Second, some researchers proposed that atmospheric gravity waves (AGW) propagate into the ionosphere, and disturb it before EQs [46,52,59]. The proposed source of AGW is the long-period ground oscillation or appearance of thermal anomalies on the ground. The former was inferred from some observations that co-seismic ground vibration actually excited AGW which propagated into the ionosphere (e.g. [8]). However, there is no report that long-period ground oscillations were detected at the pre-seismic stage even by high-sensitive superconducting gravimeter observations so far. The latter proposed source of AGW is the pre-seismic temperature rise, “thermal anomalies”, reaching 2–4°C or higher in a wide area around impending EQs, based on satellite observation of enhanced infrared (IR) emission from the ground sur-

Earthquakes, Electromagnetic Signals of, Figure 10  
Concept of LAI coupling (modified from [33])

face [7,70,72]. Many models have been put forward to explain the origin of the “thermal anomalies”, including latent heat release at condensing water vapor due to enhanced radon emission. Pulinets [60] develops a scenario where the “thermal anomalies” give rise to ionospheric anomalies. Freund et al. [19] cast another interpretation on the enhanced IR emission based on their *p*-hole model mentioned above. When *p*-holes appear on the surface of the unstressed area, they form a positive charge layer and recombine to form the more stable  $O^--O^-$  bond, emitting IR as de-excitation energy.

### Future Directions

It seems that, despite much circumstantial evidence, earthquake related electromagnetic signals, in particular those at the pre-seismic stage, have not yet been completely accepted as real physical quantities. Putting the common indifference and prejudice of the conventional scientific community against new science aside, it seems appropriate at this stage to recognize that there are legitimate reasons for the critical views. In fact, most of the problems of fundamental importance in seismo-electromagnetics are still unresolved.

To name a few, propagation of high-frequency EM signals in conductive earth has been proven unequivocally enough neither empirically nor theoretically. Techniques

of direction finding of EM signals at various frequency ranges and atmospheric-ionospheric anomalies have not shown sufficiently credible results yet. Solving these problems will be important issues in near future investigation.

The mechanisms of signal generation are still far from established. The majority of proposed mechanisms attribute pre-seismic signals to effects such as piezo-electric, electro-kinetic, charged dislocations, *p*-holes, and exoelectrons, all induced by stress release at micro-fracturing in the last stage of EQ preparation. In such cases, critics demand that by far the largest signals should be observed at the instance of the main shocks when the largest stress drop takes place. However, as described above, all the “co-seismically” observed electric or ULF signals are associated with the arrivals of seismic waves (to be called co-seismic wave) and are not co-seismic in the true sense. For higher frequency signals, even co-seismic wave signals have not been confirmed. This fact is a popular basis for negating the EQ-related signals in general. However, this very fact, i. e., the non-observation of true co-seismic signals in any frequency range may present some important clues with regard to the mechanism of both the signal generation and earthquakes as follows.

Numerous lab-experiments show strong co-fracturing signals in the form of high frequency EM waves. They are very different from the low frequency signals observed during pre-seismic stages. Thus, one explanation for non-

observation of co-seismic signals in the ULF range is (1) field observation uses a low-pass recording system to avoid high frequency noise, and (2) high frequency signals are attenuated in short distance in the earth. However, this explanation seems to suffer from a weak point as follows: Since it takes some seconds for the fault motion of a large EQ to terminate, the overall signals should contain a low frequency component powerful enough to be caught by the low-pass recording system. Moreover, even higher frequency wave monitoring systems have not captured any co-seismic signals. All these seem to speak for non-generation of co-seismic signals of any frequency in the field and researchers had to devise some ad hoc scenarios as to how to reconcile with lab results, often invoking over-growth of micro-faults by the time of main shocks to produce signals. For pre-seismic signal generation, these suggested mechanisms assume pre-seismic micro-fractures, which in fact, are micro-EQs that may be observed by high sensitivity seismic networks. Although depending on the required size, there has been no such observation, which constitutes another objection to pre-seismic EM signals.

The pressure-stimulated currents cited above regards the SES generation as a critical phenomenon. SES is supposed to be spontaneously generated when the gradually increasing tectonic stress level reaches a critical value. This seems to be the only proposed mechanism which needs no stress release by micro-fracturing or any special events, although it makes the causal relationship between SES and EQ less apparent. For the same reason, this mechanism does not need to generate any strong signals at EQ itself. Some of the other mechanisms, such as electro-kinetic, deformation-induced charged flow or *p*-holes flow mentioned earlier might be modified to fit the observation by incorporating the concept of critical state since they only need a development of stress gradient for signal generation.

Experimental verification of these mechanisms is urgently needed as it has been decisively inadequate. In any case, it should be kept in mind that the EQ preparation and EQ itself are different physical processes, the former being a gradual stress increasing process, whereas the latter is an instantaneous stress drop.

No true co-seismic signal in contrast to lab fracture experiments presents a question if the EQ is a fracture or not. It is now well-known that the EQ is a sudden sliding of pre-existing faults. However, according to Yoshida et al. [94], even stick-slip experiments on dry granite revealed strong signals at the time of slip which were understood as due to the piezo-electric effect. Non-generation of co-seismic EM signals still remains an important problem requiring further investigation.

Important unsolved questions are by no means confined to pre-seismic signal emissions. On the contrary, even more fundamental unsolved problems lie in LAI coupling. Here, the very origin on the ground to cause any of the suggested elementary agents, such as anomalous atmospheric electric field, atmospheric gravity wave, and thermal anomaly, is unknown. So far, observations on these features have been carried out by various researchers independently, so that the integration of fragmentary results for constructing a unified physical scenario of the whole process has been difficult. Since very active multi-national as well as multi-disciplinary cooperative research has been underway recently, involving GPS-TEC estimation and even topside measurement of the ionosphere by satellites of several nations, substantial progress in the upper end of LAI coupling is expected in the near future. Lately, active pursuit of EQ-related ionospheric anomalies has been made through topside and in-situ observation by satellites such as the French micro-satellite DEMETER [58]. However, the lower initiating side of the LAI coupling appears much more difficult to elucidate. It would require long sustained pre-seismic ground-based network observations on such phenomena as long-period ground motion and radon emission in as many earthquake prone areas as possible. But these tedious efforts should be enhanced on a global scale at all cost. Finally, it may be added that Kamogawa [33] pointed out that reported atmospheric-ionospheric anomalies might be caused by some EM phenomena which also trigger seismicity. For instance, suggestions have been made that geomagnetic storms [67] and cloud-to-ground lightning [42,57] may trigger EQs. It may be worthwhile to keep such a possibility of difference in cause and effect in mind in the future studies.

### Glossary

**Partially molten rock** The partially molten state is a thermodynamic state between solidus and liquidus temperatures, where both solid and liquid phases co-exist. In the Earth's interior, partial melting of rocks occurs in the upper mantle and/or crust beneath volcanic areas.

**Melt** Liquid phase in partially molten rocks or completely molten rock above the liquidus temperature is called melt. Density of melt is about 10% lower than solid. Hence, melt phase in the partially molten rocks tend to ascend toward the Earth's surface.

**Aqueous fluid** H<sub>2</sub>O-rich fluid. In a subducting oceanic plate, at the depths of several tens of km, aqueous fluids are released by the dehydration of hydrated minerals. Aqueous fluids, having much lower density and viscosity than melts, tend to ascend due to the buoyancy force.

**Seismic tomographic image** A number of seismometer networks have been placed on the surface of the Earth to record the seismic wave propagation from seismic sources at depths to the surface. Using the traveltime data obtained from these observations, three-dimensional seismic velocity structures in the Earth can be obtained, with a process called seismic tomographic imaging. By using P and S wave traveltimes,  $V_P$  and  $V_S$  structures, respectively, can be obtained.

### Definition of the Subject

The dynamics of solid-liquid composite systems are of great relevance to many problems in the earth sciences, including how melts or aqueous fluids generated by partial melting or dehydration migrate through the mantle and crust toward the surface, how deformation and fracture in these regions are influenced by the existence of fluids, and also how these fluids can be observed in the seismic tomographic images. The mechanical and transport properties of the solid-liquid composite systems strongly depend on liquid volume fraction and pore geometry, such as pore shape, pore size, and a detailed porosity distribution. Therefore, the microstructural processes that control pore geometry influence macroscopic dynamics, and vice versa. This article introduces a general continuum mechanical theory to treat the macroscopic dynamics of solid-liquid composite systems with a special emphasis on how such interactions with pore geometry can be described. Although intensive experimental and modeling approaches have been performed to investigate the interactive evolution of pore geometry and matrix deformation or fluid flow, many problems still remain unsolved and the actual liquid content and pore geometries in the crust and mantle are poorly understood. Therefore, in the latter part of this article, by applying the general theoretical framework introduced in the former part to the seismic wave propagation, the determinability of porosity and pore geometry from seismic tomographic images is discussed in detail. Due to the recent advances in seismic tomography, we can obtain three-dimensional and highly resolved images of both  $V_P$  and  $V_S$  structures. From the  $V_P$  or  $V_S$  structure alone, neither porosity nor pore geometry can be determined independently. However, if both  $V_P$  and  $V_S$  structures are available, porosity and pore geometry can be determined independently, thus providing valuable information complementary to experimental and modeling approaches. A practical method to determine porosity and pore geometry from the  $V_P$  and  $V_S$  images is presented.

### Introduction

Melt segregation from partially molten mantle or crust to the surface is the fundamental process of volcanism. In arc volcanism, aqueous fluids derived from the dehydrating subducting slab migrate through the mantle wedge and play an important role in the melting process. Modeling approaches to these fluid migration processes have been developed to explain various chemical and petrological observations, e. g. [13,20,35,37]. To make in situ observations of these fluids, seismic and/or electromagnetic tomographic images of the partially molten regions are

produced. These images are then interpreted using methods built on experimental and theoretical studies of the effects of fluids on seismic and electromagnetic properties, e. g. [2,23,24,44]. The effects of fluids on the tectonic and/or volcanic earthquake source process have also been of great interests; recently, observations of deep low-frequency earthquakes and tremors have been considered to be indicators of the presence or active migration of fluids in the crust and mantle, e. g. [9,26,29].

Fluids in the crust and mantle exist as solid-liquid composite systems in which fluid-filled pores are included in the solid matrix. Solid-liquid composite systems are characterized by high structural sensitivity. When the liquid volume fraction increases from zero to a few tens of %, the mechanical and transport properties of the system change greatly from those of a solid to those of a liquid. These properties are not simply determined by the liquid volume fraction but also strongly depend on the geometry of the liquid-filled pores. Here, the term pore geometry represents not only pore shape, but also pore size, orientation, and homogeneous or heterogeneous porosity distribution. Therefore, liquid content and pore geometry strongly influence the melt segregation and/or matrix deformation dynamics. Pore geometry is not constant but can change interactively with the macroscopic dynamics. Experimental and modeling approaches have been performed to investigate the interactive evolution of pore geometry and matrix deformation or fluid flow, e. g. [11,35,39]. However, many problems, including a poor understanding of the underlying physics, discrepancies between the experimental and modeling results, and the issue of scaling laboratory results to km scale, remain unsolved and detailed forward approaches to the interactions are the subjects of future studies.

Remarkable progress has been made in the seismic observations of the solid-liquid composite systems in the crust and mantle. Due to the recent advances in seismic tomography, we can now obtain three-dimensional and highly-resolved images of both  $V_p$  and  $V_s$  structures. Because the seismic velocity depends on both liquid volume fraction and pore geometry, neither can be estimated independently from  $V_p$  or  $V_s$  alone. However, when both  $V_p$  and  $V_s$  are available, the liquid volume fraction and pore geometry can be estimated independently. By using  $V_p$  and  $V_s$  images, an inverse approach to estimate the actual pore geometry and fluid content in the crust and mantle can be performed, yielding complementary information to the experimental and modeling approaches mentioned above. Therefore, in the present introduction of the dynamics of solid-liquid composite systems, elastic wave propagation is discussed in detail with a special focus on

the determinability of fluid content and pore geometry from seismic tomographic data.

First, in Sect. “**General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems**”, I introduce a general continuum mechanical formulation of the macroscopic dynamics of solid-liquid composite systems, with a special emphasis on how structural sensitivity is described. The elastic version of this theory, called “linear poroelasticity”, was developed by Biot and coworkers, e. g. [5,6,31,48]. This theory, which assumes infinitesimal strain in the solid phase, is applicable to the propagation of elastic waves. A more general version applicable to large deformations was developed based on the fluid dynamic theory, and applied to the melt segregation dynamics in partially molten mantle, e. g. [7,20]. On the one hand, in most reviews of the theory of linear poroelasticity, the governing equations are introduced empirically and are difficult to compare to the mass and momentum conservation equations used in the usual continuum mechanical formulation, e. g. [48]. However, in those reviews, detailed explanations are given for the meaning of the macroscopic constitutive relation that describes the structural sensitive character of the solid-liquid composite systems. On the other hand, in most reviews of the general fluid-dynamical formulation the mass and momentum conservations can be easily confirmed, but the physical meanings of the macroscopic constitutive relation and the structural-sensitive character are difficult to understand. Therefore, by taking advantage of both fields of study, I introduce here a general fluid-dynamical formulation with a detailed explanation of the macroscopic constitutive relation. The general formulation includes as a special case the theory of linear poroelasticity. The governing equations introduced in Sect. “**General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems**” include several structural-sensitive parameters that are given as functions of liquid volume fraction and pore geometry. Provided an evolution equation of pore geometry is obtained in future studies, it will be possible to investigate the interaction between pore geometry and macroscopic dynamics by solving the governing equations including the constitutive relation together with the evolution equation.

In Sect. “**Overview of Applications**”, a brief summary of the various applications of the general theory introduced in Sect. “**General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems**” is presented. In Sects. “**Derivation of Wave Equations**” to “**Dispersion and Attenuation of Waves in Solid-Liquid Composite Systems**”, the theory is applied to the elastic wave propagation in a solid-liquid composite system; we linearize the general formulation and derive the wave

equations (Sect. “**Derivation of Wave Equations**”). Based on the detailed descriptions of  $V_p$  and  $V_s$  obtained from the wave equations, the effects of liquid volume fraction, pore geometry, and liquid compressibility on the velocities are summarized systematically (Sects. “**Porosity and Pore Shape**” to “**Determinability of Porosity and Pore Shape from Elastic Wave Velocities**”). To assess the determinability of pore geometry, the usual forward modeling based on a priori assumed pore geometries, e.g. [15,17,18,27,41] are not enough, and a systematic treatment of general pore geometries is required, which is enabled by the introduction of the concept of equivalent aspect ratio (Sect. “**Porosity and Pore Shape**”). The determinability of porosity and pore geometry from seismic tomographic data is discussed in Sect. “**Application to Seismic Tomographic Images**”. In Sect. “**Dispersion and Attenuation of Waves in Solid-Liquid Composite Systems**”, so as to clarify the limitation in the application of the theoretical results, I briefly discuss the attenuation and dispersion of elastic waves. In this article, the term ‘liquid’ is used with the same meaning as ‘fluid’. Hence, ‘liquid’ in this paper includes ‘gas’.

### General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems

A schematic illustration of a solid-liquid composite system considered in this article is shown in Fig. 1a. Length scales less than the grain size are referred to as “microscopic”; length scales greater than the grain size are referred to as “macroscopic”. Solid-liquid composite systems are characterized by large differences in mechanical properties between solid and liquid phases, and hence the stress and velocity fields that develop under external forces are usually highly heterogeneous at the microscopic scale. However, when studying macroscopic dynamics such as mantle-scale melt segregation and propagation of seismic waves with wavelengths much larger than the grain size, it is not practical to solve both the microscopic and macroscopic processes simultaneously. In this section, I review the theoretical framework to treat the macroscopic dynamics separately from the microscopic processes. In this theory, macroscopic dynamics of solid-liquid composite systems are described within the framework of continuum mechanics, using the macroscopic variables obtained by averaging the microscopic fields. The averages within the solid and liquid phases are taken separately, so that the theory can be applied to the phenomena involving a relative motion between the two phases. Although microscopic variables do not explicitly appear in the governing equations, several parameters included in these equa-

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 1

**a** A solid-liquid composite system with a representative elementary volume (REV) at position  $x$ . **b** REV consisting of solid (thick blue) and liquid (light blue) phases. **c** Liquid phase in REV and the averaged quantities representing the macroscopic mechanical state of the liquid. **d** Solid phase in REV and the averaged quantities representing the macroscopic mechanical state of the solid

tions are sensitive to the microstructures and thus the microscopic processes do affect the macroscopic dynamics through these parameters. In this review, a special emphasis is given to these structurally sensitive parameters.

### Macroscopic Variables

We consider a region called REV (representative elementary volume), which is small enough to consider as a point in the macroscopic scale but large enough to contain a number of solid grains. Macroscopic quantities are defined by the average of the corresponding quantities in REV, where the averages within the liquid phase and those within the solid phase are taken separately. The averaging procedure can be defined by using a window function  $W$  and phase function  $A$ . By considering the REV as a cuboid with edge length  $L_i$ , the window function  $W(\mathbf{x})$  takes the value 1 at  $-L_i/2 \leq x_i \leq L_i/2$  ( $i = x, y, z$ ) and value 0 otherwise. The phase function  $A(\mathbf{x})$  takes the value 1 if the position  $\mathbf{x}$  is in the liquid phase, and value 0 in the solid phase;  $A$  and  $1 - A$  quantify the properties of the liquid and solid phases, respectively. Let  $a(\mathbf{x}, t)$  be a microscopic

field of the physical quantity  $a$ , which is a function of the position  $\mathbf{x}$  and time  $t$ . The phasic average of  $a$  in the liquid phase ( $a^L$ ) or solid phase ( $a^S$ ) is defined by

$$\begin{aligned} a^L(\mathbf{x}, t) &= \frac{1}{V\phi} \int W(\boldsymbol{\xi} - \mathbf{x}) A(\boldsymbol{\xi}, t) a(\boldsymbol{\xi}, t) dV_{\boldsymbol{\xi}} \\ a^S(\mathbf{x}, t) &= \frac{1}{V(1-\phi)} \int W(\boldsymbol{\xi} - \mathbf{x}) (1 - A(\boldsymbol{\xi}, t)) \cdot a(\boldsymbol{\xi}, t) dV_{\boldsymbol{\xi}}, \end{aligned} \quad (1)$$

where  $V(=L_x L_y L_z)$  represents the volume of REV and  $\phi$  represents the liquid volume fraction, defined as

$$\phi(\mathbf{x}, t) = \frac{1}{V} \int W(\boldsymbol{\xi} - \mathbf{x}) A(\boldsymbol{\xi}, t) dV_{\boldsymbol{\xi}}. \quad (2)$$

The volume integrals in Eqs. (1)–(2) are taken over whole of the solid-liquid system.

The dynamic state of the solid-liquid composite system at a spatially-fixed position  $\mathbf{x}$  is described by the following 7 macroscopic variables defined by Eqs. (1) and (2):

$\phi(\mathbf{x}, t)$ ...liquid volume fraction (nondimensional)

$\rho^L(\mathbf{x}, t)$ ...density of liquid ( $\text{kg/m}^3$ )

$\rho^S(\mathbf{x}, t)$ ...density of solid ( $\text{kg/m}^3$ )

$\mathbf{u}^L(\mathbf{x}, t)$ ...displacement of liquid (m)

$\mathbf{u}^S(\mathbf{x}, t)$ ...displacement of solid (m)

$p^L(\mathbf{x}, t)$ ...liquid pressure (Pa), with compression positive

$\sigma_{ij}^S(\mathbf{x}, t)$ ...solid stress (Pa), with tension positive.

It is rigorous to define  $\mathbf{u}^L$  and  $\mathbf{u}^S$  by using mass-weighted average [7]. However, for simplicity, the density heterogeneity within each phase is assumed to be small and the mass-weighted average is approximated by the phasic average.

## Governing Equations

The seven variables introduced in Sect. “**Macroscopic Variables**” are governed by the following seven equations:

mass conservation of liquid

$$\frac{\partial(\phi\rho^L)}{\partial t} + \nabla \cdot (\phi\rho^L\dot{\mathbf{u}}^L) = \Gamma \quad (A)$$

mass conservation of solid

$$\frac{\partial\{(1-\phi)\rho^S\}}{\partial t} + \nabla \cdot \{(1-\phi)\rho^S\dot{\mathbf{u}}^S\} = -\Gamma \quad (B)$$

intrinsic constitutive relation of liquid

$$\frac{\delta\rho^L}{\rho^L} = \frac{1}{k_L}\delta p^L \quad (C)$$

intrinsic constitutive relation of solid

$$\frac{\delta\rho^S}{\rho^S} = \frac{1}{k_S}\delta p^S \quad (D)$$

macroscopic constitutive relation of solid framework

$$\epsilon_{ij} = S_{ijkl} (\sigma_{kl}^S + p^L \delta_{kl}) - \frac{1}{3k_S} p^L \delta_{ij} \quad (E)$$

linear momentum conservation of liquid

$$\phi\rho^L\ddot{\mathbf{u}}^L = -\nabla(\phi p^L) + \phi\rho^L\mathbf{g} + \mathbf{I} \quad (F)$$

linear momentum conservation of solid

$$(1-\phi)\rho^S\ddot{\mathbf{u}}^S = \nabla \cdot \{(1-\phi)\sigma^S\} + (1-\phi)\rho^S\mathbf{g} - \mathbf{I}, \quad (G)$$

where  $\mathbf{I}$  ( $\text{N/m}^3$ ) in Eqs. (F) and (G) represents the interaction between the solid and liquid phases (the force applied to the liquid from the solid is taken positive), and is explicitly written as

$$\mathbf{I} = -\frac{\eta_L\phi^2}{k_\phi} (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S) + p^L\nabla\phi. \quad (3)$$

The  $\Gamma$  ( $\text{kg/s/m}^3$ ) in Eqs. (A) and (B) represents the net mass flux from the solid to the liquid,  $k_L$  and  $k_S$  (Pa) in Eqs. (C), (D), and (E) represent the intrinsic bulk moduli of the liquid and solid, respectively,  $p^S = -(\sigma_{xx}^S + \sigma_{yy}^S + \sigma_{zz}^S)/3$  (Pa) in Eq. (D) represents the solid pressure (compression positive),  $\epsilon_{ij}$  in the left hand side of Eq. (E) represents the framework strain (extension positive), whose definition is given in Sect. “Equation (E)”,  $S_{ijkl}$  ( $\text{Pa}^{-1}$ ) in Eq. (E) represents the elastic compliance tensor of the solid framework,  $\mathbf{g}$  ( $\text{N/kg}$ ) in Eqs. (F) and (G) represents the gravitational acceleration vector, and  $\eta_L$  (Pa s) and  $k_\phi$  ( $\text{m}^2$ ) in Eq. (3) represent the liquid viscosity and permeability, respectively. For  $\alpha = S, L$ ,  $\dot{\mathbf{u}}^\alpha = D\mathbf{u}^\alpha/Dt$  and  $\ddot{\mathbf{u}}^\alpha = D\dot{\mathbf{u}}^\alpha/Dt$  represent velocity and acceleration vectors, respectively, where  $D/Dt = \partial/\partial t + \dot{\mathbf{u}}^\alpha \cdot \nabla$ . Also,  $\nabla \cdot \sigma = \partial\sigma_{ij}/\partial x_j = \sigma_{ij,j}$ . The summation convention for repeated subscripts is employed.

These equations, except for Eq. (E), are rigorously derived by averaging the mass and linear momentum conservation equations and constitutive relations required in the microscopic scale [7]. The physical meanings of Eqs. (A)–(D) are made clear by analogy with the standard fluid dynamic equations. The term  $\Gamma$  included in Eqs. (A)–(B) is zero unless melting/solidification or dissolution/precipitation occurs. The parameters that are sensitive to the microstructures are  $S_{ijkl}$  and  $k_\phi$  included in Eqs. (E)–(G). Therefore, in the following part of this

section, detailed discussions of these three equations are given. In Sect. “**Semi-Intuitive Derivations of Equations (E), (F), and (G)**”, derivations of Eqs. (E)–(G) are given in a semi-intuitive manner to clarify the physical meaning of these equations and the structural-sensitive parameters. Several important aspects of these equations are also discussed in Sects. “**Relation to the Effective Medium Theory**”–“**Fundamental Assumption for Stress Heterogeneity**”.

### Semi-Intuitive Derivations of Equations (E), (F), and (G)

**Equations (F) and (G)** Equations (F) and (G) describe the linear momentum conservations for the liquid and solid phases, respectively, in the REV. The left hand sides (LHS) of these equations represent the acceleration terms. The right hand sides (RHS) represent the total forces applied on each system, including the body force and the surface force. The surface force is applied through the boundary surface of each system; this boundary is made of the boundary on the surface of REV (black boundary in Figs. 2a and 2b) and the boundary with the other phase (red boundary in Figs. 2a and 2b). The former boundary (black) exists within each phase and the latter boundary (red) exists on the phase boundary. In the RHS of Eq. (F) or (G), the second term represents the body force due to gravity, and the first and the third terms represent the surface forces applied through the black and red boundaries, respectively. The surface force through the red boundary is the interaction between solid and liquid, and hence the third term in the RHS of Eq. (F), I, and that of Eq. (G),  $-I$ , are of the same magnitude and of opposite sign.

Equation (3) shows that interaction I consists of two terms, corresponding to the contributions from the traction components tangential and normal to the phase boundary. The first term, corresponding to the tangential component, represents the viscous drag force proportional to the relative velocity of the two phases. The permeability  $k_\phi$  included in the proportionality constant depends on the detailed geometry of the liquid-filled pores. The second term in the RHS of Eq. (3) represents the contribution from the normal component of traction, which is determined by the liquid pressure. An intuitive explanation for the proportional dependence of this force on the porosity gradient is given in Fig. 3, in which a simple pore geometry is assumed. A more rigorous derivation of this term for general pore geometries is presented in Sect. “**Fundamental Assumption for Stress Heterogeneity**”, where the assumption needed to derive this term is clarified and its validity is discussed. In the dynamics of solid-liquid com-

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 2

**a** Forces applied on the liquid phase in REV. **b** Forces applied on the solid phase in REV. Forces applied on each system consist of body force (orange arrow) and surface force (black and red arrows). The body force is due to gravity. The surface force is applied through the boundary surface of each system, which is divided into the boundary on the surface of REV (black boundary) and the boundary with the other phase (red boundary). The surface force applied through the red boundary is shown by dividing into normal and tangential components to the interface (red arrows). Solid stress is taken to be tension positive and liquid pressure is taken to be compression positive

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 3

Interaction between the solid and liquid phases through the phase boundary (red boundary) is schematically shown for a simple pore geometry with a porosity gradient. The forces applied from solid to liquid are shown. The total force of the force component normal to the phase boundary does not vanish if porosity gradient is not zero, and that tangential to the phase boundary does not vanish if average velocity of liquid relative to solid is not zero

posite systems, the motion of each phase is significantly affected by the interaction with the other phase through the phase boundary.

Note that Eqs. (F) and (G) are derived by implicitly assuming a connectivity of each phase (black boundary in

Earth's Crust and Upper Mantle, Dynamics of Solid–Liquid Systems in, Figure 4

**a** A stress state of the solid phase in REV, generally represented by the solid stress  $\sigma_{ij}^S$  (tension positive) and liquid pressure  $p^L$  (compression positive), is expressed by the superposition of **b** effective stress state, defined by solid stress  $\sigma_{ij}^S + p^L \delta_{ij}$  and liquid pressure 0, and **c** uniform stress state, defined by solid stress  $-p^L \delta_{ij}$  and liquid pressure  $p^L$ . Equation (E) in the text states that the framework strain under a given stress state is obtained by the superposition of the framework strain under the effective stress state and that under the uniform stress state

Figs. 2a and 2b). Therefore, we need to be careful in applying the present theory to end-member systems of suspensions of solid or isolated inclusions of liquid, in which one phase is dispersed in the other phase without connectivity.

**Equation (E)** The framework strain  $\epsilon_{ij}$  in the LHS of Eq. (E) is defined by using the macroscopic displacement of the solid  $\mathbf{u}^S$  as

$$\epsilon_{ij} = \frac{1}{2} \left( \frac{\partial u_i^S}{\partial x_j} + \frac{\partial u_j^S}{\partial x_i} \right), \quad (4)$$

and hence  $\epsilon_{ij}$  represents the macroscopic deformation of the solid framework. Equation (E) provides a macroscopic constitutive relationship between the framework strain and the macroscopic (averaged) stress state of the framework. The coefficient  $S_{ijkl}$  included in this equation is not only determined by the solid intrinsic properties, but shows a large structural sensitivity, which plays a significant role in the dynamics of solid-liquid composite systems. Equation (E) is one of the key equations characterizing the two-phase dynamics. I present here a semi-intuitive derivation of Eq. (E).

As shown in Fig. 4a, a macroscopic stress state of the solid framework is generally described by the solid stress  $\sigma_{ij}^S$  applied through the boundary on the surface of REV (black boundary) and liquid pressure  $p^L$  applied through the boundary with the liquid phase (red boundary). The framework strain under this stress state is calculated by the superposition of the framework strain under stress

$\sigma_{ij}^S + p^L \delta_{ij}$  applied through the black boundary while leaving the red boundary as a free surface (Fig. 4b) plus the framework strain under uniform pressure  $p^L$  applied to all boundaries (Fig. 4c). The assumption of the superposition is valid when the response of the solid framework to the applied stresses is linear. The term  $\sigma_{ij}^S + p^L \delta_{ij}$  is called the effective stress. Figure 4b shows that the elastic compliance tensor  $S_{ijkl}$  specifying the effect of effective stress on the framework strain describes the mechanical properties of the ‘skeleton’ (solid framework obtained by replacing the regions occupied by the liquid phase with a vacuum), which is not only determined by the intrinsic properties of solid but also strongly depends on the porosity and pore geometry. For a given solid-liquid composite system,  $S_{ijkl}$  is estimated by using experimental and/or modeling approaches, some of which are presented in a later section. The framework strain under a given pressure  $p^L$  applied to all boundaries (Fig. 4c) is identical to the strain of REV completely filled with solid ( $\phi = 0$ ) under uniform pressure  $p^L$ , and hence is determined only by the intrinsic bulk modulus of the solid phase (the last term in the RHS of Eq. (E)).

In the derivation mentioned above, the solid phase is assumed to deform elastically. For an isotropic system, Eq. (E) is written as

$$\epsilon_{ij} = \frac{1}{3k_{sk}} \left( \frac{\sigma_{kk}^S}{3} + p^L \right) \delta_{ij} + \frac{1}{2\mu_{sk}} \left( \sigma_{ij}^S - \frac{\sigma_{kk}^S}{3} \delta_{ij} \right) - \frac{1}{3k_S} p^L \delta_{ij}, \quad (E_e)$$

where  $k_{sk}$  and  $\mu_{sk}$  represent the bulk and shear moduli, respectively, of the skeleton. Similarly, when the solid phase deforms viscously, the macroscopic constitutive relation for an isotropic system is written as

$$\dot{\epsilon}_{ij} = \frac{1}{3\xi_{sk}} \left( \frac{\sigma_{kk}^S}{3} + p^L \right) \delta_{ij} + \frac{1}{2\eta_{sk}} \left( \sigma_{ij}^S - \frac{\sigma_{kk}^S}{3} \delta_{ij} \right), \quad (\text{E}_v)$$

where  $\xi_{sk}$  and  $\eta_{sk}$  represent the bulk and shear viscosities, respectively, of the skeleton. Because viscous deformation is usually large in amplitude, the volumetric deformation due to the intrinsic compressibility of the solid phase, which corresponds to the 3rd term in the RHS of Eq. (E<sub>c</sub>), is neglected in Eq. (E<sub>v</sub>). Similar to  $k_{sk}$  and  $\mu_{sk}$ ,  $\xi_{sk}$  and  $\eta_{sk}$  are not only determined by the intrinsic property of the solid phase but also strongly depend on the porosity and pore geometry. Although the intrinsic compressibility of the solid phase is neglected in Eq. (E<sub>v</sub>), the volumetric component of the framework strain rate controlled by  $\xi_{sk}$  cannot be neglected. This is because even when the solid phase is made of incompressible material, the solid framework can change its volume by changing the porosity. This demonstrates the essential difference between the skeleton property and the intrinsic property of the solid. A more general description of the viscous constitutive relation is given by neglecting the last term in the RHS of Eq. (E) and replacing  $\epsilon_{ij}$  and elastic compliance tensor  $S_{ijkl}$  by  $\dot{\epsilon}_{ij}$  and viscous compliance tensor  $S_{ijkl}^V$ , respectively.

### Relation to the Effective Medium Theory

The structural sensitivity of the skeleton properties  $S_{ijkl}$  plays an important role in the two-phase dynamics. To predict quantitatively the microstructural effects on the skeleton properties, an effective medium theory has been developed. However, the applicability of these theoretical results to Eq. (E) is not self-evident, because the definition of the macroscopic strain given by Eq. (4) is different from that of the average strain used in the effective medium theory. In the effective medium theory, it is well-known that the stress and strain fields of the solid phase are highly heterogeneous at the microscopic scale, so that the local stress can be largely different from the macroscopic stress. However, in the fluid dynamical formulation of the two-phase dynamics, this point is not emphasized and a confusion between microscopic and macroscopic stresses sometimes occurs (Sect. “**Fundamental Assumption for Stress Heterogeneity**”). Therefore, it is important to establish a connection between

the fluid dynamical formulation and the effective medium theory.

When the skeleton properties are calculated in the effective medium theory, the effective properties of the solid-liquid composites are calculated under either drained conditions, in which the liquid pressure is kept constant, or under dry conditions, in which the liquid phase with zero bulk and shear moduli is kept under undrained conditions. In both cases, the space which remains after subtracting the solid phase from REV is considered to be filled with the pore phase. The microscopic displacement field in the pore phase can be obtained from the undrained solution by setting the bulk and shear moduli of the liquid to zero. The displacement field in the solid phase is continuously connected with that in the pore phase and there is no relative motion between the solid and pore phases. The effective properties under the dry (or drained) condition is given by

$$\epsilon_{ij}^B = S_{ijkl}^{\text{dry}} \sigma_{kl}^B, \quad (5)$$

where  $\epsilon_{ij}^B$  and  $\sigma_{ij}^B$  represent the average strain and stress, respectively, over both solid and pore phases,

$$\begin{cases} \sigma_{ij}^B &= (1 - \phi) \sigma_{ij}^S \\ \epsilon_{ij}^B &= (1 - \phi) \epsilon_{ij}^S + \phi \epsilon_{ij}^P, \end{cases} \quad (6)$$

the superscript “B” means bulk, and

$$\epsilon_{ij}^\alpha = \frac{1}{2} \left\langle \frac{\partial u_i}{\partial \xi_j} + \frac{\partial u_j}{\partial \xi_i} \right\rangle_\alpha \quad (\alpha = S, P) \quad (7)$$

represents the phasic average of strain in the solid or pore phase, e. g. [21,50]. To clarify the relationship between  $S_{ijkl}$  and  $S_{ijkl}^{\text{dry}}$ , the relationship between  $\epsilon_{ij}$  and  $\epsilon_{ij}^B$  needs to be specified.

Let  $\langle a \rangle_\alpha$  ( $\alpha = S, L$ ) be the phasic average of the quantity  $a$  defined in Eqs. (1). Let  $\Sigma_{\text{black}}^\alpha$  ( $\alpha = S, L$ ) be the boundary of the phase  $\alpha$  on the surface of REV (black boundary in Figs. 2 and 4) and let  $\Sigma_{\text{red}}$  be the phase boundary in REV (red boundary in Figs. 2 and 4). Let  $n_i$  be the outward unit normal to these boundaries, where the positive direction at  $\Sigma_{\text{red}}$  is outward to the liquid phase. From the definition of phasic average  $\langle \cdot \rangle_S$ , we obtain

$$\begin{aligned} & \frac{\partial \langle u_i \rangle_S}{\partial x_j} \\ &= \frac{\partial}{\partial x_j} \left[ \frac{1}{V(1 - \phi)} \int W(\xi - \mathbf{x})(1 - A(\xi)) u_i(\xi) dV_\xi \right] \end{aligned}$$

$$\begin{aligned}
 &= \frac{\partial \phi}{\partial x_j} \frac{1}{V(1-\phi)^2} \int W(\boldsymbol{\xi} - \mathbf{x})(1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \\
 &+ \frac{1}{V(1-\phi)} \frac{\partial}{\partial x_j} \left[ \int W(\boldsymbol{\xi} - \mathbf{x})(1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \right] \\
 &= \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} \\
 &+ \frac{1}{V(1-\phi)} \int -\frac{\partial W(\boldsymbol{\xi} - \mathbf{x})}{\partial \xi_j} (1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \\
 &= \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} \\
 &- \frac{1}{V(1-\phi)} \int \frac{\partial \{W(\boldsymbol{\xi} - \mathbf{x}) \cdot (1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})\}}{\partial \xi_j} dV_{\boldsymbol{\xi}} \\
 &+ \frac{1}{V(1-\phi)} \int W(\boldsymbol{\xi} - \mathbf{x})(1 - A(\boldsymbol{\xi})) \frac{\partial u_i(\boldsymbol{\xi})}{\partial \xi_j} dV_{\boldsymbol{\xi}} \\
 &+ \frac{1}{V(1-\phi)} \int W(\boldsymbol{\xi} - \mathbf{x}) \frac{\partial (1 - A(\boldsymbol{\xi}))}{\partial \xi_j} u_i(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \\
 &= \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} + \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_S \\
 &+ \frac{1}{V(1-\phi)} \int W(\boldsymbol{\xi} - \mathbf{x}) \frac{\partial (1 - A(\boldsymbol{\xi}))}{\partial \xi_j} u_i(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \\
 &= \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} + \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_S \\
 &+ \frac{1}{V(1-\phi)} \int_{\Sigma_{\text{red}}} u_i(\boldsymbol{\xi})n_j(\boldsymbol{\xi})dS_{\boldsymbol{\xi}}, \quad (8)
 \end{aligned}$$

where the volume integral of factor  $\partial\{W(\boldsymbol{\xi} - \mathbf{x})(1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})\}/\partial\xi_j$  in the RHS of the 4th equation is converted to the surface integral of  $W(\boldsymbol{\xi} - \mathbf{x})(1 - A(\boldsymbol{\xi}))u_i(\boldsymbol{\xi})$  on the outermost boundary of the solid-liquid system, which is zero because  $W(\boldsymbol{\xi} - \mathbf{x})$  is zero outside the REV.

Because the displacement field  $u_i$  of the solid phase can be continuously connected to  $u_i$  of the pore phase, by using Gauss's theorem, the integral over  $\Sigma_{\text{red}}$  in the third term on the RHS of the last equation of (8) can be rewritten in terms of the volume integral in the pore phase. Because the boundary of the pore phase is given by  $\Sigma_{\text{red}}$  and  $\Sigma_{\text{black}}^L$ , we thus obtain

$$\begin{aligned}
 &\frac{\partial \langle u_i \rangle_S}{\partial x_j} \\
 &= \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_S + \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} \\
 &+ \frac{1}{V(1-\phi)} \int_{\Sigma_{\text{red}} + \Sigma_{\text{black}}^L} u_i(\boldsymbol{\xi})n_j(\boldsymbol{\xi})dS_{\boldsymbol{\xi}} \\
 &- \frac{1}{V(1-\phi)} \int_{\Sigma_{\text{black}}^L} u_i(\boldsymbol{\xi})n_j(\boldsymbol{\xi})dS_{\boldsymbol{\xi}}
 \end{aligned}$$

$$\begin{aligned}
 &= \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_S + \frac{\langle u_i \rangle_S}{1-\phi} \frac{\partial \phi}{\partial x_j} \\
 &+ \frac{\phi}{(1-\phi)} \frac{1}{V\phi} \int W(\boldsymbol{\xi} - \mathbf{x})A(\boldsymbol{\xi}) \frac{\partial u_i}{\partial \xi_j} dV_{\boldsymbol{\xi}} \\
 &- \frac{1}{(1-\phi)} \frac{\partial (\phi \langle u_i \rangle_S)}{\partial x_j} \\
 &= \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_S + \frac{\phi}{1-\phi} \left\langle \frac{\partial u_i}{\partial \xi_j} \right\rangle_P - \frac{\phi}{1-\phi} \frac{\partial \langle u_i \rangle_S}{\partial x_j}, \quad (9)
 \end{aligned}$$

where  $u_i$  at the surface of REV ( $\Sigma_{\text{black}}^L$  and  $\Sigma_{\text{black}}^S$ ) is considered to be the same between the solid and pore phases, because there is no relative motion between these two phases. From Eqs. (4) and (9), we obtain

$$\begin{aligned}
 \epsilon_{ij} &= (1-\phi)\epsilon_{ij}^S + \phi\epsilon_{ij}^P \\
 &= \epsilon_{ij}^B. \quad (10)
 \end{aligned}$$

Therefore, a simple conversion formula can be obtained linking  $S_{ijkl}^{\text{dry}}$  and  $S_{ijkl}$

$$S_{ijkl}^{\text{dry}} = (1-\phi)S_{ijkl}. \quad (11)$$

We further discuss the peculiarity of Eq. (E) that it cannot be derived by the phasic average of the microscopic constitutive relationship. Because the microscopic stress and strain fields in the solid phase are related to each other by the intrinsic constitutive relationship of the solid phase, we may take the average of this relationship over the solid phase in REV, to obtain

$$\epsilon_{ij}^S = S_{ijkl}^{\text{intrinsic}} \sigma_{kl}^S, \quad (12)$$

where  $S_{ijkl}^{\text{intrinsic}}$  represents the solid intrinsic properties. By comparing Eq. (E) to Eq. (12), it is apparent that the significant difference between  $S_{ijkl}$  and  $S_{ijkl}^{\text{intrinsic}}$  comes from the significant difference between  $\epsilon_{ij}$  and  $\epsilon_{ij}^S$  in that  $\epsilon_{ij}$  represents not only  $\epsilon_{ij}^S$  but also  $\epsilon_{ij}^P$ . From the definition of  $\phi$ ,

$$\begin{aligned}
 \frac{\partial \phi}{\partial x_i} &= \frac{\partial}{\partial x_i} \left[ \frac{1}{V} \int W(\boldsymbol{\xi} - \mathbf{x})A(\boldsymbol{\xi})dV_{\boldsymbol{\xi}} \right] \\
 &= \frac{-1}{V} \int W(\boldsymbol{\xi} - \mathbf{x})n_i(\boldsymbol{\xi})dS_{\boldsymbol{\xi}}. \quad (13)
 \end{aligned}$$

Then, from Eqs. (4), (8), and (13),  $\epsilon_{ij}$  can be rewritten as

$$\epsilon_{ij} = \epsilon_{ij}^S + \frac{\int_{\Sigma_{\text{red}}} ((u_i(\boldsymbol{\xi}) - \langle u_i \rangle_S) n_j(\boldsymbol{\xi}) + (u_j(\boldsymbol{\xi}) - \langle u_j \rangle_S) n_i(\boldsymbol{\xi})) dS_{\boldsymbol{\xi}}}{2V(1-\phi)}. \quad (14)$$

Thus, a significant difference between  $\epsilon_{ij}$  and  $\epsilon_{ij}^S$  implies a significant contribution from the second term in the RHS

of (14). This means that the microscopic displacement field of the solid phase at the boundary with the liquid can be systematically different from the average displacement of the solid phase. An example of such systematic deviation can be seen in the compaction of the solid framework, where a contraction of the solid phase observed macroscopically is compensated by a displacement of the solid-liquid phase boundary into the pore space.

### Fundamental Assumption for Stress Heterogeneity

A fundamental assumption implicitly used in formulating the dynamics of solid-liquid composite systems is that the microscopic stress field is homogeneous in the liquid phase but can be heterogeneous in the solid phase. This point is rarely stated explicitly. Here, I discuss this assumption first with respect to the liquid phase and then with respect to the solid phase.

The second term in the RHS of Eq. (3) represents the total force due to the normal traction component applied to the liquid phase through the phase boundary (red boundary). This term is derived as

$$\begin{aligned}
& -\frac{1}{V} \int_{\Sigma_{\text{red}}} p(\xi) n_i(\xi) dS_\xi \\
&= -\frac{1}{V} \int_{\Sigma_{\text{red}} + \Sigma_{\text{black}}^{\text{L}}} p(\xi) n_i(\xi) dS_\xi \\
&\quad + \frac{1}{V} \int_{\Sigma_{\text{black}}^{\text{L}}} p(\xi) n_i(\xi) dS_\xi \\
&= -\frac{1}{V} \int_{\text{REV}} A(\xi) \frac{\partial p(\xi)}{\partial \xi_i} dV_\xi + \frac{1}{V} \int_{\Sigma_{\text{black}}^{\text{L}}} p(\xi) n_i(\xi) dS_\xi \\
&= -\phi \left\langle \frac{\partial p}{\partial \xi_i} \right\rangle_{\text{L}} + \frac{\partial(\langle p \rangle_{\text{L}} \phi)}{\partial x_i} \\
&= -\phi \frac{\partial \langle p \rangle_{\text{L}}}{\partial x_i} + \frac{\partial(\langle p \rangle_{\text{L}} \phi)}{\partial x_i} \\
&= p^{\text{L}} \frac{\partial \phi}{\partial x_i},
\end{aligned} \tag{15}$$

where the relationship

$$\left\langle \frac{\partial p}{\partial \xi_i} \right\rangle_{\text{L}} = \frac{\partial \langle p \rangle_{\text{L}}}{\partial x_i} \tag{16}$$

is assumed to obtain the 4th equation. The validity of this assumption is checked as follows. In the same manner as Eq. (8), we obtain

$$\frac{\partial \langle p \rangle_{\text{L}}}{\partial x_i} = \frac{-\langle p \rangle_{\text{L}}}{\phi} \frac{\partial \phi}{\partial x_i} + \left\langle \frac{\partial p}{\partial \xi_i} \right\rangle_{\text{L}} - \frac{1}{V\phi} \int_{\Sigma_{\text{red}}} p(\xi) n_i(\xi) dS_\xi. \tag{17}$$

From Eqs. (13) and (17),

$$\frac{\partial \langle p \rangle_{\text{L}}}{\partial x_i} = \left\langle \frac{\partial p}{\partial \xi_i} \right\rangle_{\text{L}} - \frac{1}{V\phi} \int_{\Sigma_{\text{red}}} (p(\xi) - \langle p \rangle_{\text{L}}) n_i(\xi) dS_\xi \tag{18}$$

is obtained. Equation (18) shows that the phasic average  $\langle \cdot \rangle_{\text{L}}$  is not exchangeable with the differential operator, and that Eq. (16) is not valid if the 2nd term in the RHS of Eq. (18) is non-negligible, that is, if the liquid pressure at the boundary with the solid phase is systematically different from the average. In solid-liquid composite systems, the stress heterogeneity within the liquid phase relaxes quickly and the liquid pressure is usually considered to be uniform in REV. Therefore, the 2nd term in the RHS of (18) is considered to be negligible. This also confirms the validity of an assumption implicitly used in Figs. 3 and 4: because the liquid pressure is homogeneous at the microscopic scale, then from the continuity of stress, the normal compressive stress of the solid phase at the solid-liquid interface is equal to the macroscopic liquid pressure  $p^{\text{L}}$ .

The inexchangeability between the differential operator and phasic average is described by Eq. (14) for the solid phase and by Eq. (18) for the liquid phase. Although the second term in the RHS of Eq. (14) was considered to be non-negligible, the corresponding term in Eq. (18) was considered to be negligible. The different treatments applied to the two phases are based on the fact that the stress heterogeneity within the liquid phase relaxes quickly but that the stress heterogeneity within the solid phase does not relax (elastic solid phase) or relaxes much more slowly (viscous solid phase). As can be seen from Fig. 4b, under nonzero effective stress, the traction applied to the surface of each solid grain is significantly different between the areas in contact with the liquid phase and the areas in contact with the neighboring grains, indicating that the microscopic stress field in each grain is highly heterogeneous. Such a heterogeneous stress field causes a systematic deviation of the microscopic displacement at the boundary with the liquid, making the second term in the RHS of Eq. (14) non-negligible.

For the solid phase, it is therefore important to recognize a possible difference between local and macroscopic stresses. However, there seems to be a confusion in some studies considering the effect of the solid-liquid interfacial tension  $\gamma_{\text{sl}}$ . When  $\gamma_{\text{sl}}$  is taken into account, the stress continuity condition required at the solid-liquid interface is replaced by the Laplace condition, e.g. [38]. Hence, the solid stress used in the Laplace condition is the local stress, which is locally determined by  $p^{\text{L}}$ ,  $\gamma_{\text{sl}}$ , and interfacial mean curvature, regardless of the macroscopic solid stress  $\sigma_{ij}^{\text{S}}$ . I emphasize this point because in the previous studies,

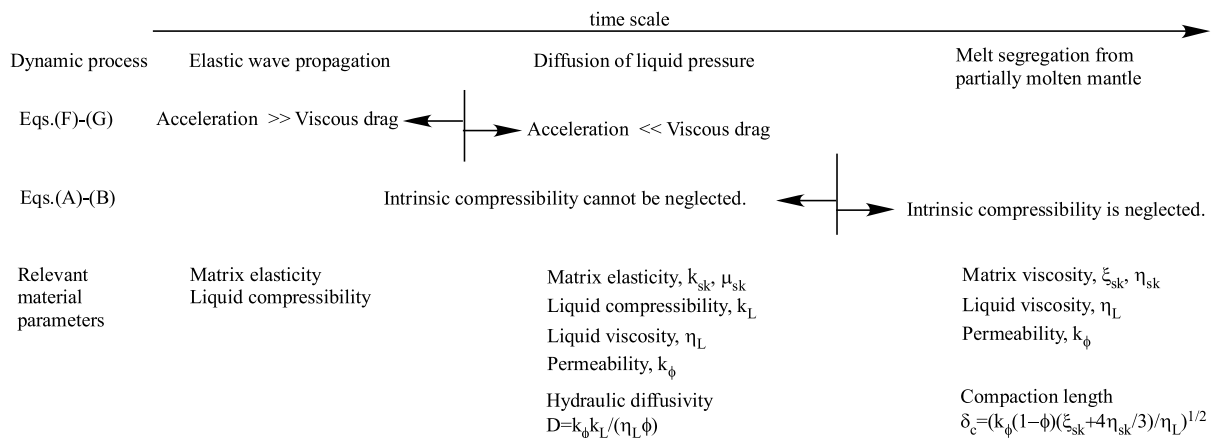

several questionable results were obtained due to the improper use of  $\sigma_{ij}^S$  in the Laplace condition, e. g. [38,46].

### Overview of Applications

The theoretical framework introduced in Sect. “General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems” is applicable to various geophysical and geological phenomena occurring in solid-liquid two-phase systems. Typical applications are summarized in Fig. 5 by classifying processes into three categories based on their time scales. The propagation of elastic waves is investigated using the wave equations derived from Eqs. (A)–(G). The application to elastic wave propagation is discussed in detail in the following sections. The time-dependent evolution of a perturbation in liquid pressure in the porous media, and the interaction between liquid pressure and matrix deformation or fracture, have long been of interest in investigations of the possible occurrence of earthquakes due to dehydration, e. g. [51] and earthquake triggering, e. g. [16]. These processes have much longer time scales than the periods of elastic waves, and the acceleration terms in Eqs. (F) and (G), which play an essential role in the wave equations, are negligible compared to the viscous drag force included in the interaction term I. Then, as is well known, the evolution equation for liquid pressure is derived in the form of a diffusion equation, where the diffusivity is given by  $D = k_\phi k_L / (\eta_L \phi)$  (hydraulic diffusivity).

Melt segregation from a partially molten mantle has been of great interest in volcanology, petrology, and

geochemistry. This process occurs over much longer time scales than the processes mentioned above, and involves large viscous deformations. Accordingly, the intrinsic compressibilities of the constituent materials are neglected. By applying the governing equations (A)–(D), (E<sub>v</sub>), and (F)–(G) to a one-dimensional column of partially molten mantle with a homogeneous porosity distribution at  $t = 0$  ( $\phi = \phi_0$  at  $z \geq -H$  and  $\phi = 0$  at  $z < -H$ ), the initial stage of melt segregation was solved analytically [20]. In most of the column, the buoyancy force  $(1 - \phi)(\rho^S - \rho^L)g$  is in equilibrium with the viscous drag force  $\eta_L \phi (\dot{u}_z^L - \dot{u}_z^S) / k_\phi$ , while within the compaction length  $\delta_c$  from the bottom ( $-H \leq z < -H + \delta_c$ ), the buoyancy force balances with the compaction resistance of the solid framework. Therefore, when the compaction length  $\delta_c = \sqrt{k_\phi (1 - \phi) (\xi_{sk} + 4\eta_{sk}/3) / \eta_L}$  is smaller than  $H$ , which is the case for the mantle, the segregation velocity is determined by the permeability  $k_\phi$ . The permeability control is more clear in the steady-state model, in which the steady-state porosity structure develops to satisfy the balance between melt production rate and melt segregation rate, which is often assumed for the decompressional melting of the upwelling mantle below a ridge [30]. However, several instabilities inherent to the solid-liquid systems that result in a time-dependent evolution of the porosity distribution have also been reported. These include the propagation of melt as solitary waves or porosity waves, e. g. [3,34], and the unstable evolution of the perturbation in melt fraction under pure shear deformation of the solid matrix [39], in which both melt migration and matrix deformation are involved. These phenomena are de-

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 5  
 Dynamic processes in solid-liquid composite systems. Typical assumptions adopted in applying the governing equations (A)–(G) in the text to these processes are shown, with the material properties relevant to the processes

scribed by Eqs. (A)–(D), (E<sub>v</sub>), and (F)–(G), where, in the solitary or porosity waves, the nonlinearity caused by the dependence of permeability on melt fraction ( $k_\phi \propto \phi^{n>1}$ ) plays an essential role and, in the latter instability, the dependence of  $\eta_{sk}$  on  $\phi$  plays an essential role. The possible occurrence of these instabilities has been of great interest, because the melt ascending velocity is significantly affected by the spatial distribution of porosity. The melt velocity and its spatial distribution determine the degree of chemical interaction between the melt and host rocks, and thus influence the major and trace element compositions. The microstructural dependences of permeability and viscous properties of the partially molten rocks affecting these instabilities are poorly understood and are the subject of future studies. The basic framework introduced in Sect. “General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems” can be further extended to take into account additional factors, such as the chemical interaction between the fluid and host rocks, e. g. [1,36] or interfacial tension e. g. [32].

## Elastic Wave Propagation in a Solid-Liquid Composite System

### Derivation of Wave Equations

In this section, the general theoretical framework introduced in Sect. “General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems” is applied to the elastic wave propagation in a solid-liquid composite system. The governing equations are linearized by considering the infinitesimal strain and displacement of a macroscopically homogeneous medium, and the wave equations are derived. The linearized equations are shown to be equivalent to the basic equations used in the theory of linear poroelasticity.

When we consider a macroscopically homogeneous solid-liquid composite system, the spatial and temporal variations in  $\phi$ ,  $\rho^L$ , and  $\rho^S$  are caused by the displacements  $\mathbf{u}^L$  and  $\mathbf{u}^S$ . Therefore, if  $\mathbf{u}^L$  and  $\mathbf{u}^S$  are infinitesimally small, such terms as  $\dot{\mathbf{u}}^L \cdot \nabla(\phi\rho^L)$  and  $\dot{\mathbf{u}}^S \cdot \nabla((1-\phi)\rho^S)$  are negligible as higher-order terms. Under these approximations, by substituting Eqs. (C) and (D) into (A)/ $\rho^L$ +(B)/ $\rho^S$ , and taking the time integration, we obtain

$$-\phi \nabla \cdot (\mathbf{u}^L - \mathbf{u}^S) = \frac{\phi}{k_L} p^L + \frac{1-\phi}{k_S} p^S + \nabla \cdot \mathbf{u}^S. \quad (19)$$

By using Eq. (E<sub>e</sub>),  $\nabla \cdot \mathbf{u}^S = \epsilon_{kk}$  in Eq. (19) can be expressed in terms of stresses. Then, Eq. (19) and Eq. (E<sub>e</sub>) are written

as

$$\begin{aligned} & \phi \nabla \cdot (\mathbf{u}^L - \mathbf{u}^S) \\ &= \phi \left( \frac{1}{k_S} - \frac{1}{k_L} \right) p^L + (1-\phi) \left( \frac{1}{K_b} - \frac{1}{k_S} \right) (p^S - p^L) \end{aligned} \quad (20)$$

$$\begin{aligned} \epsilon_{ij} &= \frac{(1-\phi)}{2N} \left( \sigma_{ij}^S - \frac{\sigma_{kk}^S}{3} \delta_{ij} \right) \\ &\quad - \frac{(1-\phi)}{3K_b} (p^S - p^L) \delta_{ij} - \frac{1}{3k_S} p^L \delta_{ij}, \end{aligned} \quad (21)$$

where  $K_b$  and  $N$  represent the bulk and shear moduli, respectively, of the skeleton and are related to  $k_{sk}$  and  $\mu_{sk}$  introduced in Eq. (E<sub>e</sub>) as  $K_b = (1-\phi)k_{sk}$  and  $N = (1-\phi)\mu_{sk}$ . In the theory of linear poroelasticity,  $K_b$  and  $N$ , rather than  $k_{sk}$  and  $\mu_{sk}$ , are commonly used. Similarly, by substituting Eq. (3) into Eqs. (F) and (G), and neglecting the effect of gravity, we obtain

$$\phi \rho^L \ddot{\mathbf{u}}^L = -\phi \nabla \cdot p^L - \frac{\eta_L \phi^2}{k_\phi} (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S) \quad (22)$$

$$(1-\phi) \rho^S \ddot{\mathbf{u}}^S = (1-\phi) \nabla \cdot \sigma^S + \frac{\eta_L \phi^2}{k_\phi} (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S). \quad (23)$$

Equations (20)–(23) are equivalent to the basic equations used in the theory of linear poroelasticity. Compared to the framework introduced in Sect. “General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems”, the number of governing equations is reduced from 7 to 4, because the variables  $\rho^L$  and  $\rho^S$  are eliminated and  $\phi$  in Eqs. (20)–(23) can be treated as constant. In the theory of linear poroelasticity, Eq. (20) is called the constitutive relation for the relative motion between the two phases, and this relation is usually introduced empirically, e. g. [48]. The present derivation from the more general framework shows that Eq. (20) is based on the requirement of mass conservation and intrinsic constitutive relations. When the acceleration terms are negligible, Eqs. (22) and (23) are further rewritten as

$$\phi (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S) = -\frac{k_\phi}{\eta_L} \nabla p^L \quad (24)$$

$$\nabla \cdot \sigma^B = 0, \quad (25)$$

where Eq. (24) represents Darcy's law, and the bulk stress  $\sigma_{ij}^B$  represents  $\sigma_{ij}^B = (1-\phi)\sigma_{ij}^S - \phi p^L \delta_{ij}$ .

By eliminating pressures and stresses from Eqs. (20)–(23), we obtain

$$\begin{aligned} (1-\phi) \rho^S \ddot{\mathbf{u}}^S &= P \nabla (\nabla \cdot \mathbf{u}^S) - N \nabla \times \nabla \times \mathbf{u}^S \\ &\quad + Q \nabla (\nabla \cdot \mathbf{u}^L) + \frac{\eta_L \phi^2}{k_\phi} (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S) \end{aligned} \quad (26)$$

$$\phi \rho^L \ddot{\mathbf{u}}^L = Q \nabla(\nabla \cdot \mathbf{u}^S) + R \nabla(\nabla \cdot \mathbf{u}^L) - \frac{\eta_L \phi^2}{k_\phi} (\dot{\mathbf{u}}^L - \dot{\mathbf{u}}^S), \quad (27)$$

where  $P$ ,  $Q$ , and  $R$  are given by

$$\begin{cases} P = K_b + \frac{4}{3}N + \frac{(1 - \phi - \frac{K_b}{k_S})^2 k_S}{1 - \phi - \frac{K_b}{k_S} + \phi \frac{k_S}{k_L}} \\ Q = \frac{\phi(1 - \phi - \frac{K_b}{k_S})k_S}{1 - \phi - \frac{K_b}{k_S} + \phi \frac{k_S}{k_L}} \\ R = \frac{\phi^2 k_S}{1 - \phi - \frac{K_b}{k_S} + \phi \frac{k_S}{k_L}} \end{cases} \quad (28)$$

By taking the curl of Eqs. (26) and (27), and using the expressions  $\Omega_S = \nabla \times \mathbf{u}^S$  and  $\Omega_L = \nabla \times \mathbf{u}^L$ , we obtain wave equations for the shear component;

$$\begin{cases} (1 - \phi)\rho^S \ddot{\Omega}_S = N \nabla^2 \Omega_S + \frac{\eta_L \phi^2}{k_\phi} (\dot{\Omega}_L - \dot{\Omega}_S) \\ \phi \rho^L \ddot{\Omega}_L = -\frac{\eta_L \phi^2}{k_\phi} (\dot{\Omega}_L - \dot{\Omega}_S) \end{cases} \quad (29)$$

By taking the divergence of Eqs. (26) and (27), and using the expressions  $e_S = \nabla \cdot \mathbf{u}^S$  and  $e_L = \nabla \cdot \mathbf{u}^L$ , we obtain wave equations for the longitudinal component;

$$\begin{cases} (1 - \phi)\rho^S \ddot{e}_S = P \nabla^2 e_S + Q \nabla^2 e_L + \frac{\eta_L \phi^2}{k_\phi} (\dot{e}_L - \dot{e}_S) \\ \phi \rho^L \ddot{e}_L = Q \nabla^2 e_S + R \nabla^2 e_L - \frac{\eta_L \phi^2}{k_\phi} (\dot{e}_L - \dot{e}_S) \end{cases} \quad (30)$$

The elastic wave propagation in a solid-liquid composite system was first formulated by Biot [5,6]. The wave equations (29)–(30) are almost the same as those obtained by Biot [5,6], except for the acceleration terms, which are slightly different. This is because the interaction  $\mathbf{I}$  given in Eq. (3) does not take into account the effect of the relative acceleration between the solid and liquid phases. If an additional term proportional to the relative acceleration is added to the RHS of Eq. (3), then the same equations as Biot [5,6] can be derived. The proportionality constant attached to the relative acceleration is called tortuosity; tortuosity represents the deviation from the straight pore channel.

The elastic waves obtained by solving Eqs. (29)–(30) are dispersive and dissipative due to the relative motion between the solid and liquid phases. However, as shown below in Sect. “Dispersion and Attenuation of Waves in Solid-Liquid Composite Systems”, the characteristic frequency for the dispersion and attenuation is much higher than the seismic frequency range. Therefore, in predicting

the seismic wave velocities, the solutions obtained at the low-frequency limit are of importance. The wave solutions at the low-frequency limit do not involve relative motions, because the velocity terms,  $\dot{\Omega}_L - \dot{\Omega}_S$  and  $\dot{e}_L - \dot{e}_S$ , if any, dominate the acceleration terms, and hence are not dispersive nor dissipative. The longitudinal and shear wave velocities at the low-frequency limit are obtained as

$$V_P = \sqrt{\frac{K_b + \frac{4}{3}N + \frac{k_S(1 - K_b/k_S)^2}{1 - \phi - K_b/k_S + \phi k_S/k_L}}{\bar{\rho}}} \quad (31)$$

$$V_S = \sqrt{\frac{N}{\bar{\rho}}}, \quad (32)$$

where  $\bar{\rho} = (1 - \phi)\rho^S + \phi\rho^L$  represents the average density of the medium. Without relative motion, neither permeability nor tortuosity affect the velocities. Therefore, Eqs. (31)–(32) are exactly the same as the results of Biot [5,6].

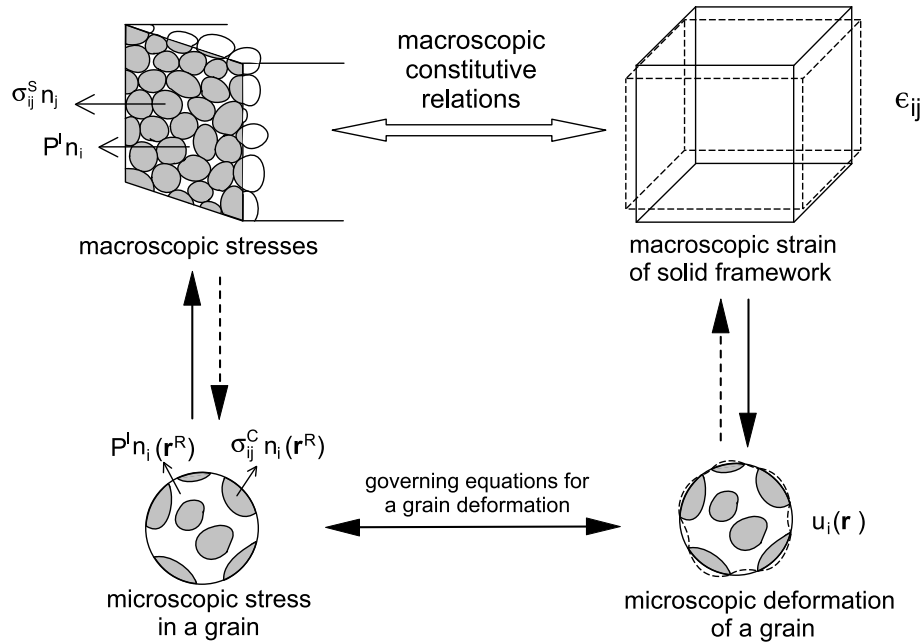

### Porosity and Pore Shape

Because the bulk and shear moduli of the skeleton,  $K_b$  and  $N$ , included in Eqs. (31)–(32) depend not only on porosity but also on pore geometry, various models assuming various pore geometries have been developed to predict  $K_b$  and  $N$  quantitatively, e. g. [15,17,18,27,41]. The oblate spheroid model (Fig. 6a), tube model (Fig. 6b),

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 6  
**Inclusion models of a solid-liquid composite system. a Oblate spheroid model. b Tube model**

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 7  
 Granular model of a solid-liquid composite system, showing the procedures to derive macroscopic constitutive relation, Eq. (E), based on the microscopic deformation of each grain [41]

granular model (Fig. 7), and crack model are four representative models in which analytical results can be obtained for  $K_b$  and  $N$  (Table 1). All but the granular model are inclusion models in which the liquid phase is modeled by inclusions contained in a continuum solid phase, and  $K_b$  and  $N$  are derived based on the effective medium theories. In the granular model, the constitutive equation (E) is derived directly. The results from the different theories can be compared based on Eq. (11). Although the connectivity of the liquid phase is not guaranteed in the inclusion models, when considering waves in the low-frequency regime where relative motion between solid and liquid does not occur, connectivity of the liquid phase is not important.

Here, by assuming a random orientation and homogeneous distribution of the pores, the macroscopic properties are assumed to be isotropic. Then,  $K_b$  and  $N$  are derived as functions of the porosity  $\phi$  and aspect ratio  $\alpha$  ( $\alpha$ =short radius/long radius) for the oblate spheroid model, as functions of the porosity  $\phi$  and parameter  $\varepsilon$  for the tube model, where  $\varepsilon$  represents the cross-sectional tube shape (Fig. 6b), as functions of the contiguity  $\varphi$  for the granular model, and as functions of the crack density parameter  $\kappa$  for the crack model. The contiguity  $\varphi$  used in the granular model is defined by the ratio of the grain-to-grain contact area relative to the total surface area of each grain;

thus,  $\varphi = 0$  when there is no grain-to-grain contact, and  $\varphi = 1$  when there is no liquid or pore phase. The crack density parameter  $\kappa$  used in the crack model is defined by  $\kappa = n_\kappa a_\kappa^3$ , where  $a_\kappa$  represents the radius of the circular crack and  $n_\kappa$  represents number density. Walsh [47] showed that in the limit of small aspect ratio,  $K_b$  and  $N$  obtained from the oblate spheroid model depend only on the crack density parameter  $\kappa = 3\phi/(4\pi\alpha)$ , and the results of the oblate spheroid model and crack model become equivalent. Therefore, the crack model can be included in the oblate spheroid model as a special case of small aspect ratio.

In the granular model, the dependence of contiguity  $\varphi$  on porosity  $\phi$  first needs to be assessed in order to specify the dependences of  $K_b$  and  $N$  on the porosity  $\phi$ . For a random packing of elastic spheres, which is often used as a model of soil, the total area of the elastic contacts of the spheres increases with raising confining pressure, and  $\varphi$  and  $\phi$  are derived as functions of confining pressure [8]. However, when the temperature is higher than a few hundreds °C, such an elastic model is not realistic. In the deep crust and mantle, solid grains are single crystals and the contiguity is related to the area of (liquid-free) grain boundaries. Because the grain boundary and crystal-liquid interface both have interfacial energies, there ex-

ists an equilibrium shape of the liquid phase which minimizes the total interfacial energy of the system. The equilibrium shapes were actually observed in the high T and high P experiments for various rock + melt and rock + aqueous fluid systems e. g. [10]. Therefore, the relationship between contiguity  $\varphi$  and porosity  $\phi$  is derived by assuming the equilibrium shape of the liquid phase. The granular model under this assumption is called the equilibrium geometry model (Table 1). Under a given liquid volume fraction  $\phi$ , the equilibrium shape is controlled by the dihedral angle  $\theta$ , which is determined by the grain boundary energy  $\gamma_{ss}$  and crystal-liquid interfacial energy  $\gamma_{sl}$  as  $\gamma_{ss}/\gamma_{sl} = 2 \cos(\theta/2)$  (Fig. 8a). The theoretical results of von Bargen and Waff [45] show that under a given  $\phi$ , the equilibrium contiguity is smaller for smaller  $\theta$  (Fig. 8b). By substituting  $\varphi$  obtained as functions of  $\phi$  and  $\theta$  into the results of the granular model,  $K_b$  and  $N$  in the equilibrium geometry model can be derived as functions of  $\phi$  and  $\theta$ . Most rock + melt systems have  $\theta$  between 20–40° and most rock + aqueous fluid systems have  $\theta$  between 40–100° [10]. When  $\theta \leq 60^\circ$ , a connected liquid network develops along the grain edges at  $\phi > 0$ . Although the tube model considers such grain edge tubules, the parameter  $\varepsilon$  in the tube model cannot be quantitatively related to the dihedral angle  $\theta$ .

Now, solid-liquid composite systems are characterized in terms of the two parameters: porosity  $\phi$  and pore shape  $x$  ( $= \alpha, \varepsilon$ , or  $\theta$ ). Because a random orientation and homogeneous distribution of the pores are assumed for simplicity, and since  $K_b$  and  $N$  do not depend on pore size, pore geometry is parameterized only by the shape. Porosity  $\phi$  and pore shape  $x$  are generally not dependent but can vary independently governed by different physics. For example, in a texturally equilibrated system, the dihedral angle  $\theta$  is determined by thermodynamic conditions such as temperature, pressure, and chemical compositions, whereas  $\phi$  can vary mechanically through flow-in or flow-out of the liquid. In a rock + water system stressed

under undrained condition, the pore shape can vary by fracture, while  $\phi$  is kept constant. In most solid-liquid systems in the Earth, neither the porosity nor the pore shape are known.

**a** Bulk modulus  $K_b$  and **b** shear modulus  $N$  of skeleton versus porosity  $\phi$ , for the oblate spheroid model with various aspect ratios  $\alpha$  and for the equilibrium geometry model with various dihedral angles  $\theta$

Because the parameter describing the pore shape is different in different models, it seems difficult to investigate the effects of pore shapes systematically. However, introduction of the concept of “equivalent aspect ratio” enables us to treat various pore shapes systematically. When the porosity  $\phi$  is small,  $K_b$  and  $N$  are closely approximated by linear functions of  $\phi$ ,

$$\begin{cases} \frac{K_b}{k_s}(\phi, x) = 1 - \phi \Lambda_{K_b}(x) \\ \frac{N}{\mu_s}(\phi, x) = 1 - \phi \Lambda_N(x) \end{cases} \quad (x = \alpha, \varepsilon, \theta), \quad (33)$$

where  $k_s$  and  $\mu_s$  represent the intrinsic bulk and shear moduli, respectively, of the solid, and the proportionality coefficients  $\Lambda_{K_b}$  and  $\Lambda_N$  are functions of pore shape  $x$  (Fig. 9). In other words, the effects of porosity and pore shape on  $K_b$  and  $N$  can be separated in such simple forms as given in Eq. (33), in which the pore shape given by  $x$  is characterized in terms of two parameters  $\Lambda_{K_b}$  and  $\Lambda_N$ . If a tube model with  $\varepsilon$  (or an equilibrium geometry model with  $\theta$ ) has almost the same values of  $\Lambda_{K_b}$  and  $\Lambda_N$  as the oblate spheroid model with  $\alpha$ ,

$$\begin{cases} \Lambda_{K_b}(x) \simeq \Lambda_{K_b}(\alpha) \\ \Lambda_N(x) \simeq \Lambda_N(\alpha) \end{cases} \quad (x = \varepsilon, \theta), \quad (34)$$

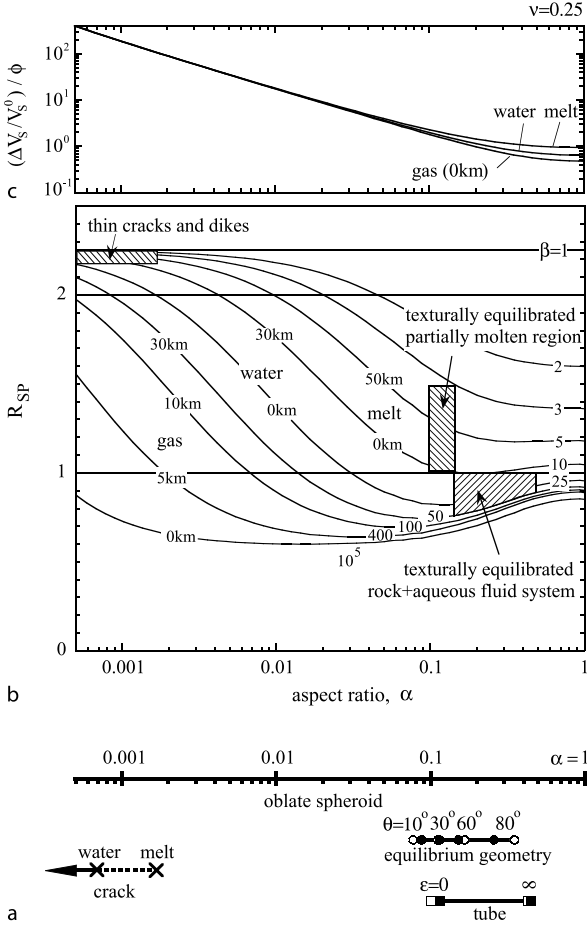

these two models yield almost the same values of  $K_b$  and  $N$  for a given  $\phi$ . This also means that  $V_P$  and  $V_S$  calculated with Eqs. (31)–(32) are almost the same in these two mod-

els. Therefore, the value of  $\alpha$  satisfying Eqs. (34) is called the equivalent aspect ratio of  $x$ ; this aspect ratio guarantees the equivalence between the different pore shapes in predicting  $V_P$  and  $V_S$ .

Figure 10a shows the relationships between the different models in terms of equivalent aspect ratio. The solid and open symbols represent the equivalent aspect ratios determined from  $\Lambda_{K_b}$  and  $\Lambda_N$ , respectively. The difference between these symbols is small, indicating that, in a practical sense, one value of equivalent aspect ratio satisfying both equations in (34) can be determined. Figure 10a shows that the tube model with  $\varepsilon = 0$ , equilibrium geometry model with  $\theta = 30^\circ$ , and oblate spheroid model with  $\alpha = 0.1$  are all equivalent. Rigorously speaking,  $\Lambda_{K_b}$  and  $\Lambda_N$  depend on the intrinsic Poisson's ratio  $\nu$  of the solid phase. The results shown in Fig. 10a are calculated for  $\nu = 0.25$ . Fortunately, however, the effects of  $\nu$  are almost the same in all models, and the equivalent aspect ratio can be determined almost independently of  $\nu$ . The present method to determine the equivalent aspect ratio from Eqs. (33)–(34) is applicable to general isotropic solid-liquid systems. By using the equivalent aspect ratio, general pore geometries can be treated systematically.

#### Determinability of Porosity and Pore Shape from Elastic Wave Velocities

It can be shown that when the porosity  $\phi$  is small, the effects of  $\phi$  on the skeleton properties  $K_b$  and  $N$  can be

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 10

**a** Equivalence of the equilibrium geometry model, tube model, and crack model to the oblate spheroid model is shown by the equivalent aspect ratio  $\alpha$ . Solid and open symbols are the equivalent aspect ratios determined from  $\Lambda_{K_b}$  and  $\Lambda_N$ , respectively. **b**  $R_{SP}$ , representing the ratio between  $V_S$  and  $V_P$  perturbations,  $(\Delta V_S/V_S^0)/(\Delta V_P/V_P^0)$ , versus pore aspect ratio  $\alpha$ , for various fluid compressibilities  $\beta = k_S/k_L$ . **c** Proportionality constant between  $V_S$  perturbation  $\Delta V_S/V_S^0$  and porosity  $\phi$  versus pore aspect ratio  $\alpha$ , for various liquid types (gas, water, and melt)

closely approximated by linear functions of  $\phi$ . In the same manner, when  $\phi$  is small, the effects of  $\phi$  on the velocities  $V_P$  and  $V_S$  can be closely approximated by linear functions of  $\phi$ . Let  $\Delta V_P = V_P^0 - V_P$  and  $\Delta V_S = V_S^0 - V_S$  be reductions in  $V_P$  and  $V_S$ , respectively, caused by liquid-filled pores, where  $V_P^0 = \sqrt{(k_S + 4\mu_S/3)/\rho^S}$  and  $V_S^0 = \sqrt{\mu_S/\rho^S}$  represent the intrinsic elastic wave velocities of the solid phase. Let  $\Delta V_P/V_P^0$  and  $\Delta V_S/V_S^0$  be perturbations in  $V_P$  and  $V_S$ , respectively. By substituting Eqs. (33) into Eqs. (31)–(32) and neglecting higher-order terms in  $\phi$  ( $\phi^n$

with  $n \geq 2$ ), we obtain

$$\begin{cases} \frac{\Delta V_P}{V_P^0} = \left[ \frac{(\beta-1)\Lambda_{K_b} + \frac{4}{3}\gamma\Lambda_N}{1 + \frac{4}{3}\gamma} - \left(1 - \frac{\rho^L}{\rho^S}\right) \right] \frac{\phi}{2} \\ \frac{\Delta V_S}{V_S^0} = \left[ \Lambda_N - \left(1 - \frac{\rho^L}{\rho^S}\right) \right] \frac{\phi}{2}, \end{cases} \quad (35)$$

where  $\beta = k_S/k_L$  and  $\gamma = \mu_S/k_S$ . Without loss of generality,  $\Lambda_{K_b}$  and  $\Lambda_N$  can be treated as functions of the equivalent aspect ratio  $\alpha$ . Equations (35) demonstrate that the velocity perturbations are affected by the five non-dimensional parameters  $\phi$ ,  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\rho^L/\rho^S$ . Because a possible variation in  $\gamma$  in response to a variation in the intrinsic Poisson's ratio  $\nu$  of the solid phase is small,  $\gamma$  can be fixed to 0.6 ( $\nu = 0.25$ ). Also, as shown below, the effect of  $\rho^L/\rho^S$  on the perturbations is small. Therefore, in a practical sense, the velocity perturbations are controlled by the three non-dimensional factors: liquid volume fraction  $\phi$ , pore aspect ratio  $\alpha$ , and liquid compressibility  $\beta$ . If only one of  $\Delta V_P/V_P^0$  and  $\Delta V_S/V_S^0$  is known,  $\phi$  cannot be determined without knowing  $\alpha$  (and  $\beta$ ). However, if both  $\Delta V_P/V_P^0$  and  $\Delta V_S/V_S^0$  are known, significant constraints can be placed on  $\phi$ ,  $\alpha$ , and/or  $\beta$ . A practical method to obtain these constraints is presented below.

First, we introduce  $R_{SP}$ , representing the ratio of the perturbations in  $V_S$  and  $V_P$ . From Eq. (35),  $R_{SP}$  is written as

$$\begin{aligned} R_{SP} &= \frac{\Delta V_S/V_S^0}{\Delta V_P/V_P^0} \\ &= \frac{\Lambda_N - \left(1 - \frac{\rho^L}{\rho^S}\right)}{\frac{(\beta-1)\Lambda_{K_b} + \frac{4}{3}\gamma\Lambda_N}{1 + \frac{4}{3}\gamma} - \left(1 - \frac{\rho^L}{\rho^S}\right)}. \end{aligned} \quad (36)$$

$R_{SP}$  can be closely related to the  $V_P/V_S$  ratio frequently used in seismology: when  $R_{SP} < 1$ , the perturbation (reduction positive) in  $V_P$  is larger than that in  $V_S$  and hence the  $V_P/V_S$  ratio decreases; when  $R_{SP} > 1$ , the perturbation in  $V_S$  is larger than that in  $V_P$  and thus the  $V_P/V_S$  ratio increases. Because  $R_{SP}$  is independent of the liquid volume fraction  $\phi$ , this factor provides a useful insight into the effects of pore shape  $\alpha$  and liquid compressibility  $\beta$  on the velocity perturbations.  $R_{SP}$  is sometimes written as  $d \ln V_S/d \ln V_P$ . Figure 10b shows  $R_{SP}$  versus pore aspect ratio  $\alpha$  for various compressibility  $\beta$  of pore fluids. Values of  $\beta$  are estimated as 5–10 for rock + melt systems, 10–40 for rock + water systems, and 50–10<sup>5</sup> for rock + ideal

gas systems in the 0–50 km depth range (Table 2). Values of  $\rho^L / \rho^S$  are estimated as 0.92, 0.33, and 0 for rock + melt, rock + water, and rock + ideal gas systems, respectively. The effect of  $\rho^L / \rho^S$  on  $R_{SP}$  is small, and practically the same figure as Fig. 10b can be obtained by simply assuming  $\rho^L / \rho^S = 1$  ([42] Fig. 4). Figure 10b shows that for a given pore shape  $\alpha$ ,  $R_{SP}$  increases with decreasing liquid compressibility  $\beta$ . Figure 10b also shows that for a fixed liquid compressibility  $\beta$ ,  $R_{SP}$  varies significantly with the variation of pore shape  $\alpha$ . When  $\beta$  is fixed to 25, for example,  $R_{SP}$  is smaller than 1 for moderate values of pore aspect ratio ( $\alpha > 0.03$ ), larger than 1 for small aspect ratio ( $< 0.03$ ), and larger than 2 for very small aspect ratio ( $< 0.0016$ ). Therefore,  $R_{SP}$  provides a good seismological indicator of pore shape.

When  $\Delta V_P / V_P^0$  and  $\Delta V_S / V_S^0$  are obtained from seismological observations or laboratory experiments,  $R_{SP}$  is calculated by taking the ratio of these two. If we know whether the liquid phase is melt, water, or gas, Fig. 10b can be used for estimating the equivalent aspect ratio  $\alpha$  from  $R_{SP}$  under known  $\beta$ . Without any additional information about the liquid phase,  $\alpha$  is estimated from  $R_{SP}$  under an assumed  $\beta$ . Figure 10c shows the proportionality coefficient between  $\Delta V_S / V_S^0$  and  $\phi$  (the 2nd equation of 35) versus  $\alpha$  for various liquid types. By applying  $\alpha$  estimated from  $R_{SP}$  to Fig. 10c, the liquid volume fraction  $\phi$  can be determined from  $\Delta V_S / V_S^0$ .

Figures 10a–10c are a complete summary of the effects of liquid volume fraction  $\phi$ , pore shape  $\alpha$ , and liq-

uid compressibility  $\beta$  on  $V_P$  and  $V_S$ . Using these figures, we can combine and confirm our understandings from the previous forward approaches, such as the different effects of gas, water, and melt, on the  $V_P / V_S$  ratio [27,49]. Also, Figs. 10b–10c represent a practical method in the inverse approach to constrain  $\phi$ ,  $\alpha$ , and/or  $\beta$  from the observation of  $V_P$  and  $V_S$ . Figures 10a–10c are based on Eqs. (33), (35), and (36) in which the higher-order terms in  $\phi$  ( $\phi^{n \geq 2}$ ) are neglected. A possible variation of  $R_{SP}$  with  $\phi$  caused by the higher-order terms in  $\phi$  can be obtained by calculating  $(\Delta V_S / V_S^0) / (\Delta V_P / V_P^0)$  directly from Eqs. (31) and (32) without using Eq. (33). Using results from the latter calculations, it is confirmed that the present method based on the linearized equations is valid for  $\Delta V_S / V_S^0 \leq 0.35$  for the equilibrium geometry model, which corresponds to  $\phi \leq 0.15$ , and valid for  $\Delta V_S / V_S^0 \leq 0.2$  for the oblate spheroid, tube, and crack models. The applicable range is large for the equilibrium geometry model because the higher-order effects neglected in obtaining Eq. (33) cancel those neglected in obtaining Eq. (35). Compared to the equilibrium geometry model, the applicable range is smaller for the oblate spheroid, tube, and crack models. To use the present method outside the applicable range, a small modification is required ([42], Appendix B).

### Application to Seismic Tomographic Images

The information on pore geometry obtainable from seismic tomographic data is the equivalent aspect ratio. Whether the actual geometry is an oblate spheroid or tube, for example, cannot be determined from seismological data. A reasonable interpretation of the derived equivalent aspect ratio requires a knowledge of probable pore geometries in the Earth. Two end-member images of pore geometry have been inferred based on experimental and field observations: one is the equilibrium geometry characterized by a dihedral angle, and the other is thin dikes and veins. In the equilibrium geometry, the pore size is much smaller than the grain size and the permeability is small. For rock + water systems, because the dihedral angle is usually larger than  $60^\circ$ , the equilibrium geometry may have nearly zero permeability. Dikes and veins can develop on much larger scales than the grain size and hence may have much larger permeability than the equilibrium geometry. Therefore, the particular geometry realized between these two end-members significantly affects the liquid migration velocity of the buoyancy ascent. As discussed in Sect. “Overview of Applications”, whether the liquid phase is in the equilibrium shape or not can provide us with valuable information about the degree of interaction between pore geometry and macroscopic dynam-

ics. It is therefore desirable to distinguish between these two end-members using seismic tomographic data. Because the equivalent aspect ratio for the equilibrium geometry is about a factor of 100 larger than that for the thin cracks and dikes (Fig. 10a), the expected values of  $R_{SP}$  are significantly different between these two end-member geometries (hatched regions in Fig. 10b); for rock + water systems,  $R_{SP}$  is  $<1$  for the equilibrium geometry and  $>2$  for thin cracks and dikes; for rock + melt systems,  $R_{SP}$  is 1–1.5 for the equilibrium geometry and  $>2$  for thin cracks and dikes. Therefore,  $R_{SP}$  can be used as a seismological indicator of the textural equilibrium, and the information on pore geometry obtained from this indicator can provide us a valuable constraint on actual fluid migration processes in the Earth. Low-velocity regions observed in the mantle wedge beneath Northeastern Japan subduction zone show a systematic change in  $R_{SP}$  with depth. Nakajima et al. [24] applied the method introduced in Sect. “**Determinability of Porosity and Pore Shape from Elastic Wave Velocities**” to seismic tomographic data and inferred a systematic change in pore geometry from an equilibrium geometry at a depth of  $\sim 90$  km to thin cracks and dikes at a depth of  $\sim 65$  km.

Beneath volcanic areas, low-velocity regions with lower  $V_P/V_S$  ratio than the surrounding regions are sometimes observed at depths of several km [22]. Rock + melt systems usually have  $\beta$  smaller than 10. This means that  $R_{SP}$  is larger than 1 regardless of  $\alpha$  (Fig. 10b) so that the

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 11

The amount of H<sub>2</sub>O bubble (weight %) in melt at which the compressibility of the mixture is equal to  $\beta = 10, 20$ , or  $50$ , is shown as a function of depth

observed low  $V_P/V_S$  ratio cannot be explained by the melt-filled pores. At these shallow depths, however, the melt phase can be a mixture of melt and H<sub>2</sub>O vapor, because H<sub>2</sub>O initially dissolved in the melt in the deeper reaches of the subduction zone starts to exsolve. Here, we briefly discuss such situation, which is not considered in Fig. 10b and Table 2. Because of the high temperature (900–1000°C) of melt, the water phase in the melt is much more compressible than the estimates in Table 2. Figure 11 shows the fraction of water (wt%) above which  $\beta$  of the mixture exceeds 10, 20, or 50. It is shown that at a depth of 3–4 km,  $\beta \geq 20$  occurs for the melt containing 0.2–0.5 wt% water as vapor phase, which is realistic in the subduction zone. Therefore, from Fig. 10b,  $R_{SP} < 1$  can occur at large  $\alpha$  and can explain the observed reduction in the  $V_P/V_S$  ratio. If the H<sub>2</sub>O vapor in the melt phase can be detected by the low  $V_P/V_S$  ratio, we can obtain valuable constraints on the water content of melts and on the evolution of a magma chamber in the crust. However, because melt viscosity is considered to be high in shallow magma chambers, it is important to be careful about wave dispersion, as discussed below.

### Dispersion and Attenuation of Waves in Solid-Liquid Composite Systems

In deriving the elastic wave velocities in Sect. “**Derivation of Wave Equations**”, it was implicitly assumed that the frequencies of the seismic waves are lower than the characteristic frequencies of several relaxation processes inherent to solid-liquid composite systems. If this assumption is not valid, the relaxation processes affect the wave velocities due to dispersion. To assess the applicability of the theoretical results presented in Sect. “**Determinability of Porosity and Pore Shape from Elastic Wave Velocities**”, I present here a brief discussion of such relaxation processes. To show the mutual relationship between dispersion and attenuation, I consider the relaxation mechanism predicted from Eqs. (29)–(30). This mechanism was first studied by Biot [5,6] and is hereafter referred to as the Biot mechanism. The behavior obtained for the Biot mechanism describes the fundamental characteristic of relaxation. Several other relaxation mechanisms inherent to the solid-liquid composites also affect wave propagation and these are further summarized below.

Let  $\omega$  and  $k$  be the angular frequency and wave number, respectively. By substituting the traveling wave solutions  $\Omega_S = \Omega_S^0 e^{-i(\omega t - kx)}$  and  $\Omega_L = \Omega_L^0 e^{-i(\omega t - kx)}$  into Eq. (29), the dispersion relation, under which non-trivial solutions exist, is obtained as

$$\left(\frac{k}{\omega}\right)^2 = \frac{\rho_U}{N} \cdot f(\omega), \quad (37)$$

where the complex function  $f(\omega) = f_1(\omega) + if_2(\omega)$  is explicitly written as

$$\begin{cases} f_1(\omega) = 1 + \frac{\Delta}{1 + \left(\frac{\omega}{\omega_c}\right)^2} \\ f_2(\omega) = \frac{\Delta \cdot \left(\frac{\omega}{\omega_c}\right)}{1 + \left(\frac{\omega}{\omega_c}\right)^2}, \end{cases} \quad (38)$$

and  $\rho_U = (1 - \phi)\rho^S$ ,  $\rho_R = (1 - \phi)\rho^S + \phi\rho^L$ ,  $\Delta = (\rho_R - \rho_U)/\rho_U$ , and  $\omega_c = \eta_L\phi/(k_\phi\rho^L)$ . The phase velocity  $V$  and attenuation  $Q^{-1}$  are defined by  $k/\omega = V^{-1}(1 + i/(2Q))$ . By assuming  $Q^{-1}$  to be small ( $f_2 \ll f_1$ ), we obtain

$$\begin{cases} V = \sqrt{\frac{N}{\rho_U \cdot f_1(\omega)}} \\ Q^{-1} = \frac{f_2(\omega)}{f_1(\omega)}. \end{cases} \quad (39)$$

The phase velocity  $V$  and attenuation  $Q^{-1}$  given by Eqs. (39) are shown in Fig. 12 as functions of the normalized frequency  $\omega/\omega_c$ . Both dispersion and attenuation occur near  $\omega/\omega_c = 1$  and the total amplitude of dispersion and peak value of  $Q^{-1}$  are equal;

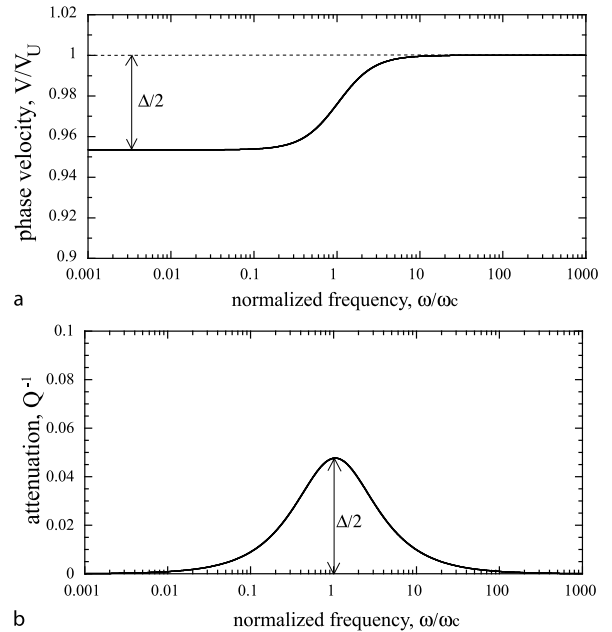

$$Q_{\text{MAX}}^{-1} = \frac{\Delta}{2} = \frac{V_U - V_R}{V_U}, \quad (40)$$

where  $V_U$  (unrelaxed velocity) represents  $V$  at  $\omega/\omega_c \gg 1$  and  $V_R$  (relaxed velocity) represents  $V$  at  $\omega/\omega_c \ll 1$ .

Although obtained for the Biot mechanism, Eqs. (38) and (39) describe the fundamental characteristics of dispersion and attenuation regardless of the individual mechanism. These equations simply mean that the dispersion and attenuation are caused by a relaxation process. When a response  $J(t)$  (e. g., strain) of a medium to a constant unit force (in the form of a Heaviside function  $H(t)$ ) applied at  $t \geq 0$  is not instantaneous but shows a time delay expressed in the form of

$$J(t) = J_U [1 + \Delta \cdot (1 - e^{-\omega_c t})] \cdot H(t), \quad (41)$$

this phenomenon is called relaxation. In other words, Eq. (41) gives a phenomenological model of relaxation. The relaxation process is characterized by relaxation strength  $\Delta$  and relaxation time scale  $\omega_c^{-1}$ . The time derivative of Eq. (41),  $\dot{J} = J_U[\delta(t) + \omega_c \Delta e^{-\omega_c t} H(t)]$ , yields the impulse response, where the Fourier transform of  $\dot{J}/J_U$  is equal to  $f(\omega) = f_1(\omega) + if_2(\omega)$  with  $f_1(\omega)$  and  $f_2(\omega)$  given by Eq. (38). Therefore, Eq. (38), which is called Debye equation [25], is a phenomenological model of relaxation in the frequency domain.

Earth's Crust and Upper Mantle, Dynamics of Solid-Liquid Systems in, Figure 12

**a** Frequency-dependent phase velocity (dispersion) and **b**  $Q^{-1}$  (attenuation) described by Debye equations (38)

Solid-liquid composite systems show several relaxation mechanisms caused by the liquid phase. One example is the Biot mechanism exemplified above, in which the density of the system relaxes from  $\rho_U$  to  $\rho_R$ . At  $\omega/\omega_c \gg 1$ , due to a dominant effect of liquid inertia, a wave field cannot cause motion in the liquid phase. Hence,  $\rho_U$  is associated only with the solid mass. At  $\omega/\omega_c \ll 1$ , due to a dominant effect of viscous drag force, relative motion does not occur between the solid and liquid phases. Hence,  $\rho_R$  is associated with the total mass. The characteristic frequency  $\omega_c$  is estimated as 200 kHz for water-saturated sandstone ( $k_\phi = 10^{-12} \text{ m}^2$ ,  $\eta_L = 10^{-3} \text{ Pa s}$ ,  $\rho^L = 10^3 \text{ kg/m}^3$ , and  $\phi = 0.2$ ). Because  $k_\phi$  in the mantle is usually smaller than the value for sandstone,  $\omega_c$  is usually much higher than the seismic frequency. The Biot mechanism for the longitudinal waves also has the value of  $\omega_c$  much higher than the seismic frequency. Therefore, the assumption of the relaxed state is valid for the Biot mechanism.

Another relaxation mechanism is squirt flow [19]. When the pore shape is not spherical, changes in pore pressure induced by the elastic waves depend on the aspect ratio and orientation of each pore. Therefore, liquid pressure becomes heterogeneous at the microscopic scale, and this pressure heterogeneity is relaxed by viscous flow of the liquid between pores (squirt flow). This causes a relaxation of the skeleton moduli from  $N_U$  and  $K_{bU}$  to  $N_R$  and

$K_{bR}$ . The relaxation strength of  $N$ ,  $(N_U - N_R)/N_R$ , is generally larger than that of  $K_b$ ,  $(K_{bU} - K_{bR})/K_{bR}$ , and therefore the effect of squirt flow is larger on  $V_S$  than on  $V_P$ . In Sect. “**General Theoretical Framework to Describe the Dynamics of Solid-Liquid Composite Systems**”, the liquid pressure was assumed to be homogeneous within REV and hence the velocities obtained in Sect. “**Derivation of Wave Equations**” represent relaxed velocities. When  $\alpha$  is large, the relaxation strength is small and the difference between the relaxed and unrelaxed velocities is not significant. As  $\alpha$  becomes smaller, the relaxation strength becomes larger, and hence the relaxed velocities can be used only when liquid pores are not isolated and the frequency of the waves are much lower than  $\omega_c = k_S \alpha^3 / \eta_L$  [28]. For water ( $\eta_L = 10^{-3}$  Pa s) and basaltic melt ( $\eta_L = 1 - 10^3$  Pa s),  $\omega_c$  approaches the seismic frequency when  $\alpha$  is smaller than  $10^{-2} - 10^{-3}$ . If the pore orientation is not random, even under the relaxed state of squirt flow, the pore pressure is different from that estimated for the random orientation. Therefore, when  $V_P$  and  $V_S$  derived in Sect. “**Determinability of Porosity and Pore Shape from Elastic Wave Velocities**” are applied to  $\alpha < 10^{-2} - 10^{-3}$ , the connectivity of the pores, characteristic frequency of squirt flow, and the randomness of pore orientation should all be checked.

As exemplified in the previous section, the presence of  $H_2O$  vapor in the melt phase can relax the liquid compressibility from that of a pure melt ( $\beta_U$ ) to that of a water-melt mixture ( $\beta_R$ ). Figure 11 is obtained by assuming that the characteristic frequency  $\omega_c$  is much higher than the seismic frequency. However,  $\omega_c$  decreases with increasing viscosity of the melt. For andesitic and rhyolitic melts, the characteristic frequency is close to or lower than the seismic frequency range [12].

### Future Directions

One practical problem limiting the determinability of porosity and pore geometry from seismological data lies in the difficulty of accurately estimating  $\Delta V_P$  and  $\Delta V_S$ . For example, a low-velocity anomaly in the upper mantle is generally caused by the superposition of high-temperature anomaly and partial melting. In order to determine porosity and pore geometry from these data,  $\Delta V_P$  and  $\Delta V_S$  associated only to the existence of liquid-filled pores (hereafter referred to as poroelastic effect) should be estimated by accurately correcting the data for the temperature effect. Recent experimental studies on the elastic properties of melt-free olivine polycrystals performed in the seismic-frequency range have demonstrated that at  $T > 1000^\circ\text{C}$  and at such low frequency, the temperature effect consists of both anharmonic and anelastic effects [14]. Unlike the an-

harmonicity, anelasticity cannot be measured by the usual experimental methods using ultrasonic waves. Because experimental data on anelasticity are still limited and the detailed mechanism of anelasticity with or without melt is poorly understood, correction of the data for the temperature effect is difficult. Also, in the crust, accurate estimation of  $\Delta V_P$  and  $\Delta V_S$  for the poroelastic effect is difficult because the effect of anelasticity has not been assessed under crustal conditions and also because the lithological heterogeneity is considered to be larger than in the mantle. Therefore, the separation of poroelastic, temperature, and lithological effects affecting the velocity perturbations is an important subject of future study. Recently, not only the  $V_P$  and  $V_S$  structures but also the three-dimensional  $Q_P$  and/or  $Q_S$  (seismic attenuation) structures and two-dimensional or three-dimensional electrical conductivity structures have become available. These structures provide additional information on liquid-filled pores, temperature anomaly, and/or lithological heterogeneity. The  $Q_P$  and/or  $Q_S$  structures, for example, are important in constraining the magnitude of the anelastic effect [24]. Although the separation of individual factors is difficult to determine from velocity structures alone, additional information from  $Q$  and/or electrical conductivity structures will be very valuable.

### Acknowledgments

The original and more simplified form of this article was published in Japanese [43]. I especially thank Tokyo Geographical Society, for the permission to use a modified version of figures and limited text. I thank S. Nagumo for helpful discussions. I also thank B. K. Holtzman and B. Chouet for reading the manuscript and providing helpful comments.

### Glossary

**Community** A group of neighbors or people with a commonality of association and generally defined by location, shared experience, or function [59].

**Community empowerment** Internally and externally nurtures a community to accept that residents live in a hazard zone, and they choose to do things as a group to maximize their safety.

**Community safety group** Existing community groups (such as Neighborhood Watch) and individuals, working with formal response organizations form a coherent affiliation in and near a hazard zone, to help maximize safety and care for all community members.

**Disaster** The interface between an extreme physical event and a vulnerable human population [81].

**Disaster lead time** The time taken from first detection of a natural disaster threat to the likely time of impact on humans or human structures.

**Disaster threat** A natural extreme event which may impact on a community.

**Effective risk communication** . That which motivates people to maximize their own safety.

**Emergency** An actual or imminent event which endangers or threatens to endanger life, property or the environment, and which requires a significant and coordinated response [55].

**Evacuation** People relocating to safely escape hazardous disaster impacts. To move from a high danger zone to relative safety.

**Hazard** A source of potential harm or a situation with a potential to cause loss. A situation or condition with potential for loss or harm to the community or environment [55]. Hazard is synonymous with ‘source of risk’ [25].

**Hazard zone** Defined geographic areas which may be subject to a natural disaster impact of flood, bush-fire, storm surge, destructive winds, earthquake, landslide or damaging hail. Hazard zones include major accident sites, including industrial, transport or mining precincts; or biological or terrorist threat or impact, or from-source predicted area(s) of pandemic spread.

**Mitigation** Any efforts taken which may reduce the impact of a threat.

**Prevention** Measures to eliminate or reduce the incidence or severity of emergencies [55].

**Ramp-up preparations** The final set of preparations and precautionary evacuations taken ahead of a forecast disaster impact. This includes earlier final actions than precipitated by formal organizations.

**Risk treatment options** Measures that modify the characteristics of hazards, communities and environments to reduce risk, e. g. prevention, preparedness, response and recovery [55].

**Vulnerability** comprises ‘resilience’ and ‘susceptibility’. ‘Resilience’ is related to ‘existing controls’ and the capacity to reduce or sustain harm. ‘Susceptibility’ is related to ‘exposure’ [25].

### Definition of the Subject

This article intends to show how system and complexity science can contribute to an understanding and improvement of evacuation processes, especially considering the roles of engaged communities at risk, the concepts of community self-help, and clear communication about local threats and remedies.

This article shows researchers in Complexity and Systems Science (CSS) a social sciences approach to maximize effective and precautionary evacuation, maximize safety, minimize loss and speed full recovery. The computational and analytical modeling tools of CSS may be considered to apply to a complex interaction of community awareness, inclination to accept the reality of a natural disaster threat, along with achieving background and final preparations to maximize safety and recovery from a natural disaster impact. This article may stimulate CSS

researchers to develop detailed models of the complex systems and complexity of melding information from Weather Bureaus and Disaster Managers, via contacts and intervening media to communities at risk, with the shared social goal of maximizing safety. This social sciences task requires cross-disciplinary approaches of respect and response.

The old disaster management model lacked the predictive and rapid communication systems now available and developing in disaster predictive models (such as a flood maps). An approach to modeling the great complexity of human behavior responding to threat is provided. Such a model must include people's prior knowledge of a threat type, and consider such fine detail as the overarching language used in a country with threat zones, and the dominant languages of all under threat. It is hoped this article stimulates CSS models to further engage in this social good of helping people get safe and stay safe through natural disasters by providing predictive tool to Authorities to better inform and encourage those at risk to action, including the possible need for precautionary evacuations ahead of a predicted impact.

Disaster management in Australia, and increasingly, globally, is focused on mitigation as part of a 'threat continuum', from acceptance that some locations are vulnerable to a hazard impact, through to recovery [13]. Emergency warnings and a possible need to evacuate are embedded as 'spikes' on that continuum. Thus, this article stresses the importance of developing ways; incentives, to mobilize aware at-risk community members to precautionary self-evacuation. For this to happen, people need to know and internalize the reality that they are in a hazard zone.

Thus, in the cost-effective philosophy of engendering self-help, the process of understanding the complexity of achieving the shared social goal in maximizing safety and minimizing loss is to engender creation of empowered communities with a high motivation for safety-oriented and precautionary action. This is likely to lead to minimized loss and disruption, and maximized recovery. This article details many elements of that process, and invites detailed development of the Sustainability Implementation Research to achieve that goal through CSS.

To model the path to collective safety, the complexity of the dynamics at play need to be clarified: impact preparedness, including possible evacuation, is a communication and social issue.

This article demonstrates that acknowledgment of hazard zones, developing community acceptance of threat and needed action needs to be at the individual, household and community levels. Evacuation modeling is needed

only for those whose homes may be at real threat of a disaster impact. For those living in a hazard zone, a fully informed community, who have internalized the reality of the threat and have worked for maximum background preparation, and have mechanisms to receive alerts and warnings of a looming threat; a community predisposed to precautionary evacuations will result.

Capturing this complexity is the challenge for modelers. Evacuation is about hazard zone residents actively monitoring a looming threat via refined communication channels detailed in this article, within a developed social predisposition to act. Some examples are given. For consideration by scientists and students internationally, this article introduces the Communication Safety Triangle and the Seven Steps to Community Safety on the Preparedness Continuum, within the new research frame of Sustainability Implementation Research (SIR).

## Introduction

The purpose of this article is to share with modelers and complexity and system scientists the social and communication issues of modeling effective safety strategies to a natural disaster threat. It is hoped, through the approaches and processes described in this article, that modelers will more clearly link physical threats with warnings and community engagement.

This article first looks at the definitions and language used in risk communication and effective warnings, leading to informal and formal evacuations, then considers some Australian policies relating to emergency management. Theories related to risk communication are presented, with examples of evacuation issues provided from Indigenous communities, and from non English speaking households. The needed conceptual shift to self-help is placed within the larger theoretical frame of paradigms and paradigms shifts.

An example of including residents to internalize threats is given, followed by a more general example of transport evacuation.

A discussion of international evacuation issues precedes a broader view of some of the institutional barriers which may restrict the uptake of the seven step approach to an aware, informed community, relying on accurate information and choosing to self evacuate as a precaution. These issues are discussed, considering effective ways of allowing people to know that they are at risk so they are inclined to evacuate themselves, as a practice. These approaches can be used or tested by other scholars. Recommendations and a summary of the key issues to maximize voluntary and safe evacuations finish this article.

### Some Key Evacuation Issues

In an era of increasing social self-help [7,55] and community empowerment [13,25,26], a part of global efforts to embrace Ecologically Sustainable Development [8,62] is to increasingly see evacuation as a social phenomenon.

This article provides a conceptual frame, the Communication Safety Triangle (CST) which includes responsible media telling people at risk what they need to know and *seven steps to community safety* (7SCS). The 7SCS help guide emergency managers and modelers to treat the possible need for evacuation as a decision-making process where the community should be aware of the potential threats and receive clear, detailed and reliable information on the possible need to evacuate, so most residents in a high impact zone self-evacuate in a precautionary way, as a practice. Examples provided in this article illustrate this new, *sustainability implementation research* (SIR) approach to disaster management.

Warnings precede a perceived need to evacuate. In the USA, the need for an integrative approach to warnings is identified: “There is a major need for better coordination among the warning providers, more effective delivery mechanisms, better education of those at risk, and new ways for building partnerships among the many public and private groups involved” [63].

Sustainability implementation is the way to achieve a sustainable future. Disaster management, effective risk communication and community self-help provide a stark and comprehensible example of what sustainability implementation means, how it will benefit societies, and will help channel us into a safer, more sustainable future. Within this approach, scientists and students become major agents for sustainability implementation, as models can illustrate the needed paths to achievement.

### Evacuation Overview

There are three types of disasters which may require evacuation: human induced and natural disasters with and without lead times. This article is focused on precautionary evacuations ahead of natural disasters with lead times (Table 1). The research and conceptual frames draw on and are applicable to all communities in hazard zones. Defining, modeling and effectively communicating to at-risk residents and travelers about specific geographic hazards and safety-oriented behaviors are core elements of successful precautionary evacuations.

Within Table 1, evacuation may be a response to an emerging hazard of indicated intensity, direction and speed. This article advocates development of informed and directed communities which will actively respond to

a communicated threat, with the vulnerable moving themselves early to places of safety, or being helped by other community members to move.

### Concepts, Language and Mathematically Modeling the Propensity to Evacuate

Precautionary self evacuation pivots on knowing who is at risk. With the help of researchers, modelers; planning and community involvement can prepare people and their valuables to minimize loss. Very public hazard maps will help people internalize that they are in a hazard zone, and what they should do. The concept is not new or alarming: every public building has emergency exit routes marked, with all that implies. Air flight comes with the mandatory emergency preparation presentation. Minute or recurrent risks to where we live or travel to should be no less public, nor more alarming than a fire drill in a public building.

### Hazard Types – Little or Considerable Warning Times

Hazards may or may not have lead times (Table 1). Sudden onset threats include: tsunami, earthquake, major eruption, major toxic spill or discharge, mine disaster, terrorist threat or attack. Signaled threats include: – cyclone, flood, fire and destructive winds. This article focuses on disasters with sufficient warning periods to be able to evacuate the vulnerable away from the predicted worst impact areas. Table 1 that with sudden onset impacts, sheltering to survive the first few minutes is critical, then moving to open; stable ground is important to avoid further aftershocks or landslide. Always take direction from local authorities. For natural disasters with lead times, Table 1 shows that, if you will clearly be safe where you are, stay put, and prepare as best you can. If, in the worst case, you may not be safe, move early (Table 1). The vulnerability of individuals needs to be considered. In a bush fire, for instance, the general advice is: if the property is well prepared [7], stay and defend. If, however, you may not be able to cope with the psychological terror of staying through the fire front, fully prepare your property, and then leave early (Table 1). If the exit route may be blocked by flood waters, or by dense smoke or fire, evacuation needs to precede that obstruction. In the ‘background’ phase of community disaster preparation, all such possible obstacles to a clear escape route (including gridlock congestion) need to be factored in to the timing of precautionary evacuation (Table 1).

Finally, as seen in the Woodgate Beach example of Sect. “**Experiences and Lessons – Some Case Studies**”, the level of community support in ensuring all residents are aware of and prepared for the ‘ramp-up’ phase of a possible disaster impact, and receive the warning as soon as

Evacuation as a Communication and Social Phenomenon, Table 1  
Evacuation decision matrix – short to long warning times

Evacuation decision matrix, Evacuation around <i>sudden onset impact</i>			
Hazard:	Landslide	Earthquake	Tsunami
<b>Possible safety-oriented response</b>	Stay in strong structure. Move across slope as soon as possible.	Get into the open or shelter under strong structure.	Immediately flee to higher ground.

