothesis is that several of the best-known sequences, such as the Parkfield earthquake sequence, ultimately deviate from the prescribed regularity. Studies of microearthquakes suggest that in some circumstances similar-sized small events may repeat themselves several times in almost identical locations.

Such results suggest that no simple, universal mode of behavior is likely to be found in earthquakes from particular fault structures. Indeed, recent studies by Ben-Zion and colleagues (see [7,8,9,10] and further references therein) have emphasized the possible role played by evolving heterogeneities and damage rheology in the occurrence patterns on a fault system, and have suggested that, according to their ages and past histories, some faults may exhibit characteristic earthquake behavior while others exhibit GR behavior and others again may alternate between the two.

For paleoseismic studies, each data point is extracted with effort from trenching along fault traces or similar exercises. Moreover, only the largest events leave traces identifiable over thousands of years or longer, while estimating magnitudes and other characteristics is at best informed guess-work. Even the dates, usually determined from some form of radio-carbon or other isotope-based method, can be subject to substantial errors.

Similarly in historical studies, such as Ambraseys' history of Persian earthquakes [1], only the largest events affecting a given region or territory are likely to appear sufficiently prominently in the historical records to allow the

size and epicenter of the earthquake to be estimated even roughly. Periods of civil war, famine, foreign invasion and bureaucratic neglect leave gaps and further uncertainties which are difficult if not impossible to resolve.

Despite such difficulties, these data provide the only records we have of seismic activity over periods stretching backwards in time beyond the last hundred years or so, and are worthy of the most serious attempts to collect and interpret.

We consider a sequence of three models, starting from the simple renewal model, then considering variants more closely linked to the elastic rebound model.

### Renewal Models

With paleological data in particular, attention is generally focused on major events along a single fault, where magnitudes are poorly constrained, and the stochastic elements are introduced primarily to describe, and if possible predict, the time intervals between events.

For a renewal process, magnitudes are neglected, and it is assumed that the successive intervals are independent, both of each other and of other processes, with a common distribution. The independence assumptions are questionable, but with no further information available, this is at least a reasonable starting model.

Let  $f(x)$  denote the density and  $F(x)$  the distribution function of the common interval distribution. If the observation record, over  $(0, T)$ , say, comprises an interval of length  $\ell_0$  to the first recorded event, then  $n$  complete intervals  $\ell_1, \ell_2, \dots, \ell_n$ , and finally an unfinished interval  $\ell_{n+1}$ , the likelihood is given by

$$L(\ell_0, \ell_1, \dots, \ell_n, \ell_{n+1}) = a(\ell_0) \left[ \prod_{i=1}^n f(\ell_i) \right] b(\ell_{n+1}), \quad (5)$$

where  $\ell_0$  and  $\ell_{n+1}$  are the incomplete intervals from the commencement of study to the first event, and from the last event to the end of the study, respectively,  $a(x) = [1 - F(x)]/\mu$ ,  $b(x) = 1 - F(x)$ ,  $\mu = \int_0^\infty uf(u)du$ .

The term  $a(x)$  at the beginning of the sequence is the appropriate form to use if the process can be supposed stationary, but nothing is known about events before the commencement of the observation period. The term  $b(x) = 1 - F(x)$  at the end of the sequence merely acknowledges the fact that the final interval has begun but not yet concluded.

The main uses of the model are in estimating long-term average or static hazards, in which case the mean of the interevent times plays the crucial role and the form of the distribution is largely irrelevant (so that a Poisson

approximation would generally be adequate). The other application is to estimating the residual time to the next event, which is governed by the extended hazard function

$$h(y|x) = f(x+y)/[1-F(x)] \quad (y \geq 0; x > 0), \quad (6)$$

giving the density of the distribution of the time  $y$  from the present to the next event, given that time  $x$  has elapsed since the last event.

Distributions commonly used in these situations include the Weibull, gamma, log-normal and Brownian first passage time (inverse normal). Recent work has tended to favor the last of these: see [79]. Two further recent studies which look carefully at the statistical issues, including those relating to errors in the occurrence times, are in [64] and [121]. In long period studies, care needs to be taken that consistent procedures have been used over the whole period, particularly in the determination of magnitude thresholds, and rules for the exclusion of aftershocks (which must be removed here since otherwise they would contradict the assumption of i.i.d. intervals).

### Time- and Slip-Predictable Models

The time-predictable model, introduced by Shimazaki and Nakata in [116], is a widely used alternative for major events along a given fault, when magnitudes as well as inter-occurrence times are available.

As in the elastic rebound model, it is supposed that stress along a particular fault builds up linearly until a critical value is reached, representing in some sense the strength of the fault. The size (magnitude) of the resulting event is not known beforehand, but is supposed to be selected randomly either from the standard G-R form or a variant suggested by the characteristic earthquake model.

Once it has occurred, the stress along the fault is instantaneously reduced by an amount determined by the magnitude of the event. Then stress build-up continues until the critical stress level is reached again. The time needed for this to occur is determined by the stress released by the previous event, and so is known, whence the 'time-predictable' title.

The major unknown in the model is the rate of stress build-up between events. If only observation times and magnitudes are available, this can be estimated, albeit crudely, by regressing the observed time intervals onto the magnitudes of the preceding events. If the magnitudes are determined up to a normal error term, with variance independent of the magnitude, this will result in a log-normal distribution for the length of the time interval following an event of given magnitude, and indeed this is commonly

used. Another approach would be to use geological data to provide an initial ('prior') distribution for the slip rate, and put the further analysis into a Bayesian framework.

A simple model used for predictive purposes in some of the papers by the Working Group on Californian Earthquakes (see [137] for example), can be represented as

$$\log T_i = A + M_i + \epsilon_i \quad (7)$$

where the  $\epsilon_i$  are independent, normally distributed errors with zero mean and constant variance, the  $M_i$  are the observed magnitudes of the events, and  $A = -\log V$  is the logarithm of the slip rate, estimated from geological and GPS studies. Given the time  $x$  since the last major event on the fault, the distribution of the remaining time  $y$  until the next event is governed by the extended hazard function of the log-normal distribution, as in the discussion (6) of the renewal model, but with the mean adjusted to take into account the extra information provided by the magnitude of the previous event.

An underlying but subtle logical difficulty with the model is that if applied on a long time basis, the assumption of i.i.d. lognormal errors leads to unbounded fluctuations in the accumulated sums

$$V \sum_1^n T_i - \sum_1^N S_i = V \sum_1^N S_i (\epsilon_i - 1),$$

where  $S_i$  is an estimate of the slip from an event with magnitude  $M_i$ . The cumulative sum on the right hand side can oscillate without bound, implying the unphysical possibility of indefinitely large fluctuations in the accumulated stress.

Shimazaki and Nakata also suggested a dual version, the *slip-predictable* model, characterized by a return after each event to a constant resting stress. The time at which the next event will occur is unknown, but given the time since the last event, the minimum expected size is determined by the stress accumulated since the previous event. [57] develops a more detailed version for use in earthquake engineering applications.

### The Stress-Release Model

The stress-release model is an attempt to address similar issues from within a stochastic point process framework (see for example Chap. 7 of [20]), incorporating both occurrence times and magnitudes. As in the previous case, it is assumed that the rate of stress build-up is constant (say  $\rho$ ), and that sizes of successive events are i.i.d. and independent of the stress level at the time of occurrence.

Most commonly they are assumed to follow the exponential form associated with the GR law, but this is not inherent in the model.

The crucial difference with the time-predictable model is that, instead of assuming that the strength of the crust is fixed, it is assumed to be variable with distribution function say  $\Phi(s)$  with density  $\phi(s)$ . The probability that the next earthquake occurs when the stress passes through  $s, s + ds$ , but not before, is then given by the hazard function  $\Psi(s) = \phi(s)/[1 - \Phi(s)]$ . This hazard function  $\Psi(s)$  determines the pattern of occurrence probabilities. Most commonly, it is taken to have an exponential form  $\Psi(s) = Ae^{\lambda s}$ , corresponding to the double exponential distribution function  $\Phi(S) = 1 - e^{-A[e^{\lambda s} - 1]}$  for the breaking strength itself. This has a well-marked mode at  $(-\log A)/\lambda$  if  $A$  is rather small.

In stochastic point process terms, the quantity  $\lambda^*(t) = \Psi[X(t)]$  can be interpreted as the *conditional intensity* of the model, meaning approximately the instantaneous occurrence rate, given the history of the process up to time  $t$ :

$$\lambda^*(t)dt \approx E[dN(t) | \mathcal{H}(t)] \approx \Pr\{dN(t) > 0 | \mathcal{H}(t)\}. \quad (8)$$

Roughly speaking, the process behaves locally like a Poisson process with instantaneous rate  $\lambda^*(t)$ , which in the stress-release model can be written more explicitly as

$$\lambda^*(t) = \Psi[X(t)] = \Psi \left[ X(0) + \rho t - \sum_1^{N(t)} S_n \right]. \quad (9)$$

This model has several useful features. First, the fact that a simple explicit form exists for the conditional intensity means that it can be readily incorporated into standard procedures for maximum likelihood estimation, simulation, and prediction (see again Chap. 7 of [20]). In particular, the likelihood ratio for a set of observed events  $(t_i, M_i)$  over the interval  $[0, T]$  can be written in the form

$$\log L/L_0 = \left[ \sum \log[\lambda^*(t_i)/\lambda] - \int_0^T [\lambda^*(u) - \lambda] du \right] + \sum_1^{N(T)} \log[g(M_i)/g_0(M_i)] \quad (10)$$

where  $\lambda$  is the rate of the background (null) model, assumed constant rate Poisson,  $g(x)$  and  $g_0(x)$  are the densities of the proposed and background magnitude distributions, and the magnitudes are assumed independent.

Second, as in earlier, related work by Knopoff [58], the current stress level, say  $X(t)$ , is Markovian, for the current value of  $X(t)$  determines the probability of the next jump

occurring, while the remaining components (size of jump, rate of build-up between jumps) are independent of the past history of the process. Hence the extensive knowledge of Markov processes can be brought to bear on the properties of  $X(t)$  (e. g. [11]).

A third point is that as the stress level increases, the rate of occurrence of new events will remain relatively high until a large enough event occurs to reduce the stress level to substantially lower values. The model therefore embodies a modest form of accelerated moment release [43].

The model assumes only a simple scalar concept for regional stress, much as in the early chapters of [83], and does not allow for stress interactions between regions. To address the latter point, the *coupled stress release model* was introduced by Shi Yaolin and students [68], to allow stress transfers between regions as well as simple stress drops. Further discussions and examples are in [4] and [71].

## Point Process Models for Regional Catalogues

### Data Consistency and Declustering

Regional catalogs, based on instrumental data from the last century or so, present a very different picture, but one with its own problems also. Of these, the two most important are the maintenance of consistency and the problem of clustering (or declustering).

It is characteristic of such catalogs that the networks supplying the data undergo many changes with the passing of the years. Although it is just these changes that have made possible the more serious statistical studies of recent years, they create their own problems in terms of lack of data consistency. Using such data for any form of long-term study requires continual vigilance over questions such as improvements and other changes in the individual network stations and their instruments, shifts in magnitude definitions or thresholds, changes in the routines used in determining epicenter locations, policy decisions over the events to be listed in the catalog, etc. Unless such factors are carefully listed and properly allowed for, they can easily lead to misinterpretation of statistical features observed in the data. As just one illustration, [18] gives some vivid examples of features of apparent physical interest which in fact have their origins in catalog artefacts induced by changes in magnitude registration.

An even more vexed question is whether, and if so how, to remove major clusters from (i. e. 'decluster') the catalog. Large aftershock sequences look simple to identify and remove, but the process is considerably more difficult than it might appear.

The possible justifications for doing so are two-fold. If it is believed that the large events are different in kind from the smaller events, then declustering is simply a procedure to isolate the events of primary importance. This assumption was once standard, and in any case the large events appear to be responsible for the major part of the large-scale tectonic motion. But with data on small events becoming ever more plentiful and increasingly reliable, their role is undergoing reassessment.

The second justification for removing aftershocks and other clusters is that they are a nuisance. They negate the assumptions of independence which lie at the basis of most standard statistical tests (e.g. for trends or periodic effects), they greatly complicate analysis and interpretation, and they require elaborate and difficult techniques to deal with explicitly.

Nevertheless, most statisticians, myself included, would tend to look askance at throwing away a substantial portion of the data on the basis of what are inevitably somewhat ad-hoc rules. Many procedures for removing aftershocks have been proposed, and the fact that none has gained general acceptance is evidence of this underlying problem. Moreover, while declustering removes the most obvious earthquake clusters, it rarely removes the clustering completely. The interpretation of results based on the remaining data remains equivocal, partly physical and partly man-induced.

For such reasons we do not discuss declustering in detail in the present article, but concentrate rather on procedures for modeling the data without removing the aftershocks.

A general caution in handling clustered data is not to presume that standard statistical procedures, especially tests, can be applied without modification. In general, the presence of clustering severely affects significance levels. For example, attention is drawn in [81] to the dangers of assessing the significance of precursory effects without properly allowing for clusters. A similar point occurs in assessing the significance of periodic effects, as was pointed out by Schuster in [112], as well as more recently in [129] and no doubt in other places.

To allow for the effects of clustering, and to examine the structuring features themselves, some form of explicit modeling is generally desirable. For example, one possible approach to highly clustered data is to remove as much of the gross clustering as possible with a basic cluster model, and then examine the residuals from fitting the model. Ogata, Zhuang and colleagues have recently developed various techniques, described in [86] and [143] for example, for examining the residuals from catalog data initially fitted by the ETAS model. Alternatively the cluster

model can be fitted locally (i.e. with parameters allowed to vary in time or in space and time), and the parameter variations examined to shed more light on the features of interest: [89] contains a compelling example of such an analysis.

We proceed to describe three types of cluster model, starting from the ETAS model itself. All three models are defined through the form of the conditional intensity function, as outlined in the discussion of the stress-release model. In all three models again, magnitudes are allocated independently and randomly, either according to the GR law, or some variant such as the tapered Pareto distribution for seismic moments. The final feature in common is that in all three models the main component in the conditional intensity is a linear combination of contributions from past events.

### The ETAS Model

The ETAS model (the initials standing for Epidemic Type Aftershock Sequence) first appeared in Ogata's paper [86], but was preceded by a series of studies by Ogata and colleagues in Tokyo on processes which, like the ETAS model itself, have conditional intensities of the linear, Hawkes type, following [34,35]. Earlier cluster models included the Neyman–Scott process, reincarnated as a 'trigger model' in [133] and [126].

In its basic time-magnitude form, the ETAS model has conditional intensity

$$\lambda^*(t, M) = \beta e^{-\beta(M-M_0)} \cdot \left\{ \mu + A \sum_{i:t_i < t} e^{\alpha(M_i-M_0)} f(t-t_i) \right\}, \quad (11)$$

where the first term on the RHS is the GR density for magnitudes,  $\mu$  is an arrival rate for background (ancestor) events, the constant  $A$  is related to the criticality of the process, the 'productivity function'  $e^{\alpha(M-M_0)}$  describes how the number of first-generating offspring increases with magnitude of the parent event, and  $f(u) = p c^p / (c+u)^{1+p}$ ,  $c > 0$ ,  $p > 0$  is the density (here a Pareto form) for the distribution of the temporal lag between the arrival or birth of the parent and that of its offspring.

In the full space-time-magnitude version

$$\lambda^\dagger(t, x, M) = \beta e^{-\beta(M-M_0)} \cdot \left\{ \mu h(x) + A \sum_{i:t_i < t} e^{\alpha(M_i-M_0)} f(t-t_i) g(x-x_i) \right\}. \quad (12)$$

The new terms are the density  $h$  of new arrivals over the spatial region, and the density  $g$  in space for the location of an ‘offspring’ event about its parent. We suppose that  $f, g$  and  $h$  are all normalized to form probability densities.

One of the main attractions of the Hawkes’ processes, including the ETAS model, is that they have a branching process interpretation, first pointed out in [36] and implicit already in the description of the conditional intensity. For example, the criticality parameter (mean number of offspring per ancestor, averaged over the magnitude distribution for the ancestor) is given by  $A/(1 - \alpha/\beta)$  for both the above forms. Thus a stable version of the process can exist only if  $\alpha < \beta$ , and then only if  $A$  is small enough. Of course, branching process ideas appear in many earthquake occurrence models, notably in Kagan’s work (e. g. [36]).

While the branching process interpretation gives much insight into the structure of the ETAS model, statistical analysis depends crucially on the representations in (11) and (12), since they lead to the relatively tractable form (10) for the likelihood.

For computational purposes, the likelihood of a general marked point process, of which the ETAS models are examples, is often written most conveniently in terms of the conditional intensity  $\lambda_g^*(t)$  for the *ground process*, the overall occurrence of points, irrespective of location or mark, and the conditional mark (in our case space and magnitude coordinates) distribution  $f^*(x, M|t)$ , so that  $\lambda^*(t, x, M) = \lambda_g^*(t) f^*(x, M|t)$ . The star indicates that the quantities so labeled are in general conditional on (and hence functions of) the histories up to time  $t$ . Provided  $f^*$  is normalized to a probability density for any given past history, we can write the likelihood ratio in the form

$$\log L_1/L_0 = \left[ \sum_{i=1}^{N(T)} \log[\lambda_g^*(t_i)/\lambda] - \int_0^T [\lambda_g(t) - \lambda] dt \right] + \sum_1^{N_g(T)} \log[f^*(x_i, M_i | t_i)/f(x_i, M_i)], \quad (13)$$

where the terms  $\lambda$  and  $f(x, M)$  relate to the rate and mark distribution for the background process (null model), here taken to be a constant rate Poisson process with independent (and usually GR) magnitudes.

This form represents the likelihood ratio as the sum of two terms, the first involving the time points only, and the second involving the marks (spatial locations) given the time points. In many models, the parameters appearing in the two terms have no common variables, in which case optimization can be carried out for the two terms separately.

Because the ETAS model fits well to catalogue data over a wide range of scales and contexts, in recent years its properties have been examined in detail, with the aim of verifying its ability, or otherwise, to reproduce specific features of the real process, such as Bath’s law or the occurrence of foreshocks; see, for example, [37,38].

Moreover, the procedures developed by Ogata and colleagues for fitting versions of the model in which the parameters can vary in both location and time, and for detecting local departures from a good fit of the model, have made the ETAS model a powerful diagnostic tool. In this way it has been used to estimate local variations in the stress field (e. g. [89,91]), or changes in seismicity due to the intrusion of ground water [30,58].

For long it was believed that an immigration component, coupled to a subcritical branching structure for the offspring, was the only way to produce a stable process with branching structure. However, it was shown recently in [12] that when the temporal lag distribution  $f(\cdot)$  of (11) is very long-tailed, a critical Hawkes process can sustain itself indefinitely as a ‘process without ancestors’. Another somewhat unexpected extension, described in [132], is to a self-similar version over an infinite range of magnitudes.

Perhaps the one serious limitation of the ETAS model is its rather poor performance as an intermediate-term predictor. The reason for this is that its predictive power is basically dependent on its ability to fit aftershock sequences. Hence it does not show significant gains, even against the Poisson model, until the time intervals between forecasts are of similar order of magnitude to the time intervals between the larger events in an aftershock sequence.

### The Kagan–Jackson Models

Kagan and Jackson have proposed a number of forms of which we refer to two, the long-term and short-term versions of [41]. The long-term version has its origins in [51], while the short-term version has its origins in [55].

In the long-term model, the current value of the conditional intensity, within a spatial region  $A$  and based on observations within  $(0, t)$ , has the form

$$\lambda^*(t, x, M) = f_t(x)g(M)h(t) \quad (14)$$

where  $h(t)$  is the overall current risk (ground process intensity),  $g(M)$  is a (fixed) magnitude distribution, commonly that corresponding to the tapered Pareto form for seismic moments, and

$$f_t(x) = \sum_{0 < t_i < t} k(x - x_i) / \sum_{0 < t_i < t} \int_A k(x' - x_i) dx'$$

$k$  being a spatial kernel function. Thus  $f_t$  is a normalized sum of contributions from previous events within the observation period and spatial region. It is time-independent except insofar as the advent of additional events requires additional renormalization.

Although the model is well-defined by its conditional intensity and an initial condition at  $t = 0$ , and can be fitted by likelihood methods much as for the ETAS model, the renormalization introduces a non-linear component into the model which makes its properties more difficult to analyze than those of the ETAS model. Moreover, like other forms of moving average model, it is non-ergodic: there is no unique stationary form to which it will converge from different initial conditions. Nevertheless, it serves the principal purpose of providing a baseline comparison for other putative prediction models for the same region.

The short-term form is very close to the spatial ETAS model. As in the ETAS model, each past event is associated with both a spatial and a temporal decay function, the temporal decay following the Omori law. Again, however, it involves a renormalization rather than the introduction of an explicit immigration term into the model, although some versions of the model allow a small quota of ‘surprises’ in parts of the region with no previous earthquakes.

An important role for both models has been to focus attention on the need for systematic, long-term evaluation and comparison of forecasting models, and to provide a more relevant null model than the constant-rate Poisson process.

### The EEPAS Model

This model grew out of several decades of experimentation with precursory swarm models by Evison and Rhoades; see [24] and [104] for more of the history and underlying concepts. The precursory swarm models identify groups of moderate-sized earthquakes as precursory swarms and use these as possible precursors of large earthquakes. Since both precursory phenomena and forecast phenomena belong ultimately to the same process of earthquake formation, a more satisfactory approach is to try and develop a joint model for both phenomena. This, in effect, is what the EEPAS model achieves. It has its own rationale, based on a theory of growth and development of crustal fractures outlined in the papers cited above, and has been successfully applied in several major seismic regions (e. g. [100] and [105]).

Much as in the ETAS model, the conditional intensity has the general form

$$\lambda^*(t, m, x) = \mu\lambda_0(t, m, x) + \sum_{t_i < t} w_i \eta(m_i) r(M | M_i) f(t - t_i | M_i) g(x - x_i | M_i), \quad (15)$$

but the details are significantly different.

First, the conditional intensity in (15) is not taken to apply to the whole catalogue from which the events on the right side are derived, but only for events above a higher threshold. Thus, the model might be used for modeling (and predicting) events over magnitude 5.8, but would take explanatory data from the catalogue of events with  $M \geq 4$ .

Second, the functions  $f$  and  $g$  are not based on Omori-type decay formula, but on logarithmic regressions for the time and space delays between an initiating event and the event it may precede, and the magnitudes of the two events. Thus for example

$$f(u | M_i) = \frac{1}{u\sigma_T\sqrt{2\pi}} \exp\left[-\frac{(\log u - a_T - b_TM_i)^2}{2\sigma_T^2}\right],$$

with an analogous expression for  $g(w)$ , while  $r(m)$  takes the form

$$r(m | M_i) = \frac{1}{\sigma_M\sqrt{2\pi}} \exp\left[-\frac{(m - a_M - b_MM_i)^2}{2\sigma_M^2}\right].$$

They differ considerably from the functional forms used in the ETAS model, but are similar to relations used in the precursory swarm models.

The weight factors  $w_i$  are commonly set to unity, but in more refined analyzes may be down-weighted when the triggering event has been identified as an aftershock. One way of finding suitable weights is to carry out an initial ETAS stochastic declustering, as in [143], and base the weights on the probability that a given event is independent.

The further normalizing factor  $\eta(m_i)$  in (15) is introduced, much as in the Kagan–Jackson models, to offset the absence of any immigration term, and to compensate for the input from earthquakes below the magnitude threshold. It is adjusted for each magnitude class  $m_i$  so that the overall rates follow the G-R law.

In practice the contribution from the baseline rate density is often so small as to be negligible.

Our impression is that the EEPAS model is currently the best-performing of the general seismicity models in the sense of producing the highest average probability gains or entropy scores (see Sect. “Assessing Probability Forecasts”) for predicting moderate to large events on intermediate time scales.

## Stochastic Models with Precursors

### General Considerations

The search for reliable earthquake precursors has a long and troubled history. High hopes in the 1970s met many disappointments, some at least arising from an inadequate appreciation of the many statistical pitfalls. These difficulties are now much better appreciated, but even so there are relatively few studies based on a satisfactory statistical model, incorporating a proper assessment of the uncertainties, and showing a significant precursory effect.

From a modeling point of view it is important to distinguish between *complete* and *partial* models. In a complete model, both the earthquakes and the precursors are included as components of an overarching joint process, the earthquakes forming one marginal process and the precursors another. In principle such a complete model should be the aim, but in most situations either the background physics is insufficiently understood, or observations on the precursors are inadequate, or the statistical analysis is too difficult, to allow such a joint analysis to proceed. In many situations also, the modeling and analysis lie outside the realms of conventional statistical models (in dealing with self-similarity, for example), raising further procedural problems.

In a partial model, no attempt is made to model the precursors as a stochastic process. They are treated as given, and their data used in regression-like procedures to modify the probabilities of earthquake occurrence. They can be used retrospectively to examine the performance of a suggested predictive relation, but their use in developing probability forecasts is limited to the short term because there is no model to forecast the future behavior of the precursors.

In the later parts of this section we illustrate some of the modeling approaches that can be used with precursors, using examples drawn mainly from our own experience.

One issue that commonly arises is that the precursory signal data are derived from observations taken at fixed sampling intervals. To match such data to the point process data for the earthquakes, it is generally easiest to switch the whole analysis to a discrete-time study. In this case the continuous time point process models of the previous sections need to be replaced by approximating discrete time models. The two most common of these are the logistic, or binary data, models, and the discrete Poisson process models, illustrated in the first two examples below. In these two classes of models, the probabilities  $p_n$  that an event occurs in the  $n$ th interval (respectively, the means  $\mu_n$  of the Poisson distribution for that interval) play the

role of the conditional intensity function  $\lambda(t)$  of the continuous time models of the previous section.

### Example 1: Logistic Regression Analysis of M8 Series

Logistic regressions are used to directly assess the effect of precursor observations on the event probabilities  $p_n$ . Suppose that at the  $n$ th interval, observations  $(U_1^n, U_2^n, \dots, U_k^n)$  are available on  $k$  precursors. Dropping the  $n$  for brevity, the logistic regression takes the general form

$$\log \left[ \frac{p}{1-p} \right] = \alpha_0 + \sum_{k=1}^K \alpha_k U_k \quad (16)$$

where the left side is the logit (log-odds) transform of the event probability, and the right side is the regression term. This representation corresponds to the canonical form for a binomial distribution as a member of the exponential family. Standard routines exist for estimating the parameters  $\alpha_k$  by maximum likelihood or closely related methods, and form part of the generalized linear model procedures.

As an example we consider the model used in [32,33] on the output from the M8 algorithm on New Zealand data.

The M8 algorithm itself is not a stochastic process model, but a decision procedure for calling an earthquake alert based on the analysis of 7 contributing series from earthquake data within a specified 'region (circle) of investigation'. It is the best known of a number of pattern-recognition algorithms developed by the Russian group headed by Keilis-Borok during the 1970s and subsequently. The basic form of the algorithm is described in [56] and [59], with recent reviews in [60,61].

The heart of the algorithm consists of a set of decision rules, based on the joint behavior of the 7 time series, for calling an alert, or more specifically the announcement of a 'TIP' (time of increased probability of an event above a given magnitude threshold) over the region of investigation. The time series are updated every six months, and a TIP extends for three years in the first instance.

A key feature of the analysis in [32,33] is that, in each six-month interval, the values of the seven series are combined by a non-linear formula (linear methods seem less effective) into the value  $U_1^n$  of a 'critical series' which is then used as the single precursor in a logistic regression model. The non-linear formula mimics the structure of the decision rules used in declaring a TIP.

The logistic regression analysis then provides the probability for the occurrence of an event over the specified magnitude threshold within the region of investigation for

the current 6-monthly period. Much of the further discussion in [32,33] is concerned with combining the outputs from overlapping regions of investigation.

Note that the analysis is typical of that for a partial model; a complete model for M8 would model the joint distribution of the M8 series and the target events.

### Example 2: Discrete-Time Poisson-Type Model for ULF Electric Signals

In a discrete-time Poisson-type model, the number of events  $Z_n$  in the  $n$ th time interval is modeled as a Poisson variable with mean  $\mu_n^*$  that is treated as a function of the past history in much the same way as the conditional intensity in the continuous-time model. The likelihood ratio against a constant mean Poisson process takes the form

$$\log L/L_0 = \sum_1^N Z_n \log(\mu_n^*/\mu) - \sum_1^N (\mu_n^* - \mu). \quad (17)$$

The analogy with the point process form (10) is very obvious, particularly as the time intervals become small so that with high probability the  $Z_n$  are either 0 or 1.

The way in which  $\mu_n^*$  depends on the past can be very general, subject only to the constraint  $\mu_n^* \geq 0$ . In particular,  $\mu_n^*$  can depend on prior observations both of the process itself and of auxiliary (precursory) variables. If a linear conditioning of the type (16) is required, the multiplicative form

$$\log \frac{\mu_n^*}{\mu} = \sum_{k=1}^K \alpha_k^{(n)} U_k^{(n)} \quad (18)$$

can be used, ensuring that  $\mu_n$  is positive, and slotting into the canonical form for the Poisson distribution as a further member of the exponential family, so that the generalized linear model procedures become available. However, the form of the likelihood (17) is usually simple enough to be maximized directly even in more general cases.

An example is the analysis of ULF (ultra low frequency) electric field data in [144].

The ULF signal referred to here is made up of small fluctuations in electric potential measured some meters below the ground surface by sensitive and well shielded electrodes. Its role as a precursor, and the physical explanation of the phenomenon, if it exists, are still unclear. The data analyzed in the paper cited come from some thirty years of recordings from stations around Beijing in China.

Here the base-line (reference) model is a self-exciting (Hawkes type) process in discrete time for the daily earthquake numbers in a wider region around Beijing. Such a model is needed as a reference model because it

takes into the inherent clustering effects of the earthquakes themselves. Otherwise there is a temptation to interpret (wrongly) all improvements over the constant rate Poisson process as due to the signals and not to the inherent clustering of the earthquakes. The regressands were the daily readings of ULF anomalies at a set of some half-dozen recording stations around Beijing, simplified to form 0-1 series of observations above a threshold. In fact the daily numbers of earthquakes were small enough for the corresponding continuous and discrete time models to be essentially identical.

Two analyzes were carried out, first with a linear Hawkes-type representation incorporating the effects of past earthquakes alone (self-exciting model), none of the ULF data being used, and second with a double (mutually exciting) linear Hawkes-type representation for the effects of both past earthquakes and ULF signals on the current rate. Likelihood ratios were taken first with respect to a constant rate Poisson process, optimizing parameters in both cases, then (as a ratio of ratios) for the first and second models against each other, to allow the improvement due to adding in the information from the ULF signals to be assessed.

In this study the model was also tested in reverse mode, to see whether the earthquakes improved the likelihood performance of a Hawkes-type model for the ULF signals alone. The results were positive in the direct mode and negative in the reverse mode. Either way, the models were partial, not complete, as no attempt was made to provide a joint model for the earthquakes and the ULF anomalies together.

Discrete-time Poisson-type models are also used as the basis for model testing within the RELM testing center in Southern California [111]. The modeler supplies the Poisson rates  $\mu(n, r, m)$  not only for each time interval ( $n$ ) but also for each spatial bin ( $r$ ) and magnitude bin ( $m$ ). The (approximative) assumption is then made that all the Poisson variables relating to a given time interval are conditionally independent given the current Poisson rates, so that a likelihood ratio of the form (17) can still be used, and made the basis of comparing different proposed models.

### Example 3: Point Process Regression Models

As already hinted at, continuous time (point process) procedures can be developed along similar lines to those in the previous example, if the past history includes information on auxiliary (precursory) variables as well as the history of the point process itself.

The form of such dependences can be very general, but if a linear form is wanted it can be incorporated through

expressions of the form

$$\log[\lambda^*(t)/\lambda_0^*(t)] = \sum_{k=1}^K \alpha_k U_k(t) \quad (19)$$

for the ratio of intensities, in a similar way to the multiplicative form for the discrete Poisson model. In the special case that  $\lambda_0(t)$  corresponds to a renewal process, this is the well-known *Cox regression model* [18]. A comprehensive treatment of models of this kind, with mainly medical and social science applications, is in [2].

Few examples of this type are known to us in the seismological literature, and this may be one area with scope for further development. For example, it is possible that the time-predictable model could be reformulated as a Cox regression model, by building in the dependence on the size of the previous event as a regressand. The closest to a model of this kind that already considered in this article is perhaps the EEPAS model, where the events used in developing the conditional intensities are mainly smaller than the events being modeled, and so could be described as precursors. Thus the conditional intensity for the larger events being modeled is regressed onto the magnitudes, times and locations of the smaller events in the catalogue. If the renormalization and immigration terms were omitted, the conditional intensity (15) of the EEPAS model would have a similar basic form to (19) above.

#### Example 4: Foreshocks

Foreshocks, with their potential for earthquake prediction, have been of interest to seismologists since the days of Omori and other earthquake pioneers. The hope that increased quantity and quality of catalogue data would lead to a more definitive picture of how, when and why foreshocks occur has not yet been realized, however. Features which would discriminate foreshocks from other earthquakes or earthquake clusters have proved hard to identify, although careful studies by Ogata and colleagues (e. g. [90]) do suggest that limited opportunities for discrimination may exist.

As precursors, foreshocks retain a specific but limited role. Some degree of forecasting power is available simply from the fact that any newly-observed event, outside those in clearly defined aftershock sequences, has the potentiality of being a foreshock. Recent studies of foreshock occurrence from this point of view are given (among others) in [46] for Southern California, [96] for large global events, [80] for New Zealand earthquakes.

The studies suggest that, leaving aside events in an obvious aftershock sequence, between 5 and 10% of earth-

quakes with magnitudes 4 and over are likely to be followed by a larger event within time and space windows of the order of 4–5 days and 20–30 km radius respectively. No very sophisticated stochastic model is required to describe such a feature: within the defined window, the probability that a larger event will occur is simply increased from its background value to about 5%, and multiplied by a standard GR factor to take into account magnitude variation; a further separate factor can be used to take into account sub-regional variations of foreshock probabilities.

In the last few decades foreshocks have been studied from a more general point of view, as evidence or otherwise of the self-similarity of earthquake occurrence. In a branching model such as the ETAS model, no foreshock feature is explicitly built into the model, but from among a given parent's offspring, one will occasionally appear with a magnitude larger than that of its parent – with frequencies again in the vicinity of 5%, approximately irrespective of the magnitude of the parent.

That just such an interpretation may apply also to real earthquakes is suggested in [25]. Foreshocks then are not a specific physical phenomenon, but just parent events which happen to have offspring larger than themselves. An interesting connection between the probability that an initial event is a foreshock (followed by a larger event as offspring), and the distribution of the Bath's law magnitude gap, is put forward in [25] and [38].

#### Further Topics

There are many further topics where stochastic modeling ideas are relevant, even if they do not necessarily involve the development and fitting of a full model. For example, the last few decades have seen considerable work on the development of procedures for producing and assessing probability forecasts, and for quantitatively describing spatial or space-time point patterns. In this section we list what seem to us to be some of the more important topics of this kind, space precluding more than very cursory accounts.

#### Generating Probability Forecasts

There is no longer any very hard and fast line between predictions and probability forecasts. It has long been recognized that any prediction of the time and place of a forthcoming event must be accompanied by some statement of the uncertainties in the prediction. But this, as discussed in the introduction, is precisely the motivation for introducing stochastic models. Using such a model, the uncertainties can be rephrased in terms of the probabilities of occurrence within specified time intervals and spatial regions,

i. e. by probability forecasts. In our view such probability forecasts represent the most useful way of summarizing information about the uncertainties regarding future events. In statistical jargon, they represent the ‘predictive distributions’ for future events, and form the basis not only for the probability forecasts themselves, but also for any associated cost-benefit analyses.

Even within a probabilistic framework, the idea that precise, medium-term or even short-term forecasts may be possible has looked increasingly like a pipe dream over the last few decades. Nevertheless, it is not yet entirely ruled out. While the emphasis in the last few decades has been on increased surveillance, improved knowledge and understanding of long-term hazards, and the reduction of risks from earthquake hazards, medium term (months to years) probability forecasts are winning a new role as refinements of more traditional long-term, static hazards for both building and insurance purposes. In addition very short term forecasts play a useful role in connection with the progression of aftershock sequences, and in developing real-time warnings for trains, gas supplies, and other facilities at high risk from a serious earthquake.

All of the models outlined in the previous sections can be used to develop probability forecasts. Typically, such forecasts are derived from simulations rather than from analytical studies. For example, simulation schemes for use with conditional intensity models are described, with further references, in Chap. 7 of [20].

For complete models, forecasting schemes making use of such procedures involve first fitting a model on all the data up to the current time, then simulating the model as far as is desired into the future, and using these simulations to estimate any required probabilities or expected values as in a Monte Carlo study.

Forecasts for partial models can proceed along similar general lines, although in the first instance the dependence on auxiliary variables restricts the probability forecasts to just the next forecasting period. To obtain forecasts beyond this first step, and in the absence of any updated precursor data, it is necessary to develop a further set of 2-step forecasts, using only the current precursor data, and so on successively, the forecasts gradually reducing in power.

### Assessing Probability Forecasts

Two main approaches to assessing probability forecasts are through likelihoods and probability gains, and through their performance in decision schemes based on the forecast probability exceeding some threshold. Since most procedures are reduced in practice to forecasts for finite

forecasting periods, we outline assessment procedures for this case only.

The *probability gain* for each forecast (i. e. for each time, time-space or other interval for which a probability is forecast) is the ratio of the forecast probability for the observed occurrence in that interval to the corresponding probability from a standard reference model, such as a simple or compound Poisson process, for that interval.

The sample averages of the log-probability-gains, or *entropy scores* in the terminology of [34], over all or certain classes of intervals or of observed outcomes, provide useful insights into the performance of the forecasts. From them one can quickly perceive the outcomes which the scheme is forecasting well, and those which it is forecasting badly.

The overall average, or more properly the expected value, of these entropy scores is called in [34] the *information gain* relative to the reference model. In a complete model, the information gain is a numerical characteristic of the model, giving an upper bound for the improvement in performance that can be expected for the proposed model, relative to the reference model, when the proposed model is the true model. In many cases it reduces to the expected value of the mean likelihood ratio. For example, if successive forecasts, derived from the use of a particular model, give probabilities  $p_1^*, p_2^*, \dots, p_N^*$  for the successive observed outcomes, and  $\bar{p}$  is a constant probability used as reference, then the sum

$$(1/N) \sum_1^N \log[p_n^*/\bar{p}]$$

is the empirical entropy score for that model as well as the mean log-likelihood ratio. It approximates the corresponding expected value (the information gain) if the model used is the true model. If the true model is unknown, as will usually be the case in practice, the above average approximates the difference in the Kullback–Leibler distances between the given model and the true model, and the reference model and the true model. For a set of models, that giving the largest entropy score should be that closest to the true model in the sense of Kullback–Leibler distance. In a partial model, expectations cannot be taken over values of the auxiliary variable, since its distribution is not included in the model specification, but at least empirical averages based on past observations can be developed. [34] gives further background and examples; the basic idea of using log-probabilities (i. e. loglikelihoods) as an indicator of forecasting performance goes back at least to [52].

We noted in Subsect. “**Example 2: Discrete-Time Poisson-Type Model for ULF Electric Signals**” that such com-

parisons of likelihood ratios form the basis of the assessment procedures used in the RELM testing center for probability forecasting schemes; see further [111].

The more traditional procedures for assessing probability forecasts suppose that the schemes are first turned into prediction schemes by predicting that an event will occur whenever the forecast probability of that event exceeds a certain threshold value. The results can then be put into a 2 x 2 table (occurrences or non-occurrences, versus predictions or non-predictions). If the entries in the table are labeled as

- (a) number of successful forecasts of occurrence,
- (b) number of failures to predict,
- (c) number of successful forecasts of non-occurrence,
- (d) number of false alarms,

the commonly used *R-score*, or *Hanssen–Kuiper skill score*, can be defined as

$$R = \frac{ac - bd}{(a + b)(c + d)} = \frac{a}{a + b} - \frac{d}{c + d} = \frac{c}{c + d} - \frac{b}{a + b}. \tag{20}$$

The *R-score* varies between  $-1$  and  $+1$ , with  $0$  denoting forecasts independent of outcomes, and the two extreme values perfect non-prediction and perfect prediction, respectively. [91] illustrates the use of the *R-score* to evaluate Chinese yearly forecasts, even though these are based on expert opinion rather than any probability model.

The usefulness of this approach was greatly extended in [84,85], by allowing the threshold probability  $p_c$  to vary and calculating for each such value the ratios

$$v(p_c) = \frac{c}{(a + c)}$$

and

$$\tau(p_c) = \frac{(a + b)}{(a + b + c + d)}$$

The resulting  $v - \tau$  diagram, obtained by plotting these quantities against each other, provides a comprehensive summary of the behavior of the probability forecasting scheme. The diagram typically consists of a convex (downwards) curve reducing to the diagonal joining the points  $(0, 1)$  and  $(1, 0)$  in the case of purely random forecasts, and to the two  $(0, 1)$  segments of the axes in the case of perfect prediction. It is essentially a Q-Q (quantile-quantile) plot of the distribution of the proportion of time on trial, and the the proportion of failures to predict. See the papers quoted or [34] for further details.

It should be emphasized that the procedures described are concerned with the scientific issues of assessing the quality of proposed models rather than the practical issues of issuing and using probability forecasts. The latter raise just as many difficulties, if not more, than the former. Among these are the need to take into account errors in the model as well as the uncertainties described by the model itself, the need to develop decision-making frameworks that can take advantage of the information within probability forecasts, and the need to address the social, political and economic consequences of issuing forecasts.

### Change-Point Models

Change-point models are used retrospectively to identify time-points at which a change occurs in quantities such as a mean value or rate. They are not themselves precursors, but are used rather to indicate the onset of a period which is anomalous in some sense, and may therefore have some precursory significance. In practice, one of the biggest difficulties in using such methods with seismicity data lies not in identifying the change point, but determining the region from which the data for the change-point analysis should taken.

The procedure consists essentially of dividing an observation time period, say  $(0, t)$ , into two segment  $(0, t_1)$  and  $(t_1, t)$ , and finding the value of  $t_1$  which maximizes the discrepancy in the values of the quantity being studied. The value of this maximized discrepancy can then be tested for significance using the null hypothesis that the values in both periods are equal.

Such a change-point technique is developed in [86] to detect the onset of precursory quiescence within a selected observation region. The data is first fitted to the ETAS model. The time axis is then transformed by the random time transformation

$$\tau = \int_0^t \lambda^*(u) du$$

which has the effect of transforming the original point process, with conditional intensity  $\lambda^*(t)$ , into a unit rate Poisson process (see, for example, Sect. 7.4 in [20]). If, however, there is a change in the parameters of the original ETAS model, this will show up as a change in the rate or other perturbation in the unit rate Poisson process, for which many tests are available.

This technique can be applied both to background events in a specified region (e. g. [140]), or to events within the course of an aftershock sequence, anticipating the occurrence of a large aftershock (e. g. [77]).

Ogata, Toda and colleagues make use of similar but more sophisticated procedures for identifying the regions and onset times of stress-shadowing through careful monitoring of activity of small events; see in particular [89,91].

A different type of change-point analysis has been developed by W. Smith for detecting changes in  $b$ -value. Although one of the earliest possibilities suggested, the precursory role of  $b$ -value changes as a precursor has never been unambiguously identified. Early papers such as [82] or [109] suggested a link to physical features such as heterogeneity of the crustal material, or changing levels of stress. The latter interpretation is at least partially supported by the branching and similar models for earthquake mechanism outlined in Sect. “**Branching Models**”.

Smith’s approach is based on modifications of the CUSUM procedure widely used in quality control contexts for detecting departures from normal behavior in a production process. They are essentially methods for detecting a change in slope of cumulative occurrences or other similar sums. For further details and reviews of earlier work on  $b$ -value changes, see [117,118].

Finally, there is the possibility of a Bayesian approach to change-point problems in seismology; some discussion and an example are given in [94].

Change point models are closely related to *hidden Markov models* in which the rates and other characteristics of the observed process change with the state of a Markov process which is hidden or at best only partly observable. Such models have been widely used in speech recognition and modeling of IT traffic (see, e. g. [72]). Their use in seismology is relatively new (see [23] for a recent example) but their potential seems worthy of further exploration.

### Moment Measures and Correlation Functions

Moment structure plays an important role in most stochastic processes, and the same is true for point processes. The main attention is on second order or correlation properties. Indeed, where distributions are more or less Gaussian, the distinction between models and second order properties is largely nominal, since a Gaussian model is fully described by its means and covariances. The same is not true for count data, for which the second order properties form an important but not in general a definitive aspect of the overall model structure, since a range of different models can be developed to fit particular second order characteristics.

Early papers in the seismological context include [16, 53,128]. There is also a considerable literature in astrophysics, relating especially to the distribution of galaxies

and the role of 2-point, 3-point and higher order correlation functions (e. g. [76]).

Second-order properties for point processes mean properties of point-pairs. Their behavior is described through the second moment measure, whose density (when it exists) is given for  $x_1 \neq x_2$  by

$$m_2(x_1, x_2)dx_1dx_2 = E[N(dx_1)N(dx_2)] .$$

Apart from a renormalization, this is also the 2-point correlation function of [53]. It is also the basis of the covariance measure, with density

$$c(x_1, x_2) = m_2(x_1, x_2) - m_1(x_1)m_1(x_2) \quad (x \neq y) .$$

This also exists in various renormalized forms, for example the radial correlation function defined, when the process is isotropic, by

$$\rho(r) = dK(r)/dA(r)$$

where  $A(r) = \pi r^2$  is the area of a circle centered on an arbitrary point of the process, and  $K(r)$  (often referred to as ‘Ripley’s  $K$ -function’) is the expected number of additional points (i. e. apart from the point at the center) in the same circle (see e. g. [22,104]).

In a general treatment, the coordinates  $x_1, x_2$  may combine both space and time components. The second moment densities then give information about the expected density of occurrence of additional points at given time or space intervals about a given point taken as origin. In this way they can display distance variations in the strength of the clustering tendency.

The second order techniques are particularly valuable when the process is stationary in time, so that spectral methods can be used. In this situation the covariance measure becomes a function of time through the difference  $t_1 - t_2$  in the time coordinates of the two points being considered:

$$c_2(x_1, x_2) = c_2(t_1 - t_2; y_1, y_2) ,$$

where  $y_1, y_2$  may represent locations or magnitudes. Taking Fourier transforms with respect to time leads to a spectral density, multivariate if the dependence on space or magnitude is retained, which can be used for the analysis of periodic effects in point processes. [133] is an early example of the spectral analysis of earthquake occurrence data. More general discussions can be found in [13] or Chap. 8 of [20].

### Principal Component Analysis

Principal components are the names given to the eigenvectors in the orthogonal decomposition of a model-derived

or empirical covariance matrix. Being symmetric and positive definite, the diagonal representation of such a matrix has non-negative eigenvalues, which measure the proportion of variation associated with the given eigenvector. Thus the principal components associated with the largest eigenvalues define those linear combinations of the observation vector components which explain the greatest amount of variability.

In geophysical applications, notably in meteorology, the observations typically arise as time sequences of observations from a set of recording stations. Each time point gives a vector observation. The principal components associated with the largest eigenvalues then often describe recognizable weather occurrence patterns, and are used as a means for identifying and classifying such patterns.

This idea admits many specializations and extensions. For stationary processes in time, for example, the covariance matrix has a special structure ( $c_{i,j} = c_{i-j}$ ) which for infinite series, or a finite series with periodic structure, causes the eigenvectors to reduce to complex exponentials  $e^{i\omega r^n}$ . These periodic terms form the principal components of the sequence, while the corresponding eigenvalues are amplitudes associated with the given frequencies. Thus standard spectral analysis can be interpreted as a special form of principal component analysis. The so-called Karhunen–Loeve theory (see e. g. [69]) is an extension to very general covariance operators admitting a diagonal decomposition.

Adaptations of these ideas for earthquake data have recently been considered by Rundle, Tiampo and colleagues (see e. g. [107,120]). Here the data is typically of point process form (0-1 functions) on a sequence of observation regions, centered either on a lattice of space or space-time points, or on the centers of a family of small fault segments over an interacting fault system. Their papers combine the Karhunen–Loeve theory with ideas originating in dynamical systems theory, and seek to extend the analysis to provide short or medium term probability forecasts.

### Fractals and Fractal Dimensions

Many of the models so far considered show long-range dependence, power-law distributions, and some form of self-similarity (similar appearances on different scales). The term ‘fractal’ is commonly used in this context, with a variety of interrelated interpretations. A wide-ranging review of such properties for earthquakes is given in [121].

In the basic text [74] of Mandelbrot, fractals are introduced as a class of geometric objects (sets) with features which repeat on a family of reducing scales. The Cantor set in one dimension and the snowflake curve in 2 dimen-

sions are well-known examples. Their characteristic feature is that the Hausdorff dimension of the fractal set may differ from the dimension of the space in which it is embedded. Thus the Cantor set has dimension  $\log_3(2) < 1$  despite being embedded in a 1-dimensional space. As in this example, these aberrant dimensions often have a non-integer value, whence the name.

Various empirical procedures have been devised for determining these fractional dimensions. For example, for a set in 2 dimensions, we may count the proportion of cells from a 2-dimensional lattice which have a non-empty intersection with the set, and consider the behavior as the cell size in the lattice approaches zero. Typically this results in a log-log relation between number of affected cells and the cell dimension, corresponding in fact to power-law behavior. Such methods can be applied also to physical sets such as the traces of faults on the earth’s surface (see [121] and [45] for examples). If a suitably linear portion of the log-log plot can be found, the slope is used as an estimate of their fractal dimension.

Because power-laws arise inevitably in the study of fractal sets, the term *fractal behavior* has come to be used loosely to describe the behavior of any probability distribution for which

$$1 - F(x) = \Pr(X > x) \sim cx^{-\alpha} ,$$

or even when power-law forms arise in features such as time or space correlation functions.

A different fractal concept derives from the work of Renyi [99]. Renyi’s dimension estimates (also called multifractal dimensions) reflect the irregularities of a measure (distribution) rather than a set. Thus, if a probability distribution on a square is used as an example, and the square is divided into a lattice of small squares  $\Delta_i$  each of side  $\Delta$ , we may consider the limit as  $\Delta \rightarrow 0$  of the ratios

$$d_q(\Delta) = \left[ \log \sum_i p(\Delta_i)^q \right] / \log \Delta \quad (q \neq 1) \quad (21)$$

with

$$d_1(\Delta) = \left[ \sum_i p(\Delta_i) \log p(\Delta_i) \right] / \log \Delta . \quad (22)$$

For each  $q$ ,  $d_q$  defines a *multifractal dimension* associated with the distribution, and for varying  $q$  the family of such dimensions defines a type of transform of the underlying probability distribution.

The term multifractal is used because the distribution may exhibit different forms of singularity, associated with different power-law behavior, at different points of

the space. In applications, for example in turbulence and meteorology as well as seismology, the process is visualized as a descending sequence of random eddies ('random cascades') with dimensions shrinking to zero. It is in this sense that Kagan [49] coined the phrase 'frozen turbulence' to describe earthquake processes in the crust.

The computations in the equations above can be applied empirically to quantities such as the counts or the energy release from earthquakes and used to estimate the multifractal dimensions of some underlying spatial distribution. For general discussions of multifractals, see [95] and [31]; the latter gives an extended discussion of applications of the theory to earthquake data.

With count data, there is a link between the multifractal dimension  $d_q$  for integer  $q$  and the  $q$ -point correlation function. In particular  $d_2$  describes the growth rate of the two-point correlation function for vanishingly small separations; see [53,131].

### Self-Similarity

Self-similarity is used in a broad sense to describe processes in space or time where, much as in a fractal set, key structural features are preserved on a descending sequence of scales. Plots of fault traces or epicenters do indeed suggest such scale invariance properties.

In stochastic process theory, self-similarity (auto-modeling) is used to denote a precisely defined property of random processes or random measures. In particular, a random measure  $\xi(A)$  defined on sets in the plane (or other Euclidean space) is said to be *self-similar*, with similarity index  $H$ , if a change of scale in the space can be compensated for by a change of scale in the quantity being measured:

$$\xi(rA) \stackrel{D}{=} r^{-H} \xi(A), \quad r > 0 \quad (23)$$

where  $\stackrel{D}{=}$  means the two sides have equal probability distributions.

Self-similar random measures of this form arise in turbulence theory, seismology, finance, and elsewhere. In one dimension, the concept can be reinterpreted as implying that a stochastic process has *self-similar increments*. Brownian and fractional Brownian motions both have increments of this type. However, the Brownian motions take both positive and negative values, whereas any random measures associated with earthquakes (for example, by way of energy release) should be non-negative.

Thus the self-similar processes arising in seismology have a rather special character, since they must be non-negative as well as self-similar. The only known examples

are purely atomic random measures:  $\xi(A)$  is obtained by summing the contributions (energies, for example) from point-events in  $A$ .

One such example is well-known: the *stable* random measures, which are characterized by a strong independence property, and a power law distribution for event sizes equivalent to a G-R relation for magnitudes. Superficially, this example matches the earthquake data rather well, but it fails to incorporate one key feature of earthquake occurrence: the lack of independence inherent in earthquake clustering. Recently, however, it was shown in [132] that it is possible to define a variant on the ETAS model which combines self-similarity with a non-trivial dependence (cluster) structure. It is not known at present how wide this class of models may be.

### Block-Slider and Related Mechanical Models

The mechanical models attempt to illuminate the processes of earthquake occurrence by devising complex mechanical systems that will reproduce many observed features of earthquake catalogs. The reason for including a brief section on such models in the present article is that one of their underlying purposes is to demonstrate that deterministic models of sufficient complexity can exhibit just that random-appearing behavior that characterizes the appearance of earthquake data. Two important issues then arise. The first is whether the mechanical models can be matched closely enough to any real seismic system to produce forecasts similar to or better than those produced by the stochastic models. The second is whether those stochastic models currently fitted to earthquake catalogs also provide good descriptions of the catalogs produced by the mechanical models. Such studies may then suggest ways in which the stochastic models themselves can be improved.

In the pioneering article [14], the mechanical system comprises a series of blocks, linearly connected by springs, which are pulled over a rough plane. The resultant movement is not smooth, but jerky, as the tension in one of the springs builds up to the point where it overcomes the frictional forces opposing motion and a slip occurs. Often movement of one block will initiate movement in a whole set of blocks.

The population of such movement sequences is then compared to a population of earthquakes. Although the motion of the system is entirely deterministic, analytic solutions are too complex to obtain in explicit form, and the behavior is irregular, with features of (pseudo)randomness. In particular a crude form of GR law generally results.

Many further mechanical models have been invented and studied, both in the laboratory and via numerical solution of the appropriate dynamical equations. Often the masses of the blocks or the spring parameters are selected at random from some plausible overall population. It is not this randomness which is the cause of the random-looking behavior, however, but rather the complexity of the movements (trajectory) of any particular system of blocks and springs or other similar elements.

One of the difficulties in matching such models to particular fault systems is to match the initial conditions, which are not easy to determine for real processes, even if they can be reproduced in the artificial system. It is precisely the relative simplicity of the stochastic model, which comes at the expense of describing many important physical details, which allows it to be fitted to catalogue data and then used to produce rough probabilistic forecasts.

In [70], one of the relatively few studies to fit point process models to the output from such mechanical systems, outputs were taken from the four different models described in [6] (see also [10]) and fitted by the simple stress release model. The four models illustrated different patterns of behavior, varying from highly random behavior with typical GR distributions, to regular, characteristic earthquake behavior. After suitable adjustment of the frequency-magnitude law in the stress-release model, it was found that the stress release model could be fitted to all four versions, and used to describe the overall energy state of the mechanical system; as such it operated as a crude predictor of the next major event in the system.

### Future Directions

There are many possible directions in which the applications of stochastic models in seismology could be extended and deepened. The fundamental limitations in the past have most commonly been limitations in data, and consequent limitations in the physical understanding of the processes. It has been the great improvement in data which has allowed the development of better and more insightful seismicity models in the last two decades; this tendency is continuing strongly and may well lead to unexpected new developments.

Two directions in particular appear to me to hold out scope for further development of stochastic models for earthquake occurrence. The first is related to the collection and integration of data on earth deformation. The extensive data now becoming available from GPS measurements have already led to new discoveries, for example 'slow earthquakes' which relieve strain without being

registered on conventional seismometers. The underlying problem is how to link the data on strain to data on seismicity. This is not easy, and is likely to require new ideas on both the physical and statistical sides.

The second relates to the systematic collection and evaluation of data on potential precursor events. Many of the ideas initiated in the 1970's have been abandoned, with the result that for most potential phenomena there exists no substantial body of data by which their effectiveness can be adequately tested, or the underlying physical processes modeled. Many controversial and so far inadequately explained phenomena fall into this category. They have the potential to generate projects of interest and importance from the physical as well as the hazard estimation viewpoints. Unfortunately collecting and archiving such data is a long-term process with uncertain future outcomes, and therefore difficult to fund under current funding criteria. The balance of scientific, public and even government opinion may change, however, and further work in these fields may be anticipated.

Fundamental work on earthquake mechanism – still a largely unsolved problem – is also likely to attract attention during the next decades, and to require a combination of physical and statistical modeling.

If these are rather long-term developments, there are many smaller scale, more immediate problems that require further investigation. On the theoretical side, one important issue is the development of improved models and procedures for analyzing data with self-similar characteristics. Another area where further research is needed, particularly in subduction regions, is in the development of better physical and statistical models for deep earthquakes, including their possible links to different forms of activity (seismic, volcanic etc) closer to the surface.

The current interest in developing testing centers for probability forecasting is likely to promote more strenuous efforts to develop improved forecasting models, whether based just on catalogue data, or allied with deformation data, or with data on other precursory phenomena. Even the existing models are capable of producing time-varying forecasts which in principle could lead to significant reductions in earthquake risk. The problem here is how to realize these reductions in practice, for example through improved insurance or disaster mitigation activities. Many questions arise, of an operations research as much as a statistical character, which warrant further study and effort. The probability forecasts themselves, if they are to be useful in such contexts, need to incorporate the uncertainties in the underlying models and hence to take on a more explicitly Bayesian character, and to be presented in such a way that they can be related to the many additional fac-

tors that have to be borne in mind when making real-life decisions.

### Acknowledgments

I am very grateful to friends and colleagues, especially David Harte, Mark Bebbington, David Rhoades and Yehuda Ben-Zion, for helpful discussions, correcting errors and plugging gaps.

### Glossary

**Seismic moment** The most fundamental measure of the size of an earthquake. In the simplest situation it represents the moment of one of the couples of forces that make up a dipolar source. In more general cases it is a 3 by 3 symmetric tensor of elementary force couples.

**Seismic radiation** The seismic waves emitted by a seismic source. For point sources these are spherical P and S waves emitted by the point tensor source.

**Seismic spectrum** The absolute value of the Fourier transform of the displacement field radiated by an earthquake in the far field. For almost all earthquakes it has a common shape: flat at low frequencies and decays like the inverse squared power at high very high values of frequency.

**Corner frequency** The low and high frequency asymptotes of the earthquake spectrum intersect at a characteristic frequency, called the corner frequency. The corner frequency scales with the size of the earthquake measured by the seismic moment.

**Radiated or seismic energy** Total energy of the seismic waves radiated by a seismic source. It can be computed from the energy flow relatively far from the source of the earthquake.

**Apparent stress** Originally defined as the product of seismic efficiency times the average stress during earthquake slip. In practice, it is computed from the ratio of radiated energy to moment release of the earthquake multiplied by the shear modulus.

**Energy release rate** Amount of energy per unit surface used to make a rupture advance by a unit distance.

**Static stress drop** The static change in shear traction between the sides of the fault occurs during an earthquake. In principle, it could be determined by measuring stress before and after the earthquake. In practice stress drop is computed using very specific source models, like a circular crack.

**Dynamic stress drop** The stress change in shear traction as a function of time while the rupture is still growing. It can only be estimated from seismic records obtained in the near field by elaborate inversion schemes. The relation between static and dynamic stress drop can only be estimated once the friction law between the sides of the fault has been defined.

### Definition of the Subject

Earthquake scaling laws provide some of the most basic knowledge about seismic sources. Since the end of the 70s, a very successful model for earthquakes was developed by seismologists. In this model earthquakes are due to rapid slip on pre-existing faults driven by steady load due to plate motion and resisted by friction between the fault walls. This model may be used to predict many of the general properties of seismic radiation that can be derived from a simple spectral shape of type omega-squared. In this article I derive general expressions for energy, moment and stress in terms of measured spectral parameters. The available data shows that earthquakes can be reduced to a single family in terms of three parameters: moment, corner frequency and radiated energy. Using specific models of rupture these three parameters can be reinterpreted in terms of moment, size and stress drop. Although details differ between the models proposed by seismologists, both seismic spectra and the wave-number spectra of slip distributions can be explained with a simple circular crack model. This does not mean that a circular crack is the best earthquake model; it means that the ensemble average of seismic sources has properties that are similar to those of simple circular shear cracks. A direct result of scaling laws is that total fracture energy must scale like radiated and strain release energy, so that fracture energy should scale with fault size as observed for many earthquakes and in certain laboratory experiments.

### Introduction

It has been 40 years since Aki [4] published his seminal paper on the scaling law of earthquakes that established that to first order seismic moment scales like the third power of the fault size. This paper came just a year after Aki [3]

made the very first measurement of seismic moment, the torque of one of the couples that make up a basic source mechanism. Not much later, in 1970, Brune introduced a very simple source model and established a generalization of Aki's [4] spectral model of earthquakes that is now known as the omega-squared model of earthquakes. Almost simultaneously, Kostrov [43], Savage [66], Sato and Hirasawa [65] and Madariaga [46] developed models of a circular faults. Radiation from a circular crack explained well the omega-squared model. Digital data was not available at the time when these models were introduced. It is nowadays an almost standard observatory practice to study the scaling law, but as many recent studies have shown, proper estimation of spectral parameters like moment and corner frequency and high frequency decay for a large range of earthquake sizes is not trivial and it is often difficult to obtain from a single instrument. In the 1990s good quality digital data, both broad band seismograms and accelerograms, became available not just from surface instruments, but also from boreholes opening the way to a new appraisal of the scaling law.

We will briefly review some of these observations and we will try to establish general properties of earthquake radiation based on the recent work by McGarr [53], Abercrombie and Rice [2], Ide et al. [35], Prieto et al. [59], etc. Our purpose is not to review the very extensive literature on the determination of seismic source parameters; most of those papers assume specific scaling laws like circular cracks, Brune's relation between corner frequency and earthquake size, etc. Our purpose here is to derive the scaling law from same basic physical concepts and to test the validity of some common assumptions in seismology. Because different authors are interested in certain specific aspects of earthquake sources, often the data from different authors is hard to combine. Some authors use the Brune's [17] empirical model as a basis for the scaling law; others use the radiation from quasidynamic circular cracks as a model leading to substantial variations. Even more serious differences come from data processing, some authors using specific attenuation corrections in order to correct for Earth's Q, others use small events as empirical Green functions, etc. These corrections are very important, but they are beyond our goal which is to try to extract information about scaling and its inferences for earthquake physics. Two aspects will be particularly discussed: how to make model independent estimates of source parameters and how to establish model independent scaling laws. Some recent evidence indicates, for instance, that stress change during earthquakes as measured by apparent stress varies independently of Moment and size, so that earthquakes are probably quantified by three independent

parameters that need to be carefully chosen. The other will be an aspect that is often overlooked in the literature: Brune's [17] model, as well as Madariaga's [46] circular crack model make very specific statements about the partition of seismic energy at the source. In particular, the scaling law implies that fracture energy is not a constant but that it scales with earthquake size in a manner that was predicted on the basis of fracture dynamics [46]; friction experiments by Ohnaka and Shen [56] and Ohnaka [55]; arguments about scaling by McGarr and Fletcher [54], and dynamic seismic source inversions [34,57].

### Earthquakes and Seismic Radiation

It is now well established that earthquakes are due to faulting and that the simplest way to measure them is to use the seismic moment  $M_0$ , introduced by Aki [3], and given by

$$M_0 = \mu \bar{D} S \quad (1)$$

where  $\mu$  is the shear or rigidity modulus of the material surrounding the fault,  $\bar{D}$  is the mean value of the final slip on the fault and  $S$  is the area of the fault rupture.  $M_0$  is the moment of one of the couples that constitute a double couple, the simplest possible model of a point-like earthquake. Radiation from a point double couple source has been completely solved by seismologists and is thus the natural starting point for the development of earthquake scaling laws.

The far-field displacement  $\mathbf{u}_c$  radiated by a point double couple source can be written in the following form:

$$\mathbf{u}_c(r, t) = \frac{1}{4\pi\rho c^3} \frac{1}{R} \mathbf{e}_c^T \cdot \mathbf{M}_0 \cdot \mathbf{e}_R(t - R/c), \quad (2)$$

(see, e. g. [5]) where the subscript  $c$  stands for P or S waves, i. e.  $c$  is either  $\alpha$ , the P wave speed, or  $\beta$ , the S wave speed;  $\rho$  is the density;  $R$  is the distance of the observation point from the source.  $\mathbf{e}_R$  is the radial unit vector in the direction of radiation. The unit vector  $\mathbf{e}_c$  is the polarization of the wave, that is  $\mathbf{e}_c = \mathbf{e}_R$  for P waves, or  $\mathbf{e}_T$  the appropriate transverse unit vector for SH or SV waves.  $\mathbf{M}_0(t)$  is the moment tensor of the source, a symmetric tensor of order three that describes the geometry and amplitude of the seismic source (see [5] for details).

Very often in seismology it is assumed that the geometry of the source can be separated from its time variation, so that the moment tensor can be written in the simpler form:

$$\mathbf{M}_0(t) = \mathbf{I}_0 M_0 s(t) \quad (3)$$

where  $\mathbf{I}_0$  is a time-invariant tensor that describes the orientation of the source,  $M_0$  is the scalar moment tensor of

the source, and  $s(t)$  is the time variation of the moment, the source time function determined by seismologists. In the following we assume that  $s(t)$  is causal, i. e. it is zero up to  $t = 0$ , and normalized so that

$$\int_0^{\infty} s(t) dt = 1 .$$

Using (3) we can now write a simpler form of (2):

$$u_c(r, t) = \frac{1}{4\pi\rho c^3} \frac{\mathcal{R}_c}{R} \Omega(t - R/c) . \quad (4)$$

For P waves,  $u_c$  is the radial component; for S waves, it is the appropriate transverse component for SH or SV waves. In (4) we have introduced the standard notation  $\Omega(t) = M_0 ds(t)/dt$  for the source time function, the signal emitted by the source as seen in the far field. The term  $\mathcal{R}_c(\theta, \phi)$  is the radiation pattern, a function of the takeoff direction of the ray from the source. In a spherical coordinate system  $(R, \theta, \phi)$  centered at the source, the radiation patterns are given by Aki and Richards [5]. We simply quote here the case of a so-called strike-slip earthquake where the fault is vertical, normal to the  $y$  axis, and slip is parallel to the  $x$  axis, so that only the  $M_{xy} = M_{yx}$  components of the moment tensor are different from zero. In this case

$$\begin{aligned} \mathcal{R}_P &= \sin^2 \theta \sin 2\phi , \\ \mathcal{R}_{SV} &= \frac{1}{2} \sin 2\theta \sin 2\phi , \\ \mathcal{R}_{SH} &= \sin \theta \cos 2\phi . \end{aligned}$$

On the  $z = 0$  plane ( $\theta = \pi/2$ ), there are no SV waves. On the other hand, on this plane, the radiation patterns of P and SH waves have typical quadrupole distributions proportional to  $\sin 2\phi$  and  $\cos 2\phi$  respectively.

### Spectral Domain Approach

At high frequencies, the signals radiated by earthquakes may become quite complex because of multipathing, scattering, etc., so that the actually observed seismogram  $u(t)$  resembles the source time function  $\Omega(t)$  only at long periods. It is usually verified that complexities in the wave propagation affect much more the phase of seismic waves than the spectral amplitudes in the Fourier transformed domain. The spectral domain approach was introduced by Aki [4], Wyss and Brune [73] and Brune [17]. Radiation from a simple point moment-tensor source can be obtained from (4) by Fourier transformation. Displacement pulses radiated from a point moment tensor in the Fourier transformed domain is then

$$u_c(r, \omega) = \frac{1}{4\pi\rho c^3} \frac{\mathcal{R}_c}{R} \tilde{\Omega}(\omega) e^{-i\omega R/c} . \quad (5)$$

Where  $\tilde{\Omega}(\omega)$  is the Fourier transform of the source time function  $\Omega(t)$ . A well-known property of the Fourier transform is that

$$\lim_{\omega \rightarrow 0} \tilde{\Omega}(\omega) = M_0 * \int_0^{\infty} \dot{s}(t) dt = M_0 \quad (6)$$

so that the in the low-frequency limit of the source time function spectrum approaches the scalar moment.

From the observation of many earthquake spectra, and from the computation of magnitudes in different frequency bands, Aki [4] and Brune [17] concluded that the seismic spectra had a universal shape with a flat low frequency asymptote given by (6), a certain characteristic frequency called **corner frequency** by seismologists, and a decay at high frequencies that tends asymptotically to  $\omega^{-2}$ . I will not repeat here the arguments that led to this model: Aki [4] proposed this spectral shape in order to explain the differences in magnitude determined from seismic waves of different frequencies. Brune's [17] argument was based on simple concepts about the high frequency radiation and the amount of energy radiated by a seismic event. The omega-squared model has now been confirmed by numerous observations and detailed studies of seismic radiation. As an example, Fig. 1 shows the displacement record of a M5 earthquake that occurred inside the Nazca plate, 99 km under Santiago de Chile on 7 January 2003. The spectrum shown at the bottom presents the typical low frequency asymptote proportional to the seismic moment, and high frequency decay proportional to  $\omega^{-2}$ . The corner frequency is approximately 1.2 Hz for this event.

In its simpler form the  $\omega^{-2}$  spectrum is [17]:

$$\tilde{\Omega}(\omega) = \frac{M_0}{1 + \omega^2/\omega_0^2} \quad (7)$$

where  $\omega_0$  is the corner frequency. Based on considerations about the spectrum of random signals, Boatwright [12] proposed the alternative model:

$$\tilde{\Omega}(\omega) = \frac{M_0}{[1 + \omega^4/\omega_0^4]^{1/2}} . \quad (8)$$

In these simple omega-squared models, seismic sources are characterized by only two independent scalar parameters: the seismic moment  $M_0$  and the corner frequency  $\omega_0$ .

Brune's model (7) explains well the spectrum of S waves, it describes also that of P waves, but the corner frequencies are different for P and S. For a long time observations were not able to distinguish between the P and S waves spectra. The first clear observations of the corner frequency ratio were made by Hanks [26]. Recent work by Abercrombie and Rice [2], Prieto et al. [59], Ide et al. [35]

Earthquake Scaling Laws, Figure 1

Example of a seismic signal and its spectrum. Recording at the PEL broad-band station of the GEOSCOPE network of a  $M = 5$  intermediate depth earthquake. The event occurred inside the subducted Nazca plate under Santiago, Chile at 99 km depth. The top panel shows the displacement, integrated from the broad band velocity record. The shear wave section used for computing the spectrum is shown with arrows. The bottom panel shows the amplitude Fourier spectrum. The low frequency and high frequency trends are indicated by the thick straight lines. The corner frequency is located at the intersection of the two asymptotes

has confirmed that P spectra have a higher corner frequency than S waves and that very roughly

$$\omega_0^P \cong 1.6\omega_0^S. \quad (9)$$

This is very close to  $\sqrt{3}$ , the ratio of P to S wave speed. This ratio is similar to that predicted for the quasi-dynamic circular crack model [46].

As mentioned earlier, not all earthquakes have displacement spectra as simple as (7), but the omega-squared model is a simple starting point for understanding seismic radiation.

From (7), it is possible to compute the spectra predicted for ground velocity:

$$\tilde{\dot{\Omega}}(\omega) = \frac{i\omega M_0}{1 + \omega^2/\omega_0^2}. \quad (10)$$

Ground velocity spectra are characterized by a peak situated roughly at the corner frequency  $\omega_0$ . In actual earthquake ground velocity spectra, this peak is usually

broadened and contains oscillations and secondary peaks, but (10) is a good approximation to the spectra of ground velocity for frequencies lower than a certain cut-off frequency called  $f_{\max}$  by Hanks [27], and is close to 6–7 Hz in many areas. At frequencies higher than  $f_{\max}$ , attenuation, propagation and scattering modify the velocity spectrum.

### Seismic Energy Radiated by Point Moment-Tensor Sources

In order to establish the most basic scaling relationship for seismic sources we have to compute the energy radiated by an omega-squared source like (8). This was actually the way Brune originally calibrated his source time function and Aki established the variation of corner frequency with moment. Assuming that the source is embedded in a homogeneous medium, and that the observation point is sufficiently far from the source, the energy flow per unit solid angle,  $e_r$  is proportional to the square of the particle velocity  $v_c$  (see [11,12,17,18,31]), so that the total flow per unit

solid angle is:

$$e_r^c = \rho c R^2 \int_0^\infty v_c^2(t) dt \quad (11)$$

where  $\rho c$  is the P or S wave impedance,  $v_c(t)$  is the ground velocity and  $R$  is again the distance of the observation point from the source. We can compute the radiated energy density replacing  $v_c(t)$  by the time derivative of the far field displacement (4), and get:

$$e_r^c = \frac{1}{16\pi^2 \rho c^5} \mathcal{R}_c^2 \int_0^\infty \dot{\Omega}^2(t) dt. \quad (12)$$

As expected the energy flow per unit solid angle does not depend on the distance from the source  $R$ . We can now apply Parseval's theorem to express the energy in terms of the source spectral amplitude

$$\int_0^\infty \dot{\Omega}^2(t) dt = \frac{1}{\pi} \int_0^\infty \omega^2 |\tilde{\Omega}(\omega)|^2 d\omega$$

and compute the total radiated energy,  $E_r$ , for each type of wave. Integrating (12) over the angles  $\theta$  and  $\phi$  we get

$$E_r^c = \frac{1}{4\pi^2 \rho c^5} \langle \mathcal{R}_c^2 \rangle \int_0^\infty \omega^2 |\tilde{\Omega}(\omega)|^2 d\omega \quad (13)$$

where

$$\langle \mathcal{R}_c^2 \rangle = \frac{1}{4\pi} \iint_{\Omega} \mathcal{R}_c^2(\theta, \phi) \sin \theta d\theta d\phi$$

is the mean-squared radiation pattern. This expression for the total radiated energy is very interesting because it does not depend on any assumption about earthquake dynamics, just on the shape of the spectra.

For the  $\omega$ -squared model (7) the integral over circular frequency in (13) can be evaluated exactly to  $(\pi/4M_0^2\omega_0^3)$ , so that the radiated energy is simply

$$E_r^c = \frac{1}{16\pi} \langle \mathcal{R}_c^2 \rangle \frac{M_0^2 \omega_0^3}{\rho c^5} \quad (14)$$

where we grouped in the last term all the dimensional variables. Let us remark that the numerical factor  $1/16\pi$  depends on the particular model assumed for the spectrum near the corner frequency. Thus, for the Boatwright model (8), the coefficient is slightly larger ( $\sqrt{2}/16\pi$ ).

Since radiated energy and moment have the same dimensional units it is customary to rewrite this expression in the non-dimensional form:

$$\frac{E_r^c}{M_0} = \frac{\langle \mathcal{R}_c \rangle^2}{16\pi} \frac{M_0}{\rho} \frac{\omega_0^3}{c^5}. \quad (15)$$

Very often this expression is written in terms of frequency  $f_0$  instead of the circular frequency ( $\omega_0 = 2\pi f_0$ ), so that

$$\frac{E_r^S}{M_0} = \frac{\pi^2 \langle \mathcal{R}_c \rangle^2}{2} \frac{M_0}{\rho} \frac{f_0^3}{c^5}. \quad (16)$$

The average radiation patterns are well known,  $\langle R_p \rangle^2 = 4/15$  and  $\langle R_s \rangle^2 = 6/15$ , see, e.g. Haskell [31], so that for S waves most authors use the following expression to quantify the ratio between the S wave radiated energy and the seismic moment

$$\frac{E_r^S}{M_0} = 1.9739 \frac{M_0}{\mu} \frac{f_0^3}{\beta^3}. \quad (17)$$

Where we used the definition of S wave speed ( $\mu = \rho\beta^2$ ). This non-dimensional relation makes no assumptions about the rupture process at the source except that the spectrum decays like  $\omega^{-2}$  at high frequencies. Note that the numerical coefficient is smaller by a factor of four from that computed by Singh and Ordaz [69]. The factor of four seems to be a misprint.

### Apparent Stress

A very important parameter of seismic sources that can be computed independently of any particular source geometry is the apparent stress. Originally, apparent stress was defined as the product of the seismic efficiency  $\eta$  by the average stress  $\bar{\sigma}$  that acts across the fault during the earthquake

$$\sigma_a = \eta \bar{\sigma},$$

efficiency  $\eta$  was in turn defined as the ratio between the radiated energy  $E_r$  and the total released energy  $W$ . Unfortunately, neither  $W$  nor the average stress can be directly inverted from seismic observations because seismic waves have no information about the average stress that acts on the fault. Wyss and Brune [73] proved that for uniform average stress,  $W$  could be written as

$$W = \frac{\bar{\sigma}}{\mu} M_0$$

so that apparent stress can be defined as

$$\sigma_a = \frac{\mu E_r^S}{M_0}.$$

This expression, originally derived for uniform average stress has become one of the most useful measures of stress

on seismic sources (see, e. g. [53]). Using the expression for radiated energy (17) we get:

$$\sigma_a = \frac{\mu E_r^S}{M_0} = 1.9739 M_0 \frac{f_0^3}{\beta^3} \tag{18}$$

an expression that depends only on three measurable quantities: total S wave radiated energy, seismic moment and corner frequency. Because the energy flow can usually be computed only for those directions where stations are available, (18) can never be evaluated very accurately. This problem still persists at present; in spite of the deployment of increasingly denser instrumental networks, there will always be large areas of the focal sphere that remain outside the domain of seismic observations because the waves in those directions are refracted away from the station networks, energy is dissipated due to attenuation, etc.

Equation (18) shows that energy moment ratio is a non-dimensional number that depends only on observable quantities ( $E_r$ ,  $M_0$  and  $f_0$ ) and wave speed. No assumption is made in Eq. (18) about particular models to convert corner frequencies into source dimensions. Let us finally remark that if  $\sigma_a$  is computed from the estimated radiated energy  $E_r$ , then the apparent stress may be considered as an independent parameter that may be used to test the relation (18).

### Time Domain Approach

In the previous section we approached seismic radiation from the spectral point of view. An alternative way to understand radiation is to approach it from the time domain. The obvious question is what is the time domain signal associated with  $\omega^{-2}$  spectrum (17)? Brune [17] proposed one of them:

$$\Omega(t) = M_0 \omega_0^2 t e^{-\omega_0 t} \quad \text{for } t > 0 \tag{19}$$

which is a causal function (i. e., it is zero for  $t < 0$ ). It is also normalized so that

$$\int_0^\infty \Omega(t) dt = M_0.$$

The high frequency content for this function is controlled by the slope discontinuity at the origin. This is however only one of many functions sharing the same spectral amplitude described by (7) and (8), leaving sufficient freedom for variations in the source time function shape.

Kanamori and Rivera [40] defined a function of finite duration  $T$ , finite moment and minimum radiated energy. They found such signal by solving a variational problem

for fixed signal duration  $T$ . The time signal is the parabola defined by

$$\Omega(t) = \frac{6M_0}{T^3} t(T-t) \tag{20}$$

for  $0 < t < T$  and 0 elsewhere. The radiated energy for this signal can be computed using the time domain expression (12). Using the integral

$$I_v = \int_0^\infty \dot{\Omega}^2(t) dt = \frac{12}{T^3} M_0^2$$

we can compute the total radiated energy as a function of  $T$ . In order to write the energy in the same form as the frequency domain expressions we determine the corner frequency from the Fourier transform of (20):

$$\tilde{\Omega}(\omega) = \frac{6M_0}{\omega^3 T^3} \left[ (\omega T - 2i) + (\omega T + 2i)e^{i\omega T} \right]. \tag{21}$$

At low frequencies this expression tends to  $M_0$ , as expected, while at high frequencies it behaves like

$$\lim_{\omega \rightarrow \infty} \tilde{\Omega}(\omega) = \frac{12M_0}{\omega^2 T^2} \frac{[1 + e^{i\omega T}]}{2}.$$

So that its envelope decreases asymptotically as  $12M_0(\omega T)^{-2}$  that is, it has the same inverse omega-squared behavior as Brune's model (7). The corner frequency for this signal computed from the intersection of the asymptotes is  $\omega_0 = \sqrt{12}/T$ . Inserting into (17) we get the following energy moment ratio:

$$\frac{E_r^c}{M_0} = \frac{\langle \mathcal{R}_c \rangle^2}{4\sqrt{12}\pi} \frac{M_0}{\rho} \frac{\omega_0^3}{c^5}. \tag{22}$$

which has a numerical coefficient that is slightly larger than that of (17). This is apparent contradiction to the method used by Kanamori and Rivera, who derived (20) from the condition that  $E_r$  be a minimum for a given moment. The reason these two results are not contradictory is that Brune's signal has infinite duration and therefore the variational principle posed by Kanamori and Rivera does not apply to it. Thus the two expressions give very similar answers, but clearly the signal (20) is not the only one that minimizes radiated energy. It is interesting to observe that all these signals decay like  $\omega^{-2}$  at high frequencies. The reason is that high frequency radiation in these models is controlled by the slope discontinuities in displacement. In Brune's signal (19) the slope discontinuity is at the origin, while in (20) there are two slope discontinuities at the origin and at  $t = T$ .

In conclusion, the radiation models proposed by seismologists share the following properties: (1) the amplitude is controlled by the seismic moment, (2) the displacement spectrum decreases like  $\omega^{-2}$  at high frequencies, (3) the spectral shape has a corner frequency  $f_0$  and (4) the radiated energy to moment ratio satisfies the relation

$$\frac{E_r^c}{M_0} = C_r \frac{M_0 f_0^3}{\rho c^5}, \tag{23}$$

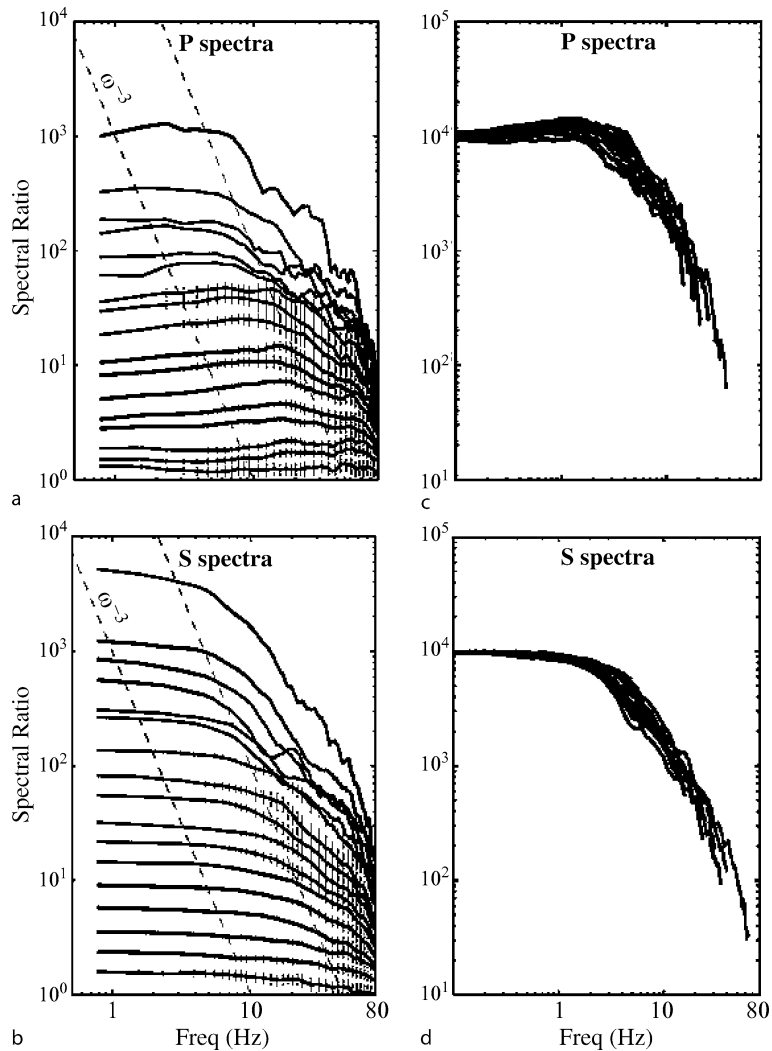

where  $C_r$  is a numerical constant on the order of two. Its consequences for energy balance are quite interesting as we shall promptly discuss.

**Aki's Scaling Law**

From observation of seismic data most authors (for recent data see, e. g., Abercrombie [1], Ide and Beroza [33] Ide et al. [35], McGarr [53]). Abercrombie and Rice [2], Prieto et al. [68] have concluded that apparent stress  $\sigma_a$  is almost independent of moment for most earthquakes. If that is correct, its immediate consequence is that moment scales like the inverse third power of the corner frequency:

$$M_0 \propto f_0^{-3}. \tag{24}$$

*If apparent stress is constant, seismic moment is inversely proportional to the cube of the corner frequency. This result*

Earthquake Scaling Laws, Figure 2  
 Scaling of the displacement spectrum in the far field as illustrated by several spectra for different size earthquakes reported by Prieto et al. [59]. Body wave spectra have the typical Brune [17] spectrum and can be collapsed into a single scaling figure by gliding the corner frequencies along an  $\omega^{-3}$  line

is independent of the particular source model used and can be tested directly from seismic observations. Figure 2 from Prieto et al. [59] illustrates this scaling law. On the left-hand side a series of spectra for different size earthquakes are shown. The corner frequencies align along a line with slope  $\omega^{-3}$ . Letting all the spectra glide along this line they computed the spectra stack shown at the right-hand side. The same properties are shared by P and S wave spectra. The P wave corner frequencies are higher by a factor of 1.6 than, those of shear waves (9).

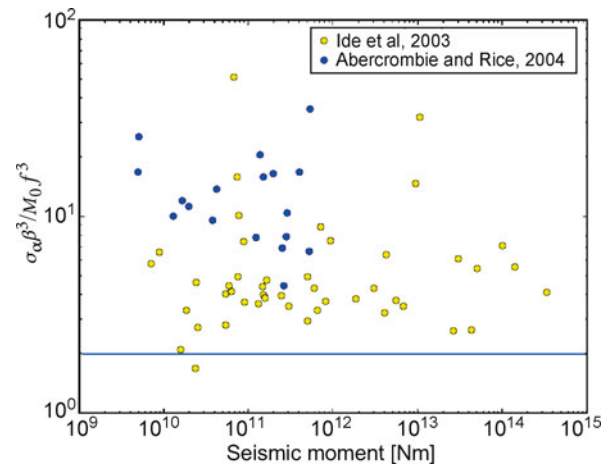

Originally, the scaling law (24) was proposed by Aki [4] following a study of spectral data from several collocated earthquakes of different magnitude. Comparing their spectra, he concluded that corner frequencies scaled with seismic moment like (24). This is the so-called **scaling law of seismic spectrum**. This law has been tested by numerous authors with increasingly reliable digital data. Figure 3 shows an example derived from data published by Ide et al. [35] and Abercrombie and Rice [2]. In this Figure I plotted the corner frequency of S waves as measured by the authors as a function of seismic moment. The moment vs. corner frequency plot clearly follows the trend of Eq. (24). The fact that in Fig. 3 moment and corner frequency scale like (24) is often taken as a proof that earthquakes scale with a single parameter: the seismic moment. This is however not sufficient to prove scaling because seismic sources require at least three independent parameters for their quantification. It has been traditional to add an additional model dependent relation in order to derive length, time and stresses from (23). The most common assumption is that the corner frequency is related to the radius of an equivalent circular crack using the frequency radius relation proposed by Brune [17]. Some authors use other similar relations derived from quasidynamic models (e. g. [46,66]). With that assumption, corner frequency can be converted into fault size and stress drop can be derived from moment and source radius.

In order to test whether earthquakes scale with a single parameter, it is necessary to obtain an additional objective measure of seismic sources. The best current candidate is the radiated energy of S waves defined by (13). Originally proposed by Boatwright [11,12,13], estimates of seismic energy have become quite common but they are still difficult to obtain as discussed by many authors including Boatwright and Fletcher [15], Abercrombie [1], McGarr [53], Ide et al. [32] Singh and Ordaz [69], etc. In the following I will test the scaling law of earthquakes by computing the non dimensional ratio  $C_r = \mu E_r \beta^3 / (M_0 f_0^3)$  from published data.

In Fig. 4 I test expression (18) for the data studied by Ide et al. [35] and Abercrombie and Rice [2]. The fig-

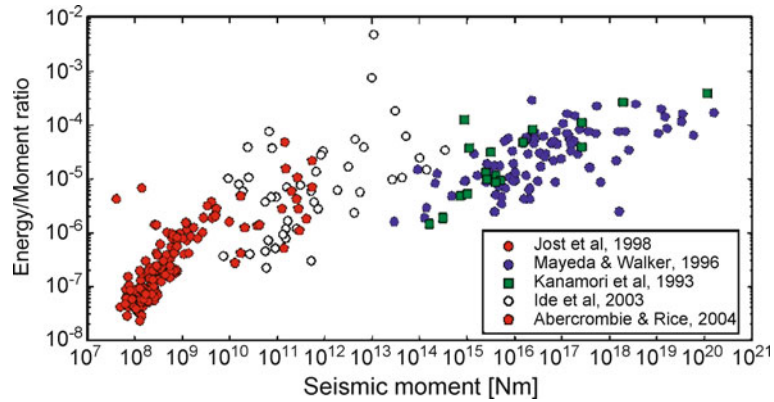

Earthquake Scaling Laws, Figure 3  
 Self-similarity of earthquake spectra. The figure includes data from two different studies by Ide et al. [32] and by Abercrombie and Rice [2]. These authors measured all the quantities needed for testing the energy/moment scaling relation (23). The line labeled  $M_0 \cong f_0^{-3}$  indicates the trend of variation of moment with corner frequency predicted by Aki's scaling law

Earthquake Scaling Laws, Figure 4  
 The nondimensional coefficient  $C_r$  defined by expression (23) plotted as a function of seismic moment. Data from Abercrombie [2] and Ide et al. [32]. The non dimensional coefficient predicted by Brune's spectral model should be equal to 1.9739 as indicated by the horizontal line. Actually it varies over almost two orders of magnitude in this data set. This may be due to errors in the measurement of radiated energy, moment and corner frequencies or it may reflect an important departure from single parameter scaling of seismic sources

ure plots the non dimensional ratio  $C_r = \mu E_r \beta^3 / M_0 f_0^3$  as a function of seismic moment. According to (23), for strict scaling of seismic sources with a single parameter, this non-dimensional ratio should be a constant, indepen-

Earthquake Scaling Laws, Figure 5

Energy moment ratio as a function of moment for 14 orders of magnitude of moment. This figure is inspired on similar plots by McGarr [53] and Ide and Beroza [33]. We used data from Jost et al. [36], Mayeda and Walker [52], Kanamori et al. [41], Ide et al. [35] and Abercrombie and Rice [2]. The data of Jost et al. [36] was not corrected for attenuation as suggested by Ide and Beroza [33]. At this scale it is obvious that moment is the most broadly variable parameter, but there is also a large spread of apparent stress, over at least three orders of magnitude

dent of the seismic moment. Figure 4 shows that there is substantial scattering of the values of the non-dimensional ratio. There are many reasons for this variation; the most obvious one is experimental error due to uncorrected path or site effects, like attenuation, scattering and site amplification. I believe that even if those errors were corrected there would remain some variation due to source complexity that is not fully explained by the assumption that all earthquakes scale with a single parameter. In the literature authors generally assume that the scaling law applies and proceed to compute model-dependent quantities like static or dynamic stress drop using very specific models of rupture (see also p. 36 in [10]).