Precautionary Evacuation (PE) decisions with lead time – signaled threats			
Considerations for evacuation decision	Hazard		
	Destructive wind/cyclone	Fire	Flood
<b>1. Vulnerability of present environment</b>	If likely to be in a storm surge, must PE; If shelter weak, must PE	House material, surrounds, water available. If poor, PE	May be inundated= PE; may be cut off, consider PE
<b>2. If 1 OK: vulnerability of individuals</b> (e. g. weak)	PE first	Asthmatics and less able: PE	Judgments of flood height. If in any doubt, PE
<b>3a. Distance to safe shelter</b>	The further, PE earlier	The further, PE earlier	The further, PE earlier
<b>3b. Safety along exit route</b>	Know in preparation	Know in preparation	Know in preparation
<b>3c. Means of travel</b>	Reliability and suitability	Reliability and suitability	Reliability and suitability
<b>4. Community cohesion</b>	Help available	Help available	Help available

possible, the able-bodied will help the less able to get out of harm's way early in the threat period, as a safety-oriented practice, minimizing the demands of the formal response groups as the likelihood of impact increases.

All effective communication involves sending signals and having them received and processed, then incorporated into the receiver's world view [27,40,41,76,81,82]. Effective risk communication [4,13], Sect. "Effective Risk Communication", motivates people to act to maximize their own safety. This may not happen if people have not internalized that the threat is real. They are in denial. Alternatively, people may be ignorant of the threat, or why it should be taken seriously. Salter [77] categorizes ignorance from pure ignorance to acts of ignoring.

### Disaster Definitions

A disaster may be seen as a negative impact of a hazard on a community as measure of vulnerability. The language of disaster mitigation evolved and is increasingly practiced since the late 1990s i. e. [13,96]. Risk is seen as a function of probability and consequence, related to exposure and the level of force embedded in the threatening hazard.

Boughton [6] points out that natural disasters are usually extremely rare for the individuals concerned but they can cause massive impacts. Because Australia is so vast, overall there are reasonably frequent natural disasters. However, in most locations they are rare indeed. Boughton [6] argues that a "natural disaster" is a natu-

ral event in which the community life is seriously and traumatically disrupted. Embracing the way forward with 'structural mitigation', "... a key step in preventing natural disasters is to prevent building damage." [6]. Like "disasters", "community" is difficult to define [84]. As developed in Sect. "Integrating Theory and Implementation", "community" is the collection of people in a close geographic area, particularly focused on near neighbors and supportive friends of those in or near a known hazard zone.

### What to Communicate

Having the right words or approaches in place *as policy* does not automatically guarantee community safety-oriented responses to disruptive warnings. Since 1989 the approach to cope with disasters has been *prevention, preparedness, response and recovery* training courses. This helps focus all concerned on the temporal sequence. The language could perhaps be refined to talk about acceptance that a threat exists, background, then 'ramp-up' (final) preparations to safe shelter; impact, then orderly return and recovery. Classically, 'response' was seen as the final, near impact flurry of 'lock down' activity [57].

Deeper than language is our conceptual frame (Sect. "Integrating Theory and Implementation"). If researchers encouraged disaster managers to move 'response' behavior back a day; a few hours to 'precautionary, early response', many of Lewis's [57] legitimate concerns would be addressed. Some disaster managers may see themselves

as dramatic figures in the early impact phase of a disaster, rather than calm, precautionary minimizers of risk. This culture has changed greatly over the last decade (Sect. “**Integrating Theory and Implementation**”). For many reasons, there is a clear divide between the US Federal response to Cyclone Katrina (2005) and to the California fires (October, 2007). This shift from passive to active can be encouraged by modelers. As part of effective risk communication to encourage precautionary impact preparedness, research with remote Indigenous communities and recently arrived, non-English speaking refugees (Sect. “**Integrating Theory and Implementation**”) showed the importance of accurate, plain English, and the use of images.

Yates [93] argues mitigation efforts need to be refined to make sure they are focused on issues from the relevant local communities. Much of the problem of non response seems that ‘the message’ to take care does not effectively get through to the target [68]. It is to do with communication, with signals sent, signals received, and their interpretation.

The types of received and interpreted messages are explored specifically in Sect. “**Integrating Theory and Implementation**”, which develops the intellectual foundation to more fully understand the semiotics of risk communication. The following outlines the concepts and relevance of semiotics.

**Semiotics** is *the study of signs* including words, sounds and such things as ‘body language’. By the ‘message conveying’ principles of semiotics we can understand how various authors on disasters and evacuations approach the topic, and which cultural signs and symbols they manipulate. For example, a sign showing a person running up slope ahead of an exaggerated tsunami wave contains all the preferred imagery to tell people what to do in a tsunami warning. Images, as seen for locating oneself in airports or finding evacuation stairs, do not use words.

The next section lays the foundations for a mathematical modeling of propensity for householder self-evacuation, centered on knowledge and refined communications acting on residents in hazard zones who are predisposed to act in their own safety.

## Mathematical Modeling

### Foundations of the Household Safety Preparedness and Action Index: the HSPA Index

This section does not consider refined algorithms to define how successfully people may respond to *Authority’s Perceived Need to Evacuate (APNE)*. This section considers the form and ingredients of how this could be done; the elements and their possible interactions to predict the

success of APNE. Unfortunately, in the previously cited Canberra 2003 bush fires, the APNE did not appear universally, nor was it properly conveyed to the residents in dire risk.

Rohrmann [75] has clearly mapped a process from the warning signal to the hoped-for response. The information and processing flow to internalized inferences is called intuitive heuristics [74]. Renn & Rohrmann [74] basically argue that people process probabilistic information on the likelihood of them needing to move, aligned and convergent with researchers like Thompson [87]. Hence the need for the seven step process (Fig. 8) to trigger a paradigm shift for people in danger zones.

As seen in formula 1, there are finite evacuation triggers (ET), ranging from no lead time  $LT_0$ , such as an earthquake, to a LT of days ( $LT_{xd}$ ), such as a cyclone. So a key component of a successful response to an APNE is the time in which to disseminate the warning ( $LT_{0-xd}$ ; Table 1) Also, Impact Severity (IS) is central to safety and loss.

As detailed in Sect. “**Integrating Theory and Implementation**” and Fig. 8; *The seven steps to community safety*, there is a convincing body of research which indicated that People’s Propensity to Respond (PPR) to an emergency warning (whether that response be to finalize preparation to stay and defend the property or evacuate as a precaution) is strongly linked to their Acceptance they are In a Hazard Zone (AIHZ).

Community Resilience (linkage and inter-support and communication – CR) is also important; along with a potential evacuee’s Knowledge Base of the hazard and safety-maximizing behavior (KB). Thinking Through to Recovery (TR) is also important. As per points 6 and 7 in the 7SCS; Fig. 8, the medium of warning delivery, and the quality of the warning information (Medium & Message: MM) is a factor in the response of those under threat. Overall, Sorenson and Mileti [81] believe that increased credibility of the warning source means the specific warning will be more effective. They also provide evidence that the electronic mass media produced the most believable public warnings. This underlines why development of formal links between all types and levels of media information about hazards and preparation from the weather bureau and emergency managers is so important. Having formal links with the media, coupled with web-delivered ‘real-terrain’ simulations of the hazard will help produce a powerful and effective ‘active warning’ regime.

Issues of Exit Route(s) (ER), Possible Travel Mode (PTM) may be crucial. A normally free-flowing exit route may be blocked by the disaster itself, or others trying to flee. This may involve accidents. People’s psychological and physical states of Well-Being (WB) will also affect po-

tential effective evacuation decisions and accomplishment. Authors like Rohrmann [75] have attempted to stylistically model some of this complexity.

Many of the earlier recognized impediments to full preparedness, like unrealistic optimism (Heller et al., [46]) are incorporated into one overarching factor of formula (1): People’s Propensity to Respond (PPR), including the centrally important feature of individual households fully accepting they are in a hazard zone, and that they need to engage in background preparation, ‘listen up’ around a hazard threat, and undertake their own, precautionary final preparations.

Cutter et al. [17] developed 11 factors indicating vulnerability caused by a major disaster, using principal components analysis within factor analysis. The resultant Social Vulnerability Index (SoVI), necessarily weights the 11 components according to the percentage of variation of analysis of counties on the USA as to resident’s vulnerability. Personal wealth, age and housing density head up the contributions of the 11 variables used to determine the SoVI of USA counties. Cutter’s SoVI contributes to the likelihood that proper preparations; including for a timely evacuation, would occur, either at a broad regional or more individual level. This SoIV is included in the HPSAI below. Its weighting remains to be tested. A final issue overarching many others is Institutional Barriers to change (IB), detailed in Sect. “Institutional Barriers to Greater Community Self-Help”. The support or other-

wise of the media can play a critical role in effective crisis communication – most messages are likely to be through the media, so the media is part of the systems complexity blend: Media Support (MS).

From the weight of SIR and the conceptual framework described in this article, the following generic formula expressing the above factors likely to impact on householder propensity for precautionary evacuations may entice other, more theoretical researchers, to develop the needed algorithms. What follows is purely a design base for others to develop predictive modeling of *People’s Propensity and Capacity to Successfully Evacuate (PPCSE – or safely and actively stay)* PPCSE is better named the *Household Preparedness and Safety Action Index: the HPSA Index* . The following is a synthesis of Bayesian Logic (Hoeting et al. [45]) and Eigenvalues.

**People’s Propensity and Capacity to Successfully Evacuate (PPCSE) or Household Preparedness and Safety Actions Index (HPSAI):**

$$\begin{aligned}
 &HPSAI \propto \\
 &f(PPR)(AIHZ)(LT_{0-xd}) \\
 &(APNE)(ET)(IS)(AIHZ)(CR)(TR)(MM)(ER) \\
 &(PTM)(WB)(SoIV)(IB)(MS)
 \end{aligned}
 \tag{1}$$

Formula (1) anticipates constants to ‘weigh’ each factor according to its contributing importance on the resultant

Evacuation as a Communication and Social Phenomenon, Figure 1  
 Factors in the Eigen plane determining *Household Preparedness and Safety Action Index*

HPSAI (see [45] p 384) for detail of the Bayesian modeling approach.

Resultant safety (*safety* being a combination of successfully evacuating to a safe place, or sheltering within the impact zone in a safe place) of those under threat will be greatest (Fig. 1) where the factors of formula (1) tend to intersect in the positive quadrant of an Eigen plane (Fig. 1) [94]. Equally, outcomes of loss will occur with, for example, short lead times, insufficient warnings of evacuation triggers or lack of belief that residents or travelers are in a hazard zone. A journal search showed few links between disasters and Eigenvalues. An exception is Fowler et al. (2007, [32]). With global warming and increased populations increasingly encroaching into obvious hazard zones, modeling to influence planning and to maximize HPSAI must be a major growth industry.

### Calibrating the Model: the Greek Fires, August '07

[98] or California in late October '07 [99] show that if various of the above variables or likely variable clusters or Eigenvalues from factor analysis have low values, people will not be placed in a strong, precautionary position of safety. This was true of fire-threatened residents in Canberra in 2003 (<http://www.abc.net.au/canberra/bushfires/>), all ultimately leading back to the mathematical weight which needs to be given to each point on in the 7SCS: especially accepting that the threat is real (and possibly imminent).

Once the above-described preparedness paradigm is internalized, it is difficult to experience any disasters news coverage without feeling some despair: cars submerged or floating in flood waters; people fleeing for their lives ahead of imminent immolation; any reports of lost lives through natural disasters with lead times of hours or longer. There are few excuses for this to remain so. In most parts of the developed world, there are prevailing technologies to detect and rapidly convey threat. Researchers are well placed to conceive, trial and link the threat information directly to prepared populations; to close the gap between knowing and acting to maximize safety, as a social exercise of community engagement and communication refinement.

Cyclone Larry [54] showed that, with general community acceptance of the reality of the threat, good warnings and a lead time of about 20 h, combined with well developed disaster management and media cooperation in getting the needed messages to people well primed to the 7SCS, there was no loss of life, although about 5000 people were directly subjected to destructive winds of a category 4/5 cyclone. Residents of the impact zone

generally followed the 7SCS, supporting the general approach of formula (1): the community was prepared and acted in a precautionary way to maximize their own safety.

The above model design offers elements/factors to maximize *People's Propensity and Capacity to Successfully Evacuate (PPCSE – or safely and actively stay); the Household Safety Preparedness and Action Index (HSPAI)*, so strengthening a paradigm among Agencies and hazard-zone residents of 'self-help' and 'community engagement' approaches; less passive than earlier approaches used in considering people's vulnerability. This generic approach is supported by model testing by Schadschneider et al. (► **Evacuation Dynamics: Empirical Results, Modeling and Applications**).

The Australian examples detailed in this article, including the national shift to mitigation (COAG 2004 [13]), best illustrated in the Woodgate Beach example (Sect. "Experiences and Lessons – Some Case Studies"), show that the conceptual frame and thus variables chosen to mathematically model evacuation propensity and capacity are more important than the results of any model using 'passive' variables or variable clusters. The advantages and means of achieving this shift from community passivity to partnerships; place- and people-based community empowerment and self-help, form the basis of this article. The above mathematical approach may help validate and guide this necessary conceptual shift.

The next section considers policy, laws, concepts and possible safety-oriented actions that words, images and stories convey to vulnerable residents in hazard zones. In Australia, policy and legislative requirements are indicated, which aim to responsibly maximize community safety [13,24,25,26,27,28,44,70]. Some new concepts, epitomized by new language phrases (with their embedded meanings) are discussed in Sect. "Integrating Theory and Implementation", especially *Community safety groups*. New phrases include 'Social Burnoffs' and 'Practice evacuations'. Like "The Communication Safety Triangle" and "Seven steps to community safety", it is hoped these expressions enter local, state and national lexicons and modeling in disaster management.

## Effective Risk Communication

### Policy and Laws on Hazard Preparedness and Evacuation

All risk communication operates within government policies and legislation. Forced evacuation may be normal in some jurisdictions for all threats; outlawed in others. Policy may encourage passivity, or be energetically pro-active

in achieving the 7SCS, both in urban planning and building materials, and community engagement. In Australia, for instance, there are many federal and regional guides to urban growth, e. g. [2]. A new urban paradigm is, perhaps, best expressed as: “Think globally, act locally, respond personally” ([2] pnp, [3] p 1). This paradigm shift can easily embrace and be informed by computer modeling of individual’s behavior, demonstrated in recent Springer’s Journal of Systems Science and Complexity articles, such as Kikuchi T & Nakamori Y [97]. Agent model analysis to explore effects of interaction and environment on individual performance [97]

From all decisions of urban development being in the hands of ‘experts’, government policy increasingly requires a dialog with local residents, through public participation. The first barrier to ecologically sustainable urban development is “... belief systems – doubting a problem exists, or supporting the status quo. [Solutions include] ... consciousness raising campaigns, public participation in decision-making, demonstration projects and incentives and disincentives” ([76] p 46). This is the KB of formula (1).

This article stresses that response models, Authorities and all residents are constrained (and empowered) by national and regional laws and policies. Research can only work within a prevailing frame, and will be welcomed by or influence prevailing policy. It is thus useful to have clear goals to achieve social or environmental ‘good’ [13,44,70]. This requires greater community involvement in mitigation, and responsible media helping to mitigate disaster impacts (MS of formula 1). In Australia, the national radio broadcaster has a binding agreement with the weather bureau and disaster managers to read issued warnings verbatim; report and engage community members in safety oriented behavior, by providing relevant information. Local community media are often willing to develop the same responsible functions.

### Risk Communication’s Core Goals

Risk communicators advise “individuals and communities to respond appropriately to a threat in order to reduce the risk of death, injury, property loss and damage.”[42]. Risk communicators and disaster managers need to formally work closely with the media to maximize social benefit.

Although it may be intended that information flows and is received accurately; that desired behavior will result, and that only communication techniques are important [49], humans tend to be irrational and optimistic, and only hear what they want to hear. It is not what

our message *is*, but what, if anything, the listener *does* with our message. To have any chance of ‘success’, information needs to have meaning which is shared between those who construct and send the warning, and those for whom the warning is meant to inform and motivate to action.

‘Action statements’ (what the at-risk person, family or community should actually do to minimize damage) are seen as central to the whole purpose of risk communication [78]. Kasperson & Stallen [49], along with Salter [77,78] and others detail risk communication messages in terms of content, clarity, understandability, consistency, relevance, accuracy, certainty, frequency, channel, credibility, public participation, ethnicity, age, gender, roles, responsibility, elements, sequencing, synopsis, prognosis, location, action, warning timing, and action statements. It is not a case of saying: “a category three cyclone will pass over Smithfield”. It is more a case of making sure the members of Smithfield hear that message, and feel moved to and competent to take well-understood personal risk-minimizing actions.

### Knowledge, Self, World Views and Messages

For precautionary evacuations to be successful, the seven steps to safety (Sect. “**Integrating Theory and Implementation**”) have occurred; or people have been coerced by authorities, or they have seen others depart, and felt insecure, so they leave as a follower of the ‘innovation’ of the ‘norm’: precautionary evacuation. This occurred in the desktop exercise in an isolated settlement in March 2007, detailed in Sect. “**Experiences and Lessons – Some Case Studies**”.

It is now difficult to understand why people needed prompting to take evasive action against the forecast Brisbane floods in 1974, but many ignored the prompts. Authorities believed houses and roads would be flooded, so people should finalize travel or evacuation early [10]. For those in the flood zone, 88% of a later survey sample reported evacuating their home. Some took this step very early, but 67% of respondents only made preparations immediately before leaving home. Twelve percent only left on foot or in boats *after waters entered the main living areas of their homes*. Almost 22% of respondents said they made no preparations, mainly because the threat was not recognized in time [10]. This well documented ‘poor’ crisis communication can help calibrate formula 1.

A key safety message surrounding floods is not to enter flood waters. Figure 2 is one example of using images to help convey the reality of a threat, and the pitfalls of belated action.

Evacuation as a Communication and Social Phenomenon, Figure 2  
 What flood-threatened residents need to consider (Photos courtesy Townsville City Council)

### Effectively Conveying Meaning

Because language is pivotal to acceptance of risk and conveyed warnings of need for evacuations, it is important that all participants reasonably agree on word meanings. This section starts in the comfort zone of simple definitions, then considers semiotics, considers core issues of world views (paradigms), and finishes with the uneasy realities of our knowledge base, our epistemological orientation. Sect. **“Integrating Theory and Implementation”** shows that some cultures do not carry the background cultural experience to absorb the meaning of cyclone or bushfire – there is no shared experience or ‘stories’ of the power of these extreme forces of nature. Some of the underlying knowledge foundations of context, intent and behavioral motivation need to be considered – how humans construct, transfer, acquire and use knowledge.

Imparting meteorological knowledge, then warnings, to target audiences to engender safety-oriented responses is a complex exercise in social empowerment, explored in Sect. **“Experiences and Lessons – Some Case Studies”**. As information promulgators, information and warning sources should understand a little of *Perception* (the raw data from the outside world entering an organism via any of the five senses), *Cognition* (internal processing, analyzing, information storage and processing), *Attitudes* (how we think and feel about particular issues, implying a predisposition to specific action), *Language use* and links to *Behavior*.

An intellectual framework to risk communication is provided by Rohrman [75]. It considers ‘the message features’: the recipient features, social influences and context which influences individual risk assessment and management, including preventative action. Rohrman and Handmer’s publications [41,42,43,75] inform the Communication Safety Triangle and the *seven steps to community safety* provided in this article.

### Philosophy for Policy Review: Crying Wolf or Worse – Applying the Precautionary Principle

From the 1990s a strong issue of debate in risk communication has been “the right to know” [4]. Some disaster managers wish to avoid false alarms, which may cause ‘concern fatigue’. This can be seen as an institutional barrier to change (Sect. **“Institutional Barriers to Greater Community Self-Help”**). ‘Avoiding undue alarm’ is in conflict with the right to know, and the precautionary principle of ESD.

The ‘precautionary’ approach is supported by the Economic Commission for Asia and the Pacific (ECAP), the World Meteorological Organization and the Red Cross Societies. The alerting of the community and its responsible authorities must begin, at least provisionally, as soon as the existence of a tropical cyclone over the seas bordering the country is known ([24] p 16). According to ECAP et al. [24], the warning challenge is less clear for predicted localized downpours and flash flooding – how much effort should be taken to warn – what is the message, how do you keep it to the affected area, and what do you want people to do? These questions resonated in Australia after billion dollar hail damage in Sydney in April 1999, or damaging flash floods in Melbourne in December 2003.

### Precautionary Evacuations

Handmer [43] reports an evacuation of 250,000 Dutch ahead of a flood threat in 1995. Eighty-eight percent of people surveyed in broad post-emergency surveys “believe that evacuation was appropriate.” [43] p 24. In part this may be because of floods experienced two years prior. Good skills in dealing with the mass media appear to have helped in the effective precautionary evacuation. The Dutch experience showed a willingness to evacuate again in future, even though the threatening flood waters did not inundate to the level feared. This compares favorably

with the 2005 boat owners' responses to Cyclone Ingrid in Port Douglas, North Queensland (Sect. "**Institutional Barriers to Greater Community Self-Help**"). Both Handmer and Goudie's research [33,36,38,41,42,43,52,53,54] show clearly that people would rather practice (make a precautionary evacuation) than incur loss. It was treated as a learning experience. The 'boy who cried wolf' argument is not acceptable. This is an important message researchers can test and convey to partnering Disaster Managers.

### Have Clear, Consistent Messages

Part of the *seven steps to community safety* is clear, reliable, explicit languages and images. Salter et al. [78] point out that the use of meteorological category systems such as 'minor', 'moderate' or 'major' carry unambiguous information about the level of disruption likely from a particular flood. Language used should not be for the convenience of the warning agencies. Its function is to convey clear unambiguous messages to the threatened public.

### Use Past Events to 'Make the Threat Real'

The purpose of risk communication is to make people perceive the threat as real, and to successfully motivate safety-oriented action. Boughton (1992, p 6) argues that awareness of hazards and disasters can be fostered by "drawing attention to media coverage of hazards in other places". Images of large scale floods and evacuation in Holland in 1995 [42] may help prompt a future flood evacuation.

### The Changing Politics of Risk Communication

Risk communication is often laden with values and political implications (Sect. "**Institutional Barriers to Greater Community Self-Help**"). For instance, in the 1990s in Cairns, north Queensland, it was argued that the reason for not having detailed local cyclone surge inundation maps made available at the corner store level was that such information may have a negative impact on local land prices. This appeared more a political decision than an attempt at effective risk communication. In 2007, such maps are freely available on the local Council web site [9].

### Sirens or Not

No or short lead time disasters are a powerful argument for warning sirens to alert people, perhaps at 2 am, to "listen to local media now". Lives will be saved in future tsunamis and bush fires with the reintroduction of sirens, as insistent triggers to "find out more now". However, "large numbers of sirens are needed to cover populated areas and to be loud enough to be heard indoors by most people. Sirens are expensive to install and maintain and can only

provide limited information" [63] p 33. Fixed public address systems or those on vehicles may be used. People who hear such sirens will be encouraged to tune to local media, and to phone others in the threat zone, to warn them of the alert. Sorenson and Mileti [81] believe sirens are most effective if used on populations without other ways of receiving the warning. Wider use would appear prudent, especially with short lead-time threats.

### Media Roles

As community media moves from 'sensationalism' [13, 71], 2007 research by Goudie confirms that community media organizations now want to become responsible conveyors of safety-oriented information to people at risk. After the Canberra fires of 2003, where 300 homes and four lives were lost in the nation's 'bush capital', all local media signed binding agreements with emergency authorities to faithfully convey provided safety information. The Communication Safety Triangle envisages local media and householders drawing detailed local threat information from the internet, with media conveying that directly to readers, watchers and listeners. This forms the basis of future 'world best practice' risk communication. In the preparation for threat impact, the reliable information will help people make informed decisions, rather than remaining trapped and inactive in uncertainty.

Risk communication is complex, involving many values, predispositions and distorting lenses. Rohrmann's [75] fine risk communication explanations show that we may tell the people at risk, but they may not interpret as intended. Clear, consistent warnings in plain English, with clear images of the threat, showing safety-oriented behavior are needed from reliable sources. Warnings, seen on a continuum of risk and preparation actions, should be able to be discussed and reinforced with information from other sources. This is most likely to produce safety-oriented behavior, with the constrained and clear assistance of the media, as responsible agents for community safety.

Given the previously fraught nature of risk communication, Sect. "**Institutional Barriers to Greater Community Self-Help**" provides a conceptual framework, with Australian examples of current community safety theory and implementation, preceding some detailed examples.

### Integrating Theory and Implementation

This section introduces a triangular model to best ensure community safety. With disaster managers central, the three elements are the community, local media and the internet. Also, there is a continuous spectrum of seven steps,

from accepting there is a risk, through early preparation, final (ramp up) preparation, which may include evacuation, surviving the hazard impact and achieving smooth recovery. An exploration of motivation leads to a discussion of 'world view', including some insights into remote Indigenous communities [36], and recently arrived, non-English speaking immigrants. The conceptual frame and steps are intended to help guide risk communicators and potential modelers through the issues of acceptance, preparations, evacuation and functional recovery. Within CSS, all these factors have some bearing on consequent behavior.

### Changing Values and Roles

In an attempt to understand why we support or ignore certain messages relevant to our safety, and thus facilitate modeling, this section considers the Dominant Social Paradigm and the New Environmental Paradigm. A paradigm is a coherent world view, "a mental image of social reality that guides expectations in a society" ([23] p 10, [29]). Shared paradigms change. The underlying philosophy shift toward disaster mitigation generates a distinct policy move toward safe, self-helping communities. Thus, the goal of disaster managers, effective risk communicators and computer modelers becomes one of championing or demonstrating the efficacy of self-help techniques and information to and within communities.

### World Views Which Accept Responsibilities of Living in a Hazard Zone

'Why do we do what we do?' has long been a central exploration of psychology. Precautionary safety behavior, in-

Behavior is explained by:

1. a person's *position in a social structure*,
2. with *constraints and incentives* as generators of *values*, which lead to
3. *general beliefs*,
4. *world view*,
5. *specific beliefs and attitudes*, generating
6. *intent*, which helps explain
7. *Behavior*.

Evacuation as a Communication and Social Phenomenon, Figure 3  
Stern's 1995 behavioral explanation model

cluding self-evacuations, may depend on a person's world view. Stern et al. [83] developed a simple and elegant model to help explain human behavior, starting with a person's position in a social structure, with constraints and incentives which generate values. Values determine general beliefs, leading to a consistent world view, specific beliefs and attitudes, which predisposes intent and helps explain behavior ([83] Fig. 3). Loosely translated, behavior results from a linked sequence starting with: the where, when and to whom of an individual's birth, the surrounding circumstances and 'cultural sheath' of their early childhood experiences, leading to acceptance or rebellion against prevailing social norms, determining an evolving world view. Once we have our coherent world view, beliefs and values give us our 'predisposition to act', our 'intent' which precedes action/behavior.

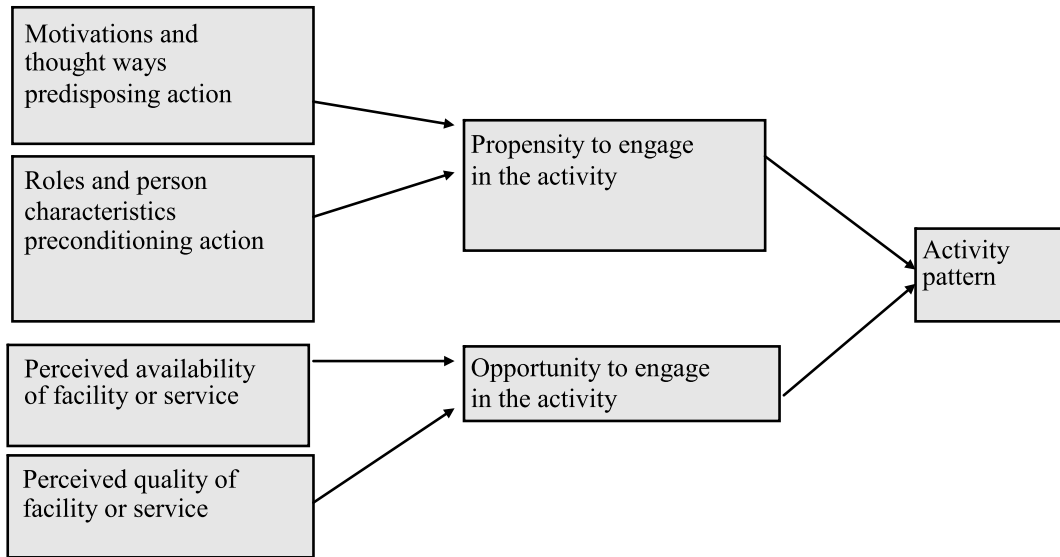

Many things now mold and modify world views, including the media, and normative world views are mutable, changeable. Aligned starkly with our shared and collective biological survival urge, and much concerted efforts by scientists and conservationists for decades; publicizing by people like Al Gore, and the authority of England's uptake of the 2006 Stern Report, there is now a global paradigm shift to the urgent need for behavioral and technological change to minimize the gross impacts of global warming, pertinent to increased disasters and needed evacuation readiness. Modeling specific hazard zones' strengths and weaknesses and broadcasting prediction simulations to the internet and TV will help mobilize those at risk.

### Why We Do What We Do

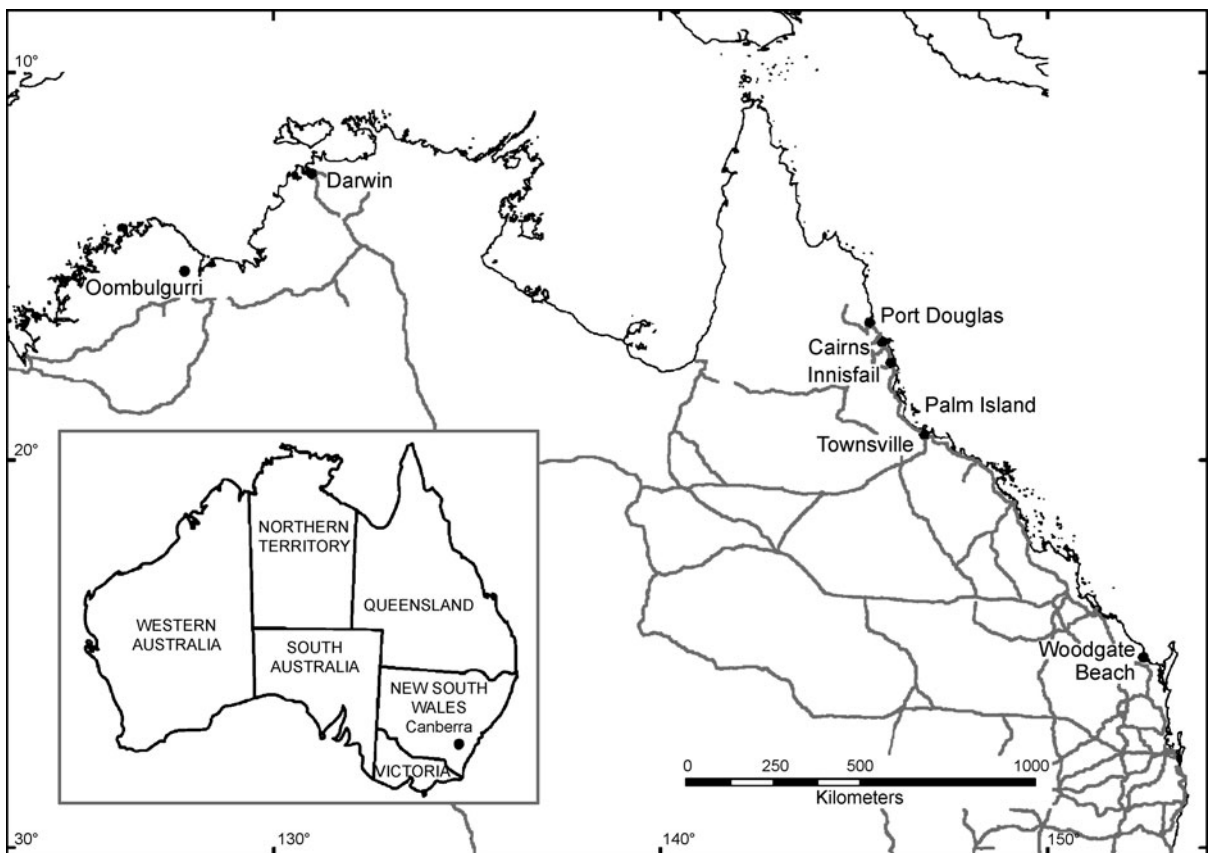

A behavioral model of causality ([91] Fig. 4) shows relationships between reported attitudes and actual behavior. However, a complex model proposed by Kitchin [51], with the strength of including social and environmental interactions shows why we do what we do: Kitchin's model includes a person's 'working and long term' memory. Internal information is processed within 'real world' context, such as cost [82], which may be processed within the 'it can't happen to me' cognitive frame [61] of subjective reality. These complex but quantifiable attributes will contribute to modeling maximum likelihood to accept, prepare and act to maximize safety.

### Learning from 18 Remote Indigenous Communities

Much of the rest of this section underlines why modelers will need to deal in great detail with 'cultural' aspects of massed responses to safety threats.

Evacuation as a Communication and Social Phenomenon, Figure 4  
Possible determinants of activity patterns (from [91])

Evacuation as a Communication and Social Phenomenon, Figure 5  
Australian study sites

The Stern model (Fig. 3) helps explain why there is such a strong sense of self-help in remote Indigenous communities [27,29,80,94] helps explain why there is such a strong sense of self-help in remote Indigenous communities [27,29,80,94]. Elders decide responses to threats, there are historic and immediate constraints, generating a value system where community members need to look out for each other.

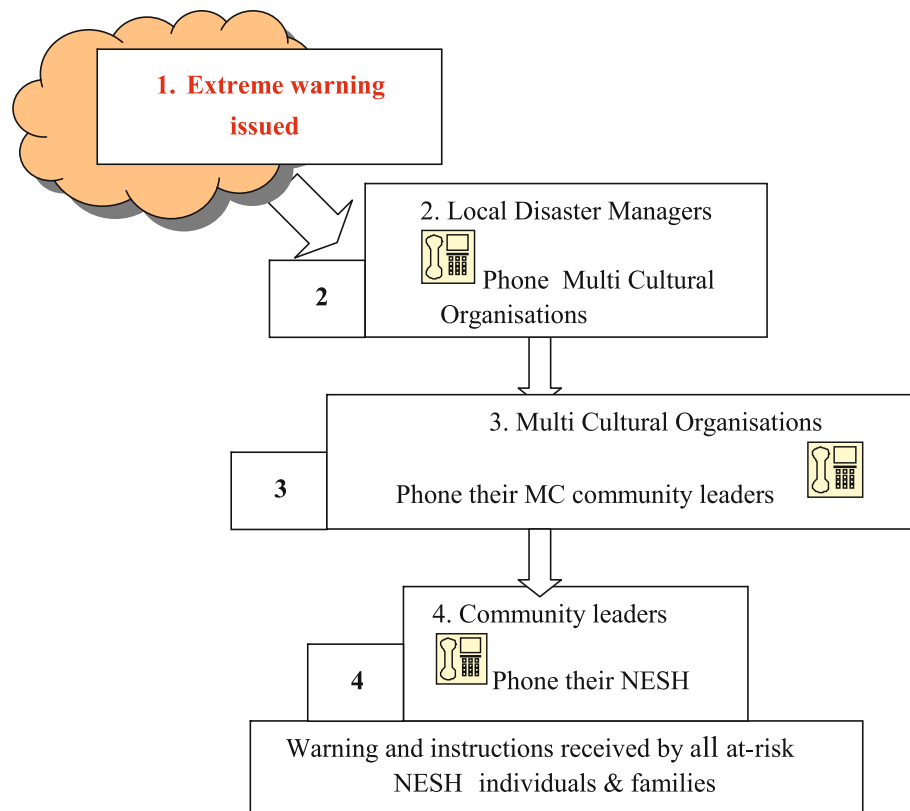

In many traditional Australian Aboriginal stories, most people drown in flood disasters, often as punishment when people do not take care of each other [36,39,64,87, 88]. If general beliefs embrace self help, including the felt need to ensure safety, and a resultant intent to achieve community safety, this should lead to safety-centered behavior.

Each community ([36] Fig.5) was not greatly concerned by weather extremes (values), but each relied on and respected their traditional reading of threats, and information from the Bureau of Meteorology (the Bureau). The world view is that flooding or worse may happen, and that the Bureau will provide adequate warning. Responses

may be inhibited by the Social Vulnerability Index (SoVI) of formula 1.

### Community Links, Phone Trees and the Web in Risk Communication for Non-English Speaking Households (NESH)

Many multicultural organizations and focus group meetings in 2005 helped develop the warnings phone tree model for NESH in Fig. 6. NESH rarely listen to the English language media. With about 30,000 NES people arriving in Australia each year [18], there is Federal government recognition of special emergency management needs [28]. This way of getting evacuation warnings through was developed once interviews revealed that practically all NESH have a mobile phone, and are closely connected with their nearest government funded Multicultural Organization and their 'community leader'; hence the phone tree. Modeling is of and for the real world, so research like this reported NESH study is needed to see what 'complex systems' may be possible. Further recommen-

Evacuation as a Communication and Social Phenomenon, Figure 6  
Multicultural phone tree disaster warnings model

dations to develop a multilingual warning web site with a simple guide to the seven steps, in relevant languages, to be accessed and used by MCO and NESH training sessions is being considered by authorities. This provides another example of the internet's latent role in effective risk communication.

The Australian Northern Territory has cyclone preparedness kits with action guides in 8 languages; the NSW Rural Fire Service has information in 27 languages. This shows the importance of modeling all possible communication avenues, encapsulated as Medium & Message: MM in the general formula for Household Preparedness and Safety Actions Index (HPSAI).

### An Holistic Approach to Community Risk Management

The seven steps for effective warnings involves community networking, 'responsible' media, and, increased web use. A 'continuum' approach to hazards which may lead to a need to evacuate is important to modelers because it is important to all people in hazard zones: they will be able to access more accurate, detailed and timely information of any looming threat, assisting Emergency Managers because a self-help public will decrease demands on formal evacuation, rescue and property protection [93]. Recovery

will be less arduous [67] if hazard impact is minimized. Reducing disaster impacts will reduce costs, to national benefit. This gives strength to supporting the very demanding goal of developing the model of formula 1.

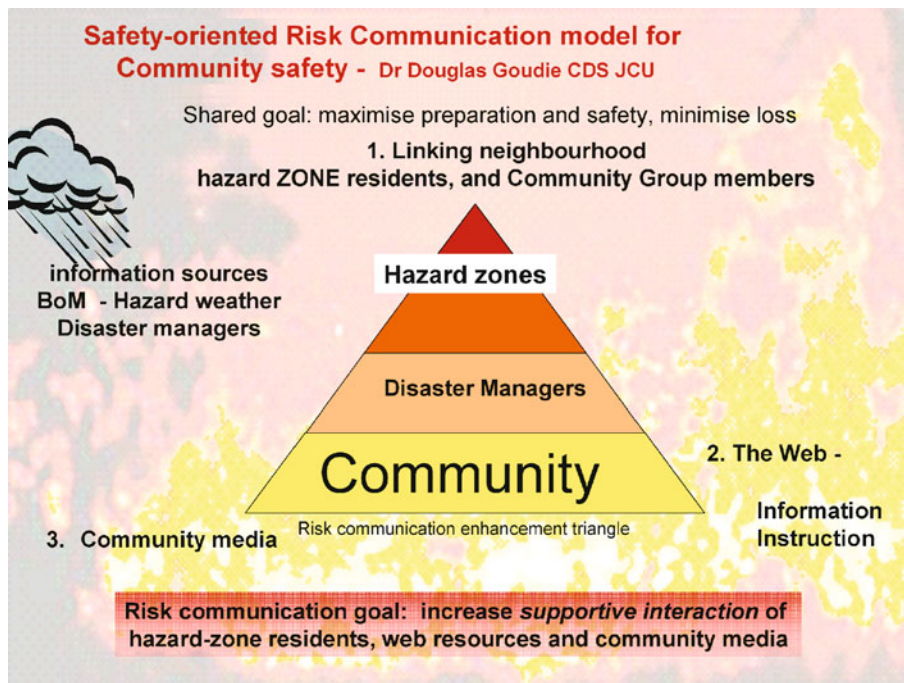

### Risk Managers

Researchers can work with risk managers to achieve "... better, timely warnings and advice on safe action during fire events" [3]. With risk managers central, Fig. 7 suggests that enhancing community links [7]; web information for residents and media outlets, and cooperation of community media with fire managers [89] will more empower householders to embrace self-help in fire safety. Figure 7, the Community Safety Triangle, with the "Seven steps to community safety" (Fig. 8) provides the conceptual frame to enable maximum safety modeling.

### Core of Risk Communication for Community Safety Through Natural Disasters

#### Building Community Links and Refining Media Delivery will Change the Household Preparedness and Safety Actions Index

The disaster safety benefits of enhanced community links fit positively with broader social policy [47]. Stronger com-

Evacuation as a Communication and Social Phenomenon, Figure 7  
The Communication Safety Triangle

**Goal: Maximise safety and recovery, and minimise loss in hazard zones.**

1. Encourage those in hazard zones to accept that the risks are real.
2. Help create an aware, informed community, predisposed to safety-oriented action, as a precaution; as a practice.
3. Encourage information-sharing and support among friends, neighbours, family.
4. Provide ‘what to do’ (action) information, via reliable sources, including web and community media delivered for background and preparation.
5. Encourage people to think right through to impact and recovery.
6. When a threat is closing in, warning messages will clearly convey: *this is real, this is coming at me. I need to make safe where I am, or move early to somewhere much safer. I will not travel during the impact period.*
7. Provide timely, effective threat warnings and fine location and forecast weather detail, and recommended local responses.

Evacuation as a Communication and Social Phenomenon, Figure 8

**Seven steps to community safety**

munity links will help ensure that threat information is easily accessed and shared; and the need to actively self-protect is internalized at the neighborhood level. Residents will benefit by enhanced community links (with such innovations as social burn offs and Community Safety Groups) in improving their general quality of local social interaction. Changing Community Resilience (CR of the formula) will then change overall preparedness, so pilot tests of change to CR will show quantifiable changes to the Household Preparedness and Safety Actions Index. Disaster web site managers will be providing a product which is rationalized to reduce national duplication of core information. This will positively change Medium & Message, MM, of the formula. Residents with few English language skills will benefit by having disaster information delivered, via the web, in language and concepts that can be internalized and acted upon.

Handmer [43] suggests that a flood, for instance is actually ‘owned’ by the communities at risk. Individuals and organizations within these communities actively seek out information and mobilize their personal networks for action. In this way of looking at the warning process, the

Evacuation as a Communication and Social Phenomenon, Table 2

**Cyclone zone people have much personal contact**

Contact with other relatives	% of total response (rounded)
Yes	25
Lots	20
Mobile contact	15
Landline Phone	30
No	10
Frequency of neighbor contact	
Often or lots	50
A bit	20
Helped/contacted during eye	15
None	15

warning specialists act as mediators between the threat and the threatened. Local knowledge is used and the whole response process remains focused on safety and loss-minimization. For this plausible vision to become fact, local capacity building will need to proceed apace with these more formal efforts to inform and maximize community safety.

The importance of ‘informal’ information sources and community links are shown in Table 2, from about 200 people interviewed immediately after Cyclone Larry in 2006 [53], showing that about 90% are deeply dependent on social and family support, if only for reassurance.

Finally for community enhancement within the CST model, there is current and lucid national disaster mitigation policy [13] [http://www.dotars.gov.au/localgovt/ndr/nat\\_disaster\\_report/naturaldis.pdf](http://www.dotars.gov.au/localgovt/ndr/nat_disaster_report/naturaldis.pdf): in the statement of the paradigm shift [13], p 13, “Principle 7 – Reform Commitment 7: develop jointly improved national practices in community awareness, education, and warnings which can be tailored to suit State, Territory and local circumstances.”

**Community Media**

“The Media: Media organizations, particularly public and private radio and television organizations, have responsibilities in ensuring that timely and appropriate warnings and advice on disasters is broadcast to communities at the request of relevant authorities. They also have a role to play in educating the community about natural disaster issues” ([13] p. 18).

**The Web**

*Rationalized web information delivery:* One national generic provider and up keeper of core information,

The stages of change from the Diffusion of Innovations theory. The vortex shape has no mathematical basis. Its purpose is to illustrate the point.

Evacuation as a Communication and Social Phenomenon, Figure 9  
O'Neil's 2004 innovation uptake model

known to all, is recommended; to which state and local government will add their unique detail. A rationalized disaster information web delivery can properly incorporate broad contents, fine (and zoom-in findable) and multi lingual information.

Simulations of predicted near-term fire or other threat movement based on the above, akin to micro scale modeling of cyclone impact forecasts will help revolutionize the way people react to fire and flood threat. With about one in three households having the internet, prior to likely power loss residents can draw on enhanced fine detail of the current fire situation, to assist in their actual decision making. Before Cyclone Larry struck, residents with web access to the Bureau copied cyclone forecast maps and distributed them to neighbors [53]. All the preceding is encapsulated in Figs. 8 and 9.

### Images Tell a Story

Images such as cyclone forecast track maps in risk communication convey more information than words alone [36,53]. With this feedback from real residents, it becomes clear that linking fire zone residents, for instance, to educative web fire images becomes an important goal (e. g. [100]).

### Community Story Telling Bonds Neighbors

The multi-pronged approach [33,52,54] fosters community 'story-telling' links [50,59,90] relating to community self-help and safety. Strengthening community bonds, working with enhanced web resources and community media [14,72] will increase community internalization of risk [31], enhancing the likelihood of safety-oriented responses, leading to and possibly including evacuation.

People need to accept the reality of the threat, indeed, feel some anxiety about the threat to help drive the intent to seek more information, or the intent to prepare [68].

With easier access to relevant web information; with greater detail of current fire behavior and *nowcasts*; fire zone residents and community radio announcers can describe the looming threat, helping timely preparations and the monumental 'stay or go' decision. Community radio, like the National public radio, the ABC, will deliver authoritative and timely risk communication directly from the refined web information.

Theory and emerging practice converge on using refined web-delivered material to households and their neighbors, and to local media, to inform and motivate residents through the whole continuum of the seven steps to community safety. The next section considers institutional barriers to change, followed by extensive research findings and lessons from Australia in disaster management to develop effective warnings and self evacuations.

### Institutional Barriers to Greater Community Self-Help

Institutional barriers to change take many forms, from 'unconsciously' avoiding consideration of the extreme event as 'too hard', to a misuse of the power relationships within bureaucracies because of fear of change, or malice. Clear examples of the 'too hard syndrome' mingled with entrenched vested interests has been denial of links between smoking and cancer, or delayed uptake of global warming mitigation.

There were Institutional Barriers for disaster managers to consider land-based flooding from torrential rains preceding a cyclone (hurricane/typhoon) [34] in many cy-

clone-prone areas. The Queensland State Planning policy [70] now explicitly refers to Probable Maximum Flood. Including maximum flooding is now part of emergency manager's internal planning base. This means the Exit Routes (ER, formula 1) are now considered in planned evacuations.

Since the early 90s researchers like Boughton [6] have suggested having drills for schools and other institutions in readiness for possible earthquakes, cyclones or other hazards. This author supports precautionary evacuation practices. There are, of course, liability barriers to easily undertaking practice evacuations. There is also uncertainty of threat, which may restrain some risk managers [86].

Institutions have cultures which may passively express antipathy to a paradigm shift toward sustainability, whilst being required to usher in sustainability [19,37]. Emergency Management Australia, the peak national body, has the slogan: *Safe, sustainable communities*. However, there is a multitude of conservative forces representing the Dominant Social Paradigm restricting innovation, despite sustainability policy. People engaging in sustainability implementation may come into conflict with institutional representatives of the old paradigm.

With most development taking place in urban settings, concepts of urban sustainability attempt to merge two different fields of human endeavor – how we modify our landscape, our built environment, and how we behave in that environment. Disaster mitigation is obliged to fuse these two seemingly disparate fields. There may be resistance to that. That resistance needs to be included in any mass disaster movement modeling. The following subsections indicate some reasons for IBs which modelers may need to consider in the IB factor.

### **Political Insecurity, Real Estate Values, or Undue Alarm**

The tension between people's right to know, government duty of care and politicians' perceptions of probability of risk on 'their shift' form a complex interplay. If maximizing safety is the shared goal, all risk communication theory suggests people will behave appropriately with the realistic threat information, motivation and 'how to' instruction on safety-oriented behavior leading into, through and recovering from a natural disaster impact.

### **Paradigms of Politics: the Real Estate Industry and Vested Interests**

Broughton [6] argues that if people know of the threats, they are likely to support politicians who make sound de-

isions for community survival. Some plans are made but they are hidden away for various financial and political reasons. This is a case in which attitudinal changes on the part of those communities may change the priorities of the decision makers and promote the interests of the community.

Those most empowered to assist in implementing projects that require independence, initiative, local links and knowledge may be the ones who prove most obstructive to innovation [1,48,56,69].

*Action Research* [16] sets out to research, develop and document socially and environmentally desired outcomes within sustainability principles. In this inclusive and 'engagement-focused' research, gaining support from the top is crucial to the success of any organizations' efforts at 'social change' [66]. If innovation uptake is viewed as a normative uptake process [12,65] and Fig. 9, then the gradual, long term paradigm shift to sustainability [30] is plausible and has a conceptual frame.

Uptake of the Communication Safety Triangle and the seven steps to community safety (Figs. 7 and 8) will make them the disaster managers' 'norm' over time, simply because that is the direction of social evolution in disaster management. It fits social policy and advanced disaster management approaches, and the technology and willingness of regional media and residents is there. All that is needed is the testing and roll-out by more innovative disaster managers. The same applies for Community Safety Groups and variants of *over-managed, locally controlled near-house "social burn-offs"* in the case of fire risk management.

Bureaucratic processes need to support the stated goals of their own work units, but individuals may be ambiguous, contradictory, belated, bullying, ill informed and, due perhaps to time pressure or arrogance, quite destructive. Such individuals may be 'corporate psychopaths' (<http://www.abc.net.au/catalyst/stories/s1360571.htm>). Instead, innovators may be seen as threatening; troublesome. Any innovative pilot project must develop strategies that will maximize change within their unique situation. Ideally, that happens within a supportive parent organization. The next section discusses the emergent issues of effective risk communication and precautionary self-evacuations.

### **Experiences and Lessons – Some Case Studies**

This section considers disaster impacts and impacts from north Queensland and from fire zones in SE Australia to illustrate the generally positive points of approaches already outlined: living flesh for modelers to understand how sub-

tle, complex but do-able successful community preparedness and willingness to act for maximum safety can be. Researching these events, gaining community and disaster managers feedback on risk communication; working closely with the Australian Bureau of Meteorology over 15 years, through the Federal disaster ‘paradigm shift’ to mitigation ([13] p 13) all inform the emergent CST and seven steps to community safety.

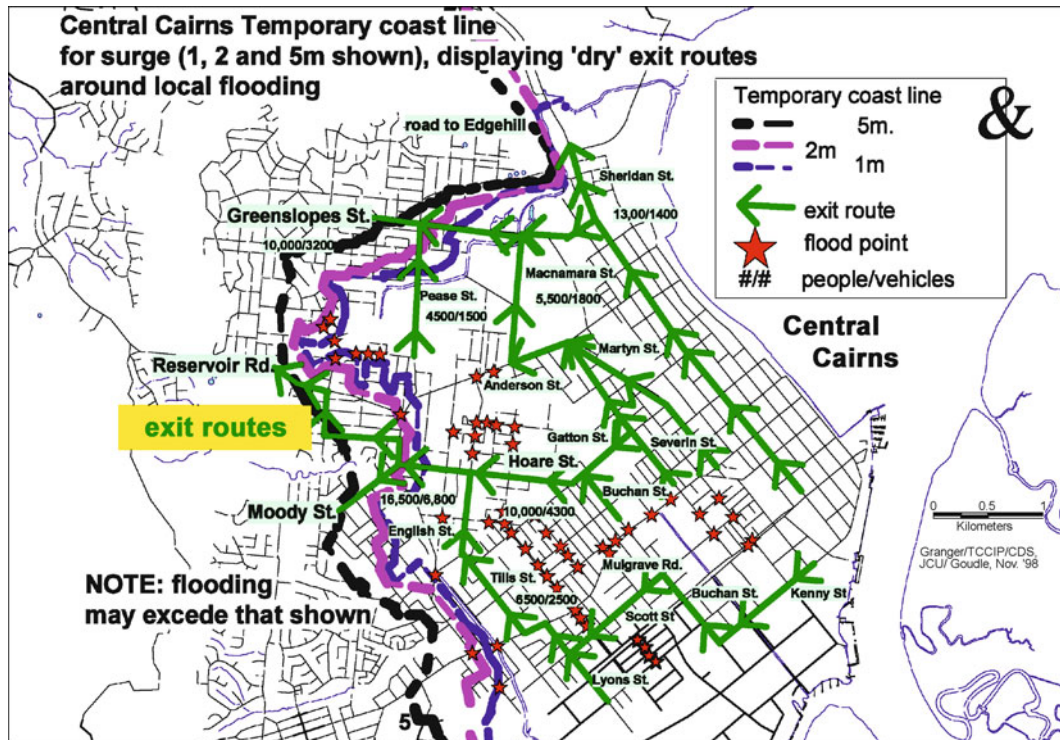

**Cairns and Storm Surge Considering Exit Routes (ER, Formula 1)**

Cairns City, North Queensland, is centered on land less than 2 m above high tide, and subject to cyclone (storm) surge of up to 5 m. A storm surge tracks just behind the eye of a cyclone, a low mound of sea water, perhaps 50 km wide and up to 3 m above normal sea level. It may flow overland for perhaps 4 h, as destructive winds to 280 km/h tear at structures, and churning seas; both laden with pounding debris, behave as battering rams and missiles. Because cyclones have such long lead times from modern electronic detection to landfall, results of this deadly combination [60] will be widespread destruction and loss

of infrastructure, but not life, with precautionary evacuations [38,72]. At the macro-observation scale, people and vehicles in motion within confining environments tend to behave like fluids, capable of modeling. Constrictions of flow paths cause congestion, as described by Helbing et al., (► **Pedestrian, Crowd and Evacuation Dynamics**), so early and precautionary evacuation will help minimize the likelihood of grid-lock.

Land-based flooding may be a core issue to effective evacuation [34,38,95], with up to 40,000 people in the vulnerable central city area and northern beach suburbs needing early, precautionary evacuation [79], Fig. 10. Cairns City Council now has a storm surge map on its public web site ([101], posted in 2006), like the public and informative flood map for the Redlands Shire, SE of Brisbane, Queensland ([102]).

Within the philosophical and moral frame of people’s “right to know”, these local governments are using the internet to inform people they are in a hazard zone, the first step in making the threat real to those residents. They have made the paradigm shift to providing fine-detailed background information which says to residents: “you are in a hazard zone, you may need to do things. Lis-

Evacuation as a Communication and Social Phenomenon, Figure 10  
 Cairns flood prone evacuation routes and schemata of wave reach and temporary coast line from 1998 information

Evacuation as a Communication and Social Phenomenon, Figure 11  
 Cloncurry reflective of likely responses to future floods

ten for warnings and be prepared to act in a precautionary way.”

Figure 11 shows that after a devastating flood in 1997, the flood-affected residents of Cloncurry, NW Queensland town would do things differently, with better warnings, when faced with rising flood waters. Remote automatic flood monitoring devices were requested, but the local downpour over a fully flooded, vast and flat landscape appeared to be the cause of the flood rising 2 m higher than any flood in the prior hundred years. Precautionary evacuation of the low-lying homes would have prevented much heartache and loss of valued possessions [52].

In 2005, north Queensland was threatened by cyclone Ingrid. Newspaper-reading residents were left in no doubt about the threat (Fig. 12); a good example of the clear warning role played by the media, and non-language image used to convey meaning (Sect. “Discussion”).

A portion of a Weather Bureau warning media bulletin for Cyclone Ingrid follows, showing, verbatim, what the nation radio broadcaster, the Indigenous Radio Network and most responsible media outlet relayed on. This is clear information, including the possible impacts (M& M of formula 1).

Media: For immediate broadcast. Transmitters in the area Cape Grenville to Cooktown are requested to use the Standard Emergency Warning Signal.

TOP PRIORITY

TROPICAL CYCLONE ADVICE NUMBER 14

Issued by the Bureau of Meteorology, Brisbane

Issued at 10:56 am on Wednesday the 9th of March 2005

A Cyclone WARNING is current for communities between Cape Grenville and

Cooktown. The warning extends inland across central Cape York Peninsula.

A Cyclone WATCH is current for coastal and island communities on the eastern Gulf of Carpentaria between Weipa and Kowanyama.

The watch south to the Gilbert River Mouth has been canceled.

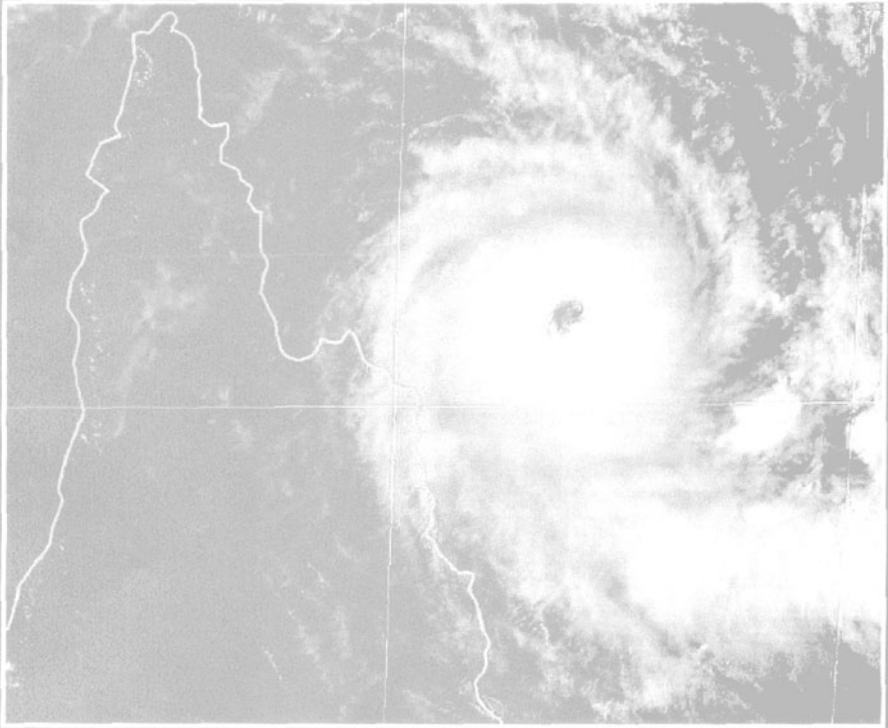

At 10:00 am EST SEVERE TROPICAL CYCLONE Ingrid, Category 4, with central pressure 935 hPa, was located near latitude 13.5 south longitude 145.5 east, which is about 140 km northeast of Cape Melville and 260 km east of Coen. The cyclone was moving westward at 11 km/h.

Severe Tropical Cyclone Ingrid poses a serious threat to the far north.

Queensland coast with very destructive wind gusts to 280 km/hr near the center. Gales are expected to develop between Cape Grenville and Cooktown

# CATEGORY 5

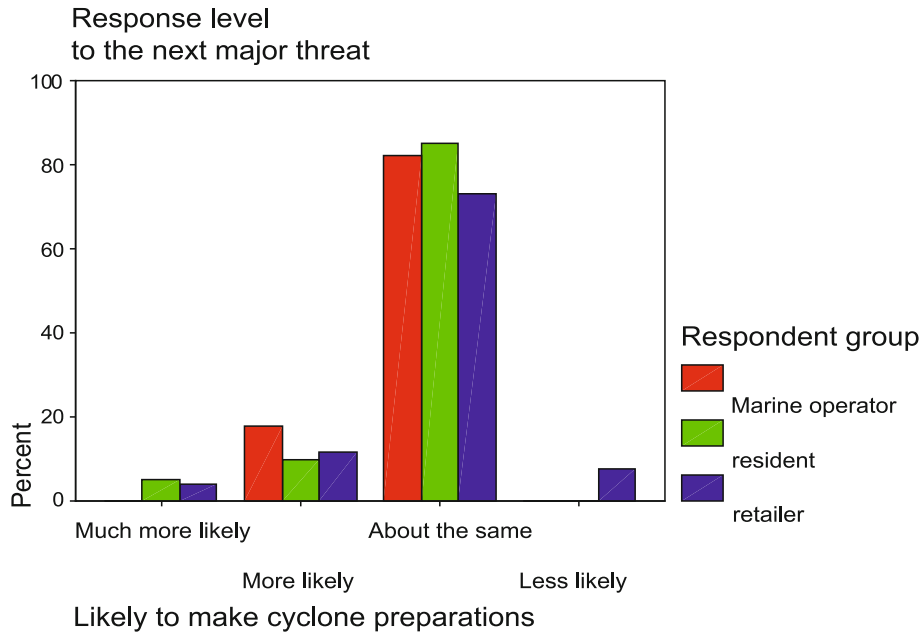

## 'A destructive core twice the size of Tracy'

AUSTRALIA'S worst cyclone in 30 years is bearing down on North Queensland as thousands of residents prepared for a double whammy of a massive king tide in the region. Category five Cyclone Ingrid was last night about 240km northeast of Cooktown, packing winds of up to 300km/h. Cyclone expert Jim Davidson said Ingrid was half the size of Cyclone Tracy, but had a core twice as big. "The destructive core is about twice the size of Tracy," he said. "Anyone in the path of this cyclone should get under cover. This is a one-off, the environmental conditions were perfect for this cyclone to form. That's why we have the intensity it is." Continued - Page 4

Evacuation as a Communication and Social Phenomenon, Figure 12  
Media coverage of threatening Cyclone Ingrid, 2005

during the afternoon. Destructive winds are expected between Coen and Cape Flattery overnight. The very destructive core of the cyclone is expected near the coast between Coen and Cape Melville on Thursday morning.

Coastal residents between Coen and Cape Flattery are specifically warned of the dangerous storm tide as the cyclone crosses the coast early Thursday. The sea is likely to rise steadily to a level significantly above the highest tides of the year with damaging

Evacuation as a Communication and Social Phenomenon, Figure 13  
 People of Port Douglas appreciated a precautionary evacuation

waves, strong currents and flooding of low-lying areas extending some way inland. People living in areas likely to be affected by this flooding should be prepared to evacuate if advised to do so.

Very heavy rain can be expected to develop on the coast and ranges north of Cooktown.

Research in Port Douglas, NQ was conducted immediately following Cyclone Ingrid, to help clarify the ‘Boy who cried wolf’ hypothesis about ‘concern fatigue’ over precautionary evacuations (Sect. “**Institutional Barriers to Greater Community Self-Help**”). Feedback from marine tourist operators and tourist businesses that removed about 60 large vessels to safe, up-creek moorings, or fully shuttered their premises and raised all stock. These preparations were arduous, and costly. The cyclone veered away from Port Douglas, with virtually no impact. Despite that, people were glad of the precautionary evacuation, as a practice (Fig. 13), reinforcing the findings of the Netherlands flood study [43]. People appreciate practice, as part of the new paradigm of a precautionary approach to hazards.

**From Those Impacted by Larry, 2006**

After Cyclone Larry, a powerful Category 4/5 severe cyclone which damaged the Innisfail region, Goudie lead

a social science research team into the impact area, interviewing households for 4 days (King et al. [53,54]), from the 150 householders survey, focused on risk communication, we learned: as with fire zone residents and those who experienced Cyclone Larry, that most people, once they have experienced a major disaster, maintain a healthy respect and inclination to act ahead of any future such threat. Hence the advocated merit of encouraging people with experience to ‘tell their story’; and community (Media and Message and Community Resilience of formula 1) to help make the threat real to others. The next section is, perhaps, at the leading edge of where disaster management will go: living community self-help. Such communities can provide pilot locations to ‘calibrate’ formula 1.

**Woodgate Beach and Community Safety Groups (CSGs)**

This section reports a collaborative process between the author and many others, mainly residents of Woodgate Beach, Queensland (Fig. 5), to develop a *Preparation and Evacuation Plan* for residents, formal response groups, the Local Government Disaster Management Group (LDMG) and Shire Council.

Through the 18 month consultation and development process, the plan needed to be realistic and achievable, relying mainly on locals working together under the LDMG

and local SES group, aiming to optimize each element of formula 1.

Community networking and self-responsibility for community safety is profoundly developed in the isolated, 700 strong, Central-coast Queensland settlement. The volunteer community safety groups were made up of dedicated people. Goudie led development of a community-based evacuation plan, aiming to: ensure maximum preparation and minimum impact on property and residents; optimizing formula 1.

There were 5 meetings, of up to 80 residents and representatives of all formal response groups, weather and earthquake experts. Meetings included researcher-led two-day 'table-top' evacuation exercise. Woodgate Beach did not develop an evacuation plan, but a preparations and evacuation plan:

### Preparations and Evacuation Self-Help Approach

To nurture aware, informed residents preparing to be safe through, and recover from natural disaster impacts.

### Overarching Evacuation Approach

- Identify vulnerable areas or houses
- Evacuate caravan park, visitors, people at risk unable to easily move themselves

### The Planning Process:

1. DEFINE THE THREATS – Fire, flood, wind, cyclone surge, earth movement, tsunami.
2. MOVE FROM WHERE TO WHERE? Fires can be fought; floods, storm surge and cyclonic winds, tsunami or earthquake cannot be. In all threats, make sure your property is as secure from impact as possible.
3. IDENTIFY THE VULNERABLE – Which buildings, infrastructure and people may be in the threat zone.

**Threats and Treatments** An all-of-community approach has developed an annual round of public education projects, press releases and pamphlets to inform residents and tourists of the annual cycle of dangers to be wary of, from cyclones to fire care and management. The Council newsletter will be a consistent source of information on threats and how to minimize risks (M & M), from the flying debris of a wind storm to being patient at a flood-swollen creek crossing.

A sequenced approach, where the aged and vulnerable are moved first from the highest risk areas will be taken, as a practice, as a precaution. To highlight the stages of

disaster and possible evacuation planning, the background preparations phase is included in this article:

### Background Preparations

1. Woodgate Beach residents recognize and act on the need for background preparations to minimize the impacts of all hazard impacts. This includes property maintenance and upkeep. This maximizes PPR of formula 1.
2. Provide newcomers with an information pack, including a copy of extracts of this Community preparations and evacuation plan (CPEP). All community members, including tourists, the elderly, infirm, and needy are incorporated into this CPEP. This enhances the KB of formula 1.
3. Provide dot points on evacuation for local residents in the *Disaster Preparedness Information Kit*, delivered to each household.
4. Expose tourists to the essence of local threats and what will be expected of them: leave early, unless they or their vehicles can actively help, under direction.
5. Define safe shelters – preferably with friends or compatible households. Organizing possible billets for any major impact on portions or all of Woodgate Beach can form a key function of the Community Safety Group. This is the CR of formula 1.
6. Go through whole plan, and address matters like the caravan park needing auxiliary power for fuel pumping before the cyclone season.

**The Community Safety Group Approach to Disaster Management** This approach is detailed to provide a guide for researchers to use as a framework for other communities:

### The Community Safety Group

**Purpose** encourage:

**1. Early Warning Alert** The CSG is an affiliation of existing community groups and neighborhood-level residents who make first contact with 'walking-distance' neighbors as soon as anyone hears of a warning that a natural disaster may be approaching their area.

**2. Final Preparations (Ramp-Up) Activation** The neighbor-level CSG will provide early local motivation for final safety preparations.

**Recovery** – Thinking Through to Recovery (TR) of formula 1.

Recovery is now seen as part of the preparations package, rather than just looking to minimizing impact. The developing approach is to see the whole threat event as one continuous process: from awareness and structural preparedness, through initial communication of threat, to final precautionary preparations and impact and rapid recovery to a fully functional community.

### International Snaps

The Center for Disaster Development within The Northumbria University, Newcastle on Tyne, coastal north east England specializes in recovery and response with an emphasis on development long term recovery and resilience-building. Embedded in this approach is to undertake mitigation. Interviewed by Goudie in May 2005, the Director reported “We use the approach that local knowledge is always drawn on, and that people involved should be in control”, KB and CR of formula (1) and agrees “all disaster management is under the umbrella of sustainable development”. Other interviewed staff support precautionary evacuation as a practice, and, independent of the media, an alert signal for people to tune in to the media.

### The Shetland Islands

Like Australia’s emerging approach to self-help communities, The Shetland Council’s Emergency Management

Planner (2005 interview) gave strong practical support to the approach of an informed, aware, self-activating community ready to act on reliable, clear, how-to emergency warnings, ranging from making safe if intrinsically out of the main impact zones, to early ‘self-evacuation’. This convergence from differently evolved and slightly different disaster management systems is grounds for optimism that the evacuation approach and formula expounded in this article has widely applicable merit.

Remote communities like the Shetlands have lessons for the mainstream in taking responsibility and perform being self reliant and oriented to robust self-help. Such isolated communities represent matured examples of the informed, aware communities, predisposed to precautionary action that mainstream populations now aspire to. Community-building is an international aspiration, achievable in urban settings.

### Hurricane Katrina

Hurricane Katrina, USA late August, 2005 (Fig. 14) has deliberately not been included in this evacuation analysis. With days of clear warning, general formal approaches to precautionary action which underpin the CST and the seven steps to safety and recovery were underplayed.

Figure 14 is included to remind all readers that hazards are real threats to real people in real hazard zones. If all the parameters to maximizing formula 1, such as Institutional

Evacuation as a Communication and Social Phenomenon, Figure 14

What no-one should have to stay through – Katrina '05 [http://news.bbc.co.uk/1/hi/in\\_pictures/4194032.stm](http://news.bbc.co.uk/1/hi/in_pictures/4194032.stm)

Barriers are not optimal to safety, great distress and loss can ensue.

This section has provided a cross-section of disaster threats, evolving reasons to empower communities, and some factors to include in modeling greater community safety. After discussion in the following section, some recommendations and future directions are provided.

Modeling not only the natural hazard but the various social and communication parameters will provide a good basis for not only simulating impact; say, of the extent of flood waters; but will also highlight which impact areas are the most and least likely to properly act in their own best safety.

## Discussion

### Risk Communication Theory and Residents in Hazard Zones

People need to know that an impact is possible before they will willingly evacuate. The concept of risk characterization [42,46,68,75,77,83] makes clear that people need a practical understanding (*the possibility of impact is real, I fully accept that*) to then illuminate practical choices. ‘Internalizing’ that *a threat is real and what you need to do to maximize your safety* may be the core goal of risk communication. This internalization and safety-oriented action may lead to a choice of precautionary evacuations. People need to make informed decisions, thus leading to decision-driven activity.

### Delivering Real-Time Warnings

The idea of subjective uncertainty [74] is well displayed by fire-zone residents who, despite all authority efforts to have them commit to an early decision to stay and defend or to leave their properties early, recurrently reported that they would decide on the day whether they would stay or go. There are tragic and recent international examples of resident’s decisions made on too little understanding or information.

The bushfire ‘stay or go’ decision point explored in 2007 research by the author with Australian fire-zone residents clarifies that decision impact on those under threat – packing up their valuables, children and pets and fleeing their house, almost certainly putting it at risk of burning down; as opposed to staying in their house and experiencing the terror of the developing bushfire, was a decision many preferred to delay. Further, many acknowledged that to leave early with all of the disruption, only to learn that the fire was not an actual threat to their property helped induces people to delay that decision point.

Subjective uncertainty is a psychological problem. The outcome of current research is to encourage the threat information gatherers and providers; the weather bureau and disaster managers, to refine information detail and use all currently available modes of dissemination to provide the threatened with the maximum amount of fine details to make that evacuation decision in an informed and timely manner. This is a clear example of where theory and the practical views of hazard zone residents converge.

The 2007 southeast Australian fire zone research shows that people who are more obviously at risk from bushfire are far more prepared than people who are at risk from an occasional but as potentially destructive bushfire. The literature [13,24,31] shows that the less frequent the event, the less prepared people are likely to be. Aligned to the goals of this publication, the formula explained in this article on the realities and complex elements of combining physical with human geography to the ‘social good’ of maximizing safety around disaster impacts is a great potential application of complexity and systems science. This complexity includes the Media (Media Support MS of formula 1).

### The Media

The media plays an ongoing role in socialization and the development of normative values. Dominick [20] argues that the media plays a key role in the cognitive development of individuals. Cognition is the act of coming to know something. Mass media can play a defining role in people’s awareness and responses to disaster threats. The CST embraces local media as an active agent in providing needed local information. Local media outlets can draw on and enhance Internet information to inform readers and listeners of ‘how to’ actions to maximize their safety. In this way the mass media can help clarify facts to help make contentious decisions (which may result in life or major property loss) by providing the fine details to reduce the uncertainty surrounding decisions that householders under threat need to make. The seven steps to community safety (Sect. “**Integrating Theory and Implementation**”) underline this core need for individuals in hazard zones to accept they are at risk and for the Internet and local media to act as providers of relevant, local, timely information for informed decision-making.

The media can play a powerful role in mobilizing communities [58], but they need to have accurate and timely information from disaster managers. The information which fire zone residents in southeastern Australia in 2007 asked for from the Internet is in full keeping with the-

ory, and a recognition that greater access to current facts will reduce uncertainty in decision-making.

### Triggering Action: Modeling and Simulating This Geographic, Communications and Psychological Complexity

The reason step one in the seven step process is so important is to counteract a psychological defense against accepting threat. We need to have a sense of personal invulnerability to get us through each day [75]. If we were scared of all possible problems we would cease to operate. The risk literature from Handmer, Goudie, Rohrmann, Salter [34,42,75,77] and many others underlines the importance of the clarity in the description of the threat and safety oriented action. Thus Acceptance they are In a Hazard Zone (AIHZ) of formula 1 is central to possible consequent safety-oriented behavior.

One reason given for risk communication failing is that it is not clear what should be done. The seven steps include a requirement that 'what to do' information be an integral part of any warning as a prelude to evacuation. The clear message is that the process of people accepting that a risk is real needs to well precede any actual impact. This is underlined by Kaspersen & Stallen [49], who also stress the importance of time perception and time horizons. Hence the importance of Knowledge Base of the hazard and safety-maximizing behavior (KB) of formula 1.

### Timely Preparation, Final Actions and Evacuations

Timeliness of warnings is paramount to the effectiveness of warnings [85]. In the early 1990s there was much psychology research on perceptions of risk probabilities, individual psychometric studies on perceptions of future time, time orientation, planning horizons, and prediction of future events. In 2007 Australian fire zone residents say they want fine, detailed information as a threat approaches, so the uncertainty of what they may face is minimized. Their planning horizons are generally well oriented to maximum safety, but the crucial 'stay or go' decision will be based on information as close to impact as allows them adequate time to act safely.

Svenson [85] and others make clear that it is not only what you may chose to do, but also when you do it. In the case of remote area warnings of flooding, for instance, when flood waters may take a week to block down-catchment roads, traveling earlier than planned may be the best way to avoid the fate of the truck shown in Fig. 15. This is an example of an 'Active warning image', along with the image of the person standing on the car roof in the flooded road crossing (Fig. 16). Images like these are of use to re-

Evacuation as a Communication and Social Phenomenon, Figure 15

Nearly crossing a flooded road – Tully NQ 2004, From: Townsville Bulletin, 28/4/4.

Conveying weather threat information - flood

Evacuation as a Communication and Social Phenomenon, Figure 16

An image dissuading people from driving in to flood waters

mind people to travel before or after expected flooding – not during the flood.

In 2007, in a two day threat and evacuation exercise in Woodgate Beach operated on the underlined imperative, from the outset, that evacuation ahead of a storm surge would need to be completed not as cyclonic winds struck, but six hours before landfall. Once the winds gusted above 100 km per hour, all peoples, including disaster managers, must be in safe shelter above cyclone surge height.

Disasters and evacuations are issues of people, information, time and space. People in threat zones are entitled to accurate and timely localized information, detailing the threat and likely time-linked movement. People also want to know, via the internet or battery operated radios, what authorities are doing. That information may influence their own actions. What they ask for is the enhancement of their 'risk decision landscape' [83].

In 1974 communication management of and responses to disasters in Darwin and Brisbane shocked Australians. Darwin's Cyclone Tracy killed 65 people, and the Brisbane floods killed 16 [10,11]. These catastrophes taught Australian emergency planners much about the importance of

effective warnings, sharing honest, complete and open information in a timely way to emergency managers, emergency workers, and those at risk to ensure sound preparation and responses. The Australian natural disasters of 1974, with major flooding elsewhere in Australia that year, also reinforced the importance of community and family ties to get people through the often profound emotional trauma allied with major natural disasters. The detailed documentation of Cyclone Tracey can help guide development of predictive models of disaster preparedness, communications and responses. With so few well documented cases, a Bayesian Logic approach could be used, some well documented disasters, communications and response cases to develop the model, others to test and refine it.

The more recent and current disaster impacts all point to the importance of communities being properly informed. Indeed, the literature on knowledge, risk and inclusion of residents in the bushfire planning process is well described by Goldammer [32]. Issues of increased encroachment on to bush edges along with climate change are causing increased international concern over fire threats, often to places without much collective wisdom over the reality of those fire threats, or the nature of the strategies needed to maximize community safety.

South Eastern Australia is seen as one of the most bushfire-prone environments in the world [92]. Boura [7], an Australian fire manager, describes the development of community fireguard groups in Victoria. These groups are managed and instructed by the Country Fire Authority, but they are residents within very localized neighborhoods. They have their counterparts in the ACT and some other Australian States. They draw on detailed, often technically advanced information from the weather bureau and fire agencies to increase local awareness and action. This is a real playing out of the theories of social amplification developed by psychologists and risk communication theorists [73]; advanced planning techniques [16] and aligned with the way many feel about the direction of emergency management in Australia [15].

### Linking the People with the Message

The foci on culture, community and social frameworks, either formal or informal neighborly links, is considered by Douglas [21]. Douglas argues that there is a need for people to understand that risk and danger exist where they live, despite a low probability that an impact may occur in any given hazard season. There is a large body of psychology which considers why people ignore clear messages which may maximize their safety [12]. Douglas speaks of artificially distorted world views. Douglas posits such bias

is rooted in over-simple views of heroic and bourgeois fiction. Changing such a normative world view has been discussed in this article in terms of a paradigm shift, well displayed by the Australian Government [13]. A model constructed from formula 1 needs to include all the subtle complex issues of social profiling.

Woodgate Beach (Sect. “Experiences and Lessons – Some Case Studies”), perhaps because of physical isolation, is fully embracing self-help, also displaying a deep culture of volunteerism that can be nurtured and emulated in ‘urban villages’. Sustainable urban planning concepts of nodes or activity centers are now well evolved as the hub of ‘urban villages’ [35]. What is happening in Woodgate Beach can be used as a model for any formula of developed social collective will to self-help, ultimately whether urban and surrounded by other neighborhoods, or more physically isolated.

Like the Ferny Creek (Victoria) community who agitated for a fixed bushfire siren after three of their neighbors were burned to death in the flash fire of 1997, community action needs a few individuals of vision and drive, residents of ‘neighborhoods’ can initiate and embrace safety-oriented behaviors and structures. The best thing the institutional systems can do is draw out, nurture and encourage these individuals to mobilize a focus on gaining threat knowledge and acting to increase community responses. Part of the community engagement in the fact they are in a threat zone, as step 1 to action, is shown in Fig. 17; a great road-side banners initiative by one section of the Victorian Country Fire Authority to make the fire threat and implications real for fire-prone residents. Figure 17 shows, in few words, that if you intend to evacuate, do it early. Figure 17 says that the support and creativity to maximize communication effectiveness (the opposite of Institutional Barriers) helps contribute to a positive Medium and Message (MM) of formula 1.

### Traditional Weather Warnings

Traditional weather warning signs include ant movement for looming flood, and general bird movement for strong winds, including cyclones [64,87,88]. On Palm Island, when the birds and animals go quiet, it signals that a major storm may be on the way [36,39]. The buildup to the summer monsoon rains is the universal experience of still, humid and hot conditions, continuing in intensity and cloud until the rains come. All cultures in all hazard zones have their traditional knowledge. Cultural Knowledge Bases (KB of formula 1) needs to be modeled into any mathematical prediction of likely propensity to respond to a natural disaster threat.

Evacuation as a Communication and Social Phenomenon, Figure 17  
Initiatives to empower residents to be prepared for fire

### Words and Images

Word and image use are critical to effective communication. A newspaper graphic ahead of the terrorist-threatened 2004 Olympic Games (Fig. 18) conveys much about the world we now occupy, and uses no words.

The need for clear messages, most likely to provoke a precautionary response, is supported by the risk communication literature of Sect. “**Effective Risk Communication**” and the communication and cognitive theory of Sect. “**Integrating Theory and Implementation**”. If this knowledge is melded to requests of remote Indigenous peoples and NESH, the safety goal of clear, plain words

Evacuation as a Communication and Social Phenomenon, Figure 18  
An image of terror in 2004 – Source: Townsville Bulletin

and images will become the risk communication norm. There are many examples of images conveying meaning, such as the internationally used figure running upstairs, with an arrow; signifying an evacuation route. The symbol for tsunami; a stylized figure racing up a steep slope with a very large wave following, threatening to engulf them is also without words, but conveys all we need to know about evacuating ahead of a tsunami: get up slope immediately.

### Images and Warning Maps

Risk communication is usually about attempts to prompt considered action by a person or community. Effective communication should make the future threat real in present thinking. Alternative responses should be outlined, along with likely consequences. To further prompt a considered and active response to the ‘action warning’, the consequences of inaction or a range of defensive actions should be made lucid. ‘Preferred’ behavior should seem reasonably attractive to ‘target individuals’ [85]. The theoretical overview of risk communication in Sect. “**Effective Risk Communication**” explains why the message must be clear to the target audience. It needs to have some cognitive content to get people thinking about how it may impact on them, and what the alternative outcomes for

them may be if the predicted impact strikes where they are. Stimulus and local risk simulations, as embedded in the Redlands shire flood map [102], should be saturation broadcast into all hazard zones. The CST should be attempted with at-risk groups; people in threat zones, encouraging them to properly think about the real threat and to indicate to people what inaction may bring. A range of safety-oriented actions should also be presented.

### Modeling Risk Communication into and Through Communities

Efforts have been made since the 1960s to see how well people understood the hazard. These studies continue [5]. The model of hearing, understanding, believing and feeling that the information is personalized so that those at risk will act has been well understood since the early 90s [81]. The general issues of credibility [18,69,70] still apply. Studies reported by Sorenson and Mileti [81] show increased knowledge as a result of risk communication efforts. People do become more aware of hazards and their personal place within the hazard threats. Unfortunately the link between knowledge and behavior remains tenuous [35].

Knowing that the normal first warning of major disruptive weather comes via the evening TV news in remote settlements, simulations will carry a high embedded likelihood of safety-oriented community response.

Sorenson and Mileti [81] showed that the believability of warnings increases as people get more warnings from officials with high credibility, and that women tend to believe emergency warnings more than men. They also showed that people higher up the socioeconomic ladder tend to believe warnings more than their counterparts. Minority groups have lower than average belief in warnings while people with a high knowledge of the hazard tend to find warnings more credible.

### New Cultures to Hazard Zones

The issues discussed in this article from remote Indigenous communities and from non-English-speaking households make clear the importance of using plain English. Work with representatives of both groups made clear that plain English and images were necessary to convey the concept of danger to people in hazard zones, concurring with the expositions of Douglas [21]. The simpler the language the better. Douglas argues that even the word 'risk' could be dropped and 'danger' used instead. Goudie's work with recent Somali arrivals in Australia showed that, like Japanese tourists and many other people from non-English-speaking backgrounds, they understood the word

and concept of 'danger', but did not, for instance, understand the word 'severe'. The importance of language clarity to the intended audiences in the MM expression of formula 1 needs emphasis.

For risk communication and evacuation advice to penetrate to all people in hazard zones, the language and images must be clear, simple, and compelling. If risk communicators construct campaigns of engagement which work for such 'marginalized' groups, the 'mainstream' can be easily included in that campaign.

### Playing the Odds

Renn and Rohrmann [74] make clear that the assumption that risk judgments and evaluations are universal processes independent of social status or national heritage are unreasonable. Goudie's Australian research with multicultural organizations shows most clearly that there are many populations in hazard zones and that each of those groups must be addressed in ways that make the hazard real to them. Findings from the Cyclone Larry research [53] also show that there are many groups other than cultural, such as 'social isolates' – the socially disenfranchised, who need special attention around disaster threats to ensure their safety.

Douglas [21] argues that risk perception and thus response is also an issue of moral and political issues. Westerners tend to consider the probability of an impact in terms of gambling whereas other cultures may need other triggers to internalize the threat and motivate them to action. The concept of a low probability event needing to be taken seriously is discussed by Douglas and others. Residents of Florida are well used to a near-annual evacuation ahead of frequent cyclones. Residents of the coastal communities of Queensland may be less likely to take the warning seriously, because they believe that there is no real chance that they will be personally affected by a cyclone. The whole issue of low probability and high impact events needs to be stressed to relevant impact zone residents.

The first and hardest step in an effective community evacuation remains convincing people in the projected impact zone that the looming threat is real. Renn and Rohrmann [74] suggest that to help make that threat real, project the expected number of fatalities or the catastrophic potential or where the threat may come from.

### Spreading the Warning

Handmer [43] recommends that the professional warning agencies should attempt to harness the "personal informational networks of individuals within formal communication systems, and by assuring that formal warning advice

is consistent with local norms and behavior” ([43] p 27). Shifting the normative values of recalcitrant disaster managers, and residents in ignorance or denial in urban risk zones becomes the key task of the *seven steps to community safety*, along with the amalgamating approach of the *community safety triangle*.

Part of the strength of the CST is that it taps into and informs an existing social predisposition for people to talk to each other, particularly in times of common threat (King and Goudie 2006). Using emergent technologies to provide real-time information to community media and households helps realize aware informed communities, predisposed to action.

With literature and research results discussed throughout this article, this discussion underlines the importance of modeling local norms, and interactive, safety-focused behavior. Emerging concepts which may be tested in further research are Community Safety groups (Sect. “**Experiences and Lessons – Some Case Studies**”) and Social Burnoffs or flood evacuation practices. The main thrust of this work is to encourage interested modelers to accurately simulate how communities understand and act on the need for safety-oriented action, where people are inclusive at the neighborhood level, acting as a self-preserving group, no matter what the ethnicity or state of surrounding populations. Neighborhood cohesion and empowerment is current social policy consistent with ESD philosophies and principles, enshrined in current planning laws such as IPA 1997 [46].

To illustrate the power of the internet, consider that any online reader globally can click on [103] and see the social aspects of Queensland’s sustainability planning law. Indeed, click on and draw from any of the web sites given. If we were not suffering from information overload and time paucity, the paradigm shift to sustainability implementation would be rapid, the modeling acted on by disaster managers and financial cost-benefit analysts. Until that time, models will help convince and guide people in testable and demonstrable ways to increase community safety. Our very busyness is perhaps the main barrier to reducing global warming and natural disaster impacts. An alternative way into a more sustainable future is centered on local needs-meeting, including nurturing more local community cohesion and sharing of reliable, safety-oriented information and safety-oriented actions.

### **Future Directions in Modeling Disaster Preparedness and Evacuations as a Social Issue**

As global warming and climate change intensifies, the need to model for preparedness and evacuations will in-

crease with more frequent and extreme weather events. The total and fine detail of all needed background preparations and ramp-up preparations are too numerous and arduous for formal disaster management organizations to implement alone, hence the increased need to promote and strongly support the role of community engagement, of community empowerment and nurturing self-help in maximizing effective natural disaster preparation, including evacuations.

Australia has matured disaster policy, law and evolving practice, all embedded in concepts of ecologically sustainable development. Researchers can access, model and test local applicability of some of the Australian experiences and culture of community self-help. Sustainability Implementation Research will become universal as the era of last-minute organizational flurries whilst goading an ignorant and passive population at threat is superseded by prepared and bonded communities who are primed to receive well-delivered warnings, often sourced from the web, and who move themselves to safety in plenty of time. Modeling this will help sell the approach to conservative disaster managers.

The Sustainability Implementation Research, including data-based simulations introduced in this article, is the logical next step to ‘action research’ of the social sciences and will become the norm in approaching all issues of sustainability where the policies are mature, but agencies are unsure how to implement the paradigm shift; the behavioral and technological shift, to agreed long-term goals.

Meaningful consultation is a defining requirement of sustainability planning and good modeling, so all future social research of merit will take the Human Geographer’s approach and “ask the local residents, involve the local residents.” Community empowerment, and its modeling means local residents are entitled to help mold their own future. With hazard management, the shared SIR goal is to empower hazard-zone communities to be aware of the threat, be basically prepared for any warning, and act, as a community, in a precautionary way to maximize safety, minimize loss, and speed recovery.

As we move forward, plain language(s), clear, widely displayed hazard maps and images of like hazard impacts will help energize hazard-zone residents to the threats and their own needed safety-oriented behavior.

Researchers and Complexity and Systems Scientists have a moral if onerous obligation to challenge any layer of government clearly exercising or imposing barriers to helping people internalize any threats, then be supported in getting safe and staying safe, recognizing that change may threaten some individuals or sections within bureaucracies. As disaster management moves from a militaristic

model of command and control to community empowerment and self help, the developing potential of the web as a key information source into hazard zones – ultimately web-to-air – will bear the fruit of greater community safety and minimized loss. Web-to-TV in disaster warning will be a fine conduit for showing residents-at-risk where the threat may be in relation to their home in a few hours. That immediacy of moving images is a compelling motivator for safety-oriented action.

In future, researchers, modelers and others involved in maximizing community safety will embrace some variations of the *communications safety triangle* and the *seven steps to community safety*, simply because they make sense; are highly cost-effective and easily web-refined from international to local conditions, populations and threats.

## Acknowledgment

I most thank my research guardian and mentor over 15 years, Prof. David King, Director of both the Australian Center for Disaster Studies and of the Center for Tropical Urban and Regional Planning. David allowed me freedom to develop as an ‘evidence-based’ scientist, to conceive core approaches to sustainability implementation research; productive in helping render positive change in both disaster management and sustainability planning.

Thanks to Australian Bureau of Meteorology staff for their interactive support to improve risk communications, listening to what real people in real hazard zones experience, how they hear warnings, and how the medium and the messages can be and are optimized. The Bureau embraces the core goal to motivate safety-oriented action by people in hazard zones. The Bureau listens and improves the message and the delivery.

The bushfire research of ’06 & 07 was funded by the Australian Bushfire Cooperative Research Center, supported by the University of Tasmania.

The 14 years of research reported in this article was not possible without the contributions of Authorities and more than 1000 Australians, old and new, who opened their organizations or doors to myself or research team members and shared their hazard experiences and specific warning needs. Thanks all.

### Glossary

**Pedestrian** A person traveling on foot. In this article, other characterizations are used depending on the context, e. g., agent or particle.

**Crowd** A large group of pedestrians moving in the same area, but not necessarily in the same direction.

**Evacuation** The movement of persons from a dangerous place due to the threat or occurrence of a disastrous event. In normal situations this is called “egress” instead.

**Flow** The flow or current  $J$  is defined as the number of persons passing a specified cross-section per unit time. The common unit of flow is “persons per second”. Specific flow is the flow per unit cross-section. The maximal flow supported by a facility (or a part of it) is called “capacity”.

**Fundamental diagram** In traffic engineering (and physics): density-dependence of the flow:  $J(\rho)$ . Due to the hydrodynamic relation  $J = \rho v b$  equivalent rep-

resentations used frequently are  $v = v(\rho)$  or  $v = v(J)$ . The fundamental diagram is probably the most important quantitative characterization of traffic systems.

**Lane formation** In bidirectional flows, lanes are often dynamically formed in which all pedestrians move in the same direction.

**Bottleneck** A limited resource for pedestrian flows, for example a door, a narrowing in a corridor, or stairs, i. e., a location of reduced capacity. At bottlenecks jamming occurs if the inflow is larger than the capacity. Other phenomena that can be observed are the formation of lanes and the zipper-effect.

**Microscopic models** Models which represent each pedestrian separately with individual properties like walking velocity or route choice behavior and the interactions between them. Typical models that belong to this class are cellular automata and the social-force model.

**Macroscopic models** Models which do not distinguish individuals. The description is based on aggregate quantities, e. g., appropriate densities. Typical models belonging to this class are fluid-dynamic approaches. Hand calculation methods which are based on related ideas and are often used in the field of (fire-safety) engineering belong to this class as well.

**Crowd disaster** An accident in which the specific behavior of the crowd is a relevant factor, e. g., through competitive and non-adaptive behavior. In the media, it is often called “panic” which is a controversial concept in crowd dynamics and should thus be avoided.

### Definition of the Subject

Today, there are many occasions on which a large number of people gathers in a rather small area. Office buildings and apartment houses grow larger and more complex. Very large events related to sports, entertainment or cultural and religious events are held all over the world on a regular basis. This brings about serious safety issues for the participants and for the organizers who must be prepared for any case of emergency or critical situation. Usually in such cases the participants must be guided away from the dangerous area as quickly as possible. Therefore the understanding of the dynamics of large groups of people is very important.

In general, evacuation is egress from an area, a building or a vessel due to a potential or actual threat. In the cases described above, the dynamics of the evacuation processes are quite complex due to the large number of people and their interaction, external factors such as fire, complex building geometries, etc. Evacuation dynamics must be described and understood on different levels: physical,

physiological, psychological, and social. Accordingly, the scientific investigation of evacuation dynamics involves many research areas and disciplines. The system “evacuation process” (i. e., the population and the environment) can be modeled on many different levels of detail, ranging from hydro-dynamic models to artificial intelligence and multi-agent systems. There are at least three aspects of evacuation dynamics that motivate its scientific investigation:

- 1) As in most many-particle systems several interesting collective phenomena can be observed that need to be explained;
- 2) Models need to be developed that are able to reproduce pedestrian dynamics in a realistic way, and
- 3) Pedestrian dynamics must be applied to facility design and to emergency preparation and management.

The investigation of evacuation dynamics is a difficult problem that requires close collaboration between different fields. The origin of the apparent complexity lies in the fact that one is concerned with a many-‘particle’ system with complex interactions that are not fully understood. Typically the systems are far from equilibrium and so are, e. g., sensitive to boundary conditions. Motion and behavior are influenced by several external factors and often crowds can be rather inhomogeneous.

In this article we want to deal with these problems from different perspectives and will not only review the theoretical background, but will also discuss some concrete applications.

## Introduction

The awareness that emergency exits are one of the most important factors to ensure the safety of persons in buildings can be traced back more than 100 years. Disasters due to the fires in the Ring theater in Vienna and the urban theater in Nizza in 1881 resulted in several hundred fatalities and led to a rethinking of the safety in buildings [24]. First, attempts were made to improve safety by using non-flammable building materials. However, the disaster at the Troquois Theater in Chicago with more than 500 fatalities, where only the decorations burned, demonstrated the need for more effective measures. This was a starting point for studying the influences of emergency exits and thus the dynamics of pedestrian streams [24,32].

In recent years there have been two major evacuation incidents which gained immense global attention. First, there was the capsizing of the Baltic Sea ferry MV Estonia (September 28, 1994, 852 casualties) [100] and, of course, the terrorist attacks of 9/11 (2,749 casualties).

Other prominent examples of the possible tragic outcomes of the dynamics of pedestrian crowds are the Hillsborough stadium disaster in Sheffield (April 15, 1989, 96 casualties) [182], the accident at Bergisel (December 4, 1999, 5 casualties) [189], the stampede in Baghdad (August 30, 2005, 1,011 casualties), the tragedy at the concert of “The Who” (December 3, 1979, 11 casualties) [73] and – very early – the events at the crowning ceremony of Tsar Nicholas II in St. Petersburg in May 1896 with 1,300 to 3,000 fatalities (sources vary considerably) [168]. In the past, tragic accidents have happened frequently in Mecca during the Hajj (1990: 1,426, 1994: 270, 1997: 343, 1998: 107, 2001: 35, 2003: 14, 2004: 244, and 2006: 364 casualties). What stands out is that the initiating events are very diverse and range from external human aggression (terrorism) to external physical dangers (fire) and rumors to various shades of greedy behavior in absence of any external danger.

Many authors have pointed out that the results of experts’ investigations and the way the media typically reports about an accident very often differ strongly [17,77,109,155,156,178]. Public discussion has a much greater tendency to identify “panic” as the cause of a disaster, while expert commissions often conclude that there either was no panic at all, or panic was merely a result of some other preceding phenomenon.

This article first discusses the empirical basis of pedestrian dynamics in Sect. “Empirical Results”. Here we introduce the basic observables and describe the main qualitative and quantitative results, focusing on collective phenomena and the fundamental diagram. It is emphasized that even for the most basic quantities, no consensus about basic behavior has been reached.

In Sect. “Modeling” various model approaches that have been applied to the description of pedestrian dynamics are reviewed.

Section “Applications” discusses more practical issues and gives a few examples for applications to safety analysis. In this regard, prediction of evacuation times is an important problem as legal regulations must often be fulfilled. Here, commercial software tools are available. A comparison shows that the results must be interpreted with care.

## Empirical Results

### Overview

Pedestrians are three-dimensional objects and a complete description of their highly developed and complicated motion sequence is rather difficult. Therefore, in pedestrian and evacuation dynamics, pedestrian motion is usu-

ally treated as two-dimensional by considering the vertical projection of the body.

In the following sections we review the present knowledge of empirical results. These are relevant not only as a basis for the development of models, but also for applications such as safety studies and legal regulations.

We start with the phenomenological description of collective effects. Some of these are known from everyday experience and will serve as benchmark tests for any kind of modeling approach. Any model that does not reproduce these effects is missing some essential part of the dynamics. Next, the foundations of a quantitative description are laid by introducing the fundamental observables of pedestrian dynamics. Difficulties arise from different conventions and definitions. Then pedestrian dynamics in several simple scenarios (corridor, stairs etc.) are discussed. Surprisingly, even for these simple cases no consensus about the basic quantitative properties exists. Finally, more complex scenarios are discussed which are combinations of the simpler elements. Investigations of scenarios such as evacuations of large buildings or ships suffer even more from lack of reliable quantitative and sometimes even qualitative results.

### Collective Effects

One of the reasons why the investigation of pedestrian dynamics is attractive for physicists is the large variety of interesting collective effects and self-organization phenomena that can be observed. These macroscopic effects reflect the individuals' microscopic interactions and thus give important information for any modeling approach.

**Jamming** Jamming and clogging typically occur for high densities at locations where the inflow exceeds capacity. Locations with reduced capacity are called *bottlenecks*. Typical examples are exits (Fig. 1) or narrowings. This kind of jamming phenomenon does not depend strongly on the microscopic dynamics of the particles. Rather it is a consequence of an exclusion principle: space occupied by one particle is not available for others.

This clogging effect is typical for a bottleneck situation. It is important for practical applications, especially evacuation simulations.

Other types of jamming occur in the case of counterflow where two groups of pedestrians mutually block each other. This happens typically at high densities and when it is not possible to turn around and move back, e. g., when the flow of people is large.

**Density waves** Density waves in pedestrian crowds can be generally characterized as quasi-periodic density varia-

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 1  
Clogging near a bottleneck. The shape of the clog is discussed in more detail in Subsect. "Theoretical Results"

tions in space and time. A typical example is the movement in a densely crowded corridor (e. g., in subway-stations close to the density that causes a complete halt of motion) where phenomena similar to stop-and-go vehicular traffic can be observed, e. g., density fluctuations in a longitudinal direction that move backwards (opposite to the movement direction of the crowd) through the corridor. More specifically, for the situation on the Jamarat Bridge in Makkah (during the Hajj pilgrimage 2006), stop-and-go waves have been reported. At densities of 7 persons per  $\text{m}^2$  upstream, moving stop-and-go waves of period 45 s have been observed that lasted for 20 minutes [59]. Fruin reports, that "at occupancies of about 7 persons per square meter the crowd becomes almost a fluid mass. Shock waves can be propagated through the mass sufficient to lift people off their feet and propel them distances of 3 m (10 ft) or more." [36].

**Lane formation** In counterflow, i. e., two groups of people moving in opposite directions, (dynamically varying) lanes are formed where people move in just one direction [135,139,197]. In this way, strong in-

interactions with oncoming pedestrians are reduced which is more comfortable and allows higher walking speeds.

The occurrence of lane formation does not require a preference of moving on one side. It also occurs in situations without left- or right-preference. However, cultural differences for the preferred side have been observed. Although this preference is not essential for the phenomenon itself, it has an influence on the kind of lanes formed and their order.

Several quantities for the quantitative characterization of lane formation have been proposed. Yamori [197] has introduced a band index which is basically the ratio of pedestrians in lanes to their total number. In [13] a characterization of lane formation through the (transversal) velocity profiles at fixed positions has been proposed. Lane formation has also been predicted to occur in colloidal mixtures driven by an external field [15,28,158]. Here, an order parameter  $\phi = \frac{1}{N} \langle \sum_{j=1}^N \phi_j \rangle$  has been introduced where  $\phi_j = 1$  if the lateral distance to all other particles of the other type is larger than a typical density-dependent length scale, and  $\phi_j = 0$  otherwise.

The number of lanes can vary considerably with the total width of the flow. Figure 2 shows a street in the city center of Cologne during World Youth Day in Cologne (August 2005) where two comparatively large lanes have been formed.

The number of lanes usually is not constant and might change in time, even if there are relatively small changes in density. The number of lanes in opposite di-

rections is not always identical. This can be interpreted as a sort of spontaneous symmetry breaking.

Quantitative empirical studies of lane formation are rare. Experimental results have been reported in [94] where two groups with varying relative sizes had to pass each other in a corridor with a width of 2 m. On one hand, similar to [197] a variety of different lane patterns were observed, ranging from 2 to 4 lanes. On the other hand, in spite of this complexity, surprisingly large flows could be measured: the sum of (specific) flow and counterflow was between 1.8 and 2.8 persons per meter per second and exceeded the specific flow for one-directional motion ( $\approx 1.4$  P/ms).

**Oscillations** In counterflow at bottlenecks, e. g., doors, one can sometimes observe oscillatory changes of the direction of motion. Once a pedestrian is able to pass the bottleneck it becomes easier for others to follow in the same direction until somebody is able to pass the bottleneck (e. g., through a fluctuation) in the opposite direction.

**Patterns at intersections** At intersections, various collective patterns of motion can be formed. A typical example is short-lived roundabouts which make motion more efficient. Even if these are connected with small detours, the formation of these patterns can be favorable since they allow for “smoother” motion.

**Emergency situations, “panic”** In emergency situations various collective phenomena have been reported that have sometimes misleadingly been attributed to *panic behavior*. However, there is strong evidence that this is not the case. Although a precise accepted definition of *panic* is missing, usually certain aspects are associated with this concept [77]. Typically “panic” is assumed to occur in situations where people compete for scarce or dwindling resources (e. g., safe space or access to an exit) which leads to selfish, asocial or even completely irrational behavior and contagion that affects large groups. A closer investigation of many crowd disasters has revealed that most of the above characteristics have played almost no role and most of the time have not been observed at all (see e. g. [73]). Often the reason for these accidents is much simpler, e. g., in several cases the capacity of the facilities was too small for the actual pedestrian traffic, e. g., Luschniki Stadium Moskau (October 20, 1982), Bergisel (December 4, 1999), pedestrian bridge Kobe (Akashi) (July 21, 2001) [186]. Therefore the term “panic” should be avoided, *crowd disaster* being a more appropriate characterization. Also it should be kept in mind that in dangerous situations it is *not* irrational to fight for resources (or for your own life), if everybody else does

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 2

The “Hohe Straße” in Cologne during World Youth Day 2005. The yellow line is the border of the two walking directions

this [18,113]. Only from the outside is this behavior perceived as irrational since it might lead to a catastrophe [178]. The latter aspect is therefore better described as *non-adaptive behavior*. We will discuss these issues in more detail in Subsect. “**Evacuations: Empirical Results**”.

## Observables

Before we review experimental studies in this section, the commonly used observables are introduced.

The flow  $J$  of a pedestrian stream gives the number of pedestrians crossing a fixed location of a facility per unit of time. Usually it is taken as a scalar quantity since only the flow normal to some cross-section is considered. There are various methods to measure flow. The most natural approach is to determine the times  $t_i$  at which pedestrians pass a fixed measurement location. The time gaps  $\Delta t_i = t_{i+1} - t_i$  between two consecutive pedestrians  $i$  and  $i + 1$  are directly related to the flow

$$J = \frac{1}{\langle \Delta t_i \rangle} \quad \text{with} \quad \langle \Delta t_i \rangle = \frac{1}{N} \sum_{i=1}^N (t_{i+1} - t_i) = \frac{t_{N+1} - t_1}{N}. \quad (1)$$

Another possibility for measuring the flow of a pedestrian stream is borrowed from fluid dynamics. The flow through a facility of width  $b$  is determined by the average density  $\rho$  and the average speed  $v$  of a pedestrian stream as

$$J = \rho v b = J_s b. \quad (2)$$

where the *specific flow*<sup>1</sup>

$$J_s = \rho v \quad (3)$$

gives the flow per unit-width. This relation is also known as *hydrodynamic relation*.

There are several problems concerning the way in which velocities, densities or time gaps are measured and the conformance of the two definitions of flow. The flow according to Eq. (1) is usually measured as a mean value over time at a certain location, while the measurement of the density in Eq. (2) is connected with an instantaneous mean value over space. This can lead to a bias caused by underestimation of fast moving pedestrians at the average over space compared to the mean value of the flow over time at a single measurement line (see the discussion for vehicular traffic e. g., in [51,81,102]). Furthermore,

<sup>1</sup>In strictly one-dimensional motion often a line density (dimension: 1/length) is used. Then the flow is given by  $J = \rho v$ .

most experimental studies measuring the flow according to Eq. (2) combine for technical reasons an *average* velocity of a single pedestrian over time with an *instantaneous* density. To ensure a correspondence of the mean values the average velocity of all pedestrians contributing to the density at a certain instant has to be considered. However this procedure is very time consuming and not realized in practice up to now. Moreover, the fact that the dimension of the test section has usually the same order of magnitude as the extent of the pedestrians can influence the averages over space. These all are possible factors why different measurements can differ in a large way, see discussion in Subsect. “**Fundamental Diagram**”.

Another way to quantify the pedestrian load of facilities has been proposed by Fruin [35]. The “pedestrian area module” is given by the reciprocal of the density. Thompson and Marchant [184] introduced the so-called “inter-person distance”  $d$ , which is measured between center coordinates of the assessing and obstructing persons. According to the “pedestrian area module” Thompson and Marchant call  $\sqrt{1/\rho}$  the “average inter-person distance” for a pedestrian stream of evenly spaced persons [184]. An alternative definition is introduced in [58] where the local density is obtained by averaging over a circular region of radius  $R$ ,

$$\rho(\mathbf{r}, t) = \sum_j f(\mathbf{r}_j(t) - \mathbf{r}), \quad (4)$$

where  $\mathbf{r}_j(t)$  are the positions of the pedestrians  $j$  encompassed by  $\mathbf{r}$  and  $f(\dots)$  is a Gaussian, distance-dependent weight function.

In contrast to the density definitions above, Predtechenskii and Milinskii [151] consider the ratio of the sum of the projection area  $f_j$  of the bodies and the total area of the pedestrian stream  $A$ , defining the (dimensionless) density  $\tilde{\rho}$  as

$$\tilde{\rho} = \frac{\sum_j f_j}{A}, \quad (5)$$

a quantity known as *occupancy* in the context of vehicular traffic. Since the projection area  $f_j$  depends strongly on the type of person (e. g., it is much smaller for a child than for an adult), the densities for different pedestrian streams consisting of the same number of persons and the same stream area can be quite different.

Beside technical problems due to camera distortions and camera perspective there are several conceptual problems, such as the association of averaged with instantaneous quantities, the need to choose an observation area in the same order of magnitude as the extent of a pedestrian together with the definition of the density of objects

with nonzero extent and much more. A detailed analysis of the ways in which measurement influences the relations is necessary but still lacking.

### Fundamental Diagram

The fundamental diagram describes the empirical relation between density  $\rho$  and flow  $J$ . The name indicates its importance and naturally it has been the subject of many investigations. Due to the hydrodynamic relation (3) there are three equivalent forms:  $J_s(\rho)$ ,  $v(\rho)$  and  $v(J_s)$ . In applications the relation is a basic input for engineering methods developed for the design and dimensioning of pedestrian facilities [35,136,150]. Furthermore, it is a quantitative benchmark for models of pedestrian dynamics [21,86,112,175].

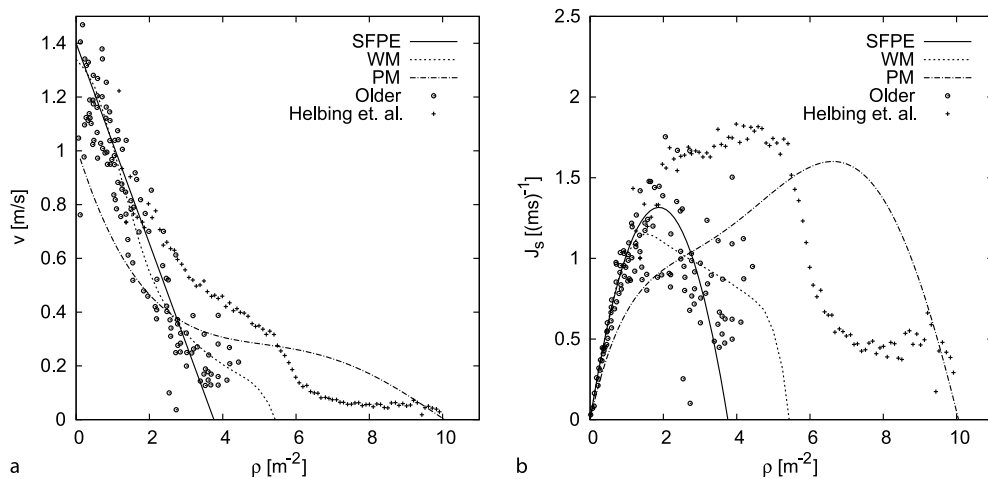

In this section we will concentrate on planar facilities such as sidewalks, corridors and halls. For various facilities such as floors, stairs or ramps, the shape of the diagrams differ, but in general it is assumed that the fundamental diagrams for the same type of facilities but having different widths merge into one diagram for the specific flow  $J_s$ . In first order this is confirmed by measurements on different widths [49,135,139,142]. However, Navin and Wheeler observed in narrow sidewalks more orderly movement leading to slightly higher specific flows than for wider sidewalks [135]. A natural lower bound for the independence of the specific flow from the width is given by the body size and the asymmetry in movement possibilities of the hu-

man body. Surprisingly, Kretz et al. found an increase of the specific flow for bottlenecks with  $b \leq 0.7$  m [93]. This will be discussed in more detail later. For the following discussion we assume facility widths larger than  $b = 0.6$  m and use the most common representations  $J_s(\rho)$  and  $v(\rho)$ .

Figure 3 shows various fundamental diagrams used in planning guidelines and measurements of two selected empirical studies representing the overall range of the data. The comparison reveals that specifications and measurements disagree considerably. In particular, the maximum of the function giving the capacity  $J_{s,\max}$  ranges from  $1.2$  ( $\text{ms}^{-1}$ ) to  $1.8$  ( $\text{ms}^{-1}$ ), the density value where the maximum flow is reached ( $\rho_c$ ) ranges from  $1.75$   $\text{m}^{-2}$  to  $7$   $\text{m}^{-2}$  and, most notably, the density  $\rho_0$ , where the velocity approaches zero due to overcrowding, ranges from  $3.8$   $\text{m}^{-2}$  to  $10$   $\text{m}^{-2}$ .

Several explanations for these deviations have been suggested, including cultural and population differences [58,116], differences between uni- and multidirectional flow [99,135,154], short-ranged fluctuations [154], influence of psychological factors given by the incentive of the movement [150] and, partially related to the latter, the type of traffic (commuters, shoppers) [139].

It seems that the most elaborate fundamental diagram is given by Weidmann who collected 25 data sets. An examination of the data which were included in Weidmann's analysis shows that most measurements with densities larger than  $\rho = 1.8$   $\text{m}^{-2}$  are performed on multidirectional streams [135,139,140,142,148]. But data gained

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 3

Fundamental diagrams for pedestrian movement in planar facilities. The lines refer to specifications according to planning guidelines (SFPE Handbook [136]), Predtechenskii and Milinskii (PM) [150], Weidmann (WM) [192]). Data points give the range of experimental measurements (Older [142] and Helbing [58])

by measurements on strictly unidirectional streams has also been considered [35,49,188]. Thus Weidmann neglected differences between uni- and multidirectional flow in accordance with Fruin, who states in his often cited book [35] that the fundamental diagrams of multidirectional and unidirectional flow differ only slightly. This disagrees with results of Navin and Wheeler [135] and Lam et al. [99] who found a reduction of the flow in dependence of directional imbalances. Here lane formation in bidirectional flow has to be considered. Bidirectional pedestrian flow includes unordered streams as well as lane-separated and thus quasi-unidirectional streams in opposite directions. A more detailed discussion and data can be found in [99,135,154]. A surprising finding is that the sum of flow and counterflow in corridors is larger than the unidirectional flow and for equally distributed loads it can be twice the unidirectional flow [94].

Another explanation is given by Helbing et al. [58] who argue that cultural and population differences are responsible for the deviations between Weidmann and their data. In contrast to this interpretation the data of Hanking and Wright [49] gained by measurements in the London subway (UK) are in good agreement with the data of Mori and Tsukaguchi [115] measured in the central business district of Osaka (Japan), both on strictly uni-directional streams. This brief discussion clearly shows that up to now there is no consensus about the origin of the discrepancies between different fundamental diagrams and how one can explain the shape of the function.

However, all diagrams agree in one characteristic: velocity decreases with increasing density. As the discussion above indicates there are many possible reasons and causes for the velocity reduction. For the movement of pedestrians along a line, a linear relation between speed and the inverse of the density was measured in [174]. The speed for walking pedestrians depends also linearly on the step size [192] and the inverse of the density can be regarded as the required length for one pedestrian to move. Thus it seems that smaller step sizes caused by a reduction of the available space with increasing density is, at least for a certain density region, one cause for the decrease of speed. However, this is only a starting point for a more elaborated modeling of the fundamental diagram.

### Bottleneck Flow

The flow of pedestrians through bottlenecks shows a rich variety of phenomena, e. g., the formation of lanes at the entrance to the bottleneck [64,66,93,176], clogging and blockages at narrow bottlenecks [24,57,93,121,122,150] or some special features of bidirectional bottleneck flow [57].

Moreover, the estimation of bottleneck capacities by the maxima of fundamental diagrams is an important tool for the design and dimensioning of pedestrian facilities.

**Capacity and Bottleneck Width** One of the most important practical questions is how the capacity of a bottleneck rises with increasing width. Studies of this dependence can be traced back to the beginning of the last century [24,32] and, up to now, have been discussed controversially. As already mentioned in the context of the fundamental diagram there are multiple possible influences on pedestrian flow and thus on the capacity. In the following, the major findings are outlined, demonstrating the complexity of the system and documenting a controversial discussion over one hundred years.

At first sight, a stepwise increase of capacity with the width appears to be natural if lanes are formed. For independent lanes, where pedestrians in one lane are not influenced by those in others, the capacity increases only if an additional lane can be formed. This is reflected in the stepwise enlargement of exit width, which has been a requirement of several building codes and design recommendations. See e. g., the discussion in [146] for the USA and GB and [130] for Germany. e. g.; the German building code requires an exit width (e. g., for a door) to be at least 90 cm plus 60 cm for every 200 persons. Independently from this simple lane model, Hoogendoorn and Daamen [64,66] measured by a laboratory experiment the trajectories of pedestrians passing a bottleneck. The trajectories show that inside a bottleneck the formation of lanes occurs, resulting from the zipper effect occurring on entry to the bottleneck. Due to the zipper effect, a self-organization phenomenon leading to an optimization of the available space and velocity; the lanes are not independent and thus do not allow passing (Fig. 4). The empirical results of [64,66] indicate a distance between lanes of  $d \approx 0.45$  m, independent of the bottleneck width  $b$ , implying a stepwise increase of capacity. However, the investigation was restricted to two values ( $b = 1.0$  m and  $b = 2.0$  m) of the width.

In contrast, the study [176] considered more values of the width and found that the lane distance increases continuously as illustrated in Fig. 4. Moreover it was shown that a continuous increase of the lane distance leads to a very weak dependence on its width of the density and velocity inside the bottleneck. Thus in reference to Eq. (2) the flow does not necessarily depend on the number of lanes. This is consistent with common guidelines and handbooks<sup>2</sup> which assume that the capacity is a linear function

<sup>2</sup>One exception is the German MVStättV [130], see above.

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 4

A sketch of the zipper effect with continuously increasing lane distances in  $x$ : The distance in the walking direction decreases with increasing lateral distance. Density and velocities are the same in all cases, but the flow increases continuously with the width of the section

of the width [35,136,150,192]. It is given by the maximum of the fundamental diagram and in reference to the specific flow concept introduced in Subsect. “Observables”, Eqs. (2), (3), the maximum grows linearly with the facility width. To find a conclusive judgment on the question if the capacity grows continuously with the width the results of different laboratory experiments [93,121,122,132,176] are compared in [176].

In the following we discuss the data of flow measurement collected in Fig. 5. The corresponding setups are sketched in Fig. 6. First, note that all presented data are taken under laboratory conditions where the test persons are advised to move normally. The data by Muir et al. [121], who studied the evacuation of airplanes (see Fig. 6b), seem to support the stepwise increase of flow with the width. They show constant flow values for  $b > 0.6$  m. But the independence of flow over the large range from  $b = 0.6$  m to  $b = 1.8$  m indicates that in this special setup the flow is not restricted by the bottleneck width. Moreover, it was shown in [176] by determination of the trajectories that the distance between lanes changes continuously, invalidating the basic assumption leading to a stepwise increasing flow. Thus all collected data for flow measurements in Fig. 5 are compatible with a continuous and almost linear increase with the bottleneck width for  $b > 0.6$  m.

The data in Fig. 5 differ considerably in values of bottleneck capacity. In particular, the flow values of Nagai [132] and Müller [122] are much higher than the maxima of empirical fundamental diagrams (see Sub-

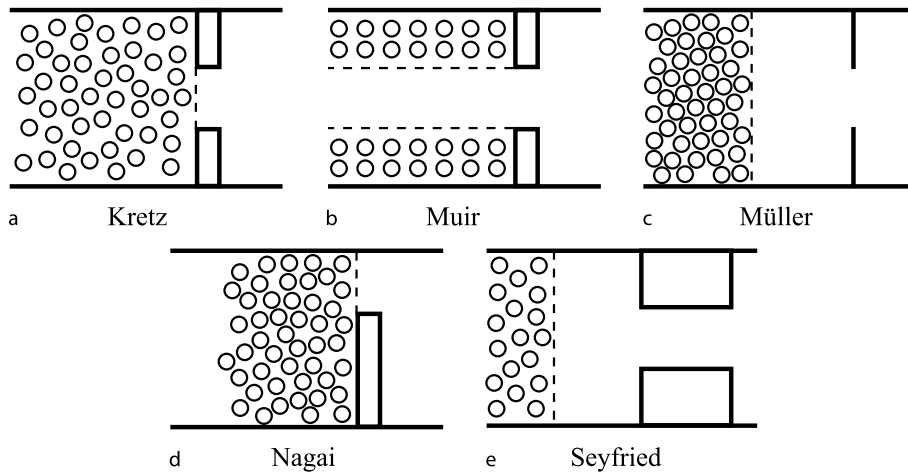

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 5

Influence of the width of a bottleneck on the flow. Experimental data [121,122,132,176] of different types of bottlenecks and initial conditions. All data are taken under laboratory conditions where the test persons are advised to move normally

sect. “Fundamental Diagram”). The influence of “panic” or pushing can be excluded since in all experiments the participants were instructed to move normally. The comparison of the different experimental setups (Fig. 6) shows that the exact geometry of the bottleneck is of only minor influence on the flow, while a high initial density in front of the bottleneck can increase the resulting flow values. This is confirmed by the study of Nagai et al., see Figure 6 in [132]. There it is shown that for  $b = 1.2$  m the flow grows from  $J = 1.04 \text{ s}^{-1}$  to  $3.31 \text{ s}^{-1}$  when the initial density is increased from  $0.4 \text{ m}^{-2}$  to  $5 \text{ m}^{-2}$ .

The linear dependence of the flow on the width has a natural limitation due to the nonzero body-size and the asymmetry given by the sequence of movement in steps. Movement of pedestrians through bottlenecks smaller than shoulder width requires a rotation of the body. Kretz et al. found in their experiment [93] that the specific flow  $J_s$  increases if the width decreases from  $b = 0.7$  m to  $b = 0.4$  m.

**Connection Between Bottleneck Flow and Fundamental Diagrams** An interesting question is how the bottleneck flow is connected to the fundamental diagram. General results for driven diffusive systems [149] show that boundary conditions only *select* between the states of the

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 6  
 Outlines of the experimental arrangements under which the data shown in Fig. 5 were taken

undisturbed system instead of creating completely different ones. Therefore it is surprising that the measured maximal flow at bottlenecks can exceed the maximum of the empirical fundamental diagram. These questions are related to the common jamming criterion. Generally, it is assumed that a jam occurs if the incoming flow exceeds the capacity of the bottleneck. In this case one expects the flow through the bottleneck to continue with the capacity (or lower values).

The data presented in [176] show a more complicated picture. While the density in front of the bottleneck amounts to  $\rho \approx 5.0(\pm 1) \text{ m}^{-2}$ , the density inside the bottleneck tunes around  $\rho \approx 1.8 \text{ m}^{-2}$ . The observation that the density inside the bottleneck is lower than in front of the bottleneck is consistent with measurements of Daamen and Hoogendoorn [20] and the description given by Predtechenskii and Milinskii in [150]. The latter assumes that in the case of a jam the flow through the bottleneck is determined by the flow in front of the bottleneck. The density inside the jam will be higher than the density associated with the capacity. Thus the reduced flow in front of the bottleneck causes a flow through the bottleneck smaller than the bottleneck capacity. Correspondingly the associated density is also smaller than that at capacity. But the discussion above cannot explain why the capacities measured at bottlenecks are significantly higher than the maxima of empirical fundamental diagrams and cast doubts on the common jamming criterion. Possible unconsidered influences are stochastic flow fluctuations, non-stationarity of the flow, flow interferences due to the necessity of local organization or changes of the incentive during the access into the bottleneck.

**Blockages in Competitive Situations** As stated above all data collected in Fig. 5 are gained by runs where the test persons were instructed to move normally. By definition a bottleneck is a limited resource and it is possible that under competitive situations pedestrian flow through bottlenecks is different from the flow in normal situations. One qualitative difference to normal situations is the occurrence of blockages. Regarding the term ‘panic’ one has to bear in mind that for the occurrence of blockages some kind of reward is essential, while the emotional state of the test persons is not. This was a result of a very interesting and often cited study by Mintz [113]. First experiments with real pedestrians have been performed by Dieckmann [24] in 1911 as a reaction to many fatalities in theater fires at the end of the 19th century. In these small scale experiments test persons were instructed to go through great trouble to pass the door as fast as possible. Even in the first run he observed a stable “wedging”. In [150] it is described how these obstruction occurs due to the formation of arches in front of the door under high pressure. This is very similar to the well-known phenomenon of *arching* occurring in the flow of granular materials through narrow openings [194].

Systematic studies including the influence of the shape and width of the bottleneck and comparisons with flow values under normal situations have been performed by Müller and Muir et al. [121,122]. Müller found that funnel-like geometries support the formation of arches and thus blockages. For further discussion, one must distinguish between temporary blockages and stable blockages leading to a zero flow. For the setup sketched in Fig. 6c Müller found that temporary blockages occur only for

$b < 1.8$  m. For  $b \leq 1.2$  m the flow shows strong pulsing due to unstable blockages. Temporal disruptions of the flow appear for  $b \leq 1.0$  m. In comparison to normal situations the flow is higher, and in general the occurrence of blockages decreases with width. However a surprising result is that for narrow bottlenecks, increasing the width can be counterproductive since it also increases the probability of blockages. Muir et al. for example note that in their setup (Fig. 6b) the enlargement of the width from  $b = 0.5$  m to  $b = 0.6$  m leads to an increase of temporary blockages. The authors explain this by differences in the perception of the situation by the test persons. While the smaller width is clearly passable only for one person, the wider width may lead to the perception that the bottleneck is sufficiently wide to allow two persons to pass through. How many people have direct access to the bottleneck is clearly influenced by the width of the corridor in front of the bottleneck. Also, Müller found hints that flow under competitive situations did not increase in general with the bottleneck width. He notes an optimal ratio of 0.75:1 between the bottleneck width and the width of the corridor in front of the bottleneck.

To reduce the occurrence of blockages, and thus evacuation times, Helbing et al. [54,55,83] suggested putting a column (asymmetrically) in front of a bottleneck. It should be emphasized that this theoretical prediction was made under the assumption that the system parameters, i. e., the basic behavior of the pedestrians, does not change in the presence of the column. This is highly questionable in real situations where a column can be perceived as an additional obstacle or can make it difficult to find the exit. In experiments [57] an increase of the flow of about 30% has been observed for a door with  $b = 0.82$  m. But this experiment was performed only for one width and the discussion above indicates the strong influence of the specific setup used. Independent of this uncertainty this concept is limited, as the occurrence of stable arches, to narrow bottlenecks. In practice narrow bottlenecks are not suitable for a large number of people and an opening in a room has other important functionalities, which would be restricted by a column.

Another finding is the observation that the total flow at bottlenecks with bidirectional movement is higher than it is for unidirectional flows [57].

## Stairs

In most evacuation scenarios stairs are important elements that are a major determinant for the evacuation time. Due to their physical dimension, which is often smaller than other parts of a building, or due to a reduced walking

speed, stairs generally must be considered as bottlenecks for the flow of evacuees. For the movement on stairs, just as for the movement on flat terrain, the fundamental diagram is of central interest. Compared to the latter there are more degrees of freedom, which influence the fundamental diagram:

- One has to distinguish between upward and downward movement.
- The influence of riser height and tread width (which determine the incline) has to be taken into account.
- For upward motion exhaustion effects lead to a strong time dependence of the free speed.

It is probably a consequence of the existence of a continuum of fundamental diagrams in dependence of the incline that there are no generally accepted fundamental diagrams for movement on stairs. However, there are studies on various details—mostly the free speed—of motion on stairs in dependence of the incline [35,38,39,46], conditions (comfortable, normal, dangerous) [151], age and sex [35], tread width [33], and the length of a stair [95]; and in consideration of various disabilities [11].

In addition there are some compilations or “meta studies”: Graat [46] compiled a list of capacity measurements and Weidmann [192] built an average of 58 single studies and found an average for the horizontal upstairs speed—the speed when the motion is projected to the horizontal level—of 0.610 m/s.

Depending on various parameters, the aforesaid studies report horizontal upward walking speeds varying over a wide range from 0.391 to 1.16 m/s. Interestingly, on one and the same short stairs it could be observed [95] that people on average walked faster up- than downwards.

There is also a model where the upstairs speed is calculated from the stair geometry (riser and tread) [183] and an empirical investigation of the collision avoidance behavior on stairs [37].

On stairs (up- as well as downward) people like to put their hand on the handrail, i. e., they tend to walk close to walls, even if there is no counterflow. This is in contrast to movement on flat terrain, where at least in situations of low density there is a tendency to keep some distance from walls.

The movement on stairs is typically associated with a reduction of the walking speed. For upward motion this follows from the increased physical effort required. This has two aspects: first, there is the physical potential energy that a pedestrian has to supply if he wants to rise in height; second, the motion process itself is more exertive – the leg has to be lifted higher – than during motion on a level, even if this motion process is executed only on the spot.

Concerning the potential energy there is no comparable effect for people going downstairs. But still one can observe jams forming at the upper end of downstairs streams. These are due to the slight hesitation that occurs when pedestrians synchronize their steps with the geometry of the (down-)stairs ahead. Therefore the bottleneck character of downstairs is less a consequence of the speed on the stairs itself and more of the transition from planar to downward movement, at least as long as the steps are not overly steep.

### Evacuations: Empirical Results

Up to now this section has focused on empirical results for pedestrian motion in rather simple scenarios. As we have seen there are many open questions where no consensus has been reached, sometimes even about the qualitative aspects. This becomes even more relevant for full-scale descriptions of evacuations from large buildings or cruise ships. These are typically a combination of many of the simpler elements, so a lack of reliable information is not surprising. In the following we will discuss several complex scenarios in more detail.

**Evacuation Experiments** In the case of an emergency, the movement of a crowd usually is more straightforward than in the general case. Commuters in a railway station, for example, or visitors of a building might have complex itineraries which are usually represented by origin-destination matrices. In the case of an evacuation, however, the aims and routes are known and usually the same, i. e., the exits and the egress routes. This is the reason why an evacuation process is rather strictly limited in space and time, i. e., its beginning and end are well-defined: the sound of the alarm, initial position of all persons, safe areas (final position of all persons), and the time at which the last person reaches the safe area. When all people have left a building or vessel and reached a safe area (or the lifeboats or life rafts), then the evacuation is finished. Therefore, it is also possible to perform evacuation trials and measure overall evacuation times. Before we go into details, we will clarify three different aspects of data on evacuation processes:

- (1) The definition and parts of evacuation time,
- (2) The different sources of data, and
- (3) The application of these data.

Concerning the evacuation time, five different phases can be distinguished [48,118,153]:

- (1) Detection time,
- (2) Awareness time,

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 7

**Empirical data can be roughly classified according to controlled/uncontrolled and emergency/normal situations**

- (3) Decision time,
- (4) Reaction time, and
- (5) Movement time.

In IMO's regulations [118,119], the first four are grouped together into *response time*. Usually, this time is called *pre-movement time*

One possible scheme for the classification of data on evacuation processes is shown in the following Fig. 7.

Please note that not only data obtained from uncontrolled or emergency situations can be used in the context of evacuation assessment. Knowledge about bottleneck capacities (i. e., flows through doors and on stairs) is especially important when assessing the layout of a building with respect to evacuation. The purpose of empirical data in the context of evacuation processes (and modeling in general) is threefold [43,71]:

- (1) Identify parameters (factors that influence the evacuation process, e. g., bottleneck widths and capacities),
- (2) Quantify (calibrate) those parameters, e. g., flow through a bottleneck in persons per meter per second, and
- (3) Validate simulation results, e. g., compare the overall evacuation time measured in an evacuation with simulation or calculation results.

The validation is usually based on data from the evacuation of complete buildings, aircraft, trains or ships. These are available from two different sources:

- (1) Full scale evacuation trials and
- (2) Real evacuations.

Evacuation trials are usually observed and videotaped. Reports of real evacuation processes are obtained from eye-

witness records and a posteriori incident investigations. Since the setting of a complete evacuation is not experimental, it is hardly possible to measure microscopic features of the crowd motion. Therefore, calibration of parameters is usually not the main purpose in evacuation trials; rather, they are carried out to gain knowledge about the overall evacuation process, the behavior of the persons, to identify the governing influences/parameters and to validate simulation results.

One major concern in evacuation exercises is the well-being of the participants. Due to practical, financial, and ethical constraints, an evacuation trial cannot be, by nature, realistic. Therefore, an evacuation exercise does not convey the increased stress of a real evacuation. To draw conclusions on the evacuation process, the walking speed observed in an exercise should not be assumed to be higher in a real evacuation [145]. Along the same lines of argument, a simplified evacuation analysis based on, e.g., a hydro-dynamic model can predict an evacuation exercise, and the same constraints apply for its results concerning the prediction of evacuation times and the evacuation process. If population parameters (such as gender, age, walking speed, etc.) are explicitly stated in the model, increased stress can be simulated by adapting these parameters.

In summary, evacuation exercises are just too expensive, time consuming, and dangerous to be a standard measure for evacuation analysis. An evacuation exercise organized by the UK Marine Coastguard Agency on the Ro-Ro ferry “Stena Invicta” held in Dover Harbor in 1996 cost more than 10,000 GBP [117]. This is one major argument for the use of evacuation simulations based on hydro-dynamic models and calculations.

**Panic, Herding, and Similar Conjectured Collective Phenomena** As already mentioned earlier in Subsect. “Collective Effects”, the concept of “panic” and its relevance for crowd disasters is rather controversial. It is usually used to describe irrational and unsocial behavior. In the context of evacuations, empirical evidence shows that this type of behavior is rare [3,17,77,178]. On the other hand there are indications that fear might be “contagious” [22]. Related concepts like “herding” and “stampede” imply a certain similarity between the behavior of human crowds and animal behavior. This terminology is quite often used in the public media. *Herding* has been described in animal experiments [166] and is difficult to measure in human crowds. However, it seems to be natural that herding exists in certain situations, e.g., limited visibility due to failing lights or strong smoke when exits are hard to find.

*Panic* As stated earlier, “panic” behavior is usually characterized by selfish and anti-social behavior which through contagion affects large groups and even leads to completely irrational actions. Often it is assumed, especially in the media, to occur in situations where people compete for scarce or dwindling resources, which in the case of emergencies are safe space or access to an exit. However, this point of view does not stand close scrutiny and it has turned out that this behavior has played no role at all in many tragic events [73,77]. For these incidents *crowd disaster* is a much more appropriate characterization.

Furthermore, lack of social behavior seems to be more frequent during so called “acquisitive panics” or “crazes” [179] than during “flight panics”. That is, social behavior seems to be less stable if there is something to gain than if there is some external danger which threatens all members of a group. Examples of crazes (acquisitive panics) include the Victoria Hall Disaster (1883) [150], the crowning ceremony of Tsar Nicholas II (1896) [168], a governmental Christmas celebration in Aracaju (2001), the distribution of free Saris in Uttar Pradesh (2004), and the opening of an IKEA store in Jeddah (2004). Crowd accidents which occur at rock concerts and religious events as well bear more similarities with crazes than with panics.

However, it is not the case that altruism and cooperation increase with danger. The events during the capsizing of the MV Estonia (see Sect. 16.6 of [100]) show some behavioral threshold: faced with immediate life-threatening danger, most people struggle for their own survival or that of close relatives.

*Herding* Herding in a broad context means “go with the flow” or “follow the crowd”. Like “panic”, the term “herding” is often used in the context of stock market crashes, i. e., causing an avalanche effect. Like “panic” the term is usually not well defined and is used in an allegoric way. Therefore, it is advisable to avoid the term in a scientific context (apart from zoology, of course). Furthermore, “herding”, “stampede”, and “panic” have a strong connotation of “deindividuation”. The conjecture of an automatic deindividuation caused by large crowds [101] has been replaced by a social attachment theory (“the typical response to a variety of threats and disasters is not to flee but to seek the proximity of familiar persons and places”) [109].

*Stampede* Stampede is – like herding – a term from zoology where herds of large mammals, such as buffalo, collectively run in one direction and might overrun any obstacles. This is dangerous for human observers if they cannot get out of the way. The term “stampede” is sometimes used

for crowd accidents [73], too. It is furthermore assumed to be highly correlated with panic. When arguing along those lines, a stampede might be the result of “crowd panic” or vice versa.

**Shock or Density Waves** Shock waves are reported for rock concerts [180] and religious events [2,58]. They might result in people standing close to each other falling down. Pressures in dense crowds of up to 4, 450 N/m<sup>2</sup> have been reported.

Although empirical data on crowd disasters exist, e. g., in the form of reports from survivors or even video footage, it is almost impossible to derive quantitative results from them. Models that aim at describing such scenarios make predictions for certain counter-intuitive phenomena that should occur. In the faster-is-slower effect [54] a higher desired velocity leads to a slower movement of a large crowd. In the freezing-by-heating effect [53] increasing the fluctuations can lead to a more ordered state. For a thorough discussion we refer to [54,55] and references therein. However, from a statistical point of view there is insufficient data to decide the relevance of these effects in real emergency situations, not least because it is almost impossible to perform “realistic” experiments.

### Sources of Empirical Data on Evacuation Processes

The evacuation of a building can either be an isolated process (due to fire restricted to this building, a bomb threat, etc.) or it can be part of the evacuation of a complete area. We will focus on the single building evacuation, here. For the evacuation of complete areas, e. g., because of flooding or hurricanes, cf. [157] and references therein.

For passenger ships, a distinction between High Speed Craft (HSC), Ro-Ro passenger ferries, and other passenger vessels (cruise ships) is made. High Speed Craft do not have cabins and the seating arrangement is similar to aircraft. Therefore, there is a separate guideline for HSC [119]. A performance-based evacuation analysis at an early stage of design is required for HSC and Ro-Pax. There is currently no such requirement for cruise ships. For an overview of IMO’s requirements and the historical development up to 2001 cf. [27]. In addition to the five components for the overall evacuation time listed above, there are three more specific to ships:

- (6) Preparation time (for the life-saving appliances, i. e., lifeboats, life-rafts, davits, chutes),
- (7) Embarkation time, and
- (8) Launching time.

Therefore, the evacuation procedure on ships is more complex than for buildings. Additionally, SAR (Search

And Rescue) is an integral part of ship evacuation.

For High Speed Craft, the time limit is 17 minutes for evacuation [70], for Ro-Ro passenger ships it is 60 minutes [118], and for all other passenger ships (e. g., cruise ships) it is 60 minutes if the number of main vertical zones is less or equal to five and 80 minutes otherwise [118]. For HSC, no distinction is made between assembly and embarkation phases.

For aircraft, the approach can be compared to that of HSC. First, an evacuation test is mandatory and there is a time limit of 90 seconds that has to be complied to in the test [31].

In many countries there is no strict criterion for the maximum evacuation time of buildings. The requirements are based on minimum exit widths and maximum escape path lengths.

A number of real evacuations has been investigated and reports are publicly available. Among the most recent ones are: Beverly Hills Club [12], MGM Grand Hotel, [12], retail store [4], department store [1], World Trade Center [47] and [www.wtc.nist.gov](http://www.wtc.nist.gov), high-rise buildings [144, 173], theater [191] for buildings, High Speed Craft “Sleipner” [138] for HSC, an overview up to 1998 [143], exit width variation [121], double deck aircraft [74], another overview for aircraft [120], and for trains [43,169].

### Modeling

A comprehensive theory of pedestrian dynamics has to take into account three different levels of behavior (Fig. 8). At the *strategic level*, pedestrians decide which activities they like to perform and the order of these activities. With

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 8

The different levels of modeling pedestrian behavior (after [19, 65])

the choices made at the strategic level, the *tactical level* concerns the short-term decisions made by the pedestrians, e. g., choosing the precise route taking into account obstacles, density of pedestrians etc. Finally, the *operational level* describes the actual walking behavior of pedestrians, e. g., their immediate decisions necessary to avoid collisions etc.

Processes at the strategic and tactical level are usually considered to be exogenous to pedestrian simulation. Here information from other disciplines (sociology, psychology etc.) is required. In the following we will mostly be concerned with the operational level, although some of the models that we are going to describe allow us to take into account certain elements of behavior at the tactical level as well.

Modeling on the operational level is usually based on variations of models from physics. Indeed the motion of pedestrian crowds shares certain similarities with fluids and the flow of granular materials. The goal is to find models which are as simple as possible, but at the same time can reproduce “realistic” behavior in the sense that the empirical observations are reproduced. Therefore, based on the experience from physics, pedestrians are often modeled as simple “particles” that interact with each other.

There are several characteristics which can be used to classify the modeling approaches:

**Microscopic vs. macroscopic** In microscopic models each individual is represented separately. Such an approach allows us to introduce different types of pedestrians with individual properties as well as issues such as route choice. In contrast, in macroscopic models, individuals cannot be distinguished. Instead the state of the system is described by densities, usually a mass density derived from the positions of the persons and a corresponding locally averaged velocity.

**Discrete vs. continuous** Each of the three basic variables for a description of a system of pedestrians, namely space, time and state variable (e. g., velocities), can be either discrete (i. e., an integer number) or continuous (i. e., a real number). Here all combinations are possible. In a cellular automaton approach all variables are by definition discrete, whereas in hydrodynamic models all are continuous. These are the most common choices, but other combinations are used as well. Sometimes for a cellular automata approach a continuous time variable is also allowed. In computer simulation this is realized through a *random-sequential update* where at each step the particle or site to be updated (moved) is chosen randomly (from *all* particles or sites, respectively). A discrete time is usually real-

ized through a *parallel* or *synchronous update* where all particles or sites are moved at the same time. This introduces a timescale. In so-called coupled map lattices time is discrete, whereas space and state variables are continuous.

**Deterministic vs. stochastic** The dynamics of pedestrians can either be deterministic or stochastic. In the first case the behavior at a certain time is completely determined by the present state. In stochastic models, behavior is controlled by certain probabilities such that the agents can react differently in the same situation. This is one of the lessons learnt from the theory of complex systems where it has been shown for many examples that through introduction of stochasticity into rather simple systems very complex behavior can be generated. On the other hand, the stochasticity in the models reflects our lack of knowledge of the underlying physical processes that, e. g., determine the decision-making of the pedestrians. Through stochastic behavioral rules it often becomes possible to generate a rather realistic representation of complex systems such as pedestrian crowds.

This “intrinsic” stochasticity should be distinguished from “noise”. Sometimes external noise terms are added to the *macroscopic* observables, such as position or velocity. Often the main effect of these terms is to avoid certain special configurations which are considered to be unrealistic, like completely blocked states. Otherwise the behavior is very similar to the deterministic case. For true stochasticity, on the other hand, the deterministic limit usually has very different properties from the generic case.

**Rule-based vs. force-based** Interactions between the agents can be implemented in at least two different ways: In a rule-based approach agents make “decisions” based on their current situation, the nature of their neighborhood as well as their goals, etc. It focuses on the *intrinsic properties* of the agents and thus the rules are often justified from psychology. In force-based models, agents “feel” a force exerted by others and the infrastructure. They therefore emphasize *extrinsic properties* and their relevance for the motion of the agents. This is a physical approach based on the observation that the presence of others leads to deviations from a straight motion. In analogy to Newtonian mechanics a force is made responsible for these accelerations.

Cellular automata are typically rule-based models, whereas, e. g., the social-force model belongs to the force-based approaches. However, sometimes a clear

distinction cannot be made; many models combine aspects of both approaches.

**High vs. low fidelity** *Fidelity* here refers to the apparent realism of the modeling approach. High fidelity models try to capture the complexity of decision making, actions, etc. that constitute pedestrian motion in a realistic way. In contrast, in the simplest models pedestrians are represented by particles without any intelligence. Usually the behavior of these particles is determined by “forces”. This approach can be extended, e. g., by allowing different “internal” states of the particles so that they react differently to the same force depending on the internal state. This can be interpreted as some kind of “intelligence” and leads to more complex approaches, like multi-agent models. Roughly speaking, the number of parameters in a model is a good measure for fidelity in the sense introduced here, but note that higher fidelity does not necessarily mean that empirical observations are reproduced better!

It should be mentioned that a clear classification according to the characteristics outlined here is not always possible. In the following we will describe some model classes in more detail.

### Fluid-dynamic and Gas kinetic Models

Pedestrian dynamics has some obvious similarities with fluids. For example, the motion around obstacles appears to follow “streamlines”. Motion at intermediate densities is restricted (short-ranged correlations). Therefore it is not surprising that, very much like for vehicular dynamics, the earliest models of pedestrian dynamics took inspiration from hydrodynamics or gas-kinetic theory [50,61,68,69]. Typically these macroscopic models are deterministic, force-based and of low fidelity.

Henderson [60,61] has tried to establish an analogy of large crowds with a classical gas. From measurements of motion in different crowds in a low density (“gaseous”) phase he found good agreement of the velocity distribution functions with Maxwell-Boltzmann distribution [60].

Motivated by this observation, he later developed a fluid-dynamic theory of pedestrian flow [61]. Describing the interactions between the pedestrians as a collision process where the particles exchange momenta and energy, a homogeneous crowd can be described by the well-known kinetic theory of gases. However, the interpretation of the quantities is not entirely clear, e. g., what the analogues of pressure and temperature are in the context of pedestrian motion. Temperature could be identified with the velocity

variance, which is related to the distribution of desired velocities, whereas the pressure expresses the desire to move against a force in a certain direction.

The applicability of classical hydrodynamic models is based on several conservation laws. The conservation of mass, corresponding to conservation of the total number of pedestrians, is expressed through a continuity equation of the form

$$\frac{\partial \rho(\mathbf{r}, t)}{\partial t} + \nabla \cdot \mathbf{J}(\mathbf{r}, t) = 0, \quad (6)$$

which connects the local density  $\rho(\mathbf{r}, t)$  with the current  $\mathbf{J}(\mathbf{r}, t)$ . This equation can be generalized to include source and sink terms. However, the assumption of conservation of energy and momentum is not true for interactions between pedestrians which in general do not even satisfy Newton’s Third Law (“actio = reaction”). In [50] several other differences to normal fluids were pointed out, e. g., the anisotropy of interactions or the fact that pedestrians usually have an individual preferred direction of motion.

In [50] a better founded fluid-dynamical description was derived on the basis of a gas kinetic model which describes the system in terms of a density function  $f(\mathbf{r}, \mathbf{v}, t)$ . The dynamics of this function are determined by Boltzmann’s transport equation that describes its change for a given state as difference of inflow and outflow due to binary collisions.

An important new aspect in pedestrian dynamics is the existence of desired directions of motion which allows us to distinguish different groups  $\mu$  of particles. The corresponding densities  $f_\mu$  change in time due to four different effects:

1. A relaxation term with characteristic time  $\tau$  describes tendency of pedestrians to approach their intended velocities.
2. The interaction between pedestrians is modeled by a Stosszahlansatz as in the Boltzmann equation. Here, pair interactions between types  $\mu$  and  $\nu$  occur with a total rate that is proportional to the densities  $f_\mu$  and  $f_\nu$ .
3. Pedestrians are allowed to change from type  $\mu$  to  $\nu$  which, e. g., accounts for turning left or right at a crossing.
4. Additional gain and loss terms allow us to model entrances and exits where pedestrian can enter or leave the system.

The resulting fluid-dynamic equations derived from this gas kinetic approach are similar to that of ordinary fluids. However, due to the different types of pedestrians, corre-

sponding to individuals who have approximately the same desired velocity, one actually obtains a set of coupled equations describing several interacting fluids. These equations contain additional characteristic terms describing the approach to the intended velocity and the change of fluid-type due to interactions in avoidance maneuvers.

Equilibrium is approached through the tendency to walk with the intended velocity, not through interactions as in ordinary fluids. Momentum and energy are not conserved in pedestrian motion, but the relaxation towards the intended velocity describes a tendency to restore these quantities.

Unsurprisingly for a macroscopic approach, the gasekinetic models have problems at low densities. For a discussion, see e. g. [50].

**Hand Calculation method** For practical applications effective engineering tools have been developed from the hydrodynamical description. In engineering these are often called *hand calculation methods*. One could also classify some of them as queuing models since the central idea is to describe pedestrian dynamics as flow on a network with links of limited capacities. These methods allow us to calculate evacuation times in a relatively simple way that does not require any simulations. Parameters entering in the calculations can be adapted to the situation that is studied. Often they are based on empirical results, e. g., evacuation trials. Details about this kind of model can be found in Subsect. “**Calculation of Evacuation Times**”.

### Social-Force Models

The social-force model [52] is a deterministic continuum model in which interactions between pedestrians are implemented by using the concept of a *social force* or *social field* [103]. It is based on the idea that changes in behavior can be understood in terms of fields or forces. Applied to pedestrian dynamics, the social force  $\mathbf{F}_j^{(\text{soc})}$  represents the influence of the environment (other pedestrians, infrastructure) and changes the velocity  $\mathbf{v}_j$  of pedestrian  $j$ . Thus it is responsible for acceleration which justifies the interpretation as a force. The basic equation of motion for a pedestrian of mass  $m_j$  is then of the general form

$$\frac{d\mathbf{v}_j}{dt} = \mathbf{f}_j^{(\text{pers})} + \mathbf{f}_j^{(\text{soc})} + \mathbf{f}_j^{(\text{phys})} \quad (7)$$

where  $\mathbf{f}_j^{(\text{soc})} = \frac{1}{m_j} \mathbf{F}_j^{(\text{soc})} = \sum_{l \neq j} \mathbf{f}_{jl}^{(\text{soc})}$  is the total (specific) force due to other pedestrians.  $\mathbf{f}_j^{(\text{pers})}$  denotes a “personal” force which makes a pedestrian attempt to move with his or her own preferred velocity  $\mathbf{v}_j^{(0)}$  and thus acts as a driving

term. It is given by

$$\mathbf{f}_j^{(\text{pers})} = \frac{\mathbf{v}_j^{(0)} - \mathbf{v}_j}{\tau_j} \quad (8)$$

where  $\tau_j$  is reaction or acceleration time. In high density situations, physical forces  $\mathbf{f}_{jl}^{(\text{phys})}$  also become important, e. g., friction and compression when pedestrians make contact.

The most important contribution to the social force  $\mathbf{f}_j^{(\text{soc})}$  comes from the territorial effect, i. e., the private sphere. Pedestrians feel uncomfortable if they get too close to others, which effectively leads to a repulsive force between them. Similar effects are observed for the environment, e. g., people prefer not to walk too close to walls.

Since social forces are difficult to determine empirically, some assumptions must be made. Usually an exponential form is assumed. Describing the pedestrians as disks of radius  $R_j$  and position (of the center of mass)  $\mathbf{r}_j$ , the typical structure of the force between the pedestrians is described by [54]

$$\mathbf{f}_{jl}^{(\text{soc})} = A_j \exp \left[ \frac{R_{jl} - \Delta r_{jl}}{\xi_j} \right] \mathbf{n}_{jl} \quad (9)$$

with  $R_{jl} = R_j + R_l$ , the sum of the disk radii,  $\Delta r_{jl} = |\mathbf{r}_j - \mathbf{r}_l|$ , the distance between the centers of mass,  $\mathbf{n}_{jl} = \mathbf{r}_j - \mathbf{r}_l / \Delta r_{jl}$ , the normalized vector pointing from pedestrian  $l$  to  $j$ .  $A_j$  can be interpreted as strength,  $\xi_j$  as the range of the interactions.

The appeal of the social-force model is given mainly by analogy to Newtonian dynamics. For the solution of the equations of motion of Newtonian many-particle systems, well-founded molecular dynamics techniques exist. However, in most studies so far the distinctions between pedestrian and Newtonian dynamics are not discussed in detail. A straightforward implementation of the equations of motion neglecting these distinctions can lead to unrealistic movement of single pedestrians. For example, negative velocities in the main moving direction cannot be excluded in general even if asymmetric interactions (violating Newton’s Third Law) between the pedestrians are chosen. Another effect is the occurrence of velocities higher than the preferred velocity  $v_j^{(0)}$  due to the forces on pedestrians in the moving direction. To prevent this effect, additional restrictions for the degrees of freedom must be introduced, see for example [52], or the superposition of forces has to be discarded [175]. A general discussion of the limited analogy between Newtonian dynamics and the social-force model as well as the consequences for model implementations is still missing.

Apart from the ad hoc introduction of interactions, the structure of the social-force model can also be derived from an extremal principle [62,63]. It follows under the assumption that pedestrian behavior is determined by the desire to minimize a certain cost function which takes into account not only kinematic aspects and walking comfort, but also deviations from a planned route.

### Cellular Automata

Cellular automata (CA) are rule-based dynamical models that are discrete in space, time and state variable which in the case of traffic usually corresponds to velocity. Discreteness in time means that the positions of the agents are updated in well defined steps. In computer simulations this is realized through a *parallel* or *synchronous* update where all pedestrians move at the same time. The time step corresponds to a natural timescale  $\Delta t$  which could be identified, e. g., with some reaction time. This can be used for the calibration of the model which is essential for making quantitative predictions. A natural space discretization can be derived from the maximal densities observed in dense crowds which gives the minimal space requirement of one person. Usually each cell in the CA can be occupied by only one particle (exclusion principle) so that this space requirement can be identified with the cell size. In this way, a maximal density of  $6.25 \text{ P/m}^2$  [192] leads to a cell size of  $40 \times 40 \text{ cm}^2$ . Sometimes finer discretizations are more appropriate (see Subsect. “Theoretical Results”). In this case pedestrians correspond to extended particles that occupy more than one cell (e. g., four cells). The exclusion principle and the modeling of humans as non-compressible particles mimics short-range repulsive interactions, i. e., the “private-sphere”.

The dynamics are usually defined by rules which specify transition probabilities for motion to one of the neighboring cells (Fig. 9). The models differ in the specification of these probabilities as well in that of the “neighborhood”. For deterministic models, all but one are of probability zero.

The first cellular automata (CA) models [7,41,89,129] for pedestrian dynamics can be considered two-dimensional variants of the asymmetric simple exclusion process (ASEP) (for reviews, see [9,23,172]) or models for city or highway traffic [6,16,133] based on it. Most of these models represent pedestrians by particles without any internal degrees of freedom. They can move to one of the neighboring cells based on certain transition probabilities which are determined by three factors:

(1) The desired direction of motion, e. g., to find the shortest connection,

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 9

A particle, its possible directions of motion and the corresponding transition probabilities  $p_{ij}$  for the case of a von Neumann neighborhood

- (2) Interactions with other pedestrians, and
- (3) Interactions with the infrastructure (walls, doors, etc.).

**Fukui–Ishibashi Model** One of the first CA models for pedestrian dynamics was proposed by Fukui and Ishibashi [40,41] and is based on a two-dimensional variant of the ASEP. They studied bidirectional motion in a long corridor where particles moving in opposite directions were updated alternatingly. Particles move deterministically in their desired direction; only if the desired cell is occupied by an oppositely moving particle do they make a random sidestep.

Various extensions and variations of the model have been proposed, e. g., an asymmetric variant [129] where walkers prefer lane changes to the right, different update types [193], simultaneous (exchange) motion of pedestrians standing “face-to-face” [72], or the possibility of backstepping [107]. The influence of the shape of the particles has been investigated in [131]. Also other geometries [128, 181] and extensions to full 2-dimensional motion have been studied in various modifications [106,107,127]

**Blue–Adler Model** The model of Blue and Adler [7,8] is based on a variant of the Nagel–Schreckenberg model [133] of highway traffic. Pedestrian motion is considered in analogy to a multi-lane highway. The structure of the rules is similar to the basic two-lane rules suggested in [159]. The update is performed in four steps which are applied to all pedestrians in parallel. In the first step each pedestrian chooses a preferred lane. In the second step the lane changes are performed. In the third step the velocities are determined based on the available gap in the new lanes. Finally, in the fourth step the pedestrians move forward according to the velocities determined in the previous step.

In counterflow situations head-on-conflicts occur. These are resolved stochastically and with some probability opposing pedestrians are allowed to exchange positions within one time step. Note that the motion of a single pedestrian (not interacting with others) is deterministic otherwise.

Unlike the Fukui–Ishibashi model, motion is not restricted to nearest-neighbor sites. Instead, pedestrians can have different velocities  $v_{\max}$  which correspond to the maximal number of cells they are allowed to move forward. In contrast to vehicular traffic, acceleration to  $v_{\max}$  can be assumed to be instantaneous in pedestrian motion.

In order to study the effects of inhomogeneities, the pedestrians are assigned different maximal velocities  $v_{\max}$ . Fast walkers have  $v_{\max} = 4$ , standard walkers  $v_{\max} = 3$  and slow walkers  $v_{\max} = 2$ . The cell size is assumed to be  $50 \text{ cm} \times 50 \text{ cm}$ . The best agreement with empirical observations has been achieved with 5% slow and 5% fast walkers [8]. Furthermore the fundamental diagram in more complex situations, such as bi- or four-directional flows, has been investigated.

**Gipps–Marksjös Model** A more sophisticated discrete model was suggested by Gipps and Marksjös [45] in 1985. One motivation for developing a discrete model was the limited computer power at that time. Therefore a discrete model, which reproduces the properties of pedestrian motion realistically, was in many respects a real improvement over the existing continuum approaches.

Interactions between pedestrians are assumed to be repulsive, anticipating the idea of social forces (see Subsect. “**Social-Force Models**”). The pedestrians move on a grid of rectangular cells of size  $0.5 \times 0.5 \text{ m}$ . To each cell a score is assigned based on its proximity to other pedestrians. This score represents the repulsive interactions and actual motion is then determined by the competition between these repulsions and the gain of approaching the destination. Applying this procedure to all pedestrians, a potential value is assigned to each cell which is the sum of the individual contributions. The pedestrian then selects the cell of its nine neighbors (Moore neighborhood) which leads to the maximum benefit. This benefit is defined as the difference between the gain of moving closer to the destination and the cost of moving closer to other pedestrians as represented by the potential. This requires a suitable chosen gain function  $P$ .

The updating is done sequentially to avoid conflicts of several pedestrians trying to move to the same position. In order to model different velocities, faster pedestrians are updated more frequently. Note that the model dynamics are deterministic.

**Floor Field CA** Floor field CA [13,14,83,167] can also be considered as an extension of the ASEP. However, the transition probabilities to neighboring cells are no longer fixed but vary dynamically. This is motivated by the process of chemotaxis (see [5] for a review) used by some insects (e. g., ants) for communication. They create a chemical trace to guide other individuals to food sources. In this way a complex trail system is formed that has many similarities with human transport networks.

In the approach of [13] the pedestrians also create a trace. In contrast to chemotaxis, however, this trace is only virtual, although one could assume that it corresponds to some abstract representation of the path in the mind of the pedestrians. Although this is mainly a technical trick which reduces interactions to local ones that allow efficient simulations in arbitrary geometries, one could also think of the trail as representation of the paths in the mind of a pedestrian. The locality becomes important in complex geometries as no algorithm is required to check whether the interaction between particles is screened by walls, etc. The number of interaction terms always grows linearly with the number of particles.

The translation into local interactions is achieved by the introduction of so-called *floor fields*. The transition probabilities for all pedestrians depend on the strength of the floor fields in their neighborhood in such a way that transitions in the direction of larger fields are preferred. The *dynamic floor field*  $D_{ij}$  corresponds to a virtual trace which is created by the motion of the pedestrians and in turn influences the motion of other individuals. Furthermore it has its own dynamics, namely through diffusion and decay, which leads to a dilution and finally the vanishing of the trace after some time. The *static floor field*  $S_{ij}$  does not change with time since it only takes into account the effects of the surroundings. Therefore it exists even without any pedestrians present. It allows us to model, e. g., preferred areas, walls and other obstacles. Figure 10 shows the static floor field used for the simulation of evacuations from a room with a single door. Its strength decreases with increasing distance from the door. Since the pedestrians prefer motion into the direction of larger fields, this is already sufficient to find the door.

Coupling constants control the relative influence of both fields. For a strong coupling to the static field pedestrians will choose the shortest path to the exit. This corresponds to a ‘normal’ situation. A strong coupling to the dynamic field implies a strong herding behavior where pedestrians try to follow the lead of others. This often happens in emergency situations.

The model uses a fully parallel update. Therefore conflicts can occur where different particles choose the same

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 10

**Left:** Static floor field for the simulation of an evacuation from a large room with a single door. The door is located in the middle of the upper boundary and the field strength increases with increasing intensity. **Right:** Snapshot of the dynamical floor field created by people leaving the room

destination cell. This is relevant for high density situations and happens in all models with parallel update if motion in different directions is allowed. Conflicts have been considered a technical problem for a long time and usually the dynamics have been modified in order to avoid them. The simplest method is to update pedestrians sequentially instead of using fully parallel dynamics. However, this leads to other problems, e. g., the identification of the relevant timescale. Therefore it has been suggested in [84,85] to take these conflicts seriously as an important part of the dynamics.

For the floor field model it has been shown in [85] that the behavior becomes more realistic if not all conflicts are resolved by allowing one pedestrian to move while the others stay at their positions. Instead with probability  $\mu \in [0, 1]$ , which is called the friction parameter, the movement of *all* involved pedestrians is denied [85] (see Fig. 11).

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 11

Refused movement due to the friction parameter  $\mu$  (for  $m = 4$ )

This allows one to describe clogging effects between the pedestrians in a much more detailed way [85].  $\mu$  works as some kind of local pressure between the pedestrians. If  $\mu$  is high, the pedestrians handicap each other trying to reach their desired target sites. This local effect can have enormous influence on macroscopic quantities like flow and evacuation time [85]. Note that the kind of friction introduced here only influences interacting particles, not the average velocity of a freely moving pedestrian.

Surprisingly, the qualitative behaviors of the floor field model and the social-force models are very similar despite the fact that the interactions are very different. In the floor field model interactions are attractive, whereas in the social-force model they are repulsive. However, in the latter interactions are between particle densities. In contrast, in the floor field model the particle density interacts with the velocity density.

### Other Approaches

**Lattice-gas models** In 1986, Frisch, Hasslacher, and Pomeau [34] showed that one does not have to take into account detailed molecular motion within fluids in order to obtain a realistic picture of (2d) fluid dynamics. They proposed a lattice gas model [164,165] on a triangular lattice with hexagonal symmetry, which is similar in spirit to CA models, but the exclusion principle is relaxed: particles with different velocities are allowed to occupy the same site. Note that the allowed velocities differ only in the direction, not absolute value. The dynamics are based on a succession of collision and propagation that can be chosen in such a way that the coarse-grained averages of this microscopic dynamic is asymptotically equivalent to the Navier–Stokes equations of incompressible fluids.

In [108] a kind of mesoscopic approach inspired by these lattice gas models has been suggested as a model for pedestrian dynamics. In analogy with the description of transport phenomena in fluids (e. g., the Boltzmann equation) the dynamics are based on a succession of collision and propagation.

Pedestrians are modeled as particles, moving on a triangular lattice, which have a preferred direction of motion  $\mathbf{c}_F$ . However, the particles do not strictly follow this direction but also have a tendency to move with the flow. Furthermore, at high densities the crowd motion is influenced by a kind of friction which slows down the pedestrians. This is achieved by reducing the number of individuals allowed to move to neighboring sites.

As in a lattice gas model [165], the dynamics now consists of two steps. In the *propagation step* each pedestrian moves to the neighbor site in the direction of its velocity

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 12

The dynamics of lattice gas models proceed in two steps. Pedestrians coming from neighboring sites interact in the collision step where velocities are redistributed. In the propagation step the pedestrians move to neighbor sites in directions determined by the collision step

vector. In the *collision step* the particles interact and new velocities (directions) are determined. In contrast to physical systems, momentum, etc., does not need to be conserved during the collision step. These considerations lead to a collision step that takes into account the favorite direction  $\mathbf{c}_F$ , the local density (the number of pedestrians at the collision site), and a quantity called mobility at all neighbor sites which is a normalized measure of the local flow after the collision.

**Optimal-Velocity Model** The optimal velocity (OV) model originally introduced for the description of highway traffic can be generalized to higher dimensions [134] which allows its application to pedestrian dynamics.

In the two-dimensional extension of the OV model the equation of motion for particle  $i$  is given by

$$\frac{d^2}{dt^2}\mathbf{x}_i(t) = a \left\{ \mathbf{v}_0 + \sum_j \mathbf{v}(\mathbf{x}_j(t) - \mathbf{x}_i(t)) - \frac{d}{dt}\mathbf{x}_i(t) \right\}, \quad (10)$$

where  $\mathbf{x}_i = (x_i, y_i)$  is the position of particle  $i$ . It can be considered as a special case of the general social-force model (7) without physical forces. The optimal-velocity function

$$\mathbf{V}(\mathbf{x}_j - \mathbf{x}_i) = f(r_{ij})(1 + \cos \varphi)\mathbf{n}_{ij}, \quad (11)$$

$$f(r_{ij}) = \alpha \{ \tanh \beta(r_{ij} - b) + c \}, \quad (12)$$

where  $r_{ij} = |\mathbf{x}_j - \mathbf{x}_i|$ ,  $\cos \varphi = (x_j - x_i)/r_{ij}$  and  $\mathbf{n}_{ij} = (\mathbf{x}_j - \mathbf{x}_i)/r_{ij}$  is determined by interactions with other pedestrians.  $\mathbf{v}_0$  is a constant vector that represents a ‘desired velocity’ at which an isolated pedestrian would move. The strength of the interaction depends on the distance  $r_{ij}$  between the  $i$ th and  $j$ th particles, and on the angle  $\varphi$  between the directions of  $\mathbf{x}_j - \mathbf{x}_i$  and the current velocity  $d\mathbf{x}_i/dt$ . Due to the term  $(1 + \cos \varphi)$ , a particle reacts more sensitively to particles in front than to those behind.

Now two cases can be distinguished: repulsive and attractive interactions. The former is relevant for pedestrian dynamics whereas the latter is more suitable for biological motion. Therefore, for pedestrian motion one chooses  $c = 1$  which implies  $f < 0$ .

A detailed analysis [134] shows that the model exhibits a rich phase diagram including the formation of various patterns.

**Other Models** We briefly mention a few other model approaches that have been suggested. In [10] a discretized version of the social-force model has been introduced and shown to reproduce qualitatively the observed collective phenomena.

In [141] a magnetic force model has been proposed where pedestrians and their goals are treated as magnetic poles of opposite sign.

Another class of models is based on ideas from queuing theory. In principle, some hand calculation methods can be considered as macroscopic queuing models. Typically, rooms are represented as nodes in the queuing network and links correspond to doors. In microscopic approaches, in the movement process each agent chooses a new node, e. g., according to some probability [105].

## Theoretical Results

As emphasized in Subject. “**Collective Effects**”, the collective effects observed in the motion of pedestrian crowds are a direct consequence of microscopic dynamics. These effects are reproduced quite well by some models, e. g., the social-force and floor-field model, at least on a qualitative level. As mentioned before, the qualitative behavior of the two models is rather similar despite the very different implementation of the interactions. This indicates a certain robustness of the collective phenomena observed.

As an example we discuss the formation of lanes in counterflow formation. Empirically one observes a strong

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 13

Lane formation in the floor-field model. The central window is the corridor and the light and dark squares are right- and left-moving pedestrians, respectively. In the bottom part well-separated lanes can be observed whereas in the top part the motion is still disordered. The right part of the figure shows the floor fields for the right-movers (*upper half*) and left-movers (*lower half*)

tendency to follow immediately in the “wake” of another person heading in the same direction. Such lane formation was reproduced in the social-force model [52,53] as well as in the floor-field model [13,76] (see Fig. 13). While the formation of lanes in general is essential to avoid deadlocks and thus keep the chance of reproducing realistic fluxes, the number of direction changes per meter cross section is a parameter which in reality crucially depends on the situation [76]: the longer a counterflow situation is assumed to persist, the fewer lanes per meter cross section can be found. The correct reproduction of counterflow is an issue for an accommodating animation, but more or less unimportant for macroscopic observables. This is probably the main reason why there seems to have been little effort put into the attempt to reproduce different “kinds” of lane formation in a controlled, situation-dependent manner.

On the quantitative side, the fundamental diagram is the first and most serious test for any model. Since most quantitative results rely on the fundamental diagram, it can be considered the most important characteristic of pedestrian dynamics. It is not only relevant for movement in a corridor or through a bottleneck, but also as an important determinant of evacuation times. However, as emphasized earlier, there is currently no consensus on the empirical form of the fundamental diagram. Therefore, a calibration of the model parameters is currently difficult.

Most cellular automata models are based on the asymmetric simple exclusion process. This strictly one-dimensional stochastic process has a fundamental diagram which is symmetric around density  $\rho = 1/2$ . Lane changes in two-dimensional extensions lead to only a small shift towards smaller densities. Despite the discrepancies in the empirical results, an almost symmetric fundamental diagram can be excluded.

Based on the experience with modeling of highway traffic [16,133], models with higher speeds have been introduced which naturally lead to an asymmetric fundamental diagram. Typically this is implemented by allowing the agents to move more than one cell per update step [82, 86,87,92,195,196]. These model variants have been shown to be flexible enough to reproduce, e. g., Weidmann’s fundamental diagram for the flow in a corridor [192] with high precision. Usually in the simulations a homogeneous population is assumed. However, in reality, different pedestrians have different properties such as walking speed, motivation, etc. This is easily taken into account in every microscopic model. There are many parameters that could potentially have an influence on the fundamental diagram. However, the current empirical situation does not allow to decide this question.

Another problem occurring in CA models has its origin in the discreteness of space. Through the choice of the lattice discretization, space is no longer isotropic. Motion in directions not parallel to the main axis of the lattice are

difficult to realize and can only be approximated by a sequence of steps parallel to the main directions.

Higher velocities also require the extension of the neighborhood of a particle which is no longer identical to the cells adjacent to the current position. A natural definition of “neighborhood” corresponds to those cells that could be reached within one time step. In this way the introduction of higher velocities also reduces the problem of space isotropy as the neighborhoods become more isotropic for larger velocities.

Other solutions to this problem have been proposed. One way is to count the number of diagonal steps and let the agent suspend from moving following certain rules which depend on the number of diagonal steps [171]. A similar idea is to sum up the real distance that an agent has moved during one round: a diagonal step counts  $\sqrt{2}$  and a horizontal or vertical step counts 1. An agent has to finish its round as soon as this sum is bigger than its speed [87]. A third possibility – which works for arbitrary speeds – is to assign selection probabilities to each of the four lattice positions adjacent to the exact final position [195,196]. Naturally these probabilities are inversely proportional to the square area between the exact final position and the lattice point, as in this case the probabilities are normalized by construction if one has a square lattice with points on all integer number combinations. However, one also could think of other methods to calculate the probability.

For the social-force model, the specification of the repulsive interaction (with and without hard core, exponential or reciprocal with distance) as well as the parameter sets for the forces changes in different publications [52,53,54,114]. In [55] the authors state that “most observed self-organization phenomena are quite insensitive to the specification of interaction forces”. However, at least for the fundamental diagram, a relation connected with all phenomena in pedestrian dynamics, this statement is questionable. As remarked in [56] the reproduction of the fundamental diagram “requires a less simple specification of the repulsive interaction forces”. Indeed in [175] it was shown that the choice of hard-core forces or repulsive soft interactions as well as the particular parameter set can strongly influence the resulting fundamental diagram regarding qualitative as well as quantitative effects.

Also a more realistic behavior at higher densities requires a modification of the basic model. Here the use of density-dependent desired velocities leads to a reduction of the otherwise unrealistically large number of collisions [10].

The particular specification of forces and the previously mentioned problem with Newton’s Third law can

lead in principle to some unwanted effects, such as momentary velocities larger than the preferred velocity [52] or the penetration of pedestrians into each other or into walls [98]. It is possible that these effects can be suppressed for certain parameter sets by contact or friction forces, but the general appearance is not excluded. Only in the first publication [52] are restrictions for the velocity explicitly formulated to prevent velocities larger than the intended speed; other authors tried to improve the model by introducing more parameters [98]. But additional parameter and artificial restrictions of variables diminish the simplicity and thus the attractiveness of the model. A general discussion of how to deal with these problems of the social-force model and a verification that the observed phenomena are not limited to a certain specification of the interaction and a special parameter set is up to now still missing.

While realistic reproduction within the empirical range of these macroscopic observables, especially the fundamental diagram, is absolutely essential to guarantee safety standards in evacuation simulations, and while a user should always be distrustful of models where no fundamental diagram has ever been published, it is by no means sufficient to exclusively check for the realism of macroscopic observables. On the microscopic level there are a large number of phenomena which need to be reproduced realistically, be it just to make a simulation animation look realistic or because microscopic effects can often easily influence macroscopic observables.

If one compares simulations of bottleneck flows with real events, one observes that in simulations the form of the queue in front of bottlenecks is often a half-circle, while in reality it is drop- or wedge-shaped. In most cases this discrepancy probably does not have an influence on the simulated evacuation time, but it is interesting to note where it originates from. Most simulation models implicitly or explicitly use some kind of utility maximization to steer the pedestrians – with the utility being foremost inversely proportional to the distance from the nearest exit. This obviously leads to half-circle-shaped queues in front of bottlenecks. So wherever one observes queues different than half-circles, people have exchanged their normal “utility function based on the distance” with something else. One such alternative utility function could be that people are just curious about what is inside or behind the bottleneck, so they seek a position where they can look into it. A more probable explanation would be that in any case it is the time distance not the spatial distance which is sought to be minimized. As anyone knows what the inescapable loss in time a bottleneck means for the whole waiting group, the precise waiting spot is not that impor-

tant. However, in societies with a strong feeling for equality, people would strongly wish to equally distribute the waiting time and keep a first-in-first-out principle, which can best be accomplished and controlled when the queue is more or less one-dimensional, respectively just as wide as the bottleneck itself.

Finally it should be mentioned that theoretical investigations based on simulations of models for pedestrian dynamics have led to the prediction of some surprising and counter-intuitive collective phenomena, such as the reduction of evacuation times through additional columns near exits (see Subsect. “**Bottleneck Flow**”) or the faster-is-slower [54] and freezing-by-heating effect [53]. However, so far the empirical evidence for the relevance or even the occurrence of these effects in real situations is rather scarce.

## Applications

In the following section we discuss more practical aspects of based on the modeling concepts presented in Sect. “**Modeling**”. Tools of different sophistication have been developed that are nowadays routinely used in safety analysis. The latter becomes more and more relevant since many public facilities must fulfill certain legal standards. As an example we mention aircrafts which must be evacuated within 90 seconds. The simulations etc. are already used in the planning stages because changes of the design at a later stage are difficult and expensive.

For this kind of safety analysis tools of different sophistication have been developed. Some of them mainly are able to predict just evacuation times whereas others are based on microscopic simulations which allow also to study various external influences (fire, smoke, ...) in much detail.

## Calculation of Evacuation Times

The basic idea of hand calculation methods has already briefly been described at the end of Subsect. “**Fluid-Dynamic and Gas Kinetic Models**”. Here we want to discuss its practical aspects in more detail.

The approach has been developed since the middle of the 1950s [185]. The basic idea of these methods is the assumption that people can be modeled to behave like fluids. Knowledge of the flow (see Eq. 1) and the technical data of the facility are then sufficient to evaluate evacuation times, etc.

Hand calculation method can be divided into two major approaches: methods with “dynamic” flow [35,42,78,79,80,136,151,152,163,192] and methods with “fixed” flow [110,123,124,125,126,137,145,173,185]. As methods

with “dynamic” flow we cite methods where the pedestrian flow is dependent on the density of the pedestrian stream (see Subsect. “**Observables**”) in the selected facility, thus the flow can be obtained from fundamental diagrams (see Subsect. “**Fundamental Diagram**”) or it is explicitly prescribed in the chosen method. This flow can change during movement through the building, e. g., by using stairs, thus the pedestrian stream has a “dynamic” flow. Methods with “fixed” flow do not use this concept of relationship between density and flow. In these methods selected facilities (e. g., stairs or doors) have a fixed flow which is independent from the density, which is usually not used in these methods. The “fixed” flow is usually based upon empirical and measured data of flow, which are specified for a special type of building, such as high-rise buildings or railway stations, for example. Because of much simplification, in these “fixed” flow methods a calculation can always be done very quickly.

Methods with “dynamic” flow allow one to describe the condition of the pedestrian flow in every part of a selected building or environment, because they are mostly based upon the continuity equation, thus it is possible to calculate different kinds of buildings. This allows the user to calculate transitions from wide to narrow, floor to door, floor to stair, etc. The disadvantage is that some these methods are very elaborate and time-intensive. But in general, a method with “dynamic” flow is not complicated to calculate, thus we want to divide hand calculation methods in simple [35,42,110,123,124,125,126,136,137,145,152,163,173,185,192] and complex [78,79,80,151] for evacuation calculation. All of these hand calculation methods are able to predict total evacuation times for a selected building, but differences between different methods still exist. Thus the user has to ensure that he is familiar with assumptions made by each method to ensure that a result is interpreted in a correct way [161].

## Simulation of Evacuation Processes

Before we go into the details of evacuation simulation, let us briefly clarify its scope and limitations and contrast it to other methods used in evacuation analysis. When analyzing evacuation processes, three different approaches can be identified:

- (1) Risk assessment,
- (2) Optimization, and
- (3) Simulation.

The aim and result of risk-assessment is a list of events and their consequences (e. g., damage, financial loss, loss of life), i. e., usually an event tree with probabilities and

expectation values for financial loss. Optimization aims at, roughly speaking, minimizing the evacuation time and reducing the area and duration of congestion. And finally, simulation describes a system with respect to its function and behavior by investigating a model of the system. This model is usually non-analytic, so does not provide explicit equations for the calculation of, e. g., evacuation time. Of course, simulations are used for “optimization” in a more general sense, too, i. e., they can be part of an optimization. This holds for risk assessment, too, if simulations are used to determine the outcomes of the different scenarios in the event tree.

In evacuation analysis the system is, generally speaking, a group of persons in an environment. More specifically, four components (sub-systems/sub-models) of the system *evacuation process* can be identified:

- (1) Geometry,
- (2) Environment,
- (3) Population, and
- (4) Hazards [43].

Any evacuation simulation must at least take into account (1) and (3). The behavior of the persons (which can be described on the strategic, tactical, and operational level—see Sect. “**Modeling**”) is part of the population sub-model. An alternative way of describing behavior is according to its algorithmic representation: no behavior modeling – functional analogy – implicit representation (equation) – rule based – artificial intelligence [43].

In the context of evacuation, hazards are first of all fire and smoke, which then require a toxicity sub-model, e. g., the fractional effective dose model (FED), to assess the physiological effect of toxic gases and temperature [25]. Further hazards to take into account might be earthquakes, flooding, or in the case of ships, list, heel, or roll motion. The sub-model environment comprises all other influences that affect the evacuation process, e. g., exit signs, surface texture, public address system, etc.

In summary, aims of an evacuation analysis and simulation are to provide feedback and hints for improvement at an early stage of design, information for safer and more rigorous regulations, improvement of emergency preparedness, training of staff, and accident investigation [43]. They usually do not provide direct results on the probability of a scenario or a systematic search for optimal geometries.

**Calculation of Overall Evacuation Time, Identification of Congestion, and Corrective Actions** The scope of this section is to show general results that can be obtained by evacuation simulations. They are general in the sense

that they can basically be obtained by any stochastic and microscopic model, i. e., apart from these two requirements, the results are not model specific. In detail, five different results of evacuation simulations can be distinguished:

- (1) Distribution of evacuation times,
- (2) Evacuation curve (number of persons evacuated vs. time),
- (3) Sequence of the evacuation (e. g., snapshots/screenshots at specific times, e. g., every minute), and
- (4) Identification of congestion, usually based on density and time.

The last point (4), in particular, needs some more explanation: congestion is defined based on density. Notwithstanding the difficulties of measuring density, we suggest density as the most suitable criterion for the identification of congestion. In addition to the mere occurrence of densities exceeding a certain threshold (say 3.5 persons per square meter), the time this threshold is exceeded is another necessary condition for a sensible definition of congestion. In the case presented here, 10% of the overall evacuation time is used. Both criteria are in accordance with the IMO regulations [118].

Based on these results, evacuation time and areas of congestion, corrective actions can be taken. The most straightforward measure would be a change of geometry, i. e., shorter or wider escape paths (floors, stairs, doors). This can be directly put into the geometry sub-model, the simulation can be re-run, and the result checked. Secondly, the signage, and therefore the orientation capability, can be improved. This is not as straightforward as geometrical changes. It does depend more heavily on the model characteristics as to how these changes influence the evacuation sequence.

We will not go into these details in the following two sections but rather show two typical examples for evacuation simulations and the results obtained. We will also not discuss the results in detail, since they are of an illustrative nature in the context of this article. The following examples are based on investigations that have been performed using a cellular automaton model which is described along with the simulation program in [90,111].

**Simulation Example 1 – Hotel** The first example we show is a hotel with 8069 persons. In Fig. 15 only the ground floor is shown. There are nine floors altogether. The upper floors influence the ground floor only via the stair landings and the exits adjacent to them. Most of the 8069 persons are initially located in the ground floor, since the theater and conference area is located there. The upper

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 14  
 Frequency distribution for the overall evacuation time (a) and evacuation curve (b)

floors are mainly covering bedrooms and some small conference areas.

The first step in our example (which might well be a useful recipe for evacuation analyses in general and is again in accordance with [118]) is to perform a statistical analysis. To this end, 500 samples are simulated. The evacuation time of a single run is the time it takes for all persons to get out. In this context, no fire or smoke are

taken into account. Since there are stochastic influences in the model used, the significant overall evacuation time is taken to be the 95-percentile (cf. Fig. 14). Finally, the maximum, minimum, mean, and significant values for the evacuation curve (number of persons evacuated vs. time) are also shown in Fig. 14.

The next figure (Fig. 16) shows the cumulated density. The thresholds (red areas) are 3.5 persons per square me-

a

b

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 15

Initial population distribution and situation after two minutes

ter and 10% of the overall evacuation time (in this case 49 seconds). The overall evacuation time is 8:13 minutes (493 seconds). This value is obtained by taking the 95-percentile of the frequency distribution for the overall evacuation times (cf. Fig. 14).

Of course, a distribution of overall evacuation times (for one scenario, i.e., the same initial parameters) can only be obtained by a stochastic model. In a deterministic model only one single value is calculated for the overall evacuation time. The variance of the overall evacuation

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 16

Density plot, i.e., cumulated person density exceeding 3.5 persons per square meter and 10% of overall evacuation time

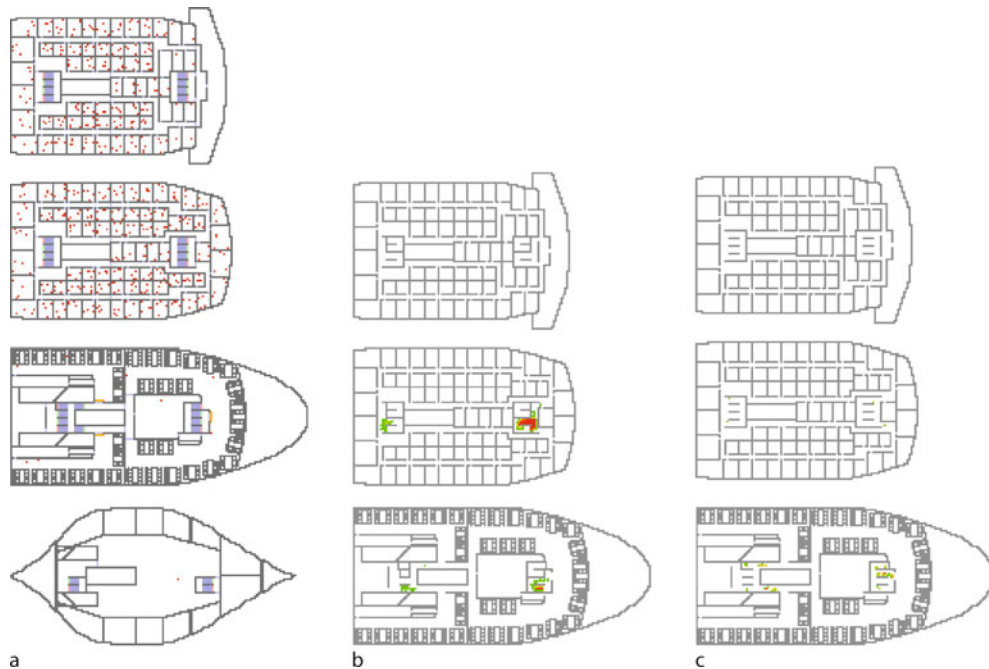

times is due to two effects in the model used here: the initial position of the persons is determined anew at the beginning of each simulation run since only the statistical properties of the overall population are set and the motion of the persons is governed by partially stochastic rules (e.g., probabilistic parameters).

**Simulation Example 2 – Passenger Ship** The second example we will show is a ship. The major difference from the previous example is the addition of (1) the assembly phase and (2) embarkation and launching.

$$\begin{aligned} T &= A + \frac{2}{3}(E + L) \\ &= f_{\text{safety}} \cdot (t_{\text{react}} + t_{\text{walk}}) + \frac{2}{3}(E + L) \\ &\leq 60 \text{ minutes} . \end{aligned}$$

Embarkation and launching time ( $E + L$ ) are required to be less than 30 minutes. For the sake of the evacuation analysis at an early design stage, the sum of embarkation and launching time can be assumed to be 30 minutes. Therefore, the requirement for  $A$  is 40 minutes. Alternatively, the embarkation and launching time can be determined by an evacuation trial.

Figure 17 shows the layout, initial population distribution (night case), density plot for the day case, and density plot for the night case. The reaction times are different for the day and the night case: 3 to 7 minutes (equally distributed) in the one and 7 to 13 minutes in the other. The

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 17

Initial distribution for the night case, density plot for the day case, and density plot for the night case for the "AENEAS steamliner"

longer reaction time in the night case results in less congestion (cf. Fig. 17). Both cases must be done in the analysis according to [118]. Additionally, a secondary night and day case are required (making up four cases altogether). In these secondary cases the main vertical zone (MVZ) leading to the longest overall individual assembly time is identified, and then either half of the stairway capacity in this zone is assumed to be not available, or 50% of the persons initially located in this zone must be led via one neighboring zone to the assembly station.

In the same way as shown for the two examples, simulations can be performed for other types of buildings and vessels. This technique has been applied to various passenger ships [112] to football stadiums [88] and the World Youth Day 2005 [88], the Jamarat Bridge in Makkah [88], a movie theater and schools (mainly for calibration and validation) [90] and airports [171]. Of course, many examples of applications based on various models can be found in the literature. For an overview, the proceedings of the PED conference series are an excellent starting point [44, 170, 190].

### Comparison of Commercial Software Tools

From a practical point of view, application of models for pedestrian dynamics and evacuation processes becomes

more and more relevant in safety analysis. This has led to the development of a number of software tools that, with different sophistication, help us study many aspects without risking the health of test persons in evacuation trials.

There are commercial, as well as non-commercial software tools. All tools might be based on different models [97, 187]. They have become very popular since the middle of the 1990s. A first comparison of different commercial software tools can be found in [191], where they were said to produce "reasonable results". Further comparisons of real evacuation data with software tools or hand calculation methods can be found in [29, 67, 91, 96, 104, 160, 161, 177]. But results predicted by different commercial software tools can differ by up to 40% for the same building [96]. Results may differ, too, when calculating with different assumptions, e.g., different reaction times, use of more or less detailed stair models, or when calculating with a real occupant load in contrast to an uncertainty analysis [96, 104]. Contrary to these results, another study [161] shows that calculations with different software tools are able to predict total evacuation times for high-rise buildings and there are no large differences as shown in [96]. In [161] the results of an evacuation trial and simulations with different commercial software tools differed for selected floors of a highrise building. The den-

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 18

Comparison of different software tools by simulating linear (*left*, narrow floor) and planar (*right*, 2 m wide floor) movement [162]

Evacuation Dynamics: Empirical Results, Modeling and Applications, Figure 19

Comparison of different software tools by simulating a simple room geometry [162]

sities were very low in this instance. In this case human behavior has a very large influence on the evacuation time. By contrast, evacuations at medium or high densities, human behavior has a smaller influence on the evacuation time of selected areas because congestion appears and continues larger than in low density situations – thus people reach the exit while congestion is still a factor [162]. In low density situations congestions are very rare, thus people move narrowly with free walking velocity through the building [162].

But the results presented in [161] also show that commercial software tools sometimes have problems with the empirical relationship of density and walking speed (see Fig. 18). Furthermore, it is very important how boundary conditions are implemented in these tools (see Fig. 19), and the investigation of a simple scenario of a single room using different software tools shows results differing by about a factor of two (see Fig. 19) [161]. In this case all software tools predict a congestion at the exit. Furthermore it is possible that the implemented algorithm fails [161].

Thus for the user it is hard to know which algorithms are implemented in closed-source tools so that such a tool must be considered as “black box” [147]. It is also quite difficult to compare results about density and appearing congestions calculated by different software tools [162] and so it is questionable how these results should be interpreted. But, as pointed out earlier, reliable empirical data are often missing so that a validation of software tools or models is quite difficult [162].

### Future Directions

The discussion has shown that the problem of crowd dynamics and evacuation processes is far from being well understood. One big problem is experimental basis. As in many human systems, it is difficult to perform controlled experiments on a sufficiently large scale. This would be necessary since data from actual emergency situations is usually not available, at least in sufficient quality. Progress should be possible by using modern video and computer technology which should allow us, in principle, to extract precise data even for the trajectories of individuals.

The full understanding of the complex dynamics of evacuation processes requires collaboration between engineering, physics, computer science, psychology, etc. Engineering in cooperation with computer science will lead to an improved empirical basis. Methods from physics allow us to develop simple but realistic models that capture the main aspects of the dynamics. Psychology is then needed to understand the interactions between individuals in sufficient detail to get a reliable set of ‘interaction’ parameters for the physical models.

In the end, we hope these joint efforts will lead to realistic models for evacuation processes that not only allow us to study these in the planning stages of facilities, but even allow for dynamical real-time evacuation control in case an emergency occurs.

### Acknowledgments

The authors would like to acknowledge the contribution of Tim Meyer-König (the developer of PedGo) and Michael Schreckenberg, Ansgar Kirchner, Bernhard Steffen for many fruitful discussions and valuable hints.

### Glossary

**Complexity** A definitive feature of nonlinear systems of interacting elements. It comprises high instability with respect to initial and boundary conditions, and complex but non-random behavior patterns (“order in chaos”).

**Extreme events** Rare events having a large impact. Such events are also known as critical phenomena, disasters, catastrophes, and crises. They persistently reoccur in hierarchical complex systems created, separately or jointly, by nature and society.

**Fast acceleration of unemployment (FAU)** The start of a strong and lasting increase of the unemployment rate.

**Pattern recognition of rare events** The methodology of artificial intelligence’ kind aimed at studying distinctive features of complex phenomena, in particular – at formulating and testing hypotheses on these features.

**Premonitory patterns** Patterns of a complex system’s behavior that emerge most frequently as an extreme event approaches.

**Recession** The American National Bureau of Economic Research defines recession as “a significant decline in economic activity spread across the economy, lasting more than a few months”. A recession may involve simultaneous decline in coincident measures of overall economic activity such as industrial production, employment, investment, and corporate profits.

**Start of the homicide surge (SHS)** The start of a strong and lasting increase in the smoothed homicide rate.

### Definition of the Subject

At stake in the development of accurate and reliable methods of prediction for social systems is the capacity of scientific reason to improve the human condition. Today’s civilization is highly vulnerable to crises arising from extreme events generated by complex and poorly understood systems. Examples include external and civil wars, terrorist attacks, crime waves, economic downturns, and famines, to name just a few. Yet more subtle effects threaten modern society, such as the inability of democratic systems to produce policies responsive to challenges like climate change, global poverty, and resource depletion.

Our capacity to predict the course of events in complex social systems is inherently limited. However, there is a new and promising approach to predicting and understanding complex systems that has emerged through the integration of studies in the social sciences and the mathematics of prediction. This entry describes and analyzes that approach and its real-world applications. These include algorithmic prediction of electoral fortunes of incumbent parties, economic recessions, surges of unemployment, and outbursts of crimes. This leads to important inferences for averting and responding to impending crises and for improving the functioning of modern democratic societies.

That approach was successfully applied also to natural disasters such as earthquakes. Ultimately, improved prediction methods enhance our capacity for understanding the world and for protecting and sustaining our civilization.

**Extreme events.** Hierarchical complex systems persistently generate extreme events – the rare fast changes that have a strong impact on the system. Depending on connotation they are also known as critical phenomena, disasters, catastrophes, and crises. This article examines the development and application of the algorithmic prediction of extreme socio-economic and political events.

**The prediction problem** is formulated as follows:

*given* are time series that describe dynamics of the sys-

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 1  
Possible outcomes of prediction

tem up to the current moment of time  $t$  and contain potential precursors of an extreme event;

to predict whether an extreme event will or will not occur during the subsequent time period  $(t, t + \tau)$ ; if the answer is “yes”, this will be the “*period of alarm*”.

As the time goes by, predictions form a discrete sequence of alarms. The possible outcomes of such a prediction are shown in Fig. 1. The actual outcome is determined unambiguously, since the extreme events are identified independently of the prediction either by the actual happening (e. g. by an election result) or by a separate algorithm (e. g. homicide surge) after they occur.

Such “yes or no” prediction is aimed not at analyzing the whole dynamics of the system, but only at identifying the occurrence of rare extreme events. In a broad field of prediction studies this prediction is different from and complementary to the classical Kolmogoroff–Wiener prediction of continuous functions, and to traditional cause-and-effect analysis.

The problem includes estimating the predictions’ accuracy: the rates of false alarms and failures to predict, and the total duration of alarms in relation to the total time considered. These characteristics represent the inevitable *probabilistic component* of prediction; they provide for statistical validation of a prediction algorithm and for optimizing preparedness to predicted events (e. g. recessions or crime surges).

**Twofold importance.** The prediction problem is pivotal in two areas:

- *Fundamental understanding of complex systems.* Prediction algorithms quantitatively define phenomena that anticipate extreme events. Such quantitative definition is pivotal for fundamental understanding of a complex system where these events occur, including

the intertwined mechanisms of system’s development and its basic features, e. g. multiple scaling, correlation range, clustering, fragmentation etc. (see Sects. “**Common Elements of Data Analyzes**”, “**Elections**”, “**US Economic Recessions**”, “**Unemployment**”). The understanding of complex systems remains a major unsolved problem of modern science, tantamount to transforming our understanding of the natural and human world.

- *Disaster preparedness.* On the practical side prediction is pivotal for coping with a variety of disasters, commonly recognized as major threats to the survival and sustainability of our civilization (e. g. [22]; see also materials of G8-UNESCO World Forum on “Education, Innovation and Research: New Partnership for Sustainable Development”, <http://g8forum.ictp.it>). The reliable advance prediction of extreme events can save lives, contribute to social and economic stability, and to improving the governing of modern societies.

## Introduction

### Predictability vs. Complexity: The Need for Holistic Approach [7,12,13,15,17,27,32]

Natural science had for many centuries regarded the Universe as a completely predictable machine. As Pierre Simon de Laplace wrote in 1776, “... if we knew exactly the laws of nature and the situation of the universe at the initial moment, we could predict exactly the situation of the same universe at a succeeding moment.” However, at the turn of the 20th century (1905) Jules Henry Poincare discovered, that “... this is not always so. It may happen that small differences in the initial conditions will produce very great ones in the final phenomena. Prediction becomes impossible”.

This instability to initial conditions is indeed a definitive attribute of complex systems. Nonetheless, through the robust integral description of such systems, it is possible to discover regular behavior patterns that transcend the inherent complexity. For that reason studying complexity requires the holistic approach that proceeds from the whole to details, as opposed to the reductionism approach that proceeds from details to the whole. It is in principle not possible “to understand a complex system by breaking it apart” [13].

Among the regular behavior patterns of complex systems are “premonitory” ones that emerge more frequently as an extreme event approaches. These premonitory patterns make complex systems predictable. The accuracy of predictions, however, is inevitably limited due to the systems’ complexity and observational errors.

Premonitory patterns and extreme events are consecutive manifestations of a system's dynamics. These patterns may not trigger extreme events but merely signal the growth of instability, making the system ripe for the emergence of extreme events.

### Methodology

The prediction algorithms described here are based on discovering premonitory patterns. The development of the algorithms requires the integration of complementary methods:

- Theoretical and numerical modeling of complex systems; this includes “universal” models considered in statistical physics and non-linear dynamics (e. g. [1,3,5,8,12,15,20,42]), and system-specific models, if available.
- Exploratory data analysis.
- Statistical analysis of limited samples, which is relevant since the prediction targets are by definition rare.
- Practical expertise, even if it is intuitive.
- Risk analysis and theory of optimal control for optimizing prediction strategy along with disaster preparedness.

**Pattern Recognition of Rare Events** This methodology provides an efficient framework for integrating diverse information into prediction algorithms [4,11,19]. This methodology has been developed by the artificial intelligence school of I. Gelfand for the study of rare phenomena of a highly complex origin. In terminology of pattern recognition, the “object of recognition” is the time moment  $t$ . The problem is to recognize whether it belongs to the period of alarm, i. e. to a time interval  $\Delta$  preceding an extreme event. An alarm starts when certain combinations of premonitory patterns emerges.

Several features of that methodology are important for predicting extreme events in the absence of a complete closed theory that would unambiguously define a prediction algorithm. First, this kind of pattern recognition relies on simple, robust parameters that overcome the bane of complexity analysis – incomplete knowledge of the system's causal mechanisms and chronic imperfections in the available data. In its efficient robustness, pattern recognition of rare events is akin to exploratory data analysis as developed by J. Tukey [50]. Second, unlike other statistical methods, e. g. regression analysis, that methodology can be used for small samples such as presidential elections or economic recessions. Also, it integrates quantitative and judgmental parameters and thereby more fully captures

the full dimensions of the prediction problem than procedures that rely strictly on quantitative variables.

Summing up, the methodology described here can help in prediction when there are (1) many causal variables, (2) qualitative knowledge about which variables are important, and (3) limited amounts of data [2].

Besides societal predictions, pattern recognition of rare events has been successfully applied in seismology and earthquake prediction (e. g. [11,19,20,44,46]), geological prospecting (e. g. [45]) and in many other fields. Review can be found in [21,47]. Tutorial materials are available at the web site of the Abdus Salam International Centre for Theoretical Physics ([http://cdsagenda5.ictp.it/full\\_display.php?da=a06219](http://cdsagenda5.ictp.it/full_display.php?da=a06219)).

**Validation of Prediction Algorithms** The algorithms include many adjustable elements, from selecting the data and defining the prediction targets, to specifying numerical parameters involved. In lieu of theory that would unambiguously determine these elements they have to be developed retrospectively, by “predicting” past extreme events. The application of the methodology to known events creates the danger of self-deceptive data-fitting: As J. von Neumann put it “*with four exponents I can fit an elephant*”. The proper validation of the prediction algorithms requires three consecutive tests.

- *Sensitivity analysis*: testing whether predictions are sensitive to variations of adjustable elements.
- *Out of sample analysis*: application of an algorithm to past data that has not been used in the algorithm's development. The test is considered successful if algorithm retains its accuracy.
- *Predicting future events* – the only decisive test of a prediction algorithm (see for example Sect. “Elections” below).

A highly efficient tool for such tests is the error Diagram, showing major characteristics of prediction accuracy [33,34,35,36,37,38,39]. Its example is given in Fig. 10. Exhaustive sets of these tests are described in [10,11,24,52].

### Common Elements of Data Analyses

The methodology discussed above was used for predicting various kinds of extreme events, as illustrated in the next four Sections. Naturally, from case to case this methodology was used in different ways, according to specifics of phenomena considered. However in all cases data analysis has essential common elements described below.

**Sequence of analysis** comprises four stages: (i) Defining prediction targets. (ii) Choosing the data (time series),

where premonitory patterns will be looked for and summing up a priori constrains on these patterns. (iii) Formulating hypothetical definition of these patterns and developing prediction algorithm; determining the error diagram. (iv) Validating and optimizing that algorithm.

**Preliminary transformation of raw data.** In predicting recessions (Sect. “US Economic Recessions”), fast acceleration of unemployment (Sect. “Unemployment”) and crime surges (Sect. “Homicide Surges”) raw data were time series of relevant monthly indicators, hypothetically containing premonitory patterns. Let  $f(m)$  be such an indicator, with integer  $m$  showing time in months. Premonitory behavior of some indicators is better captured by their linear trends.

Let  $W^f(l/q, p)$  be the local linear least-squares regression of a function  $f(m)$  within the sliding time window  $(q, p)$ :

$$W^f(l/q, p) = K^f(q, p)l + B^f(q, p), \quad q \leq l \leq p, \quad (1)$$

where integers  $l$ ,  $q$ , and  $p$  stand for time in months.

Premonitory behavior of most indicators was captured by the following two functions:

- The trend of  $f(m)$  in the  $s$  months long window,  $(m - s, m)$ . For brevity we denote

$$K^f(m/s) = K^f(m - s, m) \quad (2)$$

- The deviation of  $f(m)$  from extrapolation of its long-term regression (i. e. regression on a long time window  $(q, m - 1)$ ):

$$R^f(m/q) = f(m) - W^f(m/q, m - 1). \quad (3)$$

Both functions can be used for prediction since their values do not depend on the information about the future (after the month  $m$ ) which would be anathema in prediction.

**Discretization.** The prediction algorithms use one or several premonitory patterns. Each pattern is defined at the lowest – binary – level of resolution, as 0 or 1, distinguishing only the presence of absence of a pattern at each moment of time. Then the objects of recognition are described by binary vectors of the same length. This ensures the robustness of the prediction algorithms.

**Simple algorithm called Hamming distance** is used for classification of binary vectors in applications considered here, [14,20,28]. Each vector is either premonitory or not. Analyzing the samples of vectors of each class (“the learning material”), the algorithm determines a reference binary vector (“kernel”) with components typical for the premonitory vector. Let  $D$  be the Hamming distance of

a vector from the kernel (the number of non-coinciding binary components). The given vector is recognized as premonitory class, if  $D$  is below a certain threshold  $D^*$ . This criterion takes advantage of the clustering of precursors in time.

**Summing up**, these elements of the pattern recognition approach are common for its numerous applications, their diversity notwithstanding. Experience in the specific applications is described in Sects. “Elections”, “US Economic Recessions”, “Unemployment”, “Homicide Surges”. The conceptual summary of the accumulated experience is given in the final Sect. “Summary: Findings and Emerging Possibilities”.

## Elections

This Section describes algorithms for predicting the outcome of the US Presidential and mid-term Senatorial elections [28,29,30,31]. Elections’ time is set by the law as follows.

- National elections are held every even-numbered year, on the first Tuesday after the first Monday in November (i. e., between November 2 and November 8, inclusively).
- Presidential elections are held once every 4 years, i. e. on every other election day. People in each of the 50 states and District of Columbia are voting separately for “electors” pledged to one or another of the Presidential candidates. These electors make up the “Electoral College” which directly elects the President. Since 1860, when the present two-party system was basically established, the Electoral College reversed the decision of the popular vote only three times, in 1888, 1912, and 2000. Algorithmic prediction of such reversals is not developed so far.
- A third of Senators are elected for a 6-year term every election day; “mid-term” elections held in the middle of a Presidential term are considered here.

## Methodology

*The prediction target* is an electoral defeat of an “incumbent” party, i. e. the party holding the contested seat. Accordingly, the prediction problem is formulated as whether the incumbent party will retain this seat or lose it to the challenging party (*and not whether Republican or Democrat will win*). As is shown below, that formulation is crucial for predicting the outcomes of elections considered.

*Data.* The pre-election situation is described by robust common sense parameters defined at the lowest (binary)

level of resolution, as the *yes* or *no* answers to the questionnaires given below (Tables 1, 2). The questions are formulated in such a way that the answer *no* favors the victory of the challenging party. According to the Hamming distance analysis (Sect. “Common Elements of Data Analyzes”) the victory of the challenging party is predicted when the number of answers *no* exceeds a threshold  $D^*$ .

**Mid-term Senatorial Elections**

The prediction algorithm was developed by a retrospective analysis of the data on three elections, 1974, 1978, and 1982. The questionnaire is shown in Table 1. Victory of the challenger is predicted if the number of answers *no* is 5 or more [28,29,30].

The meaning of these questions may be broader than their literal interpretation. For example, financial contri-

butions (key 5 in Table 2) not only provide the resources required for an effective campaign, but may also constitute a poll in which the preferences are weighed by the money attached.

*Predicting future elections.* This algorithm (without any changes from year to year and from state to state) was applied in advance to the five subsequent elections, 1986–2002. Predictions are shown in Fig. 2. Altogether, 150 seats were put up for election. For each seat a separate prediction was made, 128 predictions were correct, and 22 – wrong.

*Statistical significance* of this score is 99.9%. In other words the probability to get such a score by chance is below 0.1% [28,29,30]. For some elections these predictions might be considered as trivial, since they coincide with prevailing expectation of experts. Such elections are identified by *Congressional Review*. Eliminating them from the score still results in 99% significance.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 1  
Questionnaire for mid-term Senatorial Elections [28]

1.	(Incumbency): The incumbent -party candidate is the sitting senator.
2.	(Stature): The incumbent -party candidate is a major national figure.
3.	(Contest): There was no serious contest for the incumbent -party nomination.
4.	(Party mandate): The incumbent party won the seat with 60% or more of the vote in the previous election.
5.	(Support): The incumbent -party candidate outspends the challenger by 10% or more.
6.	(Obscurity): The challenging -party candidate is not a major national figure or a past or present governor or member of Congress.
7.	(Opposition): The incumbent party is not the party of the President.
8.	(Contest): There is no serious contest for the challenging -party nomination (the nominee gains a majority of the votes cast in the first primary and beats the second-place finisher at least two to one).

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 2  
Questionnaire for Presidential elections [29,30]

KEY 1	(Party Mandate): After the midterm elections, the incumbent party holds more seats in the US House of Representatives than it did after the previous midterm elections.
KEY 2	(Contest): There is no serious contest for the incumbent -party nomination.
KEY 3	(Incumbency): The incumbent -party candidate is the sitting president.
KEY 4	(Third party): There is significant third-party or independent campaign.
KEY 5	(Short-term economy): The economy is not in recession during the election campaign.
KEY 6	(Long-term economy): Real per -capita economic growth during the term equals or exceeds mean growth during the previous two terms.
KEY 7	(Policy change): The incumbent administration effects major changes in national policy.
KEY 8	(Social unrest): There is no sustained social unrest during the term.
KEY 9	(Scandal): The incumbent administration is unattained by a major scandal.
KEY 10	(Foreign/military failure): The incumbent administration suffers no major failure in foreign or military affairs.
KEY 11	(Foreign/military success): The incumbent administration achieves a major success in foreign or military affairs.
KEY 12	(Incumbent charisma): The incumbent -party candidate is charismatic or a national hero.
KEY 13	(Challenger charisma): The challenging -party candidate is not charismatic or a national hero.

## Presidential Elections

The prediction algorithm was developed by a retrospective analysis of the data on the past 31 elections, 1860–1980; that covers the period between victories of A. Lincoln and R. Reagan inclusively. The questionnaire is shown in Table 2. Victory for the challenger is predicted if the number of answers *no* is 6 or more [29,30].

*Predicting of future elections.* This algorithm (without any changes from year to year state) was applied in advance to the six subsequent elections, 1984–2004. Predictions are shown in Fig. 3. All of them happened to be correct. In 2000 the decision of popular majority was reversed by the Electoral College; such reversals are not targeted by this algorithm [29,30].

## Understanding Elections

*Collective behavior.* The finding that aggregate-level parameters can reliably anticipate the outcome of both presidential and senatorial elections points to an electoral behavior highly integrated not only for the nation as a whole but also within the diverse American states.

- A presidential election is determined by the collective, integrated estimation of performance of incumbent administration during the previous four years.
- In case of senatorial elections the electorate has more diffused expectations of performance but puts more importance on political experience and status than in the case of presidential elections. Senate incumbents, unlike presidential ones, do not suffer from a bad economy or benefit from a good one. (This suggests that rather than punishing the party holding a Senate seat for hard times, the voters may instead regard the incumbent party as a safe port in a storm).

*Similarity.* For each election year in all states the outcomes of elections follow the same pattern that transcends the diversities of the situations in each of the individual elections.

The same pattern of the choice of the US President prevails since 1860, i. e. since election of A Lincoln, despite all the overwhelming changes in the electorate, the economy, the social order and the technology of politics during these 130 years. (For example, the electorate of 1860 did not include the groups, which constitute 3/4 of present electorate, such as women, African Americans, or most of the citizens of the Latin American, South European, Eastern European, and Jewish descent [30].

*An alternative (and more traditional) concept* of American elections focuses on the division of voters into interest and attitudinal groups. By this concept the goal of

the contestants is to attract the maximum number of voting blocks with minimal antagonism from other blocks. Electoral choice depends strongly on the factors irrelevant to the essence of the electoral dilemma (e. g. on the campaign tactics). The drawbacks of this concept are discussed in [18,30]. In sum, the work on presidential and senatorial elections described above suggests the following new ways of understanding American politics and perhaps the politics of other societies as well.

1. Fundamental shifts in the composition of the electorate, the technology of campaigning, the prevailing economic and social conditions, and the key issues of campaigns do not necessarily change the pragmatic basis on which voters choose their leaders.
2. It is governing not campaigning that counts in the outcomes of presidential elections.
3. Different factors may decide the outcome of executive as compared to legislative elections.
4. Conventional campaigning will not improve the prospects for candidates faced with an unfavorable combination of fundamental historical factors. Disadvantaged candidates have an incentive to adopt innovative campaigns that break the pattern of conventional politics.
5. All candidates would benefit from using campaigns to build a foundation for governing in the future.

## US Economic Recessions

US National Bureau of Economic Research (NBER) has identified the seven recessions that occurred in the US since 1960 (Table 3). The starting points of a recession and of the recovery from it follow the months marked by a peak and a trough of economic activity, respectively.

A peak indicates the last month before a recession, and a trough – the last month of a recession.

*Prediction targets* considered are the first month after the peak and after the trough (“the turns to the worst and to the best”, respectively). The start of the first recession, in 1960, is not among the targets, since the data do not cover a sufficient period of time preceding the recession.

*The data* used for prediction comprise the following six monthly leading economic indicators obtained from the CITIBASE data base, Jan. 1960–June 2000 (abbreviations are the same, as in [49]).

**G10FF = FYGT10 – FEDFUN** Difference between the annual interest rate on 10 year US Treasury bonds, and federal fund annual interest rate.

7	2001:03	2001:11

- IP** Industrial Production, total: index of real (constant dollars, dimensionless) output in the entire economy. This represents mainly the manufacturing industry, because of the difficulties in measuring the quantity of the output in services (such as travel agents, banking, etc.).
- LHELL** Index of “help wanted” advertising. This is put together by a private publishing company that measures the amount of job advertising (column-inches) in a number of major newspapers.
- LUINC** Average weekly number of people claiming unemployment insurance.
- INVMTQ** Total inventories in manufacturing and trade, in real dollars. Includes intermediate inventories (for example held by manufacturers, ready to be sent to retailers) and final goods inventories (goods on the shelves in stores).

**FYGM3** Interest rate on 90 day US treasury bills at an annual rate (in percent).

These indicators were already known [48,49], as those that correlate with a recession’s approach.

**Prediction of a Recession Start**

*Single indicators* exhibit the following premonitory patterns:

- G10FF:** small value
- IP and INVMTQ:** small deviation from the long-term trend  $R^f$  (3)
- FYGM3:** large deviation from the long-term trend  $R^f$
- LHELL:** small trend  $K^f$  (2)
- LUINC:** large trend  $K^f$

The prediction algorithm triggers an alarm after a month when most of the patterns emerge simultaneously. It lasts  $\Delta$  months and can be extended by the same rule, if premonitory patterns keep emerging. Formal quantitative definition of the algorithm can be found in [23] along with its validation by sensitivity and out-of-sample analyzes.

Alarms and recessions are juxtaposed in Fig. 4. We see that five recessions occurring between 1961 and 2000 were predicted by an alarm. The sixth recession started in April 2001, one month before the corresponding alarm. (Recession of 1960 was not considered for prediction, since data analyzed start just before it.)

Only the first six recessions listed in Table 1 were considered in the developing of the algorithm [23]. Duration

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 4  
Alarms (black bars) and recessions (gray bars)

of each alarm was between 1 and 14 months. Total duration of all alarms was 38 months, or 13.6% of the time interval considered. There were no false alarms. No alarms were yielded so far by subsequent prediction in advance and no recession was identified during that time.

**Prediction of a Recession End**

Prediction targets are the starting points of recovery from recessions; these points are indicated in the last column of Table 3.

The data comprise the same six indicators that indicate the approach of a recession (see Subject. "Prediction of a Recession Start"); they are analyzed only within the recessions' periods.

Data analysis shows intriguing regularity illustrated in Fig. 5:

- Financial indicators change in opposite directions before the recession and before the recovery.
- Economic indicators change in the same direction before the recession and the recovery; but the change is stronger before the recovery, i. e., the economic situation worsens.

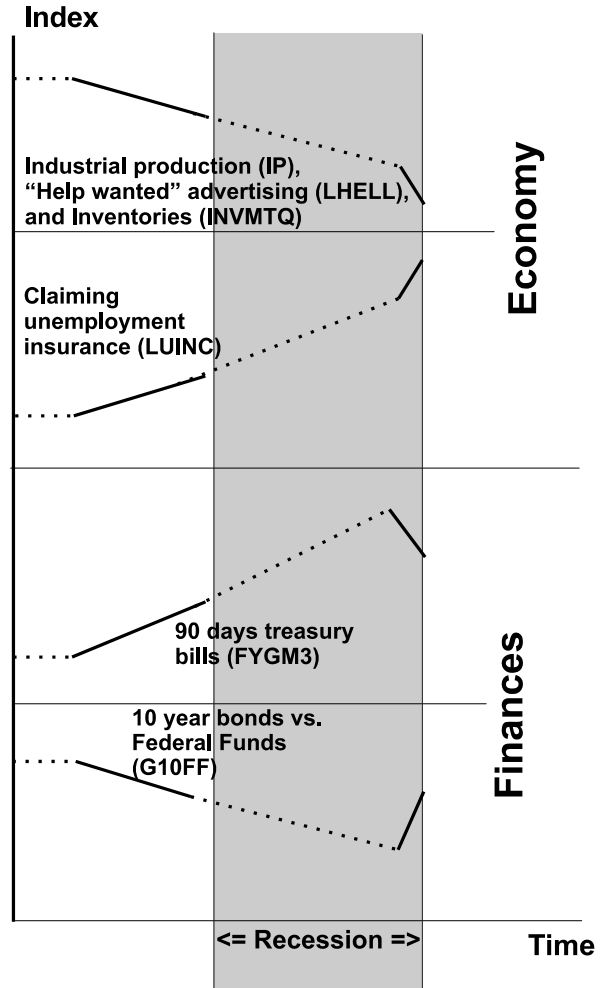

Prediction algorithm is formulated in the same terms as in the previous case but an alarm is triggered after three consecutive months when most of the patterns emerge simultaneously. The alarms predict when the recovery will start. Alarms and prediction targets are juxtaposed in Fig. 6. Duration of a single alarm is one to five months. Total duration of alarms is 16 months, which is 22% of time covered by all recessions. There are neither false alarms nor failures to predict.

**Unemployment**

Here we describe uniform prediction of the sharp and lasting unemployment surge in France, Germany, Italy, and the USA [25].

**Prediction Target**

A prediction target is schematically illustrated in Fig. 7. Thin curve shows monthly unemployment with seasonal

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 5  
Premonitory changes of indicators before the start of a recession and before its end. See explanations in the text

variations. On the thick curve seasonal variations are smoothed away. The arrow indicates a sharp upward bend of the smoothed curve. The moment of that bend is the prediction target. It is called by the acronym FAU, for "Fast Acceleration of Unemployment".

Smoothing was done as follows: Let  $u(m)$  be number of unemployed in a month  $m = 1, 2, \dots$ . After smooth-

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 6

Prediction of recovery from a recession. *Black bars* – periods of recessions. *Gray bars* – alarms preceding the end of a recession

ing out the seasonal variation we obtain time series  $U(m) = W^u(m/m - 6, m + 6)$ ; this is the linear regression over the year-long time interval  $(m - 6, m + 6)$ . A natural robust measure of unemployment acceleration at the time  $m$

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 7

Fast acceleration of unemployment (FAU): schematic definition. *Thin line* – monthly unemployment; with seasonal variations. *Thick line* – monthly unemployment, with seasonal variations smoothed away. The *arrow* indicates a FAU – the sharp bend of the smoothed curve. The moment of a FAU is the target of prediction

is the bend of the linear trend of  $U$ ; in notations used in (1) this is the function  $F(m/s) = K^U(m + s, m) - K^U(m, m - s)$ . The FAUs are identified by the local maxima of  $F(m)$  exceeding a certain threshold  $F$ . The time  $m^*$  and the height  $F^*$  of such a maximum are, respectively, the time and the magnitude of a FAU. Subsequent local minimum of  $F(m)$  identifies the month  $m_e$  when acceleration ends. Figure 8 shows thus defined FAUs for France.

### The Data

The analysis has been initially made for France and three groups of data have been analyzed.

- *Composite macroeconomic indicators of national economy*
  1. **IP**: Industrial production indicator, composed of weighted production levels in numerous sectors of the economy, in % relative to the index for 1990.
  2. **L**: Long-term interest rate on 10-year government bonds, in %.
  3. **S**: Short-term interest rate on 3-month bills, in %.
- *Characteristics of more narrow areas of French economy*
  4. **NC**: The number of new passenger car registrations, in thousands of units.
  5. **EI**: Expected prospects for the national industrial sector.
  6. **EP**: Expected prospects for manufacturers.
  7. **EO**: Estimated volume of current orders.
- *Indicators related to US economy.*

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 8

Unemployment in France. *Top*: Monthly unemployment, thousands of people. *Thin line*:  $u(m)$ , data from the OECD database; note the seasonal variations. *Thick line*:  $U(m)$ , data smoothed over one year. *Bottom*: Determination of FAUs.  $F(m)$  shows the change in the linear trend of unemployment  $U(m)$ . FAUs are attributed to the local maxima of  $F(m)$  exceeding threshold  $F = 4.0$  shown by horizontal line. The thick vertical lines show moments of the FAUs

8. **FF/\$**: Value of US dollar in French francs.
9. **AR**: The state of the American economy: is it close to a recession or not? This indicator shows the presence or absence of a current pre-recession alarm (see Subsect. “**Prediction of a Recession Start**”).

The data bases with above indicators for Europe are issued by the Organization for Economic Cooperation and Development [43] and the International Monetary Fund [16].

American analogues of indicators **IP**, **L**, and **S** are provided by CITIBASE; they are described in Sect. “**US Economic Recessions**” under abbreviations **IP**, **FYGM3** and **FIGT10** respectively.

### Prediction

Single indicators exhibit the following premonitory behavior.

- Steep upward trends of composite indicators (#1–#3). This behavior reflects “overheating” of the economy and may sound counterintuitive for industrial production (#1), since the rise of production is supposed to create more jobs. However, a particularly steep rise may create oversupply.

- Steep downward trends of economic expectations by general public (#4) and business community (#5–#8).
- Proximity of an American recession (#9). Before analysis was made such and opposite precursors might be expected for equally plausible reasons, so that this finding, if further confirmed, does provide a constraint on understanding unemployment’s dynamics.

Among different combinations of indicators the macroeconomic ones (#1–#3) jointly give relatively better predictions, with smallest rates of errors and highest stability in sensitivity tests.

*Retrospective prediction.* Macroeconomic indicators were used jointly in the Hamming distance prediction algorithm (Sect. “**Common Elements of Data Analyzes**”). Being robust and self-adjusting to regional conditions, this algorithm was applied without any changes to the four countries considered here.

Alarms and FAUs are juxtaposed in Fig. 9. Error diagram in Fig. 10 shows quality of prediction for different countries. For US the quality is lower than for European countries, though still higher than in random predictions.

*Prediction of the future FAUs* was launched for USA. The results are shown in Fig. 11. It shows that by Jan-

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 9  
 Retrospective predictions for four countries: FAUs and alarms obtained by the prediction algorithm. The thick vertical lines show the moments of FAUs in a country. Bars – the alarms starting shortly after FAUs within the periods of unemployment surge, 3 – false alarms. Shaded areas on both sides indicate the times, for which data on economic indicators were unavailable

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 10  
 Error diagram for prediction of FAUs in different countries;  $\tau$  is total duration of alarms in % to the time interval considered,  $f$  – total number of false alarms

uary 2008 two correct predictions have been made, without other false alarms or failures to predict. In November 2006 the second prediction was filed on the web site of the Anderson School of Management, University of California, Los Angeles (<http://www.uclaforecast.com/>). This

started the documented experiment in testing the algorithm by predicting future FAUs on that website.

### Homicide Surges

This section analyzes the prediction of homicide rates in an American megacity – Los Angeles, CA [24].

### Prediction Target

A prediction target is the start of a sharp and lasting acceleration of the homicide rate; it is called by the acronym SHS, for “Start of the Homicide Surge.” It is formally determined by the analysis of monthly homicides rates, with seasonal variations smoothed out, as described in Subject. “Prediction Target”. Prediction targets thus identified are shown by vertical lines in Figs. 12 and 14 below.

### The Data

The analyzed data include monthly rates of the homicides and 11 types of lesser crimes, listed in Table 2. Definitions of these crimes are given in [6].

The data are taken from two sources:

- The National Archive of Criminal Justice Data, placed on the web site (NACJD), 1975–1993.
- Data bank of the Los Angeles Police Department (LAPD) Information Technology Division), 1990–2003.

The algorithm does not use socio-economic determinants of crime, or other data that might be also useful. The objective was to develop a simple, efficient prediction model; development of comprehensive causal model would be a complementary objective.

### Prediction

Premonitory behavior of indicators is illustrated in Fig. 13. The first phase is characterized by an escalation of burglaries and assaults, but not of robberies. Later on, closer to a homicide surge, robberies also increase.

The Prediction algorithm based on Hamming distance (see Sect. “Common Elements of Data Analyzes”) uses seven indicators listed in Table 4. Other five indicators marked by \* are used in sensitivity tests; and the homicide rate is used for identification of targets SHS.

Alarms and homicide surges are juxtaposed in Fig. 14. The SHS episode in November 1994 has occurred simultaneously with the corresponding alarm. It is captured by an alarm, which starts in the month of SHS without a lead time. Prediction missed the October 1999 episode: it occurred two months before the start of the corresponding

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 11  
 Experiment in predicting future FAUs, September (1999)–January (2008). *Thin blue curve* shows monthly unemployment rate in USA, according to data of Bureau of Labor Statistics, US Department of Labor (<http://www.data.bls.gov>). *Thick curve* shows this rate with seasonal variation smoothed away. *Vertical red lines* show prediction targets – the moments of FAU, *gray bar* – the period of unemployment’s growth; *pink bars* – periods of alarms

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 12  
 Target of prediction – the Start of the Homicide Surge (“SHS”); schematic definition. *Gray bar* marks the period of homicide surge

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 13  
 Scheme of premonitory changes in crime statistics

alarm. Such delays should be taken into account for validating the algorithm. Note, however, that the last prediction did remain informative.

Altogether alarms occupy 15% of the time considered. During phase 2 (as defined in Fig. 13) this rate might be reduced [24].