Clearly moment, energy/moment ratio and apparent stress are broadly distributed. This is illustrated in Fig. 5, inspired by previous figures of the same kind by McGarr [53] and Ide and Beroza [33]. The main difference between the results reported by these two authors is that Ide and Beroza [33] introduced a correction for attenuation at high frequencies. The figure shows the energy/moment ratio as a function of moment over 15 orders of magnitude of seismic moment. The sources of data [2,35,36,41,52] are not the same as those used by McGarr [53] and Ide and Beroza [33], because not all the data they used is published. I did not include small mine earthquakes from South Africa because it is not clear whether those events are due to frictional slip of pre-existing surfaces (see, e.g. [63]). For such a broad range of moments, the variation in energy-moment ratio is bounded, but it ranges over close to three orders of magnitude. It is clear that for the group of earthquakes reported in Fig. 5, apparent stress changes

were important and deserve further work. This is not completely unexpected: a multitude of observations point out that stresses in the seismic zones are highly variable as well as the geometry of faulting.

### Earthquake Fault Models: The Scaling of Geometry and Stress

The previous discussion focused on the properties of seismic radiation from moment tensor sources and the time and frequency dependence of the moment rate function. Actually, the Brune spectrum and Aki's scaling law can be retrieved from seismic waves without any reference to a particular fault model. In order to understand how the moment is related to source dimensions and the origin of omega-squared radiation, we have to introduce a specific fault model. We will proceed in two steps: first we will study a simple source model that explains most of the observations and, in a second step, we will discuss how this model can be generalized.

A fault is defined as a rupture in the earth crust with a relative displacement of its two sides. The relative displacement between the two sides of the fault (or fault slip) will be denoted by  $\mathbf{D}(\mathbf{x}, t)$ , a vector function of position on the fault ( $\mathbf{x}$ ) and time ( $t$ ). Thus, in general,  $\mathbf{D}$  may vary in amplitude and direction over the fault plane and at each point is a function of time. The scalar seismic moment of an earthquake defined in (1) depends on source area and slip on the fault. It is essentially a static measurement of earthquake size. Corner frequency, on the other hand, is a measure of the duration of the earthquake signal which

is controlled by the time it takes for the rupture front to propagate across the fault. Thus, corner frequencies depend clearly on fault size, but one can expect this relation to be complex and very dependent on the details of the rupture process. This is often ignored in practical work, and simple source models are adopted in order to express the scaling law (23) in terms of source dimension. The argument in favor of this approach is that in order to build scaling laws that extend over several orders of magnitude of moment we may ignore the details of slip and geometry. Let us start by studying a simple circular crack, probably the simplest realistic fault model one can consider.

In a simplified model of fracture, the relative slip  $D$  of the two sides of a fault is produced by the relaxation of the shear stress transmitted across the fault. Shear stress changes with time due to the slow motion of plates, orogeny and a number of other processes that transfer stresses in the Earth's crust. When shear stress exceeds the strength of the material or the friction that maintains the fault locked, slip on the fault starts and, simultaneously, shear stress relaxes to a lower value until all motion on the fault ceases. This process is obviously very complex; detailed studies of even the simplest models of faulting show that stress relaxation at any point on the fault is complex function of not just local stress release on the fault but of other slipping points and of wave propagation on the fault. Solving such a complex problem is only worth the effort for very special, very well recorded events. For most other earthquakes we want to make global estimates of stress relaxation, and related them to the simple spectral model we studied in the previous section.

Let the shear stress acting on the fault plane before and after the occurrence of an earthquake be  $T_0$  and  $T_f$ , respectively. We define stress drop  $\Delta\sigma$ , as the difference

$$\Delta\sigma = T_0 - T_f. \quad (25)$$

The stress drop represents the part of the acting stress which is used to produce the slip of the fault so that  $\Delta\sigma$  is related to slip  $D$ . The relation between stress drop and slip will be in general very complex: it will depend on the geometry of the fault, but also on certain fundamental assumptions about the stress field in the earth. In general, stress will be much more heterogeneous than slip because, at least in the static case, stress is a generalized derivative of stress. We will discuss these properties briefly in Sect. "Earthquake Dynamics and the Scaling of Energy". We will assume here that the stress distribution has to be such that a finite amount of energy is released during faulting. This assumption is the basis of fracture mechanics, leading to the condition that stress may have at most inverse square root singularities on the fault surface

(see, e.g. [22,45,60]). In the early work on faults, many authors assumed that earthquakes were due to dislocations, slip distributions that present slip discontinuities at their borders. The best known example of such model is the Haskell [30] rectangular dislocation model. This model produces non-integrable stress concentrations around the edges of the fault that store an infinite amount of strain energy [48]. Thus, even if this model radiates a finite amount of energy it can not be used to estimate energy balance during seismic rupture. This paradox was well known in mechanics, where dislocations and cracks are treated as very different phenomena.

### The Static Circular Crack

A simple model that may be used to explain many of the scaling laws observed in earthquake seismology is that of a static circular ("penny shaped") crack of radius  $a$  lying on the  $x, y$  plane. We assume that the fault is loaded by a uniform initial shear stress  $T_0$ , and that  $T_f$ , the final stress, is also uniform inside the fault. The slip on the fault produced by a constant static stress drop  $\Delta\sigma$  inside a circular crack was computed by Eshelby [20] and Keilis-Borok [42]

$$D(r) = \frac{24}{7\pi} \frac{\Delta\sigma}{\mu} \sqrt{a^2 - r^2}, \quad (26)$$

where  $r$  is the radial distance from the center of the crack on the  $(x, y)$  plane,  $a$  is the radius of the crack, and  $\mu$  is the elastic rigidity of the medium surrounding the crack. Slip has the typical elliptical shape associated with cracks. The distribution of slip and the stress change for a circular crack are schematically shown in Fig. 6. Using the definition of the seismic moment (1) we can determine the scalar seismic moment for this circular fault:

$$M_0 = \frac{16}{7} \Delta\sigma a^3 \quad (27)$$

so that the moment is the product of the stress drop times the cube of the fault size. This simple relation will be used to explain the seismic scaling law in terms of fault radius and stress drop. Other fault geometries produce somewhat different scaling laws, including products of fault length and fault width. Unfortunately, as far as I know, no other geometry can be solved in such a simple closed form as the circular crack.

We can also compute the static strain energy change in the elastic medium surrounding the circular fault. This is defined as

$$\Delta W = \frac{1}{2} \int_S \Delta\sigma D dS. \quad (28)$$

Earthquake Scaling Laws, Figure 6  
 The simple static circular crack. The upper panel shows the slip distribution as a function of radius. The bottom panel shows the stress change produced by the slip at the top

From simple thermodynamic considerations,  $\Delta W$  should be negative so that stress drop and slip should have opposite signs. For the circular crack this can be easily computed replacing the slip distribution (26) in this integral. Integrating, we find

$$\Delta W = \frac{8}{7} \frac{\Delta\sigma^2}{\mu} a^3 \quad (29)$$

where we have omitted the negative sign, so that  $\Delta W$  should be interpreted as the reduction of strain energy from the elastic body caused by the earthquake. Dividing (27) into (29) we find that the strain energy to moment ratio for the circular crack is just.

$$\frac{\Delta W}{M_0} = \frac{1}{2} \frac{\Delta\sigma}{\mu} \quad (30)$$

In the very early studies of seismic rupture it was sometimes assumed that radiated energy was equal to strain energy change, i.e.  $\Delta W = E_r$ . In that case apparent stress  $\sigma_a = 1/2 \Delta\sigma$  his assumption is sometimes referred to as the Orowan [58] model. This model is very unlikely to hold for real earthquakes: if all the available energy were radiated, there would be no energy left for producing rupture propagation and consequently rupture should propagate exactly at the P wave or the S wave speeds or should stop immediately in front of any obstacle (see [21,44]).

The circular crack model has been used to quantify numerous earthquakes for which the moment was estimated from the amplitude of seismic waves, and the source radius was estimated from corner frequencies, surface deformation, etc. The result is that for shallow earthquakes in the seismogenic zones like the San Andreas Fault, or the North Anatolian Fault in Turkey, average stress drops are of the order of 1–10 MPa. For deeper events in subduction zones, stress drops can reach several tens of MPa. Thus, average stresses do not vary much, compared to the variation of moment over more than 15 orders of magnitude.

### Brune's [17] Model of Seismic Radiation

Brune developed a model of seismic radiation based on the observation that seismic spectra had the omega-squared spectral shape (7). Brune [17] proposed a model only for shear waves; although, as we already mentioned, P waves have a similar spectral shape with a corner frequency that is different from that of S waves. In his 1970 paper proposed also a relation between the corner frequency  $f_0$  and the source radius  $a$  of a circular fault:

$$f_0 = 0.3724 \frac{\beta}{a} \quad (31)$$

That is, the corner frequency is inversely proportional to the size of the fault. The origin of the coefficient 0.3724 that appears in (31) is very important because it has major consequences for the partitioning of elastic energy. Although the steps followed by Brune were different, we can obtain his results in the following way.

Replacing the expression for moment of a circular crack (27) into the expression for energy moment ratio (17) we get

$$\frac{E_r^S}{M_0} = 4.5118 \frac{\Delta\sigma}{\mu} \frac{a^3 f_0^3}{\beta^3} \quad (32)$$

inserting Brune's expression for the corner frequency (31) into (32) we get the apparent stress

$$\sigma_a = \frac{\mu E_r^S}{M_0} = 0.2331 \Delta\sigma \quad (33)$$

So that apparent stress drop in Brune's model is proportional to the static stress drop  $\Delta\sigma$ . This result, derived by Singh and Ordaz [69], has a very interesting consequence for the energy balance in earthquakes. Indeed, inserting the relation (30) between moment and strain energy change during an earthquake into (34), we get

$$E_r^S = 0.466 \Delta W \quad (34)$$

Earthquake Scaling Laws, Figure 7

Apparent stress versus stress drop for the data reported by Ide et al. [32] and Abercrombie and Rice [2]. This figure suggests that apparent stresses computed directly from radiated energy and moment are not independent of stress drop computed for a static circular crack model

That is Brune's model makes the implicit assumption that the energy radiated in the form of S waves is 46.6% of the available strain energy. This was computed by Brune [17]; he found that S waves carried 44% of the available energy in his Equation (40). The number cited here, 46.6% is due to Brune's [18] correction of (31). I think that this is a very important consequence of the corner frequency source radius relationship (31), that is not often cited in the literature.

We can now test whether stress drops computed using the static circular crack model produces are or not independent of the apparent stresses computed from the energy moment ratio  $E_r/M_0$ .

In Fig. 7 we plot the ratio of apparent stress to stress drop for the data of Ide et al. [35] and Abercrombie and Rice [2]. The relation is roughly linear but the ratio is not well defined, although it is clearly less than 1 for most of the events.

### Earthquake Dynamics and the Scaling of Energy

Earthquakes are dynamic processes in which rupture propagates under the control of friction that acts between the two sides of the fault as they slip. The study of the friction law that actually operates on seismic faults is a major problem in seismology and fracture mechanics. Laboratory experiments, seismic observations and field studies are needed to solve this complex problem. In this section we will attempt to establish some general

properties of seismic sources without getting involved with fine details about friction and rupture propagation (see the contribution by Ampuero in the present volume for a fuller discussion). The main question in this context is: can we establish some general properties of seismic ruptures that are independent of the details of friction? Do the observations of seismic spectra and scaling laws constrain in any way the overall properties of seismic sources? This approach has been taken in recent years by many authors, some have tried to convert slip models inverted from near field seismic observations to determine energy balance [16,34]; others have tried to do the same by remarking that dynamic ruptures only propagate at reasonable rupture speeds for a very limited range of seismic parameters [57]; or, very recently, have tried to derive general properties of the friction law from the scaling of seismic spectra [2]. We will follow the latter approach because I believe that it is very promising.

### The Dynamic Circular Crack Model

Perhaps, the simplest fault model that can be imagined is a circular crack that grows from a point at a constant or variable rupture speed and then stops at the rim of the fault, arrested by the presence of unbreakable barriers. This model is the natural dynamic equivalent to the static circular crack discussed in the previous section. The circular crack problem is posed in terms of stresses not of slip, but the rupture process is fixed in advance so that rupture does not develop spontaneously. This is the only unrealistic feature of this model, hence it is considered as quasidynamic, that is, rupture is kinematically defined, but slip is computed solving the elastodynamic equations. This model was carefully studied by a number of authors in the 1970s [43,46,47,62,65].

Let us consider a rupture that starts from a point and then spreads self-similarly at constant rupture speed  $v_r$  without ever stopping. Slip on this model is driven by stress drop inside the fault. The solution of this problem is somewhat difficult to obtain because it requires very advanced use of self-similar solutions to the wave equation and its complete solution for displacements and stresses must be computed using the Cagniard de Hoop method [62]. Fortunately, the solution for slip across the fault found by Kostrov [43] is surprisingly simple. Slip in the circular fault is parallel to the direction of stress drop on the fault and it has the typical elliptical shape:

$$D(r, t) = C(v_r) \frac{\Delta\sigma}{\mu} \sqrt{v_r^2 t^2 - r^2} \quad (35)$$

where  $r$  is the radius in a cylindrical coordinate system centered on the point of rupture initiation.  $v_r t$  is the instantaneous radius of the rupture at time  $t$ .  $\Delta\sigma$  is the dynamic stress drop assumed to be constant inside the rupture zone,  $\mu$  is the elastic rigidity, and  $C(v_r)$  is a slowly varying function of the rupture velocity  $v_r$ . For most practical purposes  $C \sim 1$ . This simple solution constitutes a key result containing one of the most important properties of circular cracks. Slip inside the fault scales with the ratio of stress drop over rigidity times the instantaneous radius of the fault. As rupture develops, slip increases with the size of the rupture zone.

### Energy Release Rate for a Dynamic Circular Crack

We can determine the energy release rate for Kostrov’s model (35) from the behavior of stresses near the edge of the crack. At time  $t$ , the fault radius is  $r = v_r t$ , the slip velocity field derived from (35) has the form

$$V(r, t) = C(v_r) \frac{\Delta\sigma}{\mu} \frac{v_r^2 t}{\sqrt{v_r^2 t^2 - r^2}} \tag{36}$$

so that, near the rupture front, the velocity field presents the well known inverse-squared root singularity predicted by dynamic crack theory [22,45]. We can then approximate the singularity in slip rate in the general form

$$V(r, t) = \frac{V_d}{\sqrt{2\pi}} \frac{1}{\sqrt{v_r t - r}} \tag{37}$$

where  $V_d$  is the velocity intensity factor, a measure of the amplitude of the square root singularity in slip velocity that moves with the rupture front. This velocity singularity is associated with a dynamic stress concentration ahead of the rupture front

$$\Delta\sigma(r, t) = \frac{K_d}{\sqrt{2\pi}} \frac{1}{\sqrt{r - v_r t}} \tag{38}$$

which is also of the inverse square root type.  $K_d$  is the dynamic stress intensity factor. The amplitudes  $V_d$  and  $K_d$  are linearly related to each other with a coefficient that is different for fracture modes II and III. Avoiding details that are discussed by Freund [22], we can write

$$V_d = a(v_r) \frac{K_d}{\mu} v_r \tag{39}$$

where  $a(v_r)$  is a coefficient that depends on the instantaneous rupture velocity  $v_r$ .

We can compute the energy release rate near the border of the fault directly from these expressions, using several results from Kostrov [43] and Madariaga [47]:

$$G_c(v_r) = \frac{K_d V_d}{v_r} = a(v_r) \frac{K_d^2}{2\mu} \tag{40}$$

Earthquake Scaling Laws, Figure 8  
**The  $g(v_r)$  function of rupture velocity. This function controls the fraction of strain energy that is used as fracture energy in a quasi-dynamic circular shear crack that ruptures at a constant rupture speed**

that is, the energy release rate  $G_c$  near the crack front is proportional to the square of the dynamic stress intensity factor. Since the dynamic stress intensity factor  $K_d$  tends to zero at high rupture speeds, the energy release rate  $G_c$  also decreases at high speed rates. Thus, the faster the rupture, the less energy is spent in making the rupture advance.

For the circular crack, the energy release rate is not uniform around the perimeter of the circular fault because it is different in mode II (in-plane) and mode III (anti-plane). From results by Madariaga [46] we get for a circular crack

$$G_c(v_r, r) = \frac{g(v_r)}{3} \frac{\Delta\sigma^2}{\mu} r. \tag{41}$$

Where  $g(v_r)$  is a monotonically decreasing function of rupture speed shown in Fig. 8. An exact expression for  $g(v_r)$  was proposed by Madariaga [46], but his Eq. (30) contains a misprint that was corrected by Ide [32].

### The Scaling of Energy Release Rate with Earthquake Size

We can now estimate the energy used for the propagation of the seismic rupture using the previous estimate for Brune’s [17] model (34). We can establish the following global energy balance for an earthquake that is well modeled by Brune calibration of the shear wave spectra.

As rupture propagates, strain energy released by faulting  $\Delta W$  is used in part to produce seismic waves, and in part to make fracture advance (measured by the energy re-

lease rate  $G_c$ ). Assuming that  $G_c$  is constant over the fault surface we find the following earthquake energy balance

$$\Delta W = E_r + G_c S \quad (42)$$

where  $S$  is the area of the fault. In order to estimate  $G_c$ , we need to estimate the total radiated energy  $E_r$ . Brune's model is only suitable to compute S wave radiated energy which as shown by Eq. (34) is 46.6% of the available strain energy. Energy transported by P waves can be computed using either theoretical arguments or observations of P to S energy ratios. This question was examined by Boatwright and Fletcher [15] who concluded that, theoretically at least, a crack-like source should produce about 15 times more energy carried by S waves than P wave energy. This number is confirmed by observations reported by Abercrombie and Rice [2], Prieto et al. [59]. We can thus estimate that radiated energy in the Brune model is roughly 50% of the strain energy released by the earthquake; the other 50% goes into rupture work, i. e.

$$G_c S \approx \frac{1}{2} \Delta W. \quad (43)$$

Using the expression (29) for  $\Delta W$  we get

$$G_c \approx \frac{1}{2} \frac{\Delta W}{\pi a^2} = \frac{4}{7\pi} \frac{\Delta \sigma^2}{\mu} a. \quad (44)$$

That is, if we adopt Brune's model, *energy release rate scales with fault size*.

In the previous calculation we assumed that  $G_c$  was uniform inside the fault. A better assumption would be that, as the rupture propagates,  $G_c$  grows with the radius as in the simple quasi-dynamic model of Madariaga [46],

$$G_c(r) = \frac{\Delta \sigma^2}{3\mu} r g(v_r) \quad (45)$$

where  $g(v_r)$  will be determined for Brune's model. The total energy release during rupture is then

$$\int_S G_c(r) dS = \frac{2\pi}{9} \frac{\Delta \sigma^2}{\mu} g(v_r) a^3.$$

Using (43) again we get

$$g(v_r) = \frac{18}{7\pi} = 0.818. \quad (46)$$

Thus, Brune's model is equivalent to a circular quasidynamic shear crack propagating such that the energy release rate grows with fault radius like

$$G_c = \frac{6}{7\pi} \frac{\Delta \sigma^2}{\mu} r.$$

Thus, whether we use a constant energy release rate on the fault (44), or a more realistic model where energy release grows with the radius of the fault, we find that energy release rate grows with fault radius in Brune's model. This result confirms that energy release rate scales with the fault radius and that it adjusts as the fault grows [55,56].

The relation between energy release rate and fault size was studied by Abercrombie and Rice [2] using their own data and data from a number of previous studies. They reached the conclusion that  $G_c$  grows with radius roughly like  $r^{0.4}$ , not like the radius as in (41) and (47). Abercrombie and Rice estimated  $G_c$  from the expression

$$G_c = \frac{1}{2} (\Delta \sigma - \sigma_a) D$$

where  $D$  is slip. This expression is entirely compatible with ours, so that the reason  $G_c$  scales with the power 0.4 of the radius is that stress drops scale with earthquake size, specially if  $\Delta \sigma$  is not linearly related to  $\sigma_a$  as shown in Fig. 7. After checking Fig. 8 of Abercrombie and Rice [2], I conclude that they obtained scaling with a power of 0.4 using the full data set, including much larger earthquakes. For the Cajon pass earthquakes studied by Abercrombie and Rice the power of radius in scaling is much closer to one. Seismic data have now reached the quality necessary to test different hypothesis about the scaling of rupture energy in order to see whether larger earthquakes are really different from smaller ones.

### Scaling of Energy, Magnitude and Moment

Kanamori [38] introduced the so-called moment magnitude,  $M_w$ , assuming that all available strain energy was converted into seismic waves, i. e. that  $E_r \approx \Delta W$ . This assumption means that no energy is used to propagate fracture so that  $G_c = 0$ . Using the definition of strain energy change, (28), we get Kanks and Kanamori [28]:

$$E_r = \frac{1}{2} \Delta \sigma \bar{D} S, \quad (47)$$

where  $\bar{D}$  is the average slip of the earthquake and  $S$  its source area.

This expression shows that from the radiated energy we only have information about the stress drop, not about the absolute stress level acting on the fault during faulting. Rewriting expression (27)

$$M_0 = \frac{16}{7\pi^{3/2}} \Delta \sigma S^{3/2} \quad (48)$$

and taking logarithms

$$\log M_0 = \frac{3}{2} \log S + \log \left( \frac{16\Delta\sigma}{7\pi^{3/2}} \right). \quad (49)$$

From this equation it follows that, for constant stress drop scaling,  $\log S$  should be proportional to  $2/3 \log M_0$ . This hypothesis had been shown empirically to be valid for a large range of values of  $M_0$  [39]. We noticed however that more recent data (Fig. 6) shows that stress drop varies over 3 orders of magnitudes, at least in the data reported by Ide and Beroza [33].

Assuming constant stress drop, Kanamori [38] defined the moment magnitude  $M_w$  based on the empirical relation of Gutenberg and Richter [23,24] between surface wave magnitude and seismic energy (in Joules):  $\log E_r = 1.5M_S + 4.8$ . Hanks and Kanamori [28] proposed the moment magnitude scale

$$M_W = \frac{2}{3} \log M_0 - 6.07 \quad (50)$$

where  $M_0$  is measured in Nm. The moment magnitude has become the standard way to measure the size of earthquakes. Both  $M_w$  and seismic moment  $M_0$  (Nm) can be related to other magnitude measurements by a number of empirical relations. (see, e. g. [39]).

Radiated seismic energy can not be computed directly from (47) because it needs to be corrected for the part of the strain energy that is used to propagate the fracture (see, (42)).

### More General Scaling Relations Derived from the Scaling Law of Earthquake Spectra

In the two previous sections several scaling relations have been established which relate the parameters involved in the fracture process of earthquakes. It has been shown that slips and slip velocities scale linearly with stress drop, which is the most fundamental scaling parameter (pp. 202–211 in [67]). If the average stress drop measured over the whole fault plane is roughly constant for all earthquakes, the slip on the fault should scale with the dimensions of the fault ( $L$ ) which for small earthquakes represents the length ( $L$ ) or radius of the fault and for large earthquakes the width ( $W$ ). An unsolved issue, due mostly to lack of data for very long strike slip earthquakes, is that of a possible difference in the scaling of the seismic moment with fault length, between large and small earthquakes. Strike slip earthquakes with seismic moment less than  $10^{21}$  Nm ( $M_w < 8$ ) should scale with  $L^3$ , while larger ones with  $L^2$ .

Many other relations can be established starting from the basic scaling laws discussed earlier in this chapter. For instance, maximum and average slip for earthquakes scale like the cubic root of moment for most earthquakes [53,54], but these scaling relations can be derived from the basic relations discussed earlier.

### More Realistic Radiation Model

In reality earthquakes occur in a complex medium that is usually heterogeneous and dissipative. Seismic waves become diffracted, reflected, and in general suffer from multipathing in those structures. Accurate seismic modeling would require perfect knowledge of Earth's structure. It is well known and understood that structural complexities dominate signals at certain frequency bands. For this reason the simple model presented here can be used to understand the main features of earthquakes at long wavelengths, while the more sophisticated approaches that attempt to model every detail of the wave form are reserved only for more advanced studies. Here, like in many other areas of geophysics, a balance between simplicity and concepts must be kept against numerical complexity that may not always be warranted by lack of knowledge of the details of Earth's structure. If the simple approach were not possible, then many standard methods to study earthquakes would be impossible to use. A good balance between simple, but robust concepts and the sophisticated reproduction of the complex details of real wave propagation is a permanent challenge for seismologists.

### Why Does the Spectrum Decay Like $\omega$ Squared?

We have seen that seismic data is in very broad agreement with the general features of Brune's spectral model (7). We have explained the scaling of low frequencies in terms of simple static source models, the corner frequency and the high frequency decay are explained by the energy balance Eq. (32). Seismic energy must be finite and a well defined fraction of the available strain energy. These conditions require that the spectrum of seismic energy is integrable in expression (13). General properties of Fourier transform can be invoked to demonstrate that in the time domain displacement signals are continuous functions of time with discontinuous derivatives. That is, the velocity field emitted by a seismic source in the far field contains jumps in particle velocity as is the case with the seismic signals proposed by Brune (19) or by Kanamori and Rivera (20). For the dynamic circular crack studied in this section, the velocity jumps are emitted when rupture stops abruptly at the rim of the circle of radius  $a$ . The

nature of these stopping phases has been carefully studied by a number of authors, including Madariaga [46,47], Boatwright [12], Spudich and Frazer [71] and Bernard and Madariaga [8]. Their study is very complex and beyond the purpose of the present article, we will use a simpler approach based on a scaling argument.

Let us now consider how the stopping phases scale with earthquake size and stress drop. In the omega squared model, the high frequency decay of the far-field displacement produced by shear waves can be written in the very general form

$$u_s(r, \omega) = C(\theta, \varphi) \frac{M_0 \omega_0^2}{\mu \beta} \frac{1}{R} \omega^{-2},$$

where we lumped the numerical coefficients and the radiation pattern in the single non-dimensional coefficient  $C(\theta, \varphi)$ .  $R$ ,  $\theta$  and  $\varphi$  are spherical coordinates at a reference point on the fault. Using the expressions for  $M_0$  and corner frequency in terms of fault radius and stress drop we obtain

$$u(r, \omega) = C(\theta, \varphi) \frac{\Delta \sigma a \beta}{\mu} \frac{1}{R} \omega^{-2} \quad (51)$$

with a slightly different dimension-less coefficient. The far field waves scale at high frequencies like the product of stress drop times the radius of the fault. That is exactly what was predicted by Madariaga [47] for a circular crack. It is interesting to remark that the factor  $\Delta \sigma a$  actually comes from the product of the stress intensity factor  $K$  and the square root of the radius  $a$ . Although the scaling of high frequencies was derived here for a very special circular crack model, it can be easily generalized to ruptures of any shape, splitting the factor  $\Delta \sigma a$  into a stress intensity factor and the square root of the local radius of curvature of the wave front of the stopping phase.

The previous model for the radiation of omega squared high frequency waves can be extended to more complex source models, in particular to source models that contain a number of subfaults (see, e. g., [14]). The high frequency seismic waves emitted by such a model are due to stopping phases emitted all along their propagation process. Each such stopping phase contributes to enriching the high frequency contents of the seismic waves. The incoherent sum of those phases produces a total spectrum that scales with fault radius as in (51). In this sense, omega squared decay is the signature of the presence of cracks on the fault. Recent work has shown that omega squared waves are emitted every time the rupture front changes rupture velocity, or that the rupture is deviated from a plane by the presence of fault kinks or discontinuities.

## Kinematics and Statistical Models for Fault Slip

So far we have discussed a dynamic crack approach to understanding earthquake scaling. Another method to describe seismic sources radiation was introduced by Haskell [30]. He assumed that earthquakes could be described by simple propagating dislocations leaving a constant slip in their trail. The most common such model is that of a flat rectangular fault with constant slip in it. Such model is mechanically impossible, because it needs infinite amount of energy to be created. Curiously, though, the Haskell model produces a finite amount of radiated energy and the radiated field can be computed exactly both in the far [31] and near field [48]. Because the strain energy change produced by Haskell's model is infinite, an energy balance equation like (42) can not be established. In Haskell model all of the energy released from the medium is absorbed by the dislocation motion and seismic radiation is just a secondary feature of the source processes.

Dislocation models have appeared in a different form, derived from statistical considerations about the distribution of slip on faults. In his seminal paper, Andrews [6] established some basic statistical properties of slip distributions that are actually based on Haskell's [31] original study of the power spectra of slip and the correlation functions of slip. His analysis is based on some general features of fractal surfaces and distributions; here we will look at these scaling relationships from the point of view of the circular crack model that we discussed in previous sections.

The slip function of a circular crack was defined in (26). This is a function of radius only so that its Fourier transform is very easy to compute using the Hankel transform:

$$\tilde{D}(k) = 2\pi \int_0^\infty D(r) J_0(kr) r dr \quad (52)$$

where  $k$  is the radial wave-number,  $J_0$  is the Bessel function of degree zero. Inserting the expression (26) in (52) and integrating we get

$$\tilde{D}(k) = \frac{48}{7} \frac{\Delta \sigma}{\mu} a^3 \frac{\sin(ak) - ak \cos(ak)}{k^3 a^3}. \quad (53)$$

At low wave-number, when  $k$  tends to 0, the spectrum (53) tends to the value

$$\tilde{D}(0) = \frac{16}{7} \frac{\Delta \sigma}{\mu} a^3 = \frac{M_0}{\mu}$$

that is, the low wave number limit of the slip spectrum is the seismic moment, just as the low frequency limit of Brune's spectrum is the seismic moment. This is of course

not a coincidence but a consequence of the fact that the seismic moment is the source of low frequency waves. At high wave numbers, when  $ka \gg 1$ , the spectrum  $D(k)$  behaves like

$$\lim_{k \rightarrow \infty} \tilde{D}(k) = -\frac{48}{7} \frac{\Delta\sigma}{\mu} a^3 \frac{\cos(ak)}{a^2 k^2}. \quad (54)$$

The slip spectrum decays like  $k^{-2}$  at high wave numbers, a property that seems to be as universal as the high frequency decay of seismic spectra with omega-squared.

The important issue is why is it  $k^{-2}$ ? The origin of the high frequency behavior of the slip spectrum can be determined with some simple properties of the Hankel transform (52). Take a circular fault of finite radius  $a$ . Then for different types of slip discontinuity we get the following asymptotic behavior:

	$\lim_{r \rightarrow a} D(r)$	$\lim_{k \rightarrow \infty} D(k)$
Constant	1	$k^{-3/2}$
Crack-like	$(a-r)^{1/2}$	$k^{-2}$
Conical	$(a-r)$	$k^{-5/2}$
Smooth	$(a-r)^{3/2}$	$k^{-3}$

Thus the high wave number behavior is a reflection of the discontinuity of slip at the border of the fault. Andrews [6] studied a slip distribution that behaves like  $(a-r)^{3/2}$  near the edge of the fault. In his case the high wave number decay is  $k^{-3}$ . Thus the high wave number behavior of slip distributions is controlled by the discontinuities of slip, a crack like discontinuity producing a  $k$ -squared distribution. Note that the spectral behavior for two-dimensional distributions is quite different than for two dimensional slip distributions. Haskell [30] used the properties of 2D Fourier transforms to derive several conclusions about earthquake spectra that do not apply to circular cracks. For a two-dimensional plane or anti-plane crack the spectrum decays like  $k^{-3/2}$ , such a spectrum is inadmissible in 3D because it would imply non-integrable stress distributions as we will show now.

The stress field associated with the circular shear crack slip can be computed in a straightforward way using the expressions provided by Eshelby [20] or Sneddon [70]. Let the fault be located on the plane  $(x,y)$  and slip be parallel to the axis  $x$ , (i. e.  $D(x) = \Delta u_x(x)$ ). In the spectral domain the associated stress drop can be computed from slip by

$$\Delta\sigma_{xz}(k) = -\frac{\mu}{2k} \left( \frac{2(\lambda + \mu)}{\lambda + 2\mu} k_x^2 + k_z^2 \right) D(k) \quad (55)$$

(see [64]). This is a relatively simple expression, but it is not easy to compute analytically because stress drop for the circular crack does not have cylindrical symmetry. Andrews [6] provided a simplification that we will use

here: assuming that the elastic constant  $\lambda = 0$  i. e. that is the elastic medium is incompressible), we get in Fourier domain:

$$\Delta\sigma_{xz}(k) = -\mu k D(k). \quad (56)$$

Multiplying (53) by  $-k$  and doing the inverse Hankel transform (see [70]) we get, approximately

$$\begin{aligned} \Delta\sigma_{xz}(r) &= -\Delta\sigma \quad \text{for } r < a, \\ \Delta\sigma_{xz}(r) &\cong K/\sqrt{r-a} \quad \text{for } r > a. \end{aligned} \quad (57)$$

That is, inside the crack, stress drop is constant while outside stress drop exhibits an inverse square root singularity typical of cracks as discussed in (38). This explains why the spectrum of a circular crack decays as  $k^{-2}$  in the wavenumber domain. The  $k^{-2}$  spectrum is the signature of the presence of a crack.

Mai and Beroza [51] computed the correlation lengths, fractal dimensions, Hurst exponents and wave number spectra of 42 earthquakes for which the slip distribution on the fault planes were available from inversion of seismic and geodetic data. They reached the conclusion that the high frequency decay had an average fractal dimension of  $2.29 + / - 0.23$  that implies a high wave number asymptotic decay of  $k^{1.71}$ , that is slip distributions determined from slip inversions tend to be rougher than the spectra of circular cracks. The origin of this exponent needs to be carefully scrutinized in terms of fault segmentation.

Bernard and Herrero [7] and Bernard et al. [9] proposed a model linking seismic radiation to the spectral properties of the distribution of slip on the fault. In their model rupture propagates in a single space direction at constant speed. In order to obtain an omega squared far field spectrum they assumed that rise time is essentially a delta function or that it scales with wave number, which is equivalent. This result needs to be confronted with dynamic simulations propagating at finite speeds and finite energy release rate. In the circular crack model, the high frequency spectrum was controlled by stopping phases, which do not exist in the Bernard et al. model. This problem needs careful attention, specially in the presence of geometrical heterogeneity that may produce stopping phases.

### Future Directions

Most properties of ensemble averaged seismic spectra and slip distributions can be explained by a simple circular crack model. Seismic waves as well as slip distributions determined from seismic and geodetic inversions carry

the signature of the crack models that are at the base of earthquake ruptures. Whether the earthquake can be modeled as a simple circular crack or as the complex sum of a distribution of such cracks the result is the same: slip is of  $k$ -squared type and seismic radiation is of  $\omega$ -squared type. Departure from these models can be expected if stress drop scales with fault size. There is no clear-cut evidence for such behavior because of the difficulties in estimating radiated energy mentioned several times in this review. The variations of stress drop required to explain observations may be an intrinsic variation of stresses depending on fault maturity, the position of the fault in the seismic cycle, etc.

In recent years the quality and quantity of seismic data has improved very significantly with the deployment of digital instruments in many active areas of the earth. This is a unique opportunity to test the self-similarity of earthquakes. If tests like those of Fig. 4 are applied to new data, the problem of the variability of radiated energy/moment ratio (or equivalent of apparent stress and stress drop) will be addressed more carefully. I would not be surprised if we finally concluded that apparent stress varies significantly among different earthquakes as suggested by Fig. 4.

### Acknowledgments

This research was partially funded by the SEISMULATORS contract with ANR under program Catastrophes Telluriques et Tsunamis, and by the Research training network SPICE of the 7th PCRD of the European Union. I am deeply indebted to Luis Rivera, Martin Mai and Art McGarr for their careful and patient review of an initial version of this paper.

### Glossary

We use the tensor notation and the summation convention for the repeating indices:

$$T_{ss} = \sum_s T_{ss}, \quad A_k B_k = \sum_k A_k B_k.$$

In some places we underline the symmetric and antisymmetric properties of the tensors using the ( $\cdot$ ), [ $\cdot$ ] brackets for indices:

$$S_{(ik)} = S_{(ki)}, \quad S_{[ik]} = -S_{[ki]}.$$

The deviatoric part of a symmetric tensor,  $T_{(ik)}^D$ , having zero value of trace, is defined as

$$T_{(ik)}^D = T_{(ik)} - \frac{1}{3} \delta_{ik} T_{(ss)}, \quad T_{(ik)}^A = \frac{1}{3} \delta_{ik} T_{(ss)},$$

$$T_{(ss)}^D = \sum_s T_{(ss)}^D = 0,$$

where  $T_{(ik)}$  is any symmetric tensor, while  $T_{(ik)}^A$  is the axial tensor.

In some places we use for the partial differentiations the following notations equivalently:

$$\frac{\partial u_n}{\partial x_k} \leftrightarrow u_{n,k}, \quad \frac{\partial U}{\partial x_\alpha} \leftrightarrow U_{,\alpha},$$

where the indices with Roman characters run from 1 to 3, while those with Greek characters run from 1 to 4.

We use the fully antisymmetric tensor

$$\varepsilon_{lps} = \begin{Bmatrix} 1 \\ 0 \\ -1 \end{Bmatrix} \text{ for } \begin{cases} \text{even permutation of} \\ \text{repeating} \\ \text{odd permutation of} \end{cases} \text{ indices};$$

this fits to the tensor notation and helps to express some operations, e. g. curl:

$$\text{curl } \psi \leftrightarrow \varepsilon_{lps} \frac{\partial}{\partial x_p} \psi_s.$$

### Definition of the Subject

The problem of rotation waves becomes actual again due to the recent observations based on very precise instruments able to measure very small rotation time rates, and due to development and new approaches to the continuum theories.

Our aim is to present a consistent theory describing a continuum subjected to complex internal processes. First, we consider all possible kinds of point-related motions and deformations (strictly speaking, a single couple is not a point-source, as a displacement derivative only tends to a point, but a double couple enters into a family of point-deformations as it can be given by the string-string deformation, that is as a shear point-nucleus).

We define the complex rotation field which includes the spin and twist; the latter describes the angular oscillations of the shear axes and related amplitude variations. Twist point deformation can be represented by the string-string and string-membrane motions. A twist vector is defined as a vector perpendicular to a string-string plane; it becomes an important counterpart to spin and a key to presented theory, in which we shall also include the axial point deformation (e. g., the thermal one).

We believe that all point motions, displacement and rotation, and point deformations, axial and twist, shall be governed by some fundamental laws, and we intend to find the invariant forms of such relations in a frame of a modified continuum theory. Such a continuum theory may give us a new insight into the complexity of processes which can be included in a continual material description; we will demonstrate that interaction of these motions and deformations can lead us to a rich variety of internal processes.

We may mention also that the theory of continuum containing all these deformations with rotational motions (spin and twist), with the inner central motion and with defects may be projected on the intrinsic properties of non-Euclidean space. We confine ourselves only to a remark that application of differential geometry is extremely enlightening for the fundamental understanding of the nonlinear processes.

The independent rotation field can be related to the additional constitutive law joining the antisymmetric stresses and rotations, as proposed by Shimbo [1,2] in his considerations on the friction and fracturing processes; the intro-

duced motion equations are equivalent to the stress moment – angular velocity relation.

For a reference to our consideration, we recall also the Kröner theory and its modifications as introduced by Teisseyre and Boratyński [3,4].

The possible dual description of any motions by means of displacement and rotation fields are being discussed and their formal equivalence concerning the propagation processes is demonstrated, but not valid for the source phenomena. Thus, we point out the importance of physically independent rotation motions in the inner granulation and fracture processes, and different types of rotational deformations are analyzed.

Our considerations bring several results for the following subjects.

For seismology:

- New description of the source processes including the role of rotational processes, and explanation of co-action of the slip and rotation motions
- Theory of the seismic rotation waves
- Thermodynamical conditions for a seismic energy release

For continuum and fracture mechanics:

- Theory of asymmetric continuum with the balance equations for the symmetric and antisymmetric stresses
- The relations between the asymmetric stresses and dislocation field
- A new approach to fracture processes with the hypothesis of the twist-shear release following the extreme angular deformation related to the internal particles, or grains constituting a continuum
- A synchronization role of the specific wave fields in the fracture processes
- Formation of a mylonite zone adjacent to fracturing and its constitutive description

For fluid mechanics:

- Theory of the asymmetric fluid continuum with the non-vanishing rates of the asymmetric stresses
- Explanation of the extreme wave phenomena (solitons)

## Asymmetric Continuum and Rotation Effects

### Introduction

Earthquake rotation effects were observed and discussed at the time when the 19th century seismological science was formed. Some eminent scientists, e.g., Charles Lyell (1797–1875), Charles Darwin (1809–1882), Robert Mallet

(1810–1881), and Alexander von Humboldt (1769–1859), raised the problem of the vortical movements, or vortex motion, induced by earthquakes. After the Lisbon earthquakes (1755) and those of Calabria (1783), many scientists focused their attention on the effects induced by such “vortical” waves. Robert Mallet was the first who precisely explained the observed rotation effects of some surface objects, pointing out the roles of the center of adherence of these objects and their inertia moment in relation to forces twisting the objects (see: Kozak [5], and Ferrari [6]). Many scholars tried to design the instruments to record the “vortical motions”, but the first instrument prepared especially to record such motions was that constructed by Filippo Cecchi, the director of the Ximeniano Observatory of Florence, in 1875. Cecchi’s electrical seismograph used sliding smoked paper. However, at that time it was too early to construct an instrument sensitive enough to obtain any traces of such wave motions.

The problem of seismic rotation waves was apparently closed after the Gutenberg [7] statement (1926) that such waves cannot propagate as they will be immediately attenuated, even when generated at the source. Of course the rotation effects remained, with the related explanation by Mallet, as objects of studies especially in the domain of the macroseismic observations.

From the contemporary point of view, two groups of achievements shall be mentioned; first, related to continuum theories, and second, related to development of the modern very precise instruments, able to record extremely small rotation time rates.

The continuum elastic theory bears from its very origin the serious limitation that the angular motions and related moments are not included. In such a situation, there was no place for a constitutive law describing the reaction between the stress moments and rotation processes. The lack of such a law automatically denies the existence of the rotation waves. We will return to these problems further on.

### Experimental Evidence

The modern instrumentation techniques and the obtained results presenting the rotation wave seismograms need more attention. First, we can mention that maybe the first rotation seismogram (see Teisseyre [8]) was achieved in an indirect way: the azimuth array of horizontal seismographs, installed in one of the coal mines in Upper Silesia, Poland, to record the nearby tremors permitted one to deduce the rotational component of motions. However, the first, fully documented, rotation seismograms were obtained at the two geodetic fundamental stations in

Germany (Wetzell) and in Australia (Cochard et al. [9]; Schreiber et al. [10]), equipped with ring-laser interferometers based on the Sagnac principle. These stations were established, primarily, to record very small deviations and disturbances of the Earth's rotational motion. However, the instruments having sensitivity up to  $10^{-9}$  rad/s were able to record the rotation motions related to many distant earthquakes.

Latter, sensors of another type – the fiber-optic interferometers – were used by Takeo [11] especially for seismic observations; one version of his sensors included the tri-axial system. Jaroszewicz et al. [12] followed this system of rotation seismographs for the study of Silesian seismic events.

In a more traditional way, Moriya (see Moriya and Teisseyre [13]) has constructed the first rotation seismograph system consisting of a pair of anti-parallel seismographs; such a system, with the common suspension of the anti-parallel pendulums was repeated in latter constructions (Wiszniewski [14]).

Data collected by the recording systems mentioned above brought at least two important results:

- Records of different events in the very near field indicate that some events, e. g., shallow volcanic and those of explosion type, differ from the common characteristics by the extremely small rotation components (Teisseyre et al. [15]).
- Correlations between the rotation seismograms obtained from the ring-laser system and the rotation motions, curl  $\mathbf{u}$ , derived from the array of seismometers (located at the same site) show almost perfect fit (Cochard et al. [9]).

Following the Cosserat theory and the micropolar and micromorphic theories (see Subsect. “**Asymmetric Continuum Theory**”), the independent rotation field, e. g., rotation related to grains or points of a continuum, were considered by Shimbo [1,2] in relation to the friction and fracture processes; the related constitutive law, we will call it the Shimbo law, joins the antisymmetric stresses with rotations and leads us towards the asymmetric continuum theory. The Shimbo law was latter generalized for the spin and twist rotation motions (Teisseyre et al. [16]; twist motion is introduced as the equivalent to oscillations of the shear axes).

We shall remind the reader that Gutenberg [7], in the frame of the classical elasticity theory, has proved that the independent rotation waves must be immediately attenuated. Now we know that this statement is due only to the fact that in the classical theory the rotations are not related to the stress or stress moment response; we cannot intro-

duce the constitutive law joining the symmetric stresses with the antisymmetric rotations.

However, in the asymmetric continuum theory such a constitutive law is required and appears as a natural element of the theory.

### Displacements and Rotations

We cannot deny that independent rotation waves do not exist in a continuum built by the point-particles; however, this question is reduced to the magnitude of the independent rotations (that is, independent of rot  $\mathbf{u}$ ) generated in the seismic sources; the rotation wave motion is assured by the Shimbo constitutive law; this constitutive law joining the antisymmetric stresses and rotation relates directly to the friction as kind of material resistance:

$$S_{[ik]} = 2\mu^* \omega_{[ik]}, \quad S_{(ik)}^D = 2\mu E_{(ik)}^D, \quad (1)$$

where we have added the constitutive law for pure shear (further on we define the pure shear oscillations as twist), the tensors  $S_{(ik)}^D$  and  $E_{(ik)}^D$  are the deviatoric stress and strain tensors, and where  $\mu$  is the rigidity modulus and the constant  $\mu^*$  is defined as rotation rigidity, the constant entering in the antisymmetric stress – angular velocity relation (this constant is not equal to the rotation modulus in the stress moment – angular velocity relation); further on, we assume that both constants are equal,  $\mu^* = \mu$ , as it follows from the seismic wave observations.

We shall notice that both motions, displacements and rotations, are interrelated, which follows also from the fact that pure rotation,  $\omega_{[s]}$ , can be presented by means of the potentials represented by some displacement field,  $\mathbf{u}^{\text{micro}}$ ; conversely, the displacements  $U$  (excluding those related to the scalar potential, e. g., those of thermal origin or that related to explosion process, that is, we put  $\frac{\partial}{\partial x_i} U_i = 0$ ) can be described by the vector potentials represented by some rotation field  $\Omega_{[.]}$ :

$$\omega_{[.]} = \text{curl } U, \quad U = l^2 \text{curl } \Omega_{[.]} \quad (2)$$

and we arrive at the possible dual approach to the continuum mechanics.