**Summary: Findings and Emerging Possibilities**

The findings described above enhance predictive understanding of extreme events and indicate yet untapped possibilities for further R&D in that field.

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Figure 14  
 Performance of prediction algorithm through 1975–2002. *Thin curve* – original time series, total monthly number of homicides in Los Angeles city, per 3,000,000 inhabitants. Data from NACJD [6] have been used for 1975–1993 and from the Data Bank of the Los Angeles Police Department (LAPD Information Technology Division) for subsequent 9 years. *Thick curve* – smoothed series, with seasonal variations eliminated. *Vertical lines* show the targets of prediction – episodes of SHS (Subsect. “Prediction Target”). *Gray bars* show the periods of homicide surge. *Red bars* show the alarms declared by the prediction algorithm [24]

Extreme Events in Socio-economic and Political Complex Systems, Predictability of, Table 4  
 Types of crimes considered (after [6])

Homicide	Robberies	Assaults	Burglaries
● All	● All	● All*	● Unlawful not forcible entry
	● With firearms	● With firearms	● Attempted forcible entry*
	● With knife or cutting instrument	● With knife or cutting instrument	
	● With other dangerous weapon	● With other dangerous weapon*	
	● Strong-arm robberies*	● Aggravated injury assaults*	

\*Analyzed in sensitivity tests only

### Pattern Recognition Approach

Information extracted from the already available data is indeed increased by this approach. To each problem considered here one may apply the following conclusion of J. Stock, a leading expert in the field: “Prediction/of recessions/requires fitting non-linear, high-dimensional models to a handful of observations generated by a possibly non-stationary economic environment... The evidence presented here suggests that these simple binary transformations of economic indicators have significant predictive content for recessions. It is striking that these models, in which the information in the data is reduced to binary indicators, have predictive contents comparable to or, in

many cases, better than that of more conventional models.” Importantly, this is achieved by using not more detailed data and models, but more robust aggregation (Subsect. “Predictability vs. Complexity: The Need for Holistic Approach”).

Partial “universality” of premonitory patterns is established by broad research in modeling and data analysis. This includes the common definition of the patterns, their self-adjustment, scaling, and similarity [9,10,20,26,42]; see also references in Sects. “Elections”, “US Economic Recessions”, “Unemployment”, “Homicide Surges”).

Relation to “cause and effect” analysis (perpetrators or witnesses?). Premonitory patterns might be either “perpetrators” contributing to causing extreme events, or the

“witnesses” – parallel manifestations of the system’s development. The cause that triggered a specific extreme event is usually identified, at least in retrospect. It may be, for example, a certain governmental decision, a change in the international situation, a natural disaster, the depletion of natural resources etc. However an actual extreme event might materialize only if the system is destabilized and “ripe” for it. Patterns of each kind signal such a ripe situation.

*What premonitory patterns to use for prediction?* Existing theories and experience reduce the number of such patterns, but too many of them remain hypothetically promising and have to be chosen by a trial and error procedure. Inevitably a prediction algorithm begins with a limited number of promising patterns. They should be sufficient for prediction, but other patterns may be equally or more useful and should be considered in further development of the algorithm. Most relevant “perpetrators” might not be included in the most useful patterns (e.g. due to their sensitivity to too many factors).

*Relation to policy-making: prediction and disaster preparedness.* Reliable predictions of future extreme events in complex societal systems would allow policy-makers to take remedial action before rather than after the onset of such afflictions as economic disasters, crime surges, etc. As in case of military intelligence predictions would be useful if their accuracy is known, albeit not necessarily high. Analysis of error diagrams allows to regulate the tradeoff between the rates of failures to predict and false alarms according to the needs of a decision-maker.

*Relation to governing and campaigning.* The findings presented here for the USA elections show that top elected officials would have better chances for reelection, if they focus on effective governing, and not on rhetoric, packaging and image-making. Candidates will benefit themselves and their parties if they run substantive campaigns that build a foundation for governing during the next term.

### Further Possibilities

**A wealth of yet untapped data and models** is readily available for the continuation of the kinds of studies described and analyzed in this article. Following are some immediate possibilities; specific examples can be found in the given references.

- *Continuing experiments in advance prediction*, for which the above findings set up a base (Sect. “**Elections**”). Successes and errors are equally important [37,38].
- *Incorporating other available data into the analysis* (Sects. “**US Economic Recessions**”, “**Unemployment**”)
  - *Predicting the same kind of extreme events in different contexts* (Sect. “**Unemployment**”)
  - *Predicting the end of a crisis* (Sect. “**US Economic Recessions**”).
  - *Multistage prediction with several lead times* (Sect. “**Homicide Surges**”)
    - Less imminent, but within reach are:
      - “*Universal*” scenarios of extreme development and low-parametric definition of an ensemble of premonitory patterns [9,51,52].
      - *Validation of an algorithm and joint optimization of prediction and preparedness strategy* [38].
      - *Developing prediction algorithms for other types of extreme events.*

The authors would be glad to provide specific information upon request.

### Generalizations

**The problems considered here** have the following common features:

- *The absence of a closed theory* that would unambiguously determine prediction methodology. This leads to the need for intense intertwining of mathematics, statistical physics and non-linear dynamics, a range of societal sciences, and practical experience (Subsect. “**Methodology**”). In reality this requires long-term collaboration of respective experts. As can be seen from the references to Sects. “**Elections**”, “**US Economic Recessions**”, “**Unemployment**”, “**Homicide Surges**” previous applications inevitably involved the teams of such experts.
- *Predictions in advance* is the only final validation of the results obtained.
- *The need for holistic analysis* driven to extreme robustness.
- *Considerable, albeit limited, universality* of the premonitory phenomena.

Two classical quotations shed the light on these features:

A. N. Kolmogoroff. “It became clear for me that it is unrealistic to have a hope for the creation of a pure theory [of the turbulent flows of fluids and gases] closed in itself. Due to the absence of such a theory we have to rely upon the hypotheses obtained by processing of the experimental data.”

M. Gell-Mann: “... if the parts of a complex system or the various aspects of a complex situation, all defined in advance, are studied carefully by experts on those parts or aspects, and the results of their work are pooled, an adequate description of the whole system or situation does

not usually emerge. ... The reason, of course, is that these parts or aspects are typically entangled with one another. ... We have to supplement the partial studies with a transdisciplinary crude look at the whole.”

*In the general scheme of things* the problem considered belongs to a much wider field – the quest for a universal theory of complex systems extended to predicting extreme events – the Holy Grail of complexity studies. This quest encompasses the natural and human-made complex systems that comprise what some analysts have called “the global village”. It requires entirely new applications of modern science, such as algebraic geometry, combinatorics, and thermodynamics. As a means for anticipating, preventing and responding to natural and manmade disasters and for improving the outcomes of economic and political systems, the methods described here may hold one key for the survival and sustainability of our civilization.

### Glossary

**Fractal** A collection of objects that have a power-law dependence of number on size.

**Fractal dimension** The power-law exponent in a fractal distribution.

### Definition of the Subject

The scale invariance of geological phenomena is one of the first concepts taught to a student of geology. When a photograph of a geological feature is taken, it is essential to include an object that defines the scale, for example, a coin or a person. It was in this context that Mandelbrot [7] introduced the concept of fractals. The length of a rocky coastline is obtained using a measuring rod with a specified length. Because of scale invariance, the length of the coastline increases as the length of the measuring rod decreases according to a power law. It is not possible to obtain a specific value for the length of a coastline due to small indentations down to a scale of millimeters or less.

A fractal distribution requires that the number of objects  $N$  with a linear size greater than  $r$  has an inverse power-law dependence on  $r$  so that

$$N = \frac{C}{r^D} \quad (1)$$

where  $C$  is a constant and the power  $D$  is the fractal dimension. This power-law scaling is the only distribution that is

scale invariant. However, the power-law dependence cannot be used to define a statistical distribution because the integral of the distribution diverges to infinity either for large values or small values of  $r$ . Thus fractal distributions never appear in compilations of statistical distributions. A variety of statistical distributions have power-law behavior either at large scales or small scales, but not both. An example is the Pareto distribution.

Many geological phenomena are scale invariant. Examples include the frequency-size distributions of fragments, faults, earthquakes, volcanic eruptions, and landslides. Stream networks and landforms exhibit scale invariance. In terms of these applications there must always be upper and lower cutoffs to the applicability of a fractal distribution. As a specific application consider earthquakes on the Earth. The number of earthquakes has a power-law dependence on the size of the rupture over a wide range of sizes. But the largest earthquake cannot exceed the size of the Earth, say  $10^4$  km. Also, the smallest earthquake cannot be smaller than the grain size of rocks, say 1 mm. But this range of scales is  $10^{10}$ . Actual earthquakes appear to satisfy fractal scaling over the range 1 m to  $10^3$  km.

An example of fractal scaling is the number-area distribution of lakes [10], this example is illustrated in Fig. 1. Excellent agreement with the fractal relation given in Eq. (1)

Fractals in Geology and Geophysics, Figure 1  
 Dependence of the cumulative number of lakes  $N$  with areas greater than  $A$  as a function of  $A$ . Also shown is the linear dimension  $r$  which is taken to be the square root of  $A$ . The straight-line correlation is with Eq. (1) taking the fractal dimension  $D = 1.90$

is obtained taking  $D = 1.90$ . The linear dimension  $r$  is taken to be the square root of the area  $A$  and the power-law (fractal) scaling extends from  $r = 100$  m to  $r = 300$  km.

## Introduction

Fractal scaling evolved primarily as an empirical means of correlating data. A number of examples are given below. More recently a theoretical basis has evolved for the applicability of fractal distributions. The foundation of this basis is the concept of self-organized criticality. A number of simple computational models have been shown to yield fractal distributions. Examples include the sand-pile model, the forest-fire model, and the slider-block model.

## Drainage Networks

Drainage networks are a universal feature of landscapes on the Earth. Small streams merge to form larger streams, large streams merge to form rivers, and so forth. Strahler [16] quantified stream networks by introducing an ordering system. When two like-order streams of order  $i$  merge they form a stream of order  $i + 1$ . Thus two  $i = 1$  streams merge to form a  $i = 2$  stream, two  $i = 2$  streams merge to form a  $i = 3$  stream and so forth. A bifurcation ratio  $R_b$  is defined by

$$R_b = \frac{N_i}{N_{i+1}} \quad (2)$$

where  $N_i$  is the number of streams of order  $i$ . A length order ratio  $R_r$  is defined by

$$R_r = \frac{r_{i+1}}{r_i} \quad (3)$$

where  $r_i$  is the mean length of streams of order  $i$ . Empirically both  $R_b$  and  $R_r$  are found to be nearly constant for a range of stream orders in a drainage basin. From Eq. (1) the fractal dimension of a drainage basin

$$D = \frac{\ln(N_i/N_{i+1})}{\ln(r_{i+1}/r_i)} = \frac{\ln R_b}{\ln R_r} \quad (4)$$

Typically  $R_b = 4.6$ ,  $R_r = 2.2$ , and the corresponding fractal dimension is  $D = 1.9$ . This scale invariant scaling of drainage networks was recognized some 20 years before the concept of fractals was introduced in 1967.

A major advance in the quantification of stream networks was made by Tokunaga [17]. This author was the first to recognize the importance of side branching, that is some  $i = 1$  streams intersect  $i = 2$ ,  $i = 3$ , and all higher-order streams. Similarly,  $i = 2$  streams intersect  $i = 3$  and higher-order streams and so forth. A fully

self-similar, side-branching topology was developed. Applications to drainage networks have been summarized by Peckham [11] and Pelletier [13].

## Fragmentation

An important application of power-law (fractal) scaling is to fragmentation. In many examples the frequency-mass distributions of fragments are fractal. Explosive fragmentation of rocks (for example in mining) give fractal distributions. At the largest scale the frequency size distribution of the tectonic plates of plate tectonics are reasonably well approximated by a power-law distribution. Fault gouge is generated by the grinding process due to earthquakes on a fault. The frequency-mass distribution of the gouge fragments is fractal. Grinding (comminution) processes are common in tectonics. Thus it is not surprising that fractal distributions are ubiquitous in geology.

As a specific example consider the frequency-mass distribution of asteroids. Direct measurements give a fractal distribution. Since asteroids are responsible for the impact craters on the moon, it is not surprising that the frequency-area distribution of lunar craters is also fractal.

Using evidence from the moon and a fractal extrapolation it is estimated that on average, a 1m diameter meteorite impacts the earth every year, that a 100 m diameter meteorite impacts every 10,000 years, and that a 10 km diameter meteorite impacts the earth every 100,000,000 years. The classic impact crater is Meteor Crater in Arizona, it is over 1 km wide and 200 m deep. Meteor Crater formed about 50,000 years ago and it is estimated that the impacting meteorite had a diameter of 30 m. The largest impact to occur in the 20th century was the June 30, 1908 Tunguska event in central Siberia. The impact was observed globally and destroyed over 1000 km<sup>2</sup> of forest. It is believed that this event was the result of a 30 m diameter meteorite that exploded in the atmosphere.

One of the major global extinctions occurred at the Cretaceous/Tertiary boundary 65 million years ago. Some 65% of the existing species were destroyed including dinosaurs. This extinction is attributed to a massive impact at the Chicxulub site on the Yucatan Peninsula, Mexico. It is estimated that the impacting meteorite had a 10 km diameter. In addition to the damage done by impacts there is evidence that impacts on the oceans have created massive tsunamis. The fractal power-law scaling can be used to quantify the risk of future impacts.

## Earthquakes

Earthquakes universally satisfy several scaling laws. The most famous of these is Gutenberg-Richter frequency-

magnitude scaling. The magnitude  $M$  of an earthquake is an empirical measure of the size of an earthquake. If the magnitude is increased by one unit it is observed that the cumulative number of earthquakes greater than the specified magnitude is reduced by a factor of 10.

For the entire earth, on average, there is 1 magnitude 8 earthquake per year, 10 magnitude 7 earthquakes per year, and 100 magnitude 6 earthquakes per year. When magnitude is converted to rupture area a fractal relation is obtained. The numbers of earthquakes that occur in a specified region and time interval have a power-law dependence on the rupture area.

The validity of this fractal scaling has important implications for probabilistic seismic risk assessment. The number of small earthquakes that occur in a region can be extrapolated to estimate the risk of larger earthquakes [1]. As an example consider southern California. On average there are 30 magnitude 4 or larger earthquakes per year. Using the fractal scaling it is estimated that the expected intervals between magnitude 6 earthquakes will be 3 years, between magnitude 7 earthquakes will be 30 years, and between magnitude 8 earthquakes will be 300 years.

The fractal scaling of earthquakes illustrate a useful aspect of fractal distributions. The fractal distribution requires two parameters. The first parameter, the fractal dimension  $D$  (known as the  $b$ -value in seismology), gives the dependence of number on size (magnitude). For earthquakes the fractal dimension is almost constant independent of the tectonic setting. The second parameter gives the level of activity. For example, this can be the number of earthquakes greater than a specified magnitude in a region. This level of activity varies widely and is an accepted measure of seismic risk. The level is essentially zero in states like Minnesota and is a maximum in California.

### Volcanic Eruptions

There is good evidence that the frequency-volume statistics of volcanic eruptions are also fractal [9]. Although it is difficult to quantify the volumes of magma and ash associated with older eruptions, the observations suggest that an eruption with a volume of  $1 \text{ km}^3$  would be expected each 10 years,  $10 \text{ km}^3$  each 100 years, and  $100 \text{ km}^3$  each 1000 years. For example, the 1991 Mount Pinatubo, Philippines eruption had an estimated volume of about  $5 \text{ km}^3$ . The most violent eruption in the last 200 years was the 1815 Tambora, Indonesia eruption with an estimated volume of  $150 \text{ km}^3$ . This eruption influenced the global climate in 1816 which was known as the year without a summer. It is estimated that the Long Valley, California eruption with an age of about 760,000 years had a volume of about

$600 \text{ km}^3$  and the Yellowstone eruptions of about 600,000 years ago had a volume of about  $2000 \text{ km}^3$ .

Although the validity of the power-law (fractal) extrapolation of volcanic eruption volumes to long periods in the past can be questioned, the extrapolation does give some indication of the risk of future eruptions to global climate. There is no doubt that the large eruptions that are known to have occurred on time scales of  $10^5$  to  $10^6$  years would have a catastrophic impact on global agricultural production.

### Landslides

Landslides are a complex natural phenomenon that constitutes a serious natural hazard in many countries. Landslides also play a major role in the evolution of landforms. Landslides are generally associated with a trigger, such as an earthquake, a rapid snowmelt, or a large storm. The landslide event can include a single landslide or many thousands. The frequency-area distribution of a landslide event quantifies the number of landslides that occur at different sizes. It is generally accepted that the number of large landslides with area  $A$  has a power-law dependence on  $A$  with an exponent in the range 1.3 to 1.5 [5].

Unlike earthquakes, a complete statistical distribution can be defined for landslides. A universal fit to an inverse-gamma distribution has been found for a number of event inventories. This distribution has a power-law (fractal) behavior for large landslides and an exponential cut-off for small landslides. The most probable landslides have areas of about  $40 \text{ m}^2$ . Very few small landslides are generated.

As a specific example we consider the 11,111 landslides generated by the magnitude 6.7 Northridge (California) earthquake on January 17, 1994. The total area of the landslides was  $23.8 \text{ km}^2$  and the area of the largest landslide was  $0.26 \text{ km}^2$ . The inventory of landslide areas had a good power-law dependence on area for areas greater than  $10^3 \text{ m}^2$  ( $10^{-3} \text{ km}^2$ ). The number of landslides generated by earthquakes have a strong dependence on earthquake magnitude. Typically earthquakes with magnitudes  $M$  less than 4 do not generate any landslides [6].

### Floods

Floods are a major hazard to many cities and estimates of flood hazards have serious economic implications. The standard measure of the flood hazard is the 100-year flood. This is quantified as the river discharge  $Q_{100}$  expected during a 100 year period. Since there is seldom a long enough history to establish  $Q_{100}$  directly, it is necessary to extrapolate smaller floods that occur more often.

One extrapolation approach is to assume that flood discharges are fractal (power-law) [3,19]. This scale invariant distribution can be expressed in terms of the ratio  $F$  of the peak discharge over a 10 year interval to the peak discharge over a 1 year interval,  $F = Q_{10}/Q_1$ . With self-similarity the parameter  $F$  is also the ratio of the 100 year peak discharge to the 10 year peak discharge,  $F = Q_{100}/Q_{10}$ . Values of  $F$  have a strong dependence on climate. In temperate climates such as the northeastern and northwestern US values are typically in the range  $F = 2-3$ . In arid and tropical climates such as the southwestern and southeastern US values are typically in the range  $F = 4-6$ .

The applicability of fractal concepts to flood forecasting is certainly controversial. In 1982, the US government adopted the log-Pearson type 3 (LP3) distribution for the legal definition of the flood hazard [20]. The LP3 is a thin-tailed distribution relative to the thicker tailed power-law (fractal) distribution. Thus the forecast 100 year flood using LP3 is considerably smaller than the forecast using the fractal approach. This difference is illustrated by considering the great 1993 Mississippi River flood. Considering data at the Keukuk, Iowa gauging station [4] this flood was found to be a typical 100 year flood using the power-law (fractal) analysis and a 1000 to 10,000 year flood using the federal LP3 formulation. Concepts of self-similarity argue for the applicability of fractal concepts for flood-frequency forecasting. This applicability also has important implications for erosion. Erosion will be dominated by the very largest floods.

### Self-Affine Fractals

Mandelbrot and Van Ness [8] extended the concept of fractals to time series. Examples of time series in geology and geophysics include global temperature, the strength of the Earth's magnetic field, and the discharge rate in a river. After periodicities and trends have been removed, the remaining values are the stochastic (noise) component of the time series. The standard approach to quantifying the noise component is to carry out a Fourier transform on the time series [2]. The power-spectral density coefficients  $S_i$  are proportional to the squares of the Fourier coefficients. The time series is a self-affine fractal if the power-spectral density coefficients have an inverse power-law dependence on frequency  $f_i$ , that is

$$S_i = \frac{C}{f_i^\beta} \quad (5)$$

where  $C$  is a constant and  $\beta$  is the power-law exponent.

For a Gaussian white noise the values in the time series are selected randomly from a Gaussian distribution.

Adjacent values are not correlated with each other. In this case the spectrum is flat and the power spectral density coefficients are not a function of frequency,  $\beta = 0$ . The classic example of a self-affine fractal is a Brownian walk. A Brownian walk is obtained by taking the running sum of a Gaussian white noise. In this case we have  $\beta = 2$ . Another important self-affine time series is a red (or pink) noise with power spectral density coefficients proportional to  $1/f$ , that is  $\beta = 1$ . We will see that the variability in the Earth's magnetic field is well approximated by a  $1/f$  noise.

Self-affine fractal time series in the range  $\beta = 0$  to 1 are known as fractional Gaussian noises. These noises are stationary and the standard deviation is a constant independent of the length of the time series. Self-affine time series with  $\beta$  larger than 1 are known as fractional Brownian walk. These motions are not stationary and the standard deviation increases as a power of the length of the time series, there is a drift. For a Brownian walk the standard deviation increases with the square root of the length of the time series.

### Topography

The height of topography along linear tracks can be considered to be a continuous time series. In this case we consider the wave number  $k_i$  (1/wave length) instead of frequency. Topography is a self-affine fractal if

$$S_i = \frac{C}{k_i^\beta} \quad (6)$$

Spectral expansions of global topography have been carried out, an example [15] is given in Fig. 2. Excellent agreement with the fractal relation given in Eq. (6) is obtained taking  $\beta = 2$ , topography is well approximated by a Brownian walk. It has also shown that this fractal behavior of topography is found for the moon, Venus, and Mars [18].

### Earth's Magnetic Field

Paleomagnetic studies have given the strength and polarity of the Earth's magnetic field as a function of time over millions of years. These studies have also shown that the field has experienced a sequence of reversals.

Spectral studies of the absolute amplitude of the field have been shown that it is a self-affine fractal [12,14]. The power-spectral density is proportional to one over the frequency, it is a  $1/f$  noise. When the fluctuations of the  $1/f$  noise take the magnitude to zero the polarity of the field reverses. The predicted distribution of polarity intervals is fractal and is in good agreement with the observed polarity intervals.

Fractals in Geology and Geophysics, Figure 2

Power spectral density  $S$  as a function of wave number  $k$  for a spherical harmonic expansion of the Earth's topography (degree  $l$ ). The straight-line correlation is with Eq. (6) taking  $\beta = 2$ , a Brownian walk

### Future Directions

There is no question that fractals are a useful empirical tool. They provide a rational means for the extrapolation and interpolation of observations. The wide applicability of power-law (fractal) distributions is generally accepted, but does this applicability have a more fundamental basis? Fractality appears to be fundamentally related to chaotic behavior and to numerical simulations exhibiting self-organized criticality. The entire area of fractals, chaos, self-organized criticality, and complexity remains extremely active, and it is impossible to predict with certainty what the future holds.

### Glossary

**Chaos** Apparently random or unpredictable behavior in systems governed by deterministic laws. The common element in these systems is a very high sensitivity to initial conditions and to the way in which a system is set in motion (Encyclopedia Britannica).

**Complexity** An attribute of nonlinear (chaotic) systems. It comprises instability and complex but not random behavior patterns – “order in chaos”.

**Earthquake** An episode of rupture and discontinuous displacement within the solid Earth. Part of the energy accumulated around the rupture is released by inelastic deformation and seismic waves. Both may cause destructive shaking of the ground, if the energy release is sufficiently large.

**Earthquake forecasting** Probabilistic extrapolation of seismic activity comprising many earthquakes.

**Earthquake prediction** Prediction of time interval, geographic area, and magnitude range where an individual future strong earthquake will occur. The prediction

is meaningful if it includes an estimated rate of false alarms.

**Earthquake preparedness** A set of actions reducing the damage from the future earthquakes. There are different levels of preparedness.

**Extreme events** Rare events of low probability but high impact on a system where they occur. In different connotations they are also known as critical transitions, disasters, catastrophes, and crises. Over time they persistently recur in both natural and constructed complex systems. In this article the extreme events are the strong earthquakes. An earthquake might be an extreme event in a certain volume of the lithosphere and part of the background seismicity in a larger volume.

**Lithosphere** The earthquake-prone outer shell of the solid Earth. In prediction research it is regarded as a hierarchical complex system.

**Premonitory seismicity patterns** Space-time-magnitude patterns of earthquake occurrences that signal the approach of a strong earthquake.

### Definition of the Subject

#### Definition

The *problem* of earthquake prediction is to find when and where a strong earthquake will occur. A prediction is formulated as a discrete sequence of alarms (Fig. 1). The accuracy of a prediction method is captured by probabilities of errors (false alarms and failures to predict) and by the total space-time occupied by alarms. (Sect. “Error Diagram”).

In terms of prediction studies this is algorithmic prediction of individual extreme events having low probability but large impact. This problem is necessarily intertwined with problems of disaster preparedness, dynamics

Geo-complexity and Earthquake Prediction, Figure 1  
Possible outcomes of prediction

of solid Earth, and modeling of extreme events in hierarchical complex systems.

*Predictability* (“*order in chaos*”). Complex systems, lithosphere included, are not predictable with unlimited precision. However, after a coarse-graining (i. e., in a not-too-detailed scale) certain regular behavior patterns emerge and a system becomes predictable, up to certain limits ([13,20,24,26,36,46,52,83]). Accordingly, earthquake prediction requires a holistic analysis, “from the whole to details”. Such analysis makes it possible to overcome the geo-complexity itself and the chronic imperfection of observations as well.

*Premonitory patterns*. Certain behavior patterns emerge more frequently as a strong earthquake draws near. Called premonitory patterns, they signal destabilization of the earthquake-prone lithosphere and thus an increase in the probability of a strong earthquake. Premonitory patterns do not necessarily contribute to causing a subsequent strong earthquake; both might be parallel manifestations of the same underlying process – the tectonic development of the Earth in multiple time-, space-, and energy- scales. For that reason premonitory patterns might emerge in a broad variety of observable fields reflecting lithosphere dynamics, and in different scales.

The algorithms considered here, based on premonitory seismicity patterns, provide alarms lasting years to months. There is ample evidence that major findings made in developing these algorithms are applicable to premonitory patterns in other fields, to predicting other geological and geotechnical disasters, and probably to determining shorter and longer alarms (Sect. “**Further Goals**”).

## Importance

Algorithmic earthquake prediction provides pivotal constraints for fundamental understanding of the dynamics of the lithosphere and other complex systems. It is also critically important for protecting the global population, economy, and environment. Vulnerability of our world to the earthquakes is rapidly growing, due to proliferation of high-risk construction (nuclear power plants, high dams, radioactive waste disposals, lifelines, etc.), deterioration of ground and infrastructure in megacities, destabilization of environment, population growth, and escalating socio-economic volatility of the global village. Today a single earthquake with its ripple effects may take up to a million lives; destroy a megacity; trigger a global economic depression (e. g. if it occurs in Tokyo); trigger an ecological catastrophe, rendering a large territory uninhabitable; or destabilize military balance in a region. Regions of low

seismicity have become highly vulnerable, e. g. European and Indian platforms, and Central and Eastern parts of the U.S. As a result the earthquakes joined the ranks of the major disasters that, in the words of J. Wisner, have become “a threat to civilization survival, as great as was ever posed by Hitler, Stalin or the atom bomb”. Earthquake prediction is necessary to reduce the damage by escalating disaster preparedness. Predictions useful for preparedness should have known, but not necessarily high, accuracy. Such is the standard practice in preparedness for all disasters, wars included.

## Introduction

Earthquakes occur in some parts of the outer shell of the solid Earth, called the lithosphere; its thickness ranges from a few kilometers near the mid-ocean ridges to a few hundred kilometers in certain continental regions. At many continental margins the lithosphere bends downward penetrating underlying mantle as seismically active subduction zones. In seismically active regions a significant part of tectonic development is realized through the earthquakes.

About a million earthquakes with magnitude 2 (energy about  $10^{15}$  erg) or more are detected each year worldwide by seismological networks. About a hundred of these cause considerable damage and few times in a decade a catastrophic earthquake occurs.

Catalogs of earthquakes provide the data for detecting premonitory seismicity patterns. Typically for complexity studies we do not have a complete set of fundamental equations that govern dynamics of seismicity and unambiguously define earthquake prediction algorithms. This is due to the multitude of mechanisms controlling seismicity – see Sect. “**Generalization: Complexity and Extreme Events**”. In lieu of such equations “... *we have to rely upon the hypotheses obtained by processing of the experimental data*” (A. Kolmogorov on transition to turbulence). Formulating and testing such hypotheses involves exploratory data analysis, numerical and laboratory modeling, and theoretical studies (Sect. “**General Scheme of Prediction**”).

Diversity of methods and urgency of the problem makes learning by doing a major if not *the* major form of knowledge transfer in prediction of extreme events ([http://cdsagenda5.ictp.it/full\\_display.php?da=a06219](http://cdsagenda5.ictp.it/full_display.php?da=a06219)).

*Reliability of the existing algorithms* has been tested by continuous prediction of future strong earthquakes in numerous regions worldwide. Each algorithm is self-adapting, i. e. applicable without any changes in the regions with different seismic regimes. Predic-

tions are filed in advance at the websites (<http://www.mitp.ru/predictions.html>; <http://www.phys.ualberta.ca/mirrors/mitp/predictions.html>; and <http://www.igpp.ucla.edu/prediction/rtp/>).

Following is the scoring for four different algorithms.

- *Algorithms M8 [32] and MSc [44]* (MSc stands for the Mendocino Scenario). Algorithm M8 gives alarms with characteristic duration years. MSc gives a second approximation to M8, reducing the area of alarm. An example of their application is shown in Fig. 2.

Continually applied since 1992, algorithm M8 has predicted 10 out of 14 large earthquakes (magnitude 8 or more) which have occurred in the major seismic belts. Alarms occupied altogether about 30% of the time-space considered. Both algorithms applied together reduced the time-space alarms to 15%, but three more target earthquakes were missed by prediction.

- *Algorithm SSE or Second Strong Earthquake [43,91]*. Its aim is to predict whether or not a second strong earthquake will follow the one that had just occurred. An alarm lasts 18 months after the first strong earthquake. An example of prediction is shown in Fig. 3. Testing by prediction in advance is set up for California, Pamir and Tien Shan, Caucasus, Iberia and Maghreb, the Dead Sea rift, and Italy. Since 1989 this algorithm

made 29 predictions; 24 of which were correct and 5 were wrong.

These scores demonstrate predictability of individual earthquakes. A predictions' accuracy is indeed limited, but sufficient to prevent a considerable part of the damage.

- *Algorithm RTP or Reverse Tracing of Precursors [37,81]*. This algorithm gives alarms with a characteristic duration of months. An example of this prediction is shown in Fig. 4. Testing by prediction in advance started only few years ago for California, Japan, the Northern Pacific, Eastern Mediterranean, and Italy with adjacent areas.

*Perspective.* It is encouraging that only a small part of readily available relevant data, models and theories have been used for prediction so far. This suggests a potential for a substantial increase of prediction accuracy.

### Lithosphere as a Hierarchical Complex System

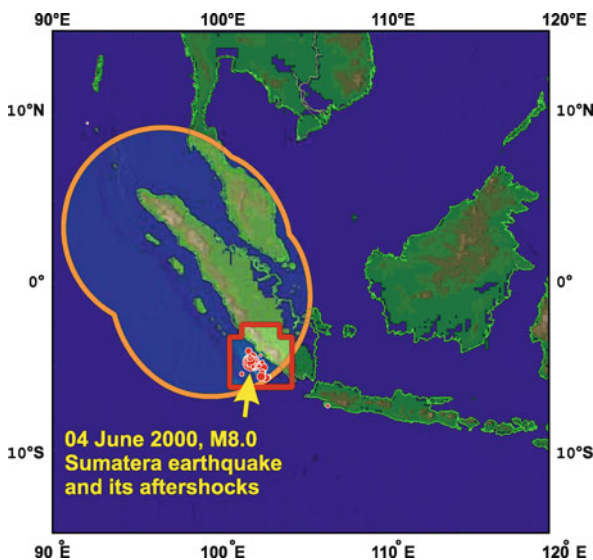

Two major factors turn the lithosphere into a hierarchical dissipative complex system [29,36,87]. The first one is a *hierarchical structure* extending from tectonic plates to grains of rocks. The second factor is *instability* caused by a multitude of nonlinear mechanisms destabilizing the strength and stress fields.

Among extreme events in that system are the strong earthquakes. *An earthquake may be an extreme event in a certain volume of the lithosphere and a part of the background seismicity in a larger volume.*

### Structure

**Blocks** The structure of the lithosphere presents a hierarchy of volumes, or blocks, which move relative to each other. The largest blocks are the major tectonic plates, of continental size. They are divided into smaller blocks, such as shields or mountain belts. After 15–20 consecutive divisions we come to about  $10^{25}$  grains of rocks of millimeter size.

**Boundary zones** Blocks are separated by relatively thin and less rigid boundary zones. They are called fault zones high in the hierarchy, then faults, sliding surfaces, and, finally, interfaces between grains of rock. Except at the bottom of the hierarchy, a boundary zone presents a similar hierarchical structure with more dense division. Some segments of the boundary zones, particularly in tectonically young regions, might be less explicitly expressed, presenting a bundle of small ruptures not yet merged into a fault, of a flexure not yet ruptured, etc.

Geo-complexity and Earthquake Prediction, Figure 2 Prediction of the Sumatra earthquake, June 4th, 2000,  $M = 8.0$  by algorithms M8 and MSc. The orange oval curve bounds the area of alarm determined by algorithm M8, the red rectangle is its reducing made by algorithm MSc. Circles show epicenters of the Sumatra earthquake and its aftershocks. After [43]

Geo-complexity and Earthquake Prediction, Figure 3

Prediction of the Northridge, California earthquake, January 28th, 1994,  $M = 6.8$  by algorithm SSE. The prediction was made by analysis of aftershocks of the Landers earthquake, June 28th, 1992,  $M = 7.6$ . An earthquake with  $M = 6.6$  or larger was expected during the 18 months after the Landers earthquake within the 169-km distance from its epicenter (shown by a circle). The Northridge earthquake occurred on January 28th, 1994, 20 days after the alarm expired. After [43]

**Nodes** These are even more densely fractured mosaic structures formed around the intersections and junctions of boundary zones. Their origin is due, roughly saying, to collision of the corners of blocks [16,39,40,55]. The nodes play a singular role in the dynamics of the lithosphere. A special type of instability is concentrated within the nodes and strong earthquakes nucleate in nodes. The epicenters of strong earthquakes worldwide are located only within some specific nodes that can be identified by pattern recognition [19,22].

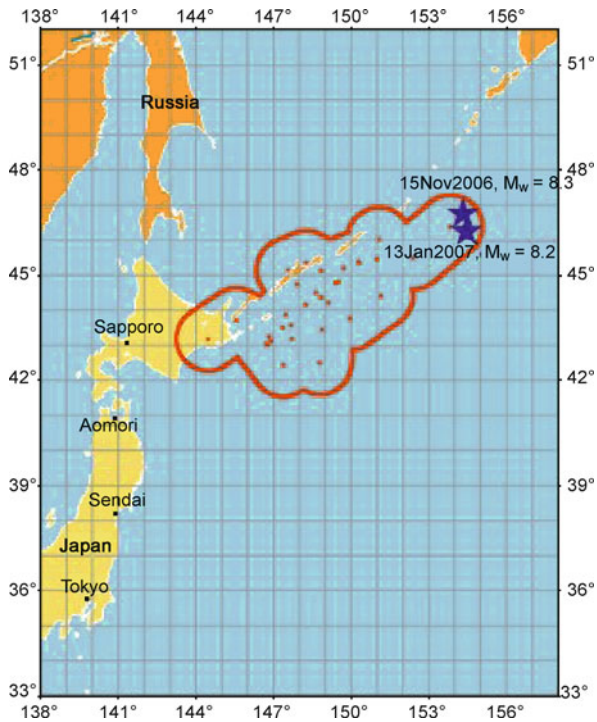

Nodes are well known in the structural geology and geomorphology and play a prominent textbook role in geological prospecting. However their connection with earthquakes is less widely recognized.

The formalized procedure for dividing a territory into blocks  $\Rightarrow$  faults  $\Rightarrow$  nodes is given in [2].

### Fault Network – A Stockpile of Instability

For brevity, the systems of boundary zones and nodes are called here fault networks. They range from the Circum Pacific seismic belt, with the giant triple junctions for the nodes, to interfaces between the grains of rocks, with the corners of grains for the nodes. Their great diversity notwithstanding, fault networks play a similar role in the lithosphere dynamics. Specifically, while tectonic energy is stored in the whole volume of the lithosphere and well beneath, the energy release is to a large extent controlled by the processes in relatively thin fault networks. This contrast is due to the following.

First, the strength of a fault network is smaller than the strength of blocks it separates: fault networks are weakened by denser fragmentation and higher permeability to

Geo-complexity and Earthquake Prediction, Figure 4  
 Prediction of Simushir, Kuril Islands earthquakes, November 15th, 2006,  $M_w = 8.3$  and January 13th, 2007,  $M_w = 8.2$  by Algorithm RTP. An earthquake with magnitude  $M_w \geq 7.2$  is predicted to occur within the time interval from September 30th, 2006, to June 30th, 2007 in the area bordered by the red curve. The red dots show epicenters of an earthquake-forming premonitory chain. The blue stars show epicenters of the predicted earthquakes

fluids. For that reason, tectonic deformations are concentrated in fault networks, whereas blocks move essentially as a whole, with a relatively smaller rate of internal deformations. In other words, in the time scale directly relevant to earthquake prediction (hundreds of years or less) the major part of the lithosphere dynamics is realized through deformation of fault networks and relative movement of blocks.

Second, the strength of a fault network is not only smaller, but also highly unstable, sensitive to many processes there. There are two different kinds of such instability. The “physical” one is originated at the micro level by a multitude of physical and chemical mechanisms reviewed in the next section. “Geometric” instability is originated at a macro level controlled by the geometry of the fault network (Sect. “**Geometric Instability**”). These instabilities largely control dynamics of seismicity, the occurrence of strong earthquakes included.

### “Physical” Instability [23,29]

As in any solid body, deformations and fracturing in the lithosphere are controlled by the relation of the strength field and stress field. The strength is in turn controlled by a great multitude of interdependent mechanisms concentrated in the fault network. We describe, for illustration, several such mechanisms starting with the impact of fluids.

### Rehbinder Effect, or Stress Corrosion [14,85]

*Mechanism* Many solid substances lose their strength when they come in contact with certain surface-active liquids. The liquid diminishes the surface tension  $\mu$  and consequently the strength, which is proportional to  $\sqrt{\mu}$  by the Griffiths criterion. When the strength drops, cracks may emerge under small stress. Then liquid penetrates the cracks and they grow, with drops of liquid propelling forward, until they dissipate. This greatly reduces the stress required to generate the fracturing. Stress corrosion was first discovered for metals and ceramics. Then such combinations of solid substances and surface-active liquids were recognized among the common ingredients of the lithosphere, e.g. basalt and sulphur solutions. When they meet, the basalt is permeated by a grid of cracks and the efficient strength may instantly drop by a factor of 10 or more due to this mechanism alone.

*Geometry of Weakened Areas* Orientation of such cracks at each point is normal to the main tensile stress. The stress field in the lithosphere may be very diverse. However, the shape of weakened areas where the cracks concentrate may be of only a few types, determined by the theory of singularities. Some examples are shown in Fig. 5, where thin lines show the trajectories of cracks; each heavy line is a separatrix, dividing the areas with different patterns of trajectories.

If a liquid infiltrates from a place shown in Fig. 5 by arrows, the cracks concentrate in the shaded area, and its strength plummets. A slight displacement of the source across the separatrix may strongly change the geometry of such fatigue; it may be diverted to quite a different place and take quite a different shape, although not an arbitrary one. Furthermore evolution of the stress field may change the type of a singularity, make it disappear or create a new one, and the geometry of fatigue will follow suit.

*Stress Corrosion is Highly Sensitive to Geochemistry of Fluids* For example, gabbro and dolerite are affected only in the presence of iron oxides; Kamchatka ultrabasic rocks

Geo-complexity and Earthquake Prediction, Figure 5  
Instability caused by stress corrosion. The geometry of weakened areas depends on the type of singularity and the place where the chemically active fluid comes in. After [14]

are affected by the andesite lava liquids only in the presence of copper oxide, etc. Migration of fluids would cause observable variations of electromagnetic and geochemical fields.

*Summing Up* Stress corrosion brings into lithosphere a strong and specific instability, which may explain many observed premonitory seismicity patterns. However the basic configurations of fatigue, as shown in Fig. 5 might be realizable only in not-too-large areas. This limitation stems from the dissipation of fluids and/or from the inhomogeneity of stress field.

**Other Mechanisms** Boundary zones feature several other mechanisms, potentially as important and certainly as complicated. A few more examples follow.

*Mechanical Lubrication* by fluids migrating through a boundary zone [7]. The ensuing instability will be enhanced by *fingers of fluids* springing out at the front of migration [6].

*Dissolution of Rocks* Its impact is magnified by the *Rikke effect* – an increase of solubility of rocks with pressure. This effect leads to a mass transfer. Solid material is dis-

solved under high stress and carried out in solution along the stress gradient to areas of lower stress, where it precipitates. The Rikke effect might be easily triggered in a crystalline massif at the corners of rock grains, where stress is likely to concentrate.

*Petrochemical Transitions* Some of them tie up or release fluids, as in the formation or decomposition of serpentines. Other transitions cause a rapid drop of density, such as in the transformation of calcite into aragonite. (This would create a vacuum and unlock the fault; the vacuum will be closed at once by hydrostatic pressure, but a rupture may be triggered.)

Instability is created also by sensitivity of dynamic friction to local physical environment [50], mechanical processes, such as multiple fracturing, buckling, viscous flow, and numerous other mechanisms [49,70].

Most of the above mechanisms are sensitive to variations of pressure and temperature.

### Geometric Instability [16]

The geometry of fault networks might be, and often is, incompatible with kinematics of tectonic movements, including earthquakes. This leads to stress accumulation, de-

formation, fracturing, and the change of fault geometry, jointly destabilizing the fault network. Two integral measures of this instability, both concentrated in the nodes, are *geometric* and *kinematic incompatibility* [16].

Each measure estimates the integrated effect of tectonic movements in a wide range of time scales, from seismicity to geodetic movements to neotectonics.

**Geometric Incompatibility** The intersection of two strike-slip faults separating moving blocks. Figure 6 is a simple example of geometric incompatibility. If the movements indicated by arrows in Fig. 6a could occur, the corners A and C would penetrate each other and an intersection point would split into a parallelogram (Fig. 6c). In the general case of a finite number of intersecting faults their intersection point would split into a polygon. Such splitting is not possible in reality; the collision at the corners leads to the accumulation of stress and deformations near the intersection followed by fracturing and changes of fault geometry. The divergence of the corners will be realized by normal faulting.

The expansion of that unrealizable polygon with time,  $S(t) = Gt^2/2$ , measures the intensity of this process. Here,  $S$  is the area of the polygon, determined by the slip rates on intersecting faults;  $t$  is the elapsed time from the collision, and  $G$  is the measure of geometric incompatibility.

Such incompatibility of structure and kinematics was first described in [55] for a triple junction. The study established a condition under which a single junction can retain its geometry as the plates move, so that the stress will not accumulate. It was suggested in [39,40] that the

general case, when that condition is not satisfied, the ensuing fracturing would not dissolve the stress accumulation, but only redistribute it among newly formed corners. This triggers further similar fracturing with the result that a hierarchy of progressively smaller and smaller faults is formed about an initial intersection. This is a node, recognizable by the dense mosaic structure, with probably self-similar fractal geometry [39].

A real fault network contains many interacting nodes. Incompatibility  $G$  is additive, and can be estimated for a network as a whole. An analogue of the Stokes theorem connects the total value of  $G$  within a territory with observations on its boundary. This removes the nearly impossible task – to take into account complex internal structure of the nodes. One can instead surround the system of nodes by a contour crossing the less complicated areas. Then the geometric incompatibility can be realistically evaluated from the movements of the fewer faults that cross the contour.

Geometric incompatibility in different nodes is interdependent, because they are connected through the movements of blocks-and-faults system. A strong earthquake in a node would redistribute values  $G$  in other nodes thus affecting the occurrence of earthquakes there. Observations indicating the interaction of nodes have been described by [73,74]. These studies demonstrate phenomenon of long-range aftershocks: a rise of seismic activity in the area, where the next strong earthquake is going to occur within about 10 years.

So far, the theory of geometric incompatibility has been developed for the two-dimensional case, with rigid blocks and horizontal movements.

Geo-complexity and Earthquake Prediction, Figure 6  
Geometric incompatibility near a single intersection of faults. a, b initial position of the blocks; c, d extrapolation of the blocks' movement; a, c the locked node: movement is physically unrealizable without fracturing or a change in the fault geometry; b, d the unlocked node. After [16]

**Kinematic Incompatibility** Relative movements on the faults would be in equilibrium with the absolute movements of blocks separated by these faults (one could be realized through the other) under the well known Saint-Venant condition of kinematic compatibility [8,56,57]. In the simplest case, shown in Fig. 6, this condition is  $K = \sum v_i = 0$ , where  $v_i$  are slip rates on the faults meeting at the intersection (thin arrows in Fig. 6). The value of  $K$  is the measure of the kinematic incompatibility, causing accumulation of stress and deformation in the blocks. A simple illustration of that phenomenon is the movement of a rectangular block between two pairs of parallel faults. The movement of the block as a whole has to be compensated for by relative movements on all the faults surrounding it: if, for example, the movement takes place on only one fault, the stress will accumulate at other faults and within the block itself thus creating kinematic incompatibility.

Like geometric incompatibility the values of  $K$  are also additive: one may sum up values at different parts of the network. And an analogue of the Stokes theorem links the value of  $K$  for a region with observations on its boundary.

### Generalization: Complexity and Extreme Events

Summing up, dynamics of the lithosphere is controlled by a wide variety of mutually dependent mechanisms concentrated predominantly within fault networks and interacting across and along the hierarchy. Each mechanism creates strong instability of the strength-stress field, particularly of the strength. Except for very special circumstances, none of these mechanisms alone prevails in the sense that the others can be neglected.

Even the primary element of the lithosphere, a grain of rock, may act simultaneously as a material point, a viscoelastic body, an aggregate of crystals, a source or absorber of energy, fluids, volume, with its body and surface involved in different processes.

Assembling the set of governing equations is unrealistic and may be misleading as well: A well-known maxim in nonlinear dynamics tells that *one cannot understand chaotic system by breaking it apart* [12]. One may rather hope for a generalized theory (or at least a model), which directly represents the gross integrated behavior of the lithosphere. That brings us to the concept that *the mechanisms destabilizing the strength of fault networks altogether turn the lithosphere into a nonlinear hierarchical dissipative system, with strong earthquakes among the extreme events*. At the emergence of that concept the lithosphere was called a chaotic system [29,66,87]; the more general term is *complex system* [20,24,31,53,78,83].

### General Scheme of Prediction

Typically for a complex system, the solid Earth exhibits a permanent background activity, a mixture of interacting processes providing the raw data for earthquake prediction. Predictions considered here are based on detecting premonitory patterns of that activity (Sect. “Definition”).

### Pattern Recognition Approach

Algorithms described here consider prediction as the pattern recognition problem: *Given* the dynamics of relevant fields in a certain area prior to some time  $t$ , *to predict* whether a strong earthquake will or will not occur within that area during the subsequent time interval  $(t, t + \Delta)$ . Some algorithms also reduce the area where it will occur.

In terms of pattern recognition, the object of recognition is the time  $t$ . The problem is to recognize whether it

belongs or not to the time interval  $\Delta$  preceding a strong earthquake. That interval is often called the *TIP* (an acronym for the *time of increased probability* of a strong earthquake). Such prediction is aimed not at the whole dynamics of seismicity but only at the rare extraordinary phenomena, strong earthquakes.

*Pattern recognition of rare events* proves to be very efficient in that approach to prediction. This methodology has been developed by the school of I. Gelfand for the study of rare phenomena of complex origin [9,19,34,71].

### Data Analysis

Prediction algorithms are designed by analysis of the learning material – a sample of past critical events and the time series hypothetically containing premonitory patterns. Analysis comprises four following steps:

1. *Detecting premonitory patterns*. Each time series considered is robustly described by the functionals  $F_k(t)$ ,  $k = 1, 2, \dots$ , capturing hypothetical patterns (Fig. 7). Hypotheses on what these patterns may be are provided by universal modeling of complex systems (Sect. “Fourth Paradigm: Dual Nature of Premonitory Phenomena”), modeling of Earth-specific processes, exploratory data analysis, and practical experience, even if it is intuitive. Pattern recognition of rare events is an efficient common framework for formulating and testing such hypotheses, their diversity notwithstanding.

With a few exceptions the functionals are defined in sliding time windows; the value of a functional is attributed to the end of the window. In the algorithms

Geo-complexity and Earthquake Prediction, Figure 7  
General scheme of prediction. After [29]

described here the time series were earthquake sequences.

2. *Discretization.* Emergence of a premonitory pattern is defined by the condition  $F_k(t) \geq C_k$ . The threshold  $C_k$  is chosen in such a way that a premonitory pattern emerges on one side of the threshold more frequently than on another side. That threshold is usually defined as a certain percentile of the functional  $F_k$ . In such robust representation of the data pattern recognition is akin to exploratory data analysis developed in [86].
3. *Formulating an algorithm.* A prediction algorithm will trigger an alarm when a certain combination of premonitory patterns emerges. This combination is determined by further application of pattern recognition procedures [36,71].
4. *Estimating reliability of an algorithm.* This is necessary, since an algorithm inevitably includes many adjustable elements, from selecting the data used for prediction and definition of prediction targets, to the values of numerical parameters. In lieu of the closed theory a priori determining all these elements they have to be adjusted retrospectively, by predicting the past extreme events. That creates the danger of self-deceptive data-fitting: *If you torture the data long enough, it will confess to anything.* Validation of the algorithms requires three consecutive tests.
  - *Sensitivity analysis:* varying adjustable elements of an algorithm.
  - *Out of sample analysis:* applying an algorithm to past data that has not been used in the algorithm's development.

- *Predicting in advance* – the only decisive test of a prediction algorithm.

Such tests take a lion's share of data analysis [17,19,36,93]. A prediction algorithm makes sense only if its performance is (i) sufficiently better than a random guess, and (ii) not too sensitive to variation of adjustable elements. Error diagrams described in the next section show whether these conditions are satisfied.

### Error Diagram

**Definition** An error diagram shows three major characteristics of a prediction's accuracy. Consider an algorithm applied to a certain territory during the time period  $T$ . During the test  $N$  strong earthquakes have occurred there and  $N_m$  of them have been missed by alarms. Altogether,  $A$  alarms have been declared and  $A_f$  of them happened to be false. The total duration of alarms is  $D$ .

Performance of an algorithm is characterized by three dimensionless parameters: the relative duration of alarms,  $\tau = D/T$ ; the rate of failures to predict,  $n = N_m/N$ ; and the rate of false alarms,  $f = A_f/A$ . These three parameters are necessary in any test of a prediction algorithm regardless of a particular methodology. They are juxtaposed on the error diagrams schematically illustrated in Fig. 8. Also called Molchan diagrams, they are used for validation and optimization of prediction algorithms and for joint optimization of prediction and preparedness [59,60,61,62,63]. In many applications parameter  $f$  is not yet considered. In

Geo-complexity and Earthquake Prediction, Figure 8

Scheme of an error diagram. Each point shows the performance of a prediction method: the rate of failures to predict,  $n$ , the relative duration of alarms,  $\tau$ , and the rate of false alarms,  $f$ . Different points correspond to different algorithms. The *diagonal* in the *left plot* corresponds to the random guess. Point *A* corresponds to the trivial optimistic strategy, when an alarm is never declared; point *B* marks the trivial pessimistic strategy, when an alarm takes place all the time; other points correspond to non-trivial predictions. Best combinations  $(n, \tau)$  lie on the envelope of these points  $\Gamma$ . After [63]

early applications they are called ROC diagrams for relative operating characteristics (e. g., [54]).

#### Four Paradigms

Central for determining premonitory patterns is what we know about them a priori. In other words – what are a priori constraints on the functionals  $F_k(t)$  that would capture these patterns (Sect. “Data Analysis”). These constraints are given by the four paradigms described in this section. They have been first found in the quest for premonitory seismicity patterns in the observed and modeled seismicity. There are compelling reasons to apply them also in a wide variety of prediction problems.

*Prehistory.* New fundamental understanding of the earthquake prediction problem was formed during the last 50 or so years, triggering entirely new lines of research. In hindsight this understanding stems from the following unrelated developments in the early sixties.

- F. Press initiated the installation of the state-of-the-art World-Wide Standardized Seismographic Network (WWSSN) later on succeeded by the Global Seismographic Network (GSN). Thus a uniform data base began to accumulate, augmented by expanding satellite observations.
- E. Lorenz discovered deterministic chaos in an ordinary natural process, thermal convection in the atmosphere [51]. This triggered recognition of deterministic chaos in a multitude of natural and socio-economic processes; however, the turn of seismicity and geodynamics in general came about 30 years later [4,29,66,87]. The phenomenon of deterministic chaos was eventually generalized by less rigorously defined and more widely applicable concept of complexity [20, 24,25].
- I. Gelfand and J. Tukey, working independently, created a new culture of exploratory data analysis that allows coping with the complexity of a process (e. g., [19,86]).
- R. Burridge and L. Knopoff [11] demonstrated that a simple system of interacting elements may reproduce a realistically complex seismicity, fitting many basic heuristic constraints. The models of interacting elements developed in statistical physics extended to seismology.
- L. Malinovskaya found a premonitory seismicity pattern reflecting the rise of seismic activity [33]. This is the first reported earthquake precursor formally defined and featuring long-range correlations and world-wide similarity.

With broader authorship:

- Plate tectonics established the connection between seismicity and large-scale dynamics of the lithosphere [41].
- Research in experimental mineralogy and rocks mechanics revealed a multitude of mechanisms that may destabilize the strength in the fault zones [70].

#### First Paradigm: Basic Types of Premonitory Patterns

*The approach of a strong earthquake is indicated by the following premonitory changes in the basic characteristics of seismicity:*

- *Rising:* Seismic activity, earthquakes clustering in space-time, earthquake correlation range, and irregularity of earthquake sequences. Rise of activity sometimes alternates with seismic quiescence.
- *Transforming:* Magnitude distribution (the Gutenberg–Richter relation). Its right end (at larger magnitudes) bends upward, and left end bends downward.
- *Reversing:* territorial distribution of seismicity.
- *Patterns of two more kinds* yet less explored: Rising response to excitation and decreasing dimensionality of the process considered (i. e. rising correlation between its components).

These patterns resemble asymptotic behavior of a thermodynamical system near the critical point in phase transition. Some patterns have been found first in observations and then in models; other patterns have been found in the opposite order. More specifics are given in [15,17,30,31,35,36,67,79,80,83,84,93].

Patterns capturing rise of intensity and clustering, have been validated by statistically significant predictions of real earthquakes [43,65]; other patterns undergo different stages of testing.

#### Second Paradigm: Long-Range Correlations

*The generation of an earthquake is not localized about its future source. A flow of earthquakes is generated by a fault network, rather than each earthquake – by a segment of a single fault. Accordingly, the signals of an approaching earthquake come not from a narrow vicinity of the source but from a much wider area.*

*What is the size of such areas?* Let  $M$  and  $L(M)$  be the earthquake magnitude and the characteristic length of its source, respectively. In the intermediate-term prediction (on a time scale of years) that size may reach  $10L(M)$ ; it might be reduced down to  $3L$  or even to  $L$  in a second approximation [43]. On a time scale of about 10 years that size reaches about  $100L$ . For example, according to [71],

the Parkfield (California) earthquake with  $M$  about 6 and  $L \approx 10$  km “... is not likely to occur until activity picks up in the Great Basin or the Gulf of California”, about 800 km away.

*Historical perspective.* An early estimate of the area where premonitory patterns are formed was obtained in [33] for a premonitory rise of seismic activity. C. Richter, who was sceptical about the feasibility of earthquake prediction, made an exception to that pattern, specifically because it was defined in large areas. He wrote [75]: “... It is important that (the authors) confirm the necessity of considering a very extensive region including the center of the approaching event. It is very rarely true that the major event is preceded by increasing activity in its immediate vicinity.”

However, such spreading of premonitory patterns has been often regarded as counterintuitive in earthquake prediction research on the grounds that earthquakes can't trigger each other at such distances. The answer is that earthquakes forming such patterns do not trigger each other but reflect an underlying large-scale dynamics of the lithosphere. Among the indisputable manifestations of that correlation are the following phenomena: migration of earthquakes along fault zones [47,52,58,90]; alternate rise of seismicity in distant areas [71] and even in distant tectonic plates [76]. Global correlations have been found also between major earthquakes and other geophysical phenomena, such as Chandler wobble, variations of magnetic field, and the velocity of Earth's rotation [34,72]. These correlations may be explained by several mechanisms not mutually exclusive. Such mechanisms range from micro-fluctuations of large scale tectonic movements to impact of migrating fluids (e. g., [1,5,7,10,69,71,82,84,89]).

### Third Paradigm: Similarity

*Premonitory phenomena are similar (identical after normalization) in the extremely diverse environments and in a broad energy range (e. g., [1,33,36]). The similarity is not unlimited however and regional variations of premonitory phenomena do emerge.*

Normalized prediction algorithms retain their prediction power in active regions and platforms, with the magnitude of target earthquakes ranging from 8.5 to 4.5. Furthermore, similarity extends to induced seismicity, and to multiple fracturing in engineering constructions and laboratory samples (e. g., [3,35,43]). Ultimately, a single but explicit demonstration of similarity was obtained for starquakes – ruptures of the crust of neutron star [45], where the conditions are extremely different than in the Earth.

Altogether the corresponding elastic energy release ranges from ergs to  $10^{25}$  ergs (even to  $10^{46}$  ergs if the starquake is counted in).

However, the performance of prediction algorithms does vary from region to region (see [21,35,63]). It is not yet clear whether this is due to imperfect normalization, or to limitations on similarity itself.

### Fourth Paradigm: Dual Nature of Premonitory Phenomena

*Some premonitory patterns are “universal”, common for hierarchical complex systems of different origin; other are specific to geometry of fault networks or to a certain physical mechanism controlling the strength and stress fields in the lithosphere.*

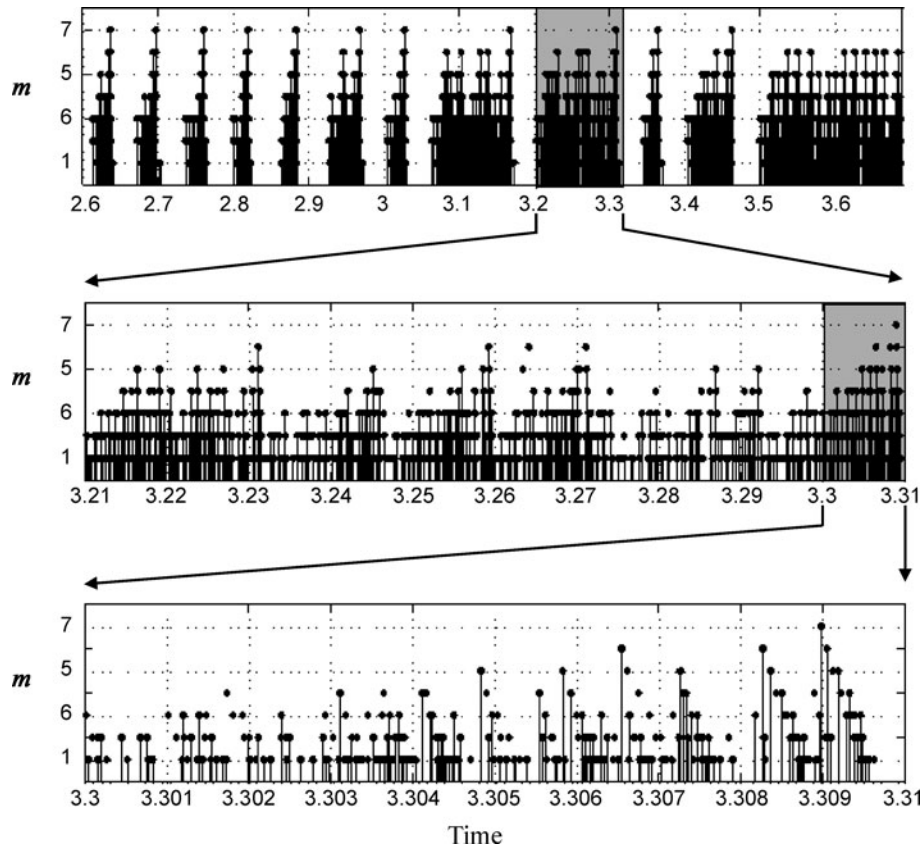

*Universal patterns.* These are most of the patterns so far known. They can be reproduced on models not specific to the Earth only, e. g. models of a statistical physics type (direct or inverse cascade, colliding cascades, percolation, dynamical clustering), models of critical phenomena in fluid dynamics, as well as Earth-specific models themselves.

Complete analytical definition of premonitory patterns was obtained recently on the branching diffusion model [18]. Definition includes only three control parameters, thus strongly reducing uncertainty in data analysis (Sect. “Data Analysis”).

Reviews of such models can be found in [15,17,36,66,83,89,93]. Discussion of particular patterns is given also in [25,42,67,68,88,92].

An example of an earthquake sequence generated by a universal model is shown in Fig. 9 [17]. The modeled seismicity exhibits major features of real seismicity: seismic cycle, switching of seismic regime, the Gutenberg–Richter relation, foreshocks and aftershocks, long-range correlation, and, finally, the premonitory seismicity patterns.

*Earth-specific patterns* are not yet incorporated in prediction algorithms. We discuss here the patterns reflecting the state of the nodes – structures where the strong earthquakes are nucleated (see Sect. “Structure”). Quantitative characteristics of that state are geometric incompatibility  $G$  (Sect. “Geometric Instability”). It shows whether the nodes are locked up or unlocked and quantifies their tendency to fracture and change of the faults geometry. Change of  $G$  might create or dissolve such feature as asperities, relaxation barriers, weak links, and replacement of seismicity by creep or “silent” earthquakes [16]. These features would migrate from node to node with velocity typical of seismicity migration: tens to hundreds km/year [90].

Geo-complexity and Earthquake Prediction, Figure 9

Synthetic earthquake sequence consecutively zoomed. *Shaded areas* mark zoomed intervals. The model shows the rich variety of behavior on different timescales. Note that the ratio of timescales for the *top* and *bottom* panels is  $10^2$ . After [17]

All this makes monitoring of  $G$  highly relevant to detecting premonitory patterns. A simple pattern of that kind is seismic quiescence around the soon-to-break nodes (e. g., [44,58,77]). A simple highly promising possibility is considering separately premonitory phenomena inside and outside of nodes (e. g., [77]).

### Earthquake Prediction and Earthquake Preparedness

Given the limited accuracy of predictions, how do we use them for damage reduction? The key to this is to escalate or de-escalate preparedness depending on the following: content of the current alarm (what and where is predicted), probability of a false alarm, and cost/benefit ratio of disaster preparedness measures. Prediction might be useful if its accuracy is *known*, even if it is not high. Such is the standard practice in preparedness for all disasters, war included.

### Diversity of Damage

Earthquakes hurt population, economy, and environment in very different ways: destruction of buildings, lifelines, etc; triggering fires; releasing of toxic, radioactive and genetically active materials; triggering other natural disasters, such as floods, avalanches, landslides, tsunamis, etc.

Equally dangerous are the socio-economic and political consequences of earthquakes: disruption of vital services (supply, medical, financial, law enforcement, etc.), epidemics, drop of production, slowdown of economy, unemployment, disruptive anxiety of population, profiteering and crime. The socio-economic consequences may be inflicted also by the undue release of predictions.

Different kinds of damage are developing at different time and space scales, ranging from immediate damage to chain reaction, lasting tens of years and spreading regionally if not worldwide.

**Diversity of Disaster Preparedness Measures** Such diversity of damage requires a hierarchy of disaster preparedness measures, from building code and insurance to mobilization of post disaster services to red alert. It takes different times, from decades to seconds to undertake different measures; having different cost they can be maintained for different time periods; and they have to be spread over different territories, from selected sites to large regions. No single stage can replace another one for damage reduction and no single measure is sufficient alone.

On the other hand many important measures are inexpensive and do not require high accuracy of prediction. An example is the Northridge, California, earthquake, 1994, which caused economic damage exceeding \$30 billion. Its prediction, published well in advance [48], was not precise – the alarm covered a time period of 18 months and an area 340 km in diameter with dramatically uneven vulnerability. However, low-cost actions, undertaken in response to this prediction (e. g. an out of turn safety inspection) would be well justified if even just a few percent of the damage were prevented.

### Joint Optimization of Prediction and Preparedness

The choice of preparedness measures is by no means unique. Different measures may supersede or mutually exclude one another, leaving the decision-maker a certain freedom of choice [38]. The definition of the prediction algorithm is not unique either. The designer of the algorithm has certain freedom to choose the tradeoff between different characteristics of its accuracy (rate of failures to predict, duration of alarms, and rate of failures to predict) by varying adjustable elements of the algorithm (Sect. “General Scheme of Prediction”). That leads to the problem, typical for decision-making with incomplete information: to optimize jointly prediction and preparedness. Figure 10 shows the scheme of such optimization. This figure shows also advantages of a new formulation of prediction: parallel applications of several versions of an algorithm.

Further discussion can be found in [27,28,63,64].

### Further Goals

Particularly encouraging for further earthquake prediction research is the wealth of relevant data, models, and theories that are available and yet untapped (the *want amidst plenty* pattern, Conference and School on Predictability of Natural Disasters for our Planet in Danger. A System View: Theory, Models, Data Analysis, 25 June – 6 July 2007, Trieste, ICTP, [http://cdsagenda5.ictp.it/full\\_display.php?ida=a06204](http://cdsagenda5.ictp.it/full_display.php?ida=a06204)). Likely within reach is a new generation

Geo-complexity and Earthquake Prediction, Figure 10

Joint optimization of prediction and preparedness based on the theory of optimal control. Dots show points on the error diagram.  $\Gamma$  is their envelope. Thin contours ( $\gamma$ ) show loss curves with constant value of a prevented loss. Optimal strategy is the tangent point of contours  $\Gamma$  and  $\gamma$ . After [63]

of prediction algorithms, about five- to ten-fold more accurate than existing ones.

In the general scheme of things, this is a part of wider developments: Emergence of the newly integrated dynamics of the solid Earth, extending from a fundamental concept succeeding plate tectonics to predictive understanding and (with luck) control of geological and geotechnical disasters. And predictive understanding of extreme events (critical phenomena) in the complex systems formed, separately and jointly, by nature and society.

### Glossary

**Confidence ellipse** As applied to a vector representing a displacement or velocity estimate, the confidence ellipse defines the region within which the value is estimated at or above a specified confidence level (e. g., 95%). Confidence ellipses are computed by propagation of errors when computing the position. The ellipse is usually plotted at the tip of a GPS vector (e. g., Fig. 9).

**GNSS** Global Navigation Satellite System. Although this acronym stands for the same phrase as GLONASS, GNSS is a generic term referring to space-based navigation systems like the Global Positioning System (GPS) operated by the U. S., Russia's GLONASS, and the Galileo system under development by the European Union.

**Kinematic GPS** A method of collecting GPS data in which the receiver is continuously or intermittently in motion. This receiver, called the rover, can receive corrections for ambiguity resolution and common errors from a nearby stationary receiver.

#### **Interferometric synthetic aperture radar (InSAR)**

A satellite-based imaging technique in which the satellite emits a radar signal and measures the phase of the returning signal after it has been scattered off the surface of the Earth. The difference in phase of the scattered waves measured during two passes of the same satellite can be used to produce a map of deformation, called an interferogram, that occurred during the time between the two satellite passes.

**International GNSS service (IGS)** An international consortium of agencies worldwide that provide data from

permanent GPS and GLONASS sites in order to generate precise orbital and satellite clock parameters.

**Ionosphere** The electrically charged portion of the atmosphere from ~60 km to ~400 km above sea level. The ionosphere is dispersive, meaning that the degree to which it delays signal propagation depends on the signal's frequency and the electron content of the ionosphere.

**Mega-thrust earthquake** A type of earthquake which causes rupture of a long portion of the interface between a subducting plate and the over-riding plate. These earthquakes involve slip on a huge surface area, making them among the largest on Earth.

**Moment magnitude ( $M_w$ )** A magnitude scale used to compare the energy released in earthquakes. The moment magnitude is computed from the seismic moment. Therefore, because  $M_w$  accounts for the full rupture length of the earthquake, the moment magnitude scale does not saturate for large events in the way that other magnitude scales do.

**Reference frame** A terrestrial reference frame is defined by a set of points on Earth whose coordinates are precisely determined in a coordinate system with a specified origin and orientation of the axes. In order to compare GPS site positions, displacements, or velocities they must all be transformed into the same reference frame. For GPS, the most commonly used reference frame is the International Terrestrial Reference Frame (ITRF) which is updated periodically.

**Rupture** The slip that occurs during an earthquake. This term is often used in discussing the way in which the slip progresses with time over the fault surface, as in "the rupture front propagated southeast."

**Satellite laser ranging (SLR)** A geodetic technique for measuring the position of points on the surface of the Earth. Observation stations emit pulses of light that bounce off retroreflectors on satellites and return to the stations. The stations record the travel time of the light which is used to calculate a range measurement.

**Slip** The distance that material on one side of a fault moves relative to that on the other side.

**Stable North America** The stable interior portion of the North American continent that is not affected by plate boundary deformation. Often this term is used in the context of a "stable North American" reference frame, meaning that GPS velocities are transformed so that the velocities at stations considered to be in the stable interior of the continent are essentially zero. Because of factors such as Glacial Isostatic Adjustment (GIA), even some GPS sites in the continental interior have nonzero velocities. These sites are typically omit-

ted when defining a stable North American reference frame.

**Strainmeter** An instrument that is capable of measuring change in distance over short baselines. These instruments typically come in two forms. The first is installed at the Earth's surface and uses a laser interferometer to measure the changes in distance over baseline lengths of 100s of meters. The second type is installed in a borehole 100s of meters deep to measure subtle changes in the diameter of the borehole. Some borehole strainmeters measure volumetric strain (e. g. the Sacks–Evertson strainmeter) and others measure three independent components of horizontal strain (e. g. the Gladwin tensor strainmeter).

**Strong motion seismograph** Seismic instrument designed to record high-amplitude shaking near an earthquake rupture. These instruments typically record acceleration, and are sometimes called accelerometers. Data recording is often triggered by the arrival of the first seismic waves, and these instruments can record acceleration several times that of gravity.

**Telesismic** Refers to seismic waves recorded at distances greater than 3000 km from the epicenter.

**Troposphere** The portion of the atmosphere from the Earth's surface to ~15 km which delays GPS signal propagation. The degree to which the GPS signal is delayed depends on the spatially and temporally varying atmospheric pressure and water vapor content.

**Very long baseline interferometry (VLBI)** A geodetic positioning technique in which radio signals from distant sources such as quasars received at an array of antennas are used to calculate precise positions.

## Definition of the Subject

The Global Positioning System (GPS) is a space-based Global Navigation Satellite System (GNSS). Using signals transmitted by GPS satellites, the positions of ground-based receivers can be calculated to high precision, making it possible to track the movement of points on the Earth's surface over time. Unlike older geodetic surveying methods which involved periodically measuring angles, distances, or elevations between points, GPS can provide three-component (latitude, longitude, and altitude) position information at a range of sampling rates and on a global scale. GPS equipment is easy to use and can be set up to collect data continuously. Since its early geophysical applications in the mid-1980s, this versatile tool, which can be used to track displacements over time periods of seconds to decades, has become indispensable for crustal

deformation studies, leading to many important insights and some surprising discoveries.

## Introduction

This article focuses on applications of GPS data to the study of tectonic, seismic, and volcanic processes. GPS has become a valuable tool for investigating other types of crustal deformation as well, including landslides (e. g., [25,50,100,128,151]), global sea-level change [150], and the ongoing rebound (termed Glacial Isostatic Adjustment or GIA) of the Earth's crust since the retreat of the ice sheets which covered much of North America and northern Europe during the last ice age (e. g., [19,80,88,95,117,141]), but these topics are beyond the scope of this article. The discussion presented here begins with an overview of how GPS works and how it is used to collect data for geophysical studies. The rest of the paper describes a variety of ways in which GPS data have been used to measure crustal deformation and investigate the underlying processes, as illustrated by examples from the literature. Since GPS is so widely used in geophysical studies, examples of many more applications exist, and the reader is encouraged to explore the literature for more information.

## Global Positioning System Measurements

### How GPS works

The US Department of Defense developed GPS to provide positioning and timing information, primarily for military purposes, that would be available any time of day, anywhere on Earth, regardless of weather conditions. The first GPS satellites were launched in 1978. Soon afterward the Soviet Union developed a similar system, called GLONASS (which, like the generic acronym GNSS, also stands for Global Navigation Satellite System), and more recently the European Space Agency has designed a satellite navigation system called Galileo which, unlike its predecessors, is dedicated to civilian and commercial, rather than military, use. The rest of this article will focus on GPS. The scope of this article permits only a brief overview. Dzurisin [40] gives a broader discussion with a focus on applications in volcanic investigations. Hofmann-Wellenhof et al. [56] give a thorough treatment of the technical details.

The GPS satellite constellation nominally consists of 24 satellites, as well as several spares. The satellites orbit 20,200 km above the Earth with orbital periods of nearly 12 hours, and each passes over a given point on the Earth's surface once per sidereal day (which is about four min-

utes shorter than a solar day). From any point on the Earth's surface, at any given time, from four to ten satellites are above the horizon (and thus potentially visible). Each satellite remains visible for approximately five out of every 12 hours [40].

The idea behind satellite positioning is that one can determine the distance between a receiver on the ground and an orbiting satellite from the time it takes a signal to travel from the satellite to the receiver. This calculation, therefore, requires a means for precise time-keeping according to a universally accepted standard. The US Naval Observatory defines "GPS time," and GPS specifications require GPS time to be within one microsecond of Coordinated Universal Time (UTC). The difference between a satellite's or receiver's internal clock and GPS time (due to clock drift) is termed "clock bias" and is accounted for in processing GPS data.

GPS satellites broadcast signals on two carrier frequencies termed L1 and L2 in the microwave band. The "coarse acquisition" (C/A) code is modulated on the L1 carrier, and the precise (P) code is modulated on both L1 and L2. A navigation message, containing information about the satellite orbits, clocks (the time given by the satellite's clock and information about the difference between that satellite's time and GPS time), and state of health, as well as ionospheric conditions, is modulated on both carriers.

The receiver "locks on" to a satellite by generating a replica of one or more of the codes modulated on the satellite signal it receives and continually cross-correlating the internally generated code with that received from the satellite until the two match. Once it has locked on to the satellite it can obtain the navigation message, determine the signal travel time, and measure the carrier signal. The apparent distance, or "pseudorange," between the GPS antenna and the satellite antenna is then calculated by multiplying the time it takes for the signal transmitted by the satellite to travel to the receiver by the speed of light. The term pseudorange emphasizes that the travel time used in this calculation includes the effects of satellite and receiver clock biases as well as a variety of other error sources, some of which may be mitigated during processing, and is therefore not equivalent to the true geometric range between the satellite and receiver. It is possible for the receiver to measure the code to a precision of about 1% of its length (293 meters for C/A-code and 29.3 meters for P-code), which results in 3 meter and 30 cm precision in calculated pseudorange. However, the P-code is generally encrypted by the military, called "anti-spoofing" or A-S, and therefore a civilian receiver cannot use this code for positioning.

The C/A code is modulated on L1, and thus this carrier can be easily measured once the receiver has locked on to the satellite using the C/A code. Because of A-S, in order to obtain the L2 carrier on which the encrypted P-code is modulated, civilian users must have receivers that apply more sophisticated signal processing techniques (see pp. 81–85 in [56]). The L1 carrier has a wavelength of 19 cm and the L2, 24.4 cm. Since the receiver can measure the carrier signal to 1% of a cycle length, much greater resolution can be achieved using the carrier phase measurements, rather than the code information, to calculate the pseudorange.

When the carrier signal is used, the satellite-receiver distance is calculated by multiplying the number of carrier cycles (which is generally not an integer) between the satellite and the receiver by the wavelength of the carrier signal. However, when a receiver locks on to a satellite, it only can measure the initial fraction of a carrier cycle that it receives. Although it measures the number of full cycles thereafter (which changes as the satellite moves overhead), the receiver has no way of knowing how many full cycles in addition to the initial fraction were between it and the satellite to begin with. This unknown number of cycles is often called the integer ambiguity and will be different for each satellite–receiver pair. In order to take advantage of the more precise positioning that can be achieved using the carrier signal, processing techniques have been developed to address the problem of integer ambiguities (see [40] for an overview and [56] for more detail).

The positions of the satellites at any given time are given by their orbital parameters. This information is transmitted as part of the navigation message, however more precise orbital information, available from the International GNSS Service (IGS), is used in scientific applications. With the satellite positions assumed known, once the distance from the receiver to at least four satellites is measured, the position in three coordinate dimensions (e. g., north, east, and vertical) of a GPS antenna on the ground can be found. Four satellites are necessary in order to solve for the three coordinate positions and the satellite and receiver clock bias. However, positioning accuracy is greatly improved with data from additional satellites as it is then possible to estimate some unknown noise sources.

Although GPS receivers are capable of determining a position in real time using internal software, for scientific applications the data are generally downloaded, and one of several processing software packages is used to obtain much more precise positions. This type of software allows the user more control over the way in which the data are processed, for instance by enabling the use of precise orbital parameters, the fixing of ambiguities, and the

application of sophisticated models for atmospheric delay and variations in the antenna phase center (the part of the antenna that actually receives the GPS signal).

It is possible to reduce or eliminate certain error sources by differencing data. These errors include atmospheric delays to signal propagation that affect neighboring GPS stations (e. g. within 10 s of km of each other) in a similar way, satellite orbital and clock errors that will be common to data from the same satellite recorded by more than one station at the same time, and receiver clock errors that are common to measurements to multiple satellites made by that receiver at the same time.

Other means of addressing error sources exist as well. For example, the ionosphere is dispersive, meaning the delay in signal propagation that it causes depends on the frequency of the signal. Because GPS uses two frequencies, the effect of this delay can be eliminated from the data. Tropospheric delay is addressed during data processing through a combination of models for the “dry” component (which is dependent on atmospheric pressure, temperature, and elevation), and treatment of the “wet” component (which shows large variability depending on water vapor content) as a stochastic parameter to be estimated. Multipath (when the GPS signal bounces off something before reaching the ground antenna) and set-up error (commonly, operator error in measuring the height of the antenna) are mitigated by antenna design, choice of station location, and surveying technique.

The military has used two means of limiting civilian access to GPS positioning capabilities. The first, called selective availability (SA), involved degrading the accuracy of the satellite orbit information broadcast by the satellites and introducing noise into the satellite clock information. This caused an approximately ten-fold increase in positioning error. Using information from a global network of continuously operating GPS stations it is possible to calculate more accurate satellite orbits for use in post-processing of GPS data. During processing, clock errors can be eliminated by differencing data from multiple stations or estimated along with station positions. Therefore, SA did not pose an insurmountable obstacle to scientific users of GPS. In May 2000 the US government discontinued SA, although it reserves the right to reinstate it if deemed necessary. The other means by which the military can reduce civilian access to GPS data is through A-S. A-S is implemented by encrypting the P-code such that only military users can decipher it, thus preventing outside parties from sending phony “GPS” signals that would prevent accurate positioning. A-S began in 1994 and continues to the present, but its effect on the accuracy of GPS positioning for scientific purposes is generally small.

## Methods of GPS Data Collection for Crustal Deformation Studies

For some geological and geophysical applications, typically those which require mapping or recording of sample locations, kinematic GPS methods are used. In these cases, a base station is used to generate corrections that are applied to measurements made by a “roving” antenna which is moved to each site of interest [40]. However, for the crustal deformation applications described in this article, the GPS antenna remains at one location for an extended period of time (usually at least eight hours). Measurements of this type are often classified as “campaign” or “continuous,” depending on the frequency of measurement and the way in which the receiver and antenna are installed. Here I give a brief description of each; Blewitt et al. [13] give a detailed discussion as well.

Before the advent of GPS as a tool for monitoring crustal deformation, other types of geodetic observations were made by periodically measuring triangulation, trilateration and leveling networks using traditional land surveying techniques. The objective was to see how the movement of the Earth’s surface changed over time, since this reflects a variety of geophysical processes. However, these techniques did not produce 3-component position data, but rather measurements of angles, distances, or elevation changes.

The surveying approach in the early years of GPS monitoring (e. g. mid-1980s to mid-1990s) was similar to that of its predecessors in that instruments were deployed temporarily, for several hours at a time, once a year or so. This approach is called “campaign” or “survey-mode” GPS (SGPS). At that time receivers were prohibitively expensive, limiting their wide-spread use. Also, there were fewer satellites in orbit, and one had to schedule surveying to coincide with the time of day for which there would be satellite coverage in the area of interest.

When collecting SGPS measurements one sets up a tripod which will hold the antenna over a marker, typically a benchmark set in the ground (Fig. 1a,b). The use of such a marker enables one to find the correct spot for future measurements months or years later. The antenna is centered using an optical plummet over a point imprinted on the marker to indicate its center (Fig. 1b). One must then measure the distance between the ground (where the benchmark is) and the antenna (where the GPS signal is actually received), and this distance will be used to convert the positions obtained from data processing to the positions of the benchmarks. As you might guess, there is considerable room for error when having to set up the antenna anew every time observations are made.

GPS: Applications in Crustal Deformation Monitoring, Figure 1

**a** Campaign GPS station located in western Nevada. In the foreground the tripod holds the antenna. The receiver will be stored in one of the boxes in the background while data are collected. Rocks are stacked on the feet of the tripod to prevent it from moving during data collection. (USGS photo) **b** Benchmark that is being observed in **a**. A benchmark often has a stamping telling which agency installed it and when. The cross in the center is the point over which the tripod is centered every time that benchmark is observed. (USGS photo) **c** Continuous GPS station located in Fremont, California. This station, P222, is part of the Plate Boundary Observatory. The antenna, protected from the elements by a domed cover, is supported by a monument with legs driven several meters into the ground. The antenna sends data to the receiver, located along with batteries in the box in the background, via a buried cable. Also visible in the background is the solar panel which provides supplemental power to the site. (UNAVCO photo, reprinted with permission)

Height measurement errors are particularly common. The repeated measurement of the same benchmark over time produces a time series like that in Fig. 2a.

As GPS receivers became less expensive, the possibility of permanently installing continuously recording GPS (CGPS) receivers became a real option. Some of the earliest continuous GPS stations for geophysical studies were installed in Japan [144]. The first continuous GPS sites in southern California were installed in 1990 at Pasadena, Pinyon Flat, and La Jolla [77]. Today several countries have extensive CGPS networks for geophysical monitoring purposes, most notably GEONET which consists of

over 1000 stations across Japan. Regional CGPS networks have existed in the US for many years covering southern California (Southern California Integrated GPS Network, or SCIGN [60]), the San Francisco Bay Area (Bay Area Regional Deformation, or BARD [72]), the Pacific Northwest (Pacific Northwest Geodetic Array, or PANGA [92]), and the Basin and Range (Basin and Range Geodetic Network, or BARGEN [10]; and Eastern Basin-Range and Yellowstone hotspot, or EBRY, <http://www.mines.utah.edu/~rbsmith/RESEARCH/UUGPS.html>). A much larger network consisting of ~850 sites is now underway. This new network, called the Plate Boundary Observatory (PBO),

GPS: Applications in Crustal Deformation Monitoring, Figure 2 Time series of changes in station positions. Both these sites are located in central California, west of the San Andreas fault. The position changes are plotted relative to the center of the North American continent. Because of the relative motion between the North American and Pacific tectonic plates, these sites are moving to the northwest over time, relative to the stable interior of the continent which is not affected by strain accumulation due to the interaction of the two plates. **a** Campaign GPS site CARX near Parkfield, California. **b** Continuous GPS station P171 of the Plate Boundary Observatory network. This station is located just south of Monterey Bay

will provide CGPS coverage for seismically and volcanically active areas throughout the western continental US and Alaska [147].

In addition to providing daily positions, CGPS sites have the advantage of permanent monumentation, thus eliminating set-up error (Fig. 1c). Having daily positions (e.g., Fig. 2b) enables much better estimates of site velocities, but the more frequent data and added precision

means it has become necessary to address additional error sources that were hidden in the noise of the less frequent measurements. These include seasonal signals and time-correlated noise likely due to monument instability, atmospheric effects, reference frame errors, or mismodeled orbits or antenna phase centers [15,33,74,86,166,170]. Despite the proliferation of CGPS stations in recent years, depending on factors such as site access and site condition, financial resources, and scientific goals, campaign-style GPS measurements are still frequently collected.

### Relative Precision

Daily repeatability (or scatter) in the time series for CGPS sites is typically 0.5 to 1.5 mm in the horizontal and  $\sim 3.5$  to 6.5 mm in the vertical. If noise that is common to all stations in the network (due, for example, to errors in satellite orbits or atmospheric delay) has been eliminated, short-term repeatabilities of  $\sim 0.5$  mm in the horizontal and  $\sim 2$  mm in the vertical can be achieved. With 1.5 to 2.5 years of CGPS data, velocity estimates with  $\sim 1$  mm/yr uncertainties are possible [13]. In contrast, SGPS position repeatability is  $\sim 3$  to 5 mm in the horizontal and  $\sim 10$  mm in the vertical [40], and  $\sim 10$  years of SGPS data would be required to reach velocity uncertainty of  $\sim 1$  mm/yr [166].

One way to improve the accuracy of GPS measurements is to extend the length of an observation session, for example from six hours to 24 hours, when estimating daily positions. The additional data mean that multipath noise (which varies throughout the day) averages out better, and it is easier to fix ambiguities and estimate tropospheric delay parameters. The accuracy of GPS measurements has also improved over time. A major reason for this has been the expansion of the global network of tracking stations that are used to calculate precise orbital information for the satellites and to define reference frames for GPS positions. Models for various noise sources have also been refined over time, and some noise sources have been mitigated, for instance by improving the stability of geodetic monuments. It should be noted that the vertical signal is generally much noisier than the horizontal because it is not possible to track satellites below the horizon, and therefore there is no position control from below.

### Applications of GPS Data to the Study of Seismic and Volcanic Hazards

GPS data provide important constraints on the underlying processes that lead to observed deformation, especially when used in combination with other data types. One of the major strengths of GPS is its ability to track positions over time spans of seconds to decades; another is that it en-

ables measurement of position changes over continental-scale baselines. This section will discuss several broad areas of study using GPS data and provide specific examples of each. Background on modeling methods will be included as necessary.

### Plate Motions

Earthquakes occur in response to stresses in the Earth's crust, and these stresses are largely due to the motion of the Earth's tectonic plates. Knowing the velocity at which the plates move gives us insight into the amount of deformation that must be accommodated on plate boundary faults, and what type of earthquakes might be expected. The Earth's plates are generally thought to be rigid, at least in their interiors (away from plate boundaries where plates interact with one another). One approach to measuring global plate motions combines rate information obtained from the age of magnetic reversals recorded in the basalt of the oceanic crust formed at mid-ocean ridges with information regarding the direction of plate motion gleaned from the orientation of transform faults and direction of slip in earthquakes. Because most such studies use a magnetic anomaly that is  $\sim 3$  million years old, the rates of plate motion inferred in this manner represent an average over the time since the Pliocene. The most commonly used plate motion model of this type is called NUVEL-1A [29,30]. This model gives relative velocities for pairs of plates. Under the assumption that the lithosphere has no net rotation with respect to the mantle below, Argus and Gordon [2] developed the NNR-NUVEL-1A model of absolute plate motions, where NNR refers to "no net rotation."

In contrast to approaches based on geologic data, geodetic techniques enable the estimation of present-day plate motions using essentially instantaneous measurements. Two such geodetic methods, Satellite Laser Ranging (SLR) and Very Long Baseline Interferometry (VLBI), were used in the 1980s to measure the positions of points on the Earth's surface. Given a good spatial distribution of sites world-wide, it is possible to use such data to estimate plate velocities. However, expense and practical considerations limited the number of sites that could be observed with SLR and VLBI. The advent of GPS provided a cost-effective alternative enabling precise three-component positioning with dense spatial coverage globally (e. g., Fig. 3).

Several studies have used GPS data, either alone or in combination with other observations, to estimate global plate motions (e. g., [4,79,124,140]), and numerous other studies have used such data in analyses focused on sub-

groups of plates. The plates are modeled as rigid, rotating, spherical caps. Their motions are expressed as Euler vectors, defined by a location of the Euler pole (point E in Fig. 4a) and the angular velocity of the plate around that pole. These parameters are related to the velocities of the GPS sites by

$$\mathbf{v} = \boldsymbol{\Omega} \times \mathbf{r} \quad (1)$$

where  $\mathbf{v}$  is the GPS velocity vector,  $\boldsymbol{\Omega}$  is the Euler vector for the plate in question, and  $\mathbf{r}$  is the position vector of the GPS site in Cartesian geocentric coordinates (e. g., [79]). The relationship given in (1) may be understood from Fig. 4. The Euler vector and position vector may be expressed as unit vectors ( $\boldsymbol{\Omega}_u$  and  $\mathbf{r}_u$ ) multiplied by their magnitudes ( $\omega$  and  $R$ )

$$\boldsymbol{\Omega} = \omega \boldsymbol{\Omega}_u \quad (2)$$

$$\mathbf{r} = R \mathbf{r}_u \quad (3)$$

where  $\omega$  is the velocity of rotation (generally in degrees or radians per million years), and  $R$  is the radius of the Earth (Fig. 4a). As shown in Fig. 4b, the distance,  $\mathbf{d}$ , that a GPS station travels during a time period  $t$  due to rotation about the Euler pole is given by

$$\mathbf{d} = \omega t R \sin \delta \quad (4)$$

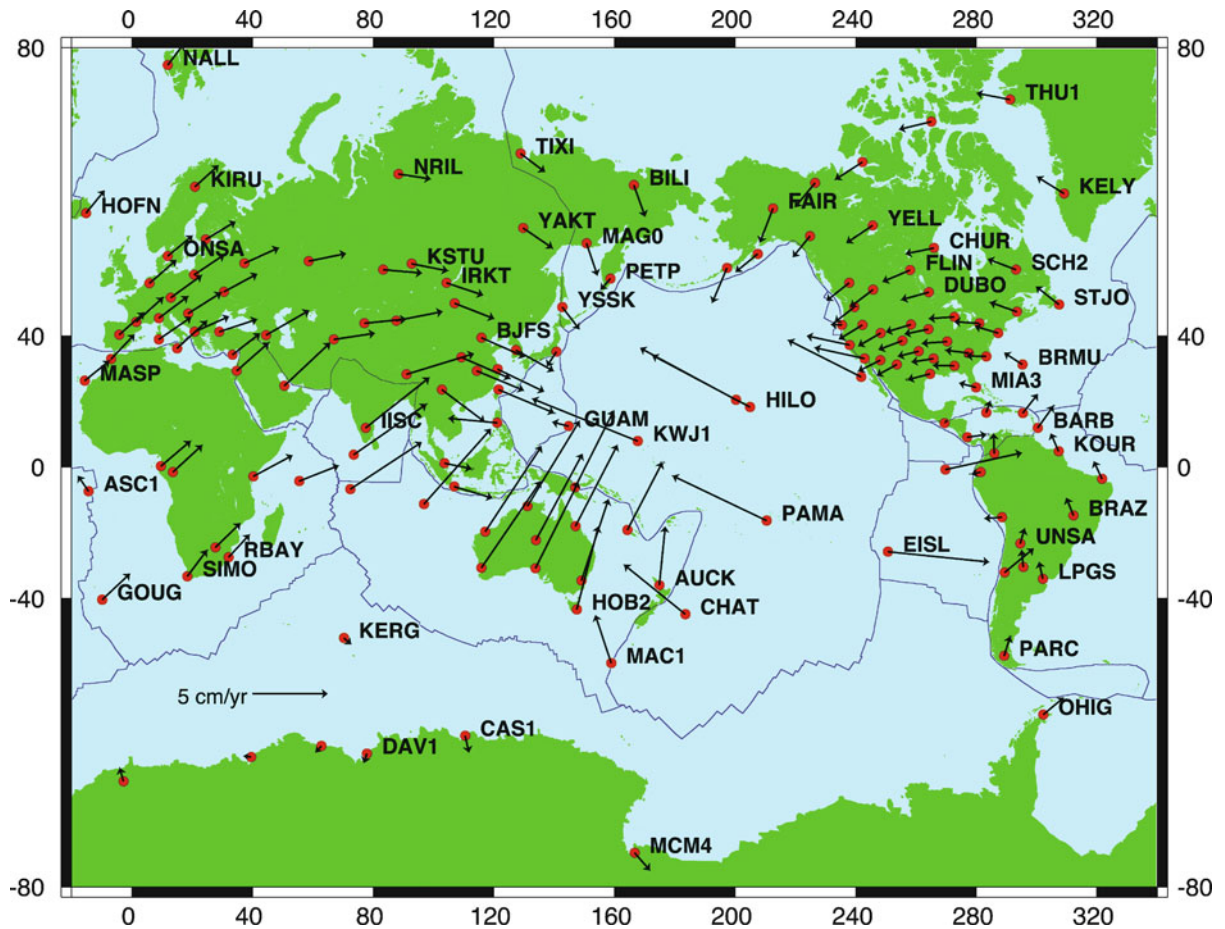

where  $\delta$  is the angular distance between  $\boldsymbol{\Omega}$  and  $\mathbf{r}$  (Fig. 4a). The quantity  $\sin \delta$  is simply the cross product of the unit vectors for the Euler vector and the position vector,

$$\sin \delta = \boldsymbol{\Omega}_u \times \mathbf{r}_u . \quad (5)$$

Therefore, plugging (2), (3), and (5) into (4), and dividing by time gives (1). The system of equations given in (1) can be solved to estimate the Euler vector that best fits the GPS data for each plate.

The early studies (e. g., [4,79]) were able to estimate velocities for only a handful of plates (e. g., six and eight, respectively). In recent years, however, the global distribution of CGPS sites has grown substantially such that Prawirodirdjo and Bock [124] estimated the velocities of 17 "major and minor tectonic plates" and Sella et al. [140] considered 19 "plates and continental blocks." The increasing precision of GPS measurements has made it possible to more rigorously test plate rigidity and the existence of purported plate boundaries, as well as address the potential systematic velocity error introduced by GIA in North America and Eurasia [124,140].

Velocities of GPS sites used in plate motion studies have repeatedly been found to be consistent with the as-

GPS: Applications in Crustal Deformation Monitoring, Figure 3  
 Velocities for a globally distributed selection of GPS sites. Figure courtesy NASA/JPL-Caltech

sumption that plates behave rigidly, as evidenced by the fact that in general a single Euler pole fits the GPS velocities for a given plate well. Moreover, estimates of global plate velocities inferred from these data have agreed with plate motions inferred from geologic and other data (e. g., NUVEL-1A). However, the improvement in size and quality of GPS datasets has highlighted some discrepancies between NUVEL-1A and the models arrived at geodetically (e. g., [140]). These differences may be due in some cases to systematic errors in the rates estimated from magnetic anomaly data in tectonically complex areas where relative plate motion is not localized at the spreading center. In other cases the difference may reflect an actual change in the rate of relative plate motion over the past 3 million years. Refining both the geologic and geodetic plate motion models continues to be an area of active research (e. g., [3,28]).

## Earthquake and Volcano Source Modeling

**Source Potency and Geometry** Although the Earth's plates behave rigidly, as evidenced by the velocities of GPS sites in the stable interiors of plates, at their edges neighboring plates interact, colliding, diverging, or sliding past each other. These processes, as well as others such as the movement of magma underground, impart stress to the Earth's crust, distorting the shape of a volume of crustal material. Some of this deformation is permanent, leading for example to mountain building. However, the brittle upper portion of the Earth's crust deforms elastically, meaning that a large portion of crustal deformation is recoverable; once the stress is relieved, the crustal material returns to its pre-stress shape. The discussion presented here will focus primarily on modeling which assumes an elastic crust, however several studies have considered

GPS: Applications in Crustal Deformation Monitoring, Figure 4 Relationship between the velocity of a GPS station and an Euler pole of rotation. Point P is the location of a GPS station, and point E is the location of the Euler pole of rotation,  $\Omega$ , that describes the motion of the plate on which point P sits. The Euler vector points from the center of the Earth to point E, and its magnitude is the rate of rotation,  $\omega$ . Point P is located at an angular distance of  $\delta$  from point E. The velocity recorded at point P due to rotation about the Euler pole is given by  $v = \Omega \times r$ , where  $r$  is the position vector of the GPS station, and its origin is the center of the earth. Therefore, the length of  $r$  is the radius of the earth,  $R$ . The gray circle that passes through the point P has radius  $R \sin \delta$ . **b** View of the gray circle in a looking along the direction of the Euler vector. The distance traveled by point P during a time period  $t$  due to the rotation given by  $\Omega$  is given by  $d$ . See text for details

the effects of nonelastic material properties (e.g., [37, 65, 135]).

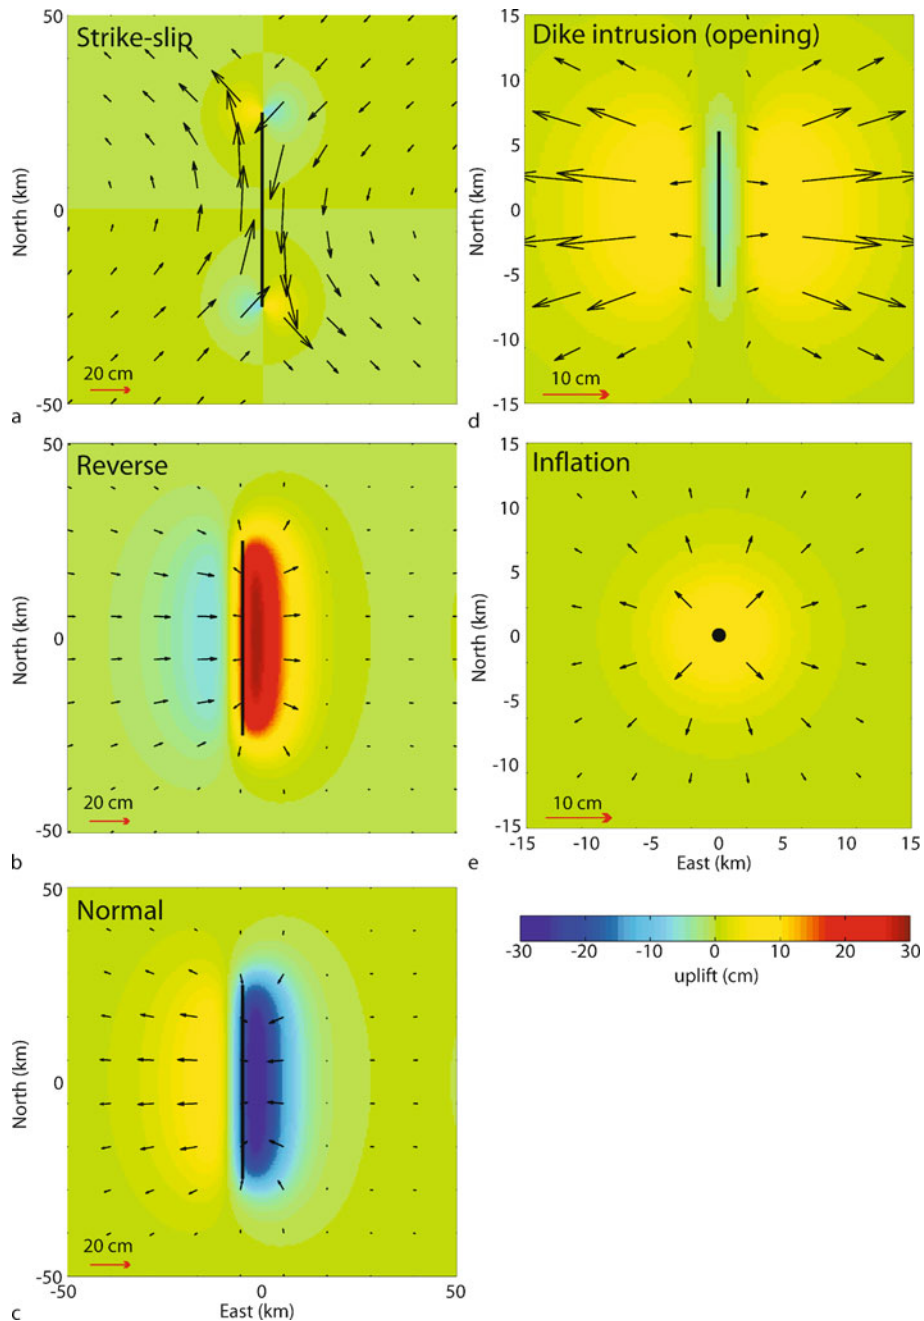

Mathematical expressions from continuum mechanics that describe the stress, strain, and displacement in an elastic solid due, for example, to a point source or to movement on a planar dislocation can be applied to the study

of crustal deformation sources using surface displacement data like those provided by GPS. Okada [109,110] presented concise analytic expressions that are used in many such studies today. Mogi [99] discussed the special case of surface displacement due to three orthogonal, equal-amplitude point sources of inflation which could represent an inflating or deflating magma body at depth. Dislocation sources are described by their dimensions, orientation, location in the Earth's crust, amount of movement (e.g. slip) which takes place across them, and the direction that the material on one side of the dislocation moves relative to that on the other (sometimes termed the "sense of slip"). Volcanic sources such as dikes and sills can be modeled by dislocations with opening rather than slip. Magma chambers are often represented by inflation sources defined by their locations, amount of inflation, and, in the case of more complicated geometries such as ellipsoidal sources, their shapes. Dzurisin [40] gives a good discussion of approaches for modeling a variety of volcanic deformation sources.

The term "source geometry" refers to all source characteristics except the amount of slip, opening, or inflation. These latter three parameters, which describe the strength of the source, are sometimes referred to as the "source potency." The surface displacement field produced in any deformation event reflects not only the source potency but also the source geometry and characteristics of the crustal material. Figure 5 presents the expected horizontal and vertical displacement due to different modes of shear slip and opening on a planar dislocation and to a point source of inflation. As can be seen, each deformation source produces characteristic surface displacement patterns. As with the estimation of plate motions described earlier, a system of equations can be written that relates a deformation source such as a dislocation in the crust to the displacements measured with GPS at the Earth's surface. In simplified terms this system of equations can be written as

$$\mathbf{d} = \mathbf{G}\mathbf{s} \quad (6)$$

where  $\mathbf{d}$  is a vector of station displacements measured by GPS,  $\mathbf{s}$  is a vector of source potency (e.g., fault slip), and  $\mathbf{G}$  is a matrix which embodies the mathematical expressions relating potency to displacements for an assumed fault geometry and elastic properties. This system of equations can be solved (or "inverted") to estimate the unknown potency that best fits the known displacements. The displacements at the Earth's surface are nonlinearly related to the source geometry, but are linearly related to the source potency. Therefore, when the source geometry is known, inverting for the potency is a linear inverse problem. In the simplest case the potency can be assumed to be uniform

GPS: Applications in Crustal Deformation Monitoring, Figure 6

Predicted displacements due to two sources. **a** Source geometry consisting of two vertical strike-slip faults and location of a GPS receiver. **b** Map view of displacement due to slip on the fault shown in red in **a**. **c** Map view of displacement due to slip on the fault shown in blue in **a**. **d** Map view of displacement due to slip on both faults. Note how the displacement at the circled locations in **b** and **c** due to the individual faults is very different from that which would be recorded by GPS in **d** due to slip on both faults

for the deformation source. In the case of a fault, this implies that the same amount of slip occurred everywhere on the fault, and the vector  $s$  would have just one element. However, in the presence of multiple sources, the total displacement at the surface is simply the sum of the contributions from all the sources (e. g., Fig. 6). This means that spatially variable fault slip can be estimated by dividing the model fault into a grid of subfaults, each of which contribute to the observed displacements, and estimating the slip on each subfault. In this case the length of the vector  $s$  would be the number of subfaults. The number of subfaults used is generally dictated by how much data are available.

Inversion of geodetic data for characteristics of deformation sources is underdetermined, meaning that a large number of source models can fit the data within errors. Having vertical and horizontal displacement measurements improves the ability to distinguish among different possible source geometries. For instance, several types of volcanic sources will produce similar patterns of vertical deformation, but with the inclusion of horizontal displacement measurements it is possible to differentiate among them. When using GPS data to estimate the spatial distribution of slip on a fault (by dividing the model fault into subfaults and estimating the slip on each), spatial smoothing is often used to provide added constraints in the inver-

sion. The justification for this is that abrupt changes in the amplitude of slip would result in high stresses on the fault surface, which is physically unlikely. The relative weight given to fitting the data and to spatial smoothness is often determined empirically (e. g., [161]). Non-negativity may also be applied, for instance to include prior knowledge about the sense of slip on a fault as a constraint on fault slip estimates.

Regardless of these means for regularizing inversions, because geodetic measurements are collected at the surface, their sensitivity to the details of a deformation source decreases with depth. GPS measurements will be most sensitive to source processes occurring in the upper few kilometers of the Earth's crust near the GPS receiver's location. Deeper sources will affect GPS sites over a broader region, but the recorded deformation signal will lack detail about the source. This can be best understood if one thinks of an earthquake that causes rupture of the Earth's surface. A GPS receiver near the fault will record data which primarily reflect the shallow slip and surface rupture close to that receiver. A receiver 15 km away from the fault will not be sensitive to the shallow, near-fault deformation, and the recorded signal will be due to large-scale features of slip on deeper parts of the fault. Likewise, a receiver at the summit of a volcano can record the movement of magma that is collecting near the crater, whereas receivers lower on the flanks of the volcano will likely not record that signal but could be expected to track deformation due to movement of magma at greater depths.

The structure of major faults such as the San Andreas has been studied extensively by mapping, imaging the spatial distribution of background seismicity, and applying geophysical techniques that use, for example, seismic reflection and refraction, gravity, or magnetic data to highlight contrasts in rock properties. Therefore, if an earthquake hypocenter is found to be located on a major fault, the source geometry may be well-known a priori. In the absence of such information, or to refine the source geometry used in inversions, the spatial distribution of aftershocks and the location and extent of any surface rupture are also used.

Traditionally, spatially sparse geodetic measurements were assumed to be insensitive to the details of the model fault geometry used in inversions. With the recent growth of spatially dense GPS networks, however, more physically realistic fault geometries have been required. Maerten et al. [84] showed that using non-planar fault geometries that better represented independent information, for example from surface rupture mapping, led to significant improvement in fits to the GPS displacements for the 1999  $M_w$  7.1 Hector Mine earthquake. Methods for precisely re-

locating seismicity (e. g., [163]) have illuminated fine-scale fault structures that were previously obscured in less-precise catalog locations. This has enabled the development of more realistic model fault geometries.

For example, Murray and Langbein [101] used displacements measured with GPS to estimate the slip distribution of the 2004  $M_6$  Parkfield, California earthquake. This event took place on the well-studied San Andreas fault in central California. Earlier work (e. g., [41,149]) had suggested that the fault was essentially vertical, with a strike of  $149^\circ$ . During the 2004 event, the coseismic displacement recorded for one GPS station, CARH, located within about 500 meters of the fault was in the opposite direction to what is predicted for a right lateral strike-slip fault (e. g., Fig. 5a). In order to fit the data for this station, an additional fault structure was needed. A sub-parallel fault called the Southwest Fracture Zone (SWFZ) which had exhibited movement in a previous earthquake at this locale was a likely candidate. Using relocated aftershocks of the 2004 event [159] as a guide, Murray and Langbein [101] developed a non-planar fault geometry that consisted of the primary San Andreas fault and a subsidiary SWFZ. These two model fault surfaces passed through the relocated seismicity and intersected the mapped surface traces of the faults at the Earth's surface. Using this fault geometry, Murray and Langbein [101] inverted the GPS data to image the coseismic and postseismic slip associated with this earthquake.

Unlike in the case of Parkfield described above, often very little is known a priori about the geometry of a deformation source. This is especially true for sources that lie completely underground such as magmatic intrusions and earthquakes that do not cause any surface rupture (e. g., "blind" thrust events). However, as discussed earlier (Figs. 5 and 6), the surface displacement field produced in any deformation event reflects not only the source potency but also the source geometry. Therefore, by observing the spatial pattern of displacement using GPS, it is possible to infer what type of source lies underground by finding the source model that best predicts the observed data, for instance by using the expressions for deformation in an elastic material. Since surface displacements are nonlinearly related to source geometry, parameters describing the geometry cannot be estimated using linear inversion techniques but rather must be found through nonlinear optimization. Cervelli et al. [21] give a good overview of several approaches to this type of problem. When estimating the geometry and potency of an earthquake or opening source, often a two-step approach is employed: first the source geometry is estimated assuming uniform fault slip or dike opening, and then the inferred geometry is held

fixed and the spatial distribution of slip or opening is estimated. As described in the following examples, the ability to infer the source geometry can help answer important questions about the underlying processes driving deformation such as whether a fault terminates in a décollement or how magma sources interact.

(a) *Deep Structure of the Chelungpu Fault, Taiwan* Johnson and Segall [65] used GPS-measured displacements caused by the 1999  $M_w$  7.6 Chi-Chi Taiwan earthquake to constrain the geometry of its rupture surface. They then went on to answer fundamental questions about the seismotectonics of Taiwan, which has formed due to the collision between the Philippine Sea plate and the Eurasian plate.

The extensive surface rupture that accompanied the Chi-Chi earthquake suggested that oblique reverse / left-lateral slip occurred on the previously known Chelungpu thrust fault which strikes north-south and dips  $\sim 30^\circ$  east. A nearly horizontal décollement structure has been interpreted to exist at depths of 6 to 10 km beneath much of Taiwan based on geologic mapping, seismicity locations, and seismic reflection profiles. In one proposed deformation model, termed the “thin-skinned” model, thrust faults like the Chelungpu fault intersect the décollement at depths of  $< 10$  km (Fig. 7). The alternative “thick-skinned” model interprets seismic and gravity data to suggest that, although a décollement may have controlled the long-term tectonic evolution of the island, more recent deformation has taken place on down-dip extensions of thrust faults with the same dip as their shallower portions (Fig. 7). In the case of the Chi-Chi earthquake, aftershocks occurred both at depths which might coincide with a décollement

and considerably deeper, potentially on the down-dip extension of the Chelungpu thrust fault.

Johnson and Segall [65] optimized the source geometry of the Chi-Chi earthquake using a half-space with laterally and vertically varying shear modulus. They showed that the GPS data required slip on a thrust plane that transitions into an essentially horizontal décollement structure at  $\sim 8$  km depth. Moreover, they showed that displacements at the north end of the fault, where the surface rupture changed to a more east-west orientation, could only be fit by an additional thrust fault, which they term a “lateral ramp,” extending to the depth of the décollement. The estimated slip distribution of the earthquake using this geometry is shown in Fig. 8. These authors use the results for the Chi-Chi event as the basis for a conceptual model in which deformation follows the thin-skinned model, and lateral ramps form north of the Chelungpu fault due to this fault’s orientation oblique to the direction of plate convergence.

(b) *Magma Plumbing System at Kilauea Volcano, Hawaii* Kilauea volcano, on the Big Island of Hawaii, consists of a summit crater as well as two rift zones, themselves consisting of several craters, extending from the summit down the flanks of the volcano (Fig. 9). Since 1983 Pu’u O’o, a collection of volcanic vents in the East Rift Zone, has been the center of eruptive activity, apparently fed by magma flowing through lava tubes from Kilauea summit.

In January 1997 a fissure eruption occurred on the East Rift Zone at Napau crater,  $\sim 3$  km closer to the summit than Pu’u O’o. In addition to uplift, the GPS instruments recorded horizontal displacements around the eruptive fissure at Napau Crater that were directed outward from

the rift zone except at the ends of the fissure where they pointed inwards, parallel to the rift (Fig. 9). The magnitude of the displacements died off quickly with distance from the fissure. This displacement pattern is characteristic of a shallow dike intrusion within the rift zone. Prior to the eruption, sites at Kilauea summit showed subsidence and a radially inward pattern due to horizontal shortening across the summit, and this accelerated drastically during the eruption. This pattern suggests deflation, and ultimately emptying, of a magmatic source beneath the summit.

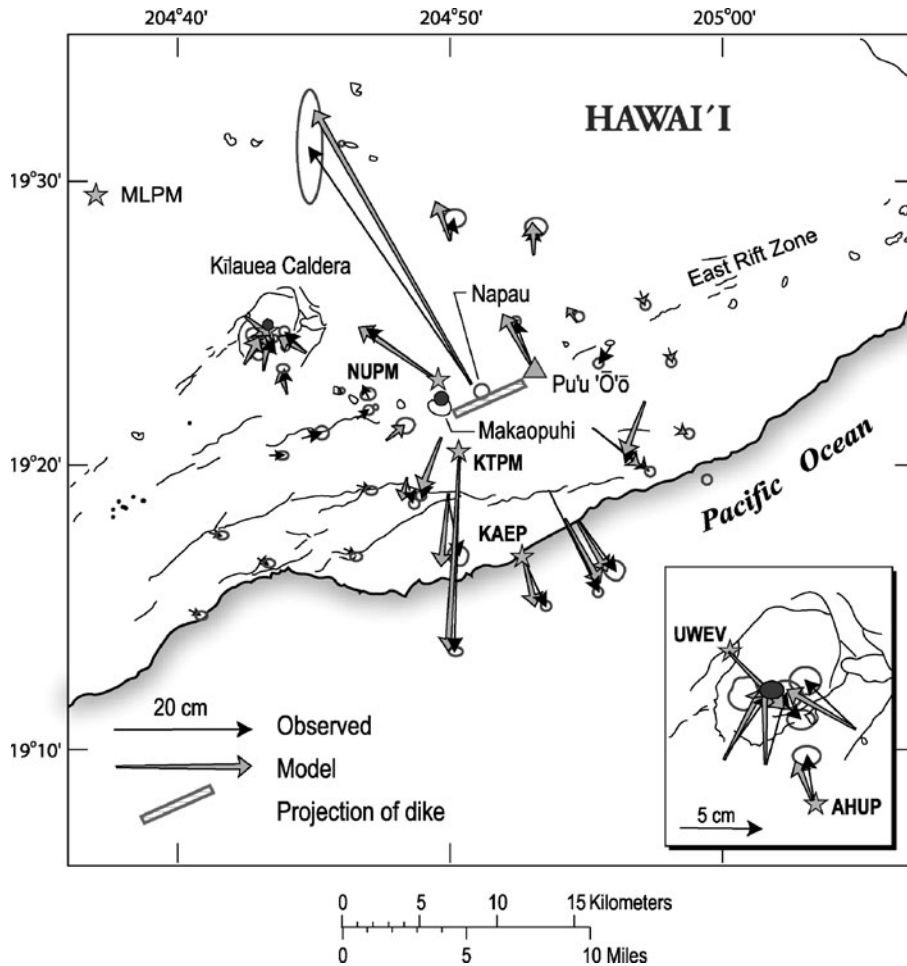

Using nonlinear optimization, Owen et al. [112] found that a source geometry consisting of a steeply dipping dike aligned with the rift and the fissures, combined with deflation both at the summit and at Makaopuhi crater, best fit the GPS observations (Fig. 9). The volume change at the two deflation sources was an order of magnitude less than the volume of the inferred dike intrusion. However, this discrepancy can be remedied if magma previously stored in a lava lake at Pu'u O'o which was seen to drain during this event, along with magma in a conduit thought to connect the summit magma chamber to Pu'u O'o, also contributed to the intrusion. That the period of time leading up to the eruption had been characterized by steady deflation of the summit indicates that dike formation was not in response to magma overpressurization at the summit, but rather some other process. Owen et al. [112] suggest that ongoing southeastward movement of the south flank of the volcano (e. g., [111]) created tensile stresses that encouraged the dike intrusion and fissure eruption at the rift. Following the eruption, inflation resumed at the summit

and the lava lake refilled, further evidence of the connection between the two magma reservoirs.

**Combined Use of Multiple Data Types** Wherever possible, multiple data types are used together to infer crustal deformation source characteristics. For example, GPS data are frequently used in combination with other geodetic measurements such as Interferometric Synthetic Aperture Radar (InSAR) [18] and leveling [38] data. GPS measurements are also often used in combination with seismic records to estimate fault slip.

(a) *GPS and InSAR* GPS data are commonly used in combination with InSAR data because of the complementary nature of these two data types. GPS observations provide three-component displacements, good horizontal precision, and (in the case of CGPS) good temporal coverage. InSAR, on the other hand, has exceptional spatial coverage, is more sensitive to vertical deformation than GPS, and does not require the deployment of instruments on the ground (thus enabling data collection from otherwise hazardous areas such as volcanoes). InSAR, jointly with GPS where possible, has been widely used to study volcanic deformation (see for example [39,40,119]). Likewise, GPS and InSAR observations, in some cases in combination with seismic data, have been used to infer the slip distribution and rupture history of numerous earthquakes including the 1992 Landers earthquake [54], the 1995 Kobe earthquake [113], the 1999 Hector Mine earthquake (e. g., [70,132,148]), and the 1999 Izmit earthquake [16,27]. Studies have explored the relative constraints on source parameters provided by each data-type, as well as approaches for optimally weighting different data types in inversions, especially when one method, like InSAR, produces many more data points than another, such as GPS (e. g., [71,126,148]). Wright et al. [168] used a combination of InSAR and GPS data to infer the slip distribution of the 2002 Denali earthquake. Because of the remote location of this event, GPS sites were clustered along roads [57,58], thus resulting in poor spatial coverage along some portions of the fault. In this situation InSAR observations helped reduce uncertainty in the slip estimates compared to estimates obtained from GPS data alone.

(b) *GPS and Seismic Data* It has long been recognized that GPS data are a useful complement to seismic records for estimating fault slip [162]. While seismic data are sensitive to the rupture process of an earthquake (the amount and temporal progression of slip), when using these data to characterize the rupture process, trade-offs exist between the time-history of slip and its spatial distribution.

GPS: Applications in Crustal Deformation Monitoring, Figure 9

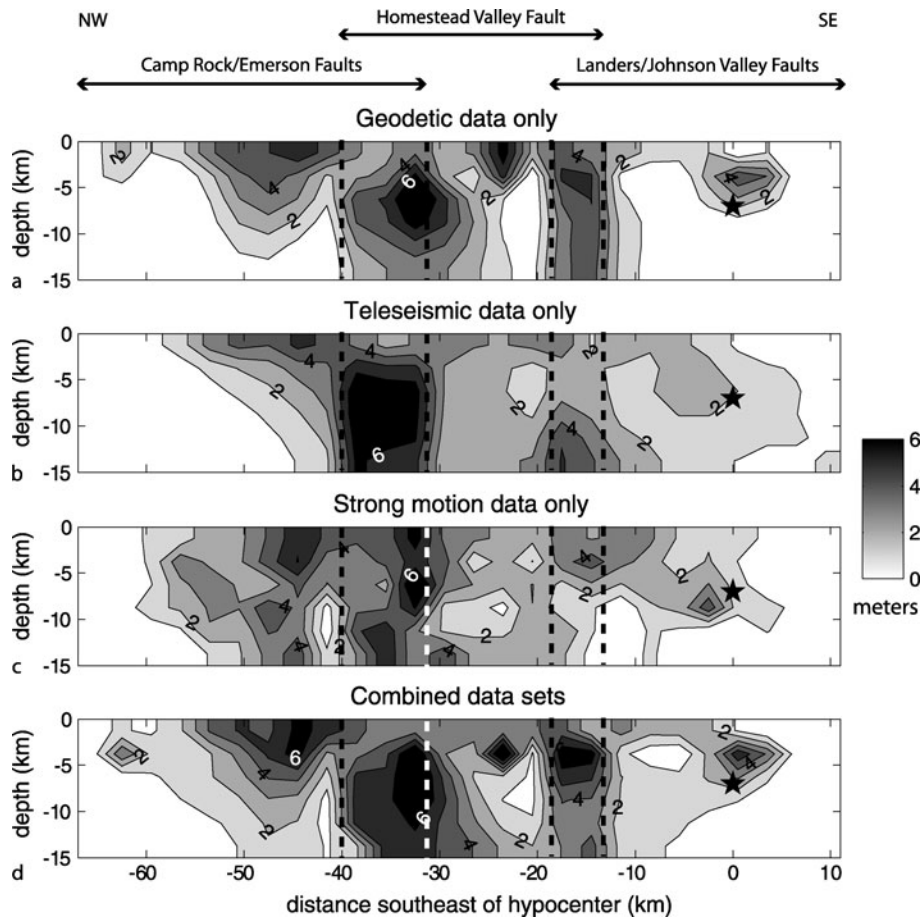

Displacements measured using GPS during the 1997 fissure eruption at Kilauea volcano. On the basis of the observations (black vectors with 95% confidence ellipses) Owen et al. [112] inferred the source of the deformation to be a combination of deflation at the summit of Kilauea (inward pointing arrows; see inset) and the intrusion of a dike along the east rift zone culminating in the eruption. The displacements predicted by this source geometry are shown by the gray arrows. CGPS sites are indicated by stars with four-character station codes. The deflation sources are shown as gray circles and the dike location by the hatched rectangle. Thin black lines are faults, fractures, and fissures. GPS offsets due to an earthquake reflect only the final (or “static”) slip distribution, and thus the slip history inferred from the seismic data can be constrained to produce a static slip distribution that fits the geodetic displacements. The combined use of these two data types tends to have the added advantage of improved instrumental coverage over the study area.

Wald and Heaton [162] conducted a comparison of slip distributions for the 1992  $M_w$  7.2 Landers earthquake inferred from strong motion, teleseismic, and geodetic data (GPS displacements and displacements calculated from trilateration measurements) individually and in

a combined inversion. For all inversions they used a consistent fault geometry parametrization comprised of three fault segments based on the aftershock locations and the extensive ground surface rupture that was mapped following the event. They corrected the geodetic data for the effects of the  $M_w$  6.2 Big Bear event and assumed that post-Landers measurements were made soon enough to avoid contamination by postseismic signals.

On inspection of the final slip distributions (Fig. 10) obtained from inversions of each of the three datasets independently, the authors identified several features that were common to all three and thus appeared to be robust

Adapted from [162]

regardless of dataset. For example, slip at the hypocenter was moderate and limited to a small depth range. Peak slip at depth occurred along the central portion of the fault, while slip became shallower at the ends (to the northwest and southeast). The greatest near-surface slip was on the Camp Rock / Emerson faults at the northwest end of the rupture. The slip distribution obtained through combined inversion of the three datasets was most similar to that from the geodetic data alone because the timing of slip is an additional degree of freedom in the inversion of teleseismic and strong motion waveform data that is not available in the inversion of static offsets. In addition to the final slip distribution, these authors imaged the temporal progression of slip on the fault surface. The rupture appears to slow as it nears the surface, as well as when it approaches the two step-over regions between fault seg-

ments. Furthermore, the authors infer that although the rupture generally propagated unilaterally northwest, each time the rupture jumped northwest to a subsequent segment it also propagated backwards down the abandoned portion of this segment southeast of the fault intersection. Thus, the combined use of geodetic and seismic data provided a more complete and robust understanding of the rupture dynamics of this earthquake, which could then be used to investigate, for example, the spatial patterns in the strength of ground shaking due to this event.

Another example of the combined use of geodetic and seismic data comes from the Dec. 26, 2004 Sumatra–Andaman earthquake, a subduction zone megathrust event which ruptured a  $\sim 1200$  km length of the plate boundary between the Indo-Australian and Eurasian

plates [11,81]. This earthquake, which produced peak-to-peak surface wave motions greater than 1 cm worldwide [115] and measurable static offsets at GPS sites at least 4500 km away [6] and probably farther [73], resulted in more than 283,000 deaths, largely due to its triggering of a major tsunami. This is the largest earthquake to have been recorded since the establishment of digital seismic networks and GPS, and both seismic and geodetic data have been critical in describing the rupture process of this earthquake.

The moment magnitude of an earthquake,  $M_w$ , is a measure of its size and may be derived from the seismic moment ( $M_o$ ), which is defined as

$$M_o = \mu sA \quad (7)$$

where  $\mu$  is the shear modulus of the faulted rock (in units of Pascals),  $s$  is the amount of fault slip during the earthquake (meters),  $A$  is the area of the surface that slipped in the earthquake (meters<sup>2</sup>), and  $M_o$  has units of Newtons  $\times$  meters. “Tsunami earthquakes” [120] are a subclass of subduction zone earthquakes defined as producing tsunamis larger than would have been predicted from their moment magnitude. Tsunami earthquakes have been observed to have slow rupture velocity with relatively little seismic energy release at high frequencies. Although the moment magnitude should represent the net amount of static slip that occurred in the earthquake, it is typically estimated from seismic data at periods of 100 to 300 seconds [81]. If significant seismic energy is released at longer periods, this method will underestimate moment magnitude. The Harvard CMT (Centroid Moment Tensor) solution for the Sumatra–Andaman event, computed using surface wave data with periods of 300 to 500 seconds, had  $M_o = 4.0 \times 10^{22}$  Nm which corresponds to  $M_w$  9.0 [81]. However, researchers quickly began to see evidence that this earthquake was in fact larger.

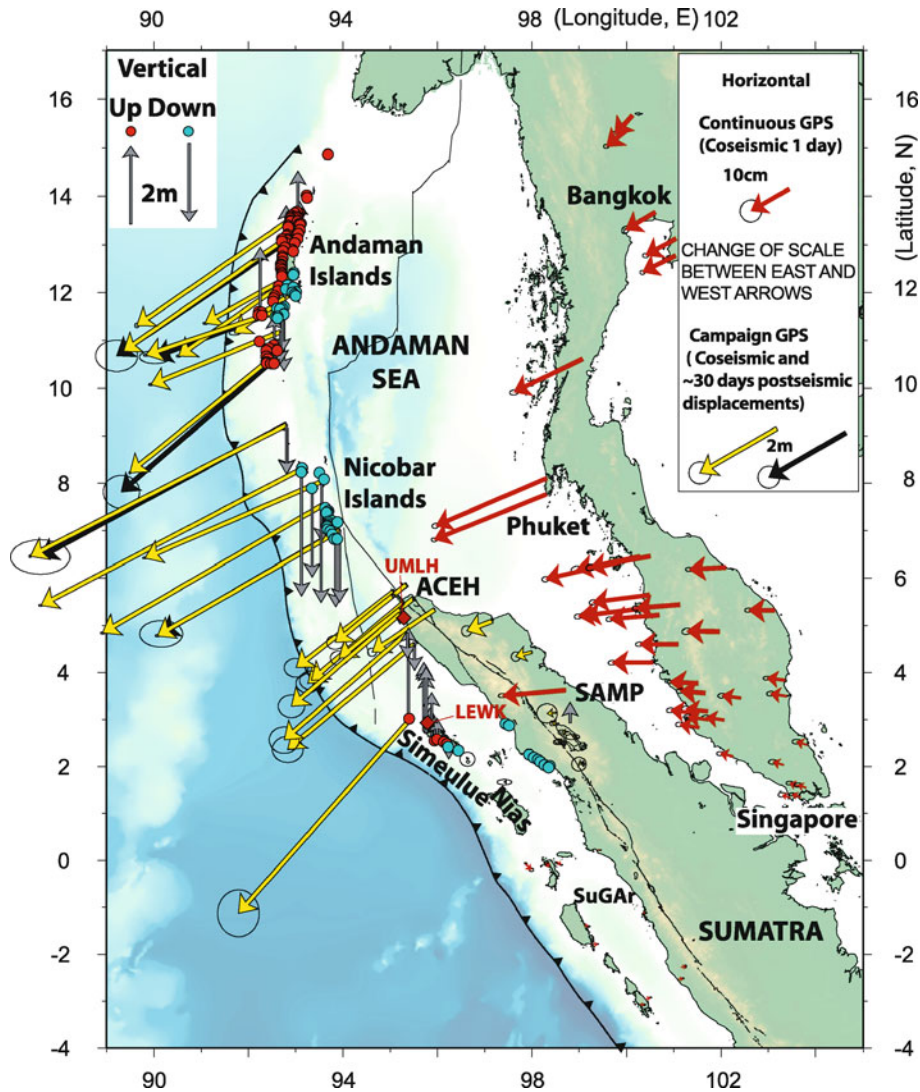

Ammon et al. [1] analyzed seismic data from a broad frequency range (including data with periods up to 54 minutes) and concluded that these observations could be fit by a model in which the majority of the rupture occurred over a 10 minute time span and slip was concentrated south of 8° N (on the southernmost ~800 km of the fault surface, Fig. 11). However, they note that the large GPS displacements reported in the Nicobar and Andaman islands would require 2- to 3-times more slip north of 8° N. Studies of the Earth’s seismic free oscillations [116,152] used these very low-frequency data (at periods up to one hour) to estimate the moment of the earthquake and found that moment increased with the period of the oscillations. These data suggest that the rup-

ture required ~10 minutes to travel from south to north, had more slip in the Nicobar and Andaman islands region than originally thought, and led to  $M_w$  estimates of 9.13 to 9.3. Park et al. [116] also point out that even slower slip (e.g. over a time span of ~1 hour) could have occurred and would be difficult to detect in the free oscillation data.

Banerjee et al. [7] compiled GPS data from several studies and used these observations to infer the static slip distribution on the rupture surface. The total moment release associated with their slip estimate is  $7.62 \times 10^{22}$  Nm (corresponding to an  $M_w$  9.22), smaller than that estimated by Stein and Okal [152], but greater than the  $6.11 \times 10^{22}$  Nm ( $M_w$  9.13) inferred from GPS data by Kreemer et al. [73]. Banerjee et al. [7] conclude that from ~2 to ~16 meters of slip on portions of the fault north of 8° N is needed to fit the GPS data from the Andaman and Nicobar islands. However, they argue that this slip did not occur slowly over a time span of an hour or more because the continuous GPS site at Phuket, Thailand showed little movement after ~10 minutes following the earthquake [160], and other sites in Thailand which should be particularly sensitive to slip on the Andaman segment given their location also do not show movement more than 10 to 20 minutes following the earthquake [53]. Although some slip estimates based on geodetic data alone have higher moment than those from seismic data alone, suggesting the occurrence of aseismic slip, Chlieh et al. [24] and Rhie et al. [129] conducted joint inversions of GPS and seismic data and were able to fit both datasets satisfactorily with a single rupture model.

Thus, although seismic data provide information on the details of fault rupture that cannot be obtained from GPS, in the case of the Sumatra–Andaman event the GPS observations provided needed constraints on the extent and duration of fault rupture, both of which had important implications for tsunami generation.

(c) *GPS and Gravity Data* GPS data have become widely used to study volcanic deformation processes, including the long-term uplift observed at calderas such as Yellowstone (Wyoming), Campi Flegrei (Italy), and Long Valley (California). Geodetic observations can constrain the source geometry and volume change [8]. They cannot, however, discriminate if the deformation is due to an influx of hydrothermal fluids or the intrusion of magma. Battaglia et al. [8,9] address this problem through the combined use of geodetic and gravity data recorded during a period of uplift in Long Valley caldera. Modeling the observed uplift using a point source will produce biased results if the true source does not possess spherical sym-

GPS: Applications in Crustal Deformation Monitoring, Figure 11

Summary of geodetic data recorded in the vicinity of the 2004 Sumatra–Andaman earthquake. The campaign GPS (yellow and black) vectors are compiled from [49,153] and contain approximately one month of postseismic deformation. The continuous GPS data come from Vigny et al. [160]. Note that the near-field vectors (those in the western part of the mapped region) and the far-field vectors use a different scale. Dots represent measurements of vertical deformation from satellite imagery [91]. The gray arrows indicate uplift and subsidence from GPS data, measurements of the vertical movement of coral heads, and mapping of shoreline changes [12,49,153]. Figure adapted from [24]

metry. Furthermore, the uplift signal of a range of source geometries can be similar, but the horizontal deformation signal can help in distinguishing among different models (e. g., [32]). Battaglia et al. [8] use a combination of vertical and horizontal geodetic measurements (GPS, leveling, and line-length data) to find the best-fitting source geometry, in their case a vertical prolate ellipsoid. Then, with that source geometry uniquely determined, they perform

a joint inversion of the uplift and gravity data to infer the volume and mass of the source, from which they obtain a density range of 1180 to 2330 kg/m<sup>3</sup> [9]. Since this density range is too high for hydrothermal fluids to be the sole source of uplift at Long Valley, these authors conclude that a silicic magma body or combination of magma and hydrothermal fluids is required to produce the observed deformation.

### Deformation over Time Scales of Decades to Seconds

We have seen that GPS data are useful for constraining models of deformation that happens rapidly, such as slip in an earthquake. However, perhaps the greatest strength of GPS is its ability to record deformation that occurs over a wide range of time periods. GPS can measure fault slip that happens too slowly to generate seismic waves (termed aseismic slip), volcanic deformation that occurs over several days or several years, and long-term interseismic strain accumulation. GPS can provide much more temporally dense measurements than InSAR and, although less sensitive, is stable to longer time periods than strainmeter data as shown in Fig. 12 [68].

**Interseismic Deformation** Interseismic deformation refers to the gradual straining of the Earth's crust that

GPS: Applications in Crustal Deformation Monitoring, Figure 12 Comparison of rate sensitivity for GPS, borehole strainmeters at 200 meters depth, and borehole tiltmeters (which measure the gradient in vertical deformation) at 2 meters depth. The x-axis indicates the time period that may be spanned by the different data types. For example, daily GPS measurements may span one day or longer. The y-axis indicates the strain rate that can be resolved as a function of the period. Strain is the change in length (area or volume) per a unit length (area or volume), and thus is unitless and can be expressed as parts per million (ppm). As can be seen from the plot, the borehole tiltmeters and strainmeters are more sensitive than GPS at shorter periods, but at periods longer than a few days and a few months, respectively, GPS measurements provide better resolution of strain rates. Figure courtesy of John Langbein

occurs during the time between moderate to large earthquakes. This strain can be caused by the build up of stress that will eventually be released during earthquakes, as well as reflect the broader-scale patterns of deformation in response to tectonic plate motion.

*(a) Block Versus Continuum Models for Deformation* As one moves from the global scale of tectonic plates to the continental scale, a major question is whether continents deform through the movement of many small rigid blocks (like plates on a smaller scale) or through more continuous deformation [157]. GPS data have been used in numerous studies to try to elucidate this hotly debated issue, and one region that has been a focus of study is the Tibetan plateau which accommodates strain due to the collision of India with Eurasia. GPS velocities for a profile of stations spanning central Tibet roughly parallel to the direction of maximum convergence between India and Eurasia show a linear gradient in the component of velocity parallel to the convergence direction. This observation has been cited as evidence for continuously distributed deformation across the region (e. g. [171]) or distributed strain combined with the movement of a small number of crustal blocks [23]. In contrast, Thatcher [158] showed that the velocities predicted by a model in which the Tibetan plateau was divided into a set of rigid, rotating crustal blocks defined by faults and other geologic features could also fit the data since the difference between the observed GPS velocities and those predicted by the block model were relatively small and did not exhibit widespread systematic spatial patterns. Although the rigid block model does not predict a linear velocity gradient across central Tibet, Thatcher [158] notes that both the block and distributed models fit the velocity profile within errors. The spatial sampling provided by GPS remains sparse across large portions of the Tibetan plateau, and it is likely that additional data will be necessary to resolve the outstanding question as to whether continental deformation in this region is primarily block-like or continuous.

*(b) Estimating Interseismic Fault Slip Rates* Following the 1906 San Francisco earthquake, H. F. Reid [127] used his observations of deformation in that event to formulate a description of the earthquake cycle which he termed “elastic rebound.” Reid recognized that strain builds up in the Earth's crust around faults during the interseismic period, and that strain is eventually released in earthquakes. Reid's hypothesis predated the theory of plate tectonics, but we now understand that the source of the ongoing stress affecting the faults is the motion of the Earth's plates. The strain build-up and release causes measurable

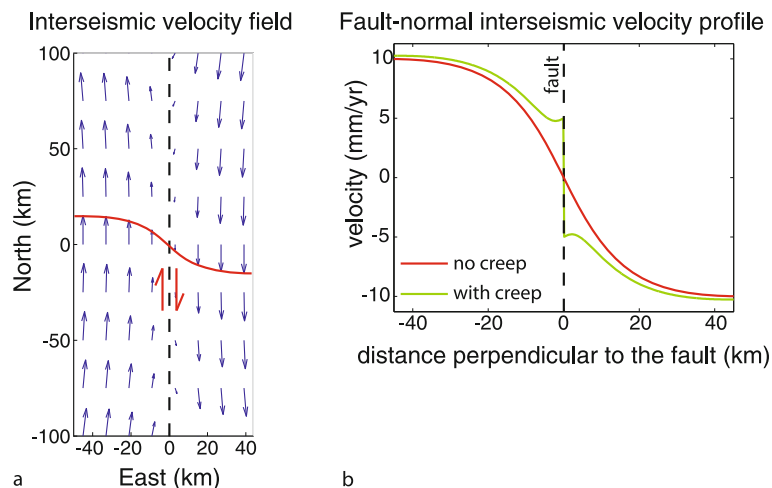

deformation of the Earth's surface. Areas where the crustal strain measured using GPS is large are likely to have earthquakes to relieve that strain. These events may take place on faults that are not visible on the earth's surface, and in this case the geodetic data can provide an important clue to the existence of seismic hazard. GPS enables measurement of deformation during all phases of the earthquake cycle.

One of the most important pieces of information needed to characterize a region's seismic hazard is an estimate of the slip rates on the major active faults that could affect that region. Most seismically active regions are at plate boundaries. The Earth's rigid plates are always moving at rates that are essentially constant over time periods comparable to earthquake recurrence intervals (e.g., hundreds to thousands of years). At plate boundaries the relative motion between two neighboring plates is accommodated on faults. The portion of the rate of relative motion that is accommodated across a given fault is that fault's slip rate. Slip rates are often estimated from geologic data, for example by dating samples collected from a location in which a measurable offset of a stream channel has occurred due to movement on a fault that crosses the stream [146]. However, slip rates can be inferred from geodetic data as well.

Below a certain depth in the Earth's crust (e.g., ~15 km for many strike-slip faults in the San Andreas system) the temperature and pressure are sufficiently high for

the crustal rock to behave plastically in response to stress, rather than experiencing brittle failure. Earthquakes occur above this depth, which is termed the "brittle-ductile transition," the "locking depth," or the "transition depth," but not below. In the time between moderate to large earthquakes most faults are largely locked above the transition depth, meaning no movement occurs across them. (It is true that very small earthquakes occur frequently on most faults, but these events affect a relatively small portion of the fault's surface area and release a tiny fraction of the energy, or moment, released in moderate and large events.) The material below the transition depth deforms gradually and continuously in response to plate motion, and a fault that is locked above the transition depth may exist as a zone of distributed shear below that depth. In the vicinity of a locked fault, the constant movement of the material below the transition depth strains the elastic crust above. This is manifest by a characteristic pattern of interseismic velocities for points on the Earth's surface near the fault. For example, the interseismic velocity profile perpendicular to a strike slip fault like the San Andreas will have a characteristic sigmoidal shape as shown in Fig. 13, the details of which reflect the locking depth and slip rate of the fault.

In regions dominated by a small number of major faults of known geometry (e.g., the San Andreas fault system in northern California, or subduction zones of Cascadia and Japan), interseismic slip rates can be inferred

GPS: Applications in Crustal Deformation Monitoring, Figure 13

**a** Expected velocity field due to interseismic slip below 15 kilometers on a vertical strike slip fault. The red curve highlights the difference in velocity near and far from the fault. **b** Expected velocity profiles for a locked fault and one that exhibits shallow creep. The locked fault is as in a. The creeping fault slips below 15 km depth and creeps in the uppermost 4 km but is locked from 4 to 15 km depth. Note that in the case of a creeping fault, there is an offset in the velocity profile close to the fault. The near-fault inflection in the green curve shows the combined effect of the strain due to slip below the locked zone and creep that reaches the Earth's surface

in much the same way as was done for earthquake slip (Eq. (6)) using relatively simple dislocation models in which the fault is prescribed to be locked above the transition depth and freely slipping below that (simulating the motion of the tectonic plates). A number of studies (e. g. [47,125]) have taken this approach to model the GPS velocities of sites in northern California as the superposition of interseismic velocity signals due to slip on the multiple sub-parallel faults that make up the San Andreas system. When the slip rate on a fault is estimated from interseismic GPS velocities, the resulting value is generally called the interseismic slip rate to emphasize that it has been estimated from data collected over a time period entirely within the interval between two earthquakes on the fault in question. When slip rates are estimated from geologic data they are often called “long-term average” rates to emphasize that they represent the rate over many earthquake cycles. In the absence of post-seismic effects or other transient deformation (described in more detail in a later section) these two slip rate estimates for a given fault should be the same. In subduction zones, interseismic velocities are often used to estimate the degree of plate “coupling,” which reflects the size of the locked zone that may rupture in a large earthquake [17,44,93,108,154,164].

As discussed earlier in the context of the Tibetan plateau, one interpretation of continental deformation patterns is that they arise from the rotation of fault-bounded blocks, and the GPS data can be used to estimate the Euler poles of rotation for each block. Data from sites near known faults may be discarded from the analysis because these observations will likely reflect the interseismic elastic strain accumulation due to the faults rather than the long-term rigid behavior of the blocks. Slip rates on the faults that bound the blocks can be calculated from the relative rates of block rotation (e. g. [158]). An alternative block modeling approach retains all the data, and the estimated block rotation rates must result in slip rates on block-bounding faults that are compatible with the patterns of strain accumulation recorded in the GPS velocity field. As with the dislocation models, a transition depth is assumed for each fault. The portion of each fault above the transition depth is treated as locked, and slip on the portion below the transition depth drives the observed strain accumulation.

Block modeling of this type lends itself to the many seismically active regions, such as southern California, that are characterized by numerous faults with complex geometries. Unlike models which represent individual faults by separate dislocations, block models are required to be self-consistent in that the rotation rates must be compatible for all blocks, slip rates have to be consistent at fault in-

tersections, and the total slip rate across the region is made to match the relative plate rate. A drawback of this approach, however, is that it is difficult to accommodate dipping faults and to constrain fault-perpendicular motion in a realistic way.

Both block models and dislocation models suffer from trade-offs between slip rate estimates on different faults and sensitivity to poor data coverage. Furthermore, it is difficult to resolve the contribution to the observed GPS velocity from strain accumulation on closely spaced faults (e. g. within two locking depths of each other), and thus slip rate estimates on neighboring faults tend to trade-off with each other and with the assumed locking depth. It will always be difficult to resolve slip rates on faults that are close together given that displacement measurements are confined to the Earth’s surface.

Several studies have applied the technique of block modeling with inclusion of elastic strain accumulation to the western United States [26,89,90]. For many faults the slip rates estimated by these studies agree to within errors with those estimated from geologic studies. However, there are some discrepancies. For example, the  $\sim 5$  mm/yr slip rate Meade and Hager [90] estimated for the San Bernardino segment of the San Andreas fault is considerably lower than the geologic estimate of  $\sim 25$  mm/yr. Discrepancies between geodetic and geologic slip rates have been found in several locations world wide, but it is not the case that one data type tends to produce consistently higher rate estimates than the other. The differences likely result from a combination of factors, including assumptions made in interpreting the data, the localized nature of geologic estimates, and the different time periods spanned by the two data types. Consistency between geodetic and geologic slip rates is an area of ongoing study.

Time varying deformation is often observed following large earthquakes. One source of this signal in many cases is the viscoelastic response of the material below the transition depth. When a large earthquake occurs it imparts stress to this material, which then deforms slowly, restressing the elastic crust above. The rate of the resulting strain would be expected to be high directly after the earthquake and die off with time. Likewise, the strain accumulation rate on the affected fault would vary throughout the earthquake cycle. These processes have been incorporated into another category of interseismic deformation models called “viscoelastic cycle” models [66,67,133,137,156], which can be used to estimate fault slip rates and earthquake recurrence times. These models account for the strain rate maxima on faults during the interseismic period as well as temporal variations in the months to years following a large earthquake.

(c) *Fault Creep* An interesting interseismic phenomenon, termed “fault creep,” is observed on several faults of the San Andreas system in central California and the San Francisco Bay Area, as well as faults in Taiwan, the Philippines, and Turkey. Faults exhibiting creep slip steadily or episodically at low average rates (e. g. 10 mm/yr). Some creep events are confined to the uppermost ~500 meters of faults, but in other cases creep occurs deeper at what are generally considered to be seismogenic depths (e. g. to a depth of ~15 km on faults of the San Andreas system). However, this fault slip is too slow to generate seismic waves. The ongoing slip of creeping faults is a nuisance, offsetting cultural features like curbs and buildings. However, ongoing creep constantly relieves stress which would otherwise be released in an earthquake and thus reduces the seismic hazard due to that fault. For example, a 2003 study of earthquake probabilities for the San Francisco Bay area found that accounting for creep on the Calaveras fault reduced the predicted rate of  $M \geq 6.7$  earthquakes on this fault by a factor of three [167]. Therefore, knowing the extent of creep is valuable in hazard assessments.

Fault creep will have a different interseismic signature than that for a fault that is locked in the seismogenic zone (Fig. 13b). Instead of the smooth transition seen across a locked fault, there will be a step because there is fault offset near the surface. Therefore, GPS data can be used to infer the depth-extent of fault creep. Several studies have used GPS data, in some cases in combination with InSAR, creepmeter, and microseismicity observations, to estimate the spatial distribution of fault creep (e. g. [64,85,103,136]).

**Temporally Varying Deformation** Continuous GPS measurements are particularly useful for observing transient, or time-varying, deformation. Sources of transient deformation include slow slip events, postseismic response, and volcanic processes.

(a) *Slow Slip Events* Slow slip events, sometimes also referred to as “slow earthquakes” or “silent earthquakes” (the latter emphasizing the lack of a seismic signature to the event), are a phenomenon in which fault slip occurs at too slow a rate to generate seismic waves. The duration of slow slip events that have been observed geodetically world-wide ranges from days (e. g. [22,106]) to years (e. g. [98,102]). Precursory transient slip with duration of minutes has been observed prior to earthquakes on mid-oceanic ridge transform faults using seismic data (e. g. [62]).

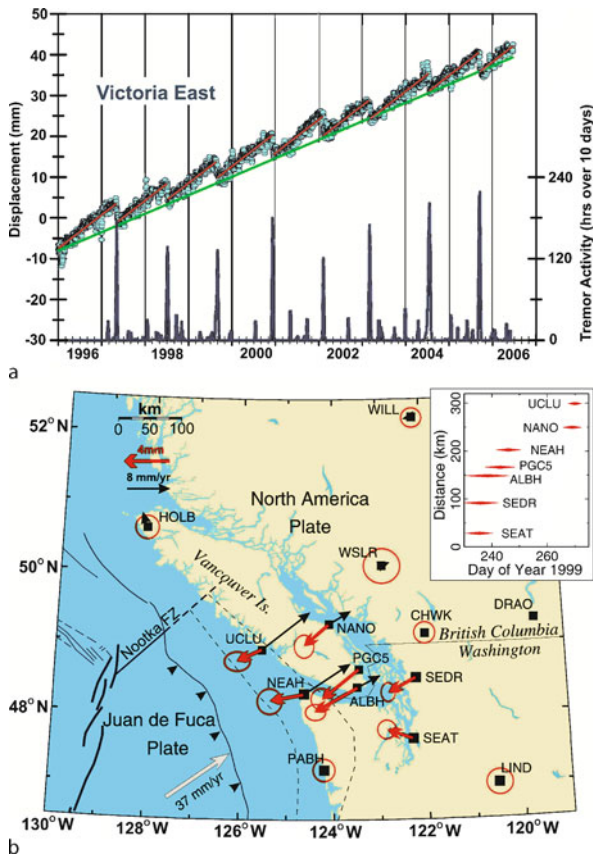

Shallow creep events and a multi-year transient increase in slip rate have been observed along the San

Andreas fault where continuous or frequent monitoring using creepmeters, strainmeters, and two-color electronic distance measuring instruments provided temporally dense measurements [51,52,75,82]. In 1996, a couple of years after the establishment of the Japanese CGPS network, evidence for slow slip in the Boso Peninsula region near Tokyo became apparent in the data [131]. As the spatial coverage of CGPS networks worldwide improved it became clear that slow slip events were much more frequent than previously thought, occurring over a variety of spatial and temporal timescales and tectonic settings.

The majority of large slow slip events observed to date have occurred in subduction zones, including those of Japan, the Pacific Northwest of the United States, Mexico, New Zealand, and Alaska. In 2001 a surprising pattern was recognized in time series for several CGPS sites in the Cascadia region in the Pacific Northwest of the United States (Fig. 14a). The subduction interface is thought to be locked near the Earth’s surface and freely slipping at greater depths. The ongoing deep slip results in interseismic motion of GPS sites toward the over-riding plate (Fig. 14b). In the case of the Cascadia sites, this means that the long-term average interseismic movement is eastward. However, it was observed that occasionally the sites briefly moved in the opposite direction, causing a step-like pattern in the position time series. An intriguing feature of the observed reversals in station velocities is that the pattern was found to repeat approximately every 14 months [94].

That several CGPS sites in the region showed a coherent reversal in the direction of motion at the same time (Fig. 14b) suggested that the source of this signal could be slip on the interface between the down-going slab and over-riding plate of the subduction zone. Modeling of the GPS data [35] indicated that the source region was a portion of the subduction interface between 30 km and 40 km depth that is a transitional zone linking the shallow fully locked and deeper fully slipping parts of the interface.

In 2002 Obara [105] reported a very low frequency seismic signal called tremor, typically observed at active volcanoes, emanating from ~30 km depth in the subduction zone of southwest Japan. A similar signal was soon discovered in Cascadia, and researchers quickly realized that the tremor occurred simultaneously with slow slip events in those locales (Fig. 14a). Furthermore, they identified the source regions of the tremor and found that it coincides spatially with the inferred source region of the slow slip [106,130]. In volcanic settings tremor is thought to be caused by the movement of fluids through conduits underground. Recent studies have found that slow slip events in subduction zones are accompanied by very low frequency earthquakes and that the tremor in these lo-

GPS: Applications in Crustal Deformation Monitoring, Figure 14  
**a** Time series for station ALBH located in Victoria British Columbia, Canada relative to stable North America. The blue dots are station positions. Although the overall interseismic movement of this site is eastward due to the ongoing strain caused by subduction (green line), every  $\sim 14$  months this site moves westward (steps in time series). The red line represents the average velocity in the time between slow slip events, which is a higher rate than the long-term interseismic movement (green line). The blue curve represents the time series of nonvolcanic seismic tremor. Periods of increased tremor activity coincide with the times at which the GPS site shows anomalous westward movement [130]. **b** Portion of the Cascadia subduction zone. Black vectors are interseismic velocities of continuous GPS sites relative to stable North America, and red vectors are anomalous displacements during the 1999 slow slip event. The inset shows relative timing of transient displacements among different sites. From [35]. Copyright, Her Majesty the Queen in right of Canada (2001)

cales is actually made up of many low amplitude low frequency events [142,143]. One interpretation is that shear slip on the subduction interface, rather than fluid flow, causes nonvolcanic tremor, implying that tremor and slow slip both arise from the same underlying process of shear slip. Although the tremor may not be directly caused by

fluid flow, the low frequency earthquakes and slow slip appear to coincide spatially with areas of high fluid pressure in the pore spaces of subduction zone rocks. The high pore pressure, perhaps resulting from metamorphic reactions that release fluid, may encourage shear slip [143].

Like Cascadia, other subduction zones, for example the Guerrero region of Mexico [83] and the Shikoku [106] and Tokai [55] regions of Japan, have also experienced, to varying degrees, quasi-periodic slow slip events. Slow slip, in some cases multiple events, has been observed in other subduction zones such as Alaska [107], New Zealand [34], and the Tokai [98] and Bungo channel [114] regions of Japan, but it remains to be seen if the transient slip is periodic. Even in Cascadia, which shows clear periodicity, there is variation in the periodicity along the strike of the subduction zone. For example, slow slip events have been observed in both northern and southern Vancouver Island with a  $\sim 14$  month periodicity, but the events in these two locations are 6 months out of phase with each other. Slow slip events in northern California, also part of the Cascadia subduction zone, have been found to have an  $\sim 11$  month recurrence interval [155]. In southwest Japan, the Shikoku region experiences short duration (on the order of a week), small amplitude slow slip events (in fact only detectable in the tiltmeter data) at six-month intervals coincident with tremor [106]. In contrast, the subduction zone beneath the Bungo channel region, which abuts the Shikoku region directly to the southwest, experiences infrequent large slow slip events lasting  $\sim 1.5$  years [114]. Similarly, in the Tokai region, short-term and long-term slow slip events seem to occur on nearly overlapping parts of the subduction zone [55,98].

Similar to fault creep, the cumulative effect of several slow slip events may be to relieve stress on the transition zone along the whole length of the subduction interface without a large earthquake. However, slow earthquakes in the subduction zones of Cascadia, Japan, and elsewhere may impart stress to the locked subduction interface up dip and thus increase the likelihood of a large earthquake [35,123]. Understanding both the mechanism of these events and what it means for seismic hazard continues to be a focus of intense study.

Transient slip has also been observed in non-subduction zone settings. GPS data have shown that the south flank of Kilauea volcano in Hawaii moves seaward at a rate of several cm/yr [111], perhaps a manifestation of the instability of the volcanic edifice. However, in 2001 it was observed that this motion sped up for a few days. Cervelli et al. [22] modeled the GPS observables during the period of increased station velocity and concluded that the source was a  $\sim M 6$  slow earthquake lasting 36 hours and gener-

ating an average of almost 9 cm of slip on a nearly horizontal thrust fault about 4.5 km underground. This observed transient signal occurred nine days after a storm caused 1 meter of rainfall on this part of the Big Island. Cervelli et al. [22] calculated that given reasonable values for the porosity and permeability of the rocks in the study area, the slow slip could have been triggered by an increase in pore fluid pressure as the rain water penetrated into faults on the volcanic edifice. Subsequently several more very similar transient events have been observed in this locale by GPS [139], not accompanied by anomalously high rainfall. Moreover, it has been recognized that these events are accompanied by increased seismicity in an adjacent area following the onset of the deformation signal. This lends credence to the interpretation that the displacement signal is due to fault slip and suggests that the transient slip triggers the seismicity. In order for slow slip to trigger the observed seismicity, the slip must occur deeper than originally thought. A model in which slip occurs at the depth of the interface between the volcano and the underlying ocean floor,  $\sim 8$  km, fits the GPS displacements as well as one in which slip occurs at more shallow depths ( $\sim 4.5$  km) [139].

*(b) Postseismic Deformation* Often following a moderate or large earthquake, continued aseismic deformation is observed. This may be due to several sources, including continued slip on the fault surface, diffusion of pore fluid, and the viscoelastic response of the lower crust (below the transition depth) and upper mantle. All of these processes are triggered by the stress changes imparted to the surrounding crust and mantle by the earthquake. More than one source can be active simultaneously, and the effects change and decay with time. The spatial and temporal evolution of postseismic signals can provide important insights into the frictional, hydrological, and rheological characteristics of the crust and upper mantle, and enable a better understanding of the way stress is redistributed in the crust, which is an important consideration in assessing seismic hazard.

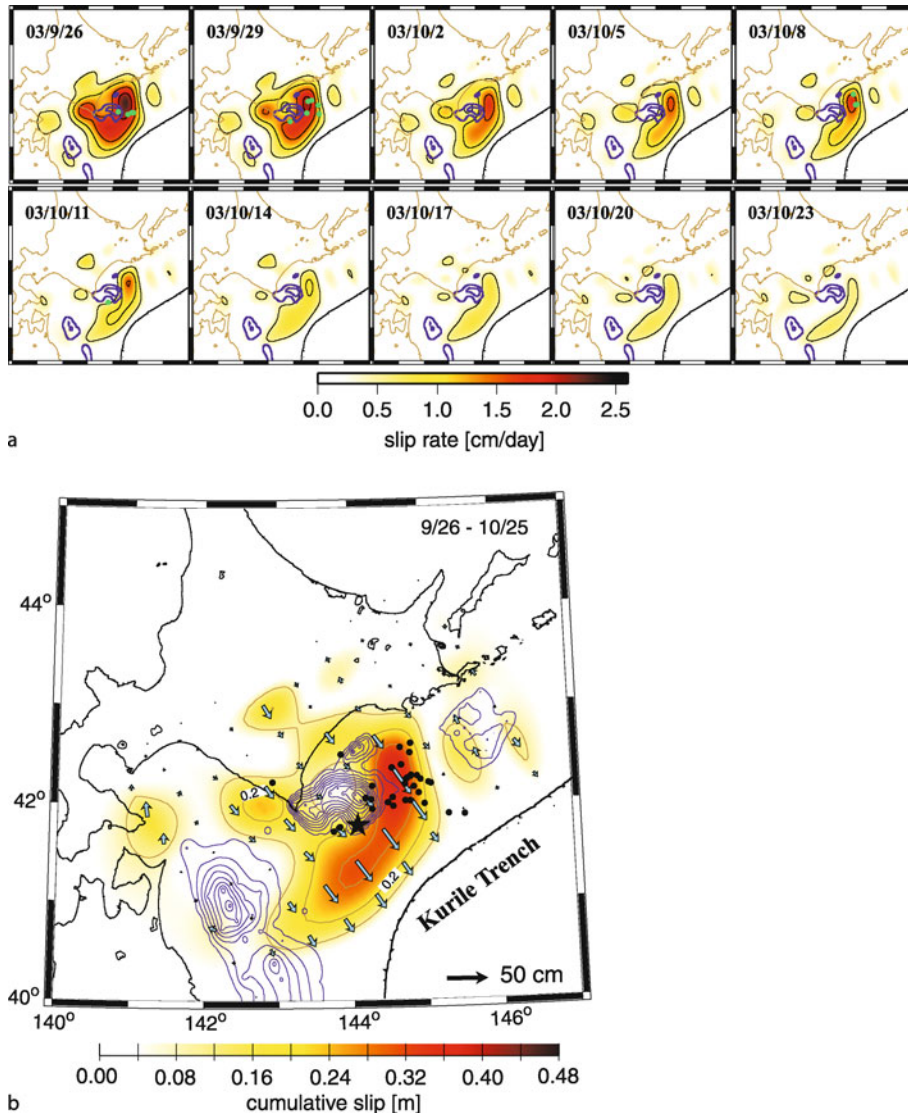

Afterslip is continued slip on the fault plane after the rapid slip which generates seismic waves has ceased. The effects can start immediately after the event (e. g. [76]) and can last for months or years, typically showing a logarithmic decay with time (e. g. [134]). Afterslip is thought to arise from the stress changes imparted by the earthquake to parts of the fault which have frictional properties that allow slow slip. Typically the total afterslip following an event is a fraction of the amount of slip that occurred coseismically. However, some events such as the Sanriku-haruka-oki [169] and Tokachi-Oki [97] earthquakes in

Japan have had afterslip with moment release approaching or, in the case of the 2004  $M_w$  6 Parkfield earthquake [76], exceeding the coseismic moment. Although the factors controlling the amount of afterslip are not fully understood, the fact that the San Andreas fault near Parkfield, as well as many subduction zone faults, are known to exhibit fault creep may be a factor.

The spatial and temporal evolution of afterslip following the 2003  $M_w$  8.0 Tokachi-Oki earthquake in Japan was estimated from GPS data using a Kalman-filtering technique [97] (Fig. 15a). The rate of afterslip started quite high and died off gradually. These authors noted that the highest afterslip rates tended to localize around the area which slipped in the earthquake. This is not unexpected as the coseismic slip area would have just experienced a reduction in shear stress which would discourage further slip here. Interestingly, the afterslip seems to avoid areas inferred to have slipped in other earthquakes that occurred in the decades prior to the Tokachi-Oki event as evidenced in the plot of cumulative afterslip in Fig. 15b. This interpretation provides support for the idea that rapid coseismic and gradual aseismic slip may occur on different parts of the fault because of variations in frictional properties. Similar results were found from an analysis of afterslip following the 2005 Nias–Simeulue thrust event [59].

As described earlier in regards to viscoelastic cycle models of interseismic deformation, the stress changes imparted by a moderate or large earthquake to the material below the elastic crust causes time-varying deformation. The geodetically recorded postseismic deformation following several large events has been interpreted to reflect viscoelastic processes (e. g. [156]). The rate at which viscoelastic postseismic deformation decays depends in part on the viscosity of the lower crust and upper mantle. The temporal decay of displacements measured with GPS have been used to infer viscosity values and thus the relative strength of these two layers (e. g. [5,31,45,46,121,122]). Estimates for the viscosity of the lower crust range from  $10^{19}$  to  $10^{21}$  Pa s, and for the upper mantle range from  $10^{17}$  to  $10^{19}$  Pa s.

Stress changes in the crust due to fault slip in an earthquake compress the pore space of rocks in some areas and cause dilation of the pore space elsewhere, depending on the orientation of the fault and sense and distribution of slip. The resulting pore pressure gradients cause fluid to flow from areas of high pressure to those of low pressure. This fluid flow causes further time-dependent strain. Such effects have been observed following several earthquakes including a pair of moderate earthquakes that occurred in 2000 in Iceland [5,69] and the  $M_w$  7.3 Landers event in California [43,118]. If poroelastic effects are confined

GPS: Applications in Crustal Deformation Monitoring, Figure 15

**a** Temporal evolution of the rate of afterslip (indicated by *colored shading*) on the subduction interface following the 2003  $M_w$  8 Tokachi-Oki earthquake. Dates given in upper left of each frame. *Blue contours* are the areas that slipped in previous earthquakes in this region. The *blue contours* in the center of the mapped area are those of the Tokachi-Oki earthquake. The *green dots* are aftershocks. **b** Cumulative afterslip in the first 30 days following the earthquake estimated from GPS data. Slip magnitude is given by the *colored shading*; the estimated amount and direction that the upper plate (the area northwest of the Kurile trench) moved relative to the lower plate is shown by the *arrows*. Afterslip tends to surround the areas inferred to have slipped in the Tokachi-Oki earthquake (epicenter given by the *black star*) and other events, shown by the *blue contours*. to the upper few kilometers of the fault zone, the spatial extent of the resulting surface deformation will be localized near the fault. Also, vertical surface displacement is a large component of the poroelastic signal. Because GPS measurements of vertical displacement are noisier than the horizontal data, and because the distribution of GPS sta-

tions may be limited near the causative fault, much of the insight into poroelastic deformation following events like the Landers earthquake and the earthquakes in Iceland has come from InSAR data.

It is unlikely that postseismic deformation associated with a given earthquake can be explained by a single pro-

cess. Given the often limited spatial and temporal data coverage and, in the case of GPS data, the sometimes poor vertical displacement control, it can be difficult to differentiate among different potential sources, e. g., afterslip, viscoelastic, and poroelastic deformation. However, the surface displacements due to each process can exhibit diagnostic patterns in time and space, which, if observed, make it possible to discern distinct causative processes. For example, due to its deeper source viscoelastic deformation should affect a broader geographic region than poroelastic deformation or shallow afterslip. Because viscoelastic deformation involves the response of material with viscosities on the order of  $10^{18}$  to  $10^{19}$  Pa s, while poroelastic processes involve the flow of aqueous fluid through the ground, the signal due to the former is expected to last considerably longer (e. g., several years) than that of the latter (e. g. several months). Several studies have analyzed postseismic deformation, in some cases observed using multiple data types, and attributed the observed deformation to a combination of two or more effects [5,43,46].

*(c) Volcano Deformation* Volcanic deformation is often characterized by transient signals. Magma or hydrothermal fluids migrate beneath the volcanic edifice, causing inflation or deflation and sometimes culminating in an intrusion or eruption. The steep flanks of volcanoes are often unstable, leading to landslides and in some cases collapse of large sections of the edifice. GPS is very well-suited to monitoring these types of deformation signals, and many of the world's volcanoes have CGPS receivers installed for this purpose. Some of the earliest GPS observations of volcanic deformation come from a submarine volcano near the Izu peninsula in Japan. Here GPS data from two receivers recorded deformation several days before volcanic tremor or visible signs of eruption were apparent [48,145].

Loss of instruments in a volcanic eruption is a real and costly risk. InSAR, which does not require any equipment on the ground, is a widely used method for monitoring volcano deformation. However, InSAR does not provide three-component deformation measurements and does not have the temporal resolution that CGPS does. InSAR also suffers from decorrelation when vegetation, snowfall, or lava flows change the land surface during the time between two image acquisitions, however it still generally provides better spatial coverage than GPS. Dzurisin [40] presents a good overview of InSAR as applied to volcano deformation.

During a recent eruption of Augustine, a stratovolcano in Alaska, GPS data proved to be a valuable complement to other monitoring systems [20]. In the summer of 2005 CGPS stations on the volcano began to record an infla-

tion signal, following an increase in microseismicity below the volcano that had begun in May 2005 or perhaps earlier. Beginning in November 2005 the rate of inflation increased rapidly, but then died off somewhat in early January 2006. The inflation signal has been interpreted as evidence for a dike intrusion into the volcanic edifice which nearly reached the surface [20]. On January 11, 2006 a series of explosive eruptions began at Augustine, destroying two of the six CGPS receivers. By January 17th, though, the eruptions had died down, as had seismicity and gas emissions. Only the GPS data from two of the remaining stations showed continued inflation. The quiescence lasted 10 days before another explosive eruption and effusive lava flows took place. This is an example in which GPS data provided early corroboration in the summer of 2005 that increased seismicity was due to magma movement into the volcanic edifice. Moreover, during the ten days of quiescence when other indicators such as seismicity and gas measurements showed little activity, the GPS data showed that further eruptive activity was likely [20].

**High-Rate GPS** Continuous GPS networks typically record data at 15- or 30-second sampling rates, which is more than adequate for obtaining daily positions. One such CGPS network, the Southern California Integrated GPS Network (SCIGN), recorded data at 30-second intervals for the 1999  $M_w$  7.1 Hector Mine earthquake. Nikolaidis et al. [104] used these data to obtain positions at every observation epoch for the time spanning the earthquake and demonstrated that these observations, although aliased, agreed with those from nearby strong ground motion instruments. However, GPS receivers are capable of recording data at much higher rates, e. g. 1 Hz or greater. In recent years, for scientific as well as surveying and navigation purposes, an increasing number of CGPS sites have been set to record high-rate data and in some cases transmit them in real-time.

Unlike seismic data, GPS receivers provide a direct measure of displacement, and the instrument stays on scale even during the strong shaking of an earthquake. This makes it possible to obtain high-rate displacement time histories without the error introduced by integrating velocity or acceleration records from seismic instruments and without the data loss that occurs when the shaking exceeds the dynamic range of a seismic instrument (Fig. 16). Although the results of Nikolaidis et al. [104] hinted at a potential application of high-rate data, this kind of observation was not yet available for an earthquake. Such an event occurred in 2002 with the  $M_w$  7.9 Denali earthquake in Alaska. Larson et al. [78], obtained displacement-time histories of seismic waves from 1 Hz GPS data recorded

GPS: Applications in Crustal Deformation Monitoring, Figure 16 Comparison of displacement time series from a GPS station and doubly integrated accelerometer data from two nearby stations of the KIKnet and Knet networks in Japan for the 2003  $M_w$  8 Tokachi-Oki earthquake. The GPS data and that from the KIKnet site (blue and green curves) agree well for the first  $\sim 50$  seconds following the arrival of the seismic signal (at  $\sim 30$  seconds). The deviation of the accelerometer data after several seconds is likely due to low frequency noise that is amplified by the double integration required to produce displacements. Additionally, the Knet site (red curve) may be affected by tilting during shaking or other problems with sensor orientation, leading to the greater deviation between the red curve and those of the other two instruments. Reprinted with permission from [96] (copyright 2006, American Geophysical Union)

during this event and showed they were in good agreement with those obtained by doubly integrating accelerometer data.

Wang et al. [165] demonstrated that GPS receivers operating at 1 Hz provide a faithful recording of signals with periods of 2 seconds or greater. However, GPS receivers will not replace seismometers for recording earthquakes since they cannot capture the higher-frequency components of the seismic waves. Rather, they provide a valuable complement to seismic data. For example, Emore et al. [42] show that high-rate GPS data can be used as a constraint when integrating accelerograms. Moreover, the combined use of seismic and high-rate GPS data extends the observable frequency and amplitude range of seismic waves considerably [78]. Miyazaki et al. [96] demonstrated that GPS seismograms measured by 1 Hz GPS could be used in a similar way to seismic data to infer the spatial and temporal progression of fault slip during the earthquake. High-rate GPS observations can be especially useful in this capacity when used in combination with seismic data (e.g. [63]).

High-rate GPS also vastly improves our ability to track early postseismic deformation. Seismic data do not record any processes, like afterslip, that do not generate seismic waves, so postseismic deformation measurements must be made using other instruments including GPS, strainmeters, and InSAR. Until CGPS networks became common, it was generally not possible to deploy instruments for post-earthquake geodetic measurements until field crews could reach the affected area, days or weeks after the event. As a result, any change in measured position from the last pre-earthquake survey until the first post-earthquake survey contained the full coseismic signal and some portion of postseismic displacement. Even the “coseismic” displacements obtained from differencing daily positions from CGPS data collected the day before and the day after the earthquake can be contaminated by postseismic signals that began immediately after the event. High-rate GPS data, on the other hand, provide a means to record the deformation signal continuously, starting in the seconds after an earthquake. An example of this was the 2004  $M_w$  6 Parkfield earthquake. Langbein et al. [76] showed that rapid postseismic displacement began immediately after the event, and these authors were able to use the high-rate time series to separate the coseismic and postseismic displacements. For other events, including the 1966  $M_w \sim 6$  Parkfield earthquake, the moment release estimated from seismic data has often been substantially lower than that estimated using geodetic data (e.g. [138]). However in the case of the 2004 Parkfield event the slip estimated from the coseismic portion of the GPS displacement signal had moment release in good agreement with that estimated from seismic data [76].

The availability and use of high-rate GPS data in real-time for geophysical applications is not yet widespread, but it is growing as more CGPS sites are installed, telemetry of high bandwidth data becomes more feasible, and approaches to processing the data are refined. These data have great potential for aiding real-time deformation monitoring on volcanoes, for early warning of major earthquakes, and for tsunami warning as well.

For example, Mattia et al. [87] highlight the value of high-rate real-time GPS data in a time-critical situation to quickly differentiate localized volcanic processes (in their case a new volcanic vent opening) from more far-reaching dangers (e.g., a feared flank failure that could have caused a local tsunami).

Real-time high-rate GPS data may soon also contribute to rapid earthquake warning and response. Hudnut et al. [61] envision a system consisting of a pair of GPS receivers straddling a fault such as the San Andreas which record data at high rate and transmit these mea-

surements in real time. In the case of a major earthquake which, within seconds, caused surface offset on the fault of more than a few centimeters, the “GPS slip-sensor” would indicate that the event was large significantly sooner than could be expected from seismic data alone. This rapid information could be used to trigger preventive measures for critical infrastructure such as transportation systems (e. g., slowing trains to help prevent derailment) and factories (e. g. halting processes involving hazardous chemicals).

Blewitt et al. [14], using data from the 2004 Sumatra earthquake, demonstrated that GPS data available in real time, even if recorded at the traditional 30-second sampling rate, can be used to reliably estimate displacements larger than about 10 mm for great earthquakes. Such information would significantly improve the robustness of tsunami warning systems, at least for oceanwide tsunamis, by giving a better indication of the true moment magnitude of the earthquake more quickly (e. g. within 15 minutes) than can be achieved with seismic data.

The patterns of strong shaking that occur during an earthquake provide a good indication as to where damage will be the most severe. The U. S. Geological Survey has implemented a system called ShakeMap which rapidly generates a map of shaking intensity based on instrumental recordings. This is a valuable tool for emergency responders and scientists in the aftermath of an earthquake, and is available to the public as well (<http://earthquake.usgs.gov/eqcenter/shakemap/>). However, in many areas seismic instrument coverage is sparse, hindering the generation of accurate and detailed maps. Dreger et al. [36] demonstrate that seismic data can be used to rapidly generate a model of fault slip during an earthquake and that such a model can significantly improve the quality of ShakeMap produced for that event. This is especially true when the direction of earthquake rupture away from the hypocenter shows a preferred orientation along strike, since shaking will be stronger at locations that coincide with this directivity. Current work is focused on incorporation of real-time high-rate GPS data into the fault slip analysis with the ultimate goal of further refining ShakeMaps.

### Future Directions

As evidenced by the applications described in this article, GPS has become an indispensable tool for monitoring crustal deformation hazards and investigating the underlying processes. It provides an affordable means of obtaining surface displacement measurements with millimeter-level precision at any time of day anywhere on earth in all weather conditions with no line of sight requirement. GPS

data complement other observations such as seismic and InSAR data by providing a direct measure of displacement in three dimensions that stays on scale. GPS can record deformation over temporal scales of seconds to decades, thus making it possible to track surface waves generated by an earthquake, postseismic deformation, slow slip events, volcanic unrest, fault creep, interseismic strain accumulation, and plate motions.

For the first decade or so, applications of GPS in crustal deformation tended toward periodic measurements in the style of earlier geodetic surveys. However, the size, power consumption, and cost of receivers have decreased steadily, while the data storage capacity has increased. This has fostered the growth of large CGPS networks, accompanied by more centralized and uniform processing and availability of results. This trend is likely to continue, and many future applications of GPS will focus on further exploiting the ability of this tool to provide temporally dense measurements for tracking deformation.

High-rate data show promise for hazard monitoring and response as well as for providing insight into the physical processes underlying time-varying deformation, especially as more sophisticated methods become available for processing these data in real-time and mitigating error sources such as multipath which are particularly problematic for high rate measurements.

In areas with few CGPS sites or where spatially dense coverage is needed to address specific scientific questions, an alternative to traditional campaign GPS measurements has recently been developed [13]. Termed “semi-permanent” or “semi-continuous” GPS, it involves rotating a pool of GPS receivers through several subsets of GPS sites such that each subset is observed for periods of multiple weeks several times a year. Each site to be observed is outfitted with a specially designed antenna mount set in a rock outcrop so that the antenna is attached in the same location and orientation every time the site is occupied, thus eliminating the set-up error inherent in many SGPS surveys. Blewitt et al. [13] have demonstrated that the scatter in the position time series as well as the uncertainties on velocities estimated using data from a semi-permanent network in Nevada are nearly as low as for CGPS networks over a comparable length of time (e. g., 1.5 years). Although this method requires sites that have rock outcrops and that are secure enough for equipment to be left unattended for extended periods of time, its use is likely to grow as it is arguably more cost-effective than either CGPS or SGPS for many applications.

Finally, a series of changes are being made to modernize the GPS signal. For instance, beginning with a generation of satellites called Block IIR-M, first launched in the

fall of 2005, a civilian code is now modulated on the L2 carrier in addition to the C/A code that has always been available on the L1 carrier. This makes it easier to obtain the L2 carrier signal and enables elimination of ionospheric delay when positioning with the code measurements alone. A new series of GPS satellites, the Block IIF, set to launch in 2007 will transmit a third carrier frequency called L5 which will aid in ambiguity resolution. The L5 observable, modulated with a civilian-accessible code, will be broadcast at a higher power than the L1 or L2, making it easier to acquire. Future satellites will transmit a second civilian code on the L1 frequency that will be more robust than the C/A code and will be interoperable with a civilian accessible code to be transmitted by the planned Galileo satellites.

### Glossary

**Attenuation relation (ground-motion prediction equation)** The term “attenuation relation” is a former shorthand notation in earthquake engineering for “empirical ground-motion attenuation relationship”, now referred to as “ground-motion prediction equation” (GMPE). Attenuation relations represent empirical scaling equations that relate observed *ground-motion intensity measures* to parameters of the earthquake source, the wave propagation from the source to the observer and the site response at the observer location.

**Dynamic rupture model** Dynamic rupture models build a physical understanding of the earthquake rupture based on the material properties around the source volume, and the initial and boundary conditions for the forces/stresses acting on the fault plane. The distribution of on-fault *slip-rate* vectors and the temporal rupture evolution is obtained by solving the elastodynamic equations of motion under an assumed constitutive law (friction model), considering the energy balance at the crack tip (Chap. 11 in [6]). See also *kinematic rupture model*.

**Ground motion intensity measures** Earthquake shaking due to seismic waves, observed at recording sites or experienced by people and structures, is commonly reported in terms of various scalar intensity measures that capture parts of the transient wave-field. Seismogram-based ground-motion intensity measures are,

for instance, peak ground acceleration (*PGA*) and peak ground velocity (*PGV*), while the modified Mercalli intensity (*MMI*) is a damage-related measure. In earthquake engineering, ground-motion intensities are often reported as *response spectra*: the response of an idealized building (modeled as a single-degree-of-freedom oscillator) of given eigenperiod  $T$  and damping  $\zeta$  (usually 5%) to a given ground-motion time series. Spectral acceleration ( $S_A$ ), spectral velocity ( $S_V$ ) and spectral displacement ( $S_D$ ) are analyzed considering the period of the structure.

**Ground motion uncertainty** In ground-motion prediction for engineering purposes, random (aleatory) variability and scientific (epistemic) uncertainty are distinguished. The latter is due to incomplete knowledge and/or limited data, and is captured by alternative empirical attenuation relations or different ground-motion simulation strategies. Aleatory variability is quantified in terms of a standard deviation of an attenuation relation or by a large number of model realizations within a particular simulation method. The distinction between aleatory variability and epistemic uncertainty is particularly useful in probabilistic seismic hazard analysis (PSHA).

**Kinematic rupture model** A kinematic rupture model characterizes the time-dependent displacement field on the rupture plane without considering the forces or stresses acting on the fault and causing its motion. The rupture process is completely specified by the spatio-temporal distribution of the slip vector, the local *slip-velocity* function on the fault, and the *rupture velocity* with which the rupture propagates over the fault plane. See also *dynamic rupture model*.

**Path effects** Seismic waves propagating through the Earth are sensitive to the detailed geologic structure along the wave path, generating pronounced waveform complexities. Considering crust and upper-mantle structure (relevant for near-field ground motions) three major elements to path effects are distinguished in practice: (a) waves in a flat-layered attenuating Earth; (b) basins and other deterministic deviations from a flat-layered model; (c) random heterogeneities in the three-dimensional velocity-density structure. The distinction between path effects and *site effects* is often ambiguous.

**Rise time** The rise time (or slip duration)  $\tau_r$  measures how long each point on the fault moves during the rupture process, and must not be confused with the *rupture duration*. The rise time is related to *the slip-velocity function*, and is usually measured as the time it takes to attain 5–95% of the final slip at each point. For

simple parametric slip-functions (e. g. boxcar, isosceles triangle or combinations thereof), the rise time is generally given by the width of this function.

**Rupture duration** The rupture duration characterizes the total time for the earthquake rupture process to complete, starting at the nucleation point (hypocenter) and lasting until the last point on the rupture plane stops sliding. Rupture duration therefore depends on **rupture velocity** and scales with the size (source dimension) of the earthquake.

**Rupture velocity** Earthquake ruptures, either modeled as propagating cracks or slip-pulses, expand over the fault plane at rupture speeds ( $v_r$ ) close to the local shear-wave velocity ( $v_s$ ), typically in the range  $0.5 \cdot v_s \leq v_r \leq 0.9 \cdot v_s$ , or about 1.0–3.5 km/sec for crustal earthquakes. However, the crack tip, the transition region from unbroken, intact rock to the currently slipping zone, does not necessarily travel at constant rupture speed. Rupture velocity may locally slow down or accelerate, even to super-shear velocities (in which case the crack front travels at speeds faster than the local shear-wave velocity), depending on the initial and boundary conditions that govern the dynamic rupture process.

**Site effects** Site effects refer to wave-propagation effects in the immediate proximity to the observation point; they are distinguished from **path effects** which comprise the complete path from the source to the receiver (although the boundary between these two is often ill defined). The local sedimentary cover, topography, strong geologic contrasts or water-table variations may contribute to site effects that modify the incoming “bedrock” seismic motions.

**Slip distribution** The slip distribution represents the cumulative slip on each point on the fault acquired during the co-seismic rupture process (i. e. small contributions from post-seismic slip episodes are ignored). A slip distribution for an earthquake is computed from the space-time integration of **slip-velocity functions** on the rupture plane.

**Slip-velocity function (Slip-rate function)** Each point participating in the rupture process experiences a time-dependent slip history during which the two sides of the fault go through a stage of acceleration, stable sliding, deceleration, and final stopping. This local displacement trajectory is often represented in terms of a slip-velocity function (or slip function) whose details depend on the dynamic rupture process and the constitutive behavior of the host rock. Slip-rate functions are often modeled using simple parametric functions.

**Source effects** Amplitudes and waveform character of seismic waves are strongly affected by source effects, i. e. by the details of the earthquake rupture process. Far-field signals carry the signature of the overall “point-source” earthquake source mechanism; near-field recordings are very sensitive to the spatio-temporal details of the rupture process, characterized in a finite-fault source model either as **kinematic** or **dynamic rupture model**.

**Static stress drop** The static stress drop  $\Delta\sigma$  represents the difference between the initial and final stress across the fault before and after an earthquake, and is related to slip on the fault. It is defined, based on a shear crack with uniform stress drop, as  $\Delta\sigma = C \cdot \mu \cdot D/L_c$ , where  $\mu$  is the shear-modulus,  $D$  the mean slip over the fault,  $L_c$  a characteristic length scale (usually the smallest dimension of the rupturing fault), and  $C$  a constant of order unity which depends on the source geometry. Using the fault width  $W$  as characteristic length, static stress drop is related to the seismic moment,  $M_o = \mu \cdot L \cdot W \cdot D = C \cdot \Delta\sigma \cdot A^{3/2}$ , where  $A$  is fault area, and  $L$  is fault length. Inferred values of static stress drop are in the range of 0.1–10 MPa, independent of seismic moment, leading to the generally assumed self-similar constant stress-drop scaling (see ► **Earthquake Scaling Laws**). The static stress drop must not be confused with the dynamic stress drop [164] which captures the time-dependent stress change on a point of the fault during the dynamic faulting event, and may be significantly higher or lower than the static stress drop.

## Definition of the Subject

The accurate prediction of the level and variability of (potentially damaging) near-source strong-ground motions in future earthquakes is one of the key challenges for seismologists and earthquake engineers. The increasing number of near-source recordings collected by dense strong-motion networks exemplifies the inherent complexity of near-field ground shaking, governed by a number of (partially interacting) physical processes. Characterizing, quantifying, and modeling (either by means of empirical scaling relations or by numerical simulations) ground-motion complexity requires the joint investigation of three dominant ingredients: (I) the physics of earthquake rupture; (II) the details of wave-propagation in heterogeneous media; (III) the effects of local site conditions.

This article discusses briefly the beginnings of strong-motion seismology and the recognition of ground-motion complexity. Using two well recorded recent earthquakes, I introduce observational aspects of near-field ground shak-

ing and the basic mathematical description for computing ground motion. The article proceeds by describing each of the three “ground-motion ingredients” in some detail, but does not attempt to provide an in-depth review of all the scientific advancements in these fields. Rather, I explain the key elements for characterizing and modeling ground-motion complexity, supplemented with a concise overview of the underlying physical processes. Current research increasingly incorporates advanced physical concepts into standard practice, therefore leading to improved strong-motion simulation approaches to accurately predict intensity and variability of near-source shaking.

## Introduction

As early as 1910 Reid [148] identified strong spatial variations of seismic shaking due to the 1906 San Francisco earthquake, which he correctly attributed to the specific geologic conditions at the locations from which shaking intensities were reported. The space-time complexity of the seismic wavefield in the vicinity of the causative fault became more widely recognized since the beginnings of strong-motion seismology in the 1930s and the establishment of strong-motion networks in the 1960s [9]. Observed peak accelerations frequently reach 1 g, occasionally even exceed 2 g, where nearby stations often show not only much lower peak amplitudes but also very different waveform character. Since the advent of modern digital instruments in the 1990s and corresponding online near-real-time databases, seismologists and earthquake engineers have access to high-quality recordings which irrefutably show the complexity of earthquake shaking. Given a particular location, near-source ground motions vary strongly for different earthquakes, and so do the motions for a single event when recorded at different sites.

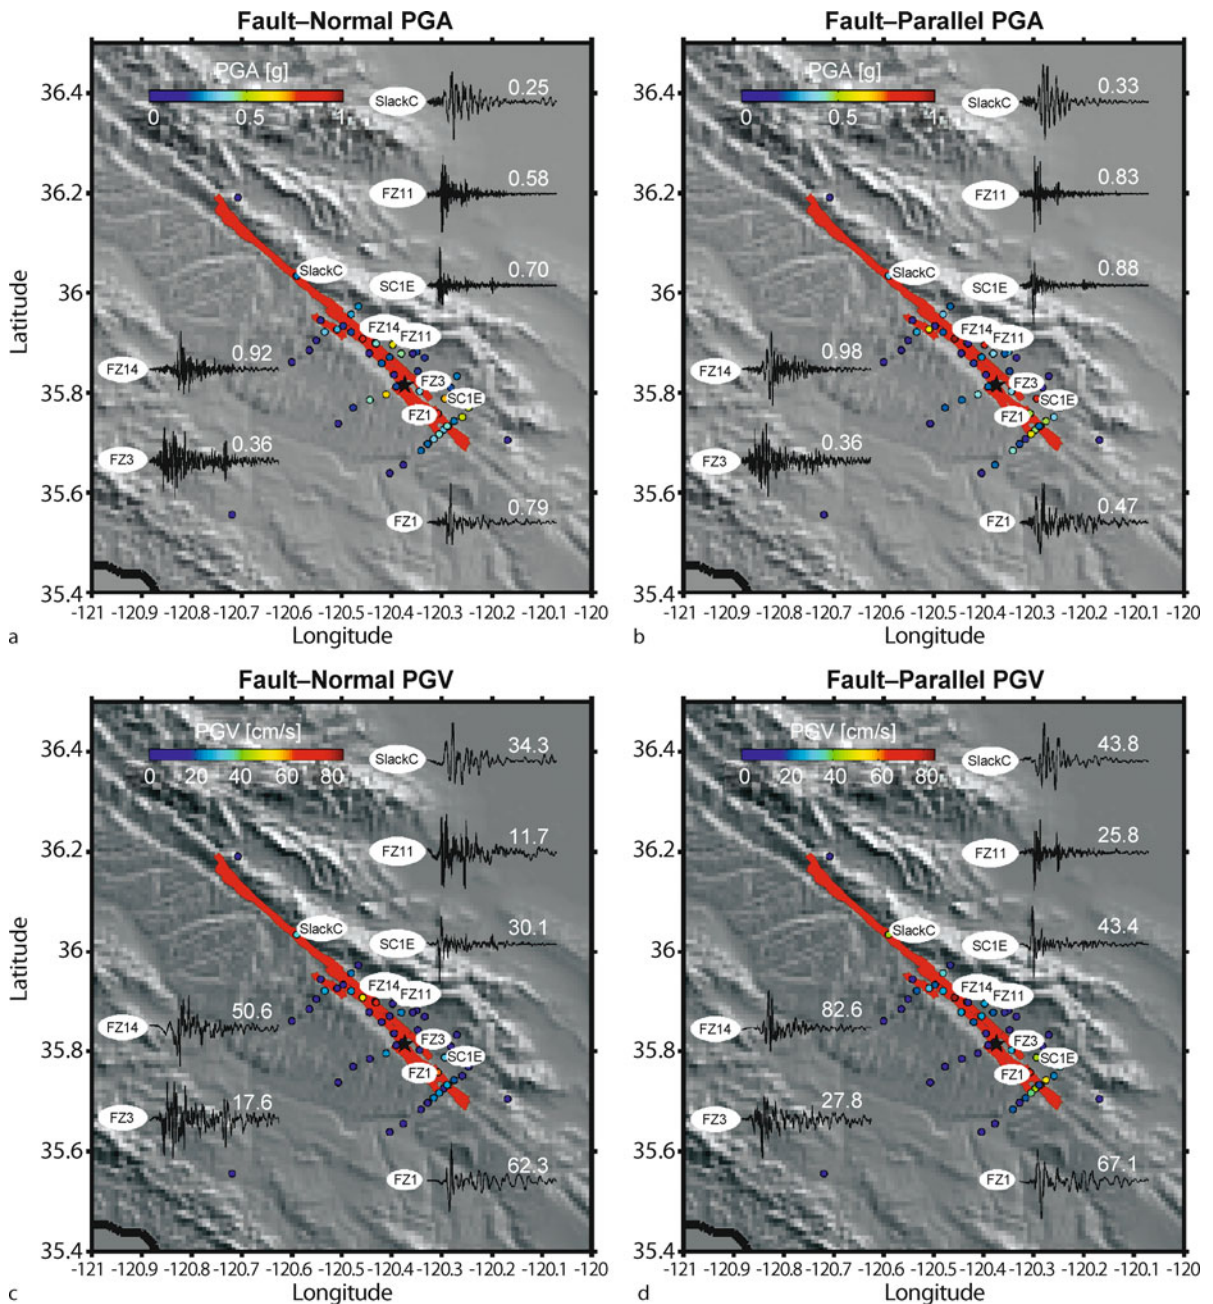

While hundreds of earthquakes happen annually in the magnitude range  $6.0 \leq M \leq 6.9$ , only about 15 events occur in the range  $7.0 \leq M \leq 7.9$ , most of which happening in remote areas and do not cause large damage. Those events are typically recorded at rather large distances (so called teleseismic events) and have weak (low amplitude) motions. Their ground-motion variability is due to differences in the large-scale wave paths through the Earth and due to the properties of the point-source representation for far-distant earthquakes. Weak-motion recordings are also obtained from small nearby earthquakes. In this article, however, we will be concerned with strong-motion observation in the near-field of (large) earthquakes. Such observations are much harder to obtain than teleseismic recordings because we cannot anticipate in detail where future earthquakes may happen (in order to opti-

mize the instrumentation) and also because large crustal earthquakes are rather infrequent.

Investigating the characteristics of near-source ground-motions is of great importance for earthquake engineers who are concerned with seismically safe design, and for seismologists who study the physical processes leading to ground-motion complexity. To illustrate the large ground-motion variability in a single earthquake, I plot horizontal peak ground accelerations and peak ground velocities recorded at 47 sites in the Sept 28, 2004, M 6.0 Parkfield earthquake (Fig. 1), contrasted with ground-motion intensities (*PGA*, *PGV*, *PGD*) for the Sept 20, 1999, M 7.6 Taiwan (Chi-Chi) earthquake, shown at 441 locations (Figs. 2–4) (waveforms from the COSMOS database, <http://db.cosmos-eq.org>). First-order observations from these data are: (i) the maximum *PGA* is larger for the smaller earthquake while the highest *PGV* values are roughly identical; (ii) ground-motions tend to be larger close to the fault trace and decay in amplitude with increasing distance from the fault. However, closer inspection reveals strong variability in the near-field motions for each earthquake. The Parkfield data exhibit ground-motion differences between the two horizontal components of motion (fault-parallel and fault-normal, both for *PGA* and *PGV*) and large variability between neighboring sites. This site dependence is even more pronounced for the Chi-Chi event. *PGA*-values are highest for sites very close to the fault, on the hanging-wall (east of the fault trace) and at a few locations in the northward and southward extension of the fault-trace. This pattern changes, however, for the recorded *PGV* and *PGD*-values which are largest on the foot-wall (west side of the fault trace) and towards the northern end of the rupture.

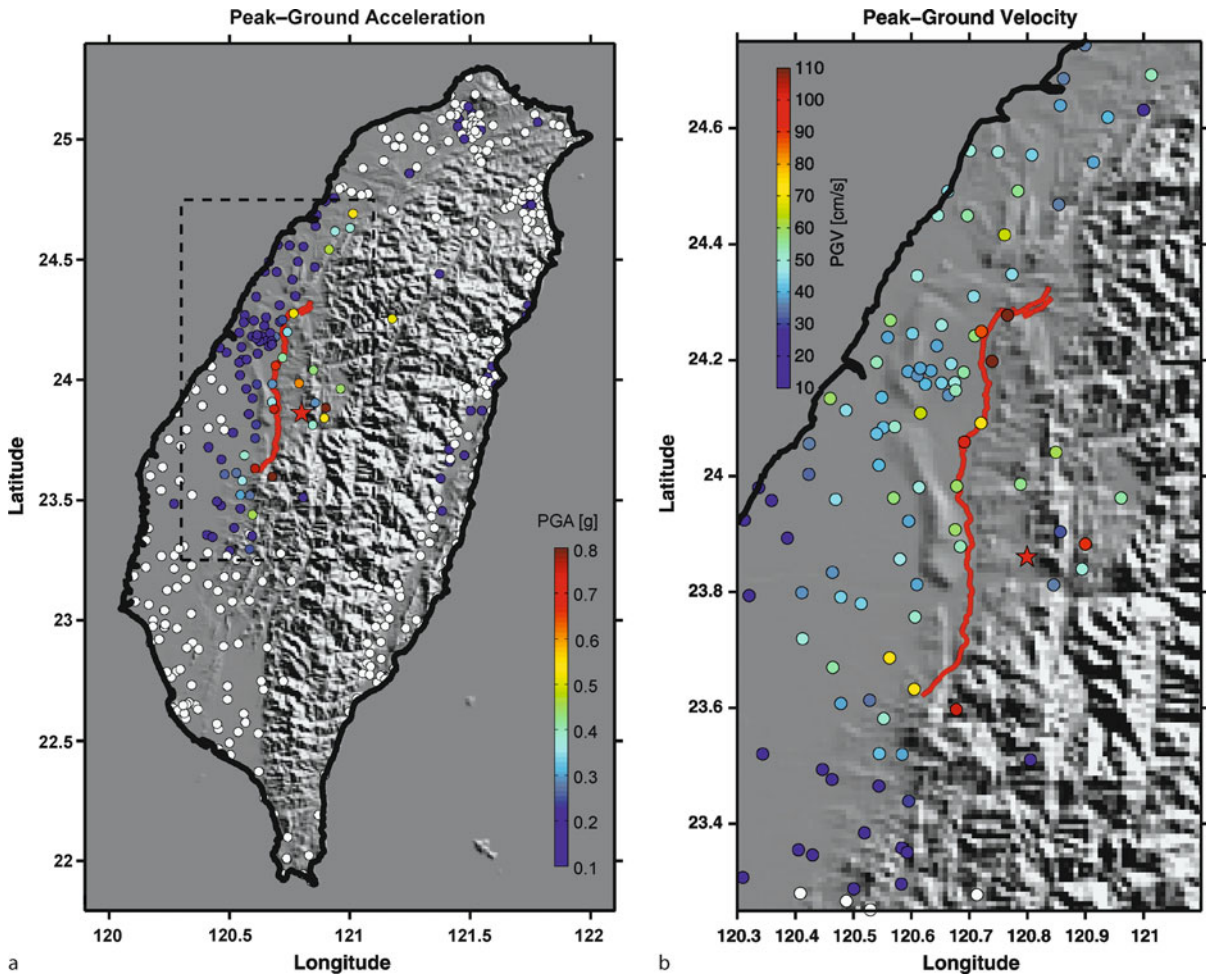

In addition to the scalar measures of shaking amplitude (intensity), Figs. 1–4 display recorded waveforms for selected sites which further illustrate the complexity and variability of near-field motions. Acceleration time series accentuate the high-frequency content of ground-motion and display an almost “shaped random noise” character, with amplitudes that increase rapidly in the beginning and then taper off gradually in the seismic coda (the incoherent wavefield after the arrival of prominent seismic phases). In contrast, velocity waveforms usually show very distinct arrivals and energetic pulses (directivity pulses) whose frequency-dependent amplitude and waveform character change with source-site geometry and rupture propagation direction. Their waveform character also varies strongly between closely spaced stations for a given event, illustrating the importance of localized source properties and site effects. Note also the large differences in ground-motion amplitudes and waveform shapes between

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 1

Ground-motion intensities (*colored circles*) for the Sept 28, 2004 Parkfield (M 6.0) earthquake, recorded at near-field stations, and selected waveforms (data from COSMOS database). The *black star* denotes the epicenter, (Lon =  $-120.374$ , Lat =  $35.815$ ) *red-lines* show the mapped fault trace of the San Andreas Fault in the Parkfield area, the *gray background* displays a shaded relief map. **a** Peak ground accelerations (PGA) of fault-normal component; **b** PGA of fault-parallel component; **c** Peak ground velocity (PGV) of fault-normal component; **d** PGV of fault-parallel component. Seismic traces are shown for 30s, the small number indicates the corresponding PGA or PGV value of that record

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 2

Ground-motion intensities (*colored circles*) for the Sept 20, 1999 Taiwan (M 7.6) earthquake, recorded at 441 locations (data from COSMOS database). The *red star* denotes the epicenter (Lon = 120.7995, Lat = 23.860), *red-lines* show the mapped fault trace of the Chelungpu fault, *heavy black lines* trace the coast line, the *gray background* displays a shaded relief map. **a** Large-scale view of PGA, white dots are sites with PGA < 0.1 g. **b** Zoomed view for PGV (white dots mark PGV < 10 cm/s). **c** Zoomed view for PGD (white dots mark PGD < 10 cm)

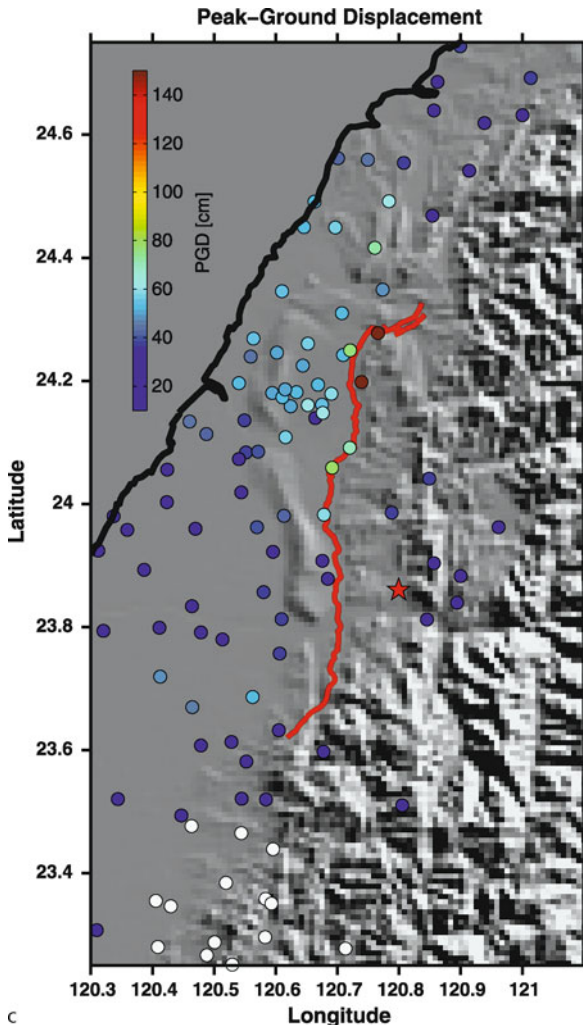

the two events for stations at similar distance to the fault, indicating the dependence on earthquake source properties of near-field ground motions. Section “**Future Directions**” compares the near-field recordings for these two earthquakes against empirical predictions for several published attenuation relations to further illustrate ground-motion complexity.

The variability in shaking intensity and the complexity in near-fault seismograms results from three physical processes: (I) the complex dynamics of earthquake rupture and the associated radiation of seismic waves; (II) the propagation of these seismic waves through the heterogeneous Earth; (III) the interaction of the seismic wave-

field with local geology/morphology, referred to as the site conditions at each observation points. Mathematically, the time-dependent ground displacement  $u_k(t)$  at a particular location  $k$  is described as

$$u_k(t) = s(t) * g_k(t) * l_k(t) \quad (1)$$

where  $*$  denotes the convolution operator,  $s(t)$  represents the **source effects** due to the earthquake rupture process,  $g_k(t)$  describes the **path effects** due to wave propagation from the source to site  $k$ , and comprises  $l_k(t)$  the **local site effects** due to the small-scale geological conditions at the  $k$ th observation point. Equation (1) quantifies ground-motion generation, omitting for simplicity

c  
Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 2  
(continued)

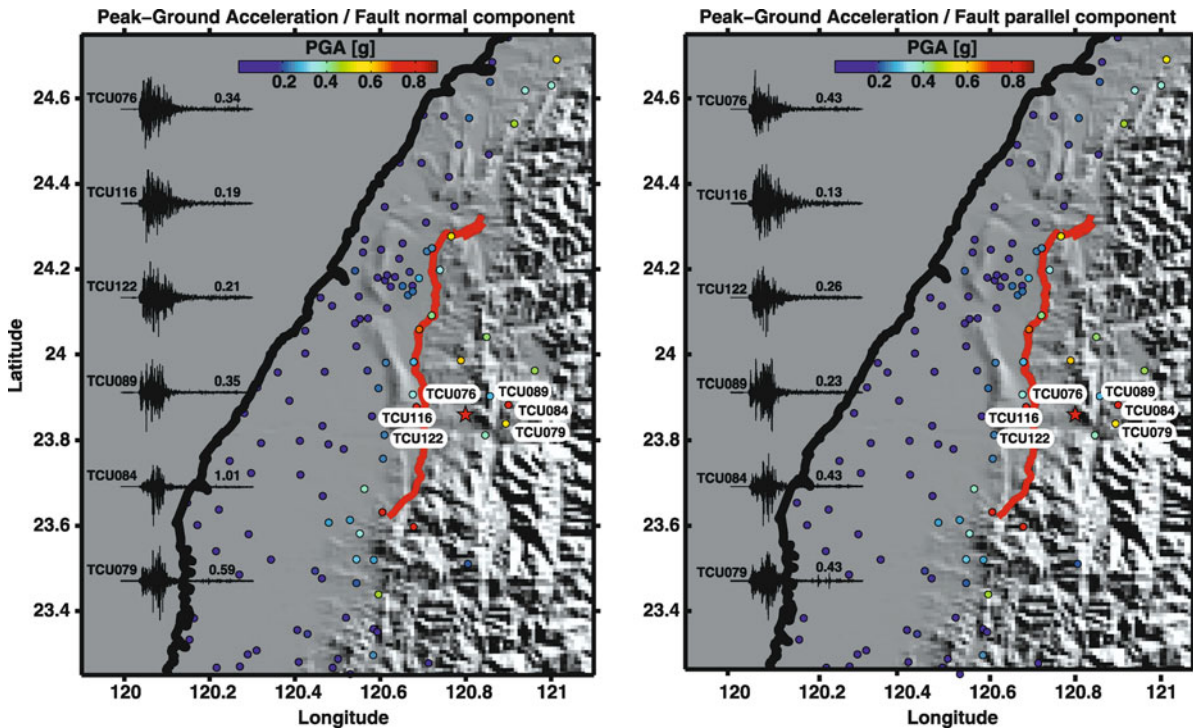

an additional instrument response  $i_k(t)$  that modulates the seismic recording. The earthquake-source contribution  $s(t)$  can be further subdivided into effects originating from the local time-dependent particle motion on the fault,  $p_{ij}(t)$ , and from rupture finiteness,  $f(t)$ . The term  $g_k(t)$  represents the Earth transfer function and contains contributions from layered Earth structure and seismic-wave attenuation, but may also comprise effects due to random heterogeneities in the Earth and/or basin and topographic structures. The factor  $l_k(t)$  describes the effects of soil structure and may also account for non-linear soil behavior.

In the following, I will use Eq. (1) as a “roadmap” for this article to illustrate the various factors of ground-

motion complexity. In Sect. “[Characterizing Earthquake Source Complexity](#)”, I present methods and relevant parameters to quantify the earthquake rupture process. Wave propagation in complex media, both deterministic and stochastic, are described in Sect. “[Wave Propagation in Complex Media: Path and Site Effects](#)”. A large body of literature exists for each of these topics, both from an observational/experimental view and from theoretical work; it is beyond the scope of this article to provide an in-depth review of all relevant material. Instead, I will focus on some of the key aspects of earthquake ruptures and waves in inhomogeneous media that are most relevant for understanding the complexity of near-field ground motions. Note also that a number of specialized articles in this encyclopedia provide more detailed information on earthquake source physics (see ▶ [Earthquake Nucleation Process](#), ▶ [Earthquake Scaling Laws](#)) and wave-propagation phenomena in complex media (see ▶ [Seismic Wave Propagation in Media with Complex Geometries, Simulation of](#), ▶ [Seismic Waves in Heterogeneous Earth, Scattering of](#)). Section “[Wave Propagation in Complex Media: Path and Site Effects](#)” also includes various aspects of local site conditions that lead to pronounced site effects, in particular non-linear site phenomena. Section “[Ground-Motion Scaling Relations](#)” focuses on empirical ground-motion prediction equations (GMPE’s). Since many studies have been published on non-linear site effects and ground-motion prediction equations, both from the seismology and the earthquake-engineering communities, an extensive review of the developments in these fields is not attempted. Instead, I concentrate on non-linear soil behavior directly beneath a site of interest that substantially affects the ground-shaking levels, and summarize some of the latest findings related to ground-motion attenuation relations. The article concludes with an outlook onto future tasks and challenges for characterizing, quantifying and predicting ground-motion complexity.

### Characterizing Earthquake Source Complexity

Geologic faults are generally geometrically complex multi-scale structures, characterized by one or more main fault strands, with associated subsidiary branches (fault segments) that form three-dimensional (3D) fault networks. However, in many cases and for almost all practical purposes, faults are approximated as planar surfaces. Using this plane-fault approximation, Fig. 5 illustrates the three main factors affecting near-source ground-motion complexity – source, path and site effects. This Section focuses on the earthquake rupture process, i.e. the source, and its properties important for ground-motion genera-

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 3

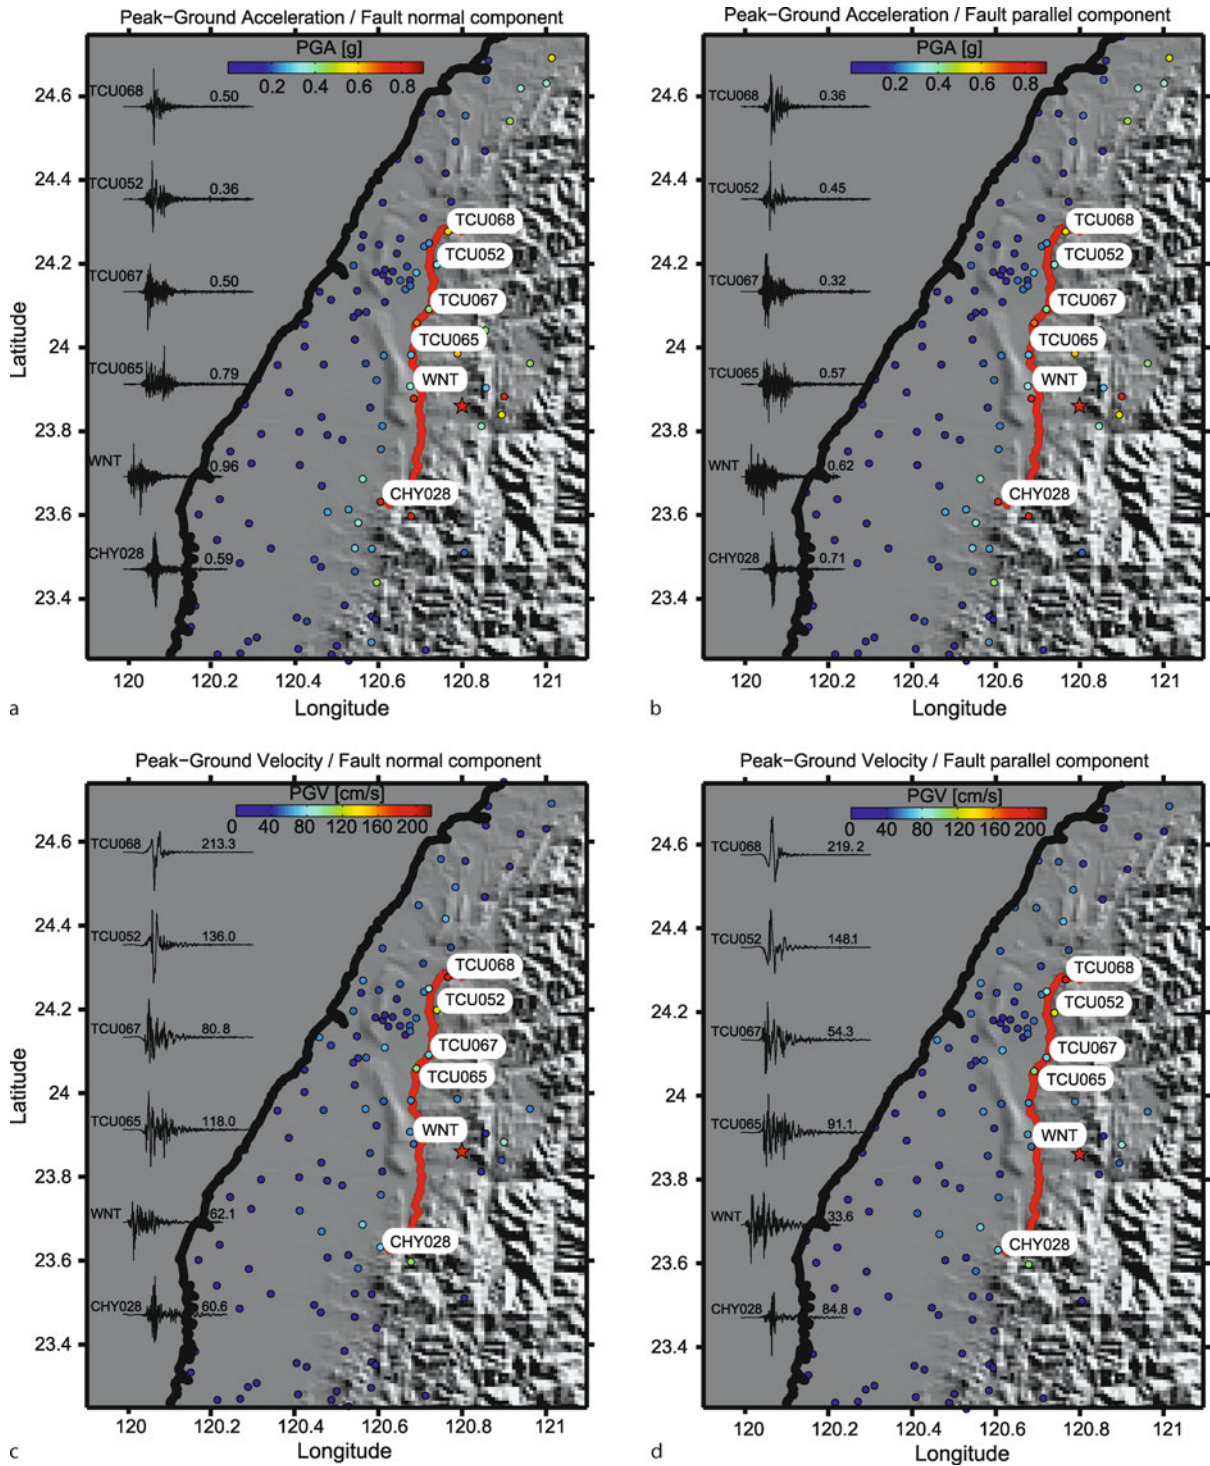

Near-field ground accelerations for the fault-normal (*left*) and fault-parallel (*right*) motion during the 1999 Chi-Chi earthquake; *waveforms* are plotted for selected stations in the vicinity of the epicenter (*red star*). Sites located on the footwall, i. e. west of the fault-trace, generally show lower ground-motions than sites located on the hanging-wall (east of the fault trace) despite similar epicentral distance

tion. A fault (shown as a planar surface with color-coded slip distribution) is embedded in a rock volume, and has a specific orientation in space described by the strike-angle  $\Phi$  (representing the azimuth of the fault's projection onto the surface, measured clockwise from North) and the dip-angle  $\delta$  (measured downward from the surface to the fault in the vertical plane perpendicular to the strike). The strike direction is defined such that, using the right-hand rule, the dip-angle is smaller than  $90^\circ$  (for a vertically dipping fault,  $\delta = 90^\circ$ , the strike direction is arbitrarily either direction).

Given the overall source geometry, the slip-vector on the fault plane defines the relative motion between the two blocks. The angle of slip, or rake angle  $\lambda$ , measured in the fault plane from the strike direction, shows the movement of the hanging wall relative to the foot wall (see inset in Fig. 5). The following definitions apply:  $\lambda = 0^\circ$  – *left-lateral strike-slip*, i. e. the hanging wall (or near-side of a vertical fault) moves horizontally to the right, so the opposite side moves to the left;  $\lambda = 180^\circ$  – *right-lateral strike-slip*, i. e. the hanging wall (or near-side of a vertical fault) moves horizontally to the left, so the opposite side moves to the

right. For  $\lambda = 90^\circ$ , the hanging wall moves upward (*thrust faulting*), for  $\lambda = 270^\circ$  the hanging wall moves downward (*normal faulting*). Figure 5 also displays the rupture model for a right-lateral strike-slip earthquake with  $\lambda = 180^\circ$  (indicated by the black arrows) on a fault-plane that dips  $80^\circ$ . The strike in this hypothetical case is undefined. The amount of displacement (slip) on each point of the fault is color-coded, white contours (at  $\Delta t = 1$  s spacing) show the expanding rupture front. Examples of past earthquakes show that the rake angle may also vary over the fault plane (Fig. 6c, d). Geometrical complexity, manifested in several fault segments, is often present (Fig. 9); in these cases the faulting-style is characterized by the predominant fault direction and slip angle.

The strength of seismic radiation is typically quantified by an earthquake magnitude, whereby a variety of magnitude scales exist. The seismic moment, defined as  $M_0 = \mu \cdot A \cdot D$ , ( $\mu$ : shear modulus in the source region;  $A = L \cdot W$ : fault area, given by fault-length  $L$  and fault-width  $W$ ;  $D$ : average displacement on the fault) is considered the best scalar quantity characterizing earthquake size. Ben-Zion [20,23] proposes to use the more basic concept of

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 4

Near-field ground accelerations (top) for the fault-normal **a** and fault-parallel **b** motions during the 1999 Chi-Chi earthquake; waveforms are plotted for selected stations along the fault trace (red line). **c** and **d** show the corresponding ground-velocities. Sites located at either end of the fault trace recorded waveforms with shorter duration of the dominant wave-energy. Velocity records in the North show strong rupture-directivity effects as high-amplitude short-duration velocity pulses

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 5

Sketch of the physical components of near-source ground motions (*top-right inset*: illustrates the source-geometry definition). A simulated earthquake rupture occurs on an assumed planar fault, with color-coded slip amplitudes (0–2.5 m) and white contours of the propagating rupture front (emanating from the hypocenter shown by the *red star*). The rupture is embedded in a gray-scale model of the Earth's crust. Darker gray-tones denote higher  $v_p$ ,  $v_s$ ,  $\rho$  than lighter gray, reflecting the overall trend of higher velocities at greater depth, locally disturbed by random heterogeneities. A basin-structure with less compliant layered sedimentary rocks exhibits complex sub-surface topography. A near-field seismogram (for an arbitrary horizontal component) is shown at a representative site A. Ground-motions are composed as the summation of the slip-functions  $s_{ij}$  at grid-points  $i, j$  on the fault, convolved with the corresponding Green's functions  $g_{ij}$  for this observer and grid points (the site term  $l_k$  in Eq. (1) is neglected for simplicity)

seismic potency,  $P_0 = A \cdot D$ , to avoid a source quantification that includes ambiguously defined or poorly known material properties; however, seismic potency is rarely used in the earthquake engineering. The moment magnitude follows from  $M_w = 2/3 \cdot \log M_0 - 6.07$  (with  $M_0$  given in Nm). The static stress drop  $\Delta\sigma$  is related to the ratio of average slip to a characteristic fault length, therefore seismic moment is proportional to static stress drop:  $M_0 \propto \Delta\sigma \cdot A^{3/2}$ . Observational evidences [106,186,187] confirm

this scaling for moderate to large earthquakes, suggesting – constant (i. e. scale-invariant) static stress drop and self-similar earthquake source scaling: large earthquakes are only scaled-up versions of small earthquakes. Other scaling relations between observable fault parameters (fault area, length, and width; average slip) and magnitude (seismic moment) [79,122,169,187] partially confirm the self-similarity of earthquake rupture, but also provide evidence for the break-down of self-similarity for very small earth-

◀ Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 6

Selection of finite-source rupture models, obtained from inversion of seismic recordings and geodetic data, for six earthquakes in the magnitude range  $4.5 \leq M_w \leq 7.5$ , illustrating the heterogeneous distribution of earthquake slip (color-coded using different color scale for each model). The *black star* denotes the hypocenter, generally located in the vicinity of a high-slip patch (also called “asperity”). a 1999 Izmit earthquake ( $M7.5$ ) [51]; b 1992 Landers earthquake ( $M7.3$ ) [184]; c 1995 Kobe event ( $M7.0$ ) [165]; d 1994 Northridge earthquake ( $M6.7$ ) [185]; e 1984 Morgan Hill event ( $M6.1$ ) [29]; f Hida Mountains event #5 ( $M4.5$ ) [96]. The rupture length of b is about half that of a; models b, c and d are drawn to scale with respect to each other. Model e has fault length  $L = 30$  km, a factor of two shorter than c, while f has source dimensions  $4 \times 4$  km<sup>2</sup>

quakes [23] and very long strike-slip earthquakes [154]. The exact physics leading to these source-scaling properties is a current topic of active research [90,91].

The overall faulting-style, defined by the dip and rake angle, affects the radiation pattern of P- and S-waves (see Chap. 4 in [6] for more details), and thus the resulting ground-motion characteristics. Together with the earthquake magnitude, the style-of-faulting is used as a predictor variable in empirical ground-motion prediction equations (see Sect. “Future Directions”). However, ground-motion complexity arises largely from the details of the rupture process (Fig. 5). The earthquake nucleates at the hypocenter (indicated by the red star), and propagates over the fault plane (white contour lines) with a rupture velocity that may exhibit local variations due to initial stress conditions and frictional properties on the fault. Stress state and friction also determine the slip-time history  $s_{ij}$  for all points  $ij$  on the fault (which start sliding once reached by the propagating rupture front). To first order, the shape of the local slip-velocity function depends on the overall fault dimensions (i. e. fault aspect ratio), the relative position of each point with respect to the rupture nucleation point and its distance to the closest fault edge [52,58,59,78] (variations in  $s_{ij}$  at four different locations on the fault plane of lower panel). The duration of slip (rise time) is related to the length of these local slip-functions. Once sliding has stopped at all points on the fault, the rupture has attained its final slip distribution (color-coded in Fig. 5) within a characteristic time (called rupture duration) which depends on fault dimensions and rupture velocity (and marginally on rise time). As depicted in Fig. 5, the slip distribution, the rupture velocity and the rise times are highly heterogeneous over the fault plane, illustrating earthquake source complexity in terms of kinematic source parameters.

The governing equation that relates ground displacement to the motion on the fault is given by a representation theorem (Chap. 3 in [6]), which we use in the following notation:

$$\mathbf{u}(\mathbf{x}, t) = \int d\tau \int_S \Delta u(\xi, \tau) c_{ijkl} v_j G_{nk,l}(\xi, \tau; \mathbf{x}, t) dS. \quad (2)$$

Equation (2) states that the time-dependent ground displacement at observer location  $\mathbf{x}$  and time  $t$  depends on the space-time integral over the space-time-dependent slip function  $\Delta u(\xi, \tau)$  on the fault plane ( $\xi$  defines the position on the fault,  $\tau$  is time), the elasticity tensor  $c_{ijkl}$ , the fault-normal vector  $v_j$ , and the Green’s tensor  $G_{nk,l}$  (subscripted comma indicate the derivative with respect to the subsequent variable). Equation (2) is related to Eq. (1), but contains the functional dependency on the source explicitly; in this context the Green’s function typically neglects the site effects  $l_k(t)$ . The term  $\int_S \Delta u(\xi, \tau) dS$  contains the time-dependent local particle motion on the fault,  $p_{ij}(t)$ , and the effects of fault finiteness,  $f(t)$ .

Equation (2) can be applied to retrieve the spatio-temporal slip distribution on the fault plane from seismic recordings (and other data) by either forward-modeling or a formal inversion procedure. Earthquake-source inversions have been carried out since the early 1980ies, manifesting the complexity of the rupture process as depicted in Figs. 6 and 9 (see also database of finite-source rupture models [121]). These earthquake source images represent kinematic rupture models that quantify  $\Delta u(\xi, \tau)$  based on observations, but do not explicitly derive  $\Delta u(\xi, \tau)$  from physical principles as attempted in dynamic rupture models e. g. [14,15,28,78].

For examining earthquake source complexity in more detail, it is mandatory we need to distinguish kinematic from dynamic rupture models, and we need to quantify slip heterogeneity (and its associated stress-change distribution) on the fault plane. It is also important to note that the position of the rupture nucleation point is not arbitrary on the fault plane for a given slip (stress) distribution but adheres to fundamental concepts of energy balance during the rupture process. This Section characterizes source complexity in space and time before introducing to *isochrone theory*, a powerful tool to visualize how the details of the rupture process determines near-fault ground-motions.

### Kinematic Rupture Models

Kinematic rupture models characterize the space-time evolution of earthquake rupture in terms of a time-dependent displacement field (distribution of slip vectors)

on a predefined fault plane without considering the forces and stresses that cause these motions on the fault. The local slip-rate (or slip-velocity) function is specified along with the rupture propagation properties. Ground motions can then be computed using Eq. (2) with any kinematic rupture model  $\Delta u(\xi, \tau)$ . Current ground-motion simulation approaches are largely based on kinematic source models since they can be efficiently generated; recent advancements try to capture at least the basic principles of source dynamics by proposing *pseudo-dynamic* source models [77,78,120]. Earthquake source inversions parameterized in terms of Eq. (2) retrieve only a kinematic rupture model which, in principle, does not need to obey any physical laws. The database of finite-source rupture models [121] provides a compilation of kinematic source models for past earthquakes, obtained by applying Eq. (2) to a variety of data and using different methods to solve the inverse problem.