When applying such equivalent approaches twice, e. g., from rotation field to displacement and again to rotations we obtain

$$\left\{ \begin{aligned} \omega_{[s]} &= \varepsilon_{smn} \frac{\partial U_n}{\partial x_m}, \quad u_i = l^2 \varepsilon_{iks} \frac{\partial \omega_s}{\partial x_k} \\ \rightarrow u_i &= -l^2 \Delta U_i \quad \text{at} \quad \frac{\partial}{\partial x_i} U_i = 0. \end{aligned} \right. \quad (3a)$$

Or otherwise:

$$\left\{ \begin{aligned} \omega_{[i]} &= \varepsilon_{iks} \frac{\partial U_s}{\partial x_k}, \quad U_s = l^2 \varepsilon_{smn} \frac{\partial \Omega_n}{\partial x_m} \\ \rightarrow \omega_{[i]} &= -l^2 \Delta \Omega_i \quad \text{at} \quad \frac{\partial}{\partial x_i} \Omega_i = 0, \end{aligned} \right. \quad (3b)$$

where  $l$  represents the basic intrinsic length measure.

The intrinsic length (Cosserat characteristic length) plays an important role in material properties; there is extensive literature related to this subject, however we limit ourselves to the remark that the displacement and rotation motions could be completely independent only for the case with  $l = 0$ , but such a case is excluded by quantum mechanics with the minimal Planck's length of the order of  $10^{-34}$  m.

Excluding the axial motions, our consideration leads us to an apparent equivalence of the two descriptions, those by means of displacements and rotations. However, there remains the problem of the scales of these motions generated at the different fracture modes in the seismic source and also the scales of these motions observed at the Earth's surface.

The observed rotation fields and effects are usually much smaller than those related to the displacement field. There are, however, some exceptions leading to situations in which rotations play an important role, e. g.: the tilt motions, the rocking and tilting components related to building structures hit by strong ground motions and, as it will be discussed further on, the rotations generated by fracture which occurred under the prevailing compression load.

These equivalent descriptions of the motions in a continuum can be combined in the asymmetric theory, but we shall note that it could be constructed as well, the continuum theory neglecting completely the displacement fields and using only the rotation motions – such a case can be called a degenerated continuum.

Therefore, keeping in mind the above remarks that the rotations contribute to displacement derivatives and that displacements may contribute to rotations, we can state that these motions are interrelated; this statement is empirically supported by the above mentioned almost perfect fit between the derived rotations, curl  $\mathbf{u}$ , and the rotations obtained from the ring-laser system data. Therefore, we think that the problem related to existence of rotation waves appears as an irrelevant question. However, we shall stress that the displacements and rotation motions differ in general, especially when considering their physical origins and effects. Instead of that problem, we propose to consider the classification of rotation motions from the point of view of their origins, scales and effects produced.

We propose the following classification:

- The micro-rotations or rotations,  $\omega$ , as related to the wave motions based on the internal friction processes (rotation rigidity), as well as to slip motions with friction/fracture processes
- The meso-rotations related to material granulation and formation of the mylonite zones under the shear load fracturing processes
- The total rotations,  $\omega^T$ , (the nomenclature introduced by Kröner [17]) related to the displacement field,  $\mathbf{u}$ ;
- The macro-rotations as related to fragmentation of material at the fracturing under compression load
- The mega-rotation effects related to the ground tilts and tilting of high objects on the ground

The important counterpart of rotational processes in the mechanics of fracturing and the related energy release shall be underlined (Teisseyre et al. [18]). Both under confining pressure and under external shears, the role of micro-fracturing in the bond breaking process is similar; however, we observe here the essential differences for rotations in larger scales.

The confining load condition leads to formation of the induced opposite arrays of dislocations, resulting in fragmentation processes and related macro-rotations. On the other hand, shear load leads to more concentrated fracturing along some planes. In the thermodynamical fracture band theory, see Subsect. “**Earthquake Thermodynamics**”, we consider the additional super-lattice formed by dislocations and the properly defined vacant dislocations; with this advanced approach we express an effective role of dislocation band structure in the shear fracture thermodynamics. Similarly, the fragmentation and macro-rotation processes become more effective for the fracturing under confining pressure. Thus, we try to find a continuum description for a number of processes leading us from an elastic solid to that undergoing successive deterioration by crushing, granulation and fragmentation.

These considerations give us ground for the classification of the basic motions.

### Basic Deformations and Simple Motions in Asymmetric Continuum

Basic and simple motions could be defined as those which may be reduced to the 3D point motion in the Cartesian or Riemann spaces, or those deformations conceived as the respective curvatures.

Considering basic motions, we can distinguish the simple motions. First the translation described by vector  $\mathbf{u}$  and the independent rotation, called spin; in a non-homogeneous continuum, the grains having different material parameters, can rotate due to an interaction of a displace-

String-string nucleus

ment field with the related moment of inertia of the grains. Then, we shall pass to the tensorial motions/deformations:

Any antisymmetric tensor can be related to the vectorial field, e. g., to spin motion; thus, we come again to the equivalent vector field. However, this simple spin motion,  $\omega_{[.]}$ , shall be treated basically as independent of the displacement rotation, however, both contribute to the total spin field,  $\omega_{[.]} + \text{curl } \mathbf{u}$ , observed, e. g. in seismology. We have already mentioned that any symmetric tensor can be split into the axial and deviatoric tensors. The axial deformation tensor relates to the point deformations representing compression/dilatation nuclei, e. g., related to thermal anomaly.

These total axial oscillation motions include the equal translation motions along all three axes and relate to that part of the displacement field which can be derived from a scalar potential (see Fig. 1).

For the point-like continuum with the axial deformations, we would obtain either the Riemannian curvature or, for more complicated cases, the Riemannian torsion tensor.

There remains the deviatoric field to consider. This field relates to pure shear deformations; it is possible to show that the deviatoric field may be used to define the new antisymmetric tensor related to the simple deforma-

tions representing another kind of rotation motion – the twist deformation. These deviatoric deformations, for continua formed by particles/grains relate to pure shear oscillations (see Fig. 2; the left side shows a spin motion and the right side a twist one).

However, considering the point motions, it is better to relate these shear deformations to the equivalent twist tensor,  $\omega_{(ks)}$ ; such motions contribute to the observed, e. g. in seismology, total shear/twist field. This field is directly related to the S-waves ( $\mathbf{u}^S = l\omega$ , where  $l$  is the effective radius of grains/particles forming the continuum and  $\omega$  is the related rotation).

In the limit related to the point-like deformations, we would arrive at the string-string type motions (see Fig. 3) leading to the another representation of twist as vector,  $\omega_{(k)}$ , perpendicular to the string-string plane and having an appropriate magnitude of a string-string deformation (invariant representation of the string-string vector is discussed in Subsect. “Spin and Twist Motions”, while determination of its amplitude Subsect. “Recording Spin and Twist Angle Variation”).

A combination of the axial oscillation motions and those related to twist deformations leads to different forms

Earthquake Source: Asymmetry and Rotation Effects, Figure 4  
String-membrane

of the point deformations: Fig. 4 relates to the string-membrane oscillations.

We shall repeat that all motions, except axial deformation, may be described by the displacement field, but this is not true for the point related spin and string-string deformation originated as the independent source motions.

Of course, there remains a number of the first, and higher order moments of these basic motions and deformations; such source models tend in a limit to a point source, but cannot be treated as exact point nuclei.

### Asymmetric Continuum Theory

We shall add to the above considerations some arguments forming the fundamentals of the asymmetric continuum theory which is based on the asymmetric stresses:

- When studying the elastic field of an edge dislocation, we find some asymmetry in relation to its components in the plane perpendicular to its line (wedge direction); in confrontation with the symmetry of shears, this fact results in the asymmetry of stresses for a continuous distribution of dislocations (for screw dislocations such a contradiction does not exist). Therefore, a direct differential relation between any density of dislocations and the related stresses cannot be adequately found in a symmetric continuum.
- Fracture usually reveals its asymmetric pattern with a main slip plane; we shall believe that the premonitory processes, as described by deformations in a continuum with defects, develop also in an asymmetric way.
- In the classical continuum, the balance of angular momentum holds only if the stresses are symmetric; here the angular motions can be introduced only artificially with the help of a length element and a reference rotation point. This classical theory has also many other limitations and therefore many trials have been undertaken to generalize it. The asymmetric theory of elasticity with asymmetric stresses and couple-stresses was founded by Nowacki [19]. However, a first generalization to include the moments in a continuum is due to Voigt in 1887 and a complete theory, including the asymmetry of stress and strain, is that known as the Cosserat theory of elasticity with the displacement vector and rotation vector [20]. Micropolar and micromorphic elastic theories were developed by Eringen and his co-workers and Mindlin (see: Eringen and Suhubi [21] and Mindlin [23]). Teisseyre [22] proposed a simpler version of the asymmetric theory which includes asymmetric stresses, strains and rotations, but in which the equations for the antisymmetric stresses differ from those of the couple moments in the Nowacki theory; their roles are interchanged, but both systems remain almost equivalent.
- Usually, when searching the fault slip solutions, we rely on classical elasticity with the friction constitutive laws introduced additionally in accordance with the experimental data. The obtained results well explain the observational data. Instead, we consider the consistent elastic continuum with asymmetric stresses and defects; such an approach enables one to study the defect interactions and elastodynamic solutions describing a slip propagation along a fault, including friction effects and related seismic radiation.
- The asymmetry of fields follows also from the notion of antisymmetric stresses considered by Shimbo [1,2] in relation to the friction processes and rotation of grains. Fracture processes develop usually along the main fault plane; hence there appears the initial asymmetry of the fracture pattern [24]; because of friction, the rotation of grains adjacent to the main slip plane causes an appearance of the antisymmetric part of the stresses and twist deformations. Following Shimbo [1,2], we introduced the constitutive law joining the antisymmetric stresses with the rotation nuclei (self-rotation field); without such a constitutive law any theory reduces both the rotation motions (except the rotation of displacements) and the related rotation waves to zero.
- In the asymmetric continuum, defined as that including both the symmetric stresses and the antisymmetric stresses, there appear also the rotational motions/deformations which split into pure spin and twist motions, the latter relate to the shear deformations of the grains; when considering the point-like nuclei, the twist deformation passes into 3D space torsion (Riemannian space).
- Experimental evidence for an appearance of spin and twist motions in a seismic field is based on the records of seismic rotation fields. For spin motion we shall be aware that the recorded rotation contains two el-

ements: a rotation of displacements and an independent spin motion. Both these elements co-act in motion propagation and represent its dual description, but differ in their origin, depending on the source processes and material properties. At fracturing under a confining load, we deal rather with a high rotation release process and therefore the spin motion for the very near seismic events usually distinctly overpasses the displacement rotation. For some events of an explosive nature, or for some near-surface volcanic events, both the pure spin motion and rotation of displacement almost disappear; some observed effects might be related to a nearby  $P \Leftrightarrow S$  conversion. For the strong motions which include a tilting component, the rotation of displacements exceeds a spin motion. In engineering seismology we observe that the rotation of displacements may exceed the pure spin motion; such an effect is due to magnification of a horizontal rotation of displacements and to the appearance of a rocking/tilting component of displacement rotation caused by the geometry of construction, especially for high buildings.

### Self-Field Nuclei: Deviations from Classical Elasticity

Any continuum could be described using the Kröner approach [17] based on a concept of internal fields excited by a density of defects and internal nuclei; stresses and strains are related by the unique constitutive law for the ideal elasticity. This approach is equivalent to another approach in which we change the constitutive law in a way appropriate to describe the plastic, viscous and relaxation effects. In the Kröner continuum with a density of the internal point-like nuclei, the elastic strains, rotations and stresses can be expressed as differences between total and self-fields.

Following the Kröner approach, we can keep the ideal elastic relation for the stresses and strains, supplemented by the constitutive law joining the antisymmetric stresses with rotations, and we introduce the self/inner stresses, strains and rotations as related to the internal nuclei or defects:  $\mathbf{S}^S$ ,  $\mathbf{E}^S$ ,  $\omega^S$ . We distinguish between the total stresses, strains and rotations related to the displacement field:  $\mathbf{S}^T$ ,  $\mathbf{E}^T$ ,  $\omega^T$ , and the asymmetric elastic stresses, strains and rotations  $\mathbf{S}$ ,  $\mathbf{E}$ ,  $\omega$ :

$$\begin{aligned} \mathbf{E} &= \mathbf{E}^T - \mathbf{E}^S, & \omega &= \omega^T - \omega^S, & \beta &= \beta^T - \beta^S, \\ \mathbf{S} &= \mathbf{S}^T - \mathbf{S}^S, \end{aligned} \quad (4a)$$

$$\mathbf{E}_{ki}^T = \mathbf{u}_{(i,k)}, \quad \omega_{i,k}^T = \mathbf{u}_{[ik]}. \quad (4b)$$

The elastic and self-deformations, strains and rotations, and stresses can be, in general, asymmetric ones (see: Teis-

seyre and Boratyński [4]); under the conditions that the antisymmetric parts of the stresses and strains, as well as the symmetric parts for elastic and self-rotations, be mutually compensated for:

$$\mathbf{E}_{[ik]} + \mathbf{E}_{[ik]}^S = 0, \quad \mathbf{S}_{[ik]} + \mathbf{S}_{[ik]}^S = 0, \quad \omega_{(ik)} + \omega_{(ik)}^S = 0. \quad (5)$$

However, referring to our earlier papers (see: Teisseyre and Boratyński [4]) we shall then assume that the respective self-parts of the asymmetric strain and rotation are equal to each other:

$$E_{[ik]}^S = \omega_{[ik]}^S, \quad \omega_{(ik)}^S = E_{(ik)}^S, \quad (6)$$

where symmetric rotation is related to the shear axes oscillations (comp.: twist definition and Figs. 2 and 3). The elastic fields  $\mathbf{S}$ ,  $\mathbf{E}$ ,  $\omega$  represent the physical fields, while the total fields  $\mathbf{S}^T$ ,  $\mathbf{E}^T$ ,  $\omega^T$  relate, according to the compatibility condition, to the displacement motions  $u_i$ , and the self-fields relate to the internal nuclei, defect densities and continuum structure.

Any deviations from the symmetry properties of fields, and any deviations from the ideal elasticity, can be described by suitable forms of the self-field, represented by the internal nuclei for both the defects and interaction fields.

The defects, dislocation and disclination densities can be defined, following Kossecka and De Witt [25], by considering the total disclosure and twist along a closed circuit (the Burgers vector and the Frank vector) and the appropriate form of the twist-bend tensor:

$$\begin{aligned} B_l &= -\oint [E_{(kl)} - \varepsilon_{lqr} \chi_{kq}^S x_r] dl_k, \\ \Omega_q &= -\oint \chi_{kq}^S dl_k = \theta_{pq} ds_p \end{aligned} \quad (7)$$

and the definitions of the dislocation and disclination densities,  $\alpha$  and  $\theta$ , become based on the self-fields  $E_{(kl)}^S$  and  $\chi_{kq}^S$ :

$$\begin{aligned} \alpha_{pl} &= -\varepsilon_{pmk} \left( \frac{\partial E_{(kl)}^S}{\partial x_m} + \varepsilon_{klq} \chi_{mq}^S \right), \\ \theta_{pq} &= -\varepsilon_{pmk} \frac{\partial \chi_{kq}^S}{\partial x_m}. \end{aligned} \quad (8)$$

After Teisseyre [26], the total twist-bend tensor can be defined as follows:

$$\chi_{mq}^T = \varepsilon_{ksq} \frac{\partial \omega_{mk}^T}{\partial x_s}, \quad \chi_{mq}^T = \chi_{mq} + \chi_{mq}^S \quad (9)$$

where, for the continuum with the asymmetric part of the stresses, we are not restricted to the compatibility condition for the twist-bend tensor (Kleman [27]).

The compatibility conditions for the asymmetric stresses and strains lead us to the physical equations for the dislocation and disclination densities in relation to the elastic fields of strain  $E_{(kl)}$  and twist-bend  $\chi_{kq}$ :

$$\alpha_{pl} = \varepsilon_{pmk} \left( \frac{\partial E_{(kl)}}{\partial x_m} + \varepsilon_{klq} \chi_{mq} \right), \quad \theta_{pq} = \varepsilon_{pmk} \frac{\partial \chi_{kq}}{\partial x_m}. \tag{10}$$

Further on we will not rely on the Kröner approach, instead we will confine ourselves to a simpler approach given by the standard asymmetric continuum theory.

### Asymmetric Continuum: Standard Theory

In opposition to the Kröner approach presented above, we may construct the asymmetric standard theory entirely related to the displacement field. Such a theory shall be based both on the symmetric and asymmetric stresses and on the related constitutive laws and motion equations. The asymmetric deformations contain the symmetric strain and antisymmetric rotation. Thus, our theory is based on two groups of relations; for the symmetric and antisymmetric fields:

$$\begin{aligned} S_{kl} &= S_{(kl)} + S_{[kl]}, & E_{kl} &= E_{(kl)}, & \omega_{kl} &= \omega_{[kl]}, \\ D_{ks} &= E_{ks} + \omega_{ks}, \end{aligned} \tag{11a}$$

where  $D_{ks}$  means the asymmetric deformation tensor.

However, when introducing the new material parameters (material structure indices):  $e^0, \chi^0$ , we may join these deformation fields in an independent way, with some reference displacement motion:

$$E_{kl} = e^0 \frac{1}{2} \left( \frac{\partial u_l}{\partial x_k} + \frac{\partial u_k}{\partial x_l} \right), \quad \omega_{kl} = \chi^0 \frac{1}{2} \left( \frac{\partial u_l}{\partial x_k} - \frac{\partial u_k}{\partial x_l} \right). \tag{11b}$$

For an internal energy stored in such a medium we obtain:

$$E = S_{(ks)} E_{ks} + S_{[ks]} \omega_{ks}.$$

The indices  $e^0, \chi^0$  are not new constitutive constants, but they define families of solutions describing the complexity of deformation processes in continua; their ratio determines the phase shift between strain and rotation tensors. In this sense, the strain and rotation can be shifted in phase as follows from the particular deformations considered.

For the particular cases of these index values,  $e^0, \chi^0$ , we have:

- The classic elasticity, obtained for  $\chi^0 = 0$ ;
- For  $e^0 = 0$  we obtain a granular/crushed medium filled with rigid spheres interacting by friction; when applying a torque load on its surface boundary, e.g., a cylindrical one, we would obtain only some angular deformation, and torque energy stored given as  $E = S_{[ks]} \omega_{ks}$ ;
- The cases with  $e^0 = \chi^0$  relate to the elastic continua with friction and different kinds of internal defects – different kinds of dislocation densities and the granulated materials;
- A continuum densely filled with the edge dislocations is described by the case  $e^0 = -1, \chi^0 = -1$ ; while that of a partial content of that density  $\alpha^E = \{0, 1\}$  by  $e^0 = 1 - 2\alpha^E, \chi^0 = \alpha^E$ ;
- A continuum filled densely with the screw dislocations would be given by  $e^0 = 2, \chi^0 = 2$ ; while that of a partial content of that density  $\alpha^S = \{0, 1\}$  by  $e^0 = 1 + \alpha^S, \chi^0 = 2\alpha^S$ .

Further on, we will consider a more general continuum with the constitutive laws, including also the time rates processes; for such cases we might discuss in a similar way the different particular cases of the material structure indices including dynamic objects.

For the symmetric part of stresses we can assume the classical constitutive relation:

$$S_{(kl)} = \lambda \delta_{kl} E_{ss} + 2\mu E_{kl}. \tag{12}$$

But there is no problem to include in it the appropriate linear deviations related to visco-plastic effects.

To construct the asymmetric theory, we assume, after Shimbo [1,2], the appropriate constitutive law for the antisymmetric part of stresses. It joins the friction/fracture rotations with the antisymmetric stresses:

$$S_{[kl]} = 2\mu \omega_{kl}, \tag{13}$$

where rigidity constant  $\mu$  plays the role of rotation rigidity entering in the antisymmetric stress-angular velocity relation (while the rotation modulus enters in the stress moment-angular velocity relation and may be considered as product of the rigidity  $\mu$  and the Cosserat characteristic length  $l$ ).

The motion equation for antisymmetric stresses  $S_{[ni]}$  shall replace the balance law for the stress moments. To this end, we take the divergence of the rotation force moment acting on a body element due to the antisymmetric stresses (rotational moment of forces per infinitesimal arm length corresponding to stress moments), and, on the other hand, the balancing term – the acceleration related

to angular momentum [3]:

$$\begin{aligned} \varepsilon_{lki} \frac{\partial^2}{\partial x_k \partial x_n} S_{[ni]} &= \rho \frac{1}{2} \varepsilon_{lki} \frac{\partial^2}{\partial t^2} \left( \frac{\partial u_i}{\partial x_k} - \frac{\partial u_k}{\partial x_i} \right) \\ &+ \varepsilon_{lki} \rho K_{[ki]}, \end{aligned} \quad (14)$$

where we have put  $e^0 = 1$  and we have introduced the body couple  $K_{[ki]}$  equivalent to body moment  $K_{[l]} = \varepsilon_{lki} \rho K_{[ki]}$ .

With the compatibility condition introduced in a similar way as for the symmetric strains:

$$I_{[ij]} = \varepsilon_{imk} \varepsilon_{jns} \frac{\partial^2}{\partial x_m \partial x_n} \omega_{ks} = 0$$

we obtain from Eqs. (11b), (13) and (14):

$$\begin{aligned} \frac{\partial^2 S_{[ki]}}{\partial x_s \partial x_s} &= 2\rho \frac{\partial^2 \omega_{ki}}{\partial t^2} + 2\rho K_{[ki]}, \quad \text{or} \\ \mu \frac{\partial^2 \omega_{ki}}{\partial x_s \partial x_s} - \rho \frac{\partial^2 \omega_{ki}}{\partial t^2} &= \rho K_{[ki]}, \end{aligned} \quad (15a)$$

where we have introduced also the body couple  $K_{[ki]}$  or body moment  $K_{[l]} = \varepsilon_{lki} \rho K_{[ki]}$ .

Otherwise, we can write:

$$\mu \frac{\partial^2}{\partial x_k \partial x_k} \omega_{[l]} - \rho \frac{\partial^2}{\partial t^2} \omega_{[l]} = \rho K_{[l]}, \quad (15b)$$

where the left-hand side of this form presents the basic expression for the resulting stress moment divergence.

These relations are equivalent to the following ones:

$$\begin{aligned} \frac{1}{l^2} \frac{\partial}{\partial x_k} M_{lk} &= \varepsilon_{lki} \frac{\partial^2}{\partial x_k \partial x_n} S_{[ni]} = \varepsilon_{lki} \frac{\partial}{\partial x_n} \frac{\partial}{\partial x_n} S_{[ki]}, \\ \frac{1}{l^2} M_{lk} &= \varepsilon_{lki} \frac{\partial}{\partial x_n} S_{[ni]} \end{aligned}$$

or defining the angular moment  $\Xi_i$ , we obtain:

$$\frac{\partial}{\partial x_k} M_{ik} = 2\mu \Xi_i, \quad \Xi_i = l^2 \varepsilon_{iks} \frac{\partial}{\partial x_n} \frac{\partial}{\partial x_s} \omega_{[kn]}.$$

From the motion equation for the symmetric part of stresses

$$\frac{\partial}{\partial x_k} S_{(kl)} = \rho \frac{\partial^2}{\partial t^2} u_l + F_l$$

and using the scalar and vector potentials

$$\begin{aligned} u_l &= l^2 \frac{\partial}{\partial x_l} \Phi + l^2 \varepsilon_{lps} \frac{\partial}{\partial x_p} \Psi_s, \\ F_l &= l^2 \frac{\partial}{\partial x_l} \Phi + l^2 \varepsilon_{lps} \frac{\partial}{\partial x_p} \Psi_s \end{aligned}$$

we obtain:

$$\begin{aligned} (\lambda + 2\mu) \frac{\partial^2}{\partial x_k \partial x_k} \varphi &= \rho \ddot{\varphi} + \Phi, \\ \mu \frac{\partial^2}{\partial x_k \partial x_k} \psi_s &= \rho \ddot{\psi}_s + \Psi_s, \end{aligned} \quad (16)$$

where according to Eq. (11b) we have introduced the index  $e^0$  and we assume  $\frac{\partial}{\partial x_s} \psi_s = 0$ ,  $\frac{\partial}{\partial x_s} \Psi_s = 0$  and where we have introduced the intrinsic length unit  $l$ .

Here the potential  $\psi_s$  may be interpreted as rotation vector motions in another scale than that defined by relation  $\text{curl } v = \omega$ :

$$\varepsilon_{mql} \frac{\partial}{\partial x_q} u_l = -l^2 \frac{\partial^2}{\partial x_k \partial x_k} \psi_m,$$

where  $\omega$  means the micro-rotations, and  $\psi$  – the meso-rotations related to the granulated material (mylonite) and shear processes.

The strain tensor and its trace can be presented with the help of the introduced potentials as follows:

$$\begin{aligned} E_{lq} &= l^2 \frac{\partial^2}{\partial x_l \partial x_q} \varphi + \frac{1}{2} l^2 \varepsilon_{lps} \frac{\partial^2}{\partial x_p \partial x_q} \psi_s \\ &+ \frac{1}{2} l^2 \varepsilon_{qps} \frac{\partial^2}{\partial x_p \partial x_l} \psi_s. \end{aligned}$$

We can divide this expression into the axial and deviatoric parts:

$$\begin{aligned} E_{kk} &= l^2 \frac{\partial^2 \varphi}{\partial x_s \partial x_s}, \\ E_{lq}^D &= l^2 \left( \frac{\partial^2 \varphi}{\partial x_l \partial x_q} - \frac{\delta_{lq}}{3} \frac{\partial^2 \varphi}{\partial x_s \partial x_s} \right. \\ &\quad \left. + \frac{1}{2} \frac{\partial}{\partial x_p} \left( \varepsilon_{lps} \frac{\partial}{\partial x_q} + \varepsilon_{qps} \frac{\partial}{\partial x_l} \right) \psi_s \right). \end{aligned} \quad (17)$$

Returning to our wave Eqs. (16) we arrive at the wave equations for the axial and deviatoric strain parts:

$$(\lambda + 2\mu) \Delta E_{kk} - \rho \frac{\partial^2 E_{kk}}{\partial t^2} = l^2 \Delta \Phi, \quad (18a)$$

$$\begin{aligned} (\lambda + \mu) \left( \frac{\partial^2 E_{ss}}{\partial x_l \partial x_q} - \frac{\delta_{lq}}{3} \frac{\partial^2 E_{ss}}{\partial x_k \partial x_k} \right) \\ + \mu \frac{\partial^2 E_{lq}^D}{\partial x_k \partial x_k} - \rho \frac{\partial^2 E_{lq}^D}{\partial t^2} \\ = l^2 \left( \frac{\partial^2 \Phi}{\partial x_l \partial x_q} - \frac{\delta_{lq} \Delta \Phi}{3} \right. \\ \left. + \frac{\varepsilon_{lps}}{2} \frac{\partial^2 \Psi}{\partial x_p \partial x_q} + \frac{\varepsilon_{qps}}{2} \frac{\partial^2 \Psi}{\partial x_p \partial x_l} \right). \end{aligned} \quad (18b)$$

In terms of the potentials we obtain

$$\begin{aligned} & \left( \mu \Delta - \rho \frac{\partial^2}{\partial t^2} \right) \left( \left( \frac{\partial^2}{\partial x_l \partial x_q} - \frac{\delta_{lq}}{3} \Delta \right) \varphi \right. \\ & \quad \left. + \frac{\partial}{2 \partial x_p} \left( \varepsilon_{lps} \frac{\partial}{\partial x_q} + \varepsilon_{qps} \frac{\partial}{\partial x_l} \right) \psi_s \right) \\ & = \left( \left( \frac{\partial^2}{\partial x_l \partial x_q} - \frac{\delta_{lq}}{3} \Delta \right) \Phi \right. \\ & \quad \left. + \frac{\partial}{2 \partial x_p} \left( \varepsilon_{lps} \frac{\partial}{\partial x_q} + \varepsilon_{qps} \frac{\partial}{\partial x_l} \right) \Psi_s \right) \end{aligned}$$

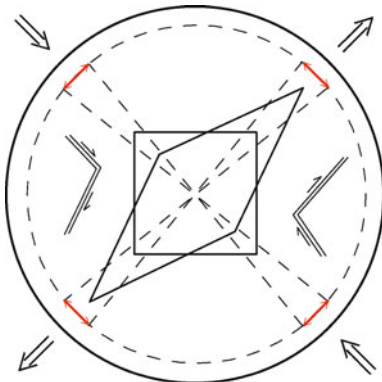

### Spin and Twist Motions

The spin motion is governed by Eq. (15a), or equivalently by its vector form Eq. (15b). We may consider the system related to the main shear axes or that related only to the off-diagonal components; in the latter case the motion equation for the deviatoric strains Eq. (18b) can be presented in the form of the rotation vector motion – the twist,  $\omega_{(s)}$ :

$$\{\omega_{(s)}\} = \{E_{23}^D, E_{31}^D, E_{12}^D\}. \quad (19a)$$

The defined twist motion,  $\omega_{(s)}$ , means the rotational oscillation of the off-diagonal shear axes of the deviatoric tensor (corresponding to oscillation of the main shear axes),  $E_{lq}^D$ , accompanied by the changes of the shear magnitude; such perturbation of the shear load may be caused by the internal fracturing processes (see Fig. 5).

Once having defined the twist vector field we can maintain its form due to the invariant properties of the

Earthquake Source: Asymmetry and Rotation Effects, Figure 5  
Twist motion: rotational oscillations of the off-diagonal shear axes and internal fractures as the sources of perturbations; in the center we present an external shear deformation, while arrows along the circle give possible oscillations of the shear axes as influenced by some intrinsic processes, e. g. the fractures marked inside

Dirac tensors applied to the symmetric off-diagonal tensor  $\omega_{(ik)}$  in its 4D form:

$$\begin{aligned} \omega_{(\lambda\kappa)} & = \omega_{(1)}\gamma^1 + \omega_{(2)}\gamma^2 + \omega_{(3)}\gamma^4\gamma^2\gamma^3 \\ & = \begin{bmatrix} 0 & -\omega_{(3)} & -\omega_{(2)} & -\omega_{(1)} \\ -\omega_{(3)} & 0 & \omega_{(1)} & -\omega_{(2)} \\ -\omega_{(2)} & \omega_{(1)} & 0 & -\omega_{(3)} \\ -\omega_{(1)} & -\omega_{(2)} & -\omega_{(3)} & 0 \end{bmatrix}, \end{aligned} \quad (19b)$$

where

$$\begin{aligned} \gamma^1 & = \begin{bmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}, \\ \gamma^2 & = \begin{bmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \\ -1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix}, \\ \gamma^3 & = i \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \end{bmatrix}, \\ \gamma^4 & = i \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}, \end{aligned} \quad (19c)$$

and

$$\gamma^4\gamma^2\gamma^3 = \begin{bmatrix} 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \end{bmatrix}.$$

In a similar way, we may define the external off-diagonal part of the right-side expression of Eq. (18b):

$$\begin{aligned} \mathbf{Y}_{(lq)} & = \\ & l^2 \left( \frac{\partial^2}{\partial x_l \partial x_q} \Phi + \frac{\partial}{2 \partial x_p} \left( \varepsilon_{lps} \frac{\partial}{\partial x_q} + \varepsilon_{qps} \frac{\partial}{\partial x_l} \right) \Psi_s \right). \end{aligned}$$

For its 4D form we can write:

$$\begin{aligned} \mathbf{Y}_{(\lambda\kappa)} & = \mathbf{Y}_{(12)}\gamma^1 + \mathbf{Y}_{(13)}\gamma^2 + \mathbf{Y}_{(23)}\gamma^4\gamma^2\gamma^3 \\ & = \begin{bmatrix} 0 & -\mathbf{Y}_{(12)} & -\mathbf{Y}_{(13)} & -\mathbf{Y}_{(23)} \\ -\mathbf{Y}_{(12)} & 0 & \mathbf{Y}_{(23)} & -\mathbf{Y}_{(13)} \\ -\mathbf{Y}_{(13)} & \mathbf{Y}_{(23)} & 0 & -\mathbf{Y}_{(12)} \\ -\mathbf{Y}_{(23)} & -\mathbf{Y}_{(13)} & -\mathbf{Y}_{(12)} & 0 \end{bmatrix}. \end{aligned}$$

Using these definitions for the off-diagonal form Eq. (19b) we obtain

$$\mu \frac{\partial^2 \omega_{(\lambda\kappa)}}{\partial x_k \partial x_k} - \rho \frac{\partial^2 \omega_{(\lambda\kappa)}}{\partial t^2} = \mathbf{Y}_{(\lambda\kappa)}. \quad (20)$$

The defined 4D twist motion,  $\omega_{(\lambda\kappa)}$ , means the rotational oscillation of the off-diagonal shear axes of the deviatoric tensor,  $E_{lq}^D$ , accompanied by the changes of the shear magnitude; such perturbation of the shear load may be caused by internal fracturing processes (Fig. 5).

The spin and twist motions form the complex rotation field defined as:

$$\omega_s = \omega_{[s]} + i\omega_{(s)} \tag{21}$$

From the balance relation (see: Subsect. “Recording Spin and Twist Angle Variation”) we obtain the relations joining the spin and twist motions.

**Defects: Dislocation and Disclination Densities**

The classical approach to the dislocation and disclination densities is based on the Kröner description of continuum with the self-fields (compare Subsect. “Self-field Nuclei: Deviations from Classical Elasticity”). In the asymmetric homogeneous continuum, the defect density can be introduced using the modified definition of disclosure,  $B_l$ , and the following definition of the twist-bend vector (compare Eqs. (7-9)) we define:

$$B_l = \oint [E_{kl} - \omega_{kl}] dl_k, \quad \Omega_q = \oint \chi_{kq}^T dl_k = \iint \theta_{kq} ds_k, \tag{22a}$$

where for

$$\chi_{mq}^T = \varepsilon_{ksq} \frac{\partial \omega_{mk}}{\partial x_s} \tag{22b}$$

the disclination density vanishes due to the compatibility conditions:

$$\theta_{pq} = \varepsilon_{pmk} \frac{\partial \chi_{kq}^T}{\partial x_m} = \chi^0 \varepsilon_{pmk} \varepsilon_{qns} \frac{\partial^2 \omega_{ks}}{\partial x_m \partial x_n} = 0.$$

For the dislocation field we obtain (compare Eq. (8)):

$$\begin{aligned} \alpha_{pl} &= \varepsilon_{pmk} \left( \frac{\partial E_{kl}}{\partial x_m} - \frac{\partial \omega_{kl}}{\partial x_m} \right) \\ &= \varepsilon_{pmk} \frac{\partial}{\partial x_m} \left( \frac{e^0}{2} \left( \frac{\partial u_l}{\partial x_k} + \frac{\partial u_k}{\partial x_l} \right) - \frac{\chi^0}{2} \left( \frac{\partial u_l}{\partial x_k} - \frac{\partial u_k}{\partial x_l} \right) \right). \end{aligned} \tag{23}$$

With the help of the constitutive relations (12) and (13) we arrive at the relation between the dislocation density and asymmetric stresses:

$$\alpha_{pl} = \frac{\varepsilon_{pmk}}{2\mu} \frac{\partial}{\partial x_m} \left( (S_{(kl)} - \frac{\nu}{1+\nu} \delta_{kl} S_{ii}) - S_{[kl]} \right). \tag{24}$$

We shall note that the material constants,  $e^0$  and  $\chi^0$ , define the types of defects and types of rotation nuclei; the complex constants will mean the constant phase shift between the fields.

Note that in the classic theory with defects, we distinguish also the different definitions for a dislocation field, e. g., the Burgers and Nye dislocations (comp: [28]).

For some particular case,  $e^0 = 1, \chi^0 = -1$ : we obtain a vanishing of defects, like:

$$B_l = \oint [E_{kl} - \omega_{kl}] dl_k = \oint \frac{\partial u_l}{\partial x_k} dl_k = 0, \quad \alpha_{pl} = 0. \tag{25}$$

This case may represent an extreme shear deformation.

We give also relations for another simple case,  $e^0 = \chi^0$ , which leads to dislocation density:

$$\begin{aligned} B_l &= \oint [E_{kl} - \omega_{kl}] dl_k = \chi^0 \oint \frac{\partial u_k}{\partial x_l} dl_k, \\ \alpha_{pl} &= \chi^0 \varepsilon_{pmk} \frac{\partial^2 u_k}{\partial x_m \partial x_l}. \end{aligned} \tag{26}$$

We can consider two particular cases, the first giving a relation between the asymmetric stresses and the edge type dislocations ( $e^0 = -1, \chi^0 = -1$ ):

$$\alpha_{pl} = -\varepsilon_{pmk} \frac{\partial^2 u_k}{\partial x_m \partial x_l} \tag{27}$$

and the other which may describe the relation between the screw-type dislocations and asymmetric stresses ( $e^0 = 2, \chi^0 = 2$ ):

$$\alpha_{pl} = 2\varepsilon_{pmk} \frac{\partial^2 u_k}{\partial x_m \partial x_l}, \tag{28}$$

where  $p = l = s$ , no summation over indices  $p$  and  $l$ .

Both of the considered cases could relate to the formation of the respective slip-discontinuities – Fig. 6.

Earthquake Source: Asymmetry and Rotation Effects, Figure 6 The edge and screw dislocation types

We find that for a suitable choice of the disclosure definition, we may arrive at different definitions of the dislocation and disclination densities; in particular, we note that for the edge and screw dislocations we shall consider different rotation nuclei.

The case (Eq. (25)) presents the extreme deformation while the further cases present the standard source models and related rotations.

### Balance Laws for the Rotation Field and the EM Analogy

The complex rotation field (21),  $\omega_s = \omega_{[s]} + i\omega_{(s)}$ , may be presented in the tensor form:

$$\begin{aligned} \varepsilon_{kis}\omega_s &= \omega_{ki} \\ &= \begin{pmatrix} 0 & \omega_{[3]} + i\omega_{(3)} & -\omega_{[2]} - i\omega_{(2)} \\ -\omega_{[3]} - i\omega_{(3)} & 0 & \omega_{[1]} + i\omega_{(1)} \\ \omega_{[2]} + i\omega_{(2)} & -\omega_{[1]} - i\omega_{(1)} & 0 \end{pmatrix}. \end{aligned} \quad (29)$$

We can write the balance condition as

$$\iint \varepsilon_{kps} \frac{\partial}{\partial x_p} \omega_s ds_k = \iint \left( \frac{\partial}{iV\partial t} \omega_k + \frac{4\pi}{\nu} J_k \right) ds_k, \quad (30)$$

where we introduce the current field  $J_k$  and velocity  $V$ .

Hence, we obtain the field equations for the complex rotation motions:

$$\varepsilon_{kps} \frac{\partial}{\partial x_p} \omega_s - \frac{\partial}{iV\partial t} \omega_k = \frac{4\pi}{\nu} J_k \quad (31a)$$

or for spin and twist motions explicitly:

$$\varepsilon_{kps} \frac{\partial \omega_{[s]}}{\partial x_p} - \frac{1}{V} \dot{\omega}_{(k)} = \frac{4\pi}{V} J_k, \quad \varepsilon_{kps} \frac{\partial \omega_{(s)}}{\partial x_p} + \frac{1}{V} \dot{\omega}_{[k]} = 0. \quad (31b)$$

These equations lead us to the related wave forms:

$$\begin{aligned} \Delta \omega_{[n]} - \frac{1}{V^2} \ddot{\omega}_{[n]} &= \frac{4\pi}{V} \varepsilon_{npk} \frac{\partial}{\partial x_p} J_k, \\ \Delta \omega_{(n)} - \frac{1}{V^2} \ddot{\omega}_{(n)} &= 4\pi \frac{\partial}{\partial x_n} \varepsilon - \frac{4\pi}{V^2} \dot{J}_n, \end{aligned} \quad (32)$$

where  $\omega_{[s],s} = 0$  and  $\omega_{(s),s} = 4\pi\varepsilon$ , and under the condition that the velocity,  $V$ , is simultaneously transformed according to relativistic rules for a sum of velocities.

The obtained wave equations coincide with those derived previously (compare Eqs. (15, and 18b) with the definition for twist – Eq. (19)).

We shall note that in the asymmetric elastic continuum, the bonds related to rotational deformations are considered as comparable to those related to elastic rigidity moduli. More complicated situations with the material constant appears in the micropolar and micromorphic theories with the infinitesimally small nuclei (Eringen [21]). In the asymmetric continuum theory, presented in our treatise, the displacements and rotations appear as equally and similarly treated independent fields. Here enter also in a natural way, the axial deformation fields, with a structure similar to that of a thermal field (comp. Eq. (18a)).

Finally, we shall note that these wave fields correspond with  $\nu \rightarrow c$  to the EM fields,  $\omega_{[n]} \rightarrow B_n$ ,  $\omega_{(n)} \rightarrow E_n$ . The form of the rotation complex tensor (Eq. (29)) is fully analogous to the definition of the complex electromagnetic field  $F_s = B_s + iE_s$ .

### Recording Spin and Twist Angle Variation

We shall find the suitable links between the defined fields and experimental data.

The spin motion can be precisely recorded by means of the Sagnac type interferometers (up to  $10^{-9}$  rad/s); there are different types of such systems, e. g., ring laser and fiber optic, to record spin motion.

The angular twist oscillations and shear-twist motions we can record using a system of rotation seismometers. Such a system is based on the rotation seismographs that can record simultaneously the spin and twist angular motions [14,15,29].

In order to obtain the rotation motions, e. g., spin and twist, around the vertical axis we need the data from two parallel horizontal pendulums of opposite orientation. The observations collected clearly indicate that both the mean values of the spin and those of twist angular motions show the seismic oscillations with the same order of magnitudes [13,15,29].

We stress that the twist field, measured in this way gives only the angular variations of the off-diagonal axes of shears (19a); however, we may note that both the spin motion and the twist variation are mutually joint (see Eq. (31)) and therefore, we might theoretically derive knowledge of the shear state from the spin observations.

We shall add that when measuring the shear deformations with the help of a system of strainmeters, we can achieve more reliable and independent data on the shear-twist variations. Moreover, the strainmeter system can measure also the axial deformations.

Finally, we shall reply to the question of how we could compare the invariant twist field (19a and 19b) with the

observed shear variations. An exact procedure requires the following: the 6 components of the shear strain determined in an observation site system shall be transformed, at each time moment, into the off-diagonal system:

$$\{E_{11}, E_{22}, E_{33}, E_{23}, E_{31}, E_{12}\} \rightarrow \{E_{23}^D, E_{31}^D, E_{12}^D\} \\ = \{\omega_{(s)}\}.$$

## Conclusions

In the standard asymmetric continuum theory the defects defined are not the material defects, but only those related to the structural deformations. This standard asymmetric theory permits one to find the differential relation between the dislocation density and the asymmetric stress field. Moreover, in this theory we may consider also other deviations related to other defects or interaction fields; to this end we could apply the Kröner approach with the elastic, self- and total fields [4].

The other important conclusion is that the influence of rotational processes in earthquake sources spreads outward, because these waves are not attenuated strongly, as it was believed according to classical ideal elasticity.

## Earthquake Source: Fracture Processes

### Introduction

We start our considerations with the thermodynamical conditions related to seismic energy release, and then we consider the rotation counterpart in the fracturing.

We shall be aware that the rotation processes of different nature and scale take part in such extremely complicated fracture phenomena, in which the dynamic processes proceed together with the simultaneous changes of material properties (see Teisseyre [30]). We shall recall the special role of rotations in the energy release effectiveness under different load conditions, and further on we shall include the rotation impact on the granulation processes accompanying the material crushing.

The constitutive laws must undergo simultaneously considerable changes, from the rigid elastic to plastic, and further, to mylonite-type material (in tectonics the mylonite means the crushed, granulated and even partly melted material in zone adjacent to fracture plane). In the narrow zones adjacent to fracturing, the shear stresses break the molecular bonds and in the crashed rock material the stresses immediately drop to a much lower level, while together with the advancing material granulation, we shall include a rapid increase of the stress and strain rates. Finally, in that narrow zone adjacent to fracturing, the stresses and strains may be gradually neglected

and progressively replaced by their time-rates. To describe these processes we shall simultaneously introduce the changes into the related constitutive relations. In result, the rock properties in this zone may even approach those characteristic for fluid. Such conditions may permit one to include in the fracture description the transport Navier–Stokes relations. The fracturing transport process, the bond breaking and granulation processes force us to include in the fracturing description, the hypothesis that the twist-shear deformations leading to the bond breaking precede the rebound rotation motion by  $\pi/2$  in phase; this means that the difference between the shear motion and spin motion shall reach minimum when the latter is shifted by  $\pi/2$  in phase.

We shall underline that the considered conditions in the mylonite zone can serve as the basis to formulate the asymmetric fluid theory with the extreme motion phenomena and dynamic defect objects.

A counterpart to the rotations and rotation energy release at fracture processes (e.g., in an earthquake source) explains fragmentation and spall processes and makes it possible to estimate the efficiency of different fracturing modes. Again we shall underline that in any theoretical approach, the elastic rotation energy can be considered only when assuming the constitutive law joining rotations with the antisymmetric stresses or stress moments.

Teisseyre et al. [18] have reexamined Dietrich's compression experiments [31], coming to the conclusion that under the compression load, there arise at some centers in the source region the induced precursory shear stresses; at a fracturing event we would arrive at the coseismic rebound compensation leading to a release of the induced stresses by the rebound process. Similarly, the precursory rotations associated with the newly formed dislocations or cracks shall have an opposite orientation to that related to the coseismic process. At the precursory stage these repeated processes lead to micro-fracturings, while during the seismic event there will occur under compression load, the fracturing with the rock fragmentation and the rebound macro-rotations at the inner centers where the precursory induced stresses accumulate.

### Earthquake Thermodynamics

Basic thermodynamic relations for line defects (dislocations and vacant dislocations) are derived under the assumption of a dense network of defects forming a kind of super-lattice [32,33,34,35]. The thermodynamic functions of line defects can be associated with defects in the super-lattice. Let us confine our considerations to the irreversible (plastic) deformations of solids.

To distinguish the thermodynamic functions used here from those used under pressure conditions, we will use the symbols with hat and we will consider only a pure shear work under shear load  $S_{(\dots)}$  and under induced friction stress moment  $S_{[\dots]}$  (see: Eqs. (13) and (14)) – we consider deformations at a constant volume; the work  $d\hat{W}$  done on a body (per unit volume), the internal energy change  $d\hat{U}$  and the heat received in an exchange with the surrounding  $dQ$  are related:

$$\begin{aligned} d\hat{W} &= SdE = S_{(\dots)}dE_{(\dots)} + S_{[\dots]}d\omega_{[\dots]} \geq 0, \\ d\hat{U} &= dQ + SdE, \end{aligned} \tag{33}$$

where  $dE_{(\dots)}$  and  $d\omega_{[\dots]}$  are increments of strain and spin.