### Dynamic Rupture Models

Dynamic rupture models build a physical understanding of the earthquake rupture process based on the material properties around the source volume, and the initial and boundary conditions for the forces/stresses acting on the fault plane [80]. The distribution of slip vectors  $\Delta u(\xi, \tau)$  on the fault plane is obtained by solving the elasto-dynamic equations of motion under the assumption of a constitutive law (i. e. a friction model), considering essentially the energy balance at the crack tip during rupture growth (for details see Chap. 11 in [6]). Dynamic rupture models have been developed for (i) canonical model to study general feature of dynamic rupture e. g. [10,58,59] (ii) for existing kinematic source models to infer their specific dynamic rupture process e. g. [14,15,126,181] (iii) for heterogeneous initial conditions in stress and/or friction and material distribution to investigate rupture details for classes of events e. g. [11,13,63,68,78,83,133,151]. Due to the high computational demands, dynamic rupture models are not (yet) developed routinely for ground-motion simulations, but rather to investigate source physics for general cases, earthquakes of special interest, and to study rupture behavior for certain classes of initial conditions.

### Quantifying Slip Heterogeneity

Recent approaches to characterize and quantify slip heterogeneity demonstrate that slip distributions exhibit statistical properties and empirical laws grounded in physical principles. First-order observations for these slip distributions (obtained in finite-source inversions based on Eq. (2)), can be made in Fig. 6, a compilation of slip models

for six earthquakes in the magnitude range  $4.5 \leq M_w \leq 7.5$ . The source dimensions increase from  $4 \times 4 \text{ km}^2$  to  $25 \times 160 \text{ km}^2$  while the corresponding maximum fault displacements grow by two orders of magnitude (from  $\sim 5 \text{ cm}$  to over  $500 \text{ cm}$ ). Mai and Beroza [122] have shown that the overall source-scaling relations of such rupture models is roughly consistent with global earthquake scaling laws (i. e.  $M_o \propto A^{3/2}$ ), but that there is evidence that the commonly assumed self-similar constant stress-drop scaling may not hold, because slip on the fault does not saturate but keeps increasing for growing fault dimensions (albeit at a progressively lower rate). The topic of general earthquake scaling laws is still hotly debated e. g. (see ► [Earthquake Scaling Laws](#) [90,91], and directly affects ground-motion prediction [188,189] (see Sect. “[Future Directions](#)”).

More fundamentally, earthquake slip is heterogeneous on the rupture plane (Fig. 6), i. e. regions of little displacement are separated from areas of high slip (often called “asperities”). The distribution and properties of these high-slip patches strongly influences seismic radiation and hence near-fault ground motions. Characterizing and quantifying slip heterogeneity is thus important for accurately predicting and simulating ground-motions for future earthquakes, but also to better understand the physics of earthquake rupture. Two basic avenues have been pursued in the recent past to quantify slip complexity: (i) a deterministic approach that counts the number of high-slip patches and extracts their properties in terms of size, displacement and other quantities [127,169]; (ii) a stochastic approach that characterizes slip heterogeneity in terms of a random-field model [113,114,123]. Results of both methods can be used for simulating stochastic slip distributions for ground-motion calculation to investigate how source complexity affects near-field ground shaking.

Before interpreting and utilizing inferred source-rupture models for future science or engineering applications, the reliability and resolution of these source-inversion images needs to be addressed. Examining the intra-event variability (source models for the same earthquake obtained by different research groups) often reveals large differences in slip distributions and temporal rupture parameters for the set of source models (online-database [121] for examples and [25] for a critical review). The degree of (dis-)similarity between these slip histories is controlled by differences in the Green’s functions (due to computational methods and the choice of the Earth model), variations in the fault parameterization, different inversion schemes and their control parameters (tuning parameters in non-linear inversion; damping/smoothing constraints in linearized multi-time-window inversion). Source-rupture

ture models are also affected by the type of data (seismic, geodetic, or both; additional geologic data), their selection and processing, and their weighting in the inversion.

Consequently, variations in inverted source models are expected, but the actual uncertainties are rarely quantified. Only recently, more efforts are devoted to perform rigorous uncertainty estimation by testing different inversion algorithms, model parameterizations, and data selection criteria for the same earthquake [56,86,116,117]. The work by Monelli and Mai [128] even estimates posteriori probability density functions for the model parameters of interest, using a non-linear inversion strategy coupled to a Bayesian inference technique. Despite the variability in imaged slip distributions for a given earthquake, several source quantities are stably estimated: rupture dimension, seismic moment and average displacement (both within a factor of 2 generally), and also the slip near the hypocenter. Estimates for the average rupture velocity may vary strongly (up to  $\sim 30\%$ ) between models for the same event because rupture speed estimates trade off with the slip-rate function. The locations of high-slip patches on the fault (“asperities”) are relatively well located if sufficient data

are used, but exceptions exist (i. e. the 1999 Izmit earthquake). The intra-event variability of maximum fault slip is generally quite high, and depends on the particular inversion strategy. However, estimates of correlation lengths or dominant wave-lengths of heterogeneous slip maps are robust for the different models of a given earthquake [123], indicating that the statistical properties of earthquake rupture are well imaged. Also the hypocenter location with respect to the regions of high-slip is estimated reliably in finite-source inversions [127].

Measuring slip heterogeneity deterministically by defining large-slip ( $\frac{1}{3} \cdot D_{\max} \leq D < \frac{2}{3} \cdot D_{\max}$ ) and very-large-slip ( $D \geq \frac{2}{3} \cdot D_{\max}$ ) asperities ( $D = D(x, z)$  is the local slip on the rupture plane,  $D_{\max}$  the corresponding maximum slip), [127] examine the scaling of total asperity area ( $A_{\text{ta}}$ ) with respect to seismic moment for 90 finite-source rupture models (Fig. 7). Without a formal regression, the measurements suggest the scaling  $\log_{10}(A_{\text{ta}}) \propto 0.5 \cdot \log_{10}(M_o)$ , meaning that the area occupied by high-slip patches grows slower with increasing magnitude than the total fault size (which scales as  $\log_{10}(A) \propto \frac{2}{3} \cdot \log_{10}(M_o)$ ). This scaling requires relatively larger maximum displace-

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 7

Asperity area, measured for  $\sim 90$  rupture models (<http://www.seismo.ethz.ch/srcmod>), plotted against seismic moment. A scaling of  $\log_{10}(A) \propto 0.5 \cdot \log_{10}(M_o)$  is shown for reference. Asperity size is measured based on slip values being a certain fraction of the maximum slip on the fault [127]:  $1/3 \cdot D_{\max} \leq D < 2/3 \cdot D_{\max}$  for “large-slip asperities”,  $D \geq 2/3 \cdot D_{\max}$  for “very-large-slip” asperities

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 8

Correlation lengths,  $a$ ,  $a_x$ ,  $a_z$ , versus moment magnitude  $M_w$  for 44 slip models (modified after [123]). Filled squares denote strike-slip earthquakes, open diamonds represent dip-slip events, vertical lines and black dots mark the  $1\sigma$ -error-estimates. The slope of  $b_1 \approx 0.5$  of the regression curves (solid lines) indicates that the correlation lengths scale self-similarly with moment magnitude

ments on the high-slip patches for large and very large earthquakes, which in turn affects seismic radiation and the scaling properties of near-fault ground motions. Large fault slip, concentrated on relatively small portions of the rupture plane, lead to large stress heterogeneity (with high static stress drop locally), thus implying large ground-motion variability for moderate to large earthquakes.

Alternatively, slip distributions (Fig. 6) can be treated as spatial random fields [113,123] to estimate the fractal dimension or the correlation lengths for an auto-correlation function (ACF). Such measurements are typically based on the two-dimensional power spectrum  $P(\mathbf{k})$  of the slip map. Assuming a simple fractal model for a random field, its power spectral density is given as

$$P(\mathbf{k}) \propto \mathbf{k}^{-\nu-1} \quad (3)$$

with wavenumber vector  $\mathbf{k}$  and scaling exponent  $\nu$ . [113] estimate one-dimensional scaling exponents for a small number of rupture models, using only horizontal slices of slip distributions, and find  $0.8 \leq \nu \leq 1.5$ , while [123] find for the two-dimensional exponents ( $\nu + 1$ ) values of about 1.7, implying a fractal dimension  $D = 2.3$ . The differences in these estimated scaling exponents can be reconciled when accounting for slightly different initial processing of the slip distributions and fitting strategies [114]. Testing a variety of auto-correlation functions to fit the spectral properties of a large number of slip distributions, [123] observe that a von Karman auto-correlation function, with its power-spectral density given by

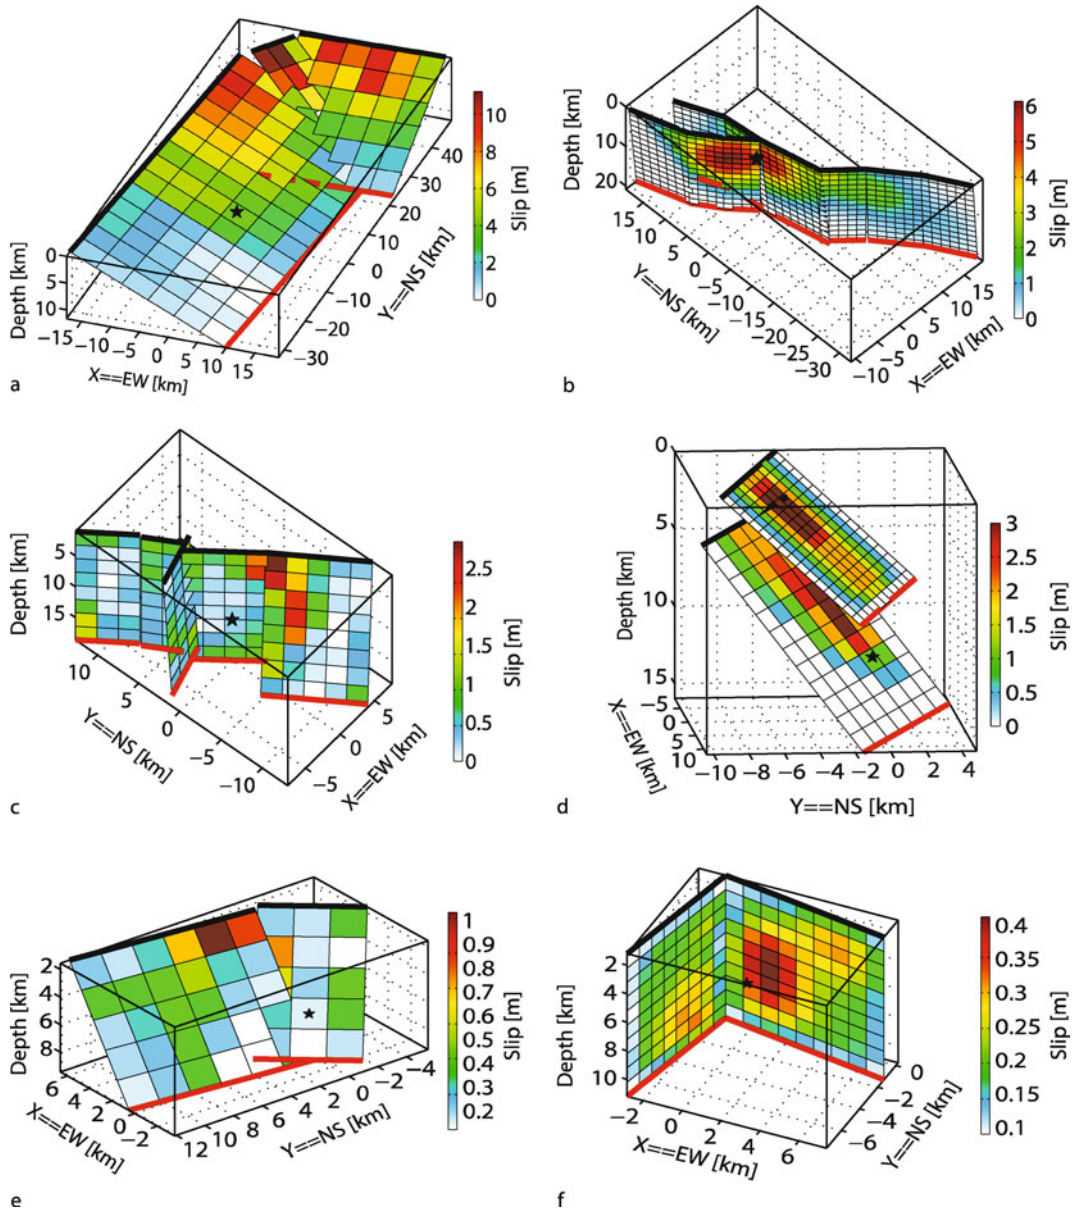

$$P(\mathbf{k}) = \frac{4\pi H}{K_H(0)} \cdot \frac{a_x \cdot a_z}{(1 + \mathbf{k}^2)^{H+1}}, \quad (4)$$

with magnitude-dependent correlation lengths  $a_x$ ,  $a_z$ , and a scale-invariant Hurst number  $H \approx 0.7$  best matches the slip heterogeneity spectra ( $K_H$ : modified Bessel function order  $H$ ;  $\mathbf{k}$  wavenumber). Figure 8 displays their estimated correlation lengths for 44 slip models [123], along with a least-squares regression that exhibits scaling relations of the form

$$\begin{aligned} \log_{10}(a_x) &\propto \frac{1}{2} M_w \\ \log_{10}(a_z) &\propto \frac{1}{3} M_w. \end{aligned} \quad (5)$$

Interestingly, the scaling law in Eq. (5) for correlation lengths of heterogeneous slip maps is similar to the relationship inferred for the deterministic measure of asperity size. This corroborates the previous argument that correlation lengths (asperity size) increases with increasing magnitude, though at a lower rate than the overall fault dimensions. Thus, to accommodate the corresponding seismic moment, the displacements (and associated stress drops) on these high-slip patches need to grow faster than a self-similar scaling would predict. This conclusion agrees with the conjecture of Heaton [88] that large earthquakes require a “very strong kick” (due to an area of large stress drop) in order to be able to grow into a very large rupture.

Treating earthquake slip as being distributed on a planar fault surface strongly simplifies geologic observations of geometrical fault complexity, where the degree of complexity depends on fault-zone maturity [20,90]. Earthquakes that break several fault segments can still be imaged with Eq. (2) using an appropriate parameterization, but planar-fault ruptures exhibit very different rupture dy-

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 9

Three-dimensional views of heterogeneous slip on geometrically complex faults, imaged using seismic and/or geodetic data. The *black star* shows the hypocenter, *thick black lines* are the top of the fault segments, *thick red lines* the bottom. a The 1999 Chi-Chi earthquake ( $M_w$  7.6) [101]; b the 1999 Hector Mine earthquake ( $M_w$  7.2) [102]; c the 2000 Tottori earthquake ( $M_w$  6.6) [100]; d the 1971 San Fernando event ( $M_w$  6.6) [87]; e the 2003 Miyagi-hokubo event ( $M_w$  6.1) [89]; f the 1997 Kagoshima earthquake ( $M_w$  6.0) [94]

namics than earthquakes that have to overcome geometrical obstacles [82,84,131,134]. Figure 9 shows a collection of such geometrically complex fault models, involving two or more segments that form either a system of sub-parallel fault planes (Fig. 9d), or a branching fault (Fig. 9b), or fault planes oriented at arbitrary angles to

each other (Fig. 9a, c, e, f). The seismic radiation from earthquakes on geometrically complex faults is more complicated than from a single-plane rupture, a topic that is investigated in the earthquake source dynamics community e.g. [14,15,43,81,82,84,131,134]. Unfortunately, little attention has been devoted in the past to rigorously exam-

ine and quantify the degree of ground-motion complexity generated by such fault systems. Thus, future research, using advanced numerical techniques on high-performance computing architecture, needs to properly represent fault systems at sufficient spatial resolution to capture the intricacies of rupture dynamics and associated seismic radiation on geometrically complex faults.

### Rupture Nucleation and Directivity

Besides the slip heterogeneity and the temporal rupture evolution (discussed later), the location of the hypocenter (point of rupture nucleation) is a critical factor affecting near-source ground motions. Some metric of hypocentral distance enters empirical attenuation relations (Sect. “Ground-Motion Scaling Relations”), while the on-fault hypocenter location determines the directivity effect [170,171]. This global directivity effect due to fault-hypocenter-site geometry results in large velocity-pulses, in particular at sites close to the fault, because of the constructive interference of S-wave energy which is continuously radiated from the propagating crack front and arrives within a short time window in the forward-direction of rupture propagation (see velocity records in Fig. 1 at station SlackC, FZ1, SC1E for the Parkfield event; Fig. 4 at station TCU052, TCU068 for the Chi-Chi event). In contrast, for sites in the backward direction of rupture propagation the arriving seismic energy is spread over a longer time interval, generating lower-frequency motions with smaller amplitudes. The directivity effect is therefore not a purely source-related phenomenon, but also depends on the observer location.

Additionally, there is an “on-fault” directivity effect which operates on smaller scales and is most prominent for large earthquakes and very near-fault sites. The on-fault directivity effect can be efficiently quantified using isochrone theory (see Sect. “Isochrone Theory”). For an explanatory description, consider the slip distribution and hypocenter location in Fig. 6a, for which the large-scale “global” directivity effect was observed towards the right (i. e. East in this case of the 1999 Izmit earthquake). However, any site located at about  $30 \leq X \leq 50$  km in along-strike distance (above the left-most high-slip region) experiences strong “local” directivity effects as the rupture propagates from the hypocenter towards the site and across the high-slip patch. In this case, the integrated slip along this rupture trajectory generates a high-amplitude short-duration pulse. Considering a more westerly hypocenter (e. g. at  $X = 30$  km instead of  $X = 65$  km) the large-scale directivity effect remains essentially unchanged while the integrated slip along the rupture trajectory for

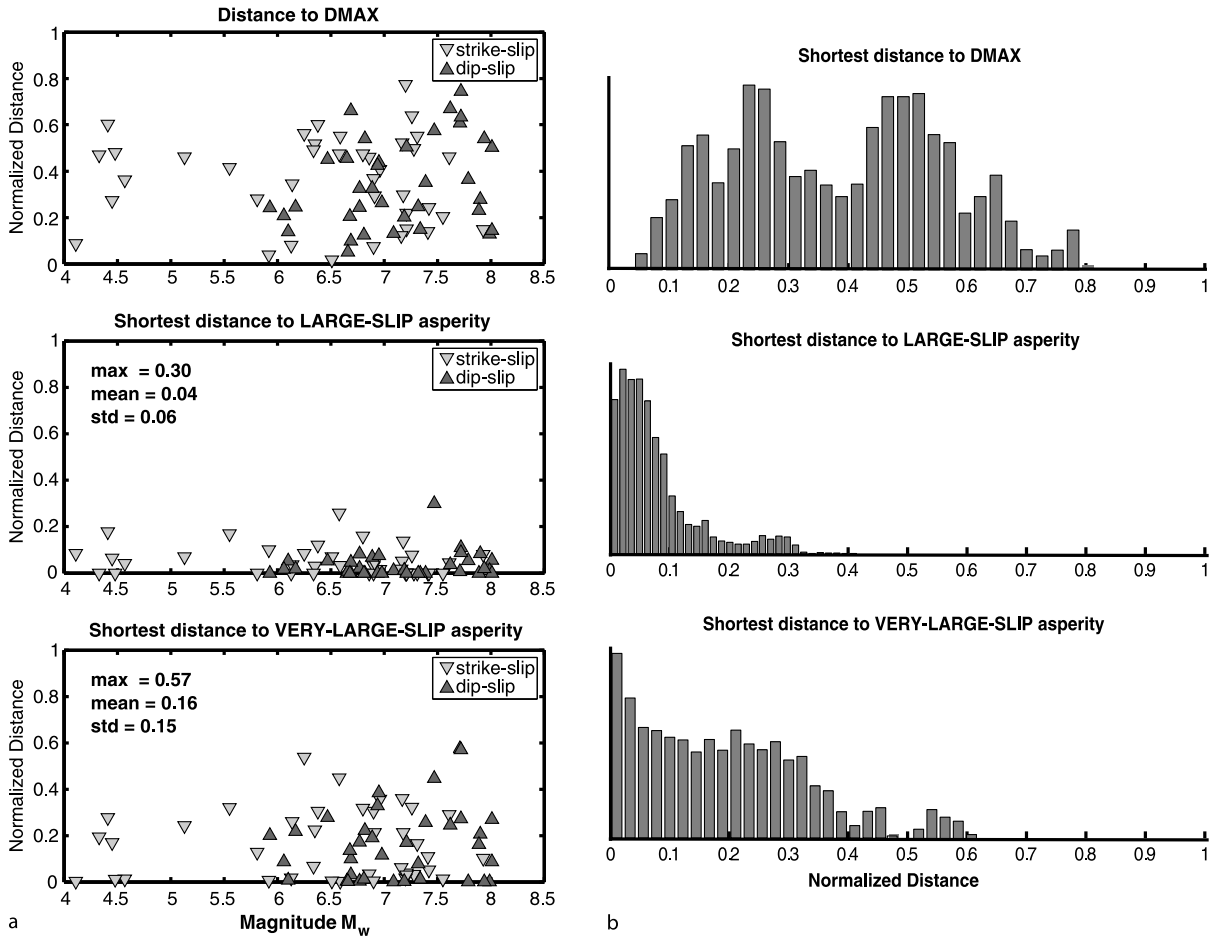

stations at  $30 \leq X \leq 50$  km is much smaller, thus diminishing on-fault directivity. The spatial relation between the hypocenter and large-slip regions plays an important role for ground-motion complexity, but is also fundamentally related to the dynamics of the rupture process.

Examining the hypocenter positions in Fig. 6 and Fig. 9, two observations are evident: (a) ruptures generally do not nucleate at the fault boundaries, but in the interior of the fault plane, but rarely exactly in the center; (b) the nucleation point is generally not located in regions of low slip (light colors,  $D \leq 0.1 \cdot D_{\max}$ ) but in areas where  $0.2 \cdot D_{\max} \leq D \leq 0.4 \cdot D_{\max}$  and the distance to a nearby large-slip zone (asperity) is small compared to the overall source dimensions [127]. This study investigated these first-order observations statistically using a database of  $\sim 80$  finite-source rupture models, and concluded that hypocenters are not randomly located on a fault but are located either within or close to regions of large slip (Fig. 10). More specifically, ruptures nucleate within or very close to large-slip asperities ( $\frac{1}{3} \cdot D_{\max} \leq D < \frac{2}{3} \cdot D_{\max}$ ), but rarely start on very-large-slip asperities ( $D \geq \frac{2}{3} \cdot D_{\max}$ ; often located far away from the hypocenter).

These observational constraints of slip heterogeneity and rupture nucleation are rooted in the energy balance of earthquake source physics, and have been confirmed by dynamic rupture simulations [78,133,151]. The essence of the physical mechanism is that a sustained large earthquake can only be generated if a sufficiently large amount of energy is furnished to the propagating crack tip to facilitate rupture growth. In a simplistic view, an earthquake can only grow in size if the energy absorbed to create new crack surface (fracture energy) balances the available elasto-static energy and the energy radiated by seismic waves (Chap. 11 in [6]). If the hypocenter is located in regions of low slip (low stress drop) and far away from any point of significant stress drop, the required fracture energy will become too large to allow further crack propagation, and the rupture will stop prematurely. The spatial correlation between hypocenter and asperity is thus consistent with this simplified energy budget of dynamic rupture. Moreover this hypocenter-asperity relation manifests the “on-fault” directivity and strongly effects seismic radiation and thus ground-motion complexity.

### Temporal Rupture Evolution

The characteristics of the slip distribution and the hypocenter position alone are insufficient to parameterize  $\Delta u(\xi, \tau)$  in Eq. (2) because the temporal rupture evolution is not yet specified. Rupture velocity and the local slip-velocity function with its associated rise time (slip duration)

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 10

Hypocenter distance to “large-slip” and “very-large-slip” regions in finite-source rupture models. **a** Raw measurements of shortest distances between hypocenter and point of maximum displacement (*top*), hypocenter and closest large-slip asperity (*middle*), and hypocenter and closest very-large-slip asperity (*bottom*), separated into strike-slip and dip-slip earthquakes. **b** Distributions of shortest distances between the hypocenter and the point of peak-slip, the closest large-slip, and the closest very-large-slip asperity, generated using Monte Carlo simulations that include hypocenter uncertainties. The distributions indicate that 16% of all hypocenters occur on a very-large-slip asperity, 35% within a large-slip asperity, and 48% right outside an asperity (compiled from [127])

need to be given, either pre-defined by means of a kinematic rupture modeling approach or solved for from physical principles in a dynamic rupture model.

**Rupture Velocity** After earthquake nucleation the rupture propagates over the fault plane with a rupture velocity  $v_r$  which generally is close to the local shear-wave velocity (typically in the range  $0.6 \cdot v_s \leq v_r \leq 0.9 \cdot v_s$ ). Seismic radiation and thus near-field motions strongly depend on rupture velocity: slow earthquakes radiate little seismic energy while fast ruptures generate higher ground-motion amplitudes. Earthquake source inversions mostly assume a constant rupture velocity over the fault plane, al-

though dynamic rupture modeling and evidence from particularly well recorded earthquakes indicates that rupture speed may vary significantly on the fault plane [16,44]. Dynamic modeling shows that the initial rupture speed (during and right after the nucleation phase) may be small (e.g.  $v_r^{\text{init}} \leq 0.5 \cdot v_s$ ), but then rapidly increases during the rupture’s dynamic breakout and propagation phase (Chap. 11 in [6]). Depending on the stress conditions and the frictional parameters on the fault, and the geometrical properties of the rupturing fault, the rupture speed may actually exhibit very strong small-scale variations (see Fig. 5 for example). Variations in rupture velocity are a source of high-frequency seismic radiation [119,173],

and thus strongly contribute to near-field ground motion complexity.

While the rupture speed for most earthquakes is lower than the local S-wave velocity (i. e. sub-shear rupture propagation), there is evidence from laboratory measurements [155] and from seismic data and source modeling e. g. [16,44,134] that the crack front may travel at super-shear speeds at least over parts of the fault plane. Such super-shear ruptures generate rather distinct ground-motion characteristics at the few sites where they were recorded, but it is not yet clear what the “generic” ground-motion signature of super-sonic rupture speed would be. [1] address some aspects of this question by kinematic rupture modeling with various rupture speeds and computing the resulting near-field motions, indicating very peculiar “mode-switching” of the seismic-energy distribution on the two horizontal components as the rupture speed becomes very large. Furthermore dynamic rupture simulations [10,58,59,63,68,134] provide physical models for the occurrence of super-shear propagation, which depends on local stress and frictional conditions on the fault plane. The potential occurrence of super-shear rupture burst [62,63] and rupture speed variations in general are critical for understanding ground-motion complexity. To efficiently include such effects into ground-motion simulations, [78] developed an initial physics-based representation of rupture-velocity heterogeneity for kinematic source modeling.

**Slip-Velocity Function and Rise Time** As the propagating rupture sweeps over the fault plane points on the fault plane are “activated” and start slipping. Each point traces an individual slip-time history (slip-velocity function) whose shape and duration depends on the stress conditions and frictional properties on the fault, but also on overall fault size and the position of each point with respect to rupture nucleation [59]. Figure 5 illustrates the variability of local slip-velocity functions  $s_{ij}$  on the fault. The slip duration (rise time  $\tau_r$ ) is usually defined by integrating the slip-velocity function and measuring the time it takes to complete 5–95% of the total displacement at each point.

Several approximations of these complicated slip-velocity functions are in use: a boxcar or isosceles-triangle function with a rise time equal to the width of the function, or symmetric and asymmetric cosine-functions. The classical approximation uses the solution of a quasi-dynamic crack model [110], showing an  $1/\sqrt{t}$ -decay after a rapid onset. Recent modifications to this Kostrov-type slip function [129,180] are compatible with earthquake dynamics, while ground-motion simulations and source in-

version often assume simple parameterization of overlapping triangles [78,92].

As Fig. 5 indicates, rise time varies over the fault plane. However many kinematic source inversions and simple source-model simulations assume constant rise time. A self-similarly expanding crack model predicts longer rise times in the center of the fault e. g. [58,110] where the rupture nucleates, but short rise times at the crack periphery due to the earlier arrival of the healing front from the crack rim. Analysis of source-inversion results [88] and dynamic rupture modeling [28] however suggest that rise times are in general short, i. e. the rupture propagates as a self-healing pulse over the fault plane with rise times determined by local healing of the rupture front.

For fixed rupture velocity and slip distribution, ground-motions are very sensitive to rise time variations. Shorter rise times lead to larger ground-motions as the seismic energy is released in a shorter time interval. The detailed shape of the slip-velocity function is less important for the seismic waveforms, because they are determined by the summation of slip-functions, convolved with the appropriate Green’s function, over the entire fault plane (effectively filtering out small-scale features of the slip-velocity parameterizations). However, the peak slip-velocity value that the slip-rate function may attain is crucial for the final ground-motion amplitudes.

### Isochrone Theory

The effects of various kinematic source parameters (slip and slip-velocity distribution, rupture propagation) on near-field ground-motions can be efficiently visualized in the framework of the isochrone theory, a high-frequency (ray-theory) approximation to calculate seismic radiation from earthquake ruptures [27,173]. By approximating the elastic wave Green’s functions with far-field body waves, surface-waves and low-frequency near-field terms are not considered in the isochrone method. It is correct, however, at higher frequencies, where far-field terms dominate, and in the distance range to the fault where surface waves have not yet developed but near-field terms are unimportant. The main aspect of this approach is that the space-time integration in Eq. (2) can be replaced by a series of line integrals over the fault for simple slip-function parameterizations. For each time  $t_i$  in the observer seismogram a line integral is computed for which the integration path comprises only those points on the fault which radiate seismic waves that arrive at the observer location at exactly the time  $t_i$ . Defining an arrival-time function, composed of the rupture-front arrival time at each point on the fault and the corresponding seismic-wave travel time to the ob-

server, the integration path represents an isochrone of this arrival-time function. The corresponding isochrone velocity,  $\mathbf{c}$  (the spatial derivative of the arrival-time function) is related to rupture velocity  $v_r$ , and thus resembles the directivity function. Since ground velocity is proportional to isochrone velocity, the characteristics of high-frequency body-waves in near-field seismograms can easily be examined with respect to arbitrarily heterogeneous slip and rupture velocity distributions.

The omission of near-field terms and surface-waves restricts the isochrone method to cases in which seismic radiation from compact slip zones or sudden changes in rupture velocity dominate the ground-motions. Such source behavior has been reported for many earthquakes, consistent with [119] who showed that the high-frequency far-field radiation is emitted at the propagating crack tip, with additional radiation coming from stopping phases as the rupture heals. The isochrone theory has also been successfully applied to earthquake source inversions [29].

The detailed theoretical development of the isochrone theory is beyond the scope of this article, but a brief description will help to illustrate the concept. Spudich and Frazer [173] link the representation theorem, Eq. (2), to geometrical ray theory (without Fraunhofer approximation) for the far-field displacements of P- and S-waves. According to [176] a simple, yet versatile, parameterization of the slip function  $s(\mathbf{y}, t)$ , is given by

$$s(\mathbf{y}, t) = \mathbf{s}_r(\mathbf{y})f_r[t - t_r(\mathbf{y})], \quad (6)$$

with rupture time  $t_r$  at positions  $\mathbf{y}$  on the fault plane, position-independent shape-function  $f_r$  for the slip-velocity function, and position-dependent amplitude  $\mathbf{s}$ . Any heterogeneous rupture model can be approximated by Eq. (6). Inserting this expression into Eq. (2), shown here for S-waves only, one obtains

$$\mathbf{u}^S(\mathbf{x}, t) = f_r(t) \cdot \int_S \mathbf{s}_r \cdot G_a^S \delta(t - t_a^S) dS \quad (7)$$

where  $t_a^S(\mathbf{y}, \mathbf{x}) = t_r(\mathbf{y}) + t^S(\mathbf{y}, \mathbf{x})$  is the arrival time function for an observer at location  $\mathbf{x}$  due to an S-wave radiated at point  $\mathbf{y}$  on the fault  $G_a^S$  is the corresponding Green's function. The surface integral in Eq. (7) is non-zero only if the argument of the  $\delta$ -function is zero. Curves  $\mathbf{y}(t_a^S, \mathbf{x})$  define the contours of equal arrival time (isochrones) at observer  $\mathbf{x}$ ; the surface-integral in Eq. (7) thus reduces to a line integral

$$\mathbf{u}^S(\mathbf{x}, t) = f_r(t) \cdot \int_{\mathbf{y}(t, \mathbf{x})} (\mathbf{s}_r \cdot G_a^S) \cdot c(\mathbf{y}, \mathbf{x}) dl \quad (8)$$

in which  $c(\mathbf{y}, \mathbf{x}) = |\nabla t^S(\mathbf{y}, \mathbf{x})|^{-1}$  represents the ‘‘isochrone velocity’’ of these curves along the fault surface ( $\nabla$  denotes

the gradient operator). Note that the isochrone velocity is related to the directivity function; isochrone theory therefore helps to visualize on-fault directivity effects [172].

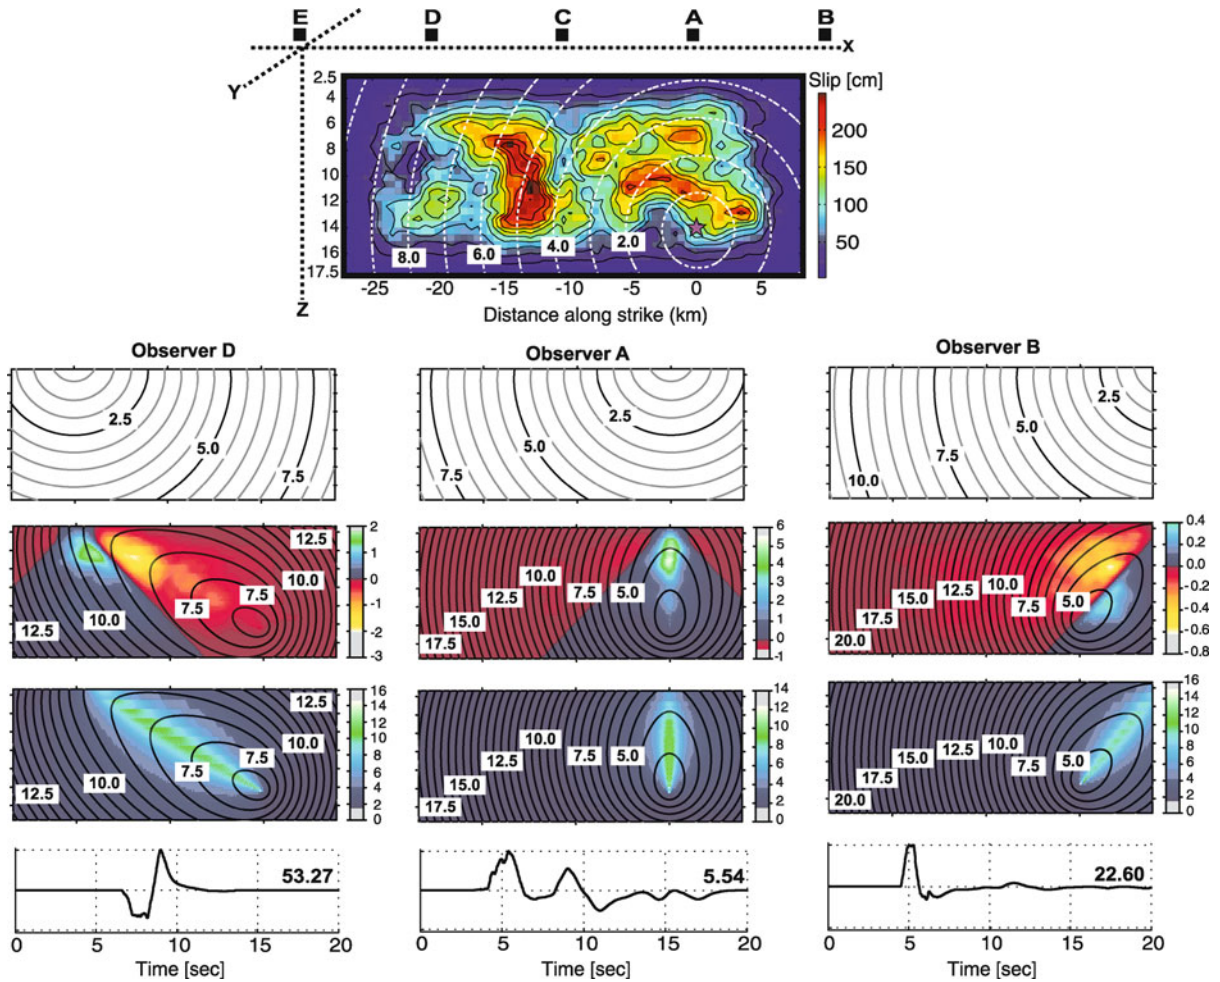

As an application of the isochrone method, we compute near-field seismograms for a hypothetical rupture ( $M_w$  6.7) with constant rupture velocity (radially spreading rupture front) at three sites, each at fault-perpendicular position  $y = 0.2$  km, but various positions along-strike (Fig. 11). A simple layered medium is assumed, and anelastic attenuation is excluded. For each observer, the S-wave travel time function (travel times from the site to each point on the fault) is shown (top panels), the color-coded integrand (Eq. (8)) with isochrone contours (spacing  $dt = 0.5$  sec) (2nd row of panels) and the isochrone velocity with isochrone contours (3rd row of panels). S-wave pulses in the fault-normal velocity seismograms (bottom) can then be attributed to isochrone properties. Consider for example observer D. The first isochrone appears at  $\sim 7$  sec, consistent with the S-wave arrival time in the seismogram. Isochrones up to 8 sec are entirely in areas where the integrand is negative (yellow to red colors), hence the down-ward initial motion. The peak velocity (53.2 cm/sec) occurs at  $t \approx 9$  sec when the corresponding isochrones hit the large-amplitude regions of the integrand (green areas). Observer D exhibits stronger directivity than observers A or B due to its position with respect to the hypocenter and the dominant asperity, generating large amplitudes due to high isochrone velocity over regions of large slip. At site D, the seismic energy radiated from the high-slip patch at  $x \approx -15$  km,  $y \approx 10$  km arrives within a short time window, whereas at site A, the contributions from this slip patch are spread over a longer time window. For site A, the isochrone velocity is smaller than for D, hence directivity is less pronounced. As a results, site A exhibits lower peak ground motions but a longer shaking duration.

The current implementation of the isochrone method [176] could be extended to include near-field terms [104] and to be applicable in three-dimensional velocity structures by adding 3D ray-tracing capabilities. Spatially variable slip-velocity functions and anelastic attenuation are further possible extensions. Finally, effects of wave-scattering in random media could be implemented using scattering operators [125,192,193,194] convolved with the local slip-rate function  $s(\mathbf{y}, t)$ .

### Wave Propagation in Complex Media: Path and Site Effects

Returning to Eq. (1), this Section discusses path effects,  $g_k(t)$ , due to source-to-site wave propagation, and local

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 11

Ground-motion simulation using isochrone theory for a hypothetical  $M_w$  6.7 earthquake, buried at 2.5 km depth and embedded in a layered medium. *Top graph:* Rupture spreads from the hypocenter (red star) at constant rupture speed ( $v_r = 2.7$  km/s, white contours) over the fault with heterogeneous slip (color-coded). *Bottom graphs:* Isochrone quantities at three sites. *Top-most panels:* S-wave arrival time function; *2nd row of panels:* isochrones overlain over the real part of the integrand in Eq. (8) (in units of  $s_r \cdot G_0^S \cdot c(y, x)$ ); *3rd row of panels:* isochrones overlain over isochrone velocity (in km/s). *Lower-most panels:* Resulting fault-normal velocity seismograms dominated by large S-wave pulses (in cm/s; peak velocity indicated at the end of each trace)

site effects,  $l_k(t)$ , due to the small-scale geological conditions at each observation point. The wave propagation from the earthquake to the observation point depends on the complexity of Earth structure, which can be separated into two parts: (i) deterministic wave-propagation within a layered medium, three-dimensional basin effects, topographic features and large-scale geological structures; (ii) wave-propagation in a stochastic random medium with small-scale heterogeneity leading to incoherently scattered wave energy. Local site effects in the shallow near-surface structure (usually the top-most 100m) beneath the observation site further complicate near-fault

ground-motions, leading to either increased or decreased motions (compared to bed-rock level), increased shaking duration, shifts in the dominant frequency of ground-motion, and perhaps nonlinearity effect. These wave-propagation effects have to be incorporated into the characterization of ground-motion complexity, and should be applied in strong-motion simulations for predicting the intensity and variability of seismic shaking. However, the success in incorporating these effects hinges on the available knowledge of seismic properties of the Earth, which in turn depends on the dominant wavelengths (frequencies) at which the Earth is sampled by observational data.

Similarly, inversion for Earth structure and forward simulation of seismic waves require an appropriate spatial discretization of the modeling region for the numerical calculations, which essentially provides an upper limit on either the maximum resolvable frequency or the size of the computational domain for ground-motion simulations.

In this Section, I first review some aspects of “deterministic” wave propagation in a flat-layered attenuating Earth, and then qualitatively describe effects of basin structures, Earth topography and local features (e. g. fault zones, narrow belts of low shear-wave velocity). I then examine aspects of wave propagation in random media and corresponding simulation methods. Site effects and nonlinearity conclude this section. Due to the large body of literature on these topics, a detailed quantitative review is not attempted in this Section. Instead I merely select a few key elements of particular interest for characterizing ground-motion complexity.

### Wave-Propagation in a Flat-Layered, Attenuating Earth

The first-order approximation of Earth’s internal structure is a radially layered medium, which for short source-site distances ( $< 600$  km) can be treated as a flat-layered structure. Many research branches in seismology successfully apply this approximation of a one-dimensional depth-dependent velocity-density model: earthquake location, arrival-time measurements of various seismic wave types, focal-mechanism determination, moment-tensor inversion, finite-source inversion. A number of well tested methods exist to compute Greens functions for a flat-layered Earth model, although the exact frequency range in which this model is accurate is difficult to determine and depends on the particular application and region. At long periods ( $T > 20$  sec and corresponding long wavelengths ( $\lambda \approx 120$  km for P-waves traveling at speed of  $v_p \approx 6$  km/sec), used for instance in moment-tensor inversions), basin structures, mountain ranges and other geologic features with minor changes in physical properties (density, wave-speed) can be ignored at spatial scales on the order of tens of kilometers, thus allowing accurate modeling of the complete low-frequency seismogram. For small areas with relatively simple Earth structure, body-wave Greens functions can be accurately synthesized up to frequencies of  $f \approx 1$  Hz, a property that is often used in finite-source inversions. In these cases, ground-motion complexity is assumed to be largely due to the heterogeneity in the rupture process, since the local, observer-specific Greens functions (containing the impulse response in a layered medium

due to point-source excitation) are simple (examples are shown in Fig. 5).

In many cases, however, sites of interest may be located on top of basin structures, in zones that are geologically different on a small-scale, or even in a narrow fault-zone belt which may have distinctly different seismic properties. By examining observed ground-motions at many sites, site-specific one-dimensional Earth models can be used to compute corresponding Greens functions, a cumbersome and error prone approach since source and receiver are located at points with different seismic properties. In such cases, 2D or 3D-models are preferable for the Greens function calculation, as they allow to appropriately include basin effects, local geology and potentially also topography, usually at the expense of reduced frequency resolution and/or a smaller computational domain.

### Effects of Sedimentary Basins, Fault-Zones, Topography

Geological basins, containing layers of compliant sedimentary rock units and covered by potentially poorly consolidated, low shear-wave-velocity sediments, have a variety of effects on incoming seismic waves. Characterizing and quantifying the basin-related ground-motion complexity is particularly important for seismic hazard studies since many major urban areas are built in geological basins that are located within or close to a seismically active region (e. g. Mexico City, Tokyo, Los Angeles).

For instance, the 1985  $M_w$  8.0 Michoacan earthquake generated major damage in Mexico City, several hundreds of kilometers away from the epicenter. While the near-source strong-motion stations did not show unusual ground motions, the shaking level in Mexico City was unexpectedly large in those parts of the town constructed on lake bed sediments [9]. Ground-motions and associated damage exhibited high spatial variability; long-period surface waves, generated at the edge of the basin, had particularly severe consequences for tall high-rise building with eigenperiods of several seconds. Many of them suffered complete collapse. Strong basin effects have been simulated for earthquakes in the greater Los Angeles area, indicating localized basin-response effects caused by surface waves generated at the edge of the basin [74,75,135,136,138] and the focusing of seismic energy due to basin geometry [76,108,138]. A particularly interesting effect has been found for the 1994  $M_w$  6.7 Northridge earthquake, attributed to an isolated high-damage area in Santa Monica to focusing effects caused by a small-scale localized 3D lens-like high-velocity structures [57].

Other prominent examples of strong basin response are given for the Wellington Basin (New Zealand) [24], for the Tokyo plain (Japan) [109,159,160,162], and the Kobe area (Japan), which was strongly damaged during the 1995 Kobe earthquake ( $M_w$  6.9). In the latter case, the largest damage did not occur in direct vicinity of the rupturing fault, but was concentrated within an elongated band offset to the southeast of the fault. Modeling studies showed that this “damage belt” was caused by constructive interference of seismic waves taking different paths: (i) directly through the low-velocity basin structure and (ii) through high-velocity rocks outside the basin and then reflected back into the basin [107,143,144]. Additionally, topographic effects may have contributed to the complexity of near-fault motions for the Kobe earthquake [145]. Another example for strong topographic effects on near-source motion is the Tarzana (California) site, located atop a small hill, which recorded a value of  $PGA = 1.78$  g on the EW-component of motion during the 1994  $M_w$  6.7 Northridge earthquake [174]. However, it is difficult to separate topographic effects from subsurface-structure properties beneath the topographic features, and firm conclusions on the contribution of topographic effects are not well defined [108].

These basin-induced or topographic site effects strongly depend on the direction from which the incoming wave field arrives, as shown by strong-motion simulations for the Basel (Switzerland) area [139] or the greater Los Angeles region [118,138]. Strong variations in the basin response, and hence ground-motions at individual sites, depend on whether the incoming waves are predominantly polarized in the direction parallel or perpendicular to the main geologic structures (i. e. the large-scale basin shape and major faults inside and bounding the basin).

Low-frequency ground-motions, modulated by basin effects, topography, or narrow fault-zone-related regions of low shear-wave velocity, exhibit also longer shaking duration (due to surface-waves arriving after the dominant S-arrivals), and potentially larger amplitudes in case of constructive interference of wave packets (often occurring as trapped waves) [141]. Due to the dependency of the basin response on the direction of the incoming wavefield and the detailed small-scale structure of the basin, individual sites within a particular basin will experience very different ground-shaking. The ground-motion complexity is thus greatly increased by these effects, and general scaling relations for ground-motion (de-)amplification and prolongation due to basin and topographic structures are difficult to derive. Only numerical simulations for particular earthquakes or specific scenario events can help to understand the corresponding ground-motion variability which

can then be related to standard ground-motion attenuation relationships (see Sect. “Ground-Motion Scaling Relations”).

While there has been considerable progress in interpreting and modeling strong-motion waveforms for frequencies  $f < 1$  Hz, one of the major challenges is to calculate reliable broadband near-source seismograms for the frequency range of engineering interest which extends to  $f \sim 10$  Hz. The works described above examine and model the low-frequency wavefield contribution, using 1D-, 2D- or 3D-finite-element, finite-difference or spectral-element techniques (see ► [Seismic Wave Propagation in Media with Complex Geometries, Simulation of](#)). Seismic source properties, Earth structure, and site effects strongly affect high-frequency motions, but computational limitations still prohibit purely deterministic ground-motion simulations for frequencies above  $f \approx 1$  Hz. Instead, at least some part of the simulation procedure needs to involve a stochastic component since Earth structure, and to some extent the earthquake source, are essentially unknown at short spatial scales required for accurate high-frequency simulations. The difficulty is thus to capture and correctly quantify the scattering properties of the Earth at the scale-lengths and frequencies that are of interest for seismic hazard purposes.

### Scattering in Inhomogeneous Media

The seismic coda, the energy in the seismogram after the prominent direct P- and S-wave arrivals, consist of P-, S- and surface-wave energy scattered in the inhomogeneous rock volume between the source and the recording site. Figures 1, 3, 4, display near-field waveforms for which the coda-characteristics show large variability. In some cases, the coda waves decay fast, in other cases they persist for a long time; the frequency content of coda waves also appears to be site dependent. These observations manifest that, scattering and attenuation of seismic waves in inhomogeneous media strongly contribute to ground-motion complexity.

The basic method of estimating attenuation properties of seismic waves uses the Fourier amplitude spectrum of observed ground motion  $\mathbf{u}(r; f)$ , for a spherical S-wave of frequency  $f$  given as

$$\mathbf{u}^S(r; f) \propto \frac{1}{r} \cdot \exp \left[ -\frac{\pi \cdot f \cdot r}{Q_S \cdot \beta} \right] \quad (9)$$

where  $r$  is distance,  $\beta$  the S-wave velocity, and  $Q_S$  is the attenuation coefficient for S-waves, containing both intrinsic anelastic attenuation and scattering attenuation. For S-waves,  $Q$ -values in the lithosphere range from  $20 \leq$

$Q_S \leq 10\,000$ , for P-waves they are about a factor of two larger [158]. However, the frequency dependence of  $Q_{S,P}$  above about  $f \approx 1$  Hz indicates that attenuation increases for higher frequencies as  $Q_{S,P}^{-1} \propto f^{-n}$  (with  $0.5 \leq n \leq 1.0$ ) [161]. While the effects of seismic wave attenuation due to geometrical spreading are well understood and can be readily measured and incorporated into ground-motion simulation methods. The scattering losses of seismic waves are more difficult to estimate.

Based on seismic array measurements, recorded coda envelopes or sonic logs from borehole measurements, several studies estimated characteristic scale lengths of seismic scattering in the Earth [71,93,152,190]. Alternatively, numerical simulations for assumed random-media realizations have been used to assess scattering properties of the Earth e.g. [65,66]. These works show that the heterogeneity spectrum of velocity fluctuations in the Earth (i. e. the random variations of P- and S-wave velocities around a depth-dependent velocity gradient) can be adequately modeled as a fractal medium (e. g. Eq. (3)) or with a correlation function that does not decay too rapidly in wavenumber domain. Smoothly varying Gaussian-type correlation functions are thus inappropriate whereas an exponential or a more general van Karman correlation function Eq. (4) well models seismic scattering in the Earth crust [93,159].

Due the tectonic history of the Earth and the multi-scale nature of geologic structures, scattering parameters depend on region and depth. Correlation lengths of  $a \approx 10$  km are inferred for wave-scattering in the lower crust e. g. [66], whereas [86] assumed  $a \approx 5$  km for upper-crustal wave-field simulations. Upper-mantle heterogeneities may be modeled with correlation length  $a \approx 20$  km. The actual velocity fluctuations are on the order of 2–10%. A concise review of seismic scattering and estimated scattering parameters is given in (see ► [Seismic Waves in Heterogeneous Earth, Scattering of](#)) [161], a thorough introduction is published by Sato and Fehler [158].

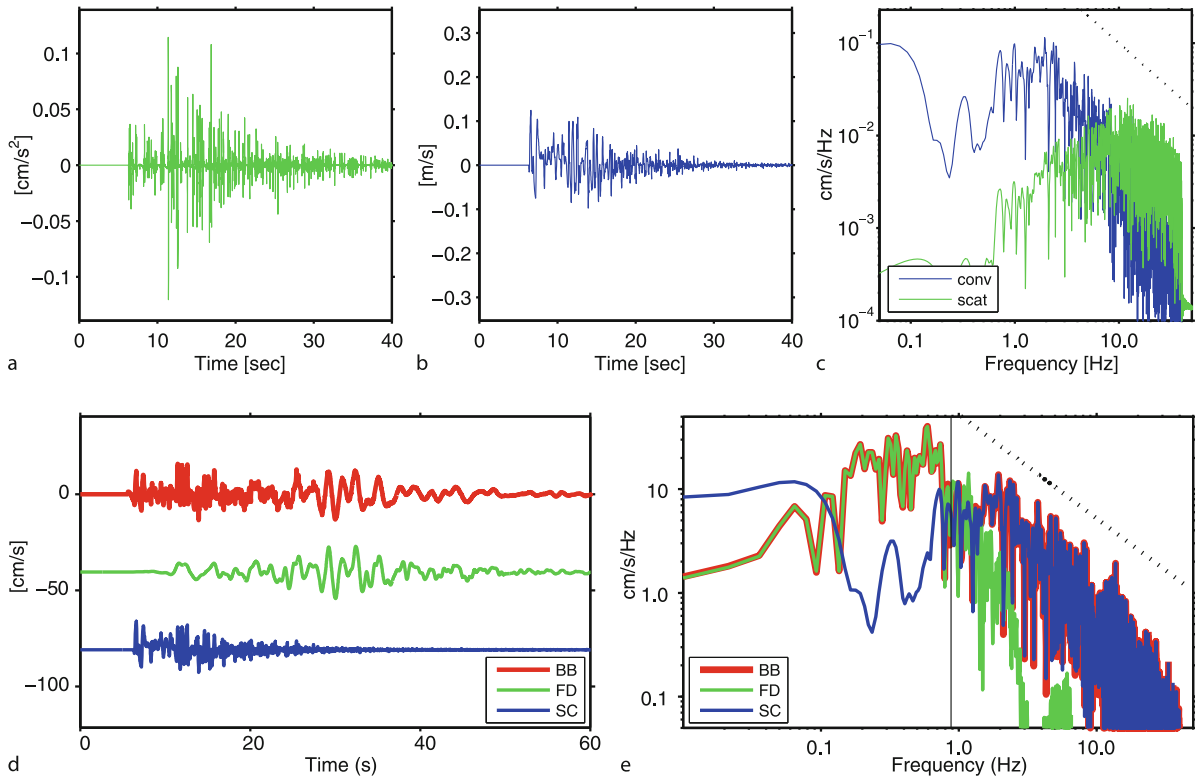

Ground-motion simulations for seismic hazard assessment or studies on the nature of ground-motion complexity should incorporate seismic scattering, i. e. or at least to some degree the stochastic nature of high-frequency seismograms. In earthquake engineering random-vibration theory has been used for this purpose e. g. [35,103], which oversimplifies the earthquake rupture process but appropriately accounts for the apparent randomness of high-frequency ground-motions. More advanced techniques combine deterministic low-frequency motions with stochastic high-frequency signals [99,146,147], in which the stochastic part reflects the short-scale variability in source prop-

erties and seismic-wave scattering. The stochastic signal used in these methods is generated as random white noise and does not contain any physical scattering mechanism.

More physical approaches calculate the 3D-seismic wavefield in a 3D-heterogeneous medium, a computationally expensive task which cannot be carried out for large-scale simulations or many scenario events for which high-frequency ground-motions are needed. To devise a simplified method, [86] have combined realistic small-scale heterogeneity in the source properties with scattering operators for a von-Karman random medium to compute broadband time histories. Their study indicates that the effects of scattering are masked by the heterogeneity in the kinematic source characterization. Note also that, near-field seismic wave scattering in a heterogeneous medium may also replicate apparent nonlinear site effects [130] (see Section “[Site Effects and Nonlinearity](#)”).

A computationally less demanding approach to include seismic scattering into ground-motion simulation uses radiative transfer theory to model the space-time distribution of the seismic-energy envelope due to scattered waves [192,194]. In this formulation, a time-dependent multiple S-to-S scattering process occurs due to a shear-dislocation point source embedded in a 3D-medium with background velocity  $v_0$  in which point-like isotropic scatterers of cross section  $\sigma_0$  are randomly distributed with density  $N$ . The total scattering coefficient is thus  $g_0 = N \cdot \sigma_0$ . The detailed theoretical developments are beyond the scope of this article, but it is worth noting that the calculation of the energy-density envelopes is computationally efficient and can be used for high-frequency ground-motion simulations [193].

The multiple S-to-S scattering theory has recently been applied to compute hybrid broadband near-field seismograms [125]. Their technique joins low-frequency 3D-finite-difference (FD) synthetics (which may contain the effects of a sedimentary basin) with site-dependent high-frequency scattering operators to synthesize broadband ground motions. The high-frequency scattering operators are convolved with an appropriate source-time function, and then these site-dependent “scatterograms” are combined in the Fourier domain with the corresponding low-frequency synthetics using a phase-matching optimization technique [124] (conceptually depicted in Fig. 12). Comparing data and simulations for a site that recorded the 1994 Northridge earthquake indicates a good agreement in terms of waveforms, amplitude spectra and spectral acceleration (Fig. 13). The model bias (logarithm of the ratio between the observed and simulated quantity) for spectral acceleration at 30 sites that recorded the 1994 Northridge event (Fig. 14a) shows only small deviations from zero, ex-

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 12

hibiting also narrow 90%-confidence limits. Considering also the general agreement between observed and simulated PGV and PGA values (Fig. 14b) indicates that such hybrid broadband wavefield simulations can reproduce ground-motion complexity, where differences at individual site remain due to unmodeled site and path effects.

Adding seismic scattering into ground-motion characterization and simulation helps to capture the large degree of complexity in the near-source seismic wavefield, and thus presents an important future research topic. Here I have only briefly discussed a few key elements of seismic scattering and its application to a specific case study. However, to fully explore the range of realistic scattering parameters, combined with the inherent complexity of the source-rupture process, requires extensive numerical simulations that need to be calibrated and validated against observational data.

### Site Effects and Nonlinearity

Site effects play a major role in characterizing and quantifying strong ground motion as they may amplify or deamplify the incoming “bedrock” motions in the uppermost velocity layers beneath the observer. Since site-amplification factors may reach two orders of magnitude [108], these effects cannot be neglected in earthquake engineering practice. A comprehensive review of various approaches to estimate and model site effects is given by Kawase [108], so I restrict the following discussion to a few key aspects.

There is no strict boundary between site effects and path effects, but site-effects usually refer to wave-field modifications in the immediate vicinity of the observer location (top 30 m of the local sedimentary cover). Usually, the time-averaged shear-wave velocity in the top 30–100 m

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 13

Comparison of data (blue) and broadband simulations (red) at a site that recorded the 1994  $M_w$  6.7 Northridge earthquake (*left*: fault-normal; *right*: fault parallel motions). Note the consistency between the Fourier amplitude spectra (vertical line denotes the matching frequency) and between the response spectra ( $\zeta = 5\%$  damping). PGA- and PGV-values are also similar

( $V_{S30}$ ) is used to define the station-specific soil classification. Site effects may be affected by the water table, and even soil-building interaction can be considered a site effect.

The classical method to estimate site effects from seismic observations is based on Eq. (1), and attempts to separate source and path from site effects. Expressing Eq. (1) in the Fourier domain and considering the ground motions due to earthquake  $j$  observed at site  $k$ , we obtain source-

site specific Fourier amplitude spectra as

$$A_{jk}(f) = S_j(f) \cdot G_{jk}(f) \cdot L_k(f). \quad (10)$$

The Green's function term,  $G_{jk}(f)$  can be expressed in terms of geometrical spreading factors with respect to the source-site distances,  $r_{jk}$ ; combining intrinsic and scattering attenuation into a common  $Q(f)$  one obtains (for

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 14a

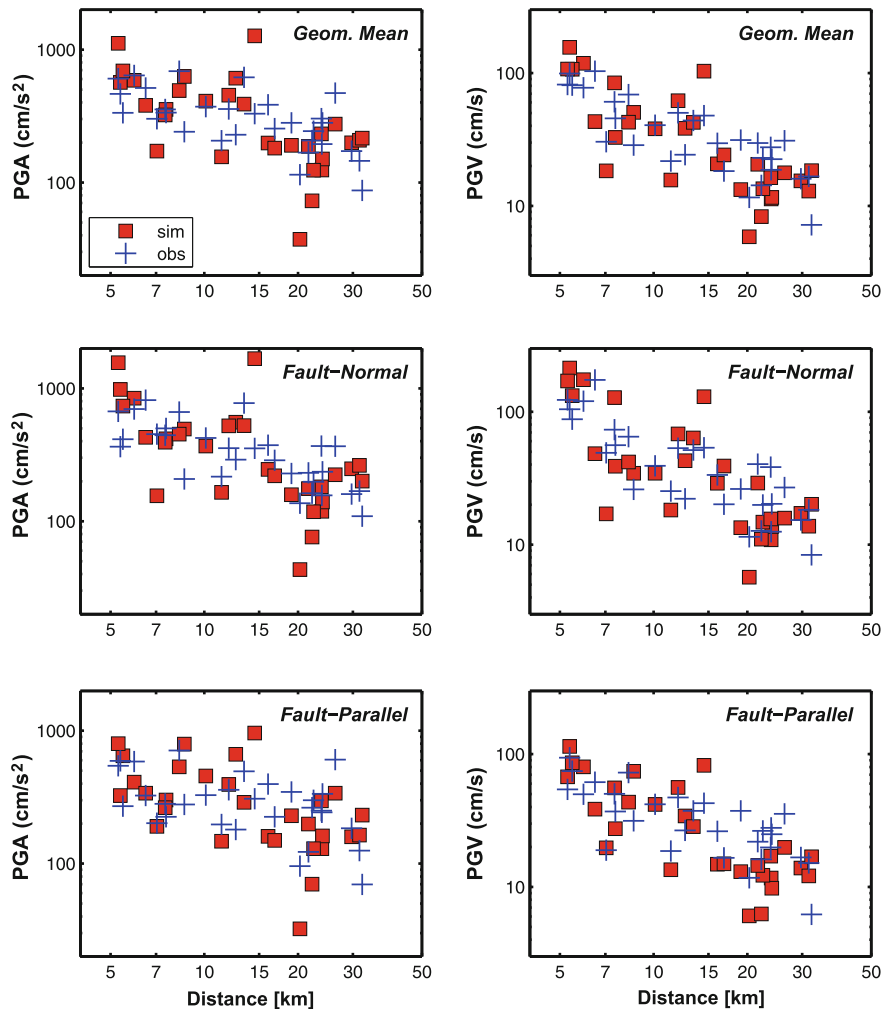

Hybrid broadband ground-motion calculations using low-frequency finite-difference synthetics and high-frequency scattering operators. The *three panel* show, for the geometric mean (*top*), the fault-normal (*center*), and fault-parallel (*bottom*) component, the model bias, computed as  $\log\left(\frac{\text{obs}}{\text{sim}}\right)$ , for spectral acceleration at 30 sites that recorded the 1994 Northridge earthquake

S-waves)

$$G_{jk}(f) = \frac{1}{r_{jk}} \cdot \exp\left[-\frac{\pi \cdot r_{jk}}{\beta \cdot Q(f)}\right] \quad (11)$$

where  $\beta$  is the representative shear-wave velocity over the entire path. Eq. (10) can then be solved by adding at least one independent constraint on either source, site or path. A common approach uses the average site factor as a reference, meaning that the logarithm of the sum of all site factors is equal to zero. Other methods select the site with the smallest site factor as reference, or make an a priori reference-site selection based on geologic or other information.

A recent method for site-effect estimation uses microtremor, ambient noise measurements, or aftershock recordings. Taking the spectral ratio of the horizontal component of motion with respect to the vertical component (so called H/V-ratios), these microtremor ratios often show similar site characteristic as inferred by independent methods [108]. However, the exact physical meaning of this H/V-ratio is not well understood, and since H/V-measurements do not directly represent the true soil amplification, those need to be supplemented and calibrated by numerical modeling [69,178]. Nonetheless, H/V-measurements are useful for microzonation studies which the detailed properties of the uppermost soil layers for a small

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 14b

Comparison of observed (*blue crosses*) and simulated (*red squares*) peak-ground acceleration (*left*) and peak-ground velocity (*right*) for 30 strong-motion sites that recorded the 1994  $M_w$  6.7 Northridge earthquake. Note the overall agreement between simulated and recorded motions. Discrepancies at individual stations are due to unmodeled ground-motion complexity

area, thus characterizing the susceptibility of particular locations to strong site effects [70].

Site-correction factors have been derived also from the seismic coda. Because coda waves essentially consist of scattered S-waves, local site amplification of the coda itself should be an average of the S-wave amplification factor for S-waves that arrive from different azimuths under different incidence angles. However, the assumption that the seismic coda consists only of scattered S-waves is too simplistic, because surface waves and strong P-coda waves may contaminate the S-wave coda. Site-effect estimation based only on S-coda measurements should be therefore interpreted with care [108].

A common assumption in seismic wave propagation is that strong and weak motions are affected in an identical manner. Analysis of near-field ground-motions provides evidence for nonlinear effects (i.e. a non-linear stress-strain relationship) [26,64,156], due to lower shear-wave velocity and increased damping within the sedimentary cover [54]. Local (or temporal) modification of the seismic properties of the rock material underneath a site or along the wave path may shift resonant modes to lower frequencies and generate reduced amplitudes. Nonlinearity occurs once a certain ground-motion intensity threshold is exceeded. Previous studies suggest  $PGA > 0.3$  g, or  $PGV > 20$  cm/sec, or peak-strains in excess of 0.06% [9],

roughly consistent with values inferred for strong-motion recordings of the 1989  $M_w$  6.9 Loma Prieta earthquake for which the threshold for large S-wave travel-time delays in repeating earthquakes occurs at  $PGA > 0.4$  g or  $PGV > 40$  cm/sec [156].

Effects of nonlinearity greatly increases the complexity of ground-motions, but only on a very localized scale. Recently, detailed spectrogram analyses of seismic recordings of the 2003  $M_w$  8:3 Tokachi-Oki (Japan) earthquake demonstrate liquefaction, quantified by a dramatically reduced high-frequency contents of the waveforms [55]. However, it is very difficult to establish general scaling laws that account for potential nonlinearity effects. In case of water-saturated loose sands, strong shaking may result in nonlinear soil liquefaction due to a rapid, temporary increase of pore water pressure, resulting in a dramatic loss of soil stiffness. Liquefaction effects are extremely important for earthquake engineering, but have received little attention from seismology in the past.

### Ground-Motion Scaling Relations

Despite the fact that observed near-source ground-motions show complicated time histories and large variability in intensity measures, there is the need in earthquake engineering and seismic-hazard analysis to devise simple approaches for estimating expected ground-motions in future earthquakes. For this reason, ground-motion prediction equations (GMPE's) are developed, providing mathematical expressions that relate shaking intensities to seismological quantities, source-site geometry, and potentially site-specific parameters. Thus, the complexity of the earthquake rupture process, the wave-propagation effects from the source to the site, and the detailed site conditions are condensed into relative simple functional forms, comprising a few parameters that constitute empirical ground-motion scaling relations.

### Development of Empirical Scaling Relations Based on Recordings of Past Events

Using strong-motion observations, ground-motion prediction equations are developed using a number of different parameterizations. The most fundamental form is given as [52]

$$Y = a_1 \cdot e^{a_2 M} \cdot R^{a_3} \cdot e^{a_4 r} \cdot e^{a_5 F} \cdot e^{a_6 S} \cdot e^\sigma \quad (12)$$

where  $Y$  is the ground-motion intensity measure of interest ( $PGA$ ,  $PGV$ ,  $S_A$ , ...).  $M$  is the earthquake's magnitude,  $r$  the source-to-site distance;  $F$  is a parameter that characterizes the type of faulting, and  $S$  captures the local site

conditions.  $R$  is an additional magnitude-dependent distance function which can take on alternative forms, for example [52]

$$R = \begin{cases} r + c_7 \cdot e^{c_8 M} \\ \sqrt{r^2 + [c_7 + e^{c_8 M}]^2} \end{cases} \quad (13)$$

This model contains some of the basic physics of earthquakes (terms with  $M$  and  $F$ ), the attenuation due to geometrical spreading of seismic waves (terms related to distance  $r$  and  $R$ ) and the site conditions ( $S$ ). Due to the approximately log-normal distribution of ground-motion intensities, attenuation relations are parameterized using the natural logarithm of  $Y$ . Correspondingly, the standard deviation of the zero-mean random error term  $\sigma$  is estimated as the standard error of  $\ln Y (\sigma_{\ln Y})$ .

Over the years, different models have been proposed to capture various aspects of the inherent complexity of near-fault shaking. One class of models assumes a functional form whose shape is magnitude-independent for all distances. A simple parametric form is given by [38]

$$\begin{aligned} \ln(Y)_{M,R,F} \\ = a_1 + a_2 \cdot M + a_3 \cdot M^2 + a_4 \cdot \ln(r + a_5) + a_6 \cdot F. \end{aligned} \quad (14)$$

However, many observations show that ground-motion intensities saturate at close distances to the fault, i. e. moderate-magnitude earthquakes ( $5.0 \leq M \leq 6.5$ ) may generate about the same level of high-frequency shaking as large magnitude events ( $M > 6.5$ ). The second class of ground-motion scaling relations captures these observations. For instance, starting from Eq. (14) Abrahamson and Silva [5] propose the relation

$$\begin{aligned} \ln(Y)_{M,R,F} = a_1 + a_2 \cdot M + a_3 \cdot M^2 \\ + (a_4 + f_1(M)) \cdot \ln(r + a_5) + a_6 \cdot F \end{aligned} \quad (15)$$

with  $f_1(M) = a_7 M$ , while Sadigh et al. [157] developed an attenuation model given by

$$\begin{aligned} \ln(Y)_{M,R,F} \\ = a_1 + a_2 \cdot M + a_3 \cdot M^2 + a_4 \cdot \ln(r + f_2(M)) + a_6 \cdot F \end{aligned} \quad (16)$$

where  $f_2(M) = c_7 \cdot e^{c_8 M}$ . The difference between these two scaling relations becomes evident at larger distances ( $r > 50$  km), while for short distances they lead to about the same ground-motion intensities (Fig. 15).

Empirical ground-motion prediction like those presented in Eqs. (14), (15), (16) have been widely applied to

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 15

Observed peak ground accelerations for the Sept 28, 2004  $M_w$  6.0 Parkfield earthquake, compared against five different empirical attenuation relationships. Data are plotted using the geometrical mean of the two horizontal components (fault-normal and fault-parallel) ( $PGA = \sqrt{PGA_{FN} \cdot PGA_{FP}}$ ), and for the maximum of the two components. The median of the observations is generally in good agreement with the empirical predictions, but the data exhibit large variability with much higher (and lower) motions than empirically predicted, independent of the closest distance to the fault. Note that the recording at station “Fault Zone 16” is not shown as it was not available at the COSMOS database. The PGA-value for site “Fault Zone 16”, located at  $\sim 0.6$  km distance from the fault, is estimated to be in the range 2.0–2.5 g [167]

global and regional ground-motion data sets, but a number of observations call for modification to these “generic” models. First of all, attenuation models for different tectonic provinces have been published accounting for variations in the regional geology [7,8,17,18,31,67,175]. While there is the need to distinguish between stable-cratonic areas (like Eastern North America), extensional regimes (like the Basin and Range province in the western US), zones of complex active tectonics (like California), or subduction zones (like in Mexico, Chile, Japan), recent work [7] suggests that data from different tectonically active areas with crustal seismicity can still be jointly analyzed. In certain regions the geologic conditions cause the presence of several of such tectonic regimes over a rather small area (e.g. Italy, Switzerland, Japan) which further complicates the development of adequate ground-motion prediction equations.

Besides the local geology, the source-site geometry greatly influences seismic shaking. In the near-fault

regime, ground-motions are strongly affected by geometrical source-site effects, leading to large long-period pulses of motion termed “directivity pulses” (see Sect. “**Isochrone Theory**”). Recent work includes such directivity pulses in the attenuation equation [170,171]. Large permanent offset of the ground due to the rupture process will also generate long-period large motions; this so-called “fling-step” is distinguished from the directivity pulse [32]. For thrust-faulting earthquakes, the “hanging-wall” effect has been shown to generate very different ground motions [3] for sites located on the hanging-wall than on the footwall (Fig. 3). This effect is explicitly included in several recent attenuation models [3,53].

An intriguing observation has been made following the large surface-breaking earthquakes in 1999 in Turkey (the Aug. 17  $M_w$  7.5 Izmit and the Nov. 12  $M_w$  7.1 Duzce events) and Taiwan (the Sept. 20  $M_w$  7.6 Chi-Chi event): near-field ground-motions were significantly lower than empirically predicted [105]. This counter-intuitive result

can partly be explained by the general differences in stress-release patterns between buried-faulting and surface-rupturing earthquakes. The primary cause for the ground-motion variation between these two classes of earthquakes lies in general differences in the dynamic rupture process and the associated energy balance of the system (see ► [Earthquake Scaling Laws](#)). Ultimately, these effects could be related to depth-dependent fault-zone properties which exhibits highly damaged rocks with intense microcracking and lower seismic velocity close to the surface, but more compliant and less damaged material at depths [22]. Fault-zone structure affect the dynamics of the rupture process [13,21,22,83] and the resulting seismic radiation [141], and therefore strongly influence the resulting ground-motion intensities.

Besides the functional form and the given geological, geometrical, and physical parameters a number of technical issues affect ground-motion scaling equations (a comprehensive review is given in [60]): (i) the choice of the ground-motion intensity measure  $Y$  determines the values for the coefficients  $a_i$  (Eqs. (12)–(16)) derived by regression analysis; (ii) the specific approach for the regression (data fitting) matters (common techniques are weighted non-linear least-squares regression, two-step regression, or random-effects regression); (iii) the data selection criteria for assembling the individual strong-motion database; (iv) data corrections may be applied to the recorded strong-motions (e. g. uniform instrument response for all records, baseline correction, frequency filtering) and also to the meta-data (magnitudes, distances, site information etc.) which represent the independent parameters.

In developing ground-motion prediction equations, a uniform and well-calibrated magnitude definition is particularly important, but in practice often difficult to achieve when merging datasets from various institutions whose magnitude values may not be compatible. The style-of-faulting factor  $F$  in Eqs. (14), (15), (16) is generally well defined, but the site-effect factor  $S$  is often poorly known. One of the most critical parameters in ground-motion scaling is the distance  $r$  between the site and the source. In particular for extended rupture planes, the applied distance metric for the source-to-site geometry becomes crucial; different source-to-site distance definitions are in use [4] but the particular choice for  $r$  in turn will affect the seismic-hazard calculations [163].

In an effort to harmonize and calibrate ground-motion data, related meta-data, and the development of empirical ground-motion prediction equations, the Pacific Earthquake Engineering Research Center (PEER) carried out the New Generation Attenuation of Ground Motions

(NGA) Project (completed in Jan. 2008). In this context, [37] for instance refine Eq. (14) to accommodate the effects of anelastic attenuation when modeling far-distance recordings ( $R > 80$  km) and to include an “effective” magnitude-dependent geometrical spreading (allowing to predict ground-motion amplitudes out to distances  $R = 400$  km). Their data-driven equation includes only terms that are truly needed to adequately fit the data, involving (i) a complicated magnitude-scaling function,  $f_M(M)$ ; (ii) a versatile distance function,  $f_D(R_{JB}, M)$ ; (iii) a site-effect function that includes potential nonlinearity effects,  $f_S(V_{S30}, R_{JB}, M)$ :

$$\ln(Y)_{M,R,F} = f_M(M) + f_D(R_{JB}, M) + f_S(V_{S30}, R_{JB}, M) + \epsilon \cdot \sigma_T. \quad (17)$$

All terms in Eq. (17) are period-dependent;  $M$  is moment magnitude,  $R_{JB}$  is the Joyner–Boore distance (the closest distance to the surface projection of the fault)  $\epsilon$  is the fractional number of standard deviations of a single predicted value of  $\ln(Y)$ , and  $\sigma_T = \sqrt{\sigma_{\text{intra}}^2 + \sigma_{\text{inter}}^2}$  describes the uncertainty by combining the intra-event and inter-event aleatory uncertainty. In this context, the exact definition for the ground-motion parameter  $Y$ , usually taken as the geometric mean of the two horizontal components, has received increased attention. Because of misaligned recording instruments or complicated (multi-)pathing of radiated waves, simple measures of “mean ground-motion” appeared to be incorrect when taking the sensor orientation as installed in the field. Works by [30,39,150] discuss the usefulness of orientation-independent ground-motion measures based on data and numerical simulations.

### Relating Earthquake Source-Scaling to Ground-Motion Prediction

When using empirical ground-motion attenuation relations for predicting the expected shaking level at a given site the analyst needs quantitative information regarding the type of faults and their properties, the fault locations with respect to the site, and the site conditions. Probabilistic seismic hazard analysis (PSHA) requires additional information about the recurrence rate of earthquakes on the chosen faults [111]. Therefore, earthquake statistics (see ► [Geo-complexity and Earthquake Prediction](#)) [111] and earthquake physics (see ► [Earthquake Scaling Laws](#)) [6] are major components for accurate seismic hazard calculations. However, ground-motion prediction Eqs. (14), (15), (16) only contain a faulting-style factor ( $F$ ) and the magnitude dependence as earthquake-source related parameters. A correct estimation of the potential magni-

tudes for earthquakes occurring on the selected faults is the most crucial step in any seismic hazard study. Earthquake physics (see ► [Earthquake Scaling Laws](#)) [6] provides the theoretical foundation for defining these magnitudes and to explain observational data and empirical relations e. g. [106,122,187].

In modern seismic hazard analysis, the magnitude  $M$  relates to moment magnitude,  $M_w$ , derived from the seismic moment as  $M_w = 2/3 \cdot \log M_0 - 6.07$ . Since  $M_0 = \mu \cdot L \cdot W \cdot D$ , source-scaling relations between observable fault dimensions (length  $L$ , width  $W$ , area  $A = L \cdot W$ , average displacement  $D$ ) and magnitude are used in empirical ground-motion prediction for obtaining self-consistent input parameters.

Based on geologic observations it is often possible to estimate the length of a fault, considering also cases with multiple segments that may rupture in individual events or jointly (these cases are then treated in PSHA using logic trees) [188]. Estimating fault width is more difficult; it may be inferred from the location of background seismicity in a crustal tectonic setting, or from modeling interseismic deformation which constrains the fault's locking depth, but often a generic fault width of  $W = [10 - 20]$  km is assumed. Several studies have published earthquake scaling relations between various fault parameters [79,120,122,169,186,187]; these source-scaling relations are not only useful for seismic hazard analysis but also provide important insight into earthquake mechanics (see ► [Earthquake Scaling Laws](#)) [164]. A generic relation between magnitude  $M_w$  and fault area  $A$  (in  $\text{km}^2$ ) is given by:

$$M_w = p + q \cdot \log_{10} A \quad (18)$$

For  $q \equiv 1$ , Eq. (18) is consistent with self-similar constant average-stress-drop scaling (see ► [Earthquake Scaling Laws](#)). Rule-of-thumb values for the coefficients in Eq. (18) are  $p = 4$  and  $q = 1$  (adapted from [187] who find  $p = 3.98$ ,  $q = 1.02$  for strike-slip earthquakes, and  $p = 4.07$ ,  $q = 0.98$  for all faulting styles), leading to a magnitude  $M_w 7$  earthquake for a fault area  $A = 1000 \text{ km}^2$ . However, a number of studies have found considerable deviations from self-similar earthquake scaling [79,122,169], and reported values in the range  $3.97 \leq p \leq 4.39$  and  $0.97 \leq q \leq 1.33$  [120]; these differences strongly affect empirically predicted ground-motion intensities and seismic hazard calculations [188,189]. For instance, [188] proposes  $p = 4.2$ ,  $q = 1$ , resulting in an  $M_w 7.2$  earthquake for  $A = 1000 \text{ km}^2$ , with twice the seismic moment and twice the displacement as an  $M_w 7.0$  rupture with identical source area. Correspondingly, Eqs. (14)–(17) lead to higher ground-motion estimates for the larger event,

consequently also different seismic hazard, due to small changes in the source-scaling relation.

### Quantifying Uncertainty in Ground-Motion Prediction Equations

Analyzing, quantifying and modeling strong-motion uncertainties is a mandatory part of any reliable seismic-hazard study [168]. The variability in source-scaling relations reflects in part the complexity of the earthquake rupture process, treated as an epistemic uncertainty (i. e. as more data become available and seismologists better understand earthquake dynamics, this variability will eventually decrease). The standard deviation of the residuals, obtained when deriving ground-motion prediction equations by regression analysis measures the aleatory variability (randomness) of ground-motion parameters. This standard deviation,  $\sigma_{InY}$ , is then partitioned into two error terms for the intra-event and inter-event variability,

$$\sigma_{InY} = \sqrt{\sigma_{inter}^2 + \sigma_{intra}^2}.$$

If the regression uses the geometric mean of the two horizontal components and the component-to-component variability is needed, a third term  $\sigma_{comp}$  has to be included. The intra-event variability can be further separated into a site-to-site component  $\sigma_{comp}$ , and the remaining variability  $\sigma_0$  (after accounting for source and site effects):

$$\sigma_{intra} = \sqrt{\sigma_s^2 + \sigma_0^2} \quad [52].$$

The standard deviation  $\sigma_{InY}$  has previously been found to be a function of magnitude (e. g. [5,157]) with decreasing variability for increasing magnitudes. However, this counter-intuitive result could be affected by a sampling bias due to fewer near-source strong-motion recordings for moderate-to-large earthquakes. More recent work suggests that  $\sigma_{InY}$  is independent of magnitude [2]. The exact value of  $\sigma_{InY}$  varies between different studies and ground-motion parameters, but is generally in the range  $0.4 \leq \sigma_{InY} \leq 0.8$ . Including this standard deviation in the ground-motion estimation is indispensable to assess the variability in shaking intensity – common practice is to use at least one or two standard deviations. However, for critical infrastructures (e. g. nuclear power plants, nuclear waste repositories), it is not clear where to truncate the ground-motion distribution (i. e. how many  $\sigma$ 's to include, [177]) since very long return periods need to be considered and conclusive physical arguments for upper limits on near-field ground motions have not yet been made. Bommer et al. [33] demonstrate that the choice of the truncation level will significantly affect seismic hazard estimates at very low probabilities (annual frequencies of

exceedance of  $10^{-6}$  and lower), while the effect on hazard at probabilities traditionally used in PSHA (annual frequencies of exceedance of  $10^{-4}$ ) is small. The reason is that low-probability seismic hazard may contain contributions from rare but extreme ground-motion values.

The preceding discussion raises the issue of defining upper bounds of near-source ground motion [33]. For instance, the maximum values for *PGA* in the NGA-database is  $PGA = 1.56\text{ g}$  (for the Tarzana record of the 1994  $M_w$  6.7 Northridge earthquake), but values of over 2 g have been reported for the 2004 Parkfield earthquake [167,168] or the 2003 Miyagi (Japan) earthquake. Note that sites and events showing the largest *PGA*-values generally do not coincide with those showing the highest *PGV*-values. For instance, the largest *PGV*-value reported in the NGA-database is 205 cm/s (observed at station TCU068 for the  $M_w$  7.6 Chi-Chi earthquake, Fig. 4), but the *PGA* at this site was only 0.53 g. *PGV*-values in the NGA-database frequently exceed 75 cm/s, and values of 100 cm/s are not uncommon. Closer inspection of the rapidly growing online databank of near-source recordings, obtained with modern dense observational networks (e.g. the K-Net and KiK-net stations in Japan) may return even higher maximum *PGA*- and *PGV*-values than listed above.

Current research addresses the physical limits to maximum ground motions, imposed by the complexity of the source-rupture process, the wave propagation, the site conditions and the strength of the rock. Investigating the combination of these complex physical processes with numerical methods and large-scale simulations helps to better understand the overall distribution of ground-motion parameters and their complexity.

An innovative observational method to examine maximum ground-motion has been developed by Brune and colleagues [19,46,47,48,49,50], based on precariously balanced rocks. These are free-standing (large) boulders, created by erosional processes, which appear as if small ground-accelerations could overturn (topple) them; this toppling-acceleration can be measured. By also dating the age of these rocks it is possible to determine which ground-motion levels have not been exceeded in the corresponding time interval in this region. These “natural seismoscopes” therefore provide important constraints for maximum shaking levels and probabilistic seismic hazard analysis.

### Comparing Observations with Empirical Predictions

The introduction of this article presents near-field ground-motion observations for two recent well recorded earth-

quakes, the  $M_w$  6.0 strike-slip earthquake in Parkfield (09/28/2004) and the  $M_w$  7.6 thrust-faulting earthquake in Taiwan (09/20/1999) (Figs. 1–4). I now compare these records against empirical predictions for a number of widely used ground-motion attenuation relations. Figures 15 and 16 display recorded *PGA* for the Parkfield event and spectral acceleration ( $S_A^{T=2\text{sec}}$ ) for the Chi-Chi earthquake, respectively. In both cases, the empirical predictions are generally consistent with the median of the observations, but the large scatter in the data also leads to observations occur far outside the standard  $1\sigma$ -bounds of the predictions.

For the Parkfield data, observed *PGA*-values are both higher and lower than empirically predicted (for  $r < 100\text{ km}$ ), and no obvious pattern is visible that may explain the large ground-motion variability (Fig. 15). Peak ground acceleration close to and above 1 g were observed at a number of stations. At one site (station “Fault Zone 16”), the *PGA*-value is estimated to be on the order of 2.0–2.5 g [167]. The plotted *PGA*-values are not corrected or grouped according to the soil classification for each site, i.e. parts of the observed variability can be attributed to site effects. However, much of the variability originates from the particular position of each station with respect to the spatial complexity of the earthquake rupture process, and, to a lesser extent, from localized wave-propagation phenomena.

Examining recorded motions and empirical predictions for the Chi-Chi earthquake reveals an overall consistency between the observed median spectral acceleration ( $S_A^{T=2\text{sec}}$ ) and ground-motion attenuation relations, despite significant scatter in the data (Fig. 16). At large distances ( $R_{JB} \geq 50\text{ km}$ ) many of the recorded motions are significantly larger than any of the empirical prediction, while at distances close to the fault ( $R_{JB} \leq 10\text{ km}$ ) most of the  $S_A$ -values are significantly lower than predicted. This unexpected behavior of lower than-predicted ground-motions for large surface-breaking earthquakes has been recently observed for a number of earthquakes [105], and is attributed to effects of earthquake source dynamics occurring in the uppermost shallow and more compliant crustal layers [126].

These two examples illustrate the large variability of near-source motions recorded at a number of stations for the same earthquake, thus characterizing the intra-event variability described above. Site, path, and source effects are responsible for this large degree of ground-motion complexity, but separating the contributions of each of these effects is difficult. Deciphering the detailed physical processes and corresponding parameters that lead to a specific near-field ground-motion is an active area of research.

Ground Motion: Complexity and Scaling in the Near Field of Earthquake Ruptures, Figure 16

Spectral accelerations (SA) at  $T = 2$  s for ground-motion recordings of the Sept 20, 2004  $M_w$  7.6 Chi-Chi (Taiwan) earthquake, compared against five different empirical attenuation relationships. Data are plotted using the geometrical mean of the two horizontal components (fault-normal and fault-parallel) ( $SA = \sqrt{SA_{FN} \cdot SA_{FP}}$ ). The Campbell & Bozorgnia [53] and Abrahamson & Silva [5] relations contain a hanging-wall factor, indicated by the *solid blue* and *black lines*, respectively; the corresponding regular relations are plotted with *dashed lines*. The median of the observations is consistent with the empirical predictions, but the data exhibit large variability, with much higher (and lower) motions than empirically predicted. Note that at large distances ( $R_{JB} \geq 50$  km) many sites reveal higher-than-predicted spectral accelerations while at very short distances ( $R_{JB} \leq 10$  km) many sites exhibit significantly lower ground-motions.

Ultimately, this will allow us to better model ground-motions and their variability for future earthquakes, a key ingredient for improved seismic hazard analysis.

### Future Directions

This article reviews the complexity of near-field ground motions, generated by the space-time-dependent heterogeneous earthquake rupture process, transformed by wave-propagation through complex geologic structure and inhomogeneous media, and finally subjected to localized site conditions. As a consequence, the waveform complexity recorded at dense strong-motion arrays provides both a challenge and an opportunity for future research.

A largely overlooked aspect of ground-motion complexity pertains to the rotational motions (also called vorticity) of the displacement field. Translational ground

displacements (velocity, acceleration) are recorded as seismograms used for monitoring seismic activity and ground motions; strain measurements capture the deformation of the Earth, but the theoretically predicted [6] ground rotation (a vectorial quantity) has rarely been reliably measured in the past. Observations of rotational motions are challenging, due to their small amplitudes [42] and inadequate instrument sensitivity, but recent work provides evidence that rotational motions are significant [95,97,98,179]. Moreover, they are particularly important for engineering applications [182,183] (see ► [Earthquake Source: Asymmetry and Rotation Effects](#) for a comprehensive review on rotational motions). As improved sensors are developed to measure rotational motions, they may become a new observable for (engineering) seismology, potentially adding complementary information on earthquake source processes, Earth structure,

and ground shaking [98]. For deciphering ground-motion complexity, rotational seismology constitutes a new emerging research field; consequently, the International Working Group on Rotational Seismology (IWGoRS) was formed in 2006 to foster the exchange of ideas, data, and software on rotational seismology.

As strong-motion arrays become more abundant and better equipped, the recorded near-source seismograms provide a wealth of information on the rupture process, the wave-propagation phenomena and the site structure. Harvesting these data to learn more about these complex physical processes will be a research focus for years to come. For example, current earthquake source inversions generally use low-pass filtered seismograms ( $f \leq 1$  Hz) because of incomplete knowledge of Earth structure at shorter wavelengths and the increasing ill-conditioning of the inverse problem as higher frequencies are included. This limitation does not allow proper imaging of high-frequency radiation on the fault, excited at small-scale geometrical complexities or by sudden changes in the dynamic rupture process. Those higher frequencies, however, are particularly damaging to much of the built environment and critical for reliable seismic hazard studies.

Currently, seismologists either estimate earthquake source properties and assume an Earth model, or simplify the source to a known mechanism to understand Earth structure. Future work will increasingly consider earthquake source modeling and imaging of Earth structure as a coupled (joint) inverse problem, potentially including shorter wavelength and/or deriving appropriate stochastic media characterizations. With the advent of high-performance computing facilities and innovative numerical methods (see ► [Seismic Wave Propagation in Media with Complex Geometries, Simulation of](#)) [61,112,149], multi-level optimization strategies will be developed to solve the highly non-linear inverse problem of inferring earthquake rupture dynamics from radiated seismic waves that propagate through heterogeneous media.

Empirical ground-motion equations remain important in engineering practice, but accurately quantifying ground-shaking variability for GMPE's continues to be difficult, despite an increasing number of near-source recordings. It is likely that each future large earthquake, recorded by a dense network, may generate unusual ground-motions outside the commonly assumed standard-deviation of current empirical predictions. Precise and reliable ground-motion estimation is the key challenge for seismologists and earthquake engineers for proper seismic hazard assessment and earthquake loss mitigation in future events. This task requires the ability to model not only median values of ground-mo-

tion intensity, but also to accurately capture their variability. Moreover, it will become increasingly important to not only model scalar ground-motion intensities, but to compute large suites of realistic synthetic near-field seismograms that reproduce the observed ground-motion complexity. Thus, innovative source-modeling approaches are required to capture the complexity of the dynamic rupture process (e.g. [77,120]). Multi-scale dynamic simulations with initial conditions based on stochastic parameter distributions [133,151], need to be coupled to large-scale broadband wave-propagation computations (e.g. [138,139]) for many realizations of heterogeneous Earth models (perhaps with stochastic properties at short wave-lengths). Such simulation-based ground-motion prediction is needed to advance the current practice in seismic hazard assessment.

## Acknowledgments

I am indebted to J. Bühler for generating several figures for this article. J. Ripperger provided simulation data for Fig. 5. Thanks to P. Spudich for computing isochrone quantities and synthetics shown in Fig. 11. Strong-motion data were taken from the COSMOS strong-motion database (<http://db.cosmos-eq.org>). Critical comments and helpful suggestions by J. Clinton, G. Cua, and S. Jonsson greatly improved the article. I am also grateful for constructive reviews by R. Harris and Y. Ben-Zion. Parts of this work was supported by the Southern California Earthquake Center; SCEC is funded by NSF Cooperative Agreement EAR-0106924 and USGS Cooperative Agreement 02HQAG0008. This is SCEC contribution number 1154.

### Glossary

**Infrasound** atmospheric sound waves with frequencies lower than the 20 Hz hearing threshold of the human ear.

**Infrasound array** four or more horizontally separated identical microphones or microbarometers with precisely known locations that optimize the reception of a specified wavelength range.

**Trace velocity** apparent horizontal phase velocity of an acoustic arrival measured by an array.

**Celerity** effective propagation speed of a signal, measured from the ratio of the total range over the total travel time along the great circle path from a source to a receiver.

**Tremor** volcanic signal consisting of a nearly continuous oscillation of the ground and atmosphere, with durations of minutes to years. Harmonic tremor may have multiple distinct spectral peaks.

**LP** Long Period event. Transient volcanic signal with durations of tens of seconds to minutes and distinct spectral peaks.

### Definition of the Subject

Infrasound may be radiated by earthquakes, tsunamis, and volcanoes through the displacement or rupture of Earth's surface and the subsequent flow and excitation of fluids. These complex and sometimes cataclysmic phenomena share some common physics, yet have different ways of converting energy into atmospheric sound. Sig-

nals from earthquakes, tsunamis, and volcanoes captured by the present generation of infrasound arrays are introduced in this chapter through case studies. Contemporary methods used in the analysis, interpretation, and modeling of these diverse signatures are discussed and some of the associated geophysical problems that remain unsolved are considered.

### Introduction

The human ear may perceive sound in the frequency band of 20 to 20,000 cycles per second (Hz). Infrasound consists of acoustic waves in the atmosphere with frequencies lower than the 20 Hz hearing threshold of the human ear. Because of reduced acoustic attenuation and scattering in the atmosphere at long infrasonic wavelengths and the large spatial scales of the physical processes driving earthquakes, tsunamis, and volcanoes, the infrasound frequency band is well suited to the remote monitoring of these events. The ambient infrasound field at any location is rich and diverse, with sources originating from the solid Earth, the ocean, the atmosphere, space-born objects, and human activity [4,39]. These acoustic pressure waves co-exist with non-acoustic atmospheric pressure fluctuations associated with meteorological changes such as wind and frontal passages (e.g. [9]). Sound propagation paths are controlled primarily by the temperature and wind stratification in the lower, middle, and upper atmosphere [16,19,24]. The effective sound velocity of the atmosphere at a given height above the ground may be approximated as the sum of the scalar sound speed, which is proportional to the square root of temperature, and the vector wind velocity, which typically may reach magnitudes of 15–20% of the sound speed in the upper atmosphere. An acoustic waveguide may efficiently direct sound to ground-based stations, and is defined by a high sound velocity layer at the upper boundary and a lower sound velocity layer near the ground. The high temperature of the mesosphere and lower thermosphere (MLT) would always refract infrasound back to the ground, but severe attenuation above ~110 km can suppress thermospheric returns. Waveguides in the troposphere and stratosphere are expected to only transmit primarily along the downwind direction. However, observations suggest that the elevated acoustic waveguide formed by the low temperature zone in the stratosphere may routinely leak energy back to the ground through scattering and diffraction [27,28,29]. Ground cooling and low altitude winds may also produce a stable waveguide in the boundary layer near the ground surface [20,42]. A new generation of global atmospheric specifications designed

for the study of infrasound propagation has been developed by integrating multiple meteorological and upper atmosphere models [19]. Validation and further refinement of these atmospheric models is ongoing [3,43].

## Infrasound Arrays

### Background

Modern infrasound array technology emerged at the turn of the 21st century after the 1996 adoption of the Comprehensive Nuclear-Test-Ban Treaty and the subsequent growth of the International Monitoring System (IMS), which was designed for the detection of clandestine nuclear test explosions [55,61]. An infrasound array generally consists of four or more horizontally separated identical microphones or microbarometers with precisely known locations that optimize the reception of a specified wavelength range. Wind is the most pernicious source of incoherent noise, and infrasound's greatest vulnerability. An array that is sheltered from the wind by forest cover, snow cover, or topographical blocking will have a low noise floor, and provide high sensitivity and robust measurements. If a wind-sheltered site is not found, wavelength-specific wind noise reducing filters have to be designed for the boundary layer conditions at the array site [1,40]. IMS-type infrasound arrays have a maximum distance between sensors of 1–3 km and use sensors with over 100 dB of dynamic range and a flat frequency response between 0.02 and 20 Hz. Portable arrays often have apertures of  $\sim 100$  m or less, and are thus optimized for smaller wavelengths (frequencies  $>1$  Hz). Infrasonic sensors for portable array applications often operate within the 0.1–100 Hz frequency band, and may overlap into the audio band. Infrasound data are typically recorded with GPS time-stamped 24-bit digitizers and are often sent via digital communications to a central processing facility for real time analysis.

### Basic Principles

A number of calibrated microphones, precisely timed and arranged in optimal spatial configurations as arrays, present the best design for recording infrasound. A wavefront is the spatial surface containing sound emitted from a source at the same time. An array relies on the principle that sound along a (possibly curved) wavefront has recognizable features, so that as the wavefront passes through the multiple sensors in an array it is possible to determine the time of passage of a specific waveform feature (for example, the peak of an explosive pulse). From the time of arrival of a waveform feature at each known sensor location, the direction of propagation of the incident wavefront as

well as its apparent propagation speed across the array can be inferred. Once the arrival direction and speed are determined, it is possible to digitally apply time-delays or phase shifts to temporally align all the microphone waveforms along a beam of energy (beamform) to improve the ratio of the signal amplitude to the ambient noise. Based on these fundamental principles, more advanced contemporary techniques permit the extraction of waveform features with a very small signal to noise ratio [12,65].

### Array Design

If two identical microphones spaced some distance from each other record identical waveforms, the two observed signals are perfectly coherent. As the microphone spacing increases beyond the characteristic wavelength of a pulse, the coherence decreases until the waveforms no longer resemble each other. Microphone arrays are designed to detect coherent signals within a specific wavelength range, and the ability of an array to accurately determine the speed and angle of arrival of coherent sound signals depends largely on the sensor distribution relative to the wavelengths of interest. A minimum of three sensors, deployed as an L, are required to discriminate incidence angle. However, a three element array has a very poor angular resolution and leaves no margin for error, as failure of a single sensor will substantially degrade its detection capability. Four or more sensors are preferable, yielding a broader frequency response and better measurement precision.

### Detection, Location, and Signal Identification

Infrasonic signals measured a few kilometers from the source can vary from powerful explosions ( $>10^2$  Pa) that dominate the recorded time series, to a background rumble ( $10^{-3}$  Pa) buried within the ambient sound field. A single infrasonic array can discriminate between a coherent signal arriving from the direction and height of the target source and a competing signal coming from a different angle and elevation [10]. Thus, arrays can 1) separate the coherent sound field from the incoherent ambient noise field, 2) identify and extract a specific infrasonic signal within the coherent ambient sound field (clutter) and 3) separate acoustic arrivals propagating through different waveguides yet originating from a signal source which may be stationary or moving. If two arrays are available, the target signal would be recorded at each array with an arrival angle pointing to the source and an arrival time consistent with the propagation path from the source to the receiver. The two array beams would intersect at the source, thus providing a geographic loca-

tion which would be confirmed and refined with the signal travel time information [25]. Thus two properly sited infrasonic arrays can unambiguously locate a source region and discriminate between sources. By optimizing detection with arrays, performing locations with two or more arrays, and characterizing preexisting sources of clutter, it is possible to acoustically recognize a source with high confidence. If other detection (such as seismic or imaging) and identification [36]) technologies are available, uncertainties in source location and identification drop substantially. This process of signal detection, location, and identification is routinely used successfully by the international community in the monitoring of natural and man-made events [27].

### Acoustic Speed and Velocity

Infrasound studies may refer to the acoustic phase velocity, group velocity, effective sound speed, trace velocity, and the celerity of an acoustic arrival. The first three quantities depend on the sound speed and wind speed in the atmosphere along the source-receiver path. The trace velocity of a signal may be measured directly by observing the apparent horizontal speed and direction of propagation of a signal across an array. The celerity of an arrival is defined as the ratio of range over the travel time, and may be conceived as the effective, or average propagation speed over the complete propagation path. Given a known source-receiver configuration, the celerity may be computed directly. Although it is tempting to use the trace velocity for identifying a given arrival, measurement and calibration uncertainties can make this procedure rather inaccurate for distant sources. Celerity estimates from various infrasonic events with known locations suggests that 1) our knowledge of the atmosphere is presently insufficient to reliably predict all infrasonic arrivals to a station under all atmospheric conditions, and, 2) diffraction and/or scattering can feed acoustic energy to waveguides that are elevated above the ground, and these elevated waveguides may also leak sound back to the ground [10].

### Analysis Method and Scope

Array processing methods allow us to extract coherent signals from the incoherent ambient sound field. One efficient and popular technique for estimating the infrasonic wave parameters is the *Progressive Multi-Channel Correlation* method (PMCC) [12]. This method, originally designed for seismic arrays, is well adapted for analyzing low-amplitude coherent waves within incoherent noise and efficient for differentiating signals of interest from background clutter [22,26]. The PMCC method was

used for array processing of the signals from earthquakes, tsunamis, and volcanoes presented in this chapter.

Acoustic-gravity waves form a class of propagating atmospheric pressure signals which were studied in detail during the early Megaton-yield atmospheric nuclear tests (e. g. [32]). These waves are affected by buoyancy, have periods longer than 50 s, and have unique source and propagation characteristics that are beyond the scope of this paper. The IMS and portable arrays discussed in this chapter are tuned to higher frequencies, so are generally not designed to process acoustic gravity waves with high precision. The reader may refer to [33] for an excellent introduction to gravity and acoustic-gravity waves.

This chapter will also omit the acoustics of structural collapses such as pyroclastics flows from volcanoes, avalanches, landslides, or rockfalls. Although such signals may portend hazardous events (e. g. [79]), this family of acoustic signals are poorly understood and even less well modeled.

### Earthquake Infrasound

Ground vibrations can produce sound in manifold ways. Relative to the atmosphere, earthquakes can act as distributed, supersonic acoustic sources moving at seismic or fault rupture velocities. When seismic surface waves travel through mountainous regions, the predominant source of infrasound is attributed to the re-radiation of pressure waves by topography [48,60,78]. In this case, the earthquake-induced displacement perpendicular to the ground surface can locally generate ground-coupled air waves. The local conversion from seismic waves to the sound pressure has been observed on microbarometers at regional and teleseismic distances [14,15,18,69]. Seismic to acoustic wave coupling at the ground-air interface will be enhanced when the horizontal phase velocity, or trace velocity, of the infrasonic waves and the seismic waves are matched. This type of seismoacoustic coupling can be particularly efficient in sediments and loosely consolidated volcanic environments with a low shear wave velocity [24].

The generation of infrasonic waves from the epicenter region has also been postulated [59,62]. At large infrasonic periods (50–100 s) acoustic-gravity waves from the sudden strong vertical ground displacements have been detected at distances of thousands kilometers from the origin [6,57]. This mechanism would also apply for large submarine earthquakes [30,58]. In all the aforementioned cases, an actual pressure wave is radiated from the ground into the atmosphere. This process is distinguished from microphonics, where the recorded signal is due to the sensor response to accelerations and ground level elevations

independently of any pressure changes occurring in the atmosphere [2,4,45]. In this case, the microphone acts as a seismometer.

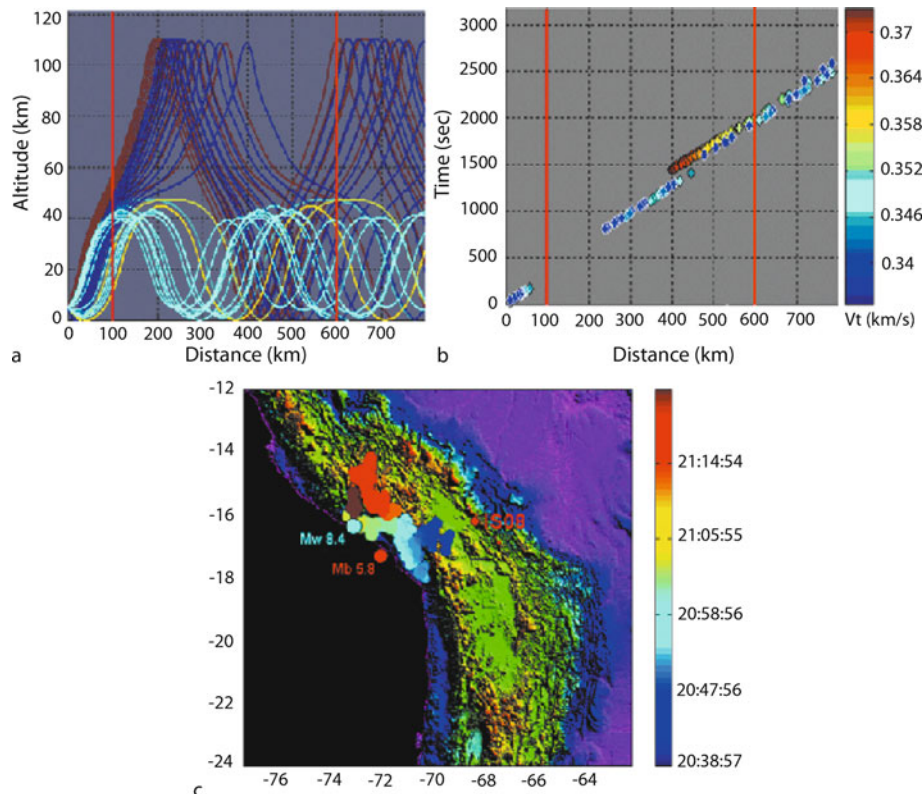

The principles introduced in the discussion of the generation, propagation, measurement, and interpretation of earthquake infrasound are applied to the progressive case studies of the Arequipa earthquake of June 23, 2001, recorded at a range of  $\sim 500$  km, the Mongolia earthquake of November 14, 2001, recorded at a range of  $\sim 1800$  km, and the Chile earthquake of June 13, 2005, detected by multiple infrasonic arrays to a maximum range of 2300 km.

### Case Study 1: $M_w$ 8.4 Arequipa Earthquake Detected by a Single Station

On June 23, 2001, at 20:33:13 UTC, a strong earthquake measuring  $M_w$  8.4 (NEIC) ripped along the coast of south-central Peru. The earthquake origin ( $16.15^\circ\text{S}$ ,  $73.40^\circ\text{W}$ , fo-

cal depth  $\sim 30$  km) was centered along the Peruvian coast about 600 km southeast of Lima and 110 km northwest of Camana (Fig. 1). The Pacific Tsunami Warning Center reported a moderate tsunami struck the Peruvian coast. Infrasonic waves associated with this event were detected for more than an hour at IMS infrasound station IS08 in La Paz, Bolivia ( $16.26^\circ\text{S}$ ,  $68.45^\circ\text{W}$ ) [48].

Due to the relative proximity of the station ( $\sim 500$  km from the epicenter), it was possible to perform relatively direct analyses of the apparent horizontal propagation speed (trace velocity) of the incident wavefield and the arrival angle of the different wave types at the array. The estimated trace velocity ranges from several kilometers per second to the sound velocity, as expected from the arrival of both seismic and infrasonic waves. Although the aperture of the IS08 array is designed for infrasonic wavelengths, array processing also yields the arrival characteristics of seismic waves. The azimuth variation for the seismic waves indicates that the rupture propagated from

Infrasound from Earthquakes, Tsunamis and Volcanoes, Figure 1

Ray traces **a** and travel time curves **b** for infrasonic waves launched almost horizontally from the epicenter area at 5 km height. The red line indicates the propagation range of the rays from the secondary sources to IS08. The color scale indicates the horizontal trace velocity of each ray. **c** Location of the sources of distant generation of infrasonic waves measured from 20:39 to 21:28 due to the  $M_w$  8.4 earthquake and the  $m_b$  5.8 aftershock (Topography data: USGS DEM & Cornell Andes Project). The colored dots indicate the arrival times (UTC) of the infrasonic waves at the station

the northwestern to the southeastern part of the fault at a speed of 3.3 km/s. However, the predominant source of infrasound is attributed to pressure waves radiated by the Andean Cordillera. This is consistent with the theory that the vibration of mountains can generate infrasonic waves which travel to the station along atmospheric waveguides. By performing basic inversions, the azimuth variation of the infrasonic waves can then be interpreted as a distribution of secondary sources along the highest mountain ranges. Using the azimuth and arrival time determination, the infrasonic radiation zone was estimated to be  $\sim 100$  by 400 km long.

### Case Study 2: $M_s$ 8.1 Mongolia Earthquake Detected by a Single Station

On November 14, 2001, at 09:26:10 UTC, a magnitude  $M_s$  8.1 earthquake rattled the mountainous western Chinese region near the Qinghai-Xinjiang border. The earthquake origin ( $36.0^\circ\text{N}$ ,  $90.5^\circ\text{E}$ , focal depth  $\sim 5$  km) was centered along the northern margin of the Tibetan Plateau at the foot of the Kunlun Mountains where substantial surface fault ruptures have occurred before. Coherent infrasonic waves associated with this event were detected for more than one hour at a distance of 1800 km from the epicenter by IMS station I34MN in Mongolia [49].

Building on the conclusions from the Arequipa earthquake analysis, both an inverse location procedure and a complete simulation of the radiated pressure field are used to locate the distant source regions. The input parameters of the location procedure include the measured signal azimuths and arrival times as well as the origin time and coordinates of the main shock. The propagation model is based on a constant velocity of 3.3 km/s for seismic surface waves propagating from the epicenter area. The atmosphere is specified by sound velocity and wind speed profiles obtained from the time-varying MSISE-90 and HWM-93 empirical reference models [25,38], and the infrasonic wave propagation was performed using 3D ray theory [73,74].

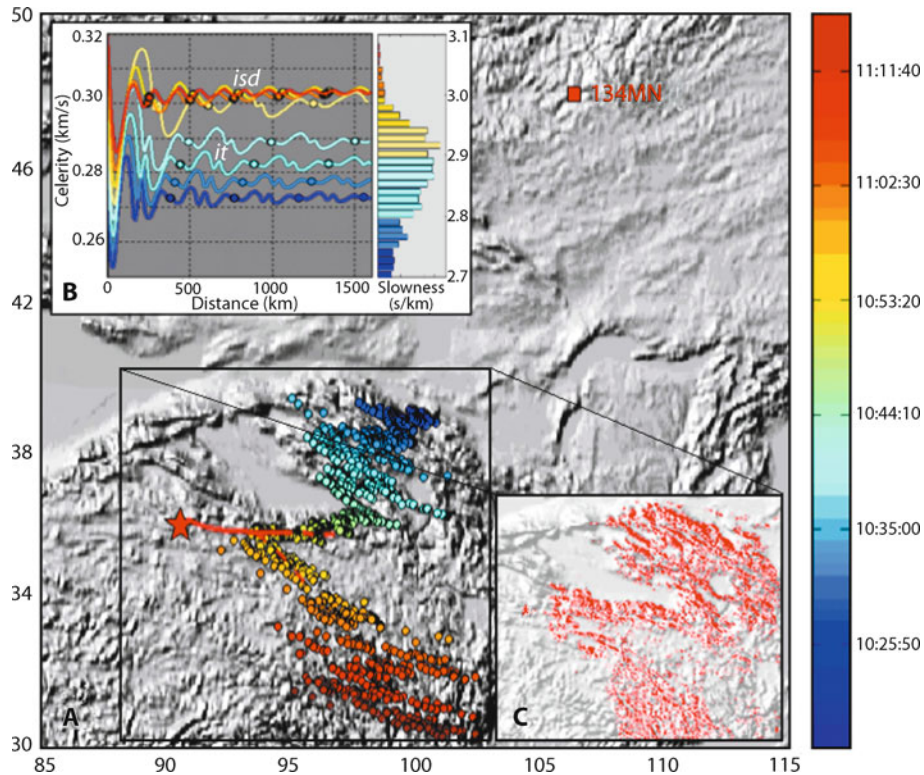

As shown by Fig. 2, two dominant guided wave groups are predicted: (i) thermospheric arrivals refracted below 120 km for slowness ranging from 2.7 to 2.9 s/km (trace velocities of 0.345–0.37 km/s), and (ii) stratospheric ducted waves refracted below 45 km for slowness values ranging from 2.9 to 3.1 s/km (0.32–0.345 km/s). Such trapped waves can be observed when the source is located above the station [75].