For the Helmholtz free energy  $\hat{F}$  and Gibbs free energy  $\hat{G}$  we have:

$$\begin{aligned} \hat{F} &= \hat{U} - T\hat{S}, & \hat{G} &= U - SE - T; \\ Td\hat{S} &\geq dQ; & d\hat{S} &\geq 0, \end{aligned} \tag{34}$$

where  $T$  is the absolute temperature and  $\hat{S}$  is the entropy;  $d\hat{S}$  would be the entropy production due to the irreversible processes occurring inside the system.

The local formulation of the second law of thermodynamics requires that the entropy production be positive wherever an irreversible process occurs [34]. It is postulated that even outside equilibrium, the entropy depends only on the same variables as at equilibrium. In order to derive the expression for the entropy production, Prigogine [36] introduced some additional assumptions. Namely, he assumed that the entropy production can be determined for conditions near equilibrium.

Formation of a dislocation gives negative contribution to the Gibbs energy [37] and therefore it is not possible to find a minimum of the Gibbs function with respect to the number of dislocations. Thus, the dislocation distribution cannot exist as a thermodynamically stable system, since the Gibbs free energy has no minimum of any equilibrium concentration of dislocations.

However, for a dense dislocation distribution there enter the repulsive interactions between dislocations, and a kind of dislocation super-lattice can be considered [32,34,35]. The “ideal super-lattice” can be treated as a reference state and the real super-lattice, in the case of dense distribution of dislocations, can be in the equilibrium state. We define the vacant dislocations in the following way: to the randomly formed network of dislocations we shall add a number of line vacancies – the vacant dislocations – in such a way that as a result we obtain the super-lattice filled by dislocations and vacant dislocations. In this situation, a real distribution of dislocations can be

described as a departure from the state of ideal super-lattice, given by the amount of vacant dislocations.

These processes are accompanied by an internal friction related to displacement formed by dislocations and hence a spin motion appears as inherently present there.

The Gibbs energy minimum can now exist as the equilibrium number of the vacant dislocations. We can consider the structure of a cross-zone consisting of bands of layerlets; such a structure favors the appearance of some macroscopic dislocations under conditions of shearing deformation. The particular values of the Burgers vector become related to particular layer thicknesses. In this sense we suppose that a fine band structure could play the role of a quantization kind factor; this problem is related to the earthquake shear band model.

Consider a continuum that contains a regular (cubic) super-lattice of dislocation lines with a certain super-lattice parameter  $\Lambda$  ( $\Lambda \gg \lambda$ ;  $\lambda$  relates to a basic rock lattice). The notion of the super-lattice is directly related to the shear band model of fracturing [34], see Fig. 7.

We associate the thermodynamic functions of line defects with the defects in a super-lattice; the Gibbs free energy may have a minimum corresponding to the equilibrium concentration of the vacant dislocations in the super-lattice. Many results can be now transferred from the thermodynamics of point defects (Varotsos and Alexopoulos [38]). The regular super-lattice, which includes the dislocations and vacant dislocations, may be described in a very rough approximation by a characteristic distance  $\Lambda$  (super-lattice constant). For the ideal super-lattice (no vacant dislocations), the mean value of distances following from distribution of dislocations defines the reference dislocation density  $\alpha^0 = \lambda/\Lambda^2$ , while for a real body with  $n$  dislocations we may add to it other  $\hat{n}$  vacant dislo-

Earthquake Source: Asymmetry and Rotation Effects, Figure 7 Shear band model

cations in such a way that the whole set  $n + \hat{n} = N$  (dislocations and vacant dislocations) fits to a regular super-lattice with the smallest error. For the density of dislocations  $\alpha$ , and vacant dislocations  $\hat{\alpha}$ , we can write [34]:

$$\alpha = \left(1 - \frac{\hat{n}}{N}\right) \frac{\lambda}{\Lambda^2}, \quad \hat{\alpha} = \frac{\hat{n}\lambda}{N\Lambda^2} \frac{\lambda}{\Lambda^2} \exp\left(-\frac{\hat{g}^f}{kT}\right), \quad (35)$$

where the number  $\hat{n}$  can be identified with an equilibrium value in relation to the formation energy of vacant dislocation  $\hat{g}^f$  per length of the crystal lattice  $\lambda$ .

The stress field and the resistance stress (e. g., the drag resistance in a dislocation motion and the friction stress in a crack motion) are defined as [37]:

$$S = \frac{\partial \hat{W}}{\partial E}, \quad S_F \equiv \frac{\partial \hat{F}}{\partial E},$$

while the Gibbs function for a crystal containing the vacant dislocations can be written as

$$\hat{G} = \hat{G}^0 + \hat{n}\hat{g}^f - T\hat{S}_c,$$

where  $\hat{S}_c$  is the configuration entropy.

Near the equilibrium state under a constant local shear  $S$  and temperature  $T$  the Gibbs energy is close to its minimum and the equilibrium values could be found as follows:

$$\begin{aligned} \left. \frac{\partial \hat{G}}{\partial \hat{n}} \right|_{S,T} = 0, \quad \hat{n}^{\text{eq}} &= N \exp\left(-\frac{\hat{g}^f}{kT}\right), \\ \hat{\alpha} &= \frac{\lambda}{\Lambda^2} \exp\left(-\frac{\hat{g}^f}{kT}\right), \quad \hat{S}_c = \hat{n} \left(k + \frac{\hat{g}^f}{T}\right), \end{aligned} \quad (36a)$$

while the Gibbs energy function becomes

$$\hat{G} = \hat{G}^0 - \hat{n}kT. \quad (36b)$$

The equilibrium free energy is less than that for an ideal super-lattice  $\hat{G}^0$ ; the difference is  $kT$  per line vacancy, per length of crystal lattice.

For the point defect thermodynamics, Varotsos and Alexopoulos [38] have introduced the so-called  $CB\Omega$  theory approximating the contribution to the Gibbs energy from the formation of point defects.

For the line vacancies, a change of the Gibbs energy depends on the stress level and resistance stress. Therefore, we postulate for the approximative value of such change per unit element (formation energy of vacant dislocation) the following expression defining the  $C\mu b\lambda^2$  model:

$$\hat{g}^f = C\mu b\lambda^2, \quad \hat{n}^{\text{eq}} = N \exp\left(-\frac{C\mu b\lambda^2}{kT}\right), \quad (37)$$

where  $C$  is constant;  $\hat{g}^f$  becomes here independent on stress load and resistance,  $\mu$  is the rigidity,  $b$  is the Burgers vector of dislocation.

Concluding, a body containing some number of dislocations cannot be in a state of equilibrium; there is no minimum of the Gibbs function, because when reducing the number of dislocations we always get a smaller value of the free energy. For a dense distribution of dislocations we can assume, due to their interaction, that there exists a certain super-lattice composed of dislocations.

The equilibrium density of the vacant dislocations may be written now with help of Eq. (37)

$$\hat{\alpha} = \frac{\lambda}{\Lambda^2} \exp\left(-\frac{C\mu b\lambda^2}{kT}\right) \quad (38)$$

and becomes useful, when looking for the most probable density value of defects after the energy release in a fracturing process. The density  $\alpha^0 = \lambda/\Lambda^2$  may be identified here with the reference density.

We can assume that before an earthquake a super-lattice is almost completely filled in by dislocations ( $n \approx N$  and  $\hat{n} \approx 0$ ). The maximum number of dislocations in arrays could reach the value  $(\Lambda/\lambda)^2$  per area  $\Lambda^2$ . The total moment for an area  $\Delta s = N\Lambda^2$  affected by the arrays of dislocation along the slip planes becomes:

$$\bar{M} = \mu\lambda\Delta s = \mu\lambda N\Lambda^2 \left(\frac{\Lambda}{\lambda}\right) = \mu N\Lambda^3.$$

After an earthquake, the number of vacant dislocations  $\hat{n}$  shall increase, probably to the equilibrium value (37) and hence we can express the seismic moment by the number of coalescence processes related to surface element  $\Lambda^2$  as equal to  $\Delta\hat{n} = \frac{\Lambda}{\lambda}\hat{n}^{\text{eq}}$ ; the factor  $\Lambda/\lambda$  expresses a maximum concentration of dislocations in the arrays.

We obtain for the seismic moment

$$\begin{aligned} \bar{M}_0 &= \bar{M}\Delta\hat{n} = \mu N\Lambda^3 \left(\frac{\Lambda}{\lambda}\right) \Delta\hat{n} \\ &= \mu N\Lambda^3 \left(\frac{\Lambda}{\lambda}\right) \exp\left(-\frac{C\mu\lambda\Lambda^2}{kT}\right), \end{aligned}$$

where  $C$  is constant for given structure.

Using the expression for a change of the free energy values we may include the formation of dislocation arrays along the glide planes and we put

$$G = G^0 + \Delta\hat{n} \left(\frac{\Lambda}{\lambda}\right) kT$$

According to these results, the total energy release  $\Delta E$  and seismic moment are:

$$\begin{aligned}\Delta E &= G - G^0 = \Delta \hat{n} \left( \frac{\Lambda}{\lambda} \right) kT \\ &= \left( \frac{\Lambda}{\lambda} \right) NkT \exp \left( -\frac{C\mu\lambda\Lambda^2}{kT} \right) \text{ and} \\ \tilde{M}_0 &= \mu\Lambda^3 \frac{\Delta E}{kT}.\end{aligned}\quad (39)$$

This formula is an important relation between the energy release density and seismic moment density; for instance, for a given  $\Delta E$  the elementary seismic moment  $\tilde{M}_0$  decreases with temperature. Free energy related to defect formation,  $\hat{g}^f$ , is proportional to  $\mu\lambda\Lambda^2$  being constant for a given structure; with growing value of  $\Lambda$  the seismic moment becomes greater.

Neglecting the term related to the formation entropy, we can write for entropy density change:

$$\Delta \tilde{S} = kN \left( \frac{\Lambda}{\lambda} \right) \left( 1 + \frac{C\mu b\lambda^2}{kT} \right) \exp \left( -\frac{C\mu\lambda\Lambda^2}{kT} \right).$$

All of these relations concern the quantities referred to the multiple of the cubic volume  $N\Lambda^3$  thus, we can correct these quantities to that related to a given source volume by introducing the factor  $\pi R^2 D / N\Lambda^3$ :

$$\begin{aligned}M_0 &= \mu\pi R^2 D \left( \frac{\Lambda}{\lambda} \right) \exp \left( -\frac{C\mu\lambda\Lambda^2}{kT} \right), \\ \Delta E &= \pi R^2 D \frac{kT}{\Lambda^2 \lambda} \exp \left( -\frac{C\mu\lambda\Lambda^2}{kT} \right) \text{ and} \\ \frac{M_0}{E^{\text{rad}}} &= \frac{\mu\Lambda^3}{\eta kT}, \\ \Delta \tilde{S} &= \pi R^2 D \frac{k}{\Lambda^2 \lambda} \left( 1 + \frac{C\mu\lambda\Lambda^2}{kT} \right) \exp \left( -\frac{C\mu\lambda\Lambda^2}{kT} \right),\end{aligned}\quad (40)$$

where  $\eta\Delta E = E^{\text{rad}}$ ,  $\eta$  is the seismic efficiency;  $E^{\text{rad}}$  is radiated energy.

In the above consideration we took into account both energies related to slip and friction processes, and thus, the total released energy includes that related to stress drop and that related to heat caused by friction processes.

Further on, we will consider the fracturing processes in an earthquake source.

### Synchronization and Fracturing

The inner stress accumulation relates to the formation of defect densities; due to the interaction between dislocations, we arrive at stress concentration at the first blocking dislocations of the formed dislocation arrays.

In the compression case with no initial shear field and due to the lower value of shear resistance, we have to assume that inside a body there appear regions with induced shear stresses of opposite signs, and induced antisymmetric stresses. The earthquake process and its energy release relate to a coalescence of dislocation arrays of opposite signs and related rotation release motion. Of course, we shall consider a fracture process as a chain of events; let us consider the micro-fracture centers formed on two perpendicular plane fragments; the induced shear stresses will be opposite on those plane fragments, but will have the common orientation of a spin motion – see Fig. 8; hence, the shears will be almost compensated for, while the spin field will remain unchanged.

The spin field,  $\omega_{[s]}$ , propagates and influences the processes in the adjacent regions; we believe that this propagation synchronizes the spin motions in the adjacent centers, in such a way that the sense of spin motion becomes the same over the whole fracture region. That means, the spin propagation assures a synchronization of fracture processes, especially under compression load where the energy release relates to the fragmentation revealed by rotation and granulation processes.

Reversely, under the shear load, while common shear deformation,  $E_{kn}^D$  (or expressed as twist  $\omega_{(s)}$ ), progresses, the spins on the main fracture differ from those on the adjacent perpendicular fragments and attenuate fracture progress on those fragments.

Accordingly, we can believe that at the compression load, the total shear stress drop will be relatively small, while the rebound rotations will release an important amount of rotation energy. At the shear load the release of shear stresses will prevail.

Earthquake Source: Asymmetry and Rotation Effects, Figure 8  
Compression load: induced shear centers and formation of fragments with related rotations

Concluding, the rotation processes in fragmentation and fracturing under compression load play an essential role. Under prevailing shear load the rebound process releases shear load with the regional stress drop, while the rotation processes play a minor role.

Further on, we will discuss the importance of the granulation processes related to rotations in meso-scale, which we can place between the bond breaking processes in the micro-scale and material fragmentation in the macro-scale.

**Granulation and Formation of Mylonite Zones**

The fracturing process, especially under the action of shearing load, is accompanied by material granulation adjacent to shear fracture planes; thus it becomes spectacular at the formation of narrow, long mylonite zones. In this process we shall take into account a special role of rotations – the meso-rotations of different scales; these rotations are related to bond breaking and friction processes.

Co-action of the spin and twist-shear motions in bond breaking, granulation and formation of mylonite material can effectively help us to explain the fracture process; the simultaneous formation of the adjacent mylonite zone appears due to such a co-action of spin and shears and of the fracture transport phenomena.

Based on the standard asymmetric continuum theory, as presented in the first part, we would like to consider the material undergoing a progressive crushing process. We may arrive even at the conditions more similar to fluid material, and thus finally shall enter into our considerations the Navier–Stokes transport equations.

Starting with the description of the rock continuum following from the standard asymmetric theory of continuum ( $S_{ik} = S_{(ik)} + S_{[ik]}, E_{ik} = E_{(ik)}, \omega_{ik} = \omega_{[ik]}$ ), we approach the final stage of the crushing/granulation process in zones adjacent to fracture planes. In these zones, simultaneously with dynamic processes, there occur changes of material properties from hard rocks to mylonite granulated material.

Approaching the final stage, the stresses, strains and rotations presented in the description of the standard asymmetric continuum become gradually neglected and progressively replaced by the constitutive relations for time-rates of stresses and strains.

The constitutive laws for rock asymmetric continuum – the relations (1) written for the deviatoric fields and for the antisymmetric fields

$$S_{(kl)}^D = 2\mu E_{kl}^D, \quad S_{[kl]} = 2\mu\omega_{kl} \tag{41}$$

– will gradually change during fracturing to those including the time dependent processes:

$$\begin{aligned} \sigma S_{(ik)}^D + \tau \dot{S}_{(ik)}^D &= 2\mu E_{ik}^D + 2\eta \dot{E}_{ik}^D, \\ \sigma S_{[ik]} + \tau \dot{S}_{[ik]} &= 2\mu E_{ik} + 2\eta \dot{\omega}_{ik}. \end{aligned} \tag{42}$$

The introduced material constants are related to magnitudes of the slip,  $u$ , and slip rate,  $v$ .

When in a narrow zone the huge shear stresses break the molecular bonds, the stresses crushing rock material immediately drop down to the low values and in the crushed mylonite material we observe the immediate increase of the stress and strain rates to such degree that the stresses and strains may be neglected in the respective constitutive relations for that narrow zone. Finally, these changes will lead to the constitutive laws for the melt and granulated parts of mylonite material in which, practically, will remain only the field time rates:

$$\dot{S}_{(ik)} = 2\eta \dot{E}_{ik}, \quad \dot{S}_{[ik]} = 2\eta \dot{\omega}_{ik}. \tag{43}$$

The direct observation of the gauge zone of the Kobe (Japan, 1995) earthquake at the Avaji island suggests that the size of an inner completely melted part of the mylonite zone ranges around couple of centimeters (private communication W. Debski).

Further on, we will assume for the sake of simplicity, that during the fracturing the mylonite material remains incompressible.

In such a way, the nucleation progresses and fracture propagates simultaneously with the granulation process in the intact material (or in the compact zone previously crushed) – see Fig. 9.

In this new description, the shear rates create the dynamic angular deformations then lead to the bond

Earthquake Source: Asymmetry and Rotation Effects, Figure 9  
Mylonite zone and neighboring deformations

breaking processes, and finally to the fracturing transport process.

We pass to the final stage; for the crushed incompressible mylonite or sand, similarly to incompressible fluids, where tensor  $\hat{\omega}_{ik}^T$  is related to spin motion (not to rotation of displacement), the mylonite viscosity is  $\eta$ , and the mylonite relaxation time is denoted by  $\tau$ .

The relations (42) define the ideal quasi-viscous mylonite for an incompressible crushed material.

Further, we assume the coincidence/identity of rotation of velocity field  $\dot{\mathbf{u}}$  with the point rotation field  $\omega$ . So, we assume that rotations of particles (micro-rotation  $\omega$ ) coincide with macro-rotations (rot  $\mathbf{u}$ ). For mylonite, such a coincidence between the micro-rotation and macro-rotation seems reasonable, and thus, our assumption that viscosity  $\eta$  coincides with rotation viscosity  $\eta^*$  may be correct.

For our narrow mylonite zone, existing already near the pre-slip planes or just simultaneously formed, we may, further on, apply the Navier–Stokes transport equation. Referring to our former considerations on the asymmetric continuum theory (see Subsect. “Spin and Twist Motions”) we may add to the spin rotational motions the oscillations of the strain shear rates (called twist motion). Such motions, especially in an earthquake source zone, are due to the friction processes.

We may note that when including these complex rotational motions in the theory we may replace the friction constitutive laws, as based on the experimental data, by the constitutive law joining the asymmetric stresses with spin and shears field oscillations or otherwise with spin and twist.

### Slip Propagation and Spin Release Hypothesis

While searching the fault slip solutions, we use the classical elasticity tools with an additional friction constitutive law based on experimental data. When instead of it we consider the asymmetric elastic continuum, we are able to include the defect interaction and we can derive the elastodynamic fault solution describing slip propagation with fracturing process and related seismic radiation.

The angular deformations preceding the bond breaking process lead to the efficient rise of the angular moments around material grains. In the narrow mylonite zone, we arrive at the equivalence between this expression and the laws introduced in the considerations on the friction resistance and slip.

The co-action of the rotation (rot  $\mathbf{u}$ , or spin  $\omega_{[.]}$ ) and shear ( $\mathbf{E}^D(\mathbf{u})$ , or twist –  $\omega_{(.)}$ ) motions can lead further to the slip fracturing motion. We assume that the bond

breaking process and granulation of material precede the slip movement: just after the bond breaking micro-process there, we would have the released rebound spin motion retarded in phase.

This hypothesis is supported by the following solution of the homogeneous wave equations for the twist and spin in a mylonite zone (see Eq. (31)):

$$\begin{aligned}\omega_{(s)} &= i\omega_{[s]}; & \omega_{[s]} &= \omega_{[s]}^0 \exp[i(k_i x_i - \omega t)], \\ \omega_{(s)} &= \omega_{(s)}^0 \exp[i(k_i x_i - \omega t)],\end{aligned}\quad (44)$$

where the six constants in  $\omega_{[s]}^0 = \text{abs}(\omega_{[s]}^0) \exp(i\psi_s)$ ,  $\omega_{(s)}^0 = \text{abs}(\omega_{(s)}^0) \exp(i\varphi_s)$  shall fulfill the six conditions.

We may consider the following 2D solution of Eq. (44) in the systems  $\{r, \varphi, z\}$ :

$$\omega_{(\varphi)}(r) = i\omega_{[\varphi]}(r), \quad \square\omega_{[\varphi]}(r) = 0.$$

The related solution corresponds to a turbulence structure. Thus, from a dislocation-slip structure formed in the earthquake premonitory domain (see: Subsect “Earthquake Thermodynamics”), gradually destroyed during a fracture process by a spin release motion, we can arrive at a turbulence structure appearing in a melted or fully granulated material.

With the introduced waves,  $\omega_{(s)} = i\omega_{[s]}$  we arrive at the possibility to study the dynamic defect objects and to explain the synchronization of the micro-fracturing processes due to an influence of the propagating waves. For the fracture processes under compression such a synchronization will assure the common sense of the induced twist and spin motions, while under shear load – the formation of a long shearing fracturing. In the last case, the spin waves related to a given slip on the main fracture plane attenuate those with the opposite spins generated at the perpendicular fragments, and due to the conjugate solution (see Eq. (44) reduce the slip motions on those fragments.

The presented conjugate solution Eq. (44) suggests that the spin rebound motion is delayed in phase by  $\pi/2$  (as we have  $\exp[i(k_i x_i - \omega t)] = \exp[ik_i x_i - i(\omega t - \pi/2)]$ ); when slip starts due to breaking of bonds, the micro-spin motions are released.

Following this assumption we expect that such a correlation between the recorded twist motions and spin motions shifted by  $\pi/2$  in phase can exist in some wavelets.

Now we can propose the following description of the fracture process.

- First, according to external load conditions the stresses rise while the disclosure and dislocation field can be neglected – the case given by relations (25).

- Next, approaching the fracture process we may observe the “accumulation” phase with the co-action of the twist and spin – the case given by relations (26).
- Finally, fracturing processes start and when entering into the time rate domain we can describe the “release” phase of the process as follows (compare: Eqs. (21–26 and 43):

$$\begin{aligned} \dot{B}_l &= \oint [E_{(kl)} + i\omega_{[kl]}] dl_k, \\ \dot{\alpha}_{pl} &= \varepsilon_{pmk} \left( \frac{\partial \dot{E}_{kl}}{\partial x_m} + i \frac{\partial \omega_{kl}}{\partial x_m} \right) \\ \dot{\alpha}_{pl} &= \frac{\varepsilon_{pmk}}{2\mu} \frac{\partial}{\partial x_m} \left( (\dot{S}_{(kl)} - \frac{\nu}{1+\nu} \delta_{kl} \dot{S}_{ii}) + i \dot{S}_{[kl]} \right), \end{aligned} \tag{45} \tag{46}$$

where we have the dynamic disclosure and  $\nu$ -dislocation density under the conditions formed by solution (see Eq. (44)), supplemented with the relations between the asymmetric stress rates and the dynamic dislocation objects ( $\nu$ -dislocations).

- This case presents a formation of dynamic discontinuities and the related dynamic processes in which the slip and bond breaking leads to the rebound spin motions delayed in phase by  $\pi/2$ .

The co-action of the spin and twist motions leads to the “accumulation” phase, while the conjugate solution (see Eq. (44)) presents a fracture process – “release” phase.

We might suppose that the fracture process could proceed with the consecutive accumulation and release micro-processes; in such a situation the related twist and spin motions will appear consecutively as pairs of wavelets in phase (or anti-phase) and those differing in phase by  $\pi/2$ . Figure 10 presents an example of the coincidence of the spin and twist motions after the Hilbert transformation shifting the angular twist record ahead in phase by  $\pi/2$ .

The presented theory, due to its simplicity, could be very useful for some problems, among others those in which macro-rotation takes an important role in the asymmetric fluid dynamics.

We can call the solution (44) as the fracture synchronization waves.

Earthquake Source: Asymmetry and Rotation Effects, Figure 10

Example of coincidence of the spin and twist angular motions (rad/s versus s) after the Hilbert transformation shifting the twist record ahead in phase by  $\pi/2$ ; upper part – the original records, lower part – the twist record transformed (from the original seismic record obtained by the system of the rotation seismometers; L’Aquila Observatory, 17.02.2006; the continuous line – twist, the broken line – spin)

Finally, we shall notice that similar solutions may exist for the electric and magnetic induction vectors:

$$D_s = iB_s \leftrightarrow D_s^0 = iB_{[s]}^0, \tag{47}$$

where this relation shall be assured by the appropriate material constants.

**Towards Asymmetric Fluid Theory and Extreme Phenomena**

Approaching the conclusions, we shall specify how we could formulate the asymmetric theory of the fluid continuum in which the stress, strain and rotation fields vanish, but their rates exist as related to the velocity field  $v$ :

$$\begin{aligned} \dot{E}_{ik} &= e^0 \frac{1}{2} \left( \frac{\partial v_k}{\partial x_i} + \frac{\partial v_i}{\partial x_k} \right), \\ \dot{\omega}_{ik} &= \chi^0 \frac{1}{2} \left( \frac{\partial v_k}{\partial x_i} - \frac{\partial v_i}{\partial x_k} \right). \end{aligned} \tag{48}$$

The velocity field  $v$  shall obey the Navier–Stokes **transport equation**.

For the sake of simplicity, let us consider the incompressible fluid ( $\dot{E}_{ss} = 0, \dot{E}_{ik} = \dot{E}_{ik}^D$ ), the basic constitutive laws are assumed similarly to those for the asymmetric continuum:

$$\dot{S}_{(ik)} = \eta \dot{E}_{ik}, \quad \dot{S}_{[ik]} = \eta \dot{\omega}_{ik}, \tag{49}$$

where  $\eta$  is viscosity.

In a similar manner, the structural dynamic objects can then be defined as defects in the standard asymmetric continuum.

The extreme motion phenomena, related to the shear rate and spin,  $\dot{E}_{(kl)} + \dot{\omega}_{(kl)}$ , could be expected for the following case (compare: Eqs. (22–26 and 43):

$$\begin{aligned} \dot{B}_l &= \oint [\dot{E}_{kl} + \dot{\omega}_{kl}] dl_k = \oint \frac{\partial v_l}{\partial x_k} dl_k = 0, \\ \dot{\alpha}_{pl} &= 0, \quad \dot{\Omega}_q = 0, \end{aligned} \tag{50}$$

while formation of the dynamic defect objects can be described as:

$$\begin{aligned} \dot{B}_l &= \oint [\dot{E}_{kl} - \dot{\omega}_{kl}] dl_k =, \\ \dot{\alpha}_{pl} &= \frac{1}{2\mu} \varepsilon_{pmk} \frac{\partial}{\partial x_m} [\dot{S}_{(kl)} - \dot{S}_{[kl]}]. \end{aligned} \tag{51}$$

The former case (see Eq. (50)) presents an extreme shear rate deformation, like soliton waves, while this case (see

Earthquake Source: Asymmetry and Rotation Effects, Figure 11 Extreme motions: soliton wave will be related to a given deformation of the circle as follows for the parameter  $C = e^0$ ; Amplitude plot (Mathematica 5.0): with AspectRatio  $\rightarrow$  Automatic:  $A = \text{Plot}[y = -Cx/2 \pm 0.5\sqrt{[(Cx) \wedge 2 - 4x \wedge 2 + 4]}], \{x, -\sqrt{[4/(4 - C \wedge 2)]}, \sqrt{[4/(4 - C \wedge 2)]}\}$

Eq. (51)) would relate to a formation of the  $v$ -slip-discontinuity.

In 2D we can show an effect of the co-action of the macro spin and twist motions in the following way; let us put  $C = e^0$  and  $\chi^0 = 1$

$$\begin{aligned} \dot{E}_{12} + \dot{\omega}_{12} &= Cv_{(2,1)} + v_{(2,1)} \\ &= C \frac{1}{2} \left( \frac{\partial v_k}{\partial x_i} + \frac{\partial v_i}{\partial x_k} \right) + \frac{1}{2} \left( \frac{\partial v_k}{\partial x_i} - \frac{\partial v_i}{\partial x_k} \right). \end{aligned}$$

For  $C = 0$  we would have only the spin motion, while a full coincidence will occur at  $C = 1$ .

The effect of such a superposition of the spin and twist motions is presented on Fig. 11.

We believe that this approach might explain some extreme fluid phenomena related to atmosphere and oceans.

The balance equations for field rates (48) at  $e^0 = \chi^0$  may lead us to the wave equations for the related spin and twist rate fields,  $\dot{\omega}_{[s]}$  and  $\dot{\omega}_{(k)}$ , as defined similarly to the relations derived in Subsect. “Balance Laws for the Rotation Field and the EM Analogy” (see: Eqs. (29 and 31):

$$\begin{aligned} \varepsilon_{kps} \frac{\partial}{\partial x_p} \dot{\omega}_{[s]} - \frac{1}{V} \frac{\partial}{\partial t} \dot{\omega}_{(k)} &= \frac{4\pi}{V} j_k, \\ \varepsilon_{kps} \frac{\partial}{\partial x_p} \dot{\omega}_{(s)} + \frac{1}{V} \frac{\partial}{\partial t} \dot{\omega}_{[k]} &= 0. \end{aligned} \tag{52}$$

The appearance of such coupled waves transversal to the transport motion brings physical background for diffraction in fluids as explained usually by the Huygens principle.

## Conclusions

Under both the confining pressure and external shear, the role of micro-fracturing in the bond breaking process is similar; however, we observe the essential differences for rotations in larger scales.

The confining condition leads to formation of induced opposite arrays of dislocations, resulting in fragmentation processes and chaotically oriented macro-rotations, leading therefore to a rotation release process.

The shear condition leads to more concentrated fracturing along some planes, high shear strain release and correlated rotations.

Both cases include formation of narrow mylonite zones adjacent to the fracturing planes or their fragments, but these processes prevail rather under shear conditions.

We draw attention to the importance of the rotations in meso-scales – between the micro-scale bond breaking process and that related to macro-rotation at material fragmentation. The meso-scale rotations are related to material granulation and become observed in any fracturing process; such motions may be revealed in the spectacular formation of the narrow, long mylonite zones under shear load conditions. Coincidence and co-action of the spin and twist-shear motions in bond breaking and formation of mylonite material help one to understand the fracture motion; the simultaneous formation of the mylonite zones appears due to common action of these motions and to fracture transport phenomena.

Rotations at source zones help to understand geometry of fracturing and releases of stress and rotation counterparts as a result of precursory and rebound processes.

We have presented also a new idea how to construct the asymmetric fluid theory with the asymmetric stress rate field.

## Final Remarks

With the additional constitutive law joining the rotations with antisymmetric part of stresses, we have proved that the rotation waves exist, even in a homogeneous elastic continuum. We have defined the twist motion as the rotational oscillation of the main shear axes including the shear magnitude variations. The derived wave equations for the twist and spin motions have been considered in relation to the processes in seismic source.

Only in the presented approach with the standard asymmetric theory may we study the co-action of the independent motions and deformations; this is due to the new relations joining the spin and slip motions. A possible phase shift between these motions leads to different families of deformation and related solutions.

We have shown how the rotations at source zones help us to understand physics and geometry of fracturing and release of stresses in the precursory and rebound processes.

The derived wave equations for spin and twist motions are similar to the EM wave equations.

Our considerations show the importance of the simultaneous recording of the translational and rotational earthquake motions, and also the strains (at least the deviatoric strains).

Finally, we have shown how to construct the asymmetric fluid theory in which, with a help of the asymmetric stress rates, the various extreme phenomena, including soliton waves, can be theoretically explained.

### Glossary

**CMT centroid moment tensor** The CMT represents the displacement of the Earth's crust that best reproduces the observed wave-field generated by an earthquake and gives the average location in time and space of the earthquake energy release. The seismic moment can be determined from the CMT.

**Convolution** Convolution is a type of integral transform combining two signals to form a third signal or output. It is the single most important technique in Digital Signal Processing. In the case of Seismology, the two signals can be e. g., the ground motion as a function of time and the response of the seismometer, and the output is the seismogram.

**Deconvolution** Does the reverse of convolution. In the case of Seismology, one uses deconvolution to remove the instrument response from the seismogram to recover the actual ground motion.

**Deep earthquake** An earthquake characterized by a hypocenter located more than 100 km below the Earth's surface.

**Hypocenter** The point within the Earth where the earthquake rupture starts. The epicenter is the projection of the hypocenter onto the Earth's surface.

**Local tsunami** A tsunami that has little effect beyond 100 km from its source.

**Magnitude**  $m_B$ : The "broad-band" body-wave magnitude, generally based on measurements of the amplitude of P-waves with periods in the 2 to 20 s range.

$M_S$ : The surface-wave magnitude.  $M_S$  is generally based on measurements of the amplitude of the surface

(Love or Rayleigh) waves with periods of about 20 s. The US tsunami warning centers have applied a correction to the IASPEI formula that allows the estimation of  $M_S$  closer to the epicenter at a period of 20 s.

$M_E$ : The "energy magnitude" scale, derived from velocity power spectra.

$M_m$ : The mantle wave magnitude, based on the measurement of the amplitude of surface waves with periods of 50–400 s.

$M_W$ : The moment magnitude or the "work magnitude" is based on the estimation of the scalar seismic moment,  $M_0$ .

$M_{wp}$ : The moment magnitude based on the initial long period P-waves.

$M_L$ : The Local magnitude scale, based on the measurement of the maximum peak-to-peak amplitude observed on a Wood-Anderson seismogram, corrected for the decrease in amplitude with increasing epicentral distance. Generally based on the analysis of Sg, Lg or Rg surface waves oscillating with periods observed out to about 600 km. from the earthquake's epicenter.

pMag: A magnitude scale based on the average of the absolute values of the first three half cycles of the P-waves recorded at local distances.

**Marogram** A recording of sea-level variations obtained by tide gauges.

**Regional tsunami** A tsunami that has observable effects up to 1000 km from its source.

**Seismic body waves** Waves that propagate through the interior of an unbounded continuum. Primary waves (P-waves) are longitudinal body waves that shake the ground in a direction parallel with the direction of travel. Secondary body waves (S-waves) are shear waves that shake the ground in a direction perpendicular to the direction of travel. There are other types of arrivals (also known as phases) visible on seismographs corresponding to reflections of P- and S-waves from the earth's surface: The pP phase is a P-wave that travels upwards from the hypocenter and reflects once off the surface and the PP phase is a P-wave that travels downwards from the epicenter and reflects once off of the surface. The definitions of the S-wave phases follow in the same manner.

**Seismic moment** The seismic moment  $M_0$ , (expressed in units of force times distance; e. g. Newton-meters, or dyne-cm) is the moment of either couple of an equivalent double couple point source representation of the slip across the fault area during the earthquake. Mathematically, the Seismic Moment,  $M_0 = \mu Ad$ , where  $\mu$  denotes the shear rigidity, or resistance of the faulting material to shearing forces,  $A$  represents the area of the

fault plane over which the slip occurs, and  $d$  represents the average co-seismic slip across  $A$ .

**Seismic waves** Elastic waves generated by movements of the earth's crust that propagate as radiated seismic energy,  $E_R$ .

**Seismic surface waves** Waves that propagate along the surface boundary of a medium, e. g. along the surface of the earth.

**Shallow earthquake** An earthquake characterized by a hypocenter located within 100 km of the Earth's surface.

**Teletsunami** A tsunami that has observable effects on coastlines more than 1000 km away from its source.

**Tsunami** A series of water waves generated by any rapid, large-scale disturbance of the sea. Most are generated by sea floor displacements from large undersea earthquakes, but they can also be caused by large submarine landslides, volcanic eruptions, calving of glaciers and even by meteorite impacts into the ocean.

**Tsunami earthquake** An earthquake that generates a much larger tsunami than expected given its seismic moment.

**Tsunami warning system** A tsunami warning system consists of a tsunami warning center such as the Pacific Tsunami Warning Center (PTWC), a formal response structure that includes Civil Defense authorities and Government Officials, and an education program that brings a minimum level of awareness and education to the coastal populations at risk.

## Definition of the Subject

Tsunamis are among nature's most destructive natural hazards. Typically generated by large, underwater earthquakes near the Earth's surface, tsunamis can cross an ocean basin in a matter of hours. Although difficult to detect, and not dangerous while propagating in deep water, tsunamis can unleash awesome destructive power when they reach coastal areas. With advance warning, populations dwelling in coastal areas can be alerted to move to higher ground and away from the coast saving many lives. Unfortunately, due to the lack of a tsunami warning system in the Indian Ocean, the Sumatra earthquake of Dec. 26, 2004 killed over 250 000 people with thousands of lives lost as far as away as East Africa many hours after the earthquake occurred. Had a tsunami warning system been in place many lives could have been saved [77].

As fast as tsunami waves are, seismic waves can travel at speeds more than 40 times greater. Because of this large disparity in speed, scientists rely on seismic methods to detect the possibility of tsunami generation and to warn

coastal populations of an approaching tsunami well in advance of its arrival. The seismic P-wave for example, travels from Alaska to Hawaii in about 7 min, whereas a tsunami will take about 5½ h to travel the same distance. Although over 200 sea-level stations reporting in near-real time are operating in the Pacific it may take an hour or more, depending on the location of the epicenter, before the existence (or not) of an actual tsunami is confirmed. In other ocean basins where the density of sea-level instruments reporting data in near real-time is less, the delay in tsunami detection is correspondingly longer. In addition, global, regional, and local seismic networks, and the infrastructure needed to process the large amounts of seismic data that they record, are widespread. For these reasons, tsunami warning centers provide initial tsunami warnings to coastal populations based entirely on seismic data.

## Introduction

A tsunami can be produced by any mechanism that causes a sudden displacement of the ocean's surface affecting a significant volume of water. Tsunamis can be generated by undersea earthquakes, landslides and volcanic explosions, calving of icebergs, and even meteorite impacts. However, the majority of tsunamis are generated by earthquakes. Not uncommon are earthquakes that trigger landslides so that both the displacement of the crust due to the earthquake, and the landslide, each contribute to the generation and size of the tsunami. Tsunamis are a devastating, natural, high fatality hazard [18]. In the absence of a proper tsunami warning system, a destructive tsunami will cause death and destruction as it encounters coastal areas while propagating across an ocean basin as it did in the case of the Sumatra tsunami of December 2004.

Although tsunamis propagate in deep water with speeds exceeding 900 km/h they are hard to detect in the open ocean. For instance, the first wave of the great Sumatra tsunami had a wave height of only one meter in deep water ( $> 500$  m) [28], and a wavelength on the order of several hundred kilometers. Consequently, people aboard ocean vessels did not feel the accelerations caused by the Sumatra tsunami as it passed under them. However, as the speed,  $v$ , of a tsunami is governed by the simple relation  $v = \sqrt{gh}$  where  $g$  is the acceleration of gravity (in m/s), and  $h$  is the thickness of the water column (in m), the tsunami will slow down as it propagates into shallow waters. At this point, the wave speed and wavelength decrease, causing the wave height to increase. Depending on the nature of the tsunami, and the shape and bathymetry

of the coastal area, the tsunami wave height can be greatly amplified, thus magnifying its destructive power.

Because most tsunamis are generated by earthquakes, and seismic waves travel more than 40 times faster than tsunamis, the first indication that a tsunami may have been generated is the earthquake itself. Depending on the earthquake's location (undersea or inland), depth (shallow or deep) in the Earth's crust, and magnitude, a warning center may be required to issue an official message product. If the earthquake is a shallow, under sea earthquake, the severity of the message will depend upon the magnitude of the earthquake. The more rapidly and accurately the tsunami warning center can characterize the earthquake source, the quicker the initial evaluation of the tsunamigenic potential of the earthquake can be disseminated.

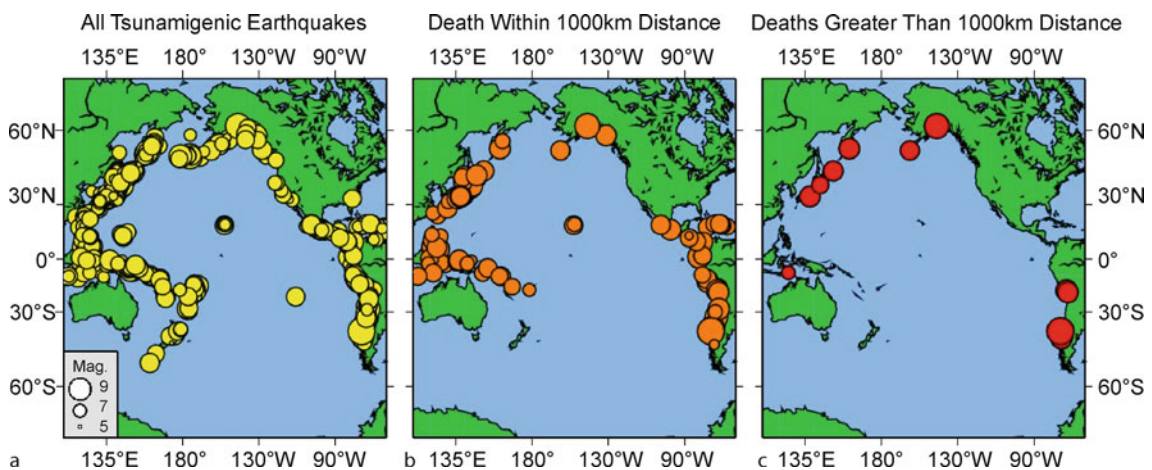

While some tsunamis are destructive, most are rather small, producing few if any casualties and little or no damage, although they are easily observable on marograms (Fig. 1). On the basis of how widespread their effects are, tsunamis can be classified as local (within 100 km of the epicenter), regional (up to 1000 km from the epicenter) or teletsunamis (greater than 1000 km from the epicenter). In the Pacific Basin there are warning centers designed to respond to tsunami threats on each of these scales.

The Richard H. Hagemeyer Pacific Tsunami Warning Center (PTWC) provides basin-wide warnings to the coastal areas of the Pacific basin. PTWC also functions as a local tsunami warning center for the Hawaii region. Other local warning centers include CPPT (French Polynesia Tsunami Warning Center) which is based in Tahiti,

GFZ-Indonesia which is based in Jakarta provides local warnings for Indonesia, and Japan's JMA (Japan Meteorological Agency) which operates Japan's tsunami warning centers provides local tsunami warnings to Japan. Examples of regional warning centers include JMA which provides regional tsunami warnings to the Northwest Pacific and the West Coast and Alaska Tsunami Warning Center (WC/ATWC) which provides regional and local warnings to the US mainland coasts and the west coast of Canada.

The tsunami warning centers themselves are not a complete tsunami warning system, they are simply the first of line of defense within the warning system. The warning system consists of three main components a) the tsunami warning centers, b) emergency management/civil defense authorities who receive tsunami warning center message products and c) a public in coastal areas that is educated in how to respond to tsunami emergencies. If any of these three components are lacking, the tsunami warning system can fail. Unfortunately, none of these components existed in the Indian Ocean at the time of the December 2004 Sumatra earthquake.

The greatest challenge for a tsunami warning system, particularly in the near field, is the slow (in terms of rupture speed) or "tsunami" earthquake. Tsunami earthquakes are so-called because they generate much larger than expected tsunamis given the size of the seismic moment of the earthquake [47]. In a well functioning tsunami warning system, residents in coastal areas are educated to immediately move inland and onto higher ground if they feel strong ground shaking and not wait for an offi-

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 1

Epicenters of tsunamigenic earthquakes occurring in the Pacific since 1 A.D. Of those earthquakes that do produce a tsunami a, most tsunamis cause no damage. Most events that cause casualties and/or damage do so within 1000 km of the epicenter b, leaving only a few great earthquake sources that generated tsunamis which caused casualties and/or damage more than a 1000 km from the epicenter, c. Data provided by the NOAA National Geophysical Data Center (NGDC), ([www.ngdc.noaa.gov/hazard/tsu.html](http://www.ngdc.noaa.gov/hazard/tsu.html))

cial tsunami alert [24]. However, because a tsunami earthquake produces much less radiated high frequency body-wave energy than normal, even a large (in terms of moment magnitude) tsunami earthquake may not be strongly felt in the near field so that this strategy of having people self-evacuate upon feeling strong ground shaking will not work. This was, unfortunately, made dramatically clear by the Java earthquake of July 17, 2006. The tsunami generated by the Java earthquake killed  $\sim 500$  people as many residents in coastal areas near the earthquake did not feel strong shaking [83]. Tsunami warning centers need to be able to properly detect the occurrence of these tsunami earthquakes.

### Tsunami Warning Center Operations

Tsunami warning center functions are much like those of a seismic observatory, i. e.: detecting, locating and characterizing the source of major earthquakes occurring around the world as fast as possible. Depending on the earthquake's location (underwater vs. inland), depth below the surface, and magnitude, tsunami warning centers may issue an official message product to advise Civil Defense/Emergency Management authorities within the warning centers AOR (area of responsibility), of the occurrence of a large earthquake and its potential for generating a tsunami. The PTWC, located in Ewa Beach, Hawaii, provides advance warning of the generation of a destructive tsunami for the Pacific Ocean Basin, and on an interim basis, for the Indian, and Caribbean ocean basins.

After consultation with the member states of the Pacific Tsunami Warning System (PTWS), the PTWC has agreed to issue tsunami bulletins for the Pacific Ocean Basin according to the criteria shown in Fig. 2.

**An Observatory (Earthquake) Message:** The PTWC sends observatory messages to certain seismological observatories and organizations for any earthquake in or near the vicinity of the Pacific, Indian, or Caribbean ocean basins for seismic events when the magnitude is larger than about 5.5. This unofficial message contains only the earthquake's epicentral location, origin time, depth, magnitude, and a list of stations used in computing these parameters. These messages contain no evaluations regarding seismic or tsunami hazard, as the magnitude of the earthquake is far too small to have a significant tsunami generation potential.

**A Tsunami Information Bulletin (TIB):** The PTWC issues this message product for any earthquake in or near the vicinity of the Pacific Basin with a magnitude in the range  $6.5 \leq M_W \leq 7.5$ . A TIB states that a destructive tsunami is not expected outside the area of the epicenter.

<b>Mw less than 6.5</b> (Mw: Moment Magnitude)	<b>Earthquake Message Only</b>
<b>Mw 6.5 to 7.5</b>	<b>Tsunami Information Bulletin</b>
<b>Mw 7.6 to 7.8</b>	<b>Regional Tsunami Warning</b>
<b>Mw &gt; 7.8</b>	<b>Expanding Warning / Watch</b>
<b>Confirmed Teletsunami</b>	<b>Pacific-Wide Warning</b>

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 2  
PTWC Bulletin Criteria for the Pacific Basin

However, it does warn of the possibility of a destructive tsunami along coastlines within 100 km of the epicenter.

**A Fixed Regional Warning Bulletin:** The PTWC issues this message product for shallow underwater earthquakes (depth  $< 100$  km) with a magnitude in the range  $7.6 \leq M_W \leq 7.8$ . This bulletin warns of the possibility of a regionally destructive tsunami within 1000 km of the epicenter. All regions within 1000 km of the epicenter are thus initially placed in a warning.

**An Expanding Watch/Warning Bulletin:** The PTWC issues this message for shallow underwater earthquakes with magnitude  $M_W \geq 7.9$ . This criteria is similar to the fixed watch/warning with the exception that this bulletin also warns of the possibility of a destructive tsunami traveling greater than 1000 km away from its source area. The use of the term "expanding" stems from the fact that the watch and warning regions expand across the Pacific as time progresses until the watch/warning is canceled. The extensions of the watch/warning area are referenced to the leading edge of the tsunami waves at the time the bulletin is issued. Areas within 3 to 6 h tsunami travel-time from the predicted current leading edge of the tsunami are placed in a watch. Areas within 3 h tsunami travel-time are placed in a warning. All other areas are placed in an advisory. Because of the expanding nature of the watch/warning, areas that were initially only placed in an advisory may eventually come to fall into the watch or warning region. If no potentially destructive tsunami is detected by sea-level stations, the watch/warning is canceled. On the other hand, if the data provided by sea-level stations provide evidence that a destructive tsunami

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 3  
Retroactive performance based on current bulletin criteria

is moving across the Pacific, the PTWC may upgrade to its most severe message, the Pacific-Wide Warning. A Pacific-Wide Warning is a tsunami warning for all coasts in the Pacific Basin. Before issuing a Pacific-Wide Warning the scientist on duty must confirm the presence of a potentially dangerous tsunami on sea-level instruments.

Figure 3 summarizes our response in retrospect, had these criteria been in place over the 20th century, after applying them to the earthquakes and tsunami that occurred during this period. The application of these criteria would have resulted in the issuance of a TIB, but no warning for 23 destructive locally generated tsunamis occurring over the last century in the Pacific Basin. At larger distances from the earthquake, the PTWC would have issued a *Fixed Regional Warning Bulletin* ahead of 20 destructive tsunamis generated in the last century, an *Expanding Watch/Warning Bulletin* for thirty-eight destructive tsunamis, as well as eight major Pacific Basin wide tsunami warnings within the same time period.

Coastlines close to the earthquake epicenter can experience tsunami waves within two to fifteen minutes after the earthquake; hence a local tsunami warning needs to be issued within a few minutes to be effective. This requires access to real-time data provided by a dense local network of seismic stations near the epicenter that allows both, the rapid location, and source characterization of the earthquake. In the case of the Hawaii region, the PTWC uses data from its own seismic network, and from the dense

seismic network maintained by the USGS Hawaii Volcano Observatory (HVO) to rapidly detect Hawaii earthquakes. These data enabled PTWC to issue an information bulletin to the state of Hawaii, and to the Pacific Basin for the Kiholo Bay earthquake ( $M_w$  6.7) within 3 min of the origin time of the earthquake [42]. However, without access to dense local seismic networks around the Pacific rim, the PTWC is unable to issue timely warnings for populations in the immediate vicinity of large earthquakes outside of Hawaii. As a result, the PTWC does not have the capability of functioning as a local warning center for areas outside of Hawaii.

The WC/ATWC of the US National Weather Service has access to dense local seismic networks on the US mainland, Puerto Rico, and Canada, and can therefore provide rapid warnings to the US and Canadian West Coast as well as to Puerto Rico and the Virgin Islands. Japan has a similar capability for its coastlines, and spurred on by the December 2004 Sumatra earthquake, several other nations such as Indonesia and New Zealand, for example, are rapidly developing and improving their seismic networks in an effort to improve their tsunami warning capabilities.

### Seismic Methods

To rapidly detect, locate, and characterize the source of earthquakes occurring around the world, tsunami warning centers rely on the Global Seismic Network (GSN

USGS/IRIS) which has many contributors in the US and worldwide. It is this unfettered access to real time seismic data supplied by a number of different networks that makes a basin-wide tsunami warning center possible. To rapidly deal with the threat posed by locally generated tsunamis to the state of Hawaii, PTWC processes seismic data from about 70 stations located in the Hawaiian Islands. The USGS HVO's dense network supplies most of this data. The US tsunami warning centers use the Earthworm software developed by the USGS to import and export seismic data [46].

PTWC duty scientists can receive automatic pages at any time, for any earthquake with magnitude  $M_W$  above  $\sim 5.5$ . The system generating these pages combines Evan's and Allen's [23] teleseismic event detection algorithm, adapted for broadband data by Wither's [84], and Whitmore's [81] teleseismic picker and associator. In the Hawaiian Islands, the application of Hirshorn and Lindh's [40] algorithm notifies duty scientists for earthquakes with magnitudes larger than about 3.5 within 10 to 20 s of the earthquakes origin time. Other software automatically locates the event, and provides a first estimate of the earthquake's magnitude, and other source parameters in real time [3,39,40,45]. PTWC duty scientists then refine and supplement the software's automated real-time hypocenter location and magnitude estimates. Determining the earthquake's depth is particularly important as earthquakes occurring at depths greater than about 100 km generally don't cause tsunamis.

Earthquakes are located using P-wave arrival times recorded at a number of seismic instruments. As both the locations of seismic instruments and P-wave travel-times as a function of distance are well known, a process analogous to triangulation is used to locate the earthquake. The pickers and associators perform these functions automatically on a continuous basis.

While the depth of the earthquake can be estimated on the basis of P-times alone, a more robust result often requires the addition of depth phases such as pP which is a P-wave that travels directly up to the earth's surface from the earthquake source and reflects once off of the Earth's surface before arriving at the seismometer. The duty scientists use pP arrival times to refine hypocentral depths of distant earthquakes (teleseisms). For earthquakes in Hawaii, observed at local distances, the S-wave arrival time would be useful for constraining earthquake depth. However, automatic picking of S-wave arrival times is not yet robust, and manual picking and incorporation of S-wave arrival times into the analyzes by a duty scientist would take too long in the local earthquake case. In addition, as the deepest earthquakes in Hawaii have a hypocenter lo-

cated about 50 km deep, (Fig. 6) which is comparable to the rupture length of an earthquake over about magnitude seven, the PTWC's local tsunami warning criteria are currently based on magnitude only.

Seismologists use a panoply of different magnitudes to characterize the seismic source. These different methods examine different parts of the seismic wave train, such as short and long period body waves (seismic waves that travel through the earth's interior like the P- and S-waves) and long period surface waves (slower seismic waves that are constrained to travel along the earth's surface). Most of these magnitude scales were developed to estimate the same quantity; the energy released by the earthquake as radiated seismic wave energy,  $E_R$ . Traditional magnitude measures such as  $M_L$  [66], and  $m_b$  (a shorter period variant of  $m_B$  Gutenberg [30,31] that examines high frequency body waves). The Gutenberg surface wave magnitude  $M_S$  [9], modified by Vanek [75] as well as the newer  $M_m$  Okal and Talandier [63], or mantle magnitude are derived from the surface waves. A relatively new and quick method,  $M_{wp}$  analyzes long period P-waves [73,74,82]. The  $M_{wp}$  magnitude is now the magnitude used in the decision process for deciding which if any official message product to issue, supplanting the  $M_S$  method which had been used for over 50 years. For large earthquakes, duty scientists also routinely estimate  $M_m$ , a very long period surface wave magnitude based on mantle waves with periods in the range 50–410 s [63]. The relationship between these magnitudes, each looking at different parts of the seismic wave spectrum of an earthquake, can be used to characterize the earthquake source [2,16,17].

When evaluating the tsunamigenic potential of an event, PTWC duty scientists also compute the quantity  $\log_{10}(E_R/M_0)$ , known as "Theta",  $\Theta$ , where  $M_0$  is the seismic moment [1]. Newman and Okal [62] showed that  $\Theta$  is anomalously small for tsunami earthquakes.

Since about the mid 1990's the two US Tsunami Warning Centers response times to potentially tsunamigenic teleseisms has decreased dramatically due to the much larger amounts of seismic data that they now receive, and to the switch from the slower  $M_S$  magnitude method to the faster  $M_{wp}$  moment magnitude method for their initial messages (Fig. 4a). For local events, using the real-time associator binder\_agl [45], and the very fast  $pMag$  scale [40], has brought the PTWC's response time down to less than 3 min (Fig. 4b).

## Earthquake Source Parameters

A fundamental problem with traditional magnitude estimates such as  $M_L$ ,  $m_b$ , and  $M_S$ , is that they are based

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 4  
 Elapsed time from earthquake origin time to issuance of first official message product for **a** earthquakes outside the Hawaii Region and **b** for earthquakes within the Hawaii Region

on the amplitudes of relatively short period seismic waves with periods usually less than 3 s for  $m_b$  and  $M_L$ , and about 20 s for  $M_S$ . When the largest rupture dimension of the earthquake exceeds the wavelength of these seismic waves, which is about 50 km for the 20 s period surface waves used for  $M_S$  [48,49], these magnitude values will start to “saturate”. Saturation in this case means that these magnitude measures will underestimate the true size of the earthquake when the periods of the amplitudes on which they are based are shorter than the corner period of the earthquake’s seismic wave spectrum [2,16,17] (see Fig. 5).

Another, equivalent explanation is that these magnitude methods, which look at waves with periods of a fraction of a second to a few tens of seconds, cannot sample enough of the energy released by an earthquake whose source duration (the length of time over which the rupture occurs) is many times larger than the periods used by these methods. As the earthquake becomes very large, one needs to examine longer period waves to avoid saturation.

K. Aki used a spectral representation to establish that earthquakes of varying size had spectra of similar shape, differing primarily in the low frequency ampli-

### Saturation of Magnitude Scales

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 5

Saturation of different classical magnitude scales with respect to non-saturating moment magnitude according to Kanamori [50]. Note that  $m_B$  refers to the original Gutenberg–Richter [32,33] body-wave magnitude scale based on amplitude measurements made on medium-period broadband instruments. It saturates at larger magnitudes when compared to the short-period based  $m_b$ ,

tude, proportional to seismic moment, and the location of the “characteristic frequency” (corner frequency of the source spectrum) which he related to the characteristic length scale of an earthquake [2]. Subsequent studies by Brune [16,17], and Savage [68] also related the corner frequency to the dimensions of the fault plane.

To circumvent the saturation problem, Kanamori defined a new magnitude scale, the moment magnitude  $M_w$ , [48], in terms of a minimum estimate of the total co-seismic strain energy drop,  $W_0$ , via Gutenberg and Richter’s energy-magnitude relationship [33]. The  $M_w$  scale, more properly a magnitude that describes the total “work” required to rupture the fault, is computed from the seismic moment,  $M_0$ , assuming 1) that the stress changes associated with large earthquakes are approximately constant, and 2) that the stress release during an earthquake is about the same as the kinetic frictional stress during faulting.  $M_w$  and its agreement with the  $M_L$  and  $M_s$  magnitude scales in their unsaturated ranges was discussed by T.C. Hanks and H. Kanamori [34] while Kanamori [50] discusses additionally the average relationship of  $M_w$  with  $m_b$  and  $m_B$ , also in the range where these magnitudes saturate (see Fig. 5).

### Traditional Amplitude Based Magnitudes at the PTWC

**Local Earthquake Magnitude Methods** Hirshorn and Lindh [40] developed a short period P-wave magnitude scale, called  $pMag$ , which is based on the average of the ab-

solute values of the amplitudes of the first three half-cycles of the initial p-waves recorded, at local distances, on short period seismometers [40,45]. The  $pMag$  scale is based on the assumption that the decrease of locally recorded initial P-wave amplitudes with increasing hypocentral distance shares a common decay curve in a given geographic area, independent of the magnitude of the earthquake. Lindh and Hirshorn incorporated  $pMag$  into Carl Johnson’s [46] local p-wave associator, binder\_agl, enabling automatic pages, containing the hypocentral parameters and a the lower bound magnitude estimate provided by  $pMag$ , within about 10 to 20 s of an events origin time. At the PTWC, the System for Processing Local Earthquakes in Real Time (SPLERT) is based on this software.

PTWC also uses a very band-limited  $M_L$  scale, based on the maximum amplitudes measured on the horizontal components of short period seismograms recorded at local hypocentral distances from earthquakes that occur in Hawaii. These short period waves attenuate about 6 times less along the path between the hypocenter and recording stations for the “deeper” population of Hawaiian earthquakes (with hypocenters (Fig. 6) located between 20 and 50 km depth), then they do along the path from source to receiver for the “shallower” event population in the lower oceanic crust (about 10–20 km below the sea surface). For this reason, PTWC adds 0.8 magnitude units to the  $M_L$  values obtained for events with hypocentral depths  $\geq 25$  km.

Because of the bimodal depth distribution of Hawaii earthquakes (Fig. 6.) our  $M_L$  calculation requires only a good enough depth estimate to discriminate between these two populations.

**Teleseismic Magnitude Methods** PTWC’s body wave magnitude method is called  $bMag$  and has similarities to the intermediate period broadband body wave  $m_B$  magnitude as defined by IASPEI. The IASPEI  $m_B$  [11,16] is based on Gutenberg’s [30,31] and Gutenberg and Richter’s  $m_B$  [32,33].  $bMag$  uses a 90 s window of broadband vertical component seismogram starting 30 s prior to the arrival of the P-wave. This window is band-pass filtered between .3 s and 5 s. The largest amplitude and its period found in the 60 s after the first P-wave arrival are chosen for use in the magnitude formula. In PTWC’s implementation, the formula used is the same as Gutenberg and Richter’s [32,33] relation, adopted by IASPEI for  $m_B$ :

$$bMag = \log(A_{\max}/T_{\max}) + Q(\Delta, z),$$

where  $\Delta$  is the epicentral distance ( $15^\circ \leq \Delta \leq 90^\circ$ ),  $z$  is the hypocentral depth,  $A_{\max}$  is the maximum wave amplitude obtained from the band-pass filtered record, and  $T_{\max}$

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 6

This figure shows the bimodal depth distribution of Hawaii earthquakes of  $M \geq 4$ , taken from the USGS Hawaiian Volcano Observatory (HVO) ANSS Catalog. The *top figure* is a histogram of all events binned by hypocentral depth. The *bottom figure* shows the magnitude vs. hypocentral depth for each event

is the period of the wave with the maximum amplitude. Gutenberg and Richter's [33] table of  $Q(\Delta, z)$  is used to provide the distance and depth correction. The largest amplitude found in the 30 s prior to the P-wave arrival time is used as the basis for the signal to noise ratio.  $bMag$  differs from the IASPEI  $m_B$  in three respects,

1.  $m_B$  uses the largest amplitude wave in the P-wave coda up to the arrival of the PP phase,
2.  $m_B$  uses a slightly different distance range ( $15^\circ \leq \Delta \leq 90^\circ$ ), and
3. for  $m_B$ , the seismogram is band-pass filtered using the band .3 s to 5 s.

$bMag$  will saturate at lower magnitudes than  $M_S$  does, so it is of limited use for large earthquakes. However,  $bMag$ , is still useful for three main reasons

1. unlike  $M_S$ ,  $bMag$  has a correction for the depth of the event's hypocenter,
2. it is useful for determining the magnitude of moderate earthquakes that occur as aftershocks of much larger earthquakes, e.g. when longer period energy is

still present in the signal from an earlier, larger event, that can adversely affect magnitude methods based on longer periods, and

3. by comparison with magnitudes based on longer periods, such as  $M_w$ , it can also provide a way to detect slow or tsunami earthquakes.

In computing  $M_S$  (first proposed by Gutenberg [9] and later revised by Vanek et al. [75]) at the PTWC, we band-pass filter 14 min of the broadband velocity seismogram with a 7 s band, from 16 to 23 s, starting 3 min before the expected arrival time of the surface waves. We then apply the following equation, similar to the IASPEI [11,75] formula:

$$M_S = \log_{10}(A_{\max}/T_{\max}) + 1.66 \log_{10}(\Delta) + 3.3 + \text{correction}.$$

The *correction* term is 0 for epicentral distances,  $\Delta$ , greater than  $16^\circ$ , and  $0.53 - 0.033\Delta$  for  $\Delta$  less than  $16^\circ$ . Note that the IASPEI implementation considers a much greater range in periods from 3 to 60 s for  $T_{\max}$  and has no need for the *correction* term. The *correction* term allows the US TWC's to compute the  $M_S$  magnitudes from stations as

close as 600 km to the epicenter at a period of 20 s. This method is susceptible to saturation effects as the magnitude reaches the high 7's.

Although  $M_S$  is no longer used as the basis for issuing bulletins, it is still helpful in diagnosing deep earthquakes, and for comparing the amount of 20 s radiated energy to the amounts of radiated energy at other periods. Deep earthquakes do not excite large surface waves. Hence if  $bMag > M_S$  the hypocenter is likely to be deep.

### The $M_{wp}$ Method

The broadband P-wave moment magnitude,  $M_{wp}$ , has replaced  $M_S$  as the magnitude upon which the US TWCs initial tsunami messages are based [73,74,82]. This is because  $M_{wp}$  uses P-waves, recorded at any epicentral distance, up to about  $90^\circ$ , when the observed initial P-waves are affected by refraction due to the earth's outer core.  $M_{wp}$  is obtained much quicker than  $M_S$ , which is based on the slower traveling surface waves, and because  $M_{wp}$  examines much longer period waves than the 20 s surface used by  $M_S$  making it less susceptible to the saturation effects discussed above.  $M_{wp}$ , as implemented at the PTWC, uses the first 120 s of the vertical component, broadband velocity seismogram, beginning at the P-wave arrival time (gray trace in Fig. 7).

The derivation of  $M_{wp}$  assumes that we can obtain the seismic moment,  $M_0$ , from the far-field P- and/or pP-wave portion of the vertical broadband displacement waveform,  $u_z(x_r, t)$ , using

$$M_0 = (4\pi\rho\alpha^3 r/F^P) \text{Max} \left| \int u_z(x_r, t) dt \right| ,$$

where  $\rho$  and  $\alpha$  are the density and P-wave velocity averaged along the propagation path,  $r$  is the epicentral distance, and  $F^P$  is the earthquake source radiation pattern [73,74,82]. At the PTWC, we follow Tsuboi [73], approximating  $\text{Max} \left| \int u_z(x_r, t) dt \right|$  by the first significant or "big" peak in the absolute value of the integrated displacement record. We prefer to use velocity seismograms,  $v(t)$ , from STS-1 or KS54000 broadband seismometers as there is then no need to deconvolve the instrument response from the data. We simply scale the data by a gain factor, because we can assume that the instrument response function is flat in the frequency band of interest. For the STS-1, or the KS54000, which both have a flat velocity up to about 350 s, this works for all but the very largest or slowest earthquakes.

We first remove any pre-event offset from  $v(t)$ , ending before the P-waves from the earthquake arrive, inte-

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 7

The first 2 min of the broadband vertical velocity seismogram (gray) recorded by the GSN USGS/IRIS broadband station COCO, on Cocos Island, about 15 degrees south of the epicenter of the  $M_W$  9.2 Sumatra Earthquake of Dec. 26, 2004. Note that this portion of the broadband velocity seismogram is not clipped. This instrument, a KS54000, has a flat frequency response to velocity to a period of about 350 s. The blue trace is the integrated displacement record (doubly integrated velocity), and the green trace is  $M_{wp}$  as a function of time

grate  $v(t)$  twice, and then multiply the absolute value of each data point by  $4\pi\rho\alpha^3$  to obtain  $M_0(t)$  in N-m (the blue trace in Fig. 7). We then apply the standard IASPEI moment magnitude formula [34]:

$$M_W = (\log_{10} M_0 - 9.1)/1.5$$

to  $M_0(t)$ , to calculate  $M_W(t)$  (the green trace in Fig. 7). To correct for the radiation pattern,  $F^P$ , we then add 0.2 to the average of the individual  $M_{wp}$  values, each obtained at different azimuths and distances from the epicenter. This is because  $\int (F^P)^2 d\Omega = 4/15$ , where  $\Omega$  is the azimuthal angle of the observation around the epicenter, and  $\sqrt{4/15} = 0.52$ . Therefore, we multiply the averaged  $M_0$  by 2, which is equivalent to adding 0.2 to  $M_{wp}$ . Finally, we apply the Whitmore et al. [82] magnitude dependent correction,  $M_{wp} = (M_{wp} - 1.3)/0.843$ , to get a final value for  $M_{wp}$ .

Figure 8 compares these final  $M_{wp}$  values resulting from this procedure with the Harvard moment magnitude  $M_W$  estimated from their CMT [19] solutions.

For some complex earthquakes, such as the  $M_W$  8.4 [19] Peru earthquake of June 21, 2001, or the great  $M_W$  9.2 [5,65,71] Sumatra earthquake of December 2004,  $M_{wp}$  (7.4 and 8.1, respectively) will underestimate  $M_W$ ,

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 8

A Scatter plot of average  $M_{wp}$  versus the  $M_W$  [19] for a set of 260 earthquakes with magnitudes in the interval  $4.8 \leq M_W \leq 9.2$  occurring from 1994 through October of 2007. Whitmore et al. [82] found that with the application of an empirical correction made to the results, satisfactory results could be obtained. Our linear, least squares fit to the 155 earthquakes (red stars) yielded a slope of 0.83, close to the Whitmore et al. [82] slope of 0.84. Since April of 2002, we have used this corrected relationship (green circles filled in yellow) to calculate  $M_{wp}$

when the first moment release is not the largest. In contrast, the PTWC's final estimate of  $M_{wp}$  8.4 for the  $M_W$  8.6 [19] Nias event of March 28, 2005 was acceptable, as it was for 9 other earthquakes in the range  $8.0 \leq M_W \leq 8.4$  (Fig. 8).

The PTWC also uses  $M_{wp}$  for large local earthquakes, occurring in the Hawaiian Islands [41,42].  $M_{wp}$  is based on the far field formulation for P-wave displacements [73]. For earthquakes whose largest source dimension is small compared to the distances at which the P-waves are observed, this assumption is satisfied. Up to approximately  $M_W$  7.5,  $M_{wp}$  calculated from these locally recorded, far field P-waves agrees well with the Harvard  $M_W$  values for the same events [41,42]. For example the PTWC calculated a value of  $M_{wp}$  6.5 for the  $M_W$  6.7 [19] Kiholo Bay event within two minutes of the initiation of rupture at the hypocenter [41,42].

### The Mantle Magnitude ( $M_m$ ) Method

Emile Okal and J. Talandier developed the  $M_m$  method in 1989 [63]. The mantle magnitude is related to the moment magnitude via the simple expression  $M_W = M_m/1.5 + 2.6$ . This work was inspired by the need to develop a magnitude method for tsunami warning centers that would not suffer the saturation problem of  $M_S$  [64]. Not only may  $M_S$  saturate as the magnitude becomes large ( $> 8$ ) but slow earthquakes can cause  $M_S$  to be seriously deficient and  $bMag$  even more so. Severely underestimating the magnitude of an earthquake can lead to a failure to warn. PTWC's implementation of the  $M_m$  method is based on analyzing Rayleigh waves obtained on vertical component seismograms.

$M_m$  being based on slow traveling long period surface waves, is available too late to be used in the decision pro-

cess for issuing an initial bulletin. Notwithstanding, it does provide a useful check on the magnitude obtained from the  $M_{wp}$  method and if there is a discrepancy between  $M_{wp}$  and  $M_W(M_m)$  on the order of 2–3 tenths or more in the 7+ magnitude range, the duty scientist may instead use the results of the  $M_m$  method in subsequent bulletins. The  $M_m$  method overcomes the limitation of saturation because it is a variable period magnitude. Multiple values of  $M_m$  are routinely computed for a number of fixed periods ranging from 50 to 270 s for each station. Because  $M_m$  may saturate at the smaller periods for great earthquakes, while at longer periods  $M_m$  will be unsaturated, Okal and Talandier's [63] procedure was to choose the largest  $M_m$  mitigating the effects of saturation.

$M_m$  is more complicated than the other methods described here as it uses frequency domain deconvolution. This can cause problems due to deconvolution noise at low magnitudes, where the amplification of noise by the deconvolution process at long periods may result in spurious magnitudes. Thus  $M_m$  works best with very long period broadband seismometers such as the KS54000's, KS36000's and STS-1's. While STS-2 seismometers tend to do well, however, the shorter period broadband seismometers tend to behave poorly at the longest periods [79]. Using the maximum  $M_m$  obtained for each sta-

tion proved to be suboptimal due the heterogeneous distribution of instruments coupled with the total automation of the procedure at the PTWC. Weinstein and Okal [79] devised a sampling method that alleviates most of these difficulties in PTWC's implementation of  $M_m$ .

The December 2004 Sumatra earthquake showed that for earthquakes with an unusually long source duration (in this case  $\sim 600$  s), even  $M_m$  at 270 s will saturate. Hence PTWC's  $M_m$  implementation will now automatically extend the period range to 410 s when the magnitude exceeds 8.0. At 410 s  $M_W(M_m)$  is 8.9 [79] for the December 2004, Sumatra earthquake, still deficient, but a marked improvement over the moment magnitude 8.5 obtained by PTWC and 8.2 obtained by the USGS (NEIC Fast Moment Tensor) on Dec. 26, 2004.  $M_m$  normally uses a 660 s window of the surface wave train, but when  $M_m$  exceeds 8.0, the window expands to 910 s. Given the mix of instruments and their distribution used at PTWC, and the effects of broadband deconvolution noise, Weinstein and Okal [79], found that the  $M_m$  method was not useful for  $M_W < 6.0$ .

Figure 9 compares  $M_W(M_m)$  values obtained for more than 200 recent earthquakes with the respective  $M_W$  values of HRV/GCMT [19] for the same events. PTWC's implementation of  $M_m$  of still tends to over estimate  $M_W$  by about .15 magnitude units for  $M_W < 7.0$ .

**Rupture Slowness Estimation (Theta Program)**

One way in which the occurrence of a tsunami earthquake may be indicated is if  $bMag$  and/or  $M_S$  are significantly smaller than  $M_W$  obtained from the longer period P-waves, or longer period mantle waves. This is made clear in Fig. 10. Note the population of 4 tsunami earthquakes that fall well off the trend. The short period magnitudes may also simply be deficient simply due to the size of the earthquake. Measuring the “rupture slowness” of the earthquake can further aid the warning centers in deciding between the two possibilities. As can be determined from Fig. 10, the body wave magnitude for July 2006, Java earthquake was deficient by nearly 1.5 magnitude units.

As mentioned earlier, a fundamental characteristic of a tsunami earthquake is the slowness of the rupture speed. Newman and Okal [62] showed that the log ratio of the radiated energy  $E_R$  [9,10], to the seismic moment  $M_0$ ,  $\text{Log}_{10}(E_R/M_0)$  (also denoted by Theta, or “ $\Theta$ ”) is anomalously small for tsunami earthquakes. A number of factors can affect this ratio such as rupture velocity, stress-drop/apparent stress, fault plane geometry, maximum strain at rupturing, and directivity (bi-lateral vs. unilateral rupture). However, for shallow thrust, low stress-

drop subduction zone earthquakes, unusually slow rupture velocity may have the largest influence on the value of  $\Theta$ .

Newman and Okal [62] showed that for tsunami quakes, the value of  $\Theta$  is usually about  $-6.0$  or less. For an earthquake with a unilateral rupture with nominal speed ( $\sim 3$  km/s), theory suggests that  $\Theta$  is about  $-4.9$  [26,69,76]. Weinstein and Okal [79] extended the original dataset of Newman and Okal [62] by including an additional 118 earthquakes. The mean value of all  $\Theta$  values is approximately  $-5.1$ . However, when averaged by event, the distribution of  $\Theta$ 's peaks precisely at  $-4.9$ , in accordance with theoretical expectations. Given the standard deviation of  $0.39$  for all  $\Theta$ 's (for the 118 earthquakes), Weinstein and Okal [79] found that values of  $\Theta$  around  $-6.0$  or below are more than  $2\sigma$  off the mean and hence clearly anomalous.

The PTWC uses broadband vertical component seismograms, obtained in the distance interval  $25^\circ \leq \Delta \leq 90^\circ$ , to compute  $\Theta$ . A window of  $75$  s is used starting approximately  $5$  s before the P-wave arrival. This is done to insure that the first arrivals are not missed by the integration. This window is deconvolved with the instrument response and the radiated energy contained between  $.1$  Hz and  $2$  Hz is computed.

In general it is thought that anomalously slow rupture speed is due to either low rigidity sediments in the fault or faulting through an accretionary prism [6,8,25,47,52,67]. In either case, the small shear rigidity associated with weak materials retards the rupture speed. As to why “slow” earthquakes produce more destructive than expected tsunamis, one can look at the well-known relation for moment magnitude:

$$M_0 = \mu Ad,$$

where  $\mu$  is the shear rigidity,  $A$  is the fault plane area and  $d$  is the average slip over the fault plane. Thus for two quakes with the same  $M_0$  and all other properties equal except for  $\mu$  and hence rupture speed, the slow quake requires a correspondingly larger slip,  $d$ , in order to achieve the same moment as the earthquake with a nominal value of  $\mu$  and hence normal rupture speed.

One problem with  $\Theta$ , is that it can be misleading and occasionally yield false indications of rupture slowness. This was made apparent by the Peru earthquake of June 23, 2001. This earthquake began with a initial event that had a moment magnitude of approximately  $7.4$ , followed almost  $60$  s later by a much larger event, which had a moment magnitude of almost  $8.4$ . [7,27,55]. Due to the  $60$  s delay, the  $\Theta$  computation used mainly P-wave coda from the first shock, and little if any energy from the main

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 10

Comparison between short-period  $\hat{m}_b$  [43] and  $M_W$  for earthquakes with  $M_W > 6$ . Note the cluster of red dots representing tsunami earthquakes. This illustrates the diagnostic potential of short-period/long-period magnitude ratios to identify unusually slow earthquakes with high tsunami potential (Kanamori 2007, Talk at the PTWC in April of 2007)

shock. As a result the PTWC initially obtained a  $\Theta$  of  $-6.1$ , using a moment based on  $M_m$ , making this earthquake appear very slow indeed. However, this result is spurious and was due to the complexity of the earthquake itself and not to actual slowness of the rupture.

Weinstein and Okal [79] found that by sliding the window over which  $\Theta$  is computed forward in time,  $\Theta$  would increase as the  $\Theta$  window overlapped with the occurrence of the main event of the Peru 2001 earthquake. Indeed for a window offset of 70 s,  $\Theta$  increases to  $-5.6$ , which is a strong trend to slowness, but not a slow or tsunami quake. This was further borne out by the size of the tsunami, which while detected on sea-level instruments around the Pacific (more than 2 m peak-to-peak in Chile), was not destructive outside of Peru.

Weinstein and Okal [79] explored the windowing technique and found that in actuality, it was a more comprehensive method than the single determination of  $\Theta$  (zero offset). Computing theta in a succession of windows separated in time by 10 s (each window spanning 70 s) up to 100 s post P-wave arrival yields a better method of detecting slowness (see Fig. 11). What Weinstein and Okal [79] found is that for true tsunami earthquakes, the variation of  $\Theta$  with offset time was small, generally no more than 0.1 log units over the entire 100 s. It is this flat trend that is probably the best discriminant for tsunami earthquakes.

In effect, the curve resulting from the window-offset technique tells us something about the source duration of the earthquake. Gigantic earthquakes have long source

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 11  
 The variation of  $\Theta$  with offset for a “normal” earthquake, b a “slow earthquake” (Java, 2006), and c a complex earthquake (Peru, 2008) respectively. In these plots  $\Theta$  is de-meaned (the mean is found on the bottom right of the plot in black) and the number next to the dots indicates how many stations were used in computing that value. These plots are taken from PTWC’s operational software

durations, and slow earthquakes have anomalously long source durations for their seismic moment. Therefore  $\Theta$  can be viewed as a measurement of how anomalous the source duration is in terms of whether the earthquake is anomalously slow, or simply anomalously large. It turns out that in the case of the Sumatra earthquake of December 2004,  $\Theta$  has little variation, even when the integration window is increased to 200 s and the offset carried out to 300 s. The magnitude of  $\Theta$  based on PTWC's  $M_W(M_m)$  of 8.5 was  $\sim -5.6$ , a trend to slowness, but not slow. Using the  $M_W$  based on normal mode studies,  $\Theta$  is  $\sim -6.1$  (with a 200 s integration window!) and discussion continues to the current day as to whether or not the Sumatra earthquake of 2004 was slow, simply had aspects of a tsunami earthquake, or none at all [5,20,53,57,70].

### Future Directions

Given the availability of high quality broadband seismic data, the tsunami warning centers can determine basic earthquake source parameters rapidly. However, the source characterization at the warning centers has rested largely on scalar measures of earthquake magnitude and slowness. The reasons for this are historical and practical. The warning centers have not always received the quantity of seismic data they do now, and in the interest of speed, the calculation of scalar measures can be accomplished with the data at hand in a small amount of time. One issue the PTWC faced during the 2004 Sumatra earthquake was that no near real-time magnitude method existed at the time that would correctly estimate the size of the Sumatra earthquake. Since then, new techniques have been developed to determine the magnitude of great earthquakes. Among these are techniques based on P-wave broadband signals [12,13,15,22,35,36,59,60] and the W-phase [21,52,55,58].

Hara [35,36] and Lomax et al. [59], both use techniques that involve estimating the source duration from the P-wave coda. This estimate is obtained by applying a high pass filter to the velocity seismogram, squaring the result and smoothing it. This procedure results in a relatively smooth curve or envelope function that tracks the variation in the velocity-squared time-series. The source duration estimate is then obtained by measuring the time from the beginning of the P-wave to the point when the envelope function falls below a certain percentage of its maximum value. However, these studies also show that the use of source duration alone is not a completely satisfactory basis for a moment magnitude estimate.

Lomax et al. [59] also measures the radiated energy of the P-wave in the interval between the P- and S-arrivals,

and uses both the radiated energy and source duration estimate to formulate a magnitude scale based on the relation  $M_0 \approx E^{1/2} \cdot T^{3/2}$  [76] where  $E$  is the high frequency radiated energy and  $T$  is the source duration estimate. Hara [35] uses the estimated source duration and the maximum displacement measured in the interval of the estimated source duration from a number of earthquakes to construct an empirical formula for the magnitude. Hara [36] showed that this technique also works well for tsunami earthquakes.

Lomax et al. [60] has derived a duration-amplitude procedure for determination of a moment magnitude,  $M_{wpd}$ , for large earthquakes within 20 min of the event origin time using teleseismic P-wave recordings. Their procedure determines apparent source durations,  $T_0$ , from high frequency, P-wave records, and estimates seismic moments via integration of broadband seismograms over the interval  $t_p$  to  $t_p + T_0$ , where  $t_p$  is the P-wave arrival time. The characteristics of this method make it an extension of  $M_{wp}$ .

De Kool et al. [22] present a variation of the  $M_{wp}$  method which estimates the asymptotic behavior of the integrated displacement seismogram caused by the P-wave arrivals. Their results for  $M_{wp}$  show less scatter than do the PTWC's  $M_{wp}$  values, described above. In addition, they have automated their method.

The method of Bormann and Wylegalla [13] and Bormann and Saul [14] calculate what they refer to as a cumulative body wave magnitude. They do this by summing up all of the peak velocity amplitudes for all pulses, which represent the rupturing of sub-faults, over the P-wave coda. For the December 2004 Sumatra earthquake they obtained an  $M_W$  of 9.3 in agreement with the estimate of Stein and Okal [71].

Since these methods are based on analyzing the P-waves in the P-S interval, they provide accurate moment magnitude estimates for great earthquakes within 20–25 min of the earthquake origin time. Therefore these estimates will come before estimates obtained by other methods like  $M_m$ .

The W-phase is a long period, up to 1000 s, wave that arrives before the S-wave (Fig. 12). It can be interpreted as a superposition of the fundamental, 1st, 2nd, and 3rd overtones of spheroidal modes or Rayleigh waves and has a group velocity of 8 km/s at 1000 s period, and 8.6 km/s at 100 s period [51,54]. Kanamori [54] has devised a magnitude scale based on the amplitude of the W-phase observed on deconvolved displacement records.

In addition to size and source duration, the warning centers are interested in more detailed properties of the source than can be obtained from the scalar measures we

## Wavelet Scalogram of the Sumatra-Andaman Earthquake

Earthquake Source Parameters, Rapid Estimates for Tsunami Warning, Figure 12

Top: (Fig. 2a and b from [58]). Displacement seismogram of the 2004 Sumatra-Andaman earthquake recorded at OBN. Bottom: Scalogram of top seismogram. A diagram which displays the wavelet scale as a function of time is called a "scalogram". Bottom figure shows the scalogram for the 2004 event. Color intensity at any point in the picture corresponds to the coefficient magnitude of a wavelet with a particular period at a particular point of the time series. The y-axis has been translated from wavelet scale into corresponding wavelet time period. The long-period component arrived at about 1500 s. The wavelet transform can simultaneously achieve: (1) Accurate frequency representation for low frequencies, and (2) Good time resolution for high frequencies [58]

have just discussed, such as direction of rupture and the distribution of slip along the fault. This information is important as it can be used by tsunami wave-height forecast models to better their predictions.

In the near future, the tsunami warning centers will incorporate the results of centroid moment tensors and finite fault modeling. Finite Fault modeling involves the inversion of seismic waveforms to recover more detailed information about the source process including the slip distribution, rupture propagation speed and moment release history [7,27,37,38,62,77]. Weinstein and Lundgren [80] explored the potential of a simple teleseismic P-wave inverse method for the rupture history of an earthquake for use in a tsunami warning center context. The calculations proceed quickly enough that a slip distribution may be available just a few minutes after a suitable set of P-waveforms are obtained. Hence finite fault modeling results can be used in tsunami wave height forecast

models to provide a timely initial estimate of tsunami wave heights.

The warning centers are also actively investigating the use of seismic arrays. Seismic arrays can be used to determine the direction along which the P-waves have propagated to the array. As the rupture propagates, this direction will change. By analyzing the seismic array data, this change in direction can be measured (by computing back azimuths) and the history of energy/moment release as well as the extent and direction of the rupture propagations can be determined [44,56].

### Acknowledgments

The authors greatly appreciate very thorough reviews by Kenji Satake, Anthony Lomax, Peter Bormann and our colleague Victor Sardina. Their comments greatly improved this manuscript. We also thank Paula Dunbar of

the National Geophysical Data Center for helping us obtain the data we needed and Nathan Becker's GMT artistry for Fig. 1. We also thank the PTWC for use of its facilities in preparing this manuscript.

### Glossary

**Dynamic stress change** a transient, often oscillatory change in the Earth's stress field.

**Static stress change** a permanent, step-like change in the Earth's stress field.

### Definition of the Subject

Geoscientists have long sought understanding of how earthquakes interact. Can earthquakes trigger other earthquakes? The answer is clearly yes over short time and distance scales, as in the case of mainshock – aftershock sequences. Over increasing time and distance scales however, this question becomes more difficult to answer. The study of dynamically triggered earthquakes explores the most distant boundaries over which earthquakes trigger other earthquakes.

Dynamic triggering to temporary and oscillatory fluctuations in the stress/strain regime in a volume of the Earth's crust. Dynamic stress fluctuations are associated with ground shaking resulting from either anthropogenic activities or natural sources. Dynamic triggering occurs as seismic waves from an initial earthquake propagate through the Earth's crust, triggering secondary earthquakes. Once the seismic wave train has passed and ground shaking ends in a given locale, the crust returns to its previous stress state modified by the combined stress drops associated with any locally triggered earthquakes.

Dynamic triggering includes wide ranging phenomenon, both geographically and in its characteristics. It has been observed across the globe in a variety of geologic

and tectonic environments. It has been shown to occur at distances from the initial earthquake rupture varying from meters [21,27,52] to over 11,000 km [103]. In the most distant cases, earthquake triggering results from dynamic stress perturbations as low as 0.01 MPa. Earthquakes have also been shown to trigger other earthquakes at a variety of time scales. In many cases triggering of earthquakes occurs during or within minutes to hours following the responsible seismic waves (e. g. [26,39,74,103]). In other cases, earthquakes occurring weeks to months after the initial earthquake have been interpreted as a delayed response to dynamic triggering (e. g. [41,89,102]). Delayed triggered responses may reflect a more complex series of physical processes. For example, dynamic waves may trigger an aseismic process such as fault creep or changes in a volcanic system, which subsequently triggers earthquakes secondarily [2,4,37,50].

This field has been an area of extensive research in the past twenty five years. It offers a potentially important key to improving our understanding of earthquake nucleation in that, in principle, we can determine in-situ perturbations in the local stress field that lead to earthquake nucleation and rupture. In particular, the availability of broadband seismic data near sites of triggered seismicity allows us to calculate the time history of stress field fluctuations responsible for earthquake nucleation given adequate knowledge of the local seismic velocity structure [28,38,103].

The study of dynamically triggered earthquakes can also help better characterize the physical condition of the Earth's crust at seismogenic depths. Many researchers were surprised that earthquakes could be triggered by stress perturbations as small as 0.01 MPa. This observation indicates the Earth's crust is on the verge of failure in areas with triggered responses to distant earthquakes. This field of research may also provide clues to the hydrologic regime at depth. It has long been recognized that water tables change in response to earthquakes thousands of km distant [17]. The link between dynamically triggered earthquakes and dynamically triggered hydrological changes is an active area of research [8,19,78].

Within the context of complexity and system science, [82] suggest that remotely triggered seismicity may reflect large activation correlation lengths (ACL) in fault systems and stress fields that have reached a state of self-organized criticality. This statistical physics approach to earthquake occurrence focuses on the exploration of both analog and computational models that can mimic observed dynamical space-time patterns spanning a wide range of spatial-temporal scales. It is not concerned with inferred (or “non-observable”) physical models for the lo-

cal processes linking dynamic stresses and brittle failure (triggered earthquakes) on faults (see [82]). In this review, however, we focus on these physical models together with a description of documented patterns of remote dynamic triggering.

## Introduction

### Introduction to Stress Triggering of Earthquakes

Earthquake triggering refers to a process by which any change in fault properties or the processes acting on a fault leads to rupture initiation. More specifically, stress triggering occurs when a change in the stress field acting on a fault leads to rupture. Stress triggering of earthquakes can result from stresses applied over a variety of time scales and with a variety of frequencies, which generally fall into three partially overlapping categories, 1) static stress triggering, 2) quasi-static stress triggering, and 3) dynamic stress triggering. In the case of static stress changes, the state of stress acting across a fault is permanently perturbed. This form of stress triggering is important in the near field of an earthquake where fault displacement significantly alters the stress field in the surrounding crust. Static stress triggering is commonly regarded as the dominant factor controlling aftershock generation (e.g. [54]). Because static stress changes decay rapidly with distance from the earthquake rupture (as  $d^{-3}$ , where  $d$  is distance from the earthquake epicenter), they are generally thought to be significant only within two to three fault lengths of the earthquake rupture. The role of static stress changes in triggering aftershocks and other earthquakes has been a vigorous and productive area of research in the past two decades (for reviews see [34,53,92,93]). The relative importance of static vs. dynamic triggering of aftershocks in the near field, however, has recently become an actively debated topic (e.g. [21,71]).

Because static stress changes in the near field develop essentially simultaneously with earthquake rupture, simple static stress triggering must appeal to other mechanisms to explain the time delay associated with many aftershocks and subsequently triggered earthquakes. In contrast, quasi-static stress triggering results from viscoelastic relaxation of the crust after an earthquake. Because quasi-static stress changes decay as  $d^{-2}$  and because viscoelastic relaxation is a time dependent process, these stress changes may explain triggered earthquakes more distant from an initial earthquake and triggered earthquakes with delay times from years to decades [72].

Dynamic stress changes decay more slowly with distance than either static stress changes or quasi-static stress changes (as  $d^{-1.5}$  for surface waves). Thus dynamic

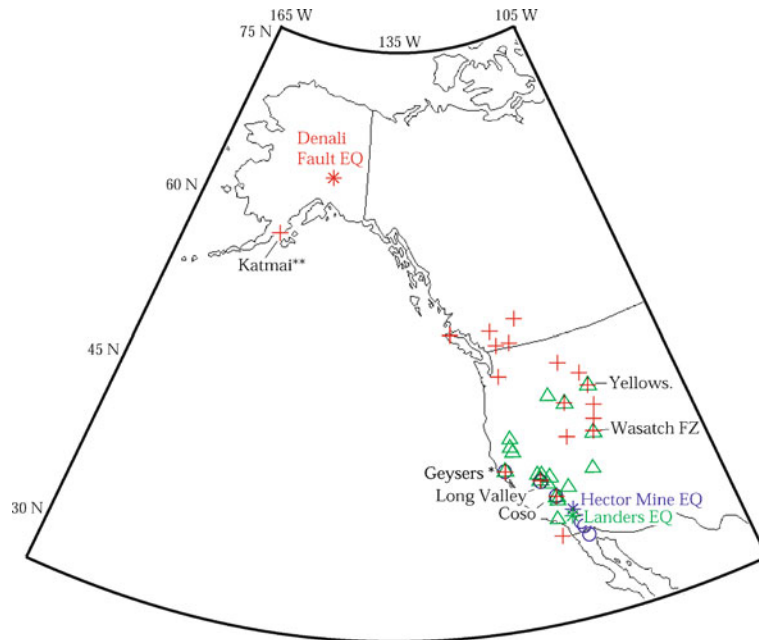

stress changes become increasingly dominant with increasing distance from the fault rupture. In this review we discuss dynamic triggering of earthquakes resulting from ground shaking due to the passing seismic wavetrain of other earthquakes. We focus on dynamic triggering due to remote earthquakes (greater than two fault lengths distance from the earthquake rupture), though we will briefly discuss the active research topic of dynamic triggering in an earthquake's aftershock zone as well. We also limit discussion to frequencies of ground shaking above  $\sim 0.01$  Hz (periods less than  $\sim 100$  s), though some work has been done on earthquakes triggered by longer wavelength fluctuations. For example, [16,95] recently found evidence that solid Earth tides can modulate background seismicity rates. Other reviews of dynamic stress triggering can be found in [23,37,92] and [38].