The slowness distribution derived from the measured trace velocity presents a maximum between 2.85 and 2.95 s/km. These values correspond to a celerity of 0.28–

0.30 km/s. The component of the wind transverse to the propagation direction deflects the rays from the original launch azimuth by  $\sim 2^\circ$ . This deviation is taken into account by correcting the measured azimuths. Figure 3a reconstructs the distant source regions using a celerity of 0.29 km/s. The spatial extent of the radiating zone is estimated to be  $9^\circ$  in latitude and  $10^\circ$  in longitude. The source distributions fall into line with the Qilian range, then borders the eastern part of the Qaidam basin and join the Kunlun range. To the south of Qaidam basin, more scattered source distributions follow the Bayan Har mounts.

To verify these locations, a simulation of the radiated pressure field was performed. First, the inversion for the rupture propagation along the fault uses a slip patches model developed by [7]. Using this extended model of rupture, synthetic seismograms of surface waves are computed using a discrete wavenumber method [8,70,72] with a one-dimensional regional crust model. The source modeling displays a strong directivity, with most of the seismic energy radiated along the main strike-slip of the fault and a maximum ground velocity placed  $\sim 300$  km to the east of the epicenter [53]. To compute the acoustic radiation of the topography surrounding the fault, the topography is divided into adjacent strip-line sources radiating energy proportional to the simulated ground velocity [41].

Compared to the wavelength of the seismic surface waves ( $\sim 60$  km), the area of each source element ( $3 \times 3 \text{ km}^2$ ) is small enough to consider isophase vibration. Due to the low frequencies of interest ( $kL > 1$ ,  $k$  and  $L$  defining the acoustic wavenumber and the side of each cell, respectively), source elements radiate essentially simultaneously with a pronounced directivity. Based on this assumption, the topography is divided in adjacent strip-line sources of length  $L$  radiating energy proportional to the simulated ground velocity  $V_l$  normal to each surface element  $l$ . Considering a distance of observation  $R_l$  significantly greater than  $L$ , the Fraunhofer approximation of the Helmholtz–Huygens integral yields:  $p_k(t) = iL(k\rho c)/2\pi \sum_{l=1}^N V_l(t_l) \Delta h_l (e^{-ikR_l})/R_l [\sin(k\hat{x}_l L/2)/(k\hat{x}_l L/2)] e^{[-ikco(t-t_l)]}$ , where  $t_l$  is the origin time of each source element,  $p_k(t)$  is the predicted pressure at the arrival time  $t$  ( $t = t_l + R_l/c_{\text{eff}}$ ),  $c_{\text{eff}}$  is the celerity in the atmosphere corresponding to the predicted wave guides (0.29 km/s),  $\rho$  is the air density,  $co$  is the sound speed,  $\Delta h_l$  if the height difference of the radiating surface and  $\hat{x}_l = \sin(\theta_l)$  is given by the angle  $\theta_l$  between the outward unit normal and the source/receiver vector. Note that the sinc function in the predicted pressure reaches its peak when the surface normal and the source-receiver vector are aligned. Thus the Fraunhofer approximation provides a means of evaluating a discretized source pressure term

Infrasonics from Earthquakes, Tsunamis and Volcanoes, Figure 2

**Propagation modeling and location of distant source regions of infrasonic waves (Topography data: ETOPO30). A** The colored dots indicate the sources location according the detected arrival times (UTC) of the infrasonic waves. Taking into account uncertainties due to the measurements and the propagation modeling, a maximum location error of 20 km is estimated for each dot. **B** Predicted celerity models versus slowness and propagation range for a source located at the main shock epicenter. The definition range of the celerity is given by the maximum of the slowness distribution derived from the measured trace velocities (Fig. 2). The circles indicate the locations of the ground reception of both ducted stratospheric (*isd* arrivals) and thermospheric paths (*it* arrivals). **C** Normalized surface pressure distribution along the Kunlun fault

for radiating strip lines of topography, where each strip will yield its largest pressure contribution when its displacement is along the source-receiver direction.

Using the simulated ground velocity and this approximation of the integral formulation, the predicted surface pressure distribution matches reasonably well with those obtained with the inverse location procedure (Fig. 2). Thus, the azimuth variations and the expansion of the signal duration suggest that the Kunlun Mountains acted as sources of infrasonic waves over a radiating zone of  $\sim 1000 \times 1000$  km. The maximum seismo-acoustic coupling is found to the east of the main shock epicenter, which is consistent with the seismic radiation pattern.

### Case Study 3: M 7.8 Chile Earthquake Detected by Multiple Stations

On June 13, 2005, a major earthquake occurred in the mountainous section of the Tarapaca Province (North

Chile) ( $19.93^{\circ}\text{S}$ – $69.03^{\circ}\text{W}$  at 22:44:33 UTC, M7.8, focal depth 117 km, USGS). The epicenter was located deep under the Andes mountain range, near Chile's border with Bolivia. At large distances from the epicenter, coherent infrasonic waves were detected by IMS infrasonic stations I08O-Bolivia, I09BR-Brazilia, and I41PA-Paraguay (410 km, 2300 km, and 1420 km from the epicenter, respectively). The multiple station recordings at different ranges and azimuths from the epicenter allowed a more complete reconstruction of the infrasonic source regions compared to what was obtained using one single station [52].

To invert for the main source regions of infrasonics, the location procedure requires the signal azimuths and arrival times measured independently by each station and the origin time and coordinates of the epicenter. A joint inversion for the source area using data from all three stations simultaneously was not used due to the pronounced directivity of the radiation pattern. Infrasonics

Infrasound from Earthquakes, Tsunamis and Volcanoes, Figure 3 Location distribution of distant source regions of infrasonic waves generated by the December 26, 2004 Sumatra earthquake. Color scales are normalized. The red triangle indicates the location of the IS52 station. Source locations are computed for seismic surface waves and tsunami waves originating from the maximum of coseismic slip

propagation was simulated using a spherical coordinate 3D ray theory formulation which accounts for topography and the spatio-temporal variations of the horizontal wind terms along the ray paths [17]. Atmospheric absorption is integrated using altitude dependent attenuation coefficients [66,67]. The atmospheric conditions of June 13, 2005 are described by the sound velocity and wind speed profiles provided by the time-varying Ground to Space (G2S) atmospheric specifications [19].

As in the previous case study, the slip patches model developed by [72] is used to check the association of regions radiating infrasound with areas of strong ground motion. The simplest extended elliptic source model able to explain the teleseismic seismograms is found, and the first and second order characteristics of the event (location, depth, duration, focal mechanism, and refined kinematic parameters such as spatial slip distribution on the fault and rupture velocity) are calculated from teleseismic body waves. Then, from the resulting extended source model, low frequency synthetic seismograms (period lower than 10 s) are computed on a grid in the vicinity of the epicenter using the discrete wavenumber method and a one-dimensional regional crust model [8]). Finally, the root mean square of the maximum velocity of the vertical and horizontal components of the surface waves is used to reconstruct the areas of strong ground motion.

The reconstructed source regions confirm that most of the energy is radiated by the vibration of land masses near the epicenter, which is consistent with the predicted areas of strong ground motion. No clear signal originates from the Altiplano. Southern high mountain ranges, even far from the epicenter, also generated infrasound. The Central Cordillera extending to altitudes greater than 5000 m efficiently produced infrasound in the direction of I09BR, although the predicted seismic movement is low in this region. Consistent with previous observations, these results suggest an amplification of the ground displacement caused by the topography surrounding the Altiplano. Such site effect could not be predicted from our seismic source modeling since the topography is not considered. The reconstructed source regions extend over  $\sim 800$  km from the Central Cordillera to the Occidental Cordillera. The spatial extent of the radiating zones differs from one station to another, which confirms the influence of shadow zone effects for nearby stations and the directivity of the radiation. As in the previous case study, the topography is modeled as a succession of adjacent strip-line sources, so that mountain ranges radiate energy essentially simultaneously with a pronounced directivity and may generate infrasound arrivals with different azimuths. This suggests that the amount of energy radiated in the direction of the receiver and the duration of the signals also depends on the orientation of the highest mountain ranges around the station.

### Summary of Earthquake Infrasound

The three case studies presented in this section build in complexity and sophistication while producing consistent results. High mountain chains rattled by large earthquakes reliably radiate infrasound and have acoustic radiation patterns that depend on the chain's orientation. Substantial contributions to the sound field are expected from steep topography, which would primarily radiate perpendicular to exposed faces. For large earthquakes occurring in mountainous regions, infrasonic measurements are valuable for the analysis of the remote effects of earthquakes and site effects over broad areas. In remote regions where there is a lack of surface motion instrumentation, infrasonic observations could lead to a rapid determination of the regions where the seismic movements are the largest.

### Tsunami Infrasound

Previous study has shown that significant infrasound is produced by breaking waves (surf) and the complex interaction of open-ocean swells (microbaroms, e. g. [76]).

However, interest in tsunami infrasound emerged when IMS infrasound arrays in the Pacific and Indian Oceans recorded distinct signatures associated with the December 26, 2004 Great Sumatra-Andaman earthquake and tsunami. As in the case of mountains stirred by continental earthquakes, islands which undergo significant surface displacements during submarine earthquakes can also produce infrasound. It also appears that the initiation and propagation of a tsunami may produce low frequency sound near the epicenter as well as along coastlines and basins. In some environments, precursory sound could potentially be used for confirmation and early warning for tsunamis. This field of research is still in its infancy, and our interpretations leave much room for further development. Substantial complexity is involved in the separation of the earthquake-generated infrasound from the sound that may be produced by the genesis and propagation of the tsunami.

### Sumatra Earthquake and Tsunami

The magnitude 9.1 Great Sumatra-Andaman earthquake of December 26, 2004 [63] is the largest earthquake since the 1964 magnitude 9.2 Great Alaska earthquake, and produced the deadliest tsunami in recorded history. In contrast to the Great Alaska earthquake, the Great Sumatra earthquake and tsunami were recorded globally by multiple digital sensor networks in the ground, ocean, atmosphere, and space. Further, the resulting signals were analyzed and interpreted using far more advanced computational capabilities than were available 40 years ago. Although the study of tsunami infrasound rose in the wake of the Sumatra-Andaman event, many fundamental questions on the generation of these deep sounds remain unanswered.

The clearest infrasonic signatures associated with the Sumatra event were captured by the station in Diego Garcia (IS52GB, Fig. 3), which recorded (1) seismic arrivals from the earthquake, (2) tertiary arrivals (T-phases) that propagated along sound channels in the ocean and coupled back into the ground, (3) infrasonic arrivals associated with either the tsunami generation mechanism near the seismic source or the motion of the ground above sea level, and (4) deep infrasound (with a dominant frequency lower than 0.06 Hz) coinciding with the propagation of the tsunami into the Bay of Bengal [30,51]. These signals were all recorded by the pressure sensors in the arrays. The seismic and T-phase recordings are a result of the sensitivity of the microphones to ground vibration (microphonics), whereas the infrasound arrivals correspond to sound propagating through atmospheric waveguides.

Similar, but not identical arrivals were observed at Diego Garcia (range of  $\sim 2900$  km) during the March 28, 2005 Nias earthquake (M8.7, which produced a non-destructive tsunami). Yet only infrasonic arrivals were observed from the April 10, 2005 Mentawai earthquakes (M6.7 and 6.5, no reported tsunami), indicating that above-water ground motion from submarine earthquakes can produce sound in the Sumatra region. The deep infrasound from the Bay of Bengal region following the Sumatra earthquake suggests that sound can be produced by the interaction of a tsunami with coastal bathymetry.

To reconstruct the main source regions of infrasound recorded at IS52 for this event, the input parameters of the location procedure included the measured signal azimuths and arrival times, and the origin time and coordinates of the epicenter. As described in the previous section, standard velocity models were used to describe the propagation of the seismic surface waves and the propagation of infrasound through the atmosphere in the direction of IS52. However, the speed of propagation of the tsunami from the epicenter needs to be added to the inversion procedure. For the December 26, 2004 earthquake, a velocity of 3.3 km/s is used for the seismic surface waves, and a speed related to the square root of the water depth for the tsunami waves.

Using the infrasonic arrivals to IMS station in Diego Garcia and Palau, the location inversion for the high frequency infrasonic component corresponded to sound originating from the mountains and possibly from the epicenter. However, a unique characteristic of the Sumatra earthquake is that it generated large amplitude coherent waves with a dominant period of  $\sim 30$  s over four hours. The infrasonic source locations derived from the inversion procedure indicate that the tsunami also created infrasonic waves at lower frequencies when it propagated in shallower water as it reached the Bay of Bengal (Fig. 3). Even lower-frequency acoustic gravity waves, with periods of hundreds of seconds, may have been produced by the underwater ground displacement [58]. For wavelengths which are much greater than the water depth, the ocean surface displacement nearly matches the submarine ground displacement above the fault plane (e. g. [44]) and may efficiently radiate long-period pressure waves into the atmosphere.

### Miyagi-Oki Earthquake and Tsunami

The events off the coast of Sumatra were  $\sim 3000$  km from the closest infrasound station in Diego Garcia. The longer ranges, coupled with the fact that all infrasound stations used in those studies were transverse to the axis of Suma-

Infrasound from Earthquakes, Tsunamis and Volcanoes, Figure 4 Estimated infrasound source locations associated with ground vibration, tsunami genesis, and the interaction of the tsunami with the coastline. The squares represent stratospheric arrivals with a celerity of 0.3 km/s. The diamonds are also stratospheric arrivals but with the celerity of 0.32 km/s predicted for that azimuth. The circles are thermospheric arrivals with a celerity of 0.27 km/s. The triangles are stratospheric arrivals with a celerity of 0.3 km/s, but with a delay time attributed to seismic seiche formation. The color of the symbols indicates the arrival time in seconds since the earthquake's origin time. The topography is from NOAA ETOPO2 data

tra, caused uncertainty in the ability to discriminate between sounds potentially produced during tsunami genesis at the ocean surface and the sounds produced by the earthquake-induced vibration of mountains and islands. In contrast, IMS infrasound station IS30 in Japan (Fig. 4) is optimally situated to recognize the different source regions of infrasound associated with the Miyagi-Oki earthquake and tsunami.

The magnitude 7.2 Miyagi-Oki earthquake occurred on August 16th, 2005 at 02:46:28 UTC. The epicenter was off the coast of Japan near Honshu (38.251°N, 142.059°E), with an estimated depth of 36 km. The earthquake caused landslides, ~60 injuries, as well as power and transportation disruptions. A local, nondestructive tsunami was observed on the coast of northern Japan with a wave height

of ~10 cm. Because of its auspicious location, station IS30 can use the angle of arrival information derived from array processing to identify infrasonic arrivals originating from mountain chains, the earthquake epicenter (which is used as the tsunami epicenter), and the coastline of the Bay of Sendai.

In contrast with the Sumatra event, where substantial energy was observed in the deep infrasound band (0.002–0.1 Hz), most of the infrasonic energy for the smaller Miyagi-Oki event was above 0.5 Hz. The arrival azimuths at IS30 range from  $-5^\circ$  to  $28^\circ$ , and do not have a well-defined temporal sequence, suggesting multiple sources, propagation paths, and possible wave types.

Using the ground to space (G2S) atmospheric profiles [19] specific to the station location and time of the event, source locations [30,51] were estimated for the infrasonic arrivals shown in Fig. 4. The first infrasonic arrivals would correspond to acoustic waves coupled to the atmosphere from the seismic vibration of land masses [49]. For ranges less than 330 km and northerly arrivals between  $-5^\circ$  and  $18^\circ$  (measured clockwise from north), the time- and site-specific G2S specifications do not support thermospheric arrivals at the station, so the observed arrivals would propagate in stratospheric waveguides with a celerity of 0.3 km/s. In contrast, for arrival azimuths of  $\sim 18^\circ$  to  $28^\circ$  originating offshore, thermospheric arrivals are also supported for ranges greater than 330 km, although the celerity of stratospheric arrivals is faster.

Multiple wave propagation paths are invoked to produce the temporal and frequency distribution of the infrasonic signals observed at IS30. The squares shown in Fig. 4 correspond to seismic vibrations radiating acoustic energy into stratospheric waveguides, thereafter propagating with a celerity of 0.3 km/s, the diamonds to stratospheric arrivals with a celerity of 0.32 km/s, and the circles correspond to thermospheric arrivals with a celerity of 0.27 km/s. Inclusion of seismic speeds made a negligible difference, as it offsets the locations by <6 km. As expected, many of the arrivals originate from land, and are consistent with the predicted seismic intensity [13,71]. Of more relevance to this paper, clear stratospheric and thermospheric arrivals arrive from the perimeter of the epicenter, which is assumed to be the region of tsunami genesis. These results are consistent with the proposed infrasonic source locations obtained by [30] for the Sumatra earthquakes, and support the idea that ocean surface displacements associated with submarine earthquakes produce infrasound [58]. The possibility that vertical ocean displacements near the epicenter may radiate sound suggests that infrasound signals may be potential discriminants for tsunami genesis.

The later arrivals (shown as triangles in Fig. 4) originate from the mountain regions to the north of the Bay of Sendai when stratospheric and thermospheric arrivals are assumed. Yet, analyses of the Great Sumatra earthquake suggest that the Bay of Bengal produced deep infrasound, and the possibility that the Bay of Sendai may also act as an acoustic source is considered. The triangles in Fig. 3 contour the coastline of the northern Bay of Sendai when a combination of a delay time and stratospheric apparent propagation speeds are considered. For a celerity of 0.3 km/s, the inferred delay time is  $\sim 250$  s. This would require an acoustic generation process that requires  $\sim 4$  min to be established over a coastal region  $\sim 100$  km long. The earthquake occurred in a shallow region, which corresponds to slow tsunami propagation speeds of  $\sim 0.05$  km/s. This would mean the tsunami would have traveled at most 12 km in 250 s, which is not enough time for the tsunami to reach the coastline and produce these signals. Thus the interaction of the small tsunami with the coastline is eliminated as a possible source.

A plausible ensonification mechanism is the local production of coastal waves by the earthquake, as in the generation of seismic seiches [5,56]. Low frequency radiation from enclosed bodies of water have been proposed by other authors [9,46]. For the Miyaki-Oki earthquake, substantial water displacement in shallow regions of the bay is strongly suggested by acoustic sources above the water near the coastline (blue and green arrivals in Fig. 4). Satellite imagery shows that the northern part of the Bay of Sendai has an abundance of lakes, bays, man-made harbor structures and rivers which may sustain seiches. Lower order seiche modes would take minutes to be established, but higher-order modes and coupled oscillations associated with the narrower of the volume dimension could sustain an ensonification process akin to microbarom generation from the ocean (e. g. [76]). Alternatively, the triangular symbols in Fig. 4 would should be shifted  $\sim 75$  km North of their shown location.

### Summary of Tsunami Infrasound

These two case studies strongly suggest that submarine earthquakes and the water level changes they induce can produce low-frequency sound. The sound may be radiated from the ocean surface during the tsunami genesis, produced by the vibration of land masses near the epicenter, or be excited by the interaction of seismic and water waves with the coastline, shallow bathymetry, and harbors.

There is some potential for using infrasound in conjunction with other technologies for remote tsunami monitoring. The effective propagation speeds of tsunami

( $\sim 50$ – $200$  m/s) and sound waves ( $\sim 300$  m/s) yield an advance warning time of at least 1.7 s/km. At 100 km, sound leads the tsunami by at least 170 s, but some of this time would be taken up by signal transmission, processing and identification, leaving less than one minute to issue an alert. However, infrasound may provide early warning in areas within shallow basins or further than a few hundred kilometers from the tsunami source region.

### Volcano Infrasound

The previous sections discussed how earthquake infrasound acoustically couples solids and gases, and tsunami infrasound couples solids, liquids, and gases. Similarly, a volcano can transmit information about its current eruptive state through vibrations induced in the ground, volcanic fluids, and atmosphere. However, there is a great deal of ambiguity about the composition of the acoustically active volcanic fluids, which may vary from vesiculated magma, through gas-ash mixtures, to steam. Although a sealed volcanic conduit can produce faint sounds through earthquakes, once the volcanic plumbing breaches the surface it can broadcast infrasound quite unambiguously.

### Basic Principles

The birth of volcano infrasound research may be traced to the cataclysmic 1883 eruption of Krakatoa, which triggered a series of interdisciplinary, international geophysical studies of the pressure signals produced by the volcano [77]. Barometric records observed throughout the US, Europe, and Russia, and reports of cannon-like sounds in surrounding islands (as far as Diego Garcia and Rodrigues Islands) demonstrated for the first time the ability of low frequency sound to propagate for thousands of kilometers.

Infrasonic signals originating inside magma conduits contain information about the pressure fluctuations driving eruption processes. These signals may be broadly categorized as explosions, long-period events, and tremor. Very large eruptions can also produce acoustic gravity waves [34,68]. Explosions are impulsive and have durations of seconds, long period events are more emergent than explosions, have distinct spectral peaks, and may last seconds to minutes, and tremor signals are sustained atmospheric vibrations that can persist from minutes to years. Decades ago, volcano seismology identified tremor and long-period events as signals indicative of near-surface intrusion of volcanic fluids (e. g. [11]). In contrast, the first infrasonic measurements of tremor from Sakurajima

were published in [64]. As the sensitivity of instrumentation and sophistication of analysis methods increased with advancing technology, the catalogue of known volcanic sounds has expanded and the ability to remotely detect hazardous eruptions has extended. Ongoing monitoring efforts suggest that relatively gentle Hawaiian and mild Strombolian activity may be consistently observed from a range of  $\sim 10$  km [20] and strong Strombolian, Vulcanian and Plinian eruptions from distances of tens to hundreds of kilometers [31,50,54,68].

The difficulty with modeling and interpreting volcanic sounds is that there is a lot of ambiguity in the geometry, composition, thermodynamics, and phase (solid, liquid, gas, or a mixture) of the volcanic interior preceding and during an eruption. In addition, there are many possible ways of exciting volcanic fluids into oscillation through unsteady and transient flow. As examples of these complications, some possible ways of exciting tremor signals in a magma conduit are described. Tremor signals are endemic to volcanoes, and are generally attributed to magma intrusion. Some plausible driving mechanisms of tremor signals and the physical properties of the materials inside volcanic pipes are discussed. In the following example, it is postulated that the harmonic spectrum of tremor events is caused by the acoustic resonance of the fluid within the magma conduit of Arenal volcano, Costa Rica [23]. The possible relationships between observed signals and the gas content of the melt, the physical conditions inside the volcano, and the flow dynamics of the volcanic fluids are discussed.

### Case Study: Tremor Signal at Arenal Volcano

This section hopes to provide an overview of the complexities of modeling volcanic sounds by considering the frequency changes in a harmonic tremor signal recorded at Arenal volcano, Costa Rica. Figure 5 shows a section of the infrasonic tremor signal shown in [23]. This signal is illustrative of most of the tremor recorded during April–May 1997 by a three-element array of infrasonic sensors and a five-element array of seismometers [35].

The prominent features of the Arenal tremor are the harmonic character of the spectra and the oscillation of the spectral bands with time. This oscillation of the spectral bands about an equilibrium value is referred to as gliding. Since steady flow cannot generate acoustic waves, it must be the pressure, volume, and flow fluctuations of the magma injection process that are driving the infrasonic signals. It is possible that the gliding of the spectral bands is caused by time-varying changes in the flow regime or the physical properties of the material in the conduit. The

resonant magma conduit model of [21] is used to explore the ramifications of having changes in the conduit length, flow velocity of a gas and in the void fraction of a magma-gas mixture.

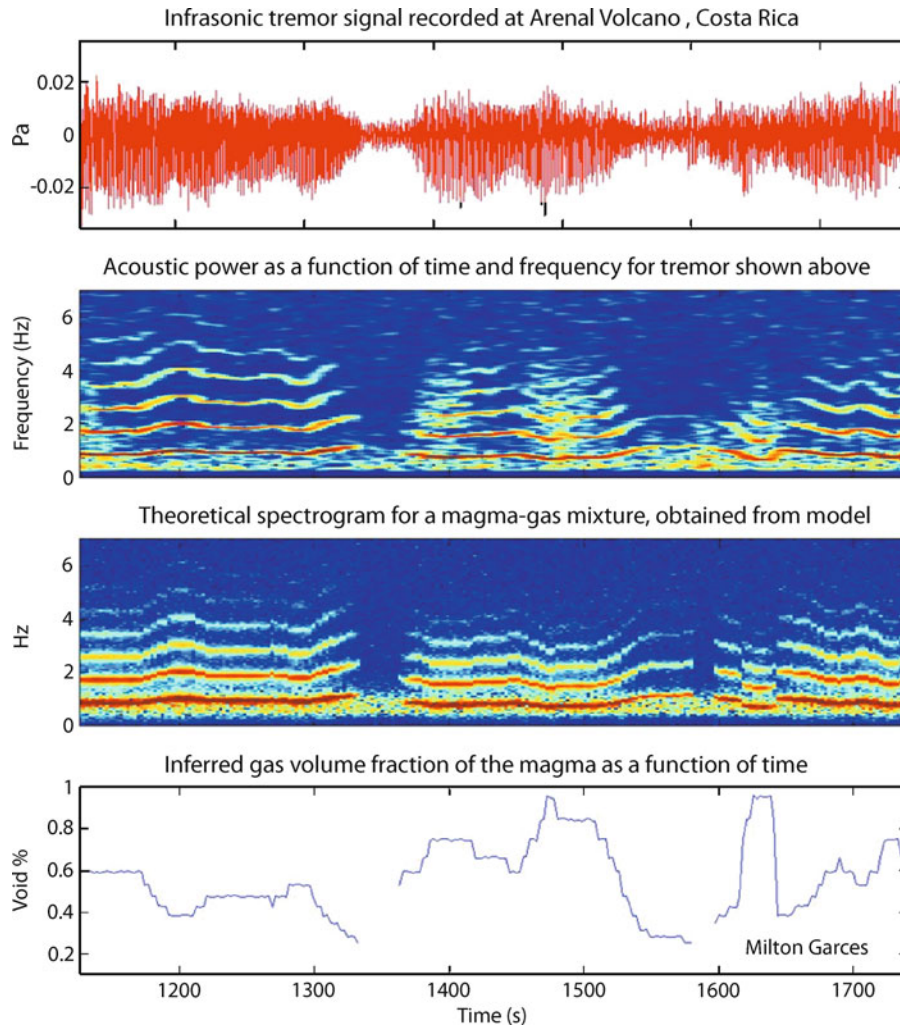

The tremor signal shown in Fig. 5 lasts over ten minutes and is not a transient event. Attempts to model the spectra with a random continuous source, as successfully done for Pavlof volcano [24], failed at Arenal because of the sharpness of the spectral peaks and the rapid rolloff at higher frequencies. The tremor signal appears to be sustained by a source mechanism that is triggering repeatedly in time. The source region may consist of a compliant gas volume within a magma-filled conduit. A bubble may form around a corner or in a constriction in a magma-filled conduit, where fluid acceleration may generate relatively stable gas-rich pockets. These cavities will be sensitive to flow fluctuations, and may act as effective acoustic sources [21].

Lava flows at Arenal and incandescent pieces ejected during explosions strongly suggests an open magma conduit associated with the infrasonic recordings. However, there is some ambiguity on whether the acoustically active part of the conduit is filled with a magma-gas or an ash-gas mixture. The source region is placed at the lower part of the magma conduit, and it is assumed that it ensonifies the magma-gas mixture above it. Although for the Arenal signal there is evidence for a buried tremor source [35], it may also be possible to have efficient atmospheric excitation from jet flow above the vent during more powerful eruptions [31]. For the purposes of our discussion, a two-layer, open vent solution representing a slow-velocity, gas rich magma floating atop a less vesiculated layer is used, as developed in Sect. 4 of [21]. The source region at the bottom of the conduit could correspond to a constriction in the conduit, where cavitation may occur due to fluid acceleration.

The sound speed of a liquid gas mixture is a strong function of the amount of bubbles, or the void fraction, in the mixture. For high void fractions, the sound speed of a magma-gas mixture may reach sound speeds of tens of meters/second, and sound would be heavily attenuated. For a resonant fluid column of length  $L$ ,  $f_n = n(1 - M^2)c/(2L)$ , where  $f_n$  is the resonant frequency of the  $n$ th spectral peak,  $M$  is the Mach number, or ratio of the flow speed to the sound speed, and  $c$  is the sound speed of the fluid.

Assuming a gas-rich magma inside a resonant magma conduit, the changes in the spectral peaks of the tremor signal may be attributed to changes in the amount of exsolved gas in the melt (Fig. 5), which would dramatically change the sound speed  $c$ . The tremor signal would cease

Infrasound from Earthquakes, Tsunamis and Volcanoes, Figure 5  
 Recorded acoustic signal, spectrogram, synthetic spectrogram, and one possible interpretation for a harmonic tremor signal observed at Arenal Volcano, Costa Rica

if the mass flux stops or becomes steady. It is unlikely that there is only gas inside the conduit because the acoustic attenuation in the gas would not be sufficient to explain the rapid amplitude decay with frequency. However, it is possible to have a gas-ash mixture, in which case it may be plausible to also explain the gliding with a change in the Mach number of the flow or a variation in the length of the resonant portion of the conduit [21].

Attenuation coefficients for dusty gases introduce an additional number of poorly characterized physical parameters, adding further ambiguity to our interpretations. It is due to these and many other complexities in modeling volcanic systems that the science of volcanology has evolved towards the synergy of geophysical observations

and geological parameters [37]. Some of the primary goals of volcanic studies are to permit reliable eruption forecasting, hazard assessment, and early warning. Although it is difficult to forecast an eruption without a clear understanding of the physical processes associated with precursory activity, it is possible to rapidly identify a powerful hazardous eruption and provide early warning.

#### Prototype Operational System: ASHE

The Acoustic Surveillance for Hazardous Eruptions (ASHE) proof-of-concept project seeks to develop and evaluate the potential for robust, operational infrasonic remote sensing of volcanic eruptions. In contrast to

other ground-based volcano surveillance systems, the autonomous ASHE arrays are sited tens to hundreds of kilometers away from the devastation zones of erupting volcanoes. The diverse eruption signals produced by Tungurahua Volcano and captured by the ASHE arrays illustrate how acoustic remote sensing may complement seismic observations and satellite remote sensing to improve continuous monitoring of wide regions of potential eruption hazard.

The prototype ASHE stations consist of a four-element infrasound array with an aperture of  $\sim 100$  m, a broadband seismic sensor, and a wind sensor [54]. A satellite dish sends the digital data in real time from the field to the Geological Survey of Canada data center in Ottawa, Canada, which distributes the data in real-time to other collaborating parties. In January of 2006 the ASHE team deployed two infrasound arrays in Ecuador [31]. These two arrays, separated by  $\sim 250$  km, were sited to detect volcanic eruption in Ecuador or Southern Colombia by one of the arrays within 15 min of the eruption, and as early within 5 min for Tungurahua and Sangai volcanoes, which were within 40 km of an array.

Three distinct types of eruption signatures can be identified at Tungurahua (Fig. 6). The first and most common is low ash-producing background tremor with a dominant frequency of 1.4 Hz (Fig. 6a). During mid-May 2006, volcanic activity changed and was temporarily characterized by large explosions followed by harmonic tremor (Fig. 6b), reminiscent of the aforementioned tremor at Arenal. However, no significant ash release was observed, and this second type of eruptive regime was characterized as ash-poor. On July 14th, 2006 a large Vulcanian to sub-Plinian eruption (Fig. 6c) produced dangerous pyroclastic flows, substantial stratospheric ash clouds, and a significant increase in tremor. Between August 16th–17th, 2006 a larger Vulcanian to Plinian eruption occurred (Fig. 6d) and was characterized by lethal pyroclastic flows, a larger stratospheric ash cloud, and considerable infrasonic tremor. As the eruption progressed, the majority of acoustic energy shifted to lower frequencies ( $<0.5$  Hz). The acoustic signatures of the two major eruptions are comparable and easily identifiable in infrasonic records due to the vast amount of energy present over a broader band of frequencies. These two eruptions injected substantial ash

Infrasound from Earthquakes, Tsunamis and Volcanoes, Figure 6

Spectrograms for different eruption styles at Tungurahua volcano. The horizontal axis represents 13 hours of data, and the vertical scale shows frequency in a logarithmic scale from 0.1 to 4 Hz. The color denotes acoustic power in decibels referenced to 1 Pa/Hz. The ocean microbarom shows up in the upper panel two panels as a red band centered about 0.2 Hz, and is not of volcanic origin. Explosive events appear as intense vertical bands

into the stratosphere, suggesting this type of acoustic signature may be used for remote infrasonic monitoring of hazardous eruptions.

Automatic analysis techniques for eruption detection prototyped by the ASHE project produce automated low-latency email notifications coupled with more detailed real-time data products which can be used by responsible operational agencies to disseminate updated information. Based on the acoustic records captured during the Tungurahua eruptions of July and August 2006, source parameters that may be estimated during large eruptions include (but may not be limited to) the start time and duration of an ash cloud injection that could pose a hazard to international aircraft at cruising altitudes.

### Summary of Volcano Infrasound

Volcanic signals incorporate many of the complexities found in earthquake and tsunami signals, and then add some because of the inherently unstable thermodynamic and hydrodynamic conditions that lead to and accompany eruptions. Because infrasound measures the excess pressure change that drives an eruption, it can be used to help unravel the dynamic physical processes driving eruptive activity. Although infrasound may be used with additional technologies in forecasting and hazard assessment, its clearest contribution is in the identification of the intensity and timing of a powerful eruption. The technology and methodology to use infrasound for acoustic remote sensing of hazardous eruptions is mature and ready to implement into operations.

### Future Directions

Although infrasound has manifold applications in near-source studies, recent advances in sensor and analysis techniques have strengthened the potential to develop infrasound as a robust remote sensing tool that may cover observational gaps in distant and inhospitable environments. Although operational acoustic monitoring systems that can help notify aircraft of hazardous eruptions have been demonstrated as viable, much work is still needed to implement these systems and establish clear relationships between ash heights, infrasonic source parameters, and atmospheric conditions. Many parts of Earth's oceans remain undersampled, and there is a great potential for the application of infrasound to the detection of tsunami-genes, the identification and tracking of severe ocean weather, and the monitoring of breaking ocean wave intensity and other coastal hazards. Much fundamental research lies ahead in the construction of functional models for these various source processes. One of the most am-

bitious projects the community has initiated is the passive acoustic tomography of the atmosphere using natural sources [50]. These studies, refined and extended over the next decades, may contribute to our long-term assessment of global climate change.

### Concluding Remarks

There is beauty in complexity, as there is perplexity in beauty. The oscillatory interaction between the solid and fluid phases of our Earth reveals a wealth of information that can be turned into knowledge by the meticulous and persistent use of observation and modeling. Infrasound captures this solid-fluid interaction at the temporal scales of tens of seconds to tens of hertz, offering alluring glimpses into the inner workings of the natural world. The heaving ground and the frothing magmas, borne of the dark depths of Earth, oft conspire with the surging oceans to pervade the skies with deep sound. The field of infrasound strives to interpret the imperceptible yet omnipresent soundscape that permeates the air about us, so as to assuage uncertainty and perchance alleviate our dread of the natural threats posed by earthquakes, tsunamis, and volcanoes.

### Acknowledgments

The authors wish to thank C. Hetzer, P. Caron, and S. McNamara for figures and analyses. Garces also extends his appreciation to M. Protti, M. Haggerty, and S. Schwartz for their contributions to the Arenal studies. D. Fee and R. Matoza provided very useful revisions to this chapter, for which we are grateful. Garces' contributions to this chapter were supported in part by the National Science Foundation (grant EAR-0609669).

### Glossary

**Mean field theory** A theoretical approximation with an interaction field that has constant strength and infinite range. In mean field approximation every domain interacts equally strongly with every other domain, regardless of their relative distance.

**Critical point** A (phase transition) point in the parameter space of a physical system where the length scale characteristic of its structure, called the correlation length  $\xi$ , becomes infinite and the system displays power law scaling behavior on all available scales. The associated critical power law exponents are universal, i. e. they are independent of the microscopic details of the system.

**Universality** Power law scaling exponents and scaling functions near a critical point are the same for a class of systems, referred to as universality class, independent of the microscopic details. Universal aspects typically depend only on a few basic physical attributes, such as symmetries, range of interactions, dimensions, and dynamics.

**Tuning parameters** Parameters such as disorder, temperature, pressure, driving force etc. that span phase diagrams. Critical values of the tuning parameters describe critical points of the phase diagrams.

**Renormalization group (RG)** A set of mathematical tools and concepts used to describe the change of physics with the observation scale. Renormalization

Group techniques can be used to identify critical points of a system as fixed points under a coarse graining transformation, and to calculate the associated critical power law exponents and the relevant tuning parameters. They can also be used to determine what changes to the system will leave the scaling exponents unchanged, and thus to establish the extent of the associated universality class of the critical point.

**Earthquake quantities** The most common form of earthquake data consists of seismic catalogs that list the time, location, and size of earthquakes in a given space-time domain. The size of earthquakes is usually specified by magnitudes associated with spectral amplitudes of seismograms at a given frequency and site-instrument conditions. The seismic potency and moment provide better physical characterizations for the overall size of earthquakes. Additional important quantities are the geometry of faulting (e. g., strike slip), stress drop at the source region, and radiated seismic energy.

**Seismic potency** A physical measure for the size of earthquakes given by the integral of slip over the rupture area during a seismic event.

**Seismic moment** A physical measure of earthquakes given by the rigidity at the source region times the seismic potency.

**Strike slip fault** A style of faulting involving pure horizontal tangential motion, predicted for situations where the maximum and minimum principal stresses are both horizontal. Prominent examples include the San Andreas fault in California, the Dead Sea transform in the Levant and the North Anatolian fault in Turkey.

### Definition of the Subject

Observations indicate that earthquakes and avalanches in magnetic systems (Barkhausen Noise) exhibit broad regimes of power law size distributions and related scale-invariant quantities. We review results of simple models for earthquakes in heterogeneous fault zones and avalanches in magnets that belong to the same universality class, and hence have many similarities. The studies highlight the roles of tuning parameters, associated with dynamic effects and property disorder, and the existence of several general dynamic regimes. The models suggest that changes in the values of the tuning parameters can modify the frequency size event statistics from a broad power law regime to a distribution of small events combined with characteristic system size events (characteristic distribution). In a certain parameter range, the earthquake model exhibits mode switching between both dis-

tributions. The properties of individual events undergo corresponding changes in different dynamic regimes. Universal scaling functions for the temporal evolution of individual events provide similar predictions for the earthquake and magnet systems. The theoretical results are generally in good agreement with observations. Additional developments may lead to improved understanding of the dynamics of earthquakes, avalanches in magnets, and the jerky response to slow driving in other systems.

## Introduction

### Global Statistics and Power Law Scaling

Earthquakes occur in a broad spectrum of sizes, ranging from unnoticeable tremors to catastrophic events. While short term earthquake prediction is still beyond reach, understanding the statistics of earthquakes might facilitate longer term prediction of large earthquakes and statistical estimates of seismic hazard. Gutenberg and Richter [29] found that the frequency of observed regional and global earthquakes versus magnitude forms a regular function over a very large range of scales (see Fig. 1). When the measure for the earthquake size is the seismic potency or moment (see “Glossary”), the frequency size statistics of regional and global earthquakes follow a power law distribution. Precise definitions and details on the seismic potency and moment are given in [1] and [3]. (In this paper we assume a unit nominal rigidity and will therefore use potency and moment interchangeably.) Omori [57] found that the decay rate of aftershocks with time follows a power law distribution. One would expect that there might be a simple explanation for why earthquakes occur in a broad range of sizes and follow regular statistical patterns!

In the last two decades it has become increasingly evident that there are many other systems that respond to slowly changing external conditions with events on extremely large ranges of scales (“crackling noise”). An example of particular interest here involves magnets, which respond to a slowly varying external field by changing their magnetization in a series of bursts or “avalanches” called Barkhausen Noise. Just like earthquakes, these avalanches come in many sizes, ranging from microscopic to macroscopic and are distributed according to a regular function over the entire range. The spectra of the source time function of earthquakes is approximately flat up to a corner frequency related to the rupture size, followed by a power law decay at higher frequencies [1,3]. Similarly, the spectra of the number of spins flipping per time during an avalanche in magnets has high frequency power law decay with a low frequency roll off [68]. For certain values of tuning parameters, earthquake and magnet quantities are

Fractal spatial structure of a medium sized avalanche of 282 785 domain flips in the 3 dimensional random field Ising model [66]. Fractal structures and power laws are characteristic of systems at their critical point. The shading represents time of the domain flips: the first domains to flip are at the right end of the avalanche, the last towards the left. The short range of the ferromagnetic interactions causes the avalanche to be spatially connected (see [66])

associated with scale invariant functions (power laws). In such cases each individual magnetic avalanche or earthquake slip has fractal spatial structure (see Fig. 2 for mag-

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Table 1

Some scaling features that are similar for magnets and earthquakes. More details on the various properties are given in the indicated sections

	Earthquake system	Magnetic system
Frequency size statistics	Power law near criticality, characteristic distribution away from criticality (Sect. "Results on the Monotonic Version of the Model")	Same as earthquakes (Sect. "Results on the Monotonic Version of the Model")
Scaling of source shape functions	Parabola for moment rate shape of events with fixed duration $T$ in simulations, scaling function skewed to the left for observational data (Sect. "Moment Rate Shapes for Monotonic Models")	Same as earthquakes (Sect. "Moment Rate Shapes for Monotonic Models")
Spatial properties of individual events	Fractal near criticality, compact away from criticality (Sect. "Non-monotonic Models" and Fig. 5)	Same as earthquakes (Sects. "Non-monotonic Models" and "Phase Diagram" and Fig. 2)
Spectral decay of source function of individual events	Flat up to a corner frequency followed by power law decay (Sect. "Introduction")	Same as earthquakes (Sect. "Introduction")

nets and Fig. 5a for earthquakes). Other systems with similar "collective events" of all available sizes include, among others, superconductors, charge density waves, and group decision making [66].

While there are several interesting recent reviews, pointing out the similarities between systems with power law event size distributions, the goal of this paper is to develop in detail some of the connections and analysis methods in earthquake and magnetic systems. Expanding on some of our earlier results, we focus especially on the role of disorder and dynamic changes in the strength threshold as potential tuning parameters to drive the system toward power law scaling behavior or away from it. Table 1 summarizes some of the similarities between magnets and earthquakes that are discussed in this review.

In Sect. "Models" we describe several magnet and earthquake models that are simple enough to make the connections transparent and easy to recognize. In Sect. "Theoretical Results" we review theoretical results obtained from these models and their comparison to experimental or observational data. Finally in Sect. "Summary" we summarize the results and discuss future work, both observationally and theoretically, that can help to improve our understanding of the dynamics of earthquakes and magnets.

## Models

### Models for Barkhausen Noise in Magnets

Hysteresis and avalanches in disordered magnetic materials have been modeled using several variants of the non-equilibrium, zero-temperature random-field Ising model (RFIM), which is one of the simplest models of magnetism, with applications far beyond magnetic systems

(for a review, see [66], and also [15,56,58]). In contrast to some other hysteresis models, like the Preisach model [44] and the Stoner–Wohlfarth model [33], where interactions between the individual hysteretic units (grains) are not included and collective behavior in the form of avalanches is not addressed, in the RFIM the inter grain coupling is an essential feature and cause for hysteresis and avalanche effects.

**The Random Field Ising Model (RFIM)** The *equilibrium* RFIM was originally introduced to study disordered magnetic materials in thermal equilibrium. We study the *nonequilibrium* version, to model hysteresis and avalanches observed *far from thermal equilibrium*. Even though the model is a toy version of the microscopic details in a magnet, near the critical point it correctly describes the large scale behavior of systems with the same general properties such as symmetries, dimensions, interaction ranges and dynamics [15], as follows from renormalization group arguments.

In the RFIM, to each site  $i$  in a simple cubic lattice is assigned a variable  $s_i$ , a so called "spin", which can take two different values,  $s_i = +1$  ("up") or  $s_i = -1$  ("down"). (This corresponds to a real magnet where a crystal anisotropy prefers the magnetic moments or elementary domains, represented by the spins, to point along a certain easy axis.) Each spin interacts with its nearest neighbors on the lattice through a positive exchange interaction,  $J_{nn}$ , which favors parallel alignment. (For the behavior on large scales the exact range of the microscopic interaction is irrelevant, so long as it is finite.) Some variations of the RFIM also include *long range* interactions due to the demagnetizing field and the dipole-dipole interactions. A general form of the Hamiltonian can be written

as [37]

$$\mathcal{H} = - \sum_{nn} J_{nn} s_i s_j - \sum_i H s_i - \sum_i h_i s_i + \sum_i \frac{J_{inf}}{N} s_i - \sum_{\{i,j\}} J_{dipole} \frac{3 \cos(\theta_{ij}) - 1}{r_{ij}^3} s_i s_j, \quad (1)$$

where  $H$  is the homogeneous external magnetic driving field,  $h_i$  is a local, uncorrelated random field, that models the disorder in the system,  $J_{inf}$  is the strength of an infinite range demagnetizing field,  $N$  is the total number of spins in the system, and  $J_{dipole}$  is the strength of the dipole-dipole interactions. The power laws of generated events are independent of the particular choice for the distribution  $\rho(h_i)$  of random fields, for a large variety of distributions. Usually a Gaussian distribution of random fields is used, with a standard deviation (“disorder”)  $R$ . As a simple approximation the model is studied at zero temperature, far from equilibrium, to describe materials with sufficiently high barriers to equilibration, so that temperature fluctuations are negligible on experimental time scales. As the magnetic field is adiabatically slowly changed between  $H = -\infty$  to  $H = +\infty$  two different *local* dynamics have been considered:

(1) in the first (“bulk”) dynamics, each spin  $s_i$  flips while decreasing its own energy. We have studied this dynamics for the original RFIM without long range interactions, i. e. for  $J_{inf} = J_{dipole} = 0$  [15,58]. This dynamics allows for *both* domain nucleation (when a spin  $s_i$  surrounded by equal valued spins flips in the opposite direction), *and* for domain wall motion (when a spin flips on the surface of a preexisting cluster of uniform spins in a background of opposite valued spins). A spin flip can trigger neighboring (or more generally, coupled) spins to flip as well, leading to an avalanche of spin flips, analogous to a real Barkhausen pulse. During an avalanche the external field is kept constant until the avalanche is finished, in accordance with the assumed adiabatic limit. The model is completely deterministic – two successive sweeps through the hysteresis loop produce the exact same sequence of avalanches (since the temperature is set to zero). This dynamics may be appropriate to describe for example hard magnetic materials with strong anisotropies. The analogue earthquake system may be associated with fault regions or fault networks that have strong geometrical and material heterogeneities.

(2) The second dynamics is a “front propagation dynamics” in which only the spins on the edge of an existing front (interface between up and down spins) flip if that decreases their energy. This dynamics can be used to model soft magnetic materials with a single or several noninter-

acting advancing domain walls and negligible new domain nucleation, due to antiferromagnetic demagnetizing fields. The front propagation model without long range interactions ( $J_{inf} = J_{dipole} = 0$ ) was originally introduced by Robbins et al. to model fluids invading porous media [43]. The analogue earthquake system for this case may be associated with a single fault zone.

### Simple Models for Inhomogeneous Earthquake Faults

Much of the previous work on simple earthquake models has involved variants of the Burridge–Knopoff (or “slid-erblock”) model, in which complex behavior is generated in a system with many degrees of freedom, and where inertia, friction laws and inherent discreteness play important roles [11,38,61]. These systems appear to exhibit power-law statistics over some range with a cutoff beyond some magnitude, and with most of the slip occurring in larger system-size events. However the understanding of the origin of the power law behavior is limited. Our approach here is to obtain an analytic understanding of a class of models and then to add in various additional features by analytic scaling arguments using tools from the theory of phase transition and the renormalization group, aided by numerical studies. There are interesting related studies using tools from statistical physics [12,63]. Some studies suggest that the power law scaling is connected to a spinodal [34]. Various cellular automata models have also been used for modeling earthquakes [40]. Rather than reviewing a large number of models, we will focus on a subgroup of models, that we found particularly well suited to clarify the connection between earthquake and magnetic systems with a jerky response to slowly changing external conditions.

**The Ben-Zion and Rice Model** A representative of the class of models that we consider is a model developed originally by Ben-Zion and Rice [2,5,6], referred to below as the BZR model. The model assumes that a narrow irregular strike-slip fault zone of horizontal length  $L$  and vertical depth  $W$  may be represented by an array of  $N \sim LW$  cells in a two dimensional planar region of length  $L$  and width  $W$ , with long range interaction, abrupt transitions in the threshold dynamics during failure, and constitutive parameters that vary from cell to cell to model the disorder (offsets etc.) of the fault zone structure (Fig. 3).

The cells represent brittle patches on the interface between two tectonic blocks that move with slow transverse velocity  $v$  in the  $x$  direction at a great distance from the fault. The interaction between cells during slip events is governed by 3-D elasticity and falls off with a distance  $r$

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 3

**Illustration of the Ben-Zion and Rice (BZR) model: projection of a 3D fault zone (top) onto a 2D interface embedded in a 3D elastic halfspace (bottom). The geometrical inhomogeneities of the physical fault zone are modeled by spatially varying constitutive parameters of the brittle patches (see [46])**

from the failure zone as  $1/r^3$ . The cells remain stuck while the stress  $\tau_i$  on each cell is increased gradually as a result of the external loading which grows adiabatically (that is we take the limit  $\nu \rightarrow 0$ ). When the stress on a cell  $i$  reaches its local failure threshold  $\tau_{s,i}$ , the cell slips until the stress is reduced to its local arrest stress  $\tau_{a,i}$ . Both failure stress and arrest stress are distributed according to some bounded probability distribution. The stress drop resulting from a cell failure is redistributed to the other cells according to the long range elastic stress transfer function. The resulting stress increase on the other cells can cause some of them to slip as well, leading to an avalanche of cell slips, or a model earthquake. A review of extensive numerical simulations with various versions of the BZR model, in relation to observed features of seismicity, criticality, and other dynamic regimes, is given in [75].

**Dynamical Weakening** The model includes dynamic weakening effects during the failure process [2,5,6]: after an initial slip in an earthquake, the strength of a failed cell is reduced to a *dynamical* value:

$$\tau_{d,i} \equiv \tau_{s,i} - \epsilon(\tau_{s,i} - \tau_{a,i}), \quad (2)$$

with  $0 \leq \epsilon \leq 1$  parametrizing the relative importance of the dynamical weakening in the system. This weakening

represents the transition from static friction to dynamic friction during the rupture. The strength of a failed cell remains at its dynamic value throughout the remainder of the earthquake. In the time intervals between earthquakes all failure thresholds heal back to their static value  $\tau_{s,i}$ .

**Dynamical Strengthening** The model can be expanded further to include dynamic strengthening represented by  $\epsilon < 0$ . Multidisciplinary observations indicate [7] that brittle failure of rock has an initial transient phase associated with strengthening, distributed deformation, and creation of new structures. Detailed frictional studies also show an initial strengthening phase associated with the creation of a new population of asperity contacts [3,19]. In mean field studies of our model (Fig. 3) discussed in Sect. “Results on Aftershocks”, we associate  $\epsilon < 0$  with regions off the main fault segments that are in an early deformation stage. The events that are triggered as the failure stresses are lowered back in the following weakening period are referred to as *aftershocks*. The Omori law [3,69,70] is obtained if we assume that the increased failure stress thresholds  $\tau_{f,i}$  are slowly lowered with time as  $\log(t)$  towards their earlier static values  $\tau_{s,i}$ , and that the stresses are distributed over a wide range of values [46].

**Related General Continuum Equations of Motion** The above model is a special case of a more general class of models for infinite systems driven by a constant drive force  $F$  [27]. We consider general equations of motion of the form:

$$\eta \partial u(\mathbf{r}, t) / \partial t = F + \sigma(\mathbf{r}, t) - f_R[u(\mathbf{r}, t), \mathbf{r}, \{u(\mathbf{r}, t' < t)\}] \quad (3)$$

where

$$\sigma(\mathbf{r}, t) = \int_{-\infty}^t dt' \int d^d r' J(\mathbf{r} - \mathbf{r}', t - t') \cdot [u(\mathbf{r}', t') - u(\mathbf{r}, t)] \quad (4)$$

is the stress and  $f_R$  is a quenched random “pinning” force crudely representing inhomogeneities in the friction, asperities, stepovers etc., which in general can depend on the local past history (e. g. as in velocity dependent friction). The dynamical variables  $u(\mathbf{r}, t)$  are assumed to represent the discontinuity across the fault plane in the component of the displacement in the direction of slip. The dynamics depend on the local history dependence of the pinning force, the stress transfer function  $J(\mathbf{r}, t)$ , and the coefficient  $\eta$  that represents the fault impedance. (In an elastic medium, the impedance depends on mass density, the

elastic parameters, and directional parameters [1].) Equation (3) can be considered a continuum description of the rules of the BZR model. Integrating out the degrees of freedom due to the bulk material on either side of the  $d=2$  dimensional fault plane leaves us with effective long range static stress transfer:  $J_s(r) \equiv \int dt J(r, t) \sim 1/r^{d+\Gamma} \sim 1/r^3$ . For a planar fault in an elastic half space,  $d = 2$  and  $\Gamma = 1$  [2,6]. The correlations in  $f_R$  are generally assumed to be short-range in  $u$  and  $\mathbf{r}$ . (For results on the BZR model with long range correlations in the disorder, see [2,27,77] and Sect. “Theoretical Results”.) In a version of the BZR earthquake model with a constant driving force  $F$ , the loading may be replaced by driving through a weak spring with spring constant  $K \sim 1/L$  coupled to the slowly moving continents far away (i. e. replacing  $F$  in Eq. (3) by  $F(\mathbf{r}, t) = K[v t - u(\mathbf{r}, t)]$ , with  $v \rightarrow 0$ ).

**Monotonic Models** Substantial simplifications occur if  $f_R$  is history independent and  $J(\mathbf{r}, t) \geq 0$  for all  $(\mathbf{r}, t)$ ; leading to *monotonic* models [27]. Related monotonic models have been studied extensively in various other contexts [25,53]. Examples include elastic depinning models for contact lines, vortex lines, liquids invading porous materials, and elastic charge density waves. Their crucial simplifying feature is that the steady state velocity  $\bar{v} \equiv \langle \partial u / \partial t \rangle$  is a history independent function of  $F$  [48]. In the context of the BZR model this corresponds to the case with zero weakening ( $\epsilon = 0$ ) and non-negative  $J$ . A crucial feature of monotonic models is that the slip profile  $\Delta u(\mathbf{r})$  of a quake is *independent of the dynamics* [48]. However, several interesting dynamical issues discussed below are associated with the effects left out of the monotonic models that can make this feature break down.

**Non-monotonic Models** (a) *Weakening*: We first consider including some weakening effects of sections which have already slipped in a given quake. This is best studied in the discrete model. In analogy to the dynamic weakening in the BZR model discussed above, we choose [27]

$$f_R = \tilde{f}_R[u(\mathbf{r}), \mathbf{r}] \{1 - \epsilon \Theta[u(\mathbf{r}, t) - u(\mathbf{r}, t - T)]\} \quad (5)$$

with  $T$  a cutoff time much longer than the duration of the largest quakes, but much smaller than the interval between the quakes. Here  $\Theta(x)$  is the Heavyside step function. As mentioned, the case  $\epsilon > 0$  represents the difference between static and dynamic friction. The effects of small weakening ( $\epsilon > 0$ ) can be analyzed perturbatively (see Sect. “Theoretical Results”).

(b) *Stress Pulses*: A similar but more subtle effect can be caused by stress pulses that result from non-posi-

itive  $J(\mathbf{r}, t)$ ; these arise naturally when one includes elastodynamic effects. We consider

$$J(\mathbf{r}, t) \sim \frac{\delta(t - \frac{r}{c})}{r^{d+\Gamma}} + \frac{\alpha \delta'(t - \frac{r}{c})}{c r^{d+\gamma}} \quad (6)$$

with  $c$  the sound speed,  $\delta(t)$  the Dirac delta distribution, and  $\delta'(t) = d\delta(t)/dt$ . The scalar approximation to elasticity in a half space corresponds to  $d = 2$ ,  $\Gamma = 1$ ,  $\gamma = 0$ , and  $\alpha = 1$  [27]. If a region slips forward, the stress at another point first has a short pulse at the sound arrival time from the second term in Eq. (6), and then settles down to its smaller static value, i. e. it is non-monotonic. The magnitude of these stress pulses and their duration is set by various aspects of the models; for example larger  $\eta$  in Eq. (3) implies weaker stress pulses as the local motion will be slower.

## Theoretical Results

Both the magnet and earthquake models of the previous section are capable of producing a large range of power law scaling of event sizes, and related scale invariant quantities in response to a slowly varying driving force or field. This section highlights similarities between these different physical systems and attempts to explain them.

### The Universality Class of the BZR Model

We first review results for the simplified monotonic case, starting with scaling relations for driving with fixed force and far field plate motion and continuing with moment rate shapes. We then discuss additional results associated with non monotonic versions of the model, including mode-switching and aftershocks.

### Results on the Monotonic Version of the Model

**General results: Depinning transition** As mentioned above, substantial simplifications occur for the monotonic version of the model, i. e. if  $f_R$  is history independent and  $J(\mathbf{r}, t) \geq 0$  for all  $(\mathbf{r}, t)$ . In [25,27,53] it is shown that for  $F$  greater than a critical force  $F_c$  the displacement grows continuously in a “sliding state” for which the mean velocity  $\bar{v} \equiv \langle \partial u / \partial t \rangle \sim (F - F_c)^\beta$ . Here  $\beta$  is a universal exponent that is independent of the microscopic details of the system. It only depends on a few fundamental properties, such as symmetries, spatial dimensions  $d$ , range of interactions, etc. [53]. Long time dynamic properties such as  $\beta$  depend in addition on the small  $\omega$  dependence of  $J(\mathbf{q}, \omega)$  [54].

For  $F$  less than the critical force  $F_c$ , the mean velocity is  $\bar{v} \equiv 0$ . If  $F$  is adiabatically slowly increased to

towards  $F_c$ , the system moves from one metastable configuration to another by a sequence of “quakes” of various sizes. The “quakes” can be characterized by their radius  $R$ , the  $d$ -dimensional area  $A$  which slips (by more than some small cutoff), their potency or moment  $M \equiv \int_A d^d \mathbf{r} \Delta u(\mathbf{r})$ , a typical displacement  $\Delta u \sim M/A$ , and a duration  $\tau$ . The critical force  $F_c$  marks a second order phase transition point. Such phase transitions are typically associated with power law scaling behavior.

In the class of earthquake models with long range interactions along the fault involving the static stress transfer  $J_s(r) \equiv \int dt J(r, t) \sim 1/r^3$ , the equations are very similar to those of a model for contact line depinning studied in ref. [25]. Using renormalization group methods it was shown in [25] that for a physical two dimensional interface (or “fault”) in a 3 dimensional elastic half space, these long range interactions are so long that the scaling behavior near  $F_c$  is correctly described by mean field theory (up to logarithmic corrections, since  $d = 2$  is the “upper critical dimension”). The main assumption in mean field theory is that the spatial and temporal fluctuations in the displacement field  $u(\mathbf{r}, t)$  are so small that the local displacement  $u(\mathbf{r}, t)$  can be replaced by a time dependent spatial average  $u(t)$ , which then needs to be determined self consistently from the behavior of the neighboring regions that contribute to the stress at a chosen point  $\mathbf{r}$  [26]. The same mean field equations are obtained when the long range interaction is approximated to be constant in space  $J(\mathbf{r}, t) = J_{mft}(t)/(LW)$ . With this approximation Eqs. (3) and (4) become

$$\eta \partial u(\mathbf{r}, t) / \partial t = F + \sigma_{mft}(\mathbf{r}, t) - f_R[u(\mathbf{r}, t), \mathbf{r}, \{u(\mathbf{r}, t') < t\}] \quad (7)$$

where

$$\sigma_{mft}(\mathbf{r}, t) = \int_{-\infty}^t dt' J_{mft}(t - t') [u(t') - u(\mathbf{r}, t)] \quad (8)$$

and the self consistency requirement is

$$\int u(\mathbf{r}, t) d^2 r / (LW) = u(t) \quad (9)$$

Many scaling exponents and scaling functions can be calculated exactly in mean field theory by solving these simplified equations of the model. In [15,26,42], several illustrative examples are given for solving similar self consistent mean field theories. There are various approaches that one may use, ranging from numerical simulations to analytical expansion and scaling analysis near a phase transition point where universal power law scaling occurs. The

approach of choice to solve the mean field equations depends on the quantity under consideration. To obtain exact results for the scaling behavior of the frequency size statistics of earthquake or avalanche events, a fairly simple approach is to use a discrete version of the model in which we treat the fault as a discrete set of dislocation patches, coupled to a mean displacement and an external driving force that slowly increases with time. (The stress  $\tau_i$  at each patch is given by Eq. (16) of Sect. “Mode-Switching” below.) As shown in [17], the sequence that describes the distance from failure of the rescaled stress variables resembles a biased random walk. The scaling behavior of the resulting random walk is known exactly from the literature. Using this mapping it then becomes straightforward to derive universal scaling predictions for the mean field earthquake frequency size distribution [17].

Furthermore, as shown in [13,25], their (and thus also our) model have the same scaling behavior as a front propagation model for a two dimensional domain wall in a soft magnet with long range dipolar magnetic interactions, driven by a slowly changing external field (see Sect. “Models”). A flipping spin in the magnet model corresponds to a slipping dislocation patch in the earthquake model. The long range elastic interactions in the earthquake model are similar to the long range dipolar magnetic interactions in the magnet model. The driven two dimensional magnetic domain wall in the (three dimensional) magnet model corresponds to the driven two dimensional earthquake fault in a three dimensional elastic half space. Since the scaling behavior of the earthquake model and that of [25] and [73] are identical, we may simply copy their results and translate them into quantities that can be extracted from seismic data. Using tools from phase transitions, such as the renormalization group (RG), near the critical force the following scaling results were derived by [13,25,53,54,73] and others:

$$\begin{aligned} \Delta u &\sim R^\xi, \\ A &\sim R^{d_f} \text{ with } d_f \leq 2 \text{ a fractal dimension,} \\ M &\sim R^{d_f + \xi}, \\ \text{and } \tau &\sim R^z. \end{aligned}$$

The differential distribution  $P(M)$  of moments  $M$  is shown in [25,54] and [26,27] to scale as

$$P(M) dM \sim dM / M^{1+B} \rho_\infty(M/\hat{M}) \quad (10)$$

with  $\rho_\infty$  a universal scaling function which decays exponentially for large argument. The cutoff  $\hat{M}$  for large moments is characterized by a correlation length – the largest likely radius –  $\xi \sim 1/(F_c - F)^\nu$  with  $\hat{M} \sim \xi^{d_f + \xi}$ .

In the same references it is shown that in mean-field theory,  $B = 1/2$ ,  $1/\nu = 1$ ,  $z = 1$  and the quakes are fractal with displacements of order the range of correlations in  $f_R(u)$ , i. e.  $\xi = 0$ .

These mean-field exponents are valid for a  $d = 2$  dimensional planar fault in a three dimensional elastic half space [7], since the physical fault operates at the upper critical dimension. As usual, at the upper critical dimension, there are logarithmic corrections to mean-field results. Using renormalization group methods one can calculate these corrections [27] and finds barely fractal quakes with  $A \sim R^2/\ln R$  so that the fraction of the area slipped decreases only as  $1/\ln r$  away from the ‘‘hypocenter’’. The typical slip is  $\Delta u \sim (\ln R)^{1/3}$  so that  $M \sim R^2/(\ln R)^{2/3}$ . The scaling form of  $P(M)$  is the same as Eq. (10) with the mean-field  $\rho_\infty$ , although for  $M \ll \hat{M}$ ,  $P(M) \sim (\ln M)^{1/3}/M^{3/2}$  so that  $B$  will be virtually indistinguishable from  $1/2$  [27]. A similar form of moment distribution and exponent value  $B = 1/2$  were obtained also for a critical stochastic branching model [71].

*More realistic driving of a fault* We now consider more realistic drive and finite-fault-size effects. As mentioned, driving the fault by very slow motion far away from the fault is roughly equivalent to driving it with a weak spring, i. e. replacing  $F$  in Eq. (3) by  $F(\mathbf{r}, t) = K[\nu t - u(\mathbf{r}, t)]$ . With  $\nu \rightarrow 0$  the system must then operate with the spring stretched to make  $F(\mathbf{r}, t) \lesssim F_c$  at least on average, to ensure  $\bar{v} = 0$ ; depending on the stiffness of the spring, it will actually operate just below  $F_c$ , as shown below. If in constant force drive the force is increased by a small amount  $\Delta F$ , the average resulting slip per area,  $\langle \Delta u \rangle \equiv \sum_i \Delta u_i/(LW)$  is given by the total potency/moment per total area  $M \equiv \int d^d \mathbf{r} \Delta u(\mathbf{r})/(LW)$ . The total moment per area observed in response to a small force increase equals the number  $n\Delta F$  of earthquakes per area that are triggered by the increase  $\Delta F$ , multiplied with the average observed moment of a single earthquake  $\langle M \rangle = \int MP(M)dM$ . The result is

$$\langle \Delta u \rangle = n\Delta F \int MP(M)dM \quad (11)$$

where  $n$  is the number of quakes per unit area per force increase  $\Delta F$ . It has been shown that  $n(F)$  is non-singular at  $F_c$  [53], so it can be treated like a constant near  $F_c$ . Plugging in Eq. (10) and the scaling laws written above and below that equation, we obtain

$$\langle \Delta u \rangle \sim \Delta F \xi^{(2\tilde{F} + \xi)(1-B)} \sim \Delta F \xi \quad (12)$$

for our case where mean field results can be used for the critical exponents. For consistency, we must have in steady

state with the spring drive,  $K\nu\Delta t = \Delta F = K\Delta u$  so that the system will operate with a correlation length  $\xi \sim 1/K^{1/\tilde{F}}$ , i. e.  $1/K$  for our case. For a fault section with linear dimensions of order  $L$ , drive either from uniformly moving fault boundaries or from a distance  $\sim L$  perpendicularly away from the fault plane will be like  $K \sim 1/L$  so the power-law quake distribution will extend out to roughly the system size  $\xi \sim L$ . For smaller quakes, i. e.  $R \ll L$ , the behavior will be the same as in the infinite system with constant  $F$  drive, but the cutoff of the distribution of moments will be like Eq. (10) with a different cutoff function  $\rho$  that depends on the shape of the fault, how it is driven, and the boundary conditions.

We have tested these conclusions numerically by simulating the BZR model, which is a discrete space, time, and displacement version of a monotonic Eq. (3), with quasistatic stress transfer appropriate for an elastic half space [2,5]. The slip,  $u$ , is purely in the horizontal direction along the fault and  $f_R[u(\mathbf{r})]$  is a series of equal height spikes with spacings which are a random function of  $\mathbf{r}$ . When  $\sigma(\mathbf{r}, t) > f_R[u(\mathbf{r}, t)]$ ,  $u(\mathbf{r})$  jumps to the next spike. This provides a way of implementing the random stress drops of the BZR model. The boundary conditions on the bottom and sides are uniform creep or slip ( $u = \nu t$ ) with infinitesimal  $\nu$  – and stress free on the top (Fig 3). The statistics of the moments of the quakes are shown by the triangles in Fig. 4. Although the uncertainties are appreciable, relatively good agreement is found with the

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 4

Histograms of moments for a simulation of a rectangular fault with  $32 \times 128$  cells for the discrete monotonic quasistatic model (with arbitrary units (a.u.)). Triangles: without dynamical weakening ( $\epsilon = 0$ ). Diamonds: with dynamic weakening of  $\epsilon = 0.95$ . ( $\epsilon$  is defined in Eq. (5).) The straight line indicates the predicted slope  $B = 1/2$  (from [27])

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 5

Distribution of horizontal slip,  $u$ , along a fault with  $32 \times 128$  cells for a *single* large quake event. Lighter shading represents larger slip during the quake. *Top*: almost fractal quake with a total moment of 1750 (and 1691 cells failing) for the monotonic model without any dynamical effects ( $\epsilon = 0$ ). *Bottom*: “crack like” quake with a total moment of 16922 (and 2095 cells failing) for the model with dynamic weakening ( $\epsilon = 0.95$ ). In both cases the system is driven by horizontally creeping fault boundaries (*sides and bottom*) while the top boundary is free (from [27])

prediction  $B = 1/2$ . One typical large quake is illustrated in Fig. 5 (top); it appears almost fractal as predicted, and tends to stay away from the bottom and sides due to the specific loading that we chose. The ratios of the moments of quakes to their areas have been studied and found to grow only very slowly with the area, as predicted from the logarithmic corrections listed below Eq. (3). This is in striking contrast to earthquakes in conventional crack models which are compact (Fig. 5 (bottom)) and have  $\Delta u \sim R$  (i. e.  $\zeta = 1$ ), so that  $M/A \sim \sqrt{A}$ . As discussed by [8], however, the scaling  $M \sim A$  appears to be consistent with observational results for small earthquakes which presumably propagate and are arrested in rough stress fields. More observational data on the scaling of the moment  $M$  with the slipping area  $A$  for smaller earthquakes would be highly desirable to test this prediction more precisely.

Because the system is at its critical dimension, the cut-off function  $\rho$  of the moment distribution appropriate to the boundary conditions, as well as various aspects of the shapes and dynamics of quakes can be computed using tools from the theory of phase transitions [26,27]. For quasistatic stress transfer,  $J(\mathbf{r}, t) \sim \delta(t)/r^3$ , in the infinite system the quake durations are found to scale as  $\tau \sim R^z$  with  $z = 1$  for a  $d = 2$  dimensional fault, with logarithmic corrections [25]. (A more physical dynamics with sound-travel-time delay has slower growth of the quakes with  $z = 1$  in all dimensions.) Due to the geometrical disorder included in the model, in either case the growth will be very irregular – including regions starting and stop-

ping – in contrast to crack models and what is often assumed in seismological analysis of earthquakes on more regular faults. Similar fractal-like quakes were simulated by Zöller et al. [75,76], for a quasi-dynamic version of the BZR model that includes stress redistribution with a finite communication speed.

**Moment Rate Shapes for Monotonic Models** In both magnet and earthquake models it has been shown that there are not just universal scaling exponents but also some experimentally accessible universal scaling functions [66]. By comparing theoretical predictions for these functions to experiments or observations, one can often test models much more accurately than by merely comparing a finite set of discrete exponents. Two such functions were first discovered for Barkhausen Noise in magnets [47,66]. The analogy between magnets and earthquakes then lead to the development of the corresponding functions for earthquakes. For slowly driven magnets, consider the time history  $V(t)$  of the number of domains flipping per unit time (Barkhausen train). It is called  $V$  because it is usually measured as a voltage in a pickup coil. An example of a Barkhausen train for a single avalanche is shown in Fig. 6.

The voltage function  $V(t)$  in magnets is the analogue of the moment rate  $dm/dt(t)$ , or the slip per unit time for earthquakes. Recent analysis allowed researchers to ob-

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 6

**Voltage train of a typical large avalanche.** Note that the voltage fluctuates drastically and the avalanche nearly stopped several times (from [37]). The analogous moment rate time trace for earthquakes (though measured with lower resolution) is shown in the right inset marked “RAW” of Fig. 8

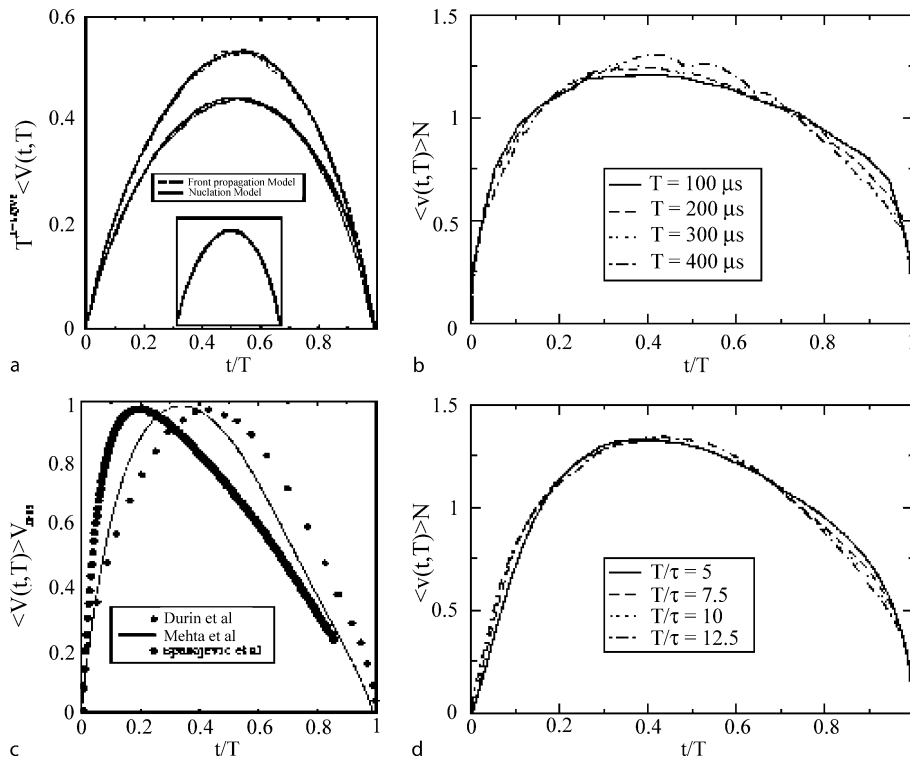

tain the moment rate  $dm_0(t)/dt$ , during the propagation of earthquake rupture for hundreds of large seismic events recorded on global networks [9,31]. The moment rates shown below are derived from inversions of teleseismically recorded seismograms on a global seismic network [62]. (The frequency-moment distribution,  $D(M_0) \sim M_0^{-1-\beta}$  of the observed data [9] has three decades of scaling and an exponent of  $\beta = 1/2 \pm 0.05$ , in close agreement with the BZR model near  $\epsilon = 0$  [46].)

For both magnets and earthquakes there are large fluctuations in  $V(t)$  and  $dm/dt(t)$  respectively (Fig. 6). However averaging the signal over many avalanches, leads to typical shapes. Figure 7 shows the average over all avalanches of fixed duration  $T$ ,  $\langle V \rangle(T, t)$  obtained from

simulations of two variants of the RFIM (a), and from three different Barkhausen noise experiments (b). Figure 8 shows  $\langle dm/dt \rangle(T, t)$  obtained for the BZR earthquake model and derived from earthquake observations respectively. The renormalization group and scaling theory [66] predict that for a self similar system at a critical point with power law size and duration distributions for avalanches, there are self similar average avalanche profiles. As shown in [46,66] one finds

$$\langle dm/dt \rangle(T, t) \sim T^{b'} g(t/T) \quad (13)$$

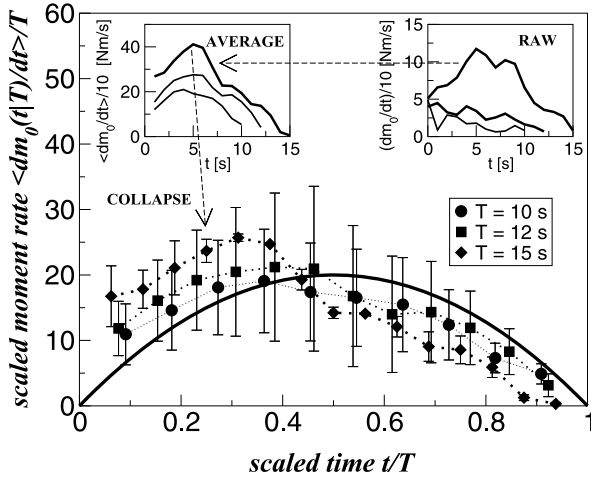

where the function  $g(x)$  is a universal scaling prediction and  $b' \equiv 1/(\sigma \nu z) - 1 = 1$  for the BZR earthquake model (as obtained from mean field theory). The corresponding

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 7

**a Theoretical average avalanche shape scaling functions** for fixed avalanche durations  $T$  denoted with  $g(t/T)$  in the text, for the nucleation and the front propagation RFIM [47]. The overall height is non universal, the curves for the two models are otherwise extremely similar. The front propagation model has  $1/\sigma \nu z = 1.72$  and, the nucleation model has  $1/\sigma \nu z = 1.75$  in this collapse. The *inset* shows the two curves rescaled to the same (non universal) height: the two curves are quantitatively different, but far more similar one to another than either is to the experimental curve in b. **b Experimental average pulse shapes from three different experiments** for fixed pulse duration, as measured by three different groups [21,23,47,67]. Notice that both theory curves are much more symmetric than those of the experiments. Notice also that the three experiments do not agree. At first this result represented a serious challenge to the idea about universality of the dynamics of crackling noise [66]. **c Pulse shape asymmetry experiment** [72]. Careful experiments show a weak but systematic duration dependence in the collapse of the average Barkhausen pulse shape. The longer pulses (larger avalanches) are systematically more symmetric (approaching the theoretical prediction). **d Pulse shape asymmetry theory** [72]. Incorporating the delay effects of eddy currents into the theoretical model produces a similar systematic effect. The non-universal effects of eddy currents are in principle irrelevant for extremely large avalanches (from [64])

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 8

A collapse of averaged earthquake pulse shapes,  $\langle dm_0(t|M_0)/dt \rangle$  with a duration of  $T$  (seconds) within 10% (given in legend), is shown. The collapse was obtained using the mean field scaling relation [37]:  $\langle dm_0(t|T)/dt \rangle \sim g(t/T)$ . In order to obtain each collapsed pulse shape, two to ten earthquakes were averaged for each value of  $T$ . In our mean field theory the universal scaling function is  $g_{mf}(x) = Ax(1-x)$  with  $x = t/T$ . We plot this functional form (bold curve) with  $A = 80$ . Note the apparent asymmetry to the left in the observed data while the theoretical curve is symmetric around its maximum. *Inset*: The raw data and the averaged data (before collapsed) (from [46])

value for  $b'$  for magnets in three dimensions is smaller – the values used for the corresponding collapses can be read off for the different versions of the RFIM from the caption of Fig. 7.

Based on universality one would expect these theoretical predictions to agree with experimental results, apart from an overall shift in time and voltage or moment rate scales. For the moment rate of earthquakes this means

$$\langle dm/dt \rangle_{\text{observation}}(T, t) = A \langle dm/dt \rangle_{\text{theory}}(T/B, t/B) \quad (14)$$

for some rescaling factors  $A$  and  $B$ , and similarly for the average voltage  $\langle V \rangle(t, T)$  in magnets. In both cases the theory predicts a symmetric looking profile. The mean field prediction for  $g(x)$  is in fact a parabola [46,66] – the theoretical prediction thus is that events grow as quickly as they decay. As seen in Figs. 7b and 8 the experimental/observational profile in both cases, however, appear skewed – the real events tend to grow more quickly than they decay! A similar asymmetry has also been observed in avalanches associated with plastic deformation [39].

For magnets this apparent disagreement has been resolved by taking greater account of a microscopic detail involving eddy currents that had been neglected by previ-

ous models. Eddy currents are transient current loops that arise in conducting magnets in response to the reorientation of a magnetic domain. These currents temporarily prevent neighboring domains from being triggered to realign in the same direction in an avalanche of domain reversals. The eddy currents decay after a microscopic time  $\tau$  given by the resistance of the material. Their delay effect thus also decays after a time  $\tau$ . If the avalanche duration is large compared to  $\tau$  this effect is negligible and the mean profile approaches the predicted symmetrical shape (see Fig. 7c and d).

The source of asymmetry in the mean moment rate profile may be similar for earthquakes [16]. It has been suggested that triggering delays – arising from a noticeable earthquake nucleation time, or an increase in the failure threshold during the formation of new cracks and subsequent weakening as rock damage increases – could be responsible for aftershocks that often follow large earthquakes [46]. On long time scales a large mainshock with smaller aftershocks can be seen as a similar asymmetry to that seen in magnets, possibly with a similar explanation.

There is a second scaling function that may be extracted from the same data: Fig. 9 shows the average over

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 9

A collapse of averaged earthquake pulse shapes,  $\langle dm_0(t|M_0)/dt \rangle$ , with the size of the moment  $M_0$  in Newton meters within 10% of each size given in the legend respectively. In order to obtain each collapsed moment rate shape, five to ten earthquakes were averaged for each value of  $M_0$ . The collapse was obtained using the mean field scaling relation [27]:  $\langle dm_0(t|M_0)/dt \rangle / M_0^{1/2} \sim f(t/M_0^{1/2})$ . In our mean field theory the universal scaling function is  $f_{mf}(x) = Axe^{-Bx^2/2}$  where  $x = t/M_0^{1/2}$ . We plot this functional form (bold curve) with  $A = 4$  and  $B = 4.9$ . *Inset*: The raw data and the averaged data (before collapsed) (see [46])

all earthquakes of fixed total moment  $M(dm/dt)(M, t)$ , both for observations and the BZR model prediction. As shown in [46,66] the theory predicts

$$(dm/dt)(M, t) \sim M^{1/2}q(t/M^{1/2}) \tag{15}$$

where the universal scaling function  $q(x) = Ax \exp -Bx^2/2$  and the universal exponents are obtained from the mean field theory for the BZR earthquake model. A comparison between prediction and observational results for this scaling function is shown in Fig. 9.

Clearly, more data, especially for small earthquakes, are needed to decrease the statistical error bars of the observational data and determine the degree of agreement between theory and observations. An alternative scaling approach to moment rate data was given by [31] and a comparison between both approaches is discussed in [46].

**Non-Monotonic Models** We first consider including weakening of the cell failure threshold by an amount  $\epsilon$  for sections which have already slipped in a given quake. This crudely models the difference in static versus dynamic friction (see Sect. “Models”, Eq. (5)). In between quakes all thus weakened thresholds heal back to their static strength. The effects of small weakening can be analyzed perturbatively.

With  $\epsilon = 0$ , consider a quake of diameter  $R_1 (\ll L$  or  $\xi)$ , with moment  $M_1$  and area  $A_1$ : i. e.  $A_1$  sites have slipped. If a small  $\epsilon$  is turned on at the end of the quake, all slipped sites that are within  $\epsilon$  of slipping will now slip again – this will be  $N_2^{ex} \sim \epsilon A_1$  sites. The simplest justifiable guess is that each of these will cause an approximately independent secondary quake. The total moment of these secondary quakes will be dominated by the largest one, so the extra moment will be  $M_2^{ex} \sim (\epsilon A_1)^{1/B}$ . (For a very large or infinite fault this is obtained from  $1 = N_2^{ex} \int_{M_2^{ex}}^{\infty} P(M)dM$ , and inserting Eq. (10).) If  $M_2^{ex} \ll M_1$  this process can continue but will not increase the total moment substantially. If  $M_2^{ex} \sim M_1$ , however, the process can continue with a larger area  $A_2$  and hence a larger  $M^{ex}$ , leading to a catastrophic runaway event. From the above exponent relations and scaling laws we obtain  $B = 1/2$  and  $A \sim M$ , so that for any  $\epsilon$ , for large enough  $M_1$ ,  $M_1 \gtrsim M_D \sim \epsilon^{-2}$ ,  $M_2^{ex}$  will be comparable to  $M_1$  and the quake will become much larger (runaway). In the force driven infinite system for  $F \lesssim F_c$ , quakes of size  $\xi$  will runaway and become infinite if  $\xi > \epsilon^{-1}$ . Since  $\xi \sim (F - F_c)^{-\nu}$  and  $1/\nu = 1$ , this will occur for  $F_c - F < C_w \epsilon$  with some constant  $C_w$ . This result is very intuitive and justifies a posteriori the assumptions leading to it: Since on slipping, the random pinning forces,  $f_R$  in a region are reduced by order  $\epsilon$ , the effective critical

force  $F_c$  for continuous slip will have been reduced by order  $\epsilon$ ; thus if  $F > F_c(\epsilon) = F_c - C_w \epsilon$ , the mean velocity  $\bar{v}$  will be nonzero. A similar effect can be caused by stress pulses associated with Eq. (6). By considering which of the sites in a long quake with  $\alpha = 0$  can be caused to slip further by such stress pulses one finds that runaway will occur for  $M \geq M_D \sim \alpha^{-4}$  for the physical case [27]. This has been checked in  $d = 1$  with  $\Gamma = 1$  and  $\gamma = 0$ , finding the predicted reduced critical force  $F_c(\alpha) \sim F_c - C_p \alpha^2$  as shown in Fig. 10 [27]. These 1-d simulations also reveal a hysteretic  $\bar{v}(F)$  curve in finite systems. This is expected to also occur with the model with weakening discussed above. Related higher dimensional systems are discussed in [60] and in [30].

We can now understand what should happen with either weakening or stress pulses in finite systems driven with a weak spring or with slowly moving boundaries. As the system is loaded, quakes of increasing size are observed. If the system is small enough that it cannot sustain quakes with  $M > M_D(\epsilon, \alpha)$ , i. e. even events within the power law scaling regime of the event size distribution, with  $M \leq M_D(\epsilon, \alpha)$ , are system spanning, then the behavior will not be much different from the monotonic case with  $\epsilon = \alpha = 0$ . In both cases there is a power law event size distribution all the way to the largest events, that are determined by the system size. This will occur if the dominant linear system size  $L$  is less than the maximum possible linear extent of an earthquake that does not become a runaway event:  $L < R_D(\epsilon, \alpha) \sim M_D^{1/2} \sim \max(C_\alpha/\alpha^2, C_\epsilon/\epsilon)$

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 10

Mean velocity vs. force for one dimensional system with a non-monotonic kernel  $J(x, t) = \delta(t - x)/x^2 + \alpha \delta'(t - x)/x$  for  $\alpha = 0.8, 0.5, 0$ . A spring or boundary loaded system will traverse the hysteresis loops in the direction indicated. Inset: the threshold force,  $F_c^\uparrow(\alpha)$ , on increasing the load;  $\Delta_\alpha = [1 - F_c^\uparrow(\alpha)/F_c^\uparrow(\alpha = 0)]^{1/2}$  is plotted vs.  $\alpha$  (from [27])

with appropriate coefficients  $C_\alpha$ ,  $C_\epsilon$ , which will depend on the amount of randomness in the fault. On the other hand, if  $L > R_D$ , quakes of size of order  $R_D$  will runaway and most of the system will slip, stopping only when the load has decreased enough to make the loading forces less than the lower end of the hysteresis loop in  $\bar{v}(F)$  (as in Fig. 10).

Because of the tendency of regions that have already slipped to slip further, and the consequent buildup of larger stresses near the boundaries of the slipped regions, large events in systems with dynamic weakening will be much more crack like than in monotonic models, probably with  $\Delta u \sim L$ . Statistics of quakes with weakening,  $\epsilon$ , reasonably large, but no stress pulses ( $\alpha = 0$ ) are shown in Fig. 4 and in [2,5,6]; note the absence of quakes with intermediate moments. A typical large event in this case is shown in Fig. 5b; it appears to be crack-like.

In this section we have shown that simple models of heterogeneous faults – with the dimensionality and long-range elastic interactions properly included – can give rise to either power-law statistics of earthquake moments or a distribution of small events combined with characteristic system size events. Which behavior – or intermediate behavior – obtains is found to depend on a number of physical properties such as frictional weakening and dynamic stress transfer, analogs of which should definitely exist in real systems. In the power-law-regime the conventionally defined Gutenberg–Richter exponent  $b \equiv 3B/2$  [3] is found to be  $b = 3/4$ . This is close to the observed  $b$ -value of global strike-slip earthquakes at depth less than 50 km [28].

**Mode-Switching** In [17] the mean field approximation of infinite range elastic interaction in the BZR model with  $N = LW$  (with  $W \sim L$ ) geometrically equal cells on the fault, is used to write the local stress  $\tau_i$  on cell  $i$  as

$$\begin{aligned} \tau_i &= J/N \sum_j (u_j - u_i) + K_L(vt - u_i) \\ &= J\bar{u} + K_L vt - (K_L + J)u_i, \end{aligned} \tag{16}$$

where  $u_i$  is the total fault offset of cell  $i$  in the horizontal ( $x$ ) direction,  $\bar{u} = (\sum_j u_j)/N$ ,  $J/N$  is the elastic coupling between cells in the mean-field approximation, and  $K_L$  is the effective loading stiffness of the bulk material surrounding the fault patch. Instead of the loading spring stiffness  $K_L$ , a conservation parameter  $c \equiv J/(K_L + J)$  is introduced, which equals the fraction of the stress drop of the failing cell, that is retained in the system after the slip. There, it is shown that for the physical loading spring stiffness  $K_L \sim 1/L$ , one has  $1 - c \sim O(1/\sqrt{N})$ . A value  $c < 1$  for a large system would be physically realized if the ex-

Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of, Figure 11  
**Phase Diagram of the BZR model, described in the text. The range  $\epsilon > 0$  represents dynamic weakening, while  $\epsilon < 0$  represents strengthening. The parameter  $1 - c$  quantifies the deviation from stress conservation in the mean field approximation of the model**

ternal drive is closer to the fault than its linear extent. To be precise, mean field theory only gives the correct physical scaling behavior near the critical point at zero weakening  $\epsilon \rightarrow 0$  and for  $c \rightarrow 1$ . In [17] it is shown, however, that in a certain parameter regime for  $\epsilon > 0$  and  $0.5 < c < 1$  indicated in the phase diagram of Fig. 11 one finds a mode switching behavior between Gutenberg–Richter statistics and characteristic earthquake statistics. Similar mode switching behavior has also been seen in a more realistic three dimensional model for coupled evolution of earthquakes and faults [4,41], and in numerical simulations with the BZR model that includes elastic stress transfer [76]. In the mean field BZR model, the activity switching results from episodic global reorganization of the mode of strain energy release of the fault system, reflected in a “configurational entropy” of stress states on the fault [17]. This is associated with a statistical competition between a tendency of a synchronized behavior leading to clusters of large earthquakes and the characteristic earthquake distribution, and a tendency for disordered response leading to Gutenberg–Richter type statistics without a preferred event size. Mode switching happens when these two opposite tendencies are roughly equal in strength. Some possible observational evidence for mode switching in earthquake data are discussed in [4].

**Results on Aftershocks** As mentioned in Sect. “Simple Models for Inhomogeneous Earthquake Faults”, we asso-

ciate regions off the main fault segments that are in an early deformation stage with dynamic strengthening  $\epsilon < 0$ . To capture basic aspects of brittle deformation on such regions in the three-dimensional volume around the main fault (Fig. 3), we change the model as follows: when any cell  $i$  slips during an earthquake, and thereby reduces its stress by  $\Delta\tau_i \equiv \tau_{f,i} - \tau_{a,i}$ , the failure stress  $\tau_{f,j}$  of every cell  $j = 1, \dots, N$  is *strengthened* by an amount  $|\epsilon|\Delta\tau_i/N$ . Once the earthquake is complete, the failure stress of each cell is slowly lowered back to its original value. This represents in a simple way the brittle deformation that occurs during an earthquake in the off-fault regions, which are first in a strengthening regime, compared to the main fault, and then have a weakening process. The events that are triggered as the failure stresses are lowered in the weakening period are referred to as *aftershocks*. The occurrence of aftershocks in this version of the model for off-fault regions is in agreement with the observation that a large fraction of observed aftershocks typically occur in off-fault regions [70]. For this version of the model with  $\epsilon < 0$ , both the primary earthquakes (i. e., mainshocks) and the triggered aftershocks are distributed according to the Gutenberg–Richter distribution, up to a cutoff moment scaling as  $1/\epsilon^2$ . Assuming that the increased failure stress thresholds  $\tau_{f,i}$  are slowly lowered with time as  $\log(t)$  towards their earlier static values  $\tau_{s,i}$ , and that the stresses are distributed over a wide range of values, we show analytically in [46] that the temporal decay of aftershock rates at long times is proportional to  $1/t$ , as in the modified Omori law  $\Delta N/\Delta t K/(t+c)^p$  with  $p = 1$  [3,69,70], where  $N$  is the cumulative number of aftershocks,  $t$  is the time after the mainshock, and  $K$ ,  $c$ , and  $p$  are empirical constants.

Remarkably, the long length scale behavior of this model can be shown [45] to be the same as the behavior of the mean field BZR model given in Eq. (16) with an added “antiferroelastic” term  $(-\epsilon|J\bar{u})$ :

$$\tau_i = J\bar{u} + K_L v t - (K_L + J)u_i - \epsilon|J\bar{u}. \quad (17)$$

In Eq. (17) every time a cell fails, it slips by an amount  $\Delta u_i$  that leads to stress loading of the other cells, lessened by  $|\epsilon|J\Delta u_i/N$  compared to our original model (Eq. (16)). On the other hand, in the global strengthening model (described above) when a cell slips the failure stresses of all cells are strengthened by  $|\epsilon|J\Delta u_i/N$ . On long length scales the global strengthening of the failure stress has equivalent effects on the earthquake statistics as the dissipation of the redistributed stress, up to corrections of order  $O(1/N)$ , so the scaling behavior for large events of both models are the same. Moreover, Eq. (17) can be rewritten as:

$$\tau_i = J[1 - |\epsilon|][\bar{u} - u_i] + K_L v t - [K_L + J|\epsilon|]u_i. \quad (18)$$

We can now absorb  $|\epsilon|$  by defining  $J' = J(1 - |\epsilon|)$  and  $K'_L = K_L + J|\epsilon|$ . Rewriting Eq. (18) with the new definitions, and dropping the  $|\epsilon|$  contribution in  $[K'_L - J|\epsilon|]v t$  since  $v \rightarrow 0$ , we find:

$$\tau_i = J'\bar{u} + K'_L v t - (K'_L + J')u_i. \quad (19)$$

Therefore we recover Eq. (16) with  $J \rightarrow J'$  and  $K_L \rightarrow K'_L$ . This amounts to changing the stress conservation parameter  $c$  (from reference [17]). For Eq. (19):

$$c = J'/(K'_L + J') = 1 - |\epsilon| \quad (20)$$

where  $K_L \rightarrow 0$  since we are concerned with the adiabatic limit. We also know (from reference [17]) that the cutoff  $S_{cf}$  for the Gutenberg–Richter distribution scales as  $S_{cf} \sim 1/(1-c)^2$ . Thus, from Eq. (20) we find that the cutoff for Eq. (17) will scale as  $\sim 1/|\epsilon|^2$ .

**Mapping to Single Interface Magnet Model** The mean field version of the single interface magnet model with infinite range antiferromagnetic interactions is given by [22,74]:

$$\dot{h}_i(t) = J[\bar{h} - h_i(t)] + H(t) - k\bar{h} + \eta_i(h) \quad (21)$$

where  $h_i(t)$  is the position of the domain wall,  $H(t)$  is the external driving field,  $k$  is the coefficient of the antiferromagnetic term, and  $\eta_i(h)$  is the pinning field. In the paper by Fisher et al. [27] it has been shown that the scaling behavior on long length scales resulting from Eq. (5), without the  $-|\epsilon|J\bar{u}$  term, is same as that of Eq. (21) without the antiferromagnetic term  $-k\bar{h}$ . Furthermore, upon inspection we see the following correspondence between the single interface magnet model (Eq. (21)), and the mean field earthquake model (Eq. (17)):

$$-k\bar{h} \iff -|\epsilon|J\bar{u} \quad (22)$$

In other words, the coefficient of the antiferromagnetic term  $k$  plays the same role in the magnet model (Eq. (21)), as the coefficient of strengthening  $|\epsilon|J$  does in the earthquake model (Eq. (17)).

## Summary

### Phase Diagram

The regimes with various statistics produced by the model are summarized by the phase diagram given in Fig. 11. The range  $\epsilon > 0$  corresponds to “mature” localized faults with a weakening rheology and characteristic earthquake statis-

tics. The value  $\epsilon = 0$  corresponds to “immature” strongly inhomogeneous fault zones and fault networks with power law statistics and scale invariant rupture properties. The range  $\epsilon < 0$  corresponds to the fracture and fault networks around large rupture zones, characterized by strengthening due to the creation of new structures and associated emerging aftershocks. The right side of the diagram summarizes the mean field theory results on mode switching described in Sect. “Mode-Switching”. The left side of the phase diagram resembles the phase diagram for avalanches in the nucleation RFIM for magnets [65]. There, too, increasing the disorder from small to large (compared to the ferromagnetic coupling between the individual domains) drives the system from a characteristic avalanche size distribution to a truncated power law, with a disorder induced critical point separating the two regimes.

It may be surprising that the discussed simple BZR model can capture many of the essential general features of earthquake statistics (or other systems with avalanches, such as driven magnetic domain walls). This can be understood through the renormalization group [10,66], a powerful mathematical tool to coarse grain a system and extract its effective behavior on long space-time scales. Many microscopic details of a system are averaged out under coarse graining, and universal aspects of the behavior on long scales depend only on a few basic properties such as symmetries, dimensions, range of interactions, weakening/strengthening, etc. When a model correctly captures those basic features, the results provide proper predictions for statistics, critical exponents, and universal scaling functions near the critical point. Consequently, many models that are in the same universality class lead to the same statistics and exponents [10,17,27,66].

## Conclusions

The phenomenology of earthquakes and avalanches in magnets exhibit a number of power law distributions and scale-invariant functions (Table 1). In search of basic model ingredients that can explain these results, we have focused on models that are rich enough to produce a diversity of observed features, while being simple enough to allow analytical predictions on long spatio-temporal scales. For the earthquake system we use the BZR model for a heterogeneous fault with threshold dynamics and long range stress-transfer interactions [2,5,6]. For the magnet system we use variants of the RFIM model with threshold dynamics and both short range and long range interactions [37,65,66,74]. In both classes of models, changes in the property disorder and dynamic effects lead to different dynamic regimes (Fig. 11). For different ranges of param-

eters, the earthquake model produces fractal and crack-like slip functions, power law frequency-size statistics, characteristic earthquake distribution, mode switching, and aftershocks. Similar features are found with the magnet models. We discussed two universal scaling functions of moment rates near criticality as a stronger test of the theory against observations than mere scaling exponents that have large error bars. As in magnetic systems, we find that our analysis for earthquakes provides a good overall agreement between theory and observations, but with a potential discrepancy in one particular universal scaling function for mean moment-rate shapes at fixed duration. The discrepancy has an interesting precedent in the context of avalanches in magnetic systems, and has been explained there in terms of non-universal time retardation effects due to eddy currents. Similar retardation effects may be due to triggering delays or strengthening effects that are responsible for aftershocks in earthquake faults. More observational data, in particular on small earthquakes would be needed to test some of the predictions in detail.

## Future Directions

We have highlighted some interesting connections between earthquake and magnet systems with a jerky response to a slowly varying driving force. Future useful studies include analysis of factors controlling nucleation processes, transitions to instabilities and final event sizes, along with a more detailed analysis of the effects of geometrical heterogeneities in the fault structure on the statistics of earthquakes. Additional observational data, particularly for small earthquakes, are needed to test predictions for the scaling of the earthquake duration and rupture area with moment, and for accurately testing our mean field predictions for moment rate shapes. Developing analytical corrections to the mean field earthquake models can provide additional important insights. Testing similar ideas in other systems with crackling noise would improve and deepen our understanding of universal behavior in disordered nonequilibrium systems.

## Glossary

**Collective intelligence** Emergent functional behavior of a large number of people that results from *interactions* of individuals rather than from individual reasoning or global optimization.

**Crowd** Agglomeration of many people in the same area at the same time. The density of the crowd is assumed to be high enough to cause continuous interactions with or reactions to other individuals.

**Crowd turbulence** Unanticipated and unintended irregular motion of individuals into different directions due to strong and rapidly changing forces in crowds of extreme density.

**Emergence** Spontaneous establishment of a qualitatively new behavior through non-linear interactions of many objects or subjects.

**Evolutionary optimization** Gradual optimization based on the effect of frequently repeated random mutations and selection processes based on some success function (“fitness”).

**Faster-is-slower effect** This term reflects the observation that certain processes (in evacuation situations, production, traffic dynamics, or logistics) take more time if performed at high speed. In other words, waiting can often help to coordinate the activities of several competing units and to speed up the average progress.

**Freezing-by-heating effect** Noise-induced blockage effect caused by the breakdown of direction-segregated walking patterns (typically two or more “lanes” characterized by a uniform direction of motion). “Noise”

means frequent variations of the walking direction due to nervousness or impatience in the crowd, e. g. also frequent overtaking maneuvers in dense, slowly moving crowds.

**Panic** Breakdown of ordered, cooperative behavior of individuals due to anxious reactions to a certain event. Often, panic is characterized by attempted escape of many individuals from a real or perceived threat in situations of a perceived struggle for survival, which may end up in trampling or crushing of people in a crowd.

**Self-organization** Spontaneous organization (i. e. formation of ordered patterns) not induced by initial or boundary conditions, by regulations or constraints. Self-organization is a result of non-linear interactions between many objects or subjects, and it often causes different kinds of spatio-temporal patterns of motion.

**Social force** Vector describing acceleration or deceleration effects that are caused by social interactions rather than by physical interactions or fields.

## Definition of the Subject

The modeling of pedestrian motion is of great theoretical and practical interest. Recent experimental efforts have revealed quantitative details of pedestrian interactions, which have been successfully cast into mathematical equations. Furthermore, corresponding computer simulations of large numbers of pedestrians have been compared with the empirically observed dynamics of crowds. Such studies have led to a deeper understanding of how collective behavior on a macroscopic scale emerges from individual human interactions. Interestingly enough, the non-linear interactions of pedestrians lead to various complex, spatio-temporal pattern-formation phenomena. This includes the emergence of lanes of uniform walking direction, oscillations of the pedestrian flow at bottlenecks, and the formation of stripes in two intersecting flows. Such self-organized patterns of motion demonstrate that efficient, “intelligent” collective dynamics can be based on simple, local interactions. Under extreme conditions, however, coordination may break down, giving rise to critical crowd conditions. Examples are “freezing-by-heating” and “faster-is-slower” effects, but also the transition to “turbulent” crowd dynamics. These observations have important implications for the optimization of pedestrian facilities, in particular for evacuation situations.

## Introduction

The emergence of new, functional or complex collective behaviors in social systems has fascinated many scientists. One of the primary questions in this field is how cooper-

ation or coordination patterns originate based on elementary individual interactions. While one could think that these are a result of intelligent human actions, it turns out that much simpler models assuming automatic responses can reproduce the observations very well. This suggests that humans are using their intelligence primarily for more complicated tasks, but also that simple interactions can lead to intelligent patterns of motion. Of course, it is reasonable to assume that these interactions are the result of a previous learning process that has optimized the automatic response in terms of minimizing collisions and delays. This, however, seems to be sufficient to explain most observations.

In this contribution, we will start with a short history of pedestrian modeling and, then, introduce a simplified model of pedestrian interactions, the “social force model”. Furthermore, we will discuss its calibration using video tracking data. Next, we will turn to the subject of crowd dynamics, as one typically finds the formation of large-scale spatio-temporal patterns of motion, when many pedestrians interact with each other. These patterns will be discussed in some detail before we will turn to evacuation situations and cases of extreme densities, where one can sometimes observe the breakdown of coordination. Finally, we will address possibilities to design improved pedestrian facilities, using special evolutionary algorithms.

## Pedestrian Dynamics

### Short History of Pedestrian Modeling

Pedestrians have been empirically studied for more than four decades [1,2,3]. The evaluation methods initially applied were based on direct observation, photographs, and time-lapse films. For a long time, the main goal of these studies was to develop a *level-of-service concept* [4], *design elements* of pedestrian facilities [5,6,7,8], or *planning guidelines* [9,10]. The latter have usually the form of *regression relations*, which are, however, not very well suited for the prediction of pedestrian flows in pedestrian zones and buildings with an exceptional architecture, or in challenging evacuation situations. Therefore, a number of simulation models have been proposed, e.g. *queuing models* [11], *transition matrix models* [12], and *stochastic models* [13], which are partly related to each other. In addition, there are models for the *route choice behavior* of pedestrians [14,15].

None of these concepts adequately takes into account the self-organization effects occurring in pedestrian crowds. These are the subject of recent experimental studies [8,16,17,18,19,20]. Most pedestrian models, however, were formulated before. A first modeling approach that

appears to be suited to reproduce spatio-temporal patterns of motion was proposed by Henderson [21], who conjectured that pedestrian crowds behave similar to gases or fluids (see also [22]). This could be partially confirmed, but a realistic gas-kinetic or fluid-dynamic theory for pedestrians must contain corrections due to their particular interactions (i.e. avoidance and deceleration maneuvers) which, of course, do not obey momentum and energy conservation. Although such a theory can be actually formulated [23,24], for practical applications a direct simulation of *individual* pedestrian motion is favorable, since this is more flexible. As a consequence, pedestrian research mainly focuses on *agent-based models* of pedestrian crowds, which also allow one to consider local coordination problems. The “social force model” [25,26] is maybe the most well-known of these models, but we also like to mention *cellular automata* of pedestrian dynamics [27,28,29,30,31,32,33] and *AI-based models* [34,35].

### The Social Force Concept

In the following, we shall shortly introduce the social force concept, which reproduces most empirical observations in a simple and natural way. Human behavior often seems to be “chaotic”, irregular, and unpredictable. So, why and under what conditions can we model it by means of forces? First of all, we need to be confronted with a phenomenon of motion in some (quasi-)continuous space, which may be also an abstract behavioral space such as an opinion scale [36]. Moreover, it is favorable to have a system where the fluctuations due to unknown influences are not large compared to the systematic, deterministic part of motion. This is usually the case in pedestrian traffic, where people are confronted with standard situations and react “automatically” rather than taking complicated decisions, e.g. if they have to evade others.

This “automatic” behavior can be interpreted as the result of a *learning process* based on trial and error [37], which can be simulated with *evolutionary algorithms* [38]. For example, pedestrians have a preferred side of walking, since an asymmetrical avoidance behavior turns out to be profitable [25,37]. The related *formation of a behavioral convention* can be described by means of *evolutionary game theory* [25,39].

Another requirement is the vectorial additivity of the separate force terms reflecting different environmental influences. This is probably an approximation, but there is some experimental evidence for it. Based on quantitative measurements for animals and test persons subject to separately or simultaneously applied stimuli of different nature and strength, one could show that the behavior in

conflict situations can be described by a superposition of forces [40,41]. This fits well into a concept by Lewin [42], according to which behavioral changes are guided by so-called *social fields* or *social forces*, which has later on been put into mathematical terms [25,43]. In some cases, social forces, which determine the amount and direction of systematic behavioral changes, can be expressed as gradients of dynamically varying potentials, which reflect the social or behavioral fields resulting from the interactions of individuals. Such a social force concept was applied to opinion formation and migration [43], and it was particularly successful in the description of collective pedestrian behavior [8,25,26,37].

For reliable simulations of pedestrian crowds, we do not need to know whether a certain pedestrian, say, turns to the right at the next intersection. It is sufficient to have a good estimate what percentage of pedestrians turns to the right. This can be either empirically measured or estimated by means of route choice models [14]. In some sense, the uncertainty about the individual behaviors is averaged out at the macroscopic level of description. Nevertheless, we will use the more flexible microscopic simulation approach based on the social force concept. According to this, the temporal change of the location  $\mathbf{r}_\alpha(t)$  of pedestrian  $\alpha$  obeys the equation of motion

$$\frac{d\mathbf{r}_\alpha(t)}{dt} = \mathbf{v}_\alpha(t). \quad (1)$$

Moreover, if  $\mathbf{f}_\alpha(t)$  denotes the sum of social forces influencing pedestrian  $\alpha$  and if  $\boldsymbol{\xi}_\alpha(t)$  are individual fluctuations reflecting unsystematic behavioral variations, the velocity changes are given by the *acceleration equation*

$$\frac{d\mathbf{v}_\alpha}{dt} = \mathbf{f}_\alpha(t) + \boldsymbol{\xi}_\alpha(t). \quad (2)$$

A particular advantage of this approach is that we can take into account the flexible usage of space by pedestrians, requiring a continuous treatment of motion. It turns out that this point is essential to reproduce the empirical observations in a natural and robust way, i. e. without having to adjust the model to each single situation and measurement site. Furthermore, it is interesting to note that, if the fluctuation term is neglected, the social force model can be interpreted as a particular *differential game*, i. e. its dynamics can be derived from the minimization of a special utility function [44].

### Specification of the Social Force Model

The social force model for pedestrians assumes that each individual  $\alpha$  is trying to move in a desired direction  $\mathbf{e}_\alpha^0$

with a desired speed  $v_\alpha^0$ , and that it adapts the actual velocity  $\mathbf{v}_\alpha$  to the desired one,  $\mathbf{v}_\alpha^0 = v_\alpha^0 \mathbf{e}_\alpha^0$ , within a certain relaxation time  $\tau_\alpha$ . The systematic part  $\mathbf{f}_\alpha(t)$  of the acceleration force of pedestrian  $\alpha$  is then given by

$$\mathbf{f}_\alpha(t) = \frac{1}{\tau_\alpha} (v_\alpha^0 \mathbf{e}_\alpha^0 - \mathbf{v}_\alpha) + \sum_{\beta(\neq\alpha)} \mathbf{f}_{\alpha\beta}(t) + \sum_i \mathbf{f}_{\alpha i}(t), \quad (3)$$

where the terms  $\mathbf{f}_{\alpha\beta}(t)$  and  $\mathbf{f}_{\alpha i}(t)$  denote the repulsive forces describing attempts to keep a certain safety distance to other pedestrians  $\beta$  and obstacles  $i$ . In very crowded situations, additional physical contact forces come into play (see Subsect. “**Force Model for Panicking Pedestrians**”). Further forces may be added to reflect attraction effects between members of a group or other influences. For details see [37].

First, we will assume a simplified interaction force of the form

$$\mathbf{f}_{\alpha\beta}(t) = \mathbf{f}(\mathbf{d}_{\alpha\beta}(t)), \quad (4)$$

where  $\mathbf{d}_{\alpha\beta} = \mathbf{r}_\alpha - \mathbf{r}_\beta$  is the distance vector pointing from pedestrian  $\beta$  to  $\alpha$ . Angular-dependent shielding effects may be furthermore taken into account by a prefactor describing the anisotropic reaction to situations in front of as compared to behind a pedestrian [26,45], see Subsect. “**Angular Dependence**”. However, we will start with a **circular specification** of the distance-dependent interaction force,

$$\mathbf{f}(\mathbf{d}_{\alpha\beta}) = A_\alpha e^{-d_{\alpha\beta}/B_\alpha} \frac{\mathbf{d}_{\alpha\beta}}{\|\mathbf{d}_{\alpha\beta}\|}, \quad (5)$$

where  $d_{\alpha\beta} = \|\mathbf{d}_{\alpha\beta}\|$  is the distance. The parameter  $A_\alpha$  reflects the *interaction strength*, and  $B_\alpha$  corresponds to the *interaction range*. While the dependence on  $\alpha$  explicitly allows for a dependence of these parameters on the single individual, we will assume a homogeneous population, i. e.  $A_\alpha = A$  and  $B_\alpha = B$  in the following. Otherwise, it would be hard to collect enough data for parameter calibration.