### Brief History of Dynamic Stress Triggering Research

The ability of earthquakes to trigger other earthquakes at great distances has been discussed in scientific literature throughout the latter half of the 20th century (see [38] for review). However, making a credible case for a causal link between two earthquakes remains a major challenge in this field. Beyond the realm of aftershock zones, it was difficult to justify statistically that one earthquake triggered another until the 1980s and 1990s. By then continuously recording telemetered seismic networks and automated processing of data became commonplace, providing reliable spatial and temporal records of earthquake occurrence at  $M \geq 1 - 2$  and the statistical leverage associated with large numbers of small earthquakes.

Dynamic triggering of earthquakes was widely accepted in the scientific community following the 1992 M 7.3 Landers earthquake in southern California. In the minutes to days following the Landers earthquake, earthquake rates increased dramatically across the western United States at distances well beyond the aftershock zone [39]. Earthquakes were triggered throughout California, Nevada, Utah, Wyoming, and Idaho at distances of up to 1250 km (Fig. 1). Although time delays of triggered events ranged from seconds to 33 hours after the arrival of the Landers earthquake wavetrain, the sudden increase in seismicity across the Western United States could not be ignored. This earthquake spawned a plethora of studies into the nature of earthquake triggering and remains one of the best studied triggering episodes to date.

The geophysical community had a unique research opportunity when the 1999 M 7.1 Hector Mine earthquake occurred. Because it was an earthquake with similar magnitude to the Landers earthquake occurring in a similar

Earthquakes, Dynamic Triggering of, Figure 1

Map showing sites of triggered seismicity in western North America from the Landers (green triangles), Hector Mine (blue circles), and Denali Fault (red crosses) earthquakes. Modified from [38], *Treatise on Geophysics*

location, it provided leverage to tune ideas about dynamically triggered seismicity and the underlying physical processes. Although the Hector Mine earthquake triggered seismicity at some of the same locations as the Landers earthquake, the Hector Mine earthquake had a much more limited triggered response (Fig. 1) [30]. The difference is likely due in part to differences in seismic radiation patterns between the two earthquakes [30,43]. The Landers earthquake ruptured unilaterally to the north, whereas the Hector Mine earthquake ruptured bilaterally, primarily to the south.

Following the Landers and Hector Mine earthquakes, the search for dynamic triggering began in earnest. Researchers across the globe began scanning earthquake catalogs and waveform data searching for dynamic triggering in a wide variety of environments (see “Sect. [Review of Dynamic Triggering Observations](#)”). At the Geysers, CA alone [91] identified 7 episodes of dynamic triggering between 1988 and 1994, making this among the most frequently triggered locations known.

Like the Landers earthquake, the 2002 M 7.9 Denali Fault earthquake triggered a widespread response across western Canada and the United States (Fig. 1) [27,33,45,64,68,74]. The increase in the number of broadband and high-dynamic range seismometers by 2002 allowed scientists to visually scan on-scale seismic data during the earth-

quake’s wavetrain. Thus, many triggered events were detected which were absent from earthquake catalogs. As an example of how instrumentation improvements increase our ability to detect dynamic triggering, [45] point out that the triggered response of the Yellowstone caldera to the Denali Fault earthquake could not have been detected at the time of the Hector Mine earthquake only three years earlier.

## Review of Dynamic Triggering Observations

### Detection of Dynamic Triggering

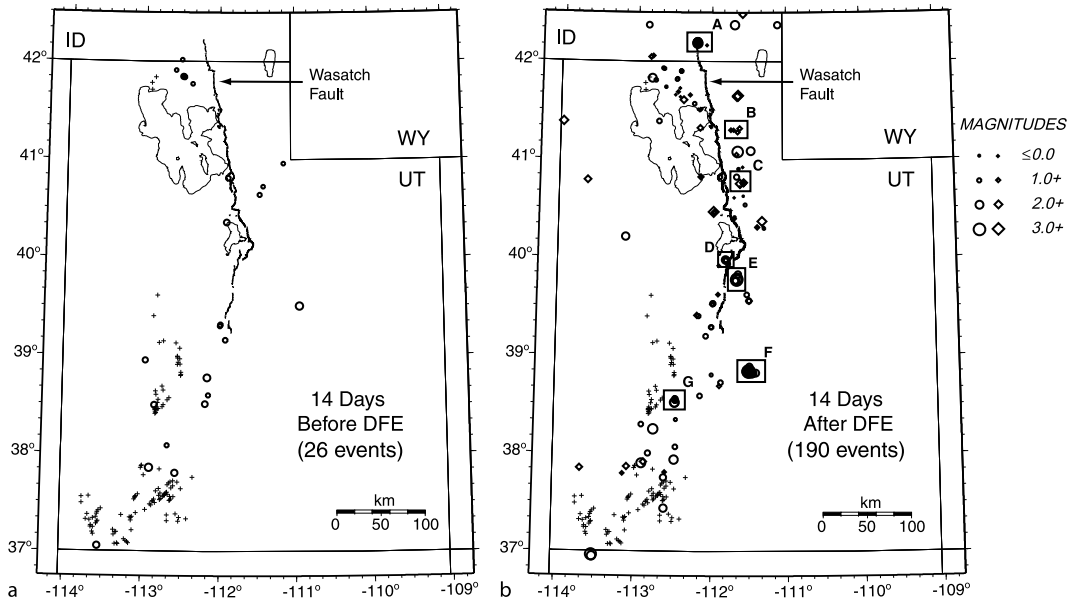

Dynamic triggering has been observed in a variety of locations around the globe. Some suggest that dynamic triggering of earthquakes is a ubiquitous process in the Earth’s crust (e.g. [26,41]). Others suggest that some areas are more likely to experience dynamic triggering of earthquakes than others (e.g. [39,64]). Observations of dynamic triggering are limited geographically due to uneven seismic network coverage and the effort applied to examining seismic data.

Following the 1992 M 7.3 Landers earthquake, dynamic triggering was recognized by the sudden increase in the number of earthquakes located through standard network processing across the western US in the days to weeks after the large earthquake. Searching earthquake

catalogs for sudden increases in seismicity after a large earthquake is one common method of identifying dynamic triggering (Figs. 2 and 3) (e.g. [6,30,39,41,68]). Identifying triggered seismicity using earthquake catalogs simplifies interpretation of triggered response with respect to background seismicity rates, as earthquake catalogs often provide stable long-term records of earthquake occurrence at a consistent threshold.

A second commonly used method of detecting dynamic triggering involves visually scanning continuous seismic data shortly before and after a large earthquake to identify a sudden increase in earthquakes too small to be detected and located through standard network processing (Fig. 4). This latter method is effective at identifying triggered seismicity in sparsely instrumented areas, identifying very small triggered earthquakes, and identifying

Earthquakes, Dynamic Triggering of, Figure 4

Seismicity triggered at Mammoth Mt. **b-c** and within the Long Valley caldera, California, **a** following the Denali Fault earthquake. **a** Catalog from NCEDC showing two swarms following the Denali fault earthquake in the caldera's south moat. The two lower panels show data from this very small earthquake swarm recorded on the broadband UNR/USGS station OMM from rotated to transverse direction, showing Denali earthquake wavetrain at Long Valley. Major arrivals are labeled. **c** Record from **b** high pass-filtered, showing small local earthquakes occurring during Denali wavetrain. Modified from [74], BSSA

earthquakes that occurred during the wavetrain from the initial earthquake (e. g. [26,47,64,74,103]). This method of detecting triggering has become more common with increasing availability of continuously recorded high-dynamic-range seismic data.

Possible instances of dynamic triggering have also been proposed based on historical accounts [40,42,44,59]. Because these studies rely on felt reports, they are generally limited to moderate to large sized triggered earthquakes that are separated in time by days to months.

With any method of detecting dynamic triggering, it must be shown that one earthquake is likely causally linked to the dynamic waves radiating from a previous earthquake, rather than by coincidence. Earthquakes near each other in time are more likely to be related than earthquakes separated in time. Additionally, earthquakes unlikely to occur randomly (e. g. large events in seismically quiet areas) are more likely to be related than earthquakes occurring commonly as background seismicity (e. g. small earthquakes in a seismically active area). To calculate the

probability that two earthquakes are related, one must first calculate the probability of each occurring randomly. This is usually done using patterns of earthquake occurrence based on local earthquake catalogs. The most commonly used statistical test to identify whether an increase in number of earthquakes is statistically significant is the Beta statistic [58]. Pankow et al. [68] also employ a binomial distribution analysis to this end. These techniques have potential pitfalls however, as they rely on assumptions about earthquake distributions and compare snapshots of seismicity in time in regions where seismicity rates fluctuate regularly [58]. Objectively determining whether one earthquake is genetically related to another remains a challenge.

Because spatial-temporal clusters of earthquakes are less common than isolated events, clusters of earthquakes temporally coincident with dynamic stresses are more easily identified as being triggered than isolated earthquakes. In the case of earthquake clusters, however, it may be difficult to discriminate between earthquakes directly trig-

gered by dynamic stresses from a remote earthquake and secondary aftershocks to directly triggered events [9]. To address this, earthquake catalogs are frequently ‘declustered’ (e. g. [45,68]). This process involves decomposing a catalog into primary and secondary earthquakes based on statistical patterns of aftershock sequences (e. g. [76]). [68] and [9] show that in some cases triggered seismicity is modeled well as an aftershock sequence. In other cases, however, triggered seismicity swarms cannot be dismissed as secondary aftershock sequences (e. g. [74,103]). In such cases it is likely that most events in a swarm were triggered directly by the dynamic waves radiated from a distant earthquake or perhaps as a secondary response to some aseismic process (e. g. fluid flow, or local deformation associated with fault creep) triggered by the dynamic waves.

### Dynamic Triggering in Volcanic and Geothermal Regimes

Although dynamic triggering has been observed in a variety of environments, many of these observations are from areas with active volcanic and hydrothermal systems (Table 1) [6,73,74]. These areas typically have high background seismicity rates indicating that the crust habitually hovers near failure and thus is particularly susceptible to dynamic triggering. Furthermore, because these areas tend to be well instrumented, dynamically triggered earthquakes may be unusually easy to detect. Here we summarize observations of triggered seismicity in volcanic and hydrothermal areas.

The Geysers geothermal field in northern California is among the most frequently triggered sites known with 9 cases of dynamic triggering documented in the past 20 years [28,74,91]. Earthquakes that have caused triggering at the Geysers range in magnitude from 6.9 to 7.9 and in distance from 212 km to 3120 km. The Coso geothermal field in southern California has also experienced repeated episodes of dynamic triggering following the M 7.3 Landers, the M 7.1 Hector Mine, and the M 7.9 Denali Fault earthquakes (Fig. 1) [39,74]. Following the Hector Mine earthquake, dynamically triggered earthquakes and ground deformation were observed near a third geothermal field – Cerro Prieto, Baja California [24,30].

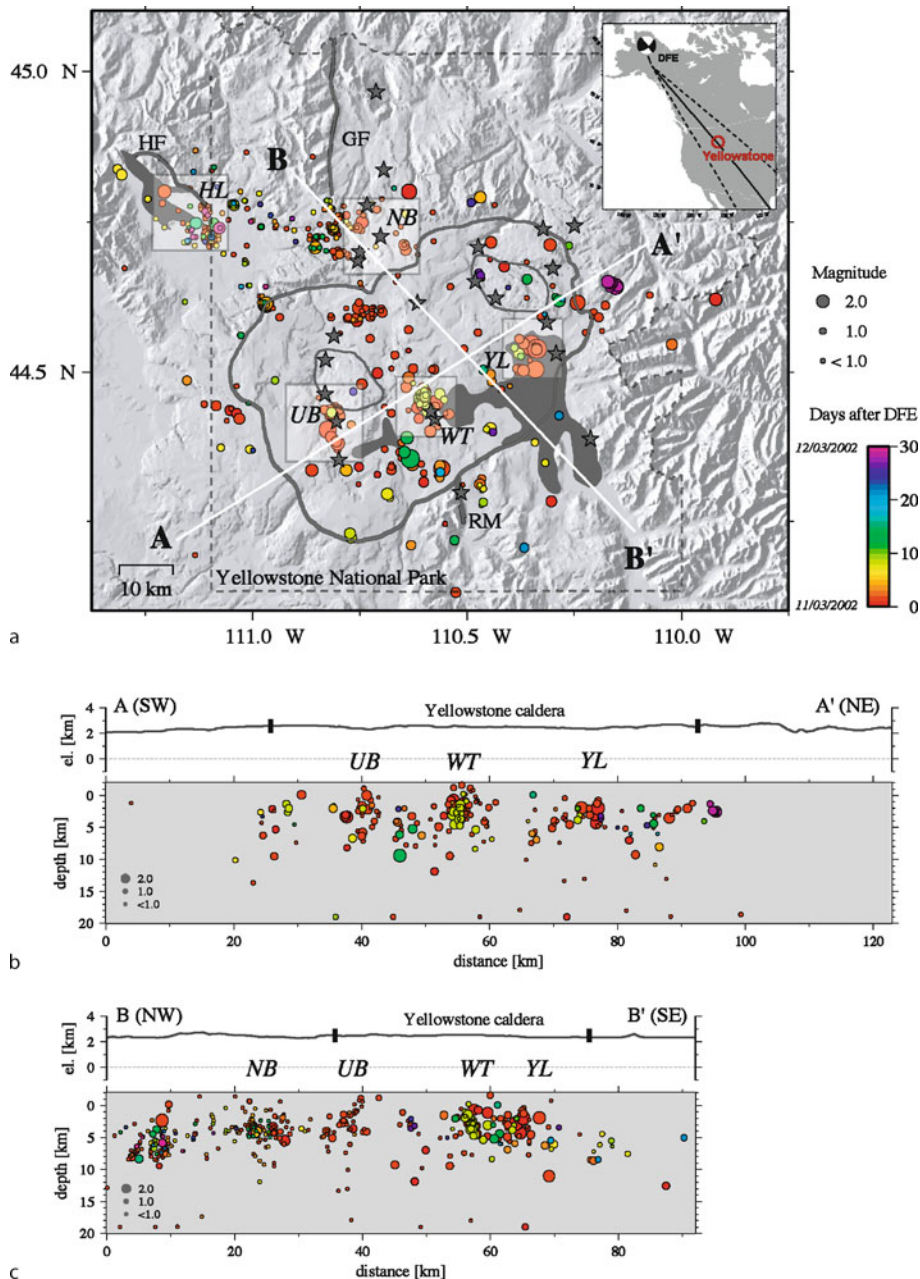

Yellowstone, Wyoming is a larger and more complicated system than the geothermal fields mentioned above, as it is a caldera system characterized by ongoing magmatic and tectonic activity, in addition to hydrothermal activity. Yellowstone had a triggered response to the M 7.3 Landers earthquake [39] and the M 7.9 Denali Fault earthquake [45,47]. The triggered response to the Denali Fault

earthquake was particularly dramatic (Figs. 5 and 6). Seismicity increased immediately following the arrival of surface waves from the Denali Fault earthquake and remained unusually high for 30 days with magnitudes ranging from  $< 0.0$  to M 3.2 [45]. The time scale of the triggered response was spatially variable (Figs. 5 and 6). Because the Denali Fault earthquake led to immediate triggering in the area of geysers and affected periodicity of geysers at Yellowstone, it is likely that changes in the hydrothermal regime induced a triggered response in some areas ([45,46]. In other areas however, the development of triggered earthquake sequences was delayed and similar to commonly observed tectonic activity [45].

Like the Yellowstone caldera, the Long Valley caldera experiences dynamic triggering with complex characteristics. The area responded to the Landers earthquake [39], the Hector Mine earthquake [50], and the Denali Fault earthquake [50,74] both seismically and geodetically, although each response varied in location and intensity (Fig. 7). The Landers earthquake produced the largest triggered response with 340 earthquakes in seven days up to M 3.4 throughout the south moat of the caldera [39]. The seismic response to the Hector Mine earthquake was comparatively short lived and limited to the region of Mammoth Mountain. After the Denali fault earthquake, the caldera area experienced two phases of triggered seismicity. A burst of  $\sim 60M \leq 0.8$  earthquakes occurred beneath Mammoth Mountain during and shortly after the arrival of the surface waves from the Denali Fault earthquake [74]. Twenty-four hours later a larger swarm of earthquakes of  $M \leq 3.4$  occurred in the Long Valley caldera’s south moat [74]. All three episodes of dynamic triggering in the Long Valley caldera were accompanied by deformation transients with geodetic moments an order of magnitude larger than the cumulative seismic moment of the triggered seismicity [36,50], though the time history and magnitude of each deformation response varied.

Iwo Jima, Japan, a volcanic island hosting a Holocene eruption, geothermal activity, and historic phreatic (steam) eruptions is a third complex caldera system which has experienced dynamic triggering of local earthquakes. [98] examined continuous waveform data of  $21M > 7$  earthquakes  $< 3000$  km distance from Iwo Jima, and identified 4 cases of resulting increased local seismicity. In all cases earthquakes were triggered locally during surface wave arrivals and persisted for 6–15 minutes.

Dynamic triggering of earthquakes has been observed at shallow depths in volcanic edifices at a variety of locales (Table 1). In the Pacific Northwest, Mt. Rainier experienced 6–8  $M < 0$  earthquakes during the wavetrain of the Denali Fault earthquake and 8  $M \leq 0.9$  earthquakes in

the following days. In response to the Landers earthquake, Mt. Lassen in northern California hosted 14 earthquakes of  $M \leq 2.8$ . Volcanoes in the Katmai Volcanic Clus-

ter, Alaska, have experienced triggered seismicity on at least seven occasions since 1999 ([64,65,73], this chapter). The largest of these triggered responses included 17 earth-

Location is location of triggered seismicity. Distance is distance from location of triggering to triggering earthquake (mainshock) epicenter. M is magnitude of mainshock. Onset is onset time of triggered activity with respect to arrival of waves from mainshock. M<sub>max</sub> is magnitude of the largest triggered earthquake. Reg describes stress regime: E-extensional or transtensional, C-compressional or transpressional, S-subduction zone. Env describes if the area is volcanic (V), geothermally active (G), or neither (N). – indicates data not available or inconclusive.

quakes of  $M \leq 2.3$ . During the wavetrain of the 2006  $M$  8.7 Sumatra–Andaman Islands earthquake, Mt. Wrangell, Alaska had triggered 14 earthquakes [103]. With the exception of the Mt. Lassen response following the Landers earthquake and the delayed events at Mt. Rainier following the Denali Fault earthquake, these earthquakes triggered in volcanic edifices were too small to be detected and located by automatic processing systems.

The Valley of Mexico is a large volcanically and geothermally active area located in the Trans Mexican Volcanic Belt. [89] searched for dynamically triggered earthquakes in the Valley of Mexico following 18  $M \geq 7.0$  Mexican earthquakes between 1920 and 1998. In seven cases, they found evidence for dynamic triggering of earthquakes within 2 days of a large earthquake. In four additional cases, seismicity increased after a large earthquake, but was delayed by up to one month. Because this study used only one station however, the potentially triggered events can only be located to within some ill-defined region surrounding the station.

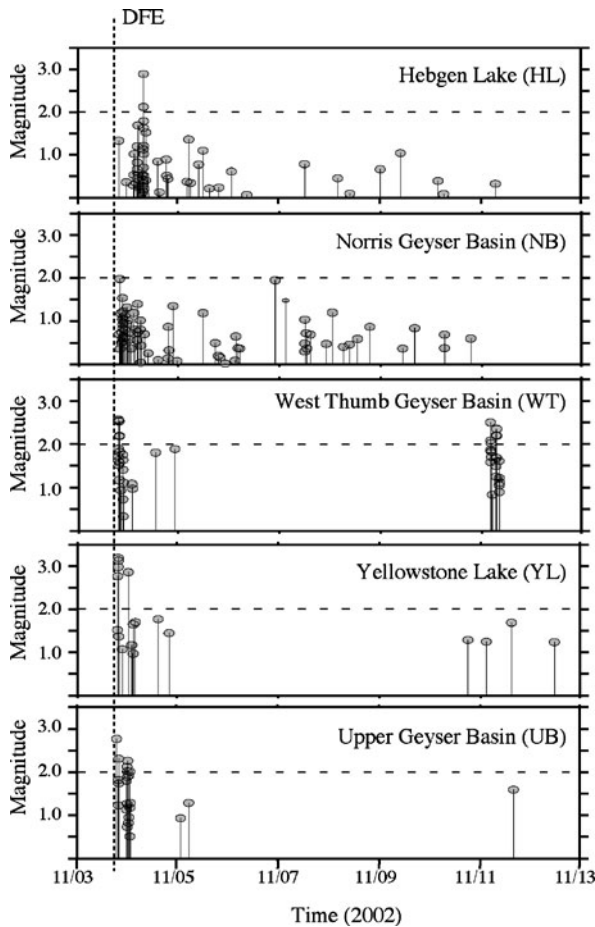

The South Iceland Seismic Zone is a transform zone in a volcanically and geothermally active area. In 2000, a  $M_w = 6.5$  earthquake in the South Iceland Seismic Zone trig-

gered widespread seismicity, including three  $M_w \sim 5.0$  earthquakes within 5 minutes of its occurrence. Coulomb failure stress calculations indicate that the two  $M > 5$  earthquakes located  $\sim 100$  km to the west on the Reykjanes Peninsula are beyond the range where static stress changes are significant [2], and thus appear to have been dynamically triggered. Furthermore, one of these  $M > 5$  earthquakes had a geodetic moment significantly larger than its seismic moment suggesting that deformation associated with aseismic fault creep may have indirectly triggered many of the smaller earthquakes in the area [2].

### Dynamic Triggering in Regimes with Limited Volcanic and Geothermal Activity

**Extensional and Transtensional Environments** The majority of occurrences of triggered seismicity documented to date have been in extensional or transtensional tectonic regimes (Table 1). In the western United States dynamic triggering following the  $M$  7.3 Landers earthquake occurred exclusively in transtensional tectonic regimes, many of which were also volcanically or geother-

Earthquakes, Dynamic Triggering of, Figure 6  
 Plot of earthquake magnitude versus time of seismicity for selected areas in Yellowstone caldera. See Fig. 5 for locations of these areas. Dashed line DFE as the origin time of the Denali Fault Earthquake. Figure reprinted from [45], BSSA

mally active, to distances of up to 1250 km [1,39]. These locations included Little Skull Mountain, Nevada; western Nevada, White Mountains, California, Mono Basin California, Cedar City Utah, the Wastach Front in central Utah, Burney, California, and Cascade, Idaho. The onset of triggering ranged from during the passage of the Landers wavetrain to 33 hours after the Landers earthquake. The largest of these earthquakes was a  $M = 5.6$  earthquake triggered beneath Little Skull Mountain, Nevada. Otherwise, triggered earthquakes had  $M \leq 3.0$ . The most vigorous responses containing tens to hundreds of triggered earthquakes occurred near Cedar City Utah, Western Nevada, and Cascade Idaho.

The  $M_w = 7.1$  Hector Mine earthquake also led to an impressive display of triggered earthquakes in exclusively extensional, transtensional, and geothermal envi-

ronments in the western United States. Triggered earthquakes began during the passage of the wavetrain near the Salton Trough in Indio and at the southern end of the Salton Sea [30,43]. In general, the triggered response to Hector Mine was less extensive and energetic than that of the Landers earthquake [30].

Following the Denali Fault earthquake seismicity was triggered in several extensional and transtensional areas in the western United States. [47] detected a  $M 4.6$  earthquake triggered during the Denali Fault earthquake wavetrain in Cascade, Idaho. Seismicity remained elevated for 25 days along a 500 km stretch of the Intermountain seismic belt in Utah, on the border of the Basin and Range province (Figs. 2 and 3) [68].

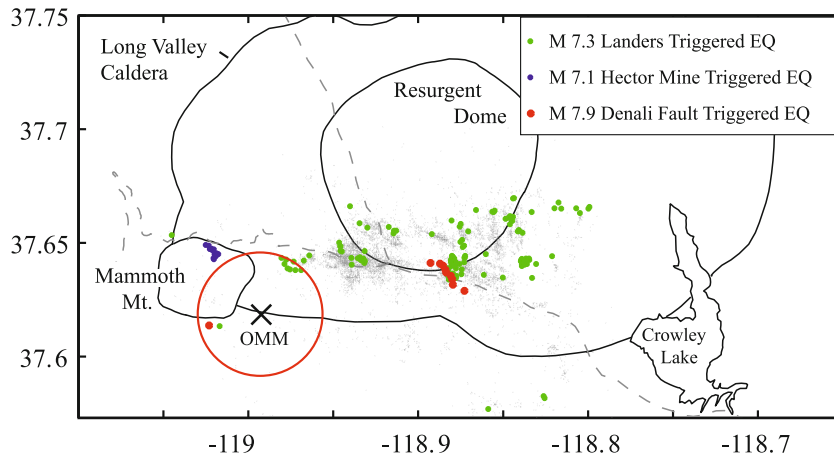

Through examining historical documents [59] identify several earthquakes in extensional/transtensional environments that may have been dynamically triggered by the  $M_w = 7.8$  1906 San Francisco earthquake, including a  $M 3.5$  and  $M 4.5$  earthquake in western Nevada and a  $M 6.1$  earthquake in the Brawley Seismic Zone near the Salton Sea in Southern California. These events are within 400–700 km from the fault rupture, thus beyond the aftershock zone of the San Francisco earthquake.

In the day following the arrival of surface waves from the  $M_w = 7.4$  Izmit, Turkey earthquake, catalog seismicity rates throughout continental Greece, 400–1000 km from the epicenter, increased significantly [6]. Greece is an area of active extension and hosts significant hydrothermal activity. Although [6] did not address a possible correlation to hydrothermal activity systematically, at least some clusters of dynamically triggered seismicity occurred in areas with active hot springs.

A second report of dynamically triggered seismicity in Europe comes the Roer Valley, the Netherlands. This area is an actively extending northern branch of the Rhine Graben System. Following a  $M_w = 5.4$  earthquake in 1992, [12] determine that a large cluster of aftershocks occurred at distance of 40 km from the mainshock. They conclude that these events are dynamically triggered because they are located beyond the zone where static stress changes are significant.

### Transpressional and Compressional Environments

Although dynamic triggering is not commonly observed in compressional environments, several studies suggest it does occur. Less than three hours after a  $M_s = 7.3$  earthquake in the Gulf of Aqaba 1995, an earthquake swarm began 500 km distant from the mainshock epicenter in a restraining bend of the Dead Sea transform fault on the Syria–Lebanon border [62]. The swarm consisted of 21 earthquakes of  $M_d \leq 3.7$ .

Earthquakes, Dynamic Triggering of, Figure 7

Map of triggered seismicity beneath Long Valley caldera and Mammoth Mountain, California, for the Landers (green), Hector Mine (blue), and Denali Fault (red) earthquakes. Gray dots show background seismicity from 1997–1998. The red circle centered on station OMM indicates area within which the earthquakes triggered by the Denali Fault earthquake must be located based on S-P phase arrival times. The single red dot was large enough to be located [74]. Modified from [38], *Treatise on Geophysics*

The central United States is a transpressional environment with low strain rates. Dynamic triggering in the central US has not yet been observed instrumentally. However, [40,44,66] suggest that dynamic triggering occurred during the 1886 Charleston, South Carolina earthquake and 1811–1812 New Madrid earthquakes based on examination of historical felt reports. Similarly, [42] describe historical evidence for dynamic triggering of a  $M \sim 7$  earthquake following the 1905 Kangra earthquake in India.

The stress state in Taiwan is variable, but generally transpressional [104]. [102] searched for dynamically triggered seismicity in the Taiwan region following 12 regional  $M 6.5+$  earthquakes occurring between 1973 and 1994. They identify 9–10 cases of increased seismicity following a large event, although the increase is small in all cases, with 1–7  $M 4$ – $4.5$  earthquakes more in the 15 days following the large earthquake than in the 15 days before.

### Dynamic Triggering in Subcrustal Environments

The occurrence of dynamically triggered earthquakes in subcrustal environments has been investigated in subduction zones in South America and Japan. [96] found that a  $M 7.6$  earthquake at 598 km depth in the Tonga trench in 2002 was followed by  $M 5.9$  and  $M 7.7$  earthquakes at 647 and 664 km depth within 2 and 7 minutes of the initial earthquake, respectively. By investigating the rupture history and Coulomb stress change resulting from the initial event, they conclude that the secondary events were triggered dynamically. They highlight 4 additional earth-

quakes of  $> 450$  km depth which have similar large aftershocks that may be dynamically triggered. During the surface waves of the  $M 8.1$  Tokachi-oki earthquake, [60] identified deep low frequency earthquakes triggered in the Nankai subduction zone through analyzing Hi-Net borehole seismic data and use of the Beta statistic. The triggering occurred during a slow slip event in a region of the subduction zone which was active with deep low frequency tremor.

### Triggered Tremor

With the exception of triggered subduction zone seismicity described above, the majority of dynamically triggered earthquakes described in this review are typical brittle failure earthquakes. For example, [43] show that the earthquakes triggered by the Hector Mine earthquake near the Salton Sea had typical spectra and stress drops, consistent with standard brittle failure source mechanism. In the last few years however researchers have demonstrated that volcanic tremor and deep non-volcanic tremor respond to dynamic waves from regional and teleseismic earthquakes as well as typical crustal earthquakes (Table 2) ([32,60,61,81]). These findings emphasize that dynamic triggering can occur in a wide variety of environments and affect multiple seismic processes in addition to brittle failure of crustal rock. They provide an intriguing new perspective on the triggering processes.

At Aso volcano, Japan, [61] identify dynamically triggered earthquakes and volcanic tremor following the 1999

Earthquakes, Dynamic Triggering of, Table 2

M 7.7 Chi-Chi earthquake. To test the uniqueness of these observations, they searched for triggered tremor at Aso following 20 other  $M_w \geq 7$  earthquakes occurring within 3000 km distance between 1995 and 2002. Five of these earthquakes triggered tremor following P wave arrivals at Aso. All occurred between 1998 and 1999, a time with usually high heat supply to the volcano's crater. As yet, this is the only documented episode of dynamically triggered volcanic tremor.

On the other side of the Pacific Ocean and a different tectonic environment, [81] identified episodes of deep non-volcanic tremor in the Cascadia subduction zone,

Canada, which were triggered by the Love waves of the M 7.9 Denali Fault earthquake. In this case tremor amplitude modulates perfectly with strain amplitude from the incident Love waves (Fig. 8).

More recently, [32] identified triggered non-volcanic tremor in seven locations in California following the Denali Fault earthquake. In all cases tremor amplitude modulates with strain amplitude from incident surface waves. Five of these are strike-slip faulting regimes. These observations are the first reported cases of non-volcanic tremor beyond subduction zones (e. g. [80]) and the San Andreas fault [67].

## Lack of Triggering Observations

Interestingly, some areas of high ambient seismicity show a notable lack of dynamically triggered seismicity. For example, the San Andreas fault near Parkfield, California showed no triggered response to the Landers earthquake [90]. Japan boasts high rates of shallow background seismicity, frequent large earthquakes from the subduction zone, high seismic network density, and a variety of crustal stress environments and volcanic and geothermal regions. However, through examining both earthquake catalogs and waveform data from individual seismic stations before and after nine large remote events, [33], show that dynamic triggering in Japan is not common, as it is in extensional regimes of the Western United States.

Similarly, Alaska abounds with crustal and subduction zone seismicity and active volcanic and geothermal systems, although network density is far lower than in Japan. Though the Katmai Volcanic cluster appears to be particularly susceptible to triggering [64,73] and dynamic triggering has been observed at Mt. Wrangell [103], dynamic triggering is rare compared to the western United States. [64] suggest that this results from unknown differences in the magmatic and hydrothermal systems of the volcanoes. [83] document a decrease in seismicity at Mt. Wrangell and Veniaminof volcanoes following the M 7.9 Denali Fault earthquake. To date these are the only documented examples of seismicity repression from a large distant earthquake.

## Characteristics of Dynamic Triggering

### Environmental Controls on Dynamic Triggering

Extensional and transtensional tectonic regimes with high levels of background seismicity are highly susceptible to dynamic triggering [38]. This may reflect the ease with which fluids can migrate upwards in these stress environments [32,38]. Because such fluids are often hot with high concentrations of dissolved solids, rapid precipitation may form high pressure compartments over rapid time scales, further enhancing a tendency toward failure. Faults in extensional stress regimes are also inherently weak compared to those in compressional environments [43,88]. [26,41] suggest that dynamic triggering is a ubiquitous process in the crust which is detected more commonly in certain areas due to high instrumentation and scrutiny levels. Only one study to date has carefully addressed this question. By comparing seismicity rates on the San Andreas fault in California and the Western United States Basin and Range Province, [90] show that the San Andreas fault is less likely to experience dynamic triggering

than similarly instrumented areas with similar levels of background seismicity in the Western United States Basin and Range province. More studies like [90] are necessary to resolve whether triggering is truly ubiquitous or favored in specific tectonic environments.

### Triggering Thresholds and Recharge Times

In most reports of remote dynamic triggering, seismicity is triggered by earthquakes of M 6.5 or greater (Table 1). Dynamic triggering responses are strongest in areas that experience strong directivity [26,30,39]. These first order observations suggest that strength of triggered response is a function of ground shaking amplitude. Although amplitude-based triggering thresholds have been suggested for some areas [28,29,31,64], a consistent triggering threshold that applies throughout the crust has not been established [38]. Large earthquakes regularly occur without dynamically triggering seismicity beyond their aftershock zones.

Lack of triggering reports below M 6.5 may reflect subtle triggered responses. [41] uses the Beta statistic to give evidence of small seismicity increases at distances of 70–110 km in the month following 14 moderate (M 5.5–7) earthquakes in California. Because this distance corresponds with where a large SMS phase should arrive, [41] suggests that the SMS phase is responsible for the triggered response in these cases.

If a simple amplitude-of-shaking threshold is required to dynamically trigger earthquakes, we would expect that even moderate earthquakes trigger seismicity near their epicenters. [21,27,52,71] give strong evidence that dynamic triggering occurs in the near field. Because it is difficult to distinguish the influence of static and dynamic stress changes in the near field, many studies of dynamic triggering have limited their investigation to the realm beyond the aftershock zone.

Because many aftershocks in the near field are likely dynamically triggered, [31] include aftershocks in a search for an amplitude-based triggering threshold. They find that peak dynamic stress distributions correlate well with aftershock and remotely triggered seismicity distributions, except in the Long Valley caldera, CA. The result of [31] is consistent with failure thresholds found in laboratory studies [49] and independent of frequency of shaking. [64] also find evidence for a ground shaking amplitude-based triggering threshold at the Katmai Volcanic Cluster, Alaska by comparing magnitude and distance of mainshock with triggered response (Fig. 9). Their magnitude-distance relationship is similar to that proposed by [28] for the Geysers, CA. However, the triggering

Earthquakes, Dynamic Triggering of, Figure 9  
 Plot of magnitude vs. distance from Mageik volcano in the Katmai Volcanic Cluster for all  $M_w > 6$  earthquakes between 1996 and 2003 located within 2000 km of Katmai. *Hollow squares* triggered seismicity in the KVC. *Solid circles* did not. *Dashed line* represents possible triggering threshold. Figure reprinted from [64], BSSA

threshold at Katmai appears to be higher than that suggested for the Geysers.

In other cases, a simple amplitude-of-shaking threshold is not consistent with data, and large amplitude ground shaking is neither a necessary nor sufficient condition to cause dynamically triggered earthquakes. [31] show that the Long Valley caldera appears to be more susceptible to triggering than other areas they studied. Because their study was based on catalog seismicity, it did not include triggered earthquakes that were too small to appear in earthquake catalogs, such as those at the Coso geothermal field in response to the Denali Fault earthquake. These events were triggered by dynamic stresses of  $< 0.01$  MPa [74] and, like Long Valley, would not fit the thresholds proposed by [29] and [31].

By comparing spectra of all earthquakes with high amplitude ground shaking in the Long Valley caldera [7] find that in this area, high-amplitude low-frequency shaking is more likely to trigger seismicity than high-amplitude high-frequency shaking. [1] come to the same conclusion after examining strong ground shaking spectra of earthquakes which did and did not trigger seismicity in the Western Great Basin. Longer wave lengths associated with low frequency ground shaking favor triggering by larger earthquakes in at least some locales. Whether remote dy-

amic triggering in both the near and far field results from the same physical process or processes remains an open question.

One parameter that may complicate the search for a triggering threshold in amplitude and/or frequency is recharge time. Because the occurrence of earthquakes releases stored strain energy, it may take time for an area to re-accumulate strain energy sufficiently to be primed for failure again following local earthquake activity or previous episodes of remotely triggered seismicity [38]. However some areas, such as the Geysers geothermal field require little to no time to recharge, as triggered seismicity episodes have been separated by time intervals of months or less [28]. Recharge times are dependent on many parameters including earthquake history, regional tectonic strain rates, and mass and heat advection rates in areas of hydrothermal and volcanic activity.

### Time Scales of Dynamic Triggering and Responsible Phases

Remote dynamic triggering of earthquakes occurs over a variety of time scales following the onset of dynamic stressing. At Aso Volcano, Japan [61] triggered tremor begins with the P-wave arrival from distant large earthquake. In the case of discrete earthquakes however, it is most common for triggering to begin during surface wave arrivals (Table 1), leading many to suggest that the specific low-frequency large-amplitude ground motions associated with surface waves initiate the failure process [1,7,38,103]. Although the onset of dynamic triggering at remote locations is most commonly observed during Rayleigh wave arrivals [38], clear cases of remote triggering of tremor on the Love wave exist as well [81].

In some cases, dynamic triggering begins hours to days after an initial stress perturbation (e.g. [39,89,102]), hinting that the physical process responsible for initiating earthquake failure evolve with time. For example the largest triggered event following the M 7.3 Landers earthquake, a M 5.6 at the Little Skull Mountain, Nevada, occurred 33 hours after the mainshock [39]. In the case of Long Valley caldera's south moat and Mt. Rainier after the Denali Fault earthquake, delayed earthquake swarms began 24 hours and 2 hours respectively after the passage of the dynamic waves from the mainshock (Fig. 4) [74]. Both of these areas also had much smaller triggered swarms during the mainshock's wavetrain.

Determining the duration and decay time of triggered swarms is more difficult than detecting their onsets, particularly in areas of high ambient seismicity. Many triggered earthquakes may be triggered secondarily as aftershocks

Earthquakes, Dynamic Triggering of, Figure 10

Phase modulated dynamically triggered earthquakes in the Katmai Volcanic Cluster following the 2007 M 8.2 Kurile earthquake: **a** short period record from station ACH showing both wavetrains for the Kurile earthquake and the larger amplitude, locally triggered earthquakes, **b** broadband record from station KABU showing wave motion of the Kurile earthquake, **c** time series from ACH and KABU zoomed in to show how local earthquakes seen clearly in red are occurring on a specific phase of the wavetrain from the Kurile earthquake

to earlier triggered earthquakes [9]. The Yellowstone response to the Denali Fault earthquake and the Long Valley caldera response to Landers are fit well with an Omori-type law decay [45]. In some cases however, triggered swarms end abruptly after the dynamic stress perturbation stops (e. g. [103]). Although our understanding of decay rates of triggered swarms is incomplete emphasizing that the subject deserves further investigation, decay rates give strong constraints on physical processes responsible for triggering.

### Phase Modulated Triggering

Recent findings show that earthquakes can be triggered during specific phases of the wavetrain. At Mt. Wrangell, Alaska, triggered earthquakes occurred preferentially during phases of the largest positive vertical ground displacement from the 2004 M 9.0 Sumatra earthquake [103]. Sim-

ilarly at Katmai Volcanic Cluster, Alaska, triggered earthquakes occurred only during specific phases of Rayleigh waves from the 2007 M 8.2 Kurile earthquake (Fig. 10). Such observations will allow us to resolve the precise dynamic stress field perturbations at the moment of earthquake nucleation on specific failure planes (e. g. [38]).

### Physical Models of Dynamic Triggering

The wide variations in the characteristics of dynamic triggering and the limited data for individual response instances admit a spectrum of competing models for the physical processes linking dynamic stresses from a large, distant earthquake to the locally triggered response. Broadly considered, published models fall into three partially overlapping categories: 1) those involving some form of stress-driven brittle failure across local fractures, 2) those involving the activation of hydrous or mag-

matic fluids, and 3) those involving some form of localized aseismic relaxation (deformation). The brittle failure models are generally consistent with the onset of locally triggered seismicity during dynamic stressing (rapid-onset triggering), including the possibility that seismicity may persist as aftershocks for some time after the dynamic stressing has stopped [21]. Under the latter two categories, the onset of local seismicity represents a second-order phenomenon driven by a first order response to dynamic stressing in the form of fluid activation or transient deformation. In principle, models under these two categories admit a significant delay in the onset of the triggered seismicity with respect to the dynamic stresses generated by a distant earthquake. Because the dynamic stress amplitudes that trigger a response at remote distances are typically an order of magnitude or more below background tectonic stress levels, all models carry the implicit assumption that a crustal volume susceptible to dynamic stress triggering must be in a near-critical stress state prior to a triggered response.

### Brittle Failure

Brittle failure models are based on the premise that the dynamic stresses propagating with the seismic waves from a distant earthquake are sufficient to nudge the local stress acting on a pre-existing dislocation beyond the threshold for the particular failure mode. This threshold may be the Griffith criteria for the tensile strength of a partially healed crack or the Coulomb criteria for frictional strength of a fault [86,87]. Crustal fluids play an important passive role in all brittle failure models by counteracting the rock matrix stress acting on a fracture through pore pressure,  $p$ , according to

$$\sigma' = \sigma - Ip$$

where  $\sigma'$  and  $\sigma$  are the effective and rock matrix stress tensors, respectively, and  $I$  is the identity tensor. Thus, pore pressure reduces the effective normal stress,  $\sigma'_n$ , acting on a fracture by opposing the rock matrix normal stress as  $\sigma'_n = \sigma_n - p$ . Alternatively, for pressure-sensitive friction models the role of pore pressure can be expressed in terms of an effective coefficient of friction as  $\mu' = \mu(1 - \lambda_p)$ , where  $\lambda_p = p/\sigma_n$ . Elevated pore pressures lower the effectively strength by moving the background stress state closer to extensional or shear failure thresholds thereby increasing vulnerability for failure by imposition of small dynamic stress perturbations.

In the simplest frictional failure model, a triggered earthquake occurs when the stress acting on a fault exceeds the Coulomb threshold for static friction, or  $CFF(t) = 0$ ,

and friction abruptly drops from static to dynamic values with  $\mu_s > \mu_d$ , respectively. Here,  $CFF(t)$  is the Coulomb Failure Function defined as

$$\begin{aligned} CFF(t) &= |\tau(t)| - \mu_s \sigma'_n(t) - C, \quad \text{or its equivalent} \\ &= |\tau(t)| - \mu'_s \sigma_n(t) - C \end{aligned}$$

where  $\sigma_n$ ,  $\sigma'_n$ ,  $\mu_s$ ,  $\mu'_s$  are defined in the preceding paragraph,  $\tau$  is the shear, and  $C$  is the cohesive strength ([34], and references therein). This simple case implies rapid-onset triggering with the triggered seismicity beginning promptly when  $CFF(t)$  first becomes positive for a fault optimally oriented for failure in the background stress field. The combination of dynamic stress components  $\Delta\tau$  and  $\Delta\sigma_n$  for which  $CFF > 0$  will depend on the wave type (e.g. Love or Rayleigh wave) and its incidence angle on the optimally oriented fault [35]. Although details vary, Love waves will generally have a greater triggering potential than Rayleigh waves when incident on vertical, strike-slip faults while the opposite is the case for incidence on inclined, dip-slip faults.

The Coulomb failure criterion applies to more elaborate non-linear friction models as well (see [18,25,31,70,100]). Because the behavior of non-linear models depend on factors such as slip history and slip rate, however, the failure threshold for static friction may vary with time, and the triggered earthquake may be delayed with respect to the time the failure criterion was first exceeded (e.g. [69]). Susceptibility to dynamic triggering may result when a dynamic stress is imposed on quasi-static loading under a conditionally stable regime (e.g. [84]). Based on their analysis of the dynamic triggering observed at Long Valley caldera, [7] conclude that this mechanism requires near-lithostatic pore pressures to be effective.

Models based on the non-linear response of granular media to dynamic stresses may apply to dynamic triggering of mature faults with a well-developed core of fault gouge. [49] document an abrupt decrease in the modulus of fault gouge under low effective normal stress ( $\sigma'_n$  0.1 MPa) when excited by dynamic strains  $> 10^{-6}$  in the laboratory. Thus, this model also requires near-lithostatic pore pressures to be effective.

Sub-critical crack growth, or stress corrosion, is another non-linear form of brittle failure that has a potential role in dynamic triggering. Under this model, a sudden increase in differential stress or an oscillatory stress applied to a pre-existing crack can lead to crack growth due to weakening of the crack tip by chemical corrosion. This can shorten the time to earthquake rupture. This process will be enhanced in an environment with fluids at elevated temperatures. It turns out that the equations governing sub-critical crack growth have the same mathemat-

ical form as rate-state friction equations above [51]. Thus near-lithostatic pore pressure appears to be a requirement for each of these non-linear brittle-failure models, at least as they apply to dynamic triggering at remote distances.

### Fluid Activation Models

In addition to their passive role in reducing the effective strength of a rock volume through ambient pore pressure, fluids may play an active role in the dynamic triggering process. Fluid activation models generally appeal to either 1) pore-pressure re-distribution associated with changes in permeability and fluid transport, or 2) state changes induced in multi-phase fluids.

Dynamic stressing may be capable of physically disrupting permeability barriers separating volumes of differing pore pressure. For example, dynamic stress may shake accumulated detritus from clogged fractures or opening partially healed fractures by extensional failure. In either case, fluid diffusion down the pressure gradient will result in a re-distribution of pore pressure with the potential for triggering seismicity in previously under-pressured volumes in a near-critically stressed state. The evolution of triggered seismicity in this case will be governed by the diffusion length for a given permeability and the proximity of the pre-existing stress state to brittle failure. [8] proposed the clogged fracture model as an explanation for the hydrologic response of water wells in southern Oregon to surface waves from  $M > 7$  earthquakes at distances of 300 km and 3850 km.

Geothermal areas may be particularly susceptible to dynamic triggering through pore pressure re-distribution. In these areas fractures are rapidly sealed by precipitation from circulating, solute-rich geothermal fluids and plastic deformation of quartz-rich rocks under elevated temperatures tend to isolate pockets of elevated pore pressure. Most active geothermal systems are located in areas of extensional tectonism. In these areas normal stresses induced by Rayleigh waves on vertical planes may open vertical fractures, allowing high-pore-pressure fluids access to shallower crustal volumes with lower pore pressure [35]. The hydraulic surge model described by [22] for volcanic and geothermal systems is a version of this process in which the brittle-plastic transition at the base of the seismogenic crust serves as a low-permeability barrier separating near-lithostatic pore pressures in the plastic regime from a hydrostatic regime in the overlying seismogenic crust. Rupturing the permeability seal by dynamic stresses would release near-lithostatic pore pressures into the brittle, seismogenic crust thereby inducing a surge in triggered seismicity.

Models for bubble excitation by dynamic stresses in a two-phase fluid (multi-phase in a partially crystallized magma) offers interesting possibilities for remotely triggered responses in geothermal and volcanic systems. This is a particularly intriguing concept for remote triggering in volcanic systems because of the importance of bubbles in eruption dynamics [57] and the source mechanisms of long-period volcanic earthquakes [13], ► **Volcanoes, Non-linear Processes in**. Advective overpressure and rectified diffusion were the first bubble models proposed as explanations for remotely triggered seismicity [10,55,94]; although subsequent work has shown that both hold less promise as viable explanations than initially thought [56].

Under the advective overpressure model, the pressure in a gas-saturated, incompressible fluid confined in a rigid container increases as  $\rho g \Delta h$  as a pre-existing bubble adhering to the wall of the container is shaken loose by passing seismic waves. The bubble ascends buoyantly a distance  $\Delta h$  through a fluid of density  $\rho$  where  $g$  is the acceleration of gravity [55]. The resulting pressure increase in the container (magma body) deforms the surrounding rock inducing small earthquakes. This model is criticized on the basis that assumptions of a ridged container and an incompressible fluid seriously violate realistic conditions in the earth [75].

Under rectified diffusion, pressure oscillations imposed on a gas-saturated fluid with pre-existing bubbles pump gas into the bubbles over multiple cycles. Gas evolves from the fluid into the bubble during the dilatational phase, when bubble surface area is maximal, and out of the bubble back into solution during compressional phase, when the bubble surface area is minimal [94]. The implied pressure gain integrated over multiple cycles is then transmitted to the surrounding rock inducing small earthquakes. [48] point out, however, that the effectiveness of this model is limited by reasonable gas diffusion rates in hydrous fluids or magma with respect to the frequencies of seismic waves driving the pressure oscillations.

More promising bubble models appeal to the strong sensitivity of bubble nucleation rate to the supersaturation pressure [56] and the results of numerical models by ► **Volcanoes, Non-linear Processes in** and [14,85], indicating that a small pressure drop imposed on a densely packed matrix of tiny bubbles can lead to rapid, diffusion-driven bubble growth. The implications of these models, however, have yet to be more fully explored in the context of dynamic triggering.

Two more speculative models involve magma instabilities triggered by dynamic stresses. In one, a loosely held crystal mush accumulated on the walls of a crystal-

lizing magma body may be dislodged by dynamic shaking. The sinking crystal mush would induce a convective plume as it displaced hotter, less dense magma. In the case of volatile-rich magma, buoyant convection would be enhanced by bubble nucleation and growth as confining pressure drops with decreasing depth [37]. Under suitable conditions, the resulting pressure increase within the magma body could evolve over days [56]. If the magma chamber was already in a near critical state, the culmination could be magma intrusion into the overlying crust or the onset of an eruption. Whether this process culminates in a simple pressure increase, an intrusion, or an eruption, the sensible onset of locally triggered seismicity and deformation might be delayed by hours to perhaps days with respect to the passing seismic waves from the distant earthquake. A second, even more speculative model appeals to dynamic stresses disrupting the solid matrix of a partially crystallized magma body thereby releasing any differential tectonic stress sustained by the solid matrix [36,37]. As the magma body relaxes with a time constant governed by the effective viscosity of the disrupted crystal mush, stress would be transferred to the surround crust inducing deformation and local seismicity. In essence, this model corresponds to the relaxation of an Eshelby inclusion in an elastic medium [20].

### Aseismic Deformation

The relaxing magma body of the previous paragraph is one example of aseismic deformation with the potential of triggering local deformation and the onset of secondary seismicity. A less speculative example involves aseismic creep on faults triggered by dynamic stressing. Deformation associated with fault creep transfers stress to the adjacent crust, which in turn triggers local seismicity, as in the example involving seismicity triggered on the Reykjanes Peninsula following the  $M = 6.5$  earthquake in the South Iceland Seismic Zone in 2000 [2]. [4] document aseismic fault slip (creep) on faults in the Salton Trough of southern California triggered by the three  $M > 6$  earthquakes in the Landers, California sequence of 1992 (the  $M = 6.1$  Joshua Tree,  $M = 7.3$  Landers, and the  $M = 6.2$  Big Bear earthquakes). In this case, all instances of triggered slip were on faults within 150 km of the  $M > 6$  earthquakes. In these examples and observations from triggering in Long Valley caldera and Sierra Prieto geothermal field in Baja California [38,50] the geodetic moment for triggered aseismic deformation exceeds the cumulative seismic moment for the triggered earthquakes by a factor of two or more. This emphasizes the importance of high-resolution deformation monitoring in ar-

reas susceptible to dynamic triggering for resolving the role of aseismic deformation in the dynamic triggering process.

### Future Directions

In the last 25 years, in the wake of the Landers earthquake, the study of dynamically triggered seismicity has given us new insight into earthquake initiation and the failure regime in the Earth's crust. Some argue that the state of stress in the crust is highly spatially variable [77]. Given this, the likelihood of triggering seismicity would also be spatially variable. [97] and [105], however, argue that the Earth's crust is critically stressed and on the verge of failure nearly everywhere. If this were the case, one might expect triggering due to small dynamic stress perturbations to be a ubiquitous phenomenon. In either case, the study of remotely triggered seismicity provides clues to spatial distribution of critically stressed crustal volumes.

Unfortunately, although we can measure stress field perturbations from dynamic waves from earthquakes, we rarely have a detailed understanding of the background stress field these perturbations are modulating. In addition, dynamically triggered earthquakes are often too small or occur in too sparsely instrumented areas to resolve reliable focal mechanisms. Because of these limitations, our understanding of how dynamic stresses from remote earthquake wavetrains induce a given crustal volume to respond with triggered seismicity remains incomplete. Advances will require more cases of dynamically triggered seismicity captured by both spatially dense seismic networks and continuous, high-resolution deformation monitoring networks.

Recent observations of phase modulated dynamic triggering offer powerful datasets of the precise time history of dynamic stress triggering. Because similarities exist between phase modulated dynamic triggering of seismicity in the shallow crust of a volcano's edifice [103] and deep in a subduction zone [81], the emerging study of non-volcanic tremor may provide new leverage on understanding how dynamic stresses influence seismic slip.

As new observations of dynamically triggered seismicity are reported, one conclusion is becoming increasingly evident: multiple causative processes exist. The wide variety in time scales over which triggering occurs and the spatial and temporal characteristics of triggered seismicity sequences and associated deformation responses cannot be fit with any one model yet proposed. Rather, different models are consistent with different episodes of triggering. For example, fluid activation and stress corrosion models

are most applicable in volcanically and geothermally active environments. In some cases, such as the complex triggered response of Yellowstone, Mt. Rainier, and the Long Valley caldera areas to the Denali Fault earthquake, multiple processes may be occurring simultaneously in the same locale, yet on different time scales. Of the physical models described above, seismicity triggered instantaneously or within seconds of the dynamic stress perturbation is consistent with models based on simple brittle failure, brittle failure with nonlinear friction effects, stress corrosion, unclogging of fractures, or rectified diffusion, whereas triggered seismicity delayed by hours to days is more consistent with models involving aseismic deformation, advective overpressure, sinking crystal plumes, or a relaxing magma body.

In the few cases where hydrologic and high-sample rate strain data are available, dynamically triggered seismicity is accompanied by changes in water levels in wells [79] and significant deformation signals [2,25,36,50]. A complete understanding of dynamic triggering will require research approaches that integrate seismic, deformation, and hydrologic datastreams. To this end, we challenge Earth scientists to broaden their thinking and tap these observations to better understand the initiation of earthquake failure.

### Glossary

**Earthquake prediction** Place of epicenter, time of occurrence, and magnitude are the three main items of earthquake prediction. Occurrence time is the most difficult to predict. Depending on the concerned time scales, prediction is usually classified as long term ( $\sim$  tens of years), intermediate term ( $\sim$  a few years), and short term (months to days) predictions. Electromagnetic signals of earthquakes are mainly concerned with the short term prediction.

**Piezo-electric effect** Piezo-electricity is the electric polarization produced in certain crystals and ceramics by the application of mechanical stress. Among rock-forming minerals, quartz is most strongly piezo-electric, but its effect is much reduced because quartz crystals are usually randomly oriented. Moreover, stress-induced piezo-electric polarization in rocks is kept canceled by compensating charges. At rapid stress drop, bulk polarization appears as the compensating charge cannot disappear instantly and decays with a time constant  $\tau = \epsilon/\sigma$ , where  $\epsilon$  is dielectric constant and  $\sigma$  electric conductivity.

**Electro-kinetic effect** Electro-kinetic effect, also called streaming potential, is caused by the presence of the solid-liquid interface. The double layer consists of ions (anions in most cases of rock-water system) that are

firmly anchored to the solid phase and ions of the opposite sign (cations) in the liquid phase attracted to them near the boundary. The liquid phase is in surplus of cations so that when the liquid flows due to a pressure gradient, an electric potential gradient is formed. It is expressed as  $\text{grad } V = -(\epsilon\zeta/\eta\sigma)\text{grad } P$ , where  $\epsilon$ ,  $\sigma$  and  $\eta$  are the dielectric constant, electric conductivity, and viscosity of the fluid, whereas  $\zeta$  is a constant called zeta potential. Thus, the streaming potential is small for high conductive and viscous liquid.

**Telluric current** Electric current flowing in the surface layer of the earth's crust is called telluric current. Mainly it consists of the current induced by extra-terrestrial geomagnetic field variations (called magneto-telluric or MT current) and the current as a part of the global circuit between ionosphere and ground. MT current carries information on the electrical structure of the earth's interior: higher (lower) frequency for shallower (deeper) structure. Telluric current can also be of man-made origin leaking from such electric sources as factories and trains. Telluric current is measured by dipoles of electrodes inserted into the ground at separate points. It has been postulated that transient anomalous telluric currents are observed before earthquakes.

### Frequency bands of electromagnetic waves

Electromagnetic waves are classified by frequency bands as follows:

ULF ( $<$  a few Hz), ELF (a few Hz  $\sim$  3 kHz), VLF (3–30 kHz), LF (30–300 kHz), MF (300–3000 kHz), HF (3–30 MHz), VHF (30–300 MHz), UHF (300–3000 MHz), SHF (3–30 GHz). Not only ULF to VHF bands, but also infrared ( $\sim 10^{13}$  Hz) and visible ( $\sim 10^{14}$  Hz) bands are considered to be involved in earthquake-related electromagnetic waves.

**Skin effect** The intensity of electromagnetic wave decreases exponentially with distance in a conductive medium. In a simple case, the distance where the intensity becomes  $1/e$ , called the skin depth  $\delta$ , is expressed as  $\delta = \sqrt{2/\mu\sigma\omega}$ , where  $\mu$  and  $\sigma$  are magnetic permeability, and electric conductivity of the medium and  $\omega$  is the angular frequency of the wave.

**Ionosphere** The upper atmosphere, where electrons are stripped off from oxygen and nitrogen atoms by solar radiation, is called the ionosphere. It consists of a D-layer (60–90 km), E-layer (90–130 km),  $F_1$ -layer (130–210 km), and  $F_2$ -layer (210–1000 km). Electron density is highest in the  $F_2$ -layer. The electron density of the ionospheric lower layer can be measured by ground-based ionosonde, whereas total electron con-

tent (TEC) of the whole ionosphere is estimated by global position system (GPS). Electric currents in the ionosphere produce transient variations of geomagnetic field. The suggestion has been made that the ionosphere is affected before earthquakes.

### Definition of the Subject

Throughout most of human history, electromagnetic phenomena associated with earthquakes have been repeatedly told. A typical one is earthquake light. Until rather recently, however, most records were in the realm of folklore [31,71]. Since earthquakes are understood as a catastrophic event to occur when slowly increasing tectonic stress in the earth's crust reaches a critical level, it may well be expected that the same stress may give rise to some electric, magnetic, or electromagnetic phenomena (EM phenomena hereafter) and some persistent research on them was initiated more or less simultaneously in varied parts of the world in the 1980s in two main streams. One was monitoring of possible emissions from focal regions in a wide range of frequency from DC to VHF, whereas the other was to monitor the anomalous transmission of man-made EM waves of varied frequencies over focal regions. Theoretical and experimental studies on the mechanism of EM phenomena have also been made. This relatively new branch of science is now called Seismo-Electromagnetics.

These EM phenomena attract high attention for their possible usefulness in earthquake prediction, which is of immense societal importance and considered as one of the last frontiers in earth sciences. Because many of the EM phenomena are observed prior to earthquakes, they may serve as their precursors, which have been difficult to find by usual seismological and geodetic methods. The extremely interdisciplinary nature of the subject matter is the distinct feature of Seismo-Electromagnetics and the backgrounds of many research fore-runners are neither seismology nor geodesy, but other fields, e. g., general geophysics, solid state, statistical, and ionospheric physics, radio, space, and even biological sciences. This situation in turn tends to make their accomplishments difficult to be understood and accepted by the conventional earthquake community. Of course, EM phenomena do not cause earthquakes. Both EM phenomena and earthquakes are considered to be caused by regional or local tectonic stresses, but some EM phenomena seem to appear shortly before the occurrence of earthquakes. That EM phenomena do not cause earthquakes may be another reason why few seismologists are interested in them.

### Introduction

Earthquake (EQ) related EM signals may be classified into two major groups, each covering wide frequency ranges. One is EM signals supposedly emitted from the focal zone and the other is anomalous transmission of EM waves over the epicentral region.

The emission type signals are reported for geo-electrical potential (telluric current) and geomagnetic field and for EM waves. The best known example of the former is the Seismic Electric Signals (SES) in the VAN-method which has been developed in Greece since the early 1980s and applied also in Japan since the 1990s [76,78,82]. SES are transient DC geo-electrical potential variations observed before EQs by dipoles of buried electrodes. Experimentally and theoretically, the VAN method is by far the best equipped method in this category and has survived debates [22,41]. Along with the current views that earthquakes are catastrophic events at a critical state of complex systems, a new time domain called Natural Time has been introduced to integrate SES with seismicity for short-term EQ prediction (e. g., [82]). Late in the 1980s, pre-seismic magnetic signals began to be reported. They were ultra low frequency (ULF) anomalous changes observed before *M*7.1 Loma–Prieta EQ, 1988 [16] and *M*7.1 Spitak EQ, 1989 [39] followed by *M*8.0 Guam EQ, 1993 [29]. Among them the case of Loma–Prieta is considered as most convincing. For the higher frequency range, there have been reports of VLF signals received by aerial antennas [3,23,95]. There have been reports from Greece that even VHF signals have also been received [9]. For high frequency signals, considering the electric conductivity of the crust, their emergence to the surface from the source regions at depth presents problems to be solved.

Pre-seismic appearance of EM signals makes them useful for EQ prediction. It has often been questioned, however, why they appear only pre-seismically and not co-seismically. This point makes the scientific community dubious about EQ-related EM signals in general. Actually, co-seismic signals are routinely observed but not reported each time for the obvious reason that they are not useful for EQ prediction. However, all the co-seismic signals observed so far were found to occur at the time of the arrival of seismic waves. They are, therefore, co-seismic wave signals and not “true” co-seismic. The fact that no true co-seismic signals are observed may be an important clue in exploring the physical mechanism of signal generation.

The generation mechanism of EM signal emission may be different for different frequencies. They may involve the electro-kinetic effects and pressure-stimulated polarization effects [79] for DC to low frequency signals, and

piezo-electric effects and exo-electron emission [10] for higher frequency ones. For the optical range like EQ light, a very different mechanism such as de-excitation of air molecules may be involved. Apart from these, a mechanism involving so-called positive holes (p-holes) in rock forming minerals under stress has also been proposed recently [18].

The second class of signals, i. e., the anomalous transmission of EM waves, began to be actively discussed in the late 1980s [24]. One of the best documented early cases may be at the 1995 Kobe earthquake in which received VLF radio waves for navigation purposes showed anomalies in both phase and amplitude a few days before the main shock [52]. Moreover, at the same Kobe EQ, it was first found that FM radio waves from stations beyond the line of sight can be received before main shocks [40].

The anomalous transmission of EM waves means that there are some anomalies in the path, i. e., ionosphere or atmosphere, over the epicentral region, which may be verified independently. Investigation to detect such changes has been vigorously conducted both by ionosonde [45] and by topside observation from satellites [63]. On the basis of these observations, the concept of Lithosphere-Atmosphere-Ionosphere (LAI) coupling through which pre-seismic changes in the earth's crust may be transferred to the upper atmosphere became one of the central issues of Seismo-EM studies.

This article does not deal with the aspects of EM studies of the earth devoted for elucidating the subterranean electrical structures. Although their EQ related structural time changes, if observed, would be of great interest, there has practically been no significant reported progress.

## Telluric Current Anomalies and Natural Time

### The VAN Method

The best example of modern research on DC electric signals is that of the VAN method [18,80,82], named after the initials of the founding Greek scientists, P. Varotsos, K. Alexopoulos, and K. Nomikos. The VAN group has been making actual short-term predictions of  $M \geq 5$  Greek EQs during well over a couple of decades. The criteria for successful prediction imposed by themselves are: < a few weeks in time, < 0.7 units in magnitude ( $M$ , hereafter), and < 100 km in epicentral distance. The length of time window depends on the type of signals.

The changes in the geo-electrical potential differences between buried electrodes, called Seismic Electric Signals (SES), are continuously monitored at many stations (Fig. 1a). At each station, several short (50–200 m) dipoles in both EW and NS directions and a few long dipoles (2–

20 km) in appropriate directions are installed. Compared with all earlier works using only one or two dipoles, adoption of the multiple dipole system was a distinct progress in noise rejection.

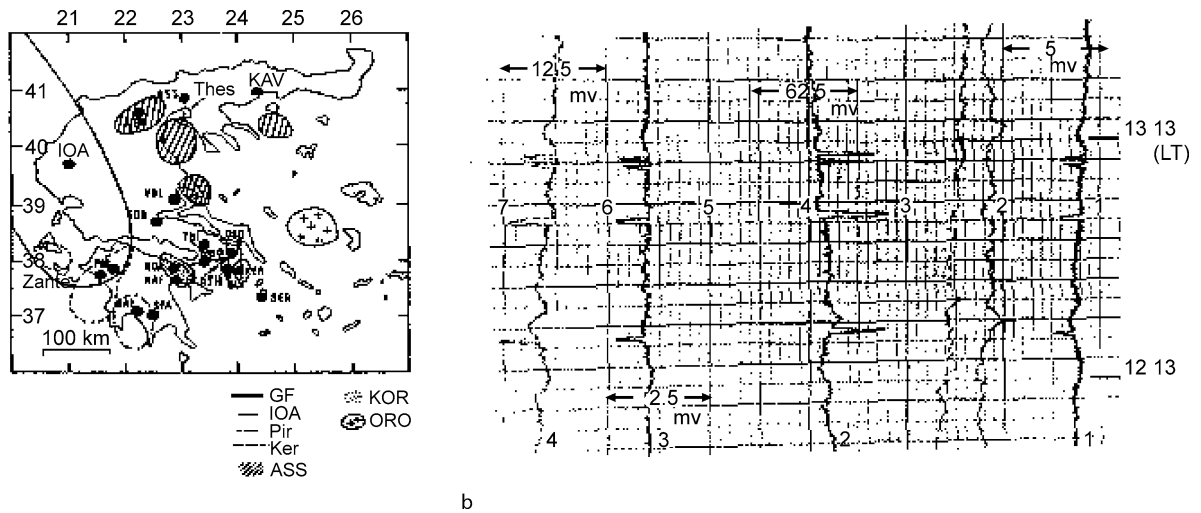

Amplitude of SES is of the order of 1 mV/100 m. There are four types of signals, i. e., single SES, SES Activity, Gradual Variation of Electric Field (GVEF), and short duration pulse. Single SES, having duration 1/2 min ~ several hours, precedes single EQ, whereas SES Activity, which consists of a number of SES in a short-time, is followed by a series of EQs before the main shock (Fig. 1b). As will be explained later, SES Activity has been playing a major role in the recent VAN work related to Natural Time analysis. GVEF has amplitude an order of magnitude larger than usual SES, but is only rarely observed for large EQ. The last type, i. e., short duration pulses appear shortly (some minutes) before EQs. These pulses, with amplitude sometimes amounting orders stronger than SES, have received rather little attention mainly because their lead time of minutes has been considered too short for useful EQ prediction.

In the VAN type of observation, noise discrimination is critically important. To eliminate noise, they have developed a set of rules as follows:

1. Changes with magneto-telluric origin can be eliminated because they appear at all the stations simultaneously.
2. SES must appear simultaneously on all of short and long dipoles, but only at the concerned station.
3. SES must satisfy the  $\Delta V/L = \text{constant}$  relation for short parallel dipoles, where  $\Delta V$  is the amplitude of SES and  $L$  the dipole length.
4. The polarity and amplitude of SES of short and long dipoles must be compatible with the assumption that the source is distant compared with the dipole lengths.

The VAN group made two major discoveries. One is the so-called "Selectivity" and the other is the so-called "VAN-relation". The Selectivity has two aspects. (1) There are only selected sites which are sensitive to SES (sensitive sites). They were found only through testing at many sites: Almost 90% of sites were insensitive. This fact gives another strong reason why earlier efforts to catch precursory electric signals failed. (2) A sensitive site is sensitive only to SES from some specific focal area(s), which are not always in close proximity. A map identifying those focal area(s), SES from which are sensed by a site, is called the "Selectivity map" of that site (Fig. 1a), which provides information on the epicentral location of the impending EQ when a SES is observed at the site. The Selectivity is considered to originate from the inhomogeneity of the subterranean electrical structures, i. e., SES goes only through conduc-

Earthquakes, Electromagnetic Signals of, Figure 1

**a** Distribution of VAN stations and “Selectivity map” of several stations as of 1996 (after [74]). For Zante, see text. **b** An example of SES Activity recorded on three short dipoles (labeled 1, 3, and 4) and long dipole (2) at Ioannina (IOA in **a**) station on August 31, 1988. Note that intensity scales in mV are different for different dipoles. The Killini–Varthelomio EQs were predicted based on these data [82]

tive channels. The VAN group has presented many model studies of channels [82]. So far, however, the real existence of such subterranean channels has not been verified by usual MT or other electric exploration techniques, possibly because the scales of the proposed channel structures are too small for the presently available resolving power.

The other discovery from the VAN research, i. e., the “VAN relation”, is the following relationship among the focal distance,  $r$ , EQ magnitude,  $M$  and the observed intensity of SES,  $\Delta V/L$ .

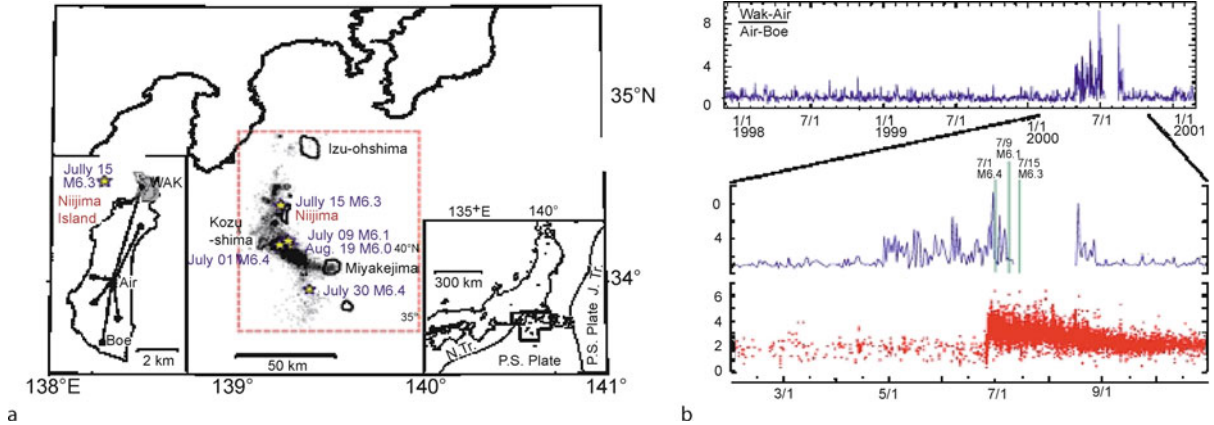

$$\log(\Delta V/L \times r) = aM + b, \quad (1)$$

where  $a$  is a constant 0.34–0.37 and  $b$  is a site-dependent constant. Once the epicentral location is estimated from the Selectivity map mentioned above,  $M$  of the impending EQ can be assessed since both  $\Delta V/L$  and  $r$  are known.

The VAN method has been a contentious subject (e. g., [22,41]). It is difficult, in principle, to prove the causal relationship between SES and EQ occurring at separate times and the only reasonable way to make the relationship credible would be to accumulate as many case studies as possible on one hand and to build plausible physical models on the other. Both endeavors have been published in papers too many to quote here and they are summarized in [82]. According to an independent evaluation (Uyeda et al. [75] and later additional check), out of 16 mb  $\geq 5.5$  EQs which occurred in the Greek region during Jan. 1, 1984–Jan. 1, 2004, 13 were successfully predicted. After the predictions of three large EQs in 1995,

there were no large EQs until another three mb  $\geq 5.5$  occurred in late 1997. It is remarkable that during the 2.5-year of quiescence no prediction was issued for the area and two out of the three 1997 events were predicted remarkably well. The score of the VAN method has been assessed by many authors. Most of the evaluations were in favor, but some were not. The low scores often resulted either when the assessors did not follow what the VAN group designated on the items such as allowable lead times for different type of SES, or the magnitude scales to use. Mulargia and Gasperini [53] claimed that “the apparent success of VAN predictions can be confidently ascribed to chance” and ignited heated debates (e. g., [22,41]). In the present authors’ view, however, VAN has well survived them. In Greece, VAN-type SES has been observed by other groups also.

In Japan, VAN-type monitoring was initiated on a trial basis in the late 1980s and was expanded in 1996 [76]. Despite the serious problems caused by the high level of artificial noise, in particular from DC-driven electric trains, the existence of the VAN-type SES has been confirmed for  $M > 5$  EQs occurring within  $\sim 20$  km or so of a station. Moreover, phenomena attesting to “Selectivity” were discovered. In the year 2000, a two-month long seismic swarm, with  $\sim 7,000$   $M \geq 3$  shocks and five  $M \geq 6$  shocks, occurred in Izu Island region: See Fig. 2a. For this swarm activity, significant pre-seismic electric disturbances were observed [77]. From about 2 months before the swarm onset on June 26, innumerable clear, un-

Earthquakes, Electromagnetic Signals of, Figure 2

**a** Seismic swarm activity in 2000 in Izu island region. *Inset in the left* shows the dipole configuration in Niijima Island. Each end of the long dipole had short dipoles. usual geo-electrical potential changes started on Niijima Island (Fig. 2). These anomalous changes appeared only in the northern part of the island, possibly reflecting the extremely heterogeneous underground structure of the volcanic region.

Co-seismic signals have been observed for many EQs. However, they always started with the arrival of seismic waves and not at the origin time of EQs. The changes are probably local effects of passing seismic waves. There may be many reasons why no true co-seismic signals are observed. One is that, as laboratory experiments show, signals generated at ruptures are in much higher frequency range, so that they cannot be registered by usual high-cut measurement (0.1–1 Hz sampling) and the second is that, even when a higher sampling rate is employed, the high frequency signals attenuate before reaching the receiver. In fact, the pre-seismic stress accumulating process giving rise to SES and the instantaneous stress releasing event are physically very different processes and there seems to be no compelling reason why they generate similar signals.

### Natural Time

Seismicity as a critical phenomenon has been actively discussed by many authors (e. g., [4,38,65,68,73]). It has been shown that SES and EQs reveal dynamic evolution characteristics to the critical stage when their time series is analyzed in the framework of natural time  $\chi$ , which was introduced by the Varotsos' group (e. g. [82,83]). The symbol  $\chi$  stands for the ancient Greek word  $\chi\rho\omicron\nu\omicron\sigma$ , which means "time". The possible usefulness of natural time analysis in predicting catastrophic events has been demonstrated

not only for the subjects of our immediate concern, but also for other critical phenomena, including sudden cardiac death [84,85].

In a time series comprised of  $N$  events, the natural time  $\chi_k = k/N$  serves as the index for the occurrence of the  $k$ th event. In natural time analysis, the evolution of the pair of two quantities ( $\chi_k, Q_k$ ) is investigated where  $Q_k$  denotes the quantity proportional to the energy of the  $k$ th event. The time series of events as shown in Fig. 3a is expressed in natural time as in Fig. 3b. For the purpose of analysis, the following function  $\Phi(\omega)$  was introduced.

$$\Phi(\omega) = \sum_{k=1}^N p_k e^{i\omega \frac{k}{N}}, \quad (2)$$

where  $p_k = Q_k / \sum_{n=1}^N Q_n$  and  $\omega = 2\pi\phi$ ,  $\phi$  standing for the frequency in natural time (natural frequency). This  $\Phi(\omega)$  should not be confused with the discrete Fourier Transform because  $\omega$  is a continuous variable. If we regard  $p_k$  as the probability density function of  $\chi$ , in analogy with probability theory, its Fourier transform  $\Phi(\omega)$  may be regarded as the characteristic function of  $\omega$ . The power spectrum of  $\Phi(\omega)$ ,  $\Pi(\omega) = |\Phi(\omega)|^2$ , for the dynamical system approaching critical state with infinitely long-range temporal correlation was calculated to be as follows (see p.259–260 in [82]):

$$\Pi(\omega) = |\Phi(\omega)|^2 = \frac{18}{5\omega^2} - \frac{6 \cos \omega}{2\omega^2} - \frac{12 \sin \omega}{5\omega^3}. \quad (3)$$

Taylor expansion of Eq. (3) gives, for small values of  $\omega$  ( $\omega \rightarrow 0$ ),

Earthquakes, Electromagnetic Signals of, Figure 3  
Time series of events, **a** in conventional time  $t$ , and **b** in the natural time  $\chi$

$$\begin{aligned} \Pi(\omega) &= 1 - \kappa_1\omega^2 + \kappa_2\omega^4 + \kappa_3\omega^6 + \kappa_4\omega^8 + \dots \\ &= 1 - 0.07\omega^2 + \dots \end{aligned} \quad (4)$$

Thus, a time series should show  $\kappa_1 \approx 0.07$  when approaching the critical stage. The reason why the natural time domain is useful when information on intervals between events is lost while retaining only information on the order and relative importance of events is an intriguing question. As to this point, Abe et al. [1] have shown that this time domain in fact is optimal for enhancing the signals in time-frequency space.

In Greece,  $\kappa_1 \approx 0.07$  was experimentally ascertained first for SES activities preceding four large EQs; 1995  $M6.6$  Kozani–Grevena EQ, 1995  $M6.5$  Eratini–Egio EQ, 1997  $M6.4$  Strofades EQ, 2001  $M6.6$  Aegean Sea EQ and later also for other major EQs, supporting this view [82,86]. Infinitely long-range temporal correlations of Greek SES were independently confirmed by Weron et al. [89].

In the case of seismicity, to investigate its time evolution, the power spectrum  $\Pi(\omega)$  of the seismicity in natural time subsequent to associated SES activity was calculated as each consecutive EQ occurred. It was, then, shown that, for major Greek EQs,  $\Pi(\omega)$  approached that of the critical state ( $\kappa_1 = 0.07$ ) a few days before the main shocks [82]. This indicated that the seismicity approached the critical state at that time. This unexpected discovery may shed new light on the EQ generation mechanism itself. At the same time, this suggests the possibility of narrowing the time window of predicting EQs to a few days, when SES data are available. It may be added, albeit different from the Natural Time defined here, that an attempt was made to identify seismic quiescence with the viewpoint that the seismic process proceeds with its internal clock called “events time scale” [66].

### Ultra Low Frequency (ULF) Anomalies

ULF generally means lower than several Hz. Research in this frequency range was started late in the 1980s. ULF

signals are advantageous over those in higher frequencies because of their large skin depth. The best-known example is the case of the  $M7.1$  Loma-Prieta (California) EQ in 1989 [16]. Observation was made at a site which happened to be at 7 km from the epicenter. The amplitude of the horizontal component started anomalous enhancement at about 2 weeks prior to and a sharp increase a few hours before the EQ. Figure 4 shows the records at 0.01 Hz band. The disturbance lasted for about 3 months after the EQ. These anomalous changes were not of solar terrestrial origins because they were not observed at other distant stations. Moreover, these have never been observed at any other time during the whole period of observation of more than 15 years. It was, thus, concluded that the anomalies were related to the EQ. Reports of observing

Earthquakes, Electromagnetic Signals of, Figure 4  
The amplitude of the geomagnetic horizontal component at 0.01 Hz band [16]

Earthquakes, Electromagnetic Signals of, Figure 5  
Change of 81 kHz electromagnetic wave observed in Tokyo [23]

pre-seismic ULF geomagnetic anomalies have been made also for  $M6.9$  Spitak (Armenia) EQ in 1988 [39] and  $M8.0$  Guam (Marianas) EQ in 1993 [29]. Further efforts in Japan and elsewhere have been summarized by Hattori [28]. It seems, however, that a more rigorous approach is needed to make the ULF studies sufficiently credible to the scientific community.

### Higher Frequency Electromagnetic Emission and Earthquake Light

Pre-seismic electromagnetic wave emission in the VLF–LF-range has been reported since the 1980s. Gokhberg et al. [23] reported pioneering observations as shown in Fig. 5. Emissions at 81 kHz increased one or two hours before  $M6.1$  and  $M5.3$  earthquakes took place and decreased after the second shock.

Asada and his group started investigation of EQ-related VLF emissions in the early 1990s [3]. They monitored the wave forms of two horizontal magnetic components of VLF waves, through which the apparent incoming direction of VLF pulses was determined. They found that, before  $M5$  class land EQs within 100 km of their stations, some pulses with a fixed incoming direction appeared and the EQs actually occurred in that direction, whereas the sources of overwhelmingly numerous and stronger noises were moving along with lightning sources (Fig. 6). Moreover, there is a well-documented report of undeniable noise in commercial MF radio bands, experienced by an automobile driver approaching Kobe, some minutes before the Kobe EQ of 1995 (see [55]).

Enomoto et al. [12] recorded anomalous pulses of geo-electrical current (HF-band) at Erimo station, Hokkaido, Japan, from February 2000 to March 2001 and from August to September 2003. The former anomalies occurred before and during the volcanic activity of Mt. Usu (200 km away), while the latter started one month before the 2003 September 26  $M8.0$  Tokachi-Oki EQ (80 km away). These

Earthquakes, Electromagnetic Signals of, Figure 6  
Rose diagram of incoming VLF signals observed on May 18, 1999 at two sites.  $M4.1$  EQ occurred at black square point on May 22 [3]

were the only anomalies during their 10-year observation period.

For the Kobe EQ, while measuring sporadic Jovian decametric emissions with a radio interferometer at an observatory at about 80 km from the epicenter, unusual pulsed emissions at 22.2 MHz were detected tens of minutes both before and after the main shock [47]. Such unusual pulses have never been observed at other times and the possible source direction was estimated to be that of the main surface exposure of the EQ fault. There was no clear co-seismic radiation. Warwick et al. [88] reported a similar observation related to the 1960 Great  $M9.5$  Chilean EQ.

Also in the high frequency range, Eftaxias et al. [9] have reported results obtained in Greece. Since 1994, they have been running a station on Zante Island in the Ionian Sea (see Fig. 1a), where installation was performed of (i) six loop antennas in EW, NS and vertical magnetic field at both 3 kHz and 10 kHz; (ii)  $\lambda/2$  electric dipoles for 41,

54, and 135 MHz and (iii) two Short Thin Wire Antennas for ULF ( $< 1$  Hz) anomalies. Sampling rate is 1 Hz. They report that MHz–kHz EM anomalies have been detected during a few days to a few hours prior to near-surface land EQ with  $M > 6$ , i. e., the 1995 Kozani-Grevena EQ and 1999 Athens EQ. The MHz radiation appeared earlier than the kHz. They interpret the phenomena as due to small-scale cracking and assume that the more grown-up cracks generate the lower frequency anomalies. They also look to the EQ as a critical phenomenon and suggest that the shift from MHz to kHz activity corresponds to an anti-persistence to persistence shift. In their observations, there was no co-seismic anomaly.

As mentioned earlier, however, transmission of EM waves in the conducting earth beyond the skin depth distance is an important unresolved problem common to all the topics reported in this section.

### EQ Light

Earthquake light (mostly co-seismic) has been reported all over the world from ancient Greek, Roman, and Chinese times. There is no doubt that the phenomena exist. Light emanates from the whole sky, or locally from the ground. The shape reported is like aurora, pole, flash, ball lightning, and so on, while the color widely ranged from blue and blue-white to red-yellow and orange. We, however, note that all reports may not be on natural phenomena but on some artificial effects such as sparks at power lines.

Galli [21] collected 148 eyewitness reports in late 19th Century Europe (see [71]). In Japan, Musha [54] collected about 2,000 eyewitness reports for 65 EQs, while Terada [69] discussed the theoretical aspects and suggested that the electro-kinetic effect may be a possible cause. From 1965 to 1967, there was a large EQ swarm at Matsushiro area in central Japan and numerous luminous phenomena were seen and photographs were taken as shown in Fig. 7 [91].

For the 1995,  $M7.3$  Kobe EQ, Enomoto and Zheng [11] examined the trace of gas emission in the Awaji fault where the rupture started. They suggested that the gas plasma emission might have emitted the light. Kamogawa et al. [37] reported some independent witnesses that a luminous object moved a long distance a few seconds before the main shock in the direction of the rupture. Ikeya and Takaki [32] numerically showed that the screening charges neutralizing the polarized piezoelectrical rock may generate a strong co-seismic electric field, and the de-excitation of nitrogen molecules excited by collision of electrons accelerated by the electric field produce the blue EQ-light.

### Lithosphere-Atmosphere-Ionosphere (LAI) Coupling

Pre-seismic atmospheric-ionospheric anomalies before EQs have been reported since the 1970s [2,20,24,27] and the concept of pre-seismic lithosphere-atmosphere-ionosphere coupling arose. Historical reviews and important works that are not introduced in this article may be tracked from references of Pulinet and Boyarchuk [61] and Kamogawa [33].

Liu et al. [43] found in Taiwan that the ionosonde measured critical plasma frequency, foF2, corresponding to the electron density of the ionospheric F2 layer, significantly decreased during afternoons within a few days before  $M \geq 6$  EQs. For example, such ionospheric anomalies appeared 3 and 4 days before the 1999  $M7.7$  Chi-Chi EQ. Similar EQ-related electron density depression occurring above Taiwan Island was observed in the GPS total electron density (TEC) [44]. From such observations, Liu et al. [45] demonstrated that the appearance of the anomalies within 5 days was statistically significant at 5% level for the  $M \geq 5.4$  EQs occurring within 150 km.

Sub-ionospheric anomalies before large EQs were reported by Gokhberg et al. [24] and Gufeld et al. [27]. They used VLF ship-navigation waves (10–20 kHz) and observed pre-seismic anomalies between the transmitter and the receiver during mid-night. Marenko [49] statistically supported the results of Gokhberg et al. [24], while Michael [50] obtained a less optimistic conclusion. Meanwhile, the studies have been further developed mainly in Russia, Japan, and Italy. For example, pre-seismic variations of terminator-times, i. e. the sunrise and sunset for VLF waves, were demonstrated [52]. Clilverd et al. [6], on the other hand, did not obtain similar positive results when they applied the terminator-time method to their 5-year data of reception at Faraday, Antarctica (receiver) of VLF waves transmitted from the northern United States. Maekawa et al. [48], measuring LF waves,

statistically investigated the correlation between sub-ionospheric anomalies and  $M \geq 6$  EQs in Japan and found that the amplitude and dispersion of received signals significantly decreased 2–6 days before the EQs. Thus, this issue is still controversial [34,64].

In the VHF range, Kushida and Kushida [40], while monitoring meteorites plunging into the high atmosphere by reflection of FM radio waves, detected anomalous reception, just a few days before the Kobe EQ, of the FM radio waves from distant (beyond the line-of-sight) stations. This was a new discovery and these authors consequently began extensive measurements on other EQs. With regard to the anomalous reception of VHF waves from transmitters beyond the line-of-sight, Fujiwara et al. [20] statistically showed significant enhancement of atmospheric anomalies lasting for a few minutes–several hours within 5 days before  $M \geq 4.8$  EQs.

## Mechanism of Pre-Seismic EM Phenomena

### Generation Mechanism of EM Signals

**Electro-Kinetic Effect** The electro-kinetic effect can be a plausible source for SES (DC) and ULF emission. Mizutani et al. [51] first proposed a model in which, during the dilatancy stage, pore pressure in the dilatant region decreases and water flows into this region from the surrounding area, generating electric and magnetic precursors of EQs. Since then, many models have been proposed (e. g., [15,93]). Fedorov et al. [13], however, suggested that the expected magnitude of seismo-EM signals in the ULF-VAN range from an electro-kinetic source may reach the detection level only for a favorable set of crustal parameters.

**Models Related to Defects in Solids** A SES-generation model by pressure-stimulated currents (PSC) was proposed by Varotsos and Alexopoulos [79]. Their model is based on the physics of the point defects in solids. The impurities and vacancies have excessive and opposite-sign effective charges and form local electric dipoles. The directions of the local electric dipoles usually distribute randomly. Under an electric field, dipoles will align in its direction. The alignment is an activation process in which the time constant is an Arrhenius-type function of stress as well as temperature. Therefore, an avalanche of alignment takes place when stress approaches a critical level (Fig. 8). It has been later suggested that, instead of electric field, inhomogeneous deformation mentioned in the next paragraph may work to align the dipoles in the direction of the stress gradient (see [14]). This model is unique among other models in that SES is generated spontaneously dur-

Earthquakes, Electromagnetic Signals of, Figure 8  
 Pressure-stimulated current  $j$  occurs at a critical pressure  $P_{cr}$  under the external electric field  $E$ .  $P_{fr}$  is the fracture pressure (after [79])

ing gradual increase of stress without requiring any sudden change of stress such as micro-fracturing. For the SES to work as a precursor, it is assumed that the critical level of stress for SES generation is lower than that of mechanical failure causing EQ. A thorough verification of the PSC model by laboratory pressure experiments is fatally lacking up to this stage.

In relation to SES generation, deformation-induced charged flow is an interesting possibility [56]. This flow was observed to take place as a result of inhomogeneous plastic deformation of ionic crystals, such as NaCl, in the direction of the stress gradient without applying electric field. It was interpreted that charge carriers are charged dislocations. Some experiments were conducted on rocks with similar results (see [82]). Independent of these, Freund and his colleagues have recently been proposing a unique mechanism for ULF electric signals ([18] and Ref. therein). They have discovered in the laboratory that when a block of igneous rock is put under stress locally, the rock turns into a battery without any external electric field (Fig. 9).

This striking phenomenon is interpreted as follows: A fraction of the oxygen anions in the rock-forming silicate minerals is not in their usual 2-valence state ( $O^{2-}$ ) but in the 1-valence state ( $O^{1-}$ ), which represent defect electrons, i. e., positive holes ( $p$ -holes). They are unstable and form more stable positive hole pairs (PHP), chemically equivalent to peroxy links,  $O_3X/\text{ox}\backslash XO_3$ , which are electrically inactive. These dormant PHPs, however, are awoken by deviatoric stress, and make the insulating host material a  $p$ -type semi-conductor. The  $p$ -holes flow out of

Earthquakes, Electromagnetic Signals of, Figure 9

Conceptual diagram of the battery current, carried by electrons which flow out of the stressed portion *S* (left) through the outer circuit and by *p*-holes which close the circuit by flowing through the unstressed portion and meeting the electrons at the far end (right), flowing out from the stressed portion *S*, (after [18])

the stressed volume because of mutual electrostatic repulsion. If scaling to earthquake size is allowed, the current thus produced may attain  $10^3$ – $10^5$  A/km<sup>3</sup>.

**Other Models** For generation of high frequency signals, models related to micro-cracking have been proposed from laboratory experiments. They are (1) Discharge of screening charge of piezo-electric polarization [31,94], (2) electrification of fresh crack surfaces [90], (3) exo-electron [10]. As to the occurrence of pre-main shock micro-cracking, there have been only a few reliable field reports. Furthermore, it might be pointed out that in these models much stronger co-seismic signals would be expected. Some ad hoc mechanism, therefore, would be needed to explain that no co-seismic signals have been observed so far in the field.

### Transmission Mechanism of EM Signals

Even if EM signals are generated around a seismic focal region, signals except in the ULF range cannot be transmitted long distance in the conductive crust due to the decay caused by the skin effect, as long as the displacement current component is negligible. Even for DC signals, geometric decay would prohibit their long distance reception in a homogeneous or simple layered earth [5]. To overcome this difficulty, Varotsos et al. [81] proposed a conductive channel model, in which electric signals are transmitted through the conductive channel to a surface point close to the upper end of the channel. Freund [17] reported that, in the laboratory experiment, mobile positively charged holes (*p*-holes) appeared on the rock surface when a stress gradient was given to the rock sample. His results implied the possibility of appearance of a positively charged area at long distance on the surface before EQs. Kamogawa and Ohtsuki [35] proposed a model to explain how the higher frequency EM waves can be observed be-

fore EQs, i. e., longitudinal plasma waves excited by exo-electrons [10] may be transformed into EM waves by the surface roughness.

### LAI Coupling Mechanism

If the pre-seismic atmospheric-ionospheric anomalies are real, some causative factors may be detected on the ground surface. Possible mechanisms of pre-seismic lithosphere-atmosphere-ionosphere coupling have been proposed by many researchers. They may be categorized in two groups as shown in Fig. 10.

First, some atmospheric electric field  $\vec{E}$  is generated on/near the ground surface during the pre-seismic period and it will cause the ionospheric anomalies [25,26,62]. Pulinets et al. [62] proposed that such an atmospheric electric field is caused by radon emission (see [30,87,92]). Alternatively, it is proposed that positively charged holes diffused from the seismic focal area to the ground surface generate the electric field [17]. However, such an electric field on the ground has not yet been observed even when pre-seismic ionospheric anomalies were detected [36].