**Elliptical Specification** Note that it is possible to express Eq. (5) as gradient of an exponentially decaying potential  $V_{\alpha\beta}$ . This circumstance can be used to formulate a generalized, elliptical interaction force via the potential

$$V_{\alpha\beta}(b_{\alpha\beta}) = AB e^{-b_{\alpha\beta}/B}, \quad (6)$$

where the variable  $b_{\alpha\beta}$  denotes the semi-minor axis  $b_{\alpha\beta}$  of the elliptical equipotential lines. This has been specified according to

$$2b_{\alpha\beta} = \sqrt{\frac{(\|\mathbf{d}_{\alpha\beta}\| + \|\mathbf{d}_{\alpha\beta} - (\mathbf{v}_\beta - \mathbf{v}_\alpha)\Delta t\|)^2}{-\|(\mathbf{v}_\beta - \mathbf{v}_\alpha)\Delta t\|^2}}, \quad (7)$$

so that both pedestrians  $\alpha$  and  $\beta$  are treated symmetrically. The repulsive force is related to the above potential via

$$\begin{aligned} f_{\alpha\beta}(\mathbf{d}_{\alpha\beta}) &= -\nabla_{\mathbf{d}_{\alpha\beta}} V_{\alpha\beta}(b_{\alpha\beta}) \\ &= -\frac{dV_{\alpha\beta}(b_{\alpha\beta})}{db_{\alpha\beta}} \nabla_{\mathbf{d}_{\alpha\beta}} b_{\alpha\beta}(\mathbf{d}_{\alpha\beta}), \end{aligned} \quad (8)$$

where  $\nabla_{\mathbf{d}_{\alpha\beta}}$  represents the gradient with respect to  $\mathbf{d}_{\alpha\beta}$ . Considering the chain rule,  $\|z\| = \sqrt{z^2}$ , and  $\nabla_z \|z\| = z/\sqrt{z^2} = z/\|z\|$ , this leads to the explicit formula

$$\begin{aligned} f_{\alpha\beta}(\mathbf{d}_{\alpha\beta}) &= Ae^{-b_{\alpha\beta}/B} \cdot \frac{\|\mathbf{d}_{\alpha\beta}\| + \|\mathbf{d}_{\alpha\beta} - \boldsymbol{\gamma}_{\alpha\beta}\|}{2b_{\alpha\beta}} \\ &\quad \cdot \frac{1}{2} \left( \frac{\mathbf{d}_{\alpha\beta}}{\|\mathbf{d}_{\alpha\beta}\|} + \frac{\mathbf{d}_{\alpha\beta} - \boldsymbol{\gamma}_{\alpha\beta}}{\|\mathbf{d}_{\alpha\beta} - \boldsymbol{\gamma}_{\alpha\beta}\|} \right) \end{aligned} \quad (9)$$

with  $\boldsymbol{\gamma}_{\alpha\beta} = (\mathbf{v}_\beta - \mathbf{v}_\alpha)\Delta t$ . We used  $\Delta t = 0.5$  s. For  $\Delta t = 0$ , we regain the expression of Eq. (5).

The elliptical specification has two major advantages compared to the circular one: First, the interactions depend not only on the distance, but also on the relative velocity. Second, the repulsive force is not strictly directed from pedestrian  $\beta$  to pedestrian  $\alpha$ , but has a lateral component. As a consequence, this leads to less confrontative, smoother (“sliding”) evading maneuvers. Note that further velocity-dependent specifications of pedestrian interaction forces have been proposed [7,26], but we will restrict to the above specifications, as these are sufficient to demonstrate the method of evolutionary model calibration.

### Evolutionary Calibration with Video Tracking Data

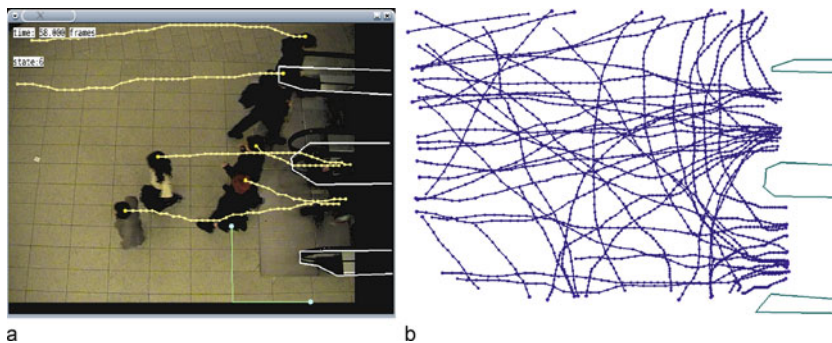

For parameter calibration, several video recordings of pedestrian crowds in different natural environments have been used. The dimensions of the recorded areas were

known, and the floor tiling or environment provided something like a “coordinate system”. The heads were automatically determined by searching for round moving structures, and the accuracy of tracking was improved by comparing actual with linearly extrapolated positions (so it would not happen so easily that the algorithm interchanged or “lost” close by pedestrians). The trajectories of the heads were then projected on two-dimensional space in a way correcting for distortion by the camera perspective. A representative plot of the resulting trajectories is shown in Fig. 1. Note that trajectory data have been obtained with infra-red sensors [47] or video cameras [48,49] for several years now, but algorithms that can simultaneously handle more than one thousand pedestrians have become available only recently [87].

For model calibration, it is recommended to use a hybrid method fusing empirical trajectory data and microscopic simulation data of pedestrian movement in space. In corresponding algorithms, a virtual pedestrian is assigned to each tracked pedestrian in the simulation domain. One then starts a simulation for a time period  $T$  (e.g. 1.5 s), in which one pedestrian  $\alpha$  is moved according to a simulation of the social force model, while the others are moved exactly according to the trajectories extracted from the videos. This procedure is performed for all pedestrians  $\alpha$  and for several different starting times  $t$ , using a fixed parameter set for the social force model.

Each simulation run is performed according to the following scheme:

1. Define a starting point and calculate the state (position  $\mathbf{r}_\alpha$ , velocity  $\mathbf{v}_\alpha$ , and acceleration  $\mathbf{a}_\alpha = d\mathbf{v}_\alpha/dt$ ) for each pedestrian  $\alpha$ .
2. Assign a desired speed  $v_\alpha^0$  to each pedestrian, e.g. the maximum speed during the pedestrian tracking time. This is sufficiently accurate, if the overall pedestrian

Pedestrian, Crowd and Evacuation Dynamics, Figure 1

Video tracking used to extract the trajectories of pedestrians from video recordings close to two escalators (after [45]). **a** Illustration of the tracking of pedestrian heads. **b** Resulting trajectories after being transformed onto the two-dimensional plane

density is not too high and the desired speed is constant in time.

3. Assign a desired goal point for each pedestrian, e. g. the end point of the trajectory.
4. Given the tracked motion of the surrounding pedestrians  $\beta$ , simulate the trajectory of pedestrian  $\alpha$  over a time period  $T$  based on the social force model, starting at the actual location  $\mathbf{r}_\alpha(t)$ .

After each simulation run, one determines the relative distance error

$$\frac{\|\mathbf{r}_\alpha^{\text{simulated}}(t+T) - \mathbf{r}_\alpha^{\text{tracked}}(t+T)\|}{\|\mathbf{r}_\alpha^{\text{tracked}}(t+T) - \mathbf{r}_\alpha^{\text{tracked}}(t)\|}. \quad (10)$$

After averaging the relative distance errors over the pedestrians  $\alpha$  and starting times  $t$ , 1 minus the result can be taken as measure of the goodness of fit (the “fitness”) of the parameter set used in the pedestrian simulation. Hence, the best possible value of the “fitness” is 1, but any deviation from the real pedestrian trajectories implies lower values.

One result of such a parameter optimization is that, for each video, there is a broad range of parameter combinations of  $A$  and  $B$  which perform almost equally well [45]. This allows one to apply additional goal functions in the parameter optimization, e. g. to determine among the best performing parameter values such parameter combinations, which perform well for *several* video recordings, using a fitness function which equally weights the fitness reached in each single video. This is how the parameter values listed in Table 1 were determined. It turns out that, in order to reach a good model performance, the pedestrian interaction force must be specified velocity dependent, as in the elliptical model.

Note that our evolutionary fitting method can be also used to determine interaction laws without prespecified

Pedestrian, Crowd and Evacuation Dynamics, Table 1  
Interaction strength  $A$  and interaction range  $B$  resulting from our evolutionary parameter calibration for the circular and elliptical specification of the interaction forces between pedestrians (see main text). The calibration was based on three different video recordings, one for low crowd density, one for medium, and one for high density. The parameter values are specified as mean value  $\pm$  standard deviation. The best fitness value obtained with the elliptical specification for the video with the lowest crowd density was as high as 0.9

Model	A	B	“Fitness”
Extrapolation	0	–	0.34
Circular	0.11 $\pm$ 0.06	0.84 $\pm$ 0.63	0.35
Elliptical	4.30 $\pm$ 3.91	1.07 $\pm$ 1.35	0.53

interaction functions. For example, one can obtain the distance dependence of pedestrian interactions without a prespecified function. For this, one adjusts the values of the force at given distances  $d_k = kd_1$  (with  $k \in \{1, 2, 3, \dots\}$ ) in an evolutionary way. To get some smoothness, linear interpolation is applied. The resulting fit curve is presented in Fig. 2 (left). It turns out that the empirical dependence of the force with distance can be well fitted by an exponential decay.

### Angular Dependence

A closer study of pedestrian interactions reveals that these are not isotropic, but dependent on the angle  $\varphi_{\alpha\beta}$  of the encounter, which is given by the formula

$$\cos(\varphi_{\alpha\beta}) = \frac{\mathbf{v}_\alpha}{\|\mathbf{v}_\alpha\|} \cdot \frac{-\mathbf{d}_{\alpha\beta}}{\|\mathbf{d}_{\alpha\beta}\|}. \quad (11)$$

Generally, pedestrians show little response to pedestrians behind them. This can be reflected by an angular-dependent prefactor  $w(\varphi_{\alpha\beta})$  of the interaction force [45]. Empirical results are represented in Fig. 2 (right). Reasonable results are obtained for the following specification of the prefactor:

$$w(\varphi_{\alpha\beta}(t)) = \left( \lambda_\alpha + (1 - \lambda_\alpha) \frac{1 + \cos(\varphi_{\alpha\beta})}{2} \right), \quad (12)$$

where  $\lambda_\alpha$  with  $0 \leq \lambda_\alpha \leq 1$  is a parameter which grows with the strength of interactions from behind. An evolutionary parameter optimization gives values  $\lambda \approx 0.1$  [45], i. e. a strong anisotropy. With such an angle-dependent prefactor, the “fitness” of the elliptical force increases from 0.53 to 0.61, when calibrated to the same set of videos. Other angular-dependent specifications split up the interaction force between pedestrians into a component against the direction of motion and another one perpendicular to it. Such a description allows for even smoother avoidance maneuvers.

### Crowd Dynamics

#### Analogies with Gases, Fluids, and Granular Media

When the density is low, pedestrians can move freely, and the observed crowd dynamics can be partially compared with the behavior of gases. At medium and high densities, however, the motion of pedestrian crowds shows some striking analogies with the motion of fluids:

1. Footprints of pedestrians in snow look similar to streamlines of fluids [15].

Pedestrian, Crowd and Evacuation Dynamics, Figure 2

Results of an evolutionary fitting of pedestrian interactions. **a** Empirically determined distance dependence of the interaction force between pedestrians (after [45]). An exponential decay fits the empirical data quite well. The dashed fit curve corresponds to Eq. (5) with the parameters  $A = 0.53$  and  $B = 1.0$ . **b** Angular dependence of the influence of other pedestrians. The direction along the positive  $x$ -axis corresponds to the walking direction of pedestrians,  $y$  to the perpendicular direction

2. At borderlines between opposite directions of walking one can observe “viscous fingering” [50,51].
3. The emergence of pedestrian streams through standing crowds [7,37,52] appears analogous to the formation of river beds [53,54].

At high densities, however, the observations have rather analogies with driven granular flows. This will be elaborated in more detail in Sects. “Force Model for Panicking Pedestrians” and “Collective Phenomena in Panic Situations”. In summary, one could say that fluid-dynamic analogies work reasonably well in normal situations, while granular aspects dominate at extreme densities. Nevertheless, the analogy is limited, since the self-driven motion and the violation of momentum conservation imply special properties of pedestrian flows. For example, one usually does not observe eddies, which typically occur in regular fluids at high enough Reynolds numbers.

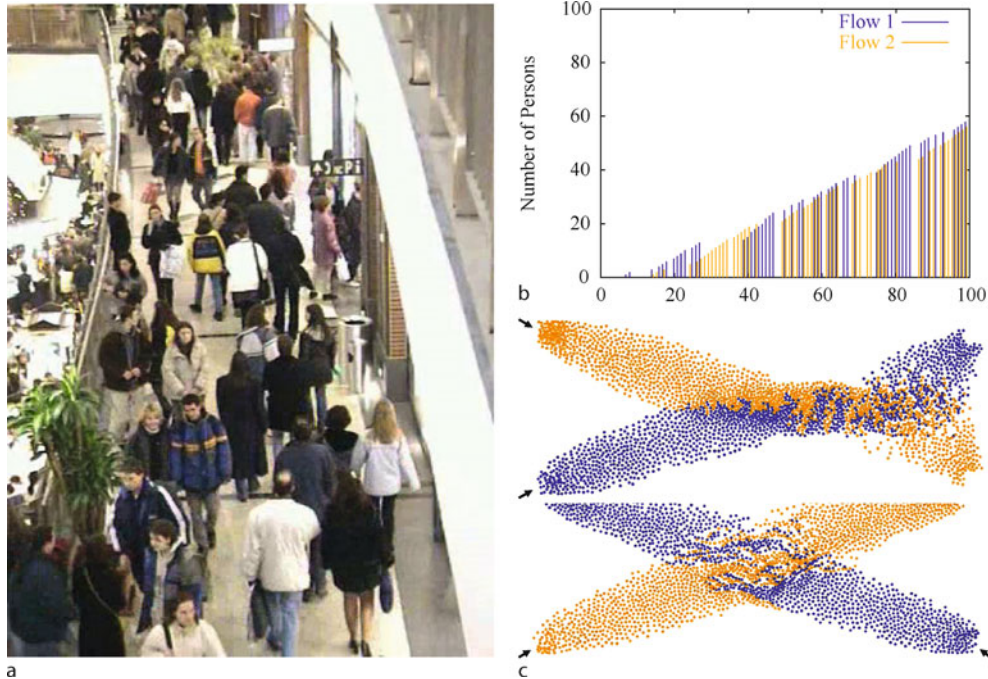

### Self-Organization of Pedestrian Crowds

Despite its simplifications, the social force model of pedestrian dynamics describes a lot of observed phenomena quite realistically. Especially, it allows one to explain various self-organized spatio-temporal patterns that are not externally planned, prescribed, or organized, e. g. by traffic signs, laws, or behavioral conventions. Instead, the spatio-temporal patterns discussed below emerge due to the non-linear interactions of pedestrians even without assuming strategical considerations, communication, or imitative behavior of pedestrians. Despite this, we may still interpret the forming cooperation patterns as phenomena that establish social order on short time scales. It is actu-

ally surprising that strangers coordinate with each other within seconds, if they have grown up in a similar environment. People from different countries, however, are sometimes irritated about local walking habits, which indicates that learning effects and cultural backgrounds still play a role in social interactions as simple as random pedestrian encounters. Rather than on particular features, however, in the following we will focus on the common, internationally reproducible observations.

**Lane Formation** In pedestrian flows one can often observe that oppositely moving pedestrians are forming lanes of uniform walking direction (see Fig. 3). This phenomenon even occurs when there is not a large distance to separate each other, e. g. on zebra crossings. However, the width of lanes increases (and their number decreases), if the interaction continues over longer distances (and if perturbations, e. g. by flows entering or leaving on the sides, are low; otherwise the phenomenon of lane formation may break down [55]).

Lane formation may be viewed as *segregation phenomenon* [56,57]. Although there is a weak preference for one side (with the corresponding behavioral convention depending on the country), the observations can only be well reproduced when repulsive pedestrian interactions are taken into account. The most relevant factor for the lane formation phenomenon is the higher relative velocity of pedestrians walking in opposite directions. Compared to people following each other, oppositely moving pedestrians have more frequent interactions until they have segregated into separate lanes by stepping aside whenever another pedestrian is encountered. The most long-lived pat-

Pedestrian, Crowd and Evacuation Dynamics, Figure 3

**Self-organization of pedestrian crowds.** **a** Photograph of lanes formed in a shopping center. Computer simulations reproduce the self-organization of such lanes very well. **b** Evaluation of the cumulative number of pedestrians passing a bottleneck from different sides. One can clearly see that the narrowing is often passed by groups of people in an oscillatory way rather than one by one. **c** Multi-agent simulation of two crossing pedestrian streams, showing the phenomenon of stripe formation. This self-organized pattern allows pedestrians to pass the other stream without having to stop, namely by moving sideways in a forwardly moving stripe. (After [8])

terns of motion are the ones which change the least. It is obvious that such patterns correspond to lanes, as they minimize the frequency and strength of avoidance maneuvers. Interestingly enough, as computer simulations show, lane formation occurs also when there is no preference for any side.

Lanes minimize frictional effects, accelerations, energy consumption, and delays in oppositely moving crowds. Therefore, one could say that they are a pattern reflecting “collective intelligence”. In fact, it is not possible for a single pedestrian to reach such a collective pattern of motion. Lane formation is a self-organized collaborative pattern of motion originating from simple pedestrian interactions. Particularly in cases of no side preference, the system behavior cannot be understood by adding up the behavior of the single individuals. This is a typical feature of complex, self-organizing systems and, in fact, a widespread characteristics of social systems. It is worth noting, however, that it does not require a conscious behavior to reach forms of social organization like the segregation of oppositely moving pedestrians into lanes. This organiza-

tion occurs automatically, although most people are not even aware of the existence of this phenomenon.

**Oscillatory Flows at Bottlenecks** At bottlenecks, bidirectional flows of moderate density are often characterized by oscillatory changes in the flow direction (see Fig. 3). For example, one can sometimes observe this at entrances of museums during crowded art exhibitions or at entrances of staff canteens during lunch time. While these oscillatory flows may be interpreted as an effect of friendly behavior (“you go first, please”), computer simulations of the social force model indicate that the collective behavior may again be understood by simple pedestrian interactions. That is, oscillatory flows occur even in the absence of communication. Therefore, they may be viewed as another self-organization phenomenon, which again reduces frictional effects and delays. That is, oscillatory flows have features of “collective intelligence”.

While this may be interpreted as result of a learning effect in a large number of similar situations (a “repeated game”), our simulations suggest an even simpler, “many-

particle” interpretation: Once a pedestrian is able to pass the narrowing, pedestrians with the same walking direction can easily follow. Hence, the number and “pressure” of waiting, “pushy” pedestrians on one side of the bottleneck becomes less than on the other side. This eventually increases their chance to occupy the passage. Finally, the “pressure difference” is large enough to stop the flow and turn the passing direction at the bottleneck. This reverses the situation, and eventually the flow direction changes again, giving rise to oscillatory flows.

**Stripe Formation in Intersecting Flows** In intersection areas, the flow of people often appears to be irregular or “chaotic”. In fact, it can be shown that there are several possible collective patterns of motion, among them rotary and oscillating flows. However, these patterns continuously compete with each other, and a temporarily dominating pattern is destroyed by another one after a short time. Obviously, there has not evolved any social convention that would establish and stabilize an ordered and efficient flow at intersections.

Self-organized patterns of motion, however, are found in situations where pedestrian flows cross each other only in two directions. In such situations, the phenomenon of

stripe formation is observed [58]. Stripe formation allows two flows to penetrate each other without requiring the pedestrians to stop. For an illustration see Fig. 3. Like lanes, stripes are a segregation phenomenon, but not a stationary one. Instead, the stripes are density waves moving into the direction of the sum of the directional vectors of both intersecting flows. Naturally, the stripes extend sideways into the direction which is perpendicular to their direction of motion. Therefore, the pedestrians move forward *with* the stripes and sideways *within* the stripes. Lane formation corresponds to the particular case of stripe formation where both directions are exactly opposite. In this case, no intersection takes place, and the stripes do not move systematically. As in lane formation, stripe formation allows to minimize obstructing interactions and to maximize the average pedestrian speeds, i. e. simple, repulsive pedestrian interactions again lead to an “intelligent” collective behavior.

### Evacuation Dynamics

While the previous section has focused on the dynamics of pedestrian crowds in normal situations, we will now turn to the description of situations in which extreme crowd

Pedestrian, Crowd and Evacuation Dynamics, Table 2

Incomplete list of major crowd disasters since 1970 after J. F. Dickie in [59], <http://www.crowddynamics.com/Main/Crowddisasters.html>, [http://SportsIllustrated.CNN.com/soccer/world/news/2000/07/09/stadium\\_disasters\\_ap/](http://SportsIllustrated.CNN.com/soccer/world/news/2000/07/09/stadium_disasters_ap/), and other internet sources, excluding fires, bomb attacks, and train or plane accidents. The number of injured people was usually a multiple of the fatalities

Date	Place	Venue	Deaths	Reason
1971	Ibrox, UK	Stadium	66	Collapse of barriers
1974	Cairo, Egypt	Stadium	48	Crowds break barriers
1982	Moscow, USSR	Stadium	340	Re-entering fans after last minute goal
1988	Katmandu, Nepal	Stadium	93	Stampede due to hailstorm
1989	Hillsborough, Sheffield, UK	Stadium	96	Fans trying to force their way into the stadium
1990	New York City	Bronx	87	Illegal happy land social club
1990	Mena, Saudi Arabia	Pedestrian Tunnel	1426	Overcrowding
1994	Mena, Saudi Arabia	Jamarat Bridge	266	Overcrowding
1996	Guatemala City, Guatemala	Stadium	83	Fans trying to force their way into the stadium
1998	Mena, Saudi Arabia		118	Overcrowding
1999	Kerala, India	Hindu Shrine	51	Collapse of parts of the shrine
1999	Minsk, Belarus	Subway Station	53	Heavy rain at rock concert
2001	Ghana, West Africa	Stadium	> 100	Panic triggered by tear gas
2004	Mena, Saudi Arabia	Jamarat Bridge	251	Overcrowding
2005	Wai, India	Religious Procession	150	Overcrowding (and fire)
2005	Bagdad, Iraq	Religious Procession	> 640	Rumors regarding suicide bomber
2005	Chennai, India	Disaster Area	42	Rush for flood relief supplies
2006	Mena, Saudi Arabia	Jamarat Bridge	363	Overcrowding
2006	Pilippines	Stadium	79	Rush for game show tickets
2006	Ibb, Yemen	Stadium	51	Rally for Yemeni president

densities occur. Such situations may arise at mass events, particularly in cases of urgent egress. While most evacuations run relatively smoothly and orderly, the situation may also get out of control and end up in terrible crowd disasters (see Table 2). In such situations, one often speaks of “panic”, although, from a scientific standpoint, the use of this term is rather controversial. Here, however, we will not be interested in the question whether “panic” actually occurs or not. We will rather focus on the issue of crowd dynamics at high densities and under psychological stress.

### Evacuation and Panic Research

Computer models have been also developed for emergency and evacuation situations [32,60,61,62,63,64,65,66,67,68]. Most research into panic, however, has been of empirical nature (see, e. g. [69,70,71,72]), carried out by social psychologists and others.

With some exceptions, panic is observed in cases of scarce or dwindling resources [69,73], which are either required for survival or anxiously desired. They are usually distinguished into escape panic (“stampedes”, bank or stock market panic) and acquisitive panic (“crazes”, speculative manias) [74,75], but in some cases this classification is questionable [76].

It is often stated that panicking people are obsessed by short-term personal interests uncontrolled by social and cultural constraints [69,74]. This is possibly a result of the reduced attention in situations of fear [69], which also causes that options like side exits are mostly ignored [70]. It is, however, mostly attributed to social contagion [69,71,73,74,75,76,77,78,79,80,81], i. e., a transition from individual to mass psychology, in which individuals transfer control over their actions to others [75], leading to conformity [82]. This “herding behavior” is in some sense irrational, as it often leads to bad overall results like dangerous overcrowding and slower escape [70,75,76]. In this way, herding behavior can increase the fatalities or, more generally, the damage in the crisis faced.

The various socio-psychological theories for this contagion assume hypnotic effects, rapport, mutual excitation of a primordial instinct, circular reactions, social facilitation (see the summary by Brown [80]), or the emergence of normative support for selfish behavior [81]. Brown [80] and Coleman [75] add another explanation related to the prisoner’s dilemma [83,84] or common goods dilemma [85], showing that it is reasonable to make one’s subsequent actions contingent upon those of others. However, the socially favorable behavior of walking orderly is unstable, which normally gives rise to rushing by everyone. These thoughtful considerations are well compatible

with many aspects discussed above and with the classical experiments by Mintz [73], which showed that jamming in escape situations depends on the reward structure (“payoff matrix”).

Nevertheless and despite of the frequent reports in the media and many published investigations of crowd disasters (see Table 2), a quantitative understanding of the observed phenomena in panic stampedes was lacking for a long time. In the following, we will close this gap.

### Situations of “Panic”

Panic stampede is one of the most tragic collective behaviors [71,72,73,74,75,77,78,79,80,81], as it often leads to the death of people who are either crushed or trampled down by others. While this behavior may be comprehensible in life-threatening situations like fires in crowded buildings [69,70], it is hard to understand in cases of a rush for good seats at a pop concert [76] or without any obvious reasons. Unfortunately, the frequency of such disasters is increasing (see Table 2), as growing population densities combined with easier transportation lead to greater mass events like pop concerts, sport events, and demonstrations. Nevertheless, systematic empirical studies of panic [73,86] are rare [69,74,76], and there is a scarcity of quantitative theories capable of predicting crowd dynamics at extreme densities [32,60,61,64,65,68]. The following features appear to be typical [46,55]:

1. In situations of escape panic, individuals are getting nervous, i. e. they tend to develop blind actionism.
2. People try to move considerably faster than normal [9].
3. Individuals start pushing, and interactions among people become physical in nature.
4. Moving and, in particular, passing of a bottleneck frequently becomes incoordinated [73].
5. At exits, jams are building up [73]. Sometimes, intermittent flows or arching and clogging are observed [9], see Fig. 4.
6. The physical interactions in jammed crowds add up and can cause dangerous pressures up to 4,500 Newtons per meter [59,70], which can bend steel barriers or tear down brick walls.
7. The strength and direction of the forces acting in large crowds can suddenly change [87], pushing people around in an uncontrollable way. This may cause people to fall.
8. Escape is slowed down by fallen or injured people turning into “obstacles”.
9. People tend to show herding behavior, i. e., to do what other people do [69,78].

Pedestrian, Crowd and Evacuation Dynamics, Figure 4  
Panicking football fans trying to escape the football stadium in Sheffield. Because of a clogging effect, it is difficult to pass the open door

10. Alternative exits are often overlooked or not efficiently used in escape situations [69,70].

The following quotations give a more personal impression of the conditions during crowd panic:

1. "They just kept pushin' forward and they would just walk right on top of you, just trample over ya like you were a piece of the ground." (After the panic at "The Who Concert Stampede" in Cincinnati.)
2. "People were climbin' over people ta get in ... an' at one point I almost started hittin' 'em, because I could not believe the animal, animalistic ways of the people, you know, nobody cared." (After the panic at "The Who Concert Stampede".)
3. "Smaller people began passing out. I attempted to lift one girl up and above to be passed back ... After several tries I was unsuccessful and near exhaustion." (After the panic at "The Who Concert Stampede".)
4. "I couldn't see the floor because of the thickness of the smoke." (After the "Hilton Hotel Fire" in Las Vegas.)
5. "The club had two exits, but the young people had access to only one", said Narend Singh, provincial minister for agriculture and environmental affairs. However, the club's owner, Rajan Naidoo, said the club had four exits, and that all were open. "I think the children panicked and headed for the main entrance where they initially came in," he said." (After the "Durban Disco Stampede".)
6. "At occupancies of about 7 persons per square meter the crowd becomes almost a fluid mass. Shock waves can be propagated through the mass, sufficient to ... propel them distances of 3 meters or more. ... People

may be literally lifted out of their shoes, and have clothing torn off. Intense crowd pressures, exacerbated by anxiety, make it difficult to breathe, which may finally cause compressive asphyxia. The heat and the thermal insulation of surrounding bodies cause some to be weakened and faint. Access to those who fall is impossible. Removal of those in distress can only be accomplished by lifting them up and passing them overhead to the exterior of the crowd." (J. Fruin in [88].)

7. "It was like a huge wave of sea gushing down on the pilgrims" (P. K. Abdul Ghafour, Arab News, after the sad crowd disaster in Mena on January 12, 2006).

### Force Model for Panicking Pedestrians

Additional, physical interaction forces  $f_{\alpha\beta}^{\text{ph}}$  come into play when pedestrians get so close to each other that they have physical contact (i. e.  $d_{\alpha\beta} < r_{\alpha\beta} = r_{\alpha} + r_{\beta}$ , where  $r_{\alpha}$  means the "radius" of pedestrian  $\alpha$ ). In this case, which is mainly relevant to panic situations, we assume also a "body force"  $k(r_{\alpha\beta} - d_{\alpha\beta})\mathbf{n}_{\alpha\beta}$  counteracting body compression and a "sliding friction force"  $\kappa(r_{\alpha\beta} - d_{\alpha\beta})\Delta v_{\beta\alpha}^t \mathbf{t}_{\alpha\beta}$  impeding relative tangential motion. Inspired by the formulas for granular interactions [89,90], we assume

$$\mathbf{f}_{\alpha\beta}^{\text{ph}}(t) = k\Theta(r_{\alpha\beta} - d_{\alpha\beta})\mathbf{n}_{\alpha\beta} + \kappa\Theta(r_{\alpha\beta} - d_{\alpha\beta})\Delta v_{\beta\alpha}^t \mathbf{t}_{\alpha\beta}, \quad (13)$$

where the function  $\Theta(z)$  is equal to its argument  $z$ , if  $z \geq 0$ , otherwise 0. Moreover,  $\mathbf{t}_{\alpha\beta} = (-n_{\alpha\beta}^2, n_{\alpha\beta}^1)$  means the tangential direction and  $\Delta v_{\beta\alpha}^t = (\mathbf{v}_{\beta} - \mathbf{v}_{\alpha}) \cdot \mathbf{t}_{\alpha\beta}$  the tangential velocity difference, while  $k$  and  $\kappa$  represent large constants. (Strictly speaking, friction effects already set in before pedestrians touch each other, because of the psychological tendency not to pass other individuals with a high relative velocity, when the distance is small.)

The interactions with the boundaries of walls and other obstacles are treated analogously to pedestrian interactions, i. e., if  $d_{\alpha i}(t)$  means the distance to obstacle or boundary  $i$ ,  $\mathbf{n}_{\alpha i}(t)$  denotes the direction perpendicular to it, and  $\mathbf{t}_{\alpha i}(t)$  the direction tangential to it, the corresponding interaction force with the boundary reads

$$\mathbf{f}_{\alpha i} = \{A_{\alpha} \exp[(r_{\alpha} - d_{\alpha i})/B_{\alpha}] + k\Theta(r_{\alpha} - d_{\alpha i})\} \times \mathbf{n}_{\alpha i} - \kappa\Theta(r_{\alpha} - d_{\alpha i})(\mathbf{v}_{\alpha} \cdot \mathbf{t}_{\alpha i})\mathbf{t}_{\alpha i}. \quad (14)$$

Finally, fire fronts are reflected by repulsive social forces similar those describing walls, but they are much stronger. The physical interactions, however, are qualitatively different, as people reached by the fire front become injured and immobile ( $\mathbf{v}_{\alpha} = \mathbf{0}$ ).

### Collective Phenomena in Panic Situations

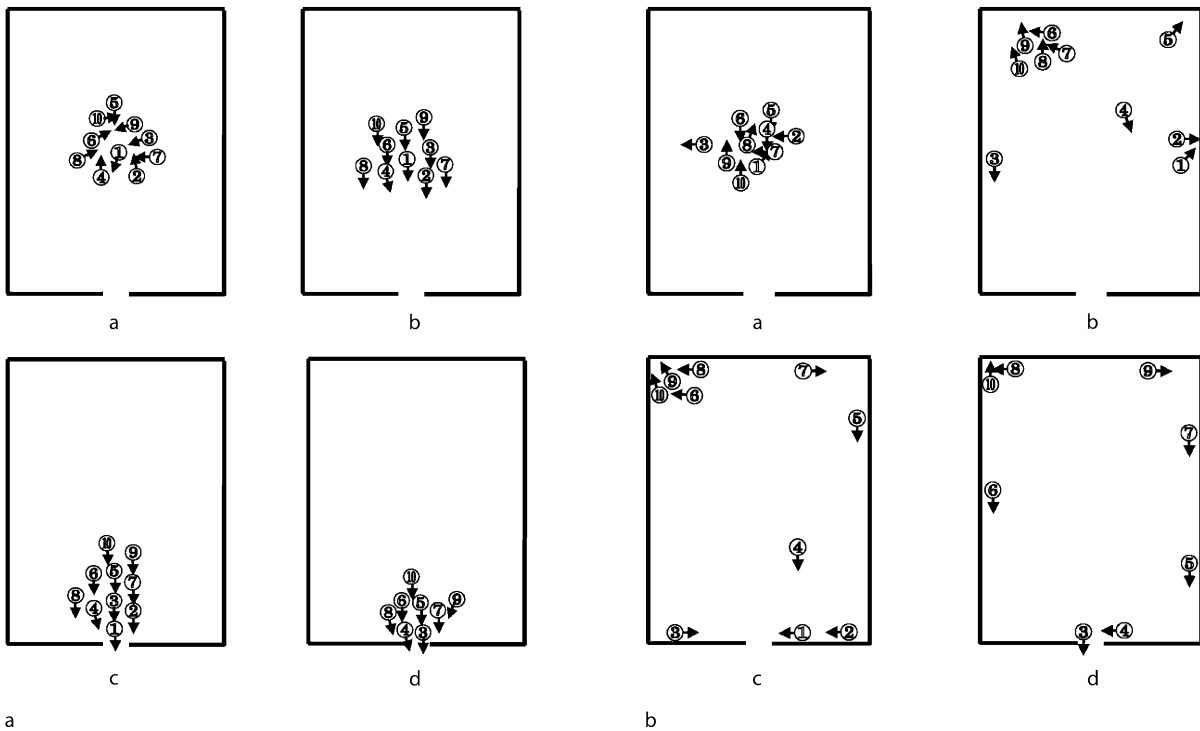

In panic situations (e. g. in some cases of emergency evacuation) the following characteristic features of pedestrian behavior are often observed:

1. People are getting nervous, resulting in a higher level of fluctuations.
2. They are trying to escape from the source of panic, which can be reflected by a significantly higher desired velocity  $v_{\alpha}^0$ .
3. Individuals in complex situations, who do not know what is the right thing to do, orient at the actions of their neighbors, i. e. they tend to do what other people do. We will describe this by an additional herding interaction.

We will now discuss the fundamental collective effects which fluctuations, increased desired velocities, and herding behavior can have. In contrast to other approaches, we do not assume or imply that individuals in panic or emergency situations would behave relentless and asocial, although they sometimes do.

**Herding and Ignorance of Available Exits** If people are not sure what is the best thing to do, there is a tendency to show a “herding behavior”, i. e. to imitate the behavior of others. Fashion, hypes and trends are examples for this. The phenomenon is also known from stock markets, and particularly pronounced when people are anxious. Such a situation is, for example, given if people need to escape from a smoky room. There, the evacuation dynamics is very different from normal leaving (see Fig. 5).

Under normal visibility, everybody easily finds an exit and uses more or less the shortest path. However, when the exit cannot be seen, evacuation is much less efficient and may take a long time. Most people tend to walk relatively straight into the direction in which they suspect an exit, but in most cases, they end up at a wall. Then, they usually move along it in one of the two possible directions, until they finally find an exit [18]. If they encounter others, there is a tendency to take a decision for one direction and move collectively. Also in case of acoustic signals, people may be attracted into the same direction. This can lead to over-crowded exits, while other exits are ignored. The same can happen even for normal visibility, when people

Pedestrian, Crowd and Evacuation Dynamics, Figure 5  
**a** Normal leaving of a room, when the exit is well visible. **b** Escape from a room with no visibility, e. g. due to dense smoke or a power blackout. (After [18])

are not well familiar with their environment and are not aware of the directions of the emergency exits.

Computer simulations suggest that neither individualistic nor herding behavior performs well [46]. Pure individualistic behavior means that each pedestrian finds an exit only accidentally, while pure herding behavior implies that the complete crowd is eventually moving into the same and probably congested direction, so that available emergency exits are not efficiently used. Optimal chances of survival are expected for a certain mixture of individualistic and herding behavior, where individualism allows *some* people to detect the exits and herding guarantees that successful solutions are imitated by small groups of others [46].

**“Freezing by Heating”** Another effect of getting nervous has been investigated in [55]. Let us assume the individual fluctuation strength is given by

$$\eta_\alpha = (1 - n_\alpha)\eta_0 + n_\alpha\eta_{\max}, \quad (15)$$

where  $n_\alpha$  with  $0 \leq n_\alpha \leq 1$  measures the nervousness of pedestrian  $\alpha$ . The parameter  $\eta_0$  means the normal and  $\eta_{\max}$  the maximum fluctuation strength. It turns out that, at sufficiently high pedestrian densities, lanes are destroyed by increasing the fluctuation strength (which is analogous to the temperature). However, instead of the expected transition from the “fluid” lane state to a disordered, “gaseous” state, a solid state is formed. It is characterized by an at least temporarily blocked, “frozen” situation so that one calls this paradoxical transition “*freezing by heating*” (see Fig. 6). Notably enough, the blocked state has a *higher* degree of order, although the internal energy is *increased* [55].

The preconditions for this unusual freezing-by-heating transition are the driving term  $v_\alpha^0 e_\alpha^0 / \tau_\alpha$  and the dissipative friction  $-v_\alpha / \tau_\alpha$ , while the sliding friction force is not required. Inhomogeneities in the channel diameter or other impurities which temporarily slow down pedestrians can further this transition at the respective places. Finally note that a transition from fluid to blocked pedes-

Pedestrian, Crowd and Evacuation Dynamics, Figure 6  
Result of the noise-induced formation of a “frozen” state in a (periodic) corridor used by oppositely moving pedestrians (after [55])

trian counter flows is also observed, when a critical density is exceeded [31,55].

**Intermittent Flows, Faster-Is-Slower Effect, and “Phantom Panic”** If the overall flow towards a bottleneck is higher than the overall outflow from it, a pedestrian queue emerges [91]. In other words, a waiting crowd is formed upstream of the bottleneck. High densities can result, if people keep heading forward, as this eventually leads to higher and higher compressions. Particularly critical situations may occur if the arrival flow is much higher than the departure flow, especially if people are trying to get towards a strongly desired goal (“acquisitive panic”) or away from a perceived source of danger (“escape panic”) with an increased driving force  $v_\alpha^0 e_\alpha^0 / \tau$ . In such situations, the high density causes coordination problems, as several people compete for the same few gaps. This typically causes body interactions and frictional effects, which can slow down crowd motion or evacuation (“*faster is slower effect*”).

A possible consequence of these coordination problems are intermittent flows. In such cases, the outflow from the bottleneck is not constant, but it is typically interrupted. While one possible origin of the intermittent flows are clogging and arching effects as known from granular flows through funnels or hoppers [89,90], stop-and-go waves have also been observed in more than 10 meter wide streets and in the 44 meters wide entrance area to the Jamarat Bridge during the pilgrimage in January 12, 2006 [87], see Fig. 7. Therefore, it seems to be important that people do not move continuously, but have minimum strides [25]. That is, once a person is stopped, he or she will not move until some space opens up in front. However, increasing impatience will eventually reduce the minimum stride, so that people eventually start moving again, even if the outflow through the bottleneck is stopped. This will lead to a further compression of the crowd.

In the worst case, such behavior can trigger a “*phantom panic*”, i. e. a crowd disaster *without* any serious reasons (e. g., in Moscow, 1982). For example, due to the “faster-is-slower effect” panic can be triggered by small pedestrian counterflows [70], which cause delays to the crowd intending to leave. Consequently, stopped pedestrians in the back, who do not see the reason for the temporary slowdown, are getting impatient and pushy. In accordance with observations [7,25], one may model this by increasing the desired velocity, for example, by the formula

$$v_\alpha^0(t) = [1 - n_\alpha(t)]v_\alpha^0(0) + n_\alpha(t)v_\alpha^{\max}. \quad (16)$$

Herein,  $v_\alpha^{\max}$  is the maximum desired velocity and  $v_\alpha^0(0)$  the initial one, corresponding to the expected velocity of

Pedestrian, Crowd and Evacuation Dynamics, Figure 7

**a** Long-term photograph showing stop-and-go waves in a densely packed street. While stopped people appear relatively sharp, people moving from right to left have a fuzzy appearance. Note that gaps propagate from *right* to *left*. **b** Empirically observed stop-and-go waves in front of the entrance to the Jamarat Bridge on January 12, 2006 (after [87]), where pilgrims moved from *left* to *right*. *Dark areas* correspond to phases of motion, *light colors* to stop phases. **c** Illustration of the “shell model”, in particular of situations where several pedestrians compete for the same gap, which causes coordination problems. **d** Stop-and-go waves resulting from the alternation of forward pedestrian motion and backward gap propagation

leaving. The time-dependent parameter

$$n_\alpha(t) = 1 - \frac{\bar{v}_\alpha(t)}{v_\alpha^0(0)} \quad (17)$$

reflects the nervousness, where  $\bar{v}_\alpha(t)$  denotes the average speed into the desired direction of motion. Altogether,

long waiting times increase the desired speed  $v_\alpha^0$  or driving force  $v_\alpha^0(t)e_\alpha^0/\tau$ , which can produce high densities and inefficient motion. This further increases the waiting times, and so on, so that this tragic feedback can eventually trigger so high pressures that people are crushed or falling and trampled. It is, therefore, imperative, to have sufficiently

wide exits and to prevent counterflows, when big crowds want to leave [46].

**Transition to Stop-and-Go Waves** Recent empirical studies of pilgrim flows in the area of Makkah, Saudi Arabia, have shown that intermittent flows occur not only when bottlenecks are obvious. On January 12, 2006, pronounced stop-and-go waves have been even observed upstream of the 44 m wide entrance to the Jamarat Bridge [87]. While the pilgrim flows were smooth and continuous (“laminar”) over many hours, at 11:53 am stop-and-go waves suddenly appeared and propagated over distances of more than 30 m (see Fig. 7). The sudden transition was related to a significant drop of the flow, i. e. with the onset of congestion [87]. Once the stop-and-go waves set in, they persisted over more than 20 min.

This phenomenon can be reproduced by a recent model based on two continuity equations, one for forward pedestrian motion and another one for backward gap propagation [91]. The model was derived from a “shell model” (see Fig. 7) and describes very well the observed alternation between backward gap propagation and forward pedestrian motion.

**Transition to “Crowd Turbulence”** On the same day, around 12:19, the density reached even higher values and the video recordings showed a sudden transition from stop-and-go waves to *irregular* flows (see Fig. 8). These irregular flows were characterized by random, unintended displacements into all possible directions, which pushed

people around. With a certain likelihood, this caused them to stumble. As the people behind were moved by the crowd as well and could not stop, fallen individuals were trampled, if they did not get back on their feet quickly enough. Tragically, the area of trampled people grew more and more in the course of time, as the fallen pilgrims became obstacles for others [87]. The result was one of the biggest crowd disasters in the history of pilgrimage.

How can we understand this transition to irregular crowd motion? A closer look at video recordings of the crowd reveals that, at this time, people were so densely packed that they were moved involuntarily by the crowd. This is reflected by random displacements into all possible directions. To distinguish these irregular flows from laminar and stop-and-go flows and due to their visual appearance, we will refer to them as “*crowd turbulence*”.

As in certain kinds of fluid flows, “turbulence” in crowds results from a sequence of instabilities in the flow pattern. Additionally, one finds a sharply peaked probability density function of velocity increments

$$V_x^\tau = V_x(\mathbf{r}, t + \tau) - V_x(\mathbf{r}, t), \quad (18)$$

which is typical for turbulence [92], if the time shift  $\tau$  is small enough [87]. One also observes a power-law scaling of the displacements indicating self-similar behavior [87]. As large eddies are not detected, however, the similarity with *fluid* turbulence is limited, but there is still an analogy to turbulence at currency exchange markets [92]. Instead of vortex cascades like in turbulent fluids, one rather finds a hierarchical fragmentation dynamics: At extreme

Pedestrian, Crowd and Evacuation Dynamics, Figure 8

Pedestrian dynamics at different densities. **a** Representative trajectories (space-time plots) of pedestrians during the laminar, stop-and-go, and turbulent flow regime. Each trajectory extends over a range of 8 meters, while the time required for this stretch is normalized to 1. To indicate the different speeds, symbols are included in the curves every 5 seconds. While the laminar flow (*top line*) is fast and smooth, motion is temporarily interrupted in stop-and-go flow (*medium line*), and backward motion can occur in “turbulent” flows (*bottom line*). **b** Example of the temporal evolution of the velocity components  $v_x(t)$  into the average direction of motion and  $v_y(t)$  perpendicular to it in “turbulent flow”, which occurs when the crowd density is extreme. One can clearly see the irregular motion into all possible directions characterizing “crowd turbulence”. For details see [87]

Pedestrian, Crowd and Evacuation Dynamics, Figure 9

**Left:** Snapshot of the on-line visualization of “crowd pressure”. Red colors (see the lower ellipses) indicate areas of critical crowd conditions. In fact, the sad crowd disaster during the Muslim pilgrimage on January 12, 2006, started in this area. **Right:** The “crowd pressure” is a quantitative measure of the onset of “crowd turbulence”. The crowd disaster started when the “crowd pressure” reached particularly high values

densities, individual motion is replaced by mass motion, but there is a stick-slip instability which leads to “rupture” when the stress in the crowd becomes too large. That is, the mass splits up into clusters of different sizes with strong velocity correlations *inside* and distance-dependent correlations *between* the clusters.

“Crowd turbulence” has further specific features [87]. Due to the physical contacts among people in extremely dense crowds, we expect commonalities with granular media. In fact, dense driven granular media may form density waves, while moving forward [93], and can display turbulent-like states [94,95]. Moreover, under quasi-static conditions [94], force chains [96] are building up, causing strong variations in the strengths and directions of local forces. As in earthquakes [97,98] this can lead to events of sudden, uncontrollable stress release with power-law distributed displacements. Such a power-law has also been discovered by video-based crowd analysis [87].

### Some Warning Signs of Critical Crowd Conditions

Turbulent waves are experienced in dozens of crowd-intensive events each year all over the world [88]. Therefore, it is necessary to understand why, where and when potentially critical situations occur. Viewing real-time video recordings is not very suited to identify critical crowd conditions: While the average density rarely exceeds values of 6 persons per square meter, the local densities can reach almost twice as large values [87]. It has been found, however, that even evaluating the local densities is not enough to identify the critical times and locations precisely, which also applies to an analysis of the velocity field [87]. The decisive quantity is rather the “crowd pressure”, i. e. the density, multiplied with the variance of speeds. It allows one to identify critical locations and times (see Fig. 9).

There are even advance warning signs of critical crowd conditions: The crowd accident on January 12, 2006 started about 10 minutes after “turbulent” crowd motion set in, i. e. after the “pressure” exceeded a value of  $0.02/s^2$  (see Fig. 9). Moreover, it occurred more than 30 min after stop-and-go waves set in, which can be easily detected in accelerated surveillance videos. Such advance warning signs of critical crowd conditions can be evaluated on-line by an automated video analysis system. In many cases, this can help one to gain time for corrective measures like flow control, pressure-relief strategies, or the separation of crowds into blocks to stop the propagation of shock-waves [87]. Such anticipative crowd control could increase the level of safety during future mass events.

### Evolutionary Optimization of Pedestrian Facilities

Having understood some of the main factors causing crowd disasters, it is interesting to ask how pedestrian facilities can be designed in a way that maximizes the efficiency of pedestrian flows and the level of safety. One of the major goals during mass events must be to avoid extreme densities. These often result from the onset of congestion at bottlenecks, which is a consequence of the breakdown of free flow and causes an increasing degree of compression. When a certain critical density is increased (which depends on the size distribution of people), this potentially implies high pressures in the crowd, particularly if people are impatient due to long delays or panic.

The danger of an onset of congestion can be minimized by avoiding bottlenecks. Notice, however, that jamming can also occur at widenings of escape routes [46]. This surprising fact results from disturbances due to pedestrians, who try to overtake each other and expand in the wider area because of their repulsive interactions.

Pedestrian, Crowd and Evacuation Dynamics, Figure 10

The evolutionary optimization based on Boolean grids [99] uses a two-stage algorithm. **a** In the randomization stage, obstacles are distributed over the grid with some randomness, thereby allowing for the generation of new topologies. **b** In the agglomeration stage, small nearby obstacles are clustered to form larger objects with smooth boundaries

These squeeze into the main stream again at the end of the widening, which acts like a bottleneck and leads to jamming. The corresponding drop of efficiency  $E$  is more pronounced,

1. if the corridor is narrow,
2. if the pedestrians have different or high desired velocities, and
3. if the pedestrian density in the corridor is high.

Obviously, the emerging pedestrian flows decisively depend on the geometry of the boundaries. They can be simulated on a computer already in the planning phase of pedestrian facilities. Their configuration and shape can be systematically varied, e. g. by means of evolutionary algorithms [28,100] and evaluated on the basis of particular mathematical performance measures [7]. Apart from the *efficiency*

$$E = \frac{1}{N} \sum_{\alpha} \frac{\mathbf{v}_{\alpha} \cdot \mathbf{e}_{\alpha}^0}{v_{\alpha}^0} \quad (19)$$

we can, for example, define the *measure of comfort*  $C = (1 - D)$  via the discomfort

$$D = \frac{1}{N} \sum_{\alpha} \frac{(\mathbf{v}_{\alpha} - \overline{\mathbf{v}_{\alpha}})^2}{(v_{\alpha}^0)^2} = \frac{1}{N} \sum_{\alpha} \left( 1 - \frac{\overline{v_{\alpha}^2}}{(v_{\alpha}^0)^2} \right). \quad (20)$$

The latter is again between 0 and 1 and reflects the frequency and degree of sudden velocity changes, i. e. the level of discontinuity of walking due to necessary avoidance maneuvers. Hence, the optimal configuration regarding the pedestrian requirements is the one with the highest values of efficiency and comfort.

During the optimization procedure, some or all of the following can be varied:

1. the location and form of planned buildings,
2. the arrangement of walkways, entrances, exits, staircases, elevators, escalators, and corridors,
3. the shape of rooms, corridors, entrances, and exits,
4. the function and time schedule. (Recreation rooms or restaurants are often continuously frequented, rooms for conferences or special events are mainly visited and left at peak periods, exhibition rooms or rooms for festivities require additional space for people standing around, and some areas are claimed by queues or through traffic.)

In contrast to early evolutionary optimization methods, recent approaches allow to change not only the dimensions of the different elements of pedestrian facilities, but also to vary their topology. The procedure of such algorithms is illustrated in Fig. 10. Highly performing designs are illustrated in Fig. 11. It turns out that, for an emergency evacuation route, it is favorable if the crowd does not move completely straight towards a bottleneck. For example, a zigzag design of the evacuation route can reduce the pressure on the crowd upstream of a bottleneck (see Fig. 12). The proposed evolutionary optimization procedure can, of course, not only be applied to the design of new pedestrian facilities, but also to a reduction of existing bottlenecks, when suitable modifications are implemented.

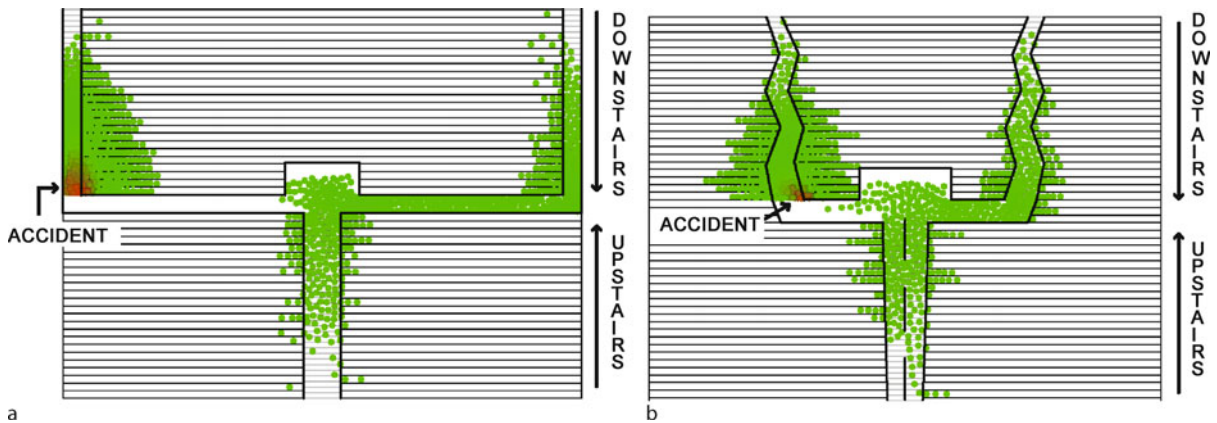

### Future Directions

In this contribution, we have presented a multi-agent approach to pedestrian and crowd dynamics. Despite the great effort required, pedestrian interactions can be well quantified by video tracking. Compared to other social interactions they turn out to be quite simple. Neverthe-

Pedestrian, Crowd and Evacuation Dynamics, Figure 11

Two examples of improved designs for cases with a bottleneck along the escape route of a large crowd, obtained with an evolutionary algorithm based on Boolean grids. People were assumed to move from left to right only. **a** Funnel-shaped escape route. **b** Zig-zag design

Pedestrian, Crowd and Evacuation Dynamics, Figure 12

**a** Conventional design of a stadium exit in an emergency scenario, where we assume that some pedestrians have fallen at the end of the downwards staircase to the left. The dark color indicates high pressures, since pedestrians are impatient and pushing from behind. **b** In the improved design, the increasing diameter of corridors can reduce waiting times and impatience (even with the same number of seats), thereby accelerating evacuation. Moreover, the zigzag design of the downwards staircases changes the pushing direction in the crowd. (After [8])

less, they cause a surprisingly large variety of self-organized patterns and short-lived social phenomena, where coordination or cooperation emerges spontaneously. For this reason, they are interesting to study, particularly as one can expect new insights into coordination mechanisms of social beings beyond the scope of classical game theory. Examples for observed self-organization phenomena in normal situations are lane formation, stripe formation, oscillations and intermittent clogging effects at bottlenecks, and the evolution of behavioral conventions (such as the preference of the right-hand side in continental Europe). Under extreme conditions (high densities or panic), however, coordination may break down, giving rise to “freezing-by-heating” or “faster-is-slower effects”, stop-and-go waves or “crowd turbulence”.

Similar observations as in pedestrian crowds are made in other social systems and settings. Therefore, we expect that realistic models of pedestrian dynamics will also promote the understanding of opinion formation and other kinds of collective behaviors. The hope is that, based on the discovered elementary mechanisms of emergence and self-organization, one can eventually also obtain a better understanding of the constituting principles of more complex social systems. At least the same underlying factors are found in many social systems: Non-linear interactions of individuals, time-dependence, heterogeneity, stochasticity, competition for scarce resources (here: Space and time), decision-making, and learning. Future work will certainly also address issues of perception, anticipation, and communication.

## Glossary

**Dimensionless density** The dimensionless density is the number of objects per excluded volume.

**Excluded volume** The *excluded volume*  $V_{\text{ex}}$  of an object is defined as the volume surrounding it, in which the center of another object must be in order for them to intersect.

**Fracture network** A fracture network is generally defined as a set of individual fractures which may or may not intersect.

**Percolation and percolation threshold** Percolation is defined as the existence of a spanning connected cluster in the fracture network. Percolation occurs when the number of fractures per unit volume is equal or larger than a certain value called the percolation threshold.

**Plane convex fractures** A plane fracture is convex if for any points  $A$  and  $B$  which belong to the fracture, all the points of the segment  $AB$  belong to the fracture.

## Definition of the Subject

The study of fractured porous media is of great practical and theoretical importance. It has been first generated by the fact that the presence of fractures can change completely the macroscopic properties of porous media which are present for instance in oil reservoirs, aquifers or waste repositories. The first contributions to this subject were made from very different standpoints by Barenblatt and

coworkers [7], Conrad and Jacquin [13], and Witherspoon and coworkers (see for instance [22]).

In the eighties, these studies were renewed by concepts such as percolation and fractals. Fracture networks were first addressed in the framework of continuum percolation by [12] and [4].

Since the mid nineties, important progress have been made in this field thanks to systematic numerical experiments which can be rationalized by using the concept of excluded volume.

## Introduction

Knowledge of geometrical properties of fracture networks is crucial to the understanding of flow and other transport processes in geological formations, both at small and large scales; introduction of fractures in a porous rock matrix seriously alters the macroscopic properties of the formation. Moreover, studies of fracture geometries during the last 30 years show that naturally occurring geological fractures exist on scales ranging from a few mm to several kilometers [33]. Therefore, fracture networks are likely to influence the transports on a large range of scales. Because of their importance, fracture networks are studied and applied in various areas such as oil and gas recovery, hydrology, nuclear waste storage and geothermal energy exploitation.

Geological fractures can be defined as discrete discontinuities within a rock mass; these breaks are characterized by the fact that their local aperture (defined as the local distance between the two surfaces which limit the fracture) is significantly smaller than their lateral extent; in other words, when they are viewed from far away, fractures can be assimilated to surfaces of discontinuity; in most cases, these surfaces are relatively plane. Fractures have varying degrees of aperture, and may in some cases be completely closed either because of deposition of material induced by fluid flow, or by displacements of the matrix.

An important property of these fracture sets or fracture network is their connectivity and their percolation properties. If a network percolates, fluid can circulate only through it and most likely much more rapidly than in the surrounding porous medium itself. Connectivity studies of fracture networks were initiated in 3D by Charlaix et al. [12] and Balberg [4].

The purpose of this paper is to provide a complete and updated view of the percolation properties of fracture networks in rocks. It is organized as follows. In Sect. “**Fracture Networks**”, fractures are modeled as plane convex polygons which enables the introduction of the concept of excluded volume  $V_{\text{ex}}$ . This volume is a simple function of

the surface and perimeter of the fractures, and it enables to introduce a dimensionless fracture density  $\rho'$  which is defined as the number of fractures per excluded volume. The tools necessary for the numerical study of the percolation thresholds are detailed and applied to mono- and poly-disperse fracture networks. It is shown that when expressed in terms of  $\rho'$ , the percolation threshold does not depend anymore on the fracture shapes. This crucial property is presented and discussed.

Section “**Determination of the Dimensionless Density from Experimental Data**” is devoted to the determination of the dimensionless density from experimental data. In most cases, these data are based on 1D and 2D measurements of fracture traces along boreholes or on exposed outcrops. These measurements necessitate extrapolation by stereological techniques to three dimensions. Significant progress can be made for plane convex fractures. Some recent applications of the methodology are given.

Finally, the independence of the dimensionless percolation threshold on the fracture shape can be extended to other properties such as other geometric properties and the macroscopic permeability of fractured rocks. These extensions are summarized in Sect. “**Role of the Dimensionless Density in Other Geometrical Properties and Permeability**”.

## Fracture Networks

A fracture network is generally defined as a set of individual fractures which may or may not intersect.

On a scale large with respect to the fracture aperture, fractures are usually modeled as convex, finite polygons possibly based on an embedding disk as shown in Fig. 1a.

This is only a simplifying assumption which however provides a standard starting point for studying fracture networks. Convex polygons can be used to analyze shape and area dependencies of geometrical and topological features in the fracture systems in a systematic way.

The individual fractures are characterized by their orientation. This orientation is usually given by two unit vectors  $\mathbf{n}$  and  $\mathbf{m}$  (cf. Fig. 1).  $\mathbf{n}$  is the normal to the fracture plane;  $\mathbf{m}$  gives the orientation of the polygon in the fracture plane.

The simplest model consists of a network in which all fractures have the same shape and are inscribed in a circle with a given radius  $R$ . The normal vectors  $\mathbf{n}$  are uniformly distributed on the unit sphere. The density  $\rho$  of this isotropic monodisperse network is defined as the number of fractures per unit volume. An illustration of such a fracture system is shown in Fig. 2a.

Next consider three-dimensional networks made up of polydisperse fractures with plane polygonal shapes. These polygons may be regular or not, but all their vertices are supposed to lie on their circumscribed circle, whose radius  $R$  provides a measure of their size. In agreement with many observations of fractured rocks [2], the statistical distribution of the fracture sizes is supposed to be given by a power law

$$n(R) = \alpha R^{-a} \quad (1)$$

where  $n(R)dR$  is the probability of fracture radii in the range  $[R, R + dR]$ ;  $\alpha$  is a normalization coefficient, and the exponent  $a$  ranges between 1 and 5. In practice,  $R$  may vary over a large interval which can span five orders of magnitude, from the size  $R_m$  of the microcracks to the size  $R_M$  of the largest fractures in the system. The normalization

Percolation, and Faults and Fractures in Rock, Figure 1

**Notations.** Convex polygons such as hexagons are created within a circle of radius  $R$  (a). This polygon requires two unit vectors  $\mathbf{n}$  and  $\mathbf{m}$  to be oriented in space (b);  $\mathbf{l}$  is a unit vector perpendicular to  $\mathbf{n}$  and  $\mathbf{m}$ . c illustrates the notations which are mostly used in Sect. “**Determination of the Dimensionless Density from Experimental Data**”

Percolation, and Faults and Fractures in Rock, Figure 2  
 Examples of three-dimensional fracture networks. **a** Monodisperse network made of identical polygons. The volume of size  $L^3$  contains 495 hexagons;  $L = 12R$  where  $R$  is the radius of the circle in which the hexagon is inscribed. **b** Polydisperse network of hexagonal fractures, with  $L' = 4$ ,  $a = 1.5$ ,  $R'_m = 0.1$ , which contains  $N_{fr} = 300$  fractures ( $\rho'_{21} = 1.25$ ,  $\rho'_3 = 2.44$ ). The unit for the coordinates is  $R_M$

condition implies that  $\alpha$  verifies

$$\alpha = \frac{a - 1}{R_m^{1-a} - R_M^{1-a}} \quad (a \neq 1); \tag{2}$$

$$\alpha = \frac{1}{\ln R_M - \ln R_m} \quad (a = 1).$$

The definition of the network density  $\rho$  for polydisperse networks should be modified. To this end, we introduce the volumetric number density of fracture per fracture size  $F(R)$ ,

$$F(R) = \rho n(R) \tag{3}$$

where  $F(R)dR$  is the number of fractures with radius in the range  $[R, R + dR]$  per unit volume.

An example of such polydisperse networks is given in Fig. 2b.

### Percolation of Fracture Networks

#### General Considerations on Continuum Percolation

**Continuum Percolation** Percolation, i. e., the existence of a spanning connected cluster in the fracture network, is a crucial topological property which conditions many other geometrical or transport properties of the network.

Percolation of discrete sites or bonds lattices has been closely studied (see, e. g. [32,37]). In these lattices, the sites or bonds are occupied with a probability  $p$ , which can be interpreted as a concentration. In large systems, percolation occurs when  $p$  exceeds a critical value  $p_c$ , known as

the percolation threshold, which depends on the underlying lattice structure. For  $p$  close to  $p_c$ , however, many geometrical or transport coefficients are known to scale as power laws of the difference  $p - p_c$ , according to the standard form

$$X \propto (p - p_c)^\alpha. \tag{4}$$

The quantity  $X$  may represent the correlation length, the fraction of sites connected to the infinite cluster, or the conductivity of the system. Different exponents are associated with the various quantities, but each is generally believed to be universal, i. e., insensitive to the details of the underlying lattice.

It is, of course, tempting to try to transpose this theoretical framework to the problem at hand. It is intuitively obvious that a fracture network will start percolating if some critical concentration is reached. The main difficulty is to define an equivalent of the probability  $p$  in discrete lattices. As shown below, this can be done by using the concept of excluded volume, introduced by [6] in the context of fracture networks.

Fracture networks belong to the general class of continuum percolation systems. Applications of continuum percolation concepts to geophysical problems have been reviewed by [9]. Continuum percolation differs from lattice percolation in several respects. First, the occupancy probability  $p$  in a discrete lattice ranges between 0 and 1, which means that there is a maximal concentration; the filling of the system can be defined relative to this upper

bound. In continuum percolation, there is generally no such upper bound. For instance, there is ideally no upper limit to the degree of fracturation of a piece of rock. Consequently, the relative concentration  $p$  has to be replaced by a volumetric density. Second, any site or bond in lattice percolation cannot have more than a maximum number  $z$  of neighbors, called the lattice coordination number, whereas there is no limitation to the number of intersections for a fracture in a network. Other differences result from the variable lengths and orientations of the bonds, in contrast with the discrete set of values imposed by a lattice, which may be significant for transport properties (see [5]).

Note that in this section we only consider “large” systems, i. e., the size of the objects in the percolation system may have a broad distribution, but the overall domain extension is supposed to widely exceed the size of the largest objects it contains. This condition may sometimes be difficult to fulfill; natural fracture networks often involve large-scale faults, which may in themselves ensure percolation if they cross the domain of investigation. [11] and later [24] considered such broad size-distributions where the probability of a spanning single fracture is non-zero.

In view of the previous considerations, two definitions of the system concentration appear possible. One is volumetric, quantified by the average number of objects in a reference volume; the other is topological, defined as the average number of connections with surrounding objects. These two definitions are nicely reconciled by the introduction of the concept of excluded volume.

The *excluded volume*  $V_{\text{ex}}$  of an object was defined by [6] as the volume surrounding it, in which the center of another object must be in order for them to intersect. We first discuss the simplest case of populations of identical objects, with volume  $V$ . For example, the excluded volumes of a sphere with volume  $V$  in 3D and of disks with area  $A$  in 2D are

$$\begin{aligned} V_{\text{ex}} &= 8V \quad \text{for spheres;} \\ A_{\text{ex}} &= 4A \quad \text{for disks in the plane.} \end{aligned} \quad (5)$$

These equations are also valid for any object with convex shape, if all the objects in the population have identical orientations.

If the objects are anisotropic and have distributed orientations, the excluded volume has to be averaged over all possible relative orientations of the intersecting objects.

Now suppose that the volumetric density of objects per unit volume is  $\rho$ . It is natural to use  $V_{\text{ex}}$  as a reference volume, and we may define the dimensionless density  $\rho'$  as the number of objects per volume  $V_{\text{ex}}$

$$\rho' = \rho V_{\text{ex}}. \quad (6)$$

On the other hand, the definition of  $V_{\text{ex}}$  implies that  $\rho'$  is also the average number of intersections per object, if they are randomly located according to a Poisson process. Therefore, given the shape of the object and its orientation distribution (and thus  $V_{\text{ex}}$ ), the definition (6) incorporates both the volumetric and topologic aspects mentioned above.

It should be emphasized however, that the definition of the excluded volume is meaningful only if the object locations are uniformly distributed in space. If there are spatial correlations, they should be replaced by a spatial integral of the pair separation distribution function (see for instance [14] for applications to the physics of liquids).

### Calculation of the Excluded Volume for Plane Convex Fractures

A general expression for the excluded volume was established very early in the context of statistical mechanics by [19], for isotropically oriented objects. For two three-dimensional convex objects  $A$  and  $B$  with volumes  $V_A$  and  $V_B$ , areas  $A_A$  and  $A_B$  and surface averaged mean radius of curvature  $R_A$  and  $R_B$ , [19] obtained the mutual exclusion volume

$$V_{\text{ex},AB} = V_A + V_B + (A_A R_B + A_B R_A). \quad (7)$$

This expression can then be averaged over the distributions of object shapes and sizes. For equal spheres, Eq. (5) is obtained. For flat convex objects randomly oriented in space with perimeters  $P_A$  and  $P_B$ , it is reduced to [12]

$$V_{\text{ex},AB} = \frac{1}{4} (A_A P_B + A_B P_A). \quad (8)$$

On averaging (8) over the size distribution of objects with identical shapes, one obtains

$$V_{\text{ex}} = \frac{1}{2} \langle A \rangle \langle P \rangle \quad (9)$$

where  $\langle \cdot \rangle$  is the statistical average. If  $A$  and  $B$  are identical, (9) yields

$$V_{\text{ex}}^{\text{iso}} = \frac{1}{2} A P. \quad (10)$$

If the population of polygons is not isotropic and has a probability distribution  $n(f)$ , which may involve the shape or the size of the polygons, the average of (8) yields

$$\begin{aligned} V_{\text{ex}}^{\text{iso}} &= \frac{1}{4} \iint n(F_1) n(F_2) (A_1 P_2 + A_2 P_1) dF_1 dF_2 \\ &= \frac{1}{2} \langle A \rangle \langle P \rangle \end{aligned} \quad (11)$$

where  $\langle A \rangle$  and  $\langle P \rangle$  are the average area and perimeter. Alternatively, the polygon orientation may be incorporated into  $n(f)$  and a general expression of  $V_{\text{ex}}$  can be obtained.

### Determinations of Continuum Percolation Thresholds

The percolation thresholds of various simple continuous systems have been determined, since the pioneering papers of [35] and [27]. These early works were reviewed by [6] and [5]. A few examples are given in Table 1, for monodisperse objects in a  $d$ -dimensional space. The critical concentration is described in terms of the average number  $\rho'_c$  of connections per object.

The influence of the orientation distribution was investigated by [29,30], and [6]. For sticks with constant length in the plane, [29] has shown that  $\rho'_c$  is identical for uniform orientation distributions in any angular sector and equal to the value 3.6 for an isotropic distribution. On the other hand, the value 3.2 for orthogonal sticks is also valid for any bimodal orientation distribution. By considering three-dimensional systems [6], also conclude that the total excluded volume at percolation is independent of the degree of anisotropy. [4] proposed a set of bounds which correspond to orthogonal and parallel object systems

$$3.2 \leq \rho'_c \leq 4.5 \quad d = 2; \quad 0.7 \leq \rho'_c \leq 2.8 \quad d = 3. \quad (12)$$

All these results were obtained by numerical simulations. One should also mention the heuristic criterion developed by [3]. They define the average “bonding distance”  $l$  as the mean distance between connected objects, which is essentially the gyration radius of the excluded volume

$$l^2 = \frac{1}{V_{\text{ex}}} \int_{V_{\text{ex}}} r^2 d^3 \mathbf{r}. \quad (13)$$

Note that  $l$  does not depend on the density of objects. They then postulate that percolation occurs when the average distance  $L_d$  between objects with at least two neighbors is smaller than or equal to  $2l$ . To evaluate  $L_d$ , they note that

Percolation, and Faults and Fractures in Rock, Table 1  
Thresholds  $\rho'_c$  for various continuum percolation systems in  $d$  dimensions

$d$	Object type	$\rho'_c$	$d$	Object type	$\rho'_c$
2	Orthogonal sticks	3.2	3	Orthogonal elongated rods	0.7
2	Randomly oriented sticks	3.6	3	Randomly oriented elongated rods	1.4
2	Disks or parallel objects	4.5	3	Orthogonal squares	2.0
			3	Randomly oriented squares	2.46
			3	Spheres or parallel objects	2.80

the number  $k$  of connections to a given object corresponds to a Poisson distribution

$$\text{Pr}(k) = \frac{\rho'^k}{k!} e^{-\rho'}. \quad (14)$$

Therefore, the density  $\rho_2$  of objects with at least two neighbors is

$$\rho_2 = \rho \left[ 1 - (1 + \rho') e^{-\rho'} \right]. \quad (15)$$

Thus, an estimate of  $L_d$  follows from

$$\frac{4}{3} \pi \left( \frac{L_d}{2} \right)^3 = \frac{1}{\rho_2}. \quad (16)$$

An equation for the critical concentration  $\rho'_c$  can be directly deduced from the statement that  $L_d = 2l$ . Although the argument is not substantiated, it is quite successful. It yields directly  $\rho'_c = 2.80$  for spheres. In two dimensions,  $L_d$  is replaced by the average distance between objects with at least 5 neighbors.

An interesting feature of this argument is that it can be easily generalized to account for spatial correlations. If  $\rho g(r)$  denotes the probability density of finding an object center at a distance  $r$  from an object located at the origin, the bonding distance is defined by the weighted average

$$l^2 = \frac{\int_{V_{\text{ex}}} r^2 g(r) d^3 \mathbf{r}}{\int_{V_{\text{ex}}} g(r) d^3 \mathbf{r}}. \quad (17)$$

Similarly, the average number of bonds per object appears as

$$\rho' = \rho \int_{V_{\text{ex}}} g(r) d^3 \mathbf{r}. \quad (18)$$

Using these two definitions, an equation for  $\rho'_c$  can be obtained. Its predictions were successfully compared by [3] to numerical simulations for systems of hard-core spheres with or without interaction potentials.

Only monodisperse objects have been addressed so far in this subsection. For polydisperse populations, there seems to be some confusion in the literature. For flat objects, the statistical derivation of the excluded volume in Sect. “Calculation of the Excluded Volume for Plane Convex Fractures” quite naturally yielded the averages (9) or (11), which account for the sizes of the two intersecting objects. For isotropic populations of segments with length  $l$  in the plane or disks with radius  $R$  in space, for instance, the averages can be expressed as

$$V_{\text{ex}} = \frac{2}{\pi} \langle l \rangle^2 \text{ segments}, \quad d = 2 \quad (19a)$$

$$V_{\text{ex}} = \frac{\pi^2}{8} \langle R^2 \rangle \langle R \rangle \text{ disks, } d = 3. \quad (19b)$$

However, another type of average has been proposed by [6], namely,

$$W_{\text{ex}} = \frac{2}{\pi} \langle l^2 \rangle \text{ segments, } d = 2 \quad (20a)$$

$$W_{\text{ex}} = \frac{\pi^2}{8} \langle R^3 \rangle \text{ disks, } d = 3. \quad (20b)$$

On the basis of the numerical simulations of [29,30], [6] and others claim that the average bond number for polydisperse objects is not given by Eq. (6) but instead by

$$\rho'' = \rho W_{\text{ex}}. \quad (21)$$

However, a careful examination of [29]'s data shows that they correspond very accurately to Eq. (6) with (19a). Finally, the derivations of [8] are based on (19b) and yield consistent results.

Actually [29], and [30] showed that  $\rho'_c$  is not invariant for similar systems of segments in the plane with various degrees of polydispersity, while  $\rho''_c$  is. [11] also observed that  $\rho''_c$  is roughly constant for very broad power-law segment size distributions. The profound meaning of this observation is that continuum percolation is not determined only by the average coordination, when connections over various ranges may coexist. As suggested by [28], this is probably because contacts between objects too close to each other are redundant to percolation.

To summarize, the density  $\rho'$  based on  $V_{\text{ex}}$  resulting from the averages (9), (11), or (19a) is always equal to the mean number of intersections per object, but it cannot be used to relate the percolation thresholds of mono- and polydisperse systems. The alternative definition  $\rho''$  in (21) is very successful in this respect and is going to be generalized as  $\rho'_3$  in (29).

## Methods

The three main tools necessary for the numerical study of the percolation properties of the fracture network models are summarized in this section.

First, the medium is assumed to be spatially periodic on a large scale. A detailed description of spatially periodic media is given by [1], and only the main characteristics of these models are briefly repeated here. The geometrical and physical properties of the system under investigation are invariant under the translations

$$\mathbf{R}_i = i_1 \mathbf{l}_1 + i_2 \mathbf{l}_2 + i_3 \mathbf{l}_3 \quad (22)$$

where  $\mathbf{i} = (i_1, i_2, i_3) \in \mathbb{Z}^3$ , and where  $\mathbf{l}_1, \mathbf{l}_2$  and  $\mathbf{l}_3$  define a unit cell where the system is studied. The entire space is tiled by replicas of this unit cell, translated by  $\mathbf{R}_i$ . All the studies presented in this chapter are performed in cubic unit cells where  $|\mathbf{l}_1| = |\mathbf{l}_2| = |\mathbf{l}_3| = L$ .

Spatial periodicity implies that fractures may cross the imaginary unit cell boundaries, and reach the neighboring cells of the periodic medium. Therefore, for polydisperse fractures,  $R_M$  should be at least smaller than  $L/2$ . Moreover, in order to represent a homogeneous medium by a periodic model, one has to set the unit cell size much larger than any finite characteristic length scale in the system. Practically speaking, because of the finite size effects which will be discussed in Sect. "Methods",  $R_M$  is at least smaller than  $L/4$ .

Second, the networks are characterized by a graph which provides all the necessary relations and information. This graph, denoted by  $\Gamma_1$ , consists of vertices which correspond to the polygons, and edges which correspond to the intersection between polygons.  $\Gamma_1$  will be used to study network percolation as a function of fracture shape, distribution and density, as well as to characterize the topological features of the percolating components of the networks.

The information relative to the intersections is stored in the graph  $\Gamma_1$ . Since the networks considered here are spatially periodic, intersections of a polygon  $P_1$  with the periodic replicas of a polygon  $P_2$  in the 26 neighboring unit cells have to be checked as well. Once the intersections have been identified, the edges of  $\Gamma_1$  are known, and  $\Gamma_1$  can be set up.

Third, in order to estimate the percolation thresholds, the classical finite-size scaling method described in [37] is used. The percolating system is studied for various cell sizes  $L$ . For given values of  $L$  and  $\rho$ , the probability  $\Pi_L(\rho)$  of having a percolating cluster is derived from numerous realizations of the system. Then, the numerical data are used to estimate  $\rho_{Lc}$  (the value for which  $\Pi_L(\rho) = 1/2$ ) and an estimate of the width  $\Delta_L$  of the transition region of  $\Pi_L(\rho)$ .  $\Pi_L(\rho)$  was fitted with an error function of the form

$$\Pi_L(\rho) = \frac{1}{\sqrt{2\pi}\Delta_L} \int_{-\infty}^{\rho} \exp\left\{-\frac{(\xi - \rho_{Lc})^2}{2(\Delta_L)^2}\right\} d\xi \quad (23)$$

where  $\rho_{Lc}$  and  $\Delta_L$  are fit parameters. Once they have been evaluated for several values of  $L$ , the asymptotic value  $\rho_{Lc}$  for infinite systems  $\rho_c$  can be derived from the two scaling relations

$$\rho_{Lc} - \rho_c \propto L^{-1/\nu} \quad \Delta_L \propto L^{-1/\nu}. \quad (24)$$

Percolation, and Faults and Fractures in Rock, Figure 3  
**a** The probability of percolation  $\Pi_L(\rho)$  vs the density  $\rho$  of fractures in fracture networks created by equal sized, regular hexagons. Data are for sample sizes  $L/R = 4(\circ), 6(+), 10(\square), 20(\nabla)$ . The solid lines are the fitted error functions. **b** The percolation thresholds  $\rho_c$  for regular polygons ( $\circ$ ) and rectangles with  $a/b = 0.5(+)$  vs  $(A_d/A_p - 1)$ . The linear fit ( $-\cdot-\cdot-$ ) yields  $\rho_c = 0.231 \pm 0.002$  for disks

**Monodisperse Fractures**

This case was addressed by [18]. Since the computer time increases proportionally to the square of the number  $N$  of objects,  $L$  (measured in units of the disk radius  $R$ ) was kept below 16 in this early contribution. Despite the small cell sizes, the scaling laws (24) are well verified, which justifies the extrapolations of  $\rho_c$  at  $L \rightarrow \infty$ . The polygons were created, and intersections identified. Percolation was checked in all possible directions  $x, y$  and  $z$ . Periodic boundary conditions were applied to the 3d graph during this search; this means that a cluster must touch two opposite faces of the unit cell, and in addition contain fractures intersecting one another across the faces.

An example of the plots of the estimated  $\Pi_L(\rho)$  data points is given in Fig. 3a, together with the fitted error functions. Plots of  $\ln(\Delta_L)$  vs  $\ln(L/R)$  were used to obtain the critical exponent  $\nu$ . The various polygons are expected to belong to the same universality class, and  $\nu$  was expected to be the same in all cases. Values were in the range  $\nu = 1.011 \pm 0.044$ . The plots of  $\rho_{Lc}$  vs  $\Delta_L$  were extrapolated for  $\Delta_L \rightarrow 0$  to find  $\rho_c$  and these extrapolations are shown in Fig. 3b as functions of the shape factor  $A_d/A_p - 1$  where  $A_d$  is the area  $\pi R^2$  of the circumscribed disk.

These results can be analyzed in terms of the average number of intersections per fracture  $\rho'$ . (10) can be applied to networks made of identical polygons

$$\frac{V_{ex}}{R^3} = \pi^2 \left(\frac{N_v}{\pi}\right)^2 \cos\left(\frac{\pi}{N_v}\right) \sin^2\left(\frac{\pi}{N_v}\right),$$

(regular  $N_v$ -polygons) (25a)

$$\frac{V_{ex}}{R^3} = \frac{8a(a+1)}{(a^2+1)^{3/2}}, \quad (\text{rectangles with aspect ratio } a)$$

(25b)

The resulting values of  $\rho'_c$  are remarkably constant (cf. [18]). For all the fracture networks, including the cases of anisotropic (rectangular) polygons,  $\rho'_c$  is within the range

$$\rho'_c = 2.26 \pm 0.04.$$

(26)

Note that (26) concords with the limits (12) set up by [4] for 3d systems.

To summarize, this set of numerical results suggests that the percolation threshold of a network of identical Poissonian polygons has a universal value, expressed as Eq. (26).

**Polydisperse Fractures**

Since natural fracture networks are likely to have more complex size and shape distributions, the extension of (26) to these cases is of great interest. The key for this extension is the definition of a proper averaging procedure for the excluded volume.

The fracture size  $R$  is always supposed to follow the power law (1). Moreover, fractures of various shapes  $S$  are considered as well as mixtures of shapes. The three length scales  $R_m, R_M$  and  $L$  define two dimensionless ratios

$$R'_m = \frac{R_m}{R_M}, \quad L' = \frac{L}{R_M}.$$

(27)

Moreover, it will be shown below that global connectivity (percolation) is no longer controlled solely by the lo-

cal one (mean coordination), in the case of size polydispersity, and the definition of the percolation parameter has to be generalized. Since shape effects are well accounted for by  $\langle v_{ex} \rangle$ , it is useful to define the dimensionless shape factor  $\langle v_{ex} \rangle$ , for a set of fractures with identical shapes, but possibly different sizes

$$\langle v_{ex} \rangle = \frac{\langle V_{ex} \rangle}{\langle R \rangle \langle R^2 \rangle} \quad (28)$$

It can then be used to define two dimensionless densities, with different weightings of the fracture sizes

$$\begin{aligned} \rho'_{21} &= \rho \langle v_{ex} \rangle \langle R^2 \rangle \langle R \rangle = \rho \langle V_{ex} \rangle ; \\ \rho'_3 &= \rho \langle v_{ex} \rangle \langle R^3 \rangle . \end{aligned} \quad (29)$$

The subscripts are reminders of the statistical moments of  $R$  involved in each definition.  $\rho'_{21}$  is the generalization of  $\rho'$  for monodisperse networks, since it can be shown that it is still equal to the mean number of intersections per fracture [2]. Both  $\rho'_{21}$  and  $\rho'_3$  reduce of course to  $\rho'$  in case of equal-sized fractures.

The main tools required to study the percolation of polydisperse networks model are similar to the ones described in Sect. "Methods".

For given values of the parameters, the probability  $\Pi$  of having a percolating cluster which spans the cell along the  $x$ -direction is derived from  $N_r$  random realizations of the system; then, the value  $\rho'_c$  for which  $\Pi = 0.5$  is estimated.  $\Pi$  and  $\rho'_c$  depend on several parameters as summarized by the formulae

$$\Pi(R'_m, L', a, S, \rho'), \quad \rho'_c(R'_m, L', a, S) \quad (30)$$

where  $\rho'$  denotes any one of the dimensionless densities defined in (29). For brevity, they will be often written as  $\Pi(L', \rho')$  and  $\rho'_c(L')$ .

In practice,  $\Pi(L', \rho')$  was evaluated from sets of 500 realizations, for about 10 values of the network density, evenly distributed in a range where  $\Pi$  varies from 0.05 to 0.95. Since there is a correspondance between  $\rho'_{21}$  and  $\rho'_3$ , for given values of  $S$ ,  $a$  and  $R_m$ , the same data sets can be used to determine  $\rho'_{21c}(L)$  and  $\rho'_{3c}(L)$ . The 95% confidence interval is estimated to be about  $\pm 0.04$  in terms of  $\rho'_{3c}(L)$ .

The influence on  $\rho'_c$  of the four parameters in Eq. (30) was systematically studied in [24]. We only state here the main result, which is that in the range  $1.5 \leq a \leq 4$ ,  $R_m \ll L$  and for (almost) any fracture shape,  $\rho'_c$  depends only on the domain size, and that in the limit of infinite domains, a unique value of  $\rho'_c(\infty)$  applies in all cases. The independence on the various parameters is illustrated in the following examples.

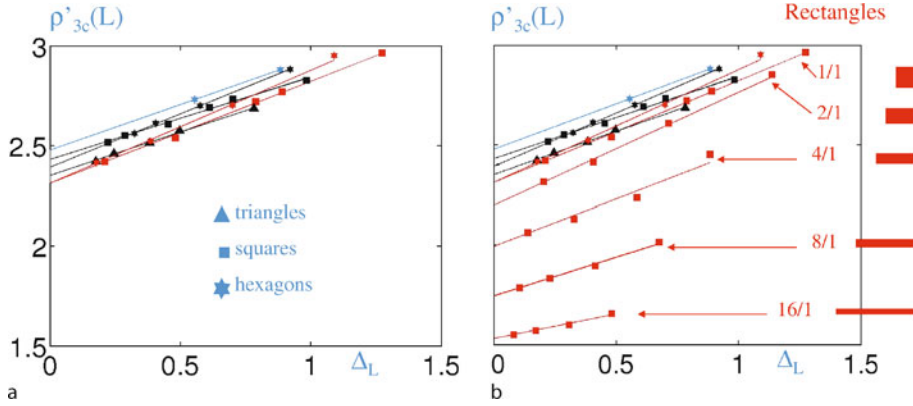

Percolation, and Faults and Fractures in Rock, Figure 4  
The percolation thresholds  $\rho'_{3c}$  (open symbols, solid lines) and  $\rho_c \langle R^3 \rangle$  (black symbols, broken lines) for networks with  $L' = 6$  and  $a = 1.5$  for regular hexagons (o), squares (□), triangles (△), mixture of hexagons and triangles, 50%–50% (▽), and mixture of hexagons and rectangles with aspect ratio 4, 50%–50% (☆)

Percolation, and Faults and Fractures in Rock, Figure 5  
The percolation threshold  $\rho'_{3c}(L', a)$  for networks of hexagonal fractures with  $R'_m = 0.1$ , versus the exponent  $a$ , for various domain sizes  $L$ . The lower line is the extrapolation of the data for  $a = 1.5$  when  $L'$  tends to infinity

In the example of Fig. 4,  $L'$  and  $a$  are kept constant, but the range of size and the fracture shapes varied. The networks contain hexagons, squares or triangles, or mixtures of hexagons with triangles or rectangles with a four to one aspect ratio. The upper set of curves shows that  $\rho'_c$  is indeed independent of  $R_m$  and  $S$ . Note that the rightmost points are actually monodisperse networks. For comparison, the thresholds  $\rho_c \langle R^3 \rangle$ , which do not include the shape factor  $\langle v_{ex} \rangle$  (see Eq. 29), are also shown in the same figure and they are clearly much more scattered. It is the incorporation of  $\langle v_{ex} \rangle$  in the definition of  $\rho'_3$  which unifies the results for the different shapes.

Conversely, the fracture shape (hexagonal) and the range of size ( $R'_m = 0.1$ ) are kept constant in the example

Percolation, and Faults and Fractures in Rock, Figure 6

The percolation threshold  $\rho'_{3c}(L')$  for mono- or polydisperse networks of fractures with various shapes, versus the width  $\Delta_L$  of the percolation transition. In a, the fractures are hexagons, squares or triangles.  $\rho'_{3c}(\infty)$  is the extrapolation for  $\Delta_L \rightarrow 0$ , which falls in the range of Eq. 31. Data for monodisperse networks of rectangles with aspect ratios from 1 to 16 are added in b

of Fig. 5, whereas the exponent  $a$  and the domain size  $L$  are varied. It is seen that  $\rho'_c$  does not vary when  $a$  ranges from 1.5 to 4. However, a definite dependence on the domain size is observed, which corresponds to the well known finite size effects.

The data for increasing  $L'$  can be extrapolated for infinite systems by use of a classical technique. The combination of (23) and (24) shows that  $\rho'_c(L) - \rho'_c(\infty)$  is proportional to the width  $\Delta_L$  of the percolation transition zone. Hence,  $\rho'_c(\infty)$  can be read on the vertical axis of the plot of  $\rho'_c(L)$  versus  $\Delta_L$ , which is shown in Fig. 6. The data for many cases, including various fracture shapes in monodisperse and polydisperse networks, are gathered in Fig. 6a. In all cases, the extrapolated values  $\rho'_{3c}(\infty)$  fall in the narrow range

$$\rho'_{3c}(R'_m, a, S, L' \rightarrow \infty) = \rho'_{3c}(\infty) \approx 2.4 \pm 0.1 . \quad (31)$$

This applies for a variety of shapes, as well as for mixtures of fractures with different shapes (see Fig. 4).

However, when the polygons become elongated,  $\rho'_{3c}(L')$  varies with the aspect ratio. Data for rectangles with aspect ratios  $A_r$  up to 16 are shown in Fig. 6b. It appears that  $\rho'_{3c}(L')$  decreases significantly when  $A_r$  increases.

This can be taken into account by using the shape factor  $\eta = 4R/P$  of the fractures. This ratio is minimum for disks, with  $\eta = 2/\pi \approx 0.637$ , and it increases up to one when the shape deviates from circularity. It turns out that a quadratic correction in terms of  $\eta$  is very successful for the representation of the data for very different and irregular fracture shapes.

Percolation, and Faults and Fractures in Rock, Figure 7

The percolation thresholds  $\rho'_{3c}(L' = 6)$  and  $\rho'_{3c}(\infty)$  for a variety of fracture shapes and size distributions, in comparison with the expressions (32), (33). The marks on the right are the predictions of [15,16,31] for infinitely elongated objects. The fracture shapes are indicated by the icons above or below the data points

All the thresholds obtained in cells with  $L' = 6$  and mono- or polydisperse size distributions with  $a = 1.5$  or 2 and  $R_m = 0.1$  are plotted in Fig. 7 as functions of  $\eta$ . This includes networks of hexagons, squares, triangles, mixtures of hexagons with rectangles or triangles, and rectangles with  $h/w$  up to 16. The data are well fitted by the expression

$$\rho'_{3c}(L') = 2.69 \left[ 1 - 4 \left( \eta - \frac{2}{\pi} \right)^2 \right] \quad (L' = 6) . \quad (32)$$

The extrapolated data for infinite systems are also presented in Fig. 7, in comparison with the corrected version

of Eq. (31),

$$\rho'_{3c}(\infty) = 2.41 \left[ 1 - 4 \left( \eta - \frac{2}{\pi} \right)^2 \right]. \quad (33)$$

In both cases, the deviations never exceed  $\pm 0.1$ . The corrective term becomes significant, i. e., larger than the error bar in (31), when  $\eta > 3/4$ , which corresponds for rectangles to aspect ratios larger than 2.

It can be noted that Eq. (33) predicts a threshold value 1.14 when  $h/w$  tends to infinity (i. e., when  $\eta \rightarrow 1$ ), which is in the range of the predictions 1.5 for prolate ellipsoids [16], 1 for capped cylinders [15] and 1.3 for elongated prisms [31], in the limit of infinite slenderness.

### Determination of the Dimensionless Density from Experimental Data

Since percolation properties are controlled by the dimensionless density  $\rho'$ , it is theoretically and practically important to derive estimations of  $\rho'$  from field data. In most cases, these data are based on 1D and 2D measurements of fracture traces along boreholes or on exposed outcrops which necessitate extrapolation by stereological techniques to 3D. Such extrapolations have already been made for specific fracture shapes by Warburton [39,40], Piggott [26], Berkowitz and Adler [8] and Sisavath et al. [36] (see also the references therein).

Our general methodology which is detailed in [38] can be illustrated by the intersection of a family of convex fractures with a line of length  $L$  which is parallel to the unit vector  $\mathbf{p}$ . Consider a fracture of surface  $A$ , of normal  $\mathbf{n}$  and of in-plane orientation  $\omega$ ; this object does not intersect the line when its center is located out of a surface of area  $A$ . Since this is valid for any in-plane orientation, the excluded volume of the line and of the surface is equal to  $AL|\mathbf{p}\cdot\mathbf{n}|$ . Hence, the average number of intersections  $\langle n_I \rangle$  per unit length between such a line and an isotropic network of a monodisperse family of fractures is

$$\langle n_I \rangle = \frac{1}{2} A \rho. \quad (34)$$

Of course, the major interests of this formula are that it does not depend on the precise shape  $S$  of the fractures and that  $\rho$  can be deduced from  $n_I$  and  $A$ . However, it depends in a crucial way on the convexity of the fractures.

### Isotropic Networks

In order to derive the average number of intersections  $\Sigma_t$  of a family of convex fractures  $\mathcal{F}(R)$  with a plane  $\Pi$  per unit area of the plane, define in  $\Pi$  a large convex region

$\mathcal{R}$  of area  $\mathcal{A}$  and perimeter  $\mathcal{P}$ . The excluded volume of  $\mathcal{F}(R)$  and  $\mathcal{R}$  is thus given by (8). The number of intersections  $d\Sigma_t$  of the fractures of size ranging from  $R$  to  $R + dR$  is proportional to the volumetric density of such fractures multiplied by the excluded volume of  $\mathcal{F}(R)$  and  $\mathcal{R}$  as expressed by (8); when  $\mathcal{A} \rightarrow \infty$ ,  $\mathcal{A} \gg \mathcal{P}$ ; therefore,

$$d\Sigma_t(R) \rightarrow \frac{1}{4} \rho P(R) n(R) dR \quad \text{when } \mathcal{A} \rightarrow \infty. \quad (35)$$

This relation can be averaged over the sizes  $R$

$$\Sigma_t = \int d\Sigma_t(R) = \frac{1}{4} \rho \langle P \rangle. \quad (36)$$

The intersections of the fractures with a plane are called *traces* or *chords*. Let  $c$  be the length of a trace as illustrated in Fig. 1c. Such an intersection of length  $c(z, \mathbf{n}, \omega)$  exists if the vertical coordinate  $z$  of the center verifies

$$z_m(\mathbf{n}, \omega) \leq z \leq z_M(\mathbf{n}, \omega). \quad (37)$$

For a given fracture of size  $R$ , the average trace length  $\langle c \rangle_R$  when the intersection exists, can be expressed as

$$\langle c \rangle_R = \frac{\int d\omega \int d\mathbf{n} \int_{z_m}^{z_M} c dz}{\int d\omega \int d\mathbf{n} \int_{z_m}^{z_M} dz}. \quad (38)$$

Surprisingly, the numerator  $N_R$  of this fraction is easier to evaluate than its denominator  $D_R$ . The most internal integral  $\int_{z_m}^{z_M} c dz$  is equal to the area  $A$  of the fracture projected onto the plane perpendicular to  $\Pi$  which contains the trace, i. e.,  $A \sin \theta$ . Therefore,  $N_R$  is equal to  $\pi^3 A$ . The derivation of  $D_R$  is slightly more involved Santalo [34]; it is proportional to the integral of the Feret (or caliper) diameter over  $\omega$ . Frenet formulae are used to express this integral. Finally,

$$\langle c \rangle_R = \pi \frac{A(R)}{P(R)}. \quad (39)$$

For polydisperse fractures, the overall average  $\langle c \rangle$  is given by

$$\langle c \rangle = \frac{\int dR \Sigma_t(R) \langle c \rangle_R}{\int dR \Sigma_t(R)} = \pi \frac{\langle A \rangle}{\langle P \rangle} \quad (40)$$

a formula which is again an obvious generalization of the disk formula (cf. (24a) of Berkowitz and Adler [8]).

The density of trace intersections  $\Sigma_p$  is defined as the number per unit surface in the observation plane of the points which are intersections of traces. Since the fractures are randomly oriented and distributed in space, the same properties are valid for the traces. Moreover, as a trivial extension of the concept of excluded volume, the excluded

surface  $S_{\text{ex}}$  of two traces of random orientations and of lengths  $c_1$  and  $c_2$  is equal to (cf. [2])

$$S_{\text{ex}} = \frac{2}{\pi} c_1 c_2. \tag{41}$$

Let  $\sigma_t(R, c)dc dR$  be the surface density of traces of length  $c$  ranging from  $c$  to  $c + dc$ , for the fractures of size  $R$  ranging from  $R$  to  $R + dR$ . Hence, the surface density of intersections of traces  $c_1$  corresponding to fractures of size  $R_1$  and of traces  $c_2$  corresponding to fractures of size  $R_2$  is

$$\sigma = \frac{1}{2} \sigma_t(R_1, c_1) \sigma_t(R_2, c_2) \frac{2}{\pi} c_1 c_2. \tag{42}$$

As a direct consequence

$$\Sigma_p = \iiint \sigma \, dc_1 \, dR_1 \, dc_2 \, dR_2. \tag{43}$$

This last expression can be split into a product of integrals since the populations 1 and 2 are independent. According to (35), (36), (43),  $\Sigma_p$  can be expressed as

$$\Sigma_p = \frac{1}{\pi} \frac{\pi^2}{16} \rho^2 \langle A \rangle^2 = \frac{\pi}{16} \rho^2 \langle A \rangle^2. \tag{44}$$

**Extensions**

Let us now examine various possible extensions of the previous formulae.

The precise shape  $S$  of the fractures is never taken into account. Therefore, all the previous formulae are valid whatever the mixture of shapes  $S$ .

For anisotropic networks, the normal vector  $\mathbf{n}$  is not uniformly distributed over the unit sphere. Let  $\theta$  and  $\varphi$  be the two polar angles of  $\mathbf{n}$  (cf. Fig. 1c); the probability that the end of  $\mathbf{n}$  for fractures of sizes in the interval  $[R, R + dR]$  belongs to the interval  $[\theta, \theta + d\theta] \times [\varphi, \varphi + d\varphi]$  is given by  $\rho n(R, \mathbf{n}) d\theta d\varphi dR$ . The statistical average  $\langle \cdot \rangle$  can be calculated with this differential element.

The first quantity which can be easily generalized is  $\langle n_I \rangle$  (cf. (34))

$$\langle n_I \rangle = \rho \iiint n(R, \mathbf{n}) A \cos \theta \, d\theta \, d\varphi \, dR = \rho \langle A | \mathbf{p} \cdot \mathbf{n} | \rangle. \tag{45}$$

The other generalized formulae are summarized in Table 2.  $\alpha$  is the angle between the normal  $\mathbf{v}$  to the plane  $\Pi$  and  $\mathbf{n}$ ; in most cases, by choosing the  $z$ -axis perpendicular to  $\Pi$ ,  $\alpha$  is equal to  $\theta$ ;  $\beta_{12}$  is the angle between the normals  $\mathbf{n}_1$  and  $\mathbf{n}_2$  to the two fractures 1 and 2.

These formulae can be specialized to networks of subvertical fractures with a horizontal observation plane  $\Pi$ .

Percolation, and Faults and Fractures in Rock, Table 2  
The major relations for the various kinds of networks.  $\mathcal{B}_{12} = \langle A_1 A_2 | \sin \beta_{12} | \rangle$

	Isotropic 3D	Anisotropic 3D	Subvertical isotropic	Subvertical anisotropic
$\langle n_I \rangle$	$\frac{1}{2} \rho \langle A \rangle$	$\rho \langle A   \mathbf{p} \cdot \mathbf{n}   \rangle$	$\frac{2}{\pi} \rho \langle A \rangle$	$\rho \langle A   \mathbf{p} \cdot \mathbf{n}   \rangle$
$\Sigma_t$	$\frac{1}{4} \rho \langle P \rangle$	$\frac{\rho}{\pi} \langle   \sin \alpha   P \rangle$	$\frac{\rho}{\pi} \langle P \rangle$	$\frac{\rho}{\pi} \langle P \rangle$
$\langle c \rangle$	$\pi \frac{\langle A \rangle}{\langle P \rangle}$	$\pi \frac{\langle A   \sin \alpha   \rangle}{\langle P   \sin \alpha   \rangle}$	$\pi \frac{\langle A \rangle}{\langle P \rangle}$	$\pi \frac{\langle A \rangle}{\langle P \rangle}$
$\Sigma_p$	$\frac{\pi}{16} \rho^2 \langle A \rangle^2$	$\frac{1}{2} \rho^2 \mathcal{A}_{12}$	$\frac{1}{\pi} \rho^2 \langle A \rangle^2$	$\frac{\rho^2}{2} \mathcal{B}_{12}$

Then,  $\alpha$  is equal to  $\pi/2$  and  $\beta_{12}$  is equal to the angles between the two traces in  $\Pi$ . Such networks can be either isotropic (i. e., the directions of the traces in  $\Pi$  are isotropic), or anisotropic. The corresponding results are detailed in Table 2.

**Discussion**

**Discrete Families of Fractures** In many practical cases, the fractures are perpendicular to a finite set of normals  $\{\mathbf{n}_i; i = 1, \dots, m\}$  with probabilities  $\{n(R, \mathbf{n}_i); i = 1, \dots, m\}$ . The integrals over  $d\theta d\varphi$  are thus replaced by the following summation for a function  $f(R, \mathbf{n}_i)$

$$\rho \sum_{i=1}^m n(R, \mathbf{n}_i) f(R, \mathbf{n}_i). \tag{46}$$

**Practical Use of the Formulae** The major interest of the formulae summarized in Table 2 is to try to use them to derive the macroscopic quantities  $\rho$ ,  $\langle A \rangle$  and  $\langle P \rangle$ . It is easy (and frustrating) to realize that only two of these quantities can be obtained. For instance, (40) implies that  $\langle A \rangle = \pi^{-1} \langle P \rangle \langle c \rangle$ ; from (36),  $\langle P \rangle = 4\rho^{-1} \Sigma_t$ ; therefore  $\langle A \rangle = 4\pi^{-1} \rho^{-1} \Sigma_t \langle c \rangle$ . When these expressions are introduced into (34) or (44), one obtains that the three following ratios should be equal to one

$$\kappa_1 = \frac{\pi}{2} \frac{\langle n_I \rangle}{\Sigma_t \langle c \rangle}, \quad \kappa_2 = \frac{\pi \Sigma_p}{\Sigma_t^2 \langle c \rangle^2}, \quad \kappa_3 = \frac{\pi}{4} \frac{\langle n_I \rangle^2}{\Sigma_p}. \tag{47}$$

The third relation is derived by eliminating  $\Sigma_t \langle c \rangle$  between  $\kappa_1$  and  $\kappa_2$ . These relations provide consistency relations between the data, but not  $\rho$ .

In other words, only two of the three quantities  $\rho$ ,  $\langle A \rangle$  and  $\langle P \rangle$  can be simultaneously derived from the average measured data. Note also that  $\kappa_1$  is insensitive to the spatial organization, and that this is not true for  $\kappa_2$  and  $\kappa_3$  which depend on trace intersections.

One can go further if some geometrical information is available which could be  $\langle V_{\text{ex}} \rangle$ . Here, we shall use a shape

factor  $\eta$  which is defined as  $\langle A \rangle \langle P \rangle^{-2}$ . For 3D isotropic networks, this expression can be combined to (40) and to (36) to yield  $\langle A \rangle$ ,  $\langle P \rangle$  and  $\rho$

$$\langle P \rangle = \frac{\langle c \rangle}{\pi \eta}, \quad \langle A \rangle = \frac{\langle c \rangle^2}{\pi^2 \eta}, \quad \rho = 4\pi \eta \frac{\Sigma_t}{\langle c \rangle} \quad (48)$$

or for a set of fractures normal to  $\mathbf{n}_i$

$$\rho_i = \frac{\pi^2 \eta_i}{|\sin \alpha_i|} \frac{\Sigma_{t_i}}{\langle c \rangle_i}. \quad (49)$$

There are many equivalent ways to derive  $\rho$ . The choice of the adequate formula depends on the available data. Note that formulae which contains  $\Sigma_p$  cannot be applied to families of parallel fractures.

When  $\rho$  and therefore  $\langle V_{ex} \rangle$  (cf. (8)) are known by one way or another, one can derive the dimensionless density  $\rho' = \rho \langle V_{ex} \rangle$  for isotropic and anisotropic networks

$$\rho' = \frac{\rho}{\pi} \langle (A_1 P_2 + A_2 P_1) |\sin \beta_{12}| \rangle \quad (50)$$

$$\rho' = \frac{\rho}{2} \langle A \rangle \langle P \rangle \quad (3d); \quad \rho' = \frac{4\rho}{\pi^2} \langle A \rangle \langle P \rangle \quad (2d). \quad (51)$$

Then, if the fracture network is not too polydisperse, one can use a classical mean field argument and approximate its properties by the properties of a monodisperse network of density  $\rho'$ .

### Applications

Several applications have already been made of the previous methodology and they can be summarized as follows. [36] showed that when data relative to fractures are collected along a line (e.g. a road or a well), estimations can be given to the major geometrical properties of the corresponding fracture networks, such as the volumetric density of fractures and their percolation character. [38] used the two dimensional maps obtained by [25] for subvertical fractures. Among other results, some of the consistency relationships (47) are well verified by these data. As previously,  $\rho'$  is estimated.

Finally [17], reconstructed a three-dimensional fracture network in a granite block from a series of experimental serial sections provided by [21]. It was visualized and its most important geometrical characteristics were studied. Though the network mostly consists of two families of fractures, it is interesting to note that a simple model of randomly oriented, monodisperse hexagons often yields a good order of magnitude for the various geometrical properties, which have been measured on the real block.

### Role of the Dimensionless Density in Other Geometrical Properties and Permeability

Though this article is focused on percolation properties, it is important to notice that the dimensionless densities which were introduced, play a crucial role in other properties as well. [18] studied two main other geometrical properties for monodisperse networks. Fracture networks partition the solid space into blocks; the block density is denoted by  $\rho_b$ . One can introduce the cyclomatic number of the graph  $\Gamma_1$  which is the number of independent cycles of this graph, and more precisely the number of cycles  $\bar{\beta}_1$  per unit volume. [18] showed that  $\rho_b$  and  $\bar{\beta}_1$  when made dimensionless by the excluded volume are independent of the fracture shapes.

Similar properties are found for the macroscopic permeability of fracture networks [20] and of fractured porous media whether they are monodisperse [10] or polydisperse [23]. In a series of contributions, the corresponding dimensionless quantities were shown to depend only on the dimensionless density  $\rho'$ . This is illustrated in Fig. 8. The porous medium has a local permeability  $K_m$  and the monodisperse fractures a conductivity  $\sigma$ . The macroscopic permeability of this medium is denoted by  $K_{eff}$ . Dimensionless quantities denoted by primes can be defined as

$$\sigma = R K_m \sigma', \quad K_{eff} = K_m K'_{eff}. \quad (52)$$

Percolation, and Faults and Fractures in Rock, Figure 8 Statistical averages of the permeability  $\langle K'_{eff} \rangle$  for samples containing  $N_{fr}=16$  or 32 fractures, with 4-, 6- or 20-gonal shapes, as functions of the network density  $\rho'$  and of the fracture conductivity  $\sigma'$ . The cell size is  $L = 4R$ . Data are for squares ( $\square$ ), rectangles with aspect ratios two to one ( $\Delta$ ) or four to one ( $\diamond$ ), hexagons (lines) and icosagons ( $\circ$ )

Figure 8 shows that the average macroscopic permeability ( $\langle K'_{\text{eff}} \rangle$ ) does not depend significantly on the fracture shape. The two major parameters are  $\rho'$  and  $\sigma'$ .

### Future Directions

The percolation properties of networks of random and convex plane fractures are successfully addressed by means of the excluded volume. Many important dimensionless properties of isotropic fracture networks only depend on the dimensionless density of fractures and not on the fracture shapes and sizes which represents a significant simplification.

These properties are not specific of fractures present in rocks and the same methodology can be applied for any other fracture system whatever the characteristic sizes and the nature of the material where it occurs.

These results should be generalized in several directions. In most cases, real fractures are not isotropically oriented and this feature should be incorporated in the next studies on this subject. The same is true for the homogeneous character of the network.

## Glossary

**Impulse** The word *impulse* is used in many areas in different ways. In classical mechanics, the impulse is the integral of force with respect to time. It is also used to refer to a fast-acting force, which is often idealized by a step function or a delta function. In this text, it is used to represent any functional form of pressure increase, either static or transient, which can generate observable signals.

**Magma, melt, liquid** Magma is a general name for molten rock. It is fluid but contains solid and gas inclusions in liquid matrix. The matrix in magma is silicate melt (which is often called just melt), and that in a hydrothermal system is water.

**Volatile** Volatile is compound in silicate melt. The major component is H<sub>2</sub>O, of which concentration is 1–5 wt% depending mainly on pressure and composition of the melt. It exsolves from melt and forms gas bubbles at relatively low pressure (ca. 100 MPa corresponding to the litho-static pressure around several kilo-meters). The second major component is CO<sub>2</sub>. Although its concentration is usually several ppm, some kinds of melts may dissolve 3–30 wt% of CO<sub>2</sub> at several GPa.

**Long period seismic events** Long-period (or very long-period) seismic events are dominant in the period from about 1 s to more than a few tens of seconds. These signals at volcanoes are considered to be generated by interaction or resonance between volcanic fluid and the surrounding medium.

**Ground deformation** Ground deformation is often observed at volcanoes when magma chambers inflate or deflate. Such ground deformation is detected by geodetic measurements such as GPS, tilt or strain meters, and the deformations often continue for a few tens of minutes to days or even months.

**Magma chamber** A magma chamber is a storage system of molten magma. It is generally hard to detect, but is probably located at from a shallow depth (ca. 1 km) to a few tens of km beneath the volcanoes. The shape and size have not been confirmed yet, but it is usually assumed to be rather round and hundreds to thousands of meters in scale. A magma storage system which has a horizontal extent is called a sill, and one which has a vertical extent is called a dike.

**Rectified diffusion and rectified heat transfer** Rectified diffusion is a mechanism which can push dissolved volatiles into bubbles in a sound field. Bubbles take in more volatiles during expansion than they discharge during contraction, mainly because of the following two non-linear effects. Firstly, during expansion the bubble radius becomes larger so that the bubble surface is also larger than the surface during contraction. Secondly, radial bubble expansion tangentially stretches the diffusion layer and sharpens the radial gradient of the volatile concentration in the diffusion layer, so that the volatile flux into the bubble. The mechanism also works to push heat into bubbles and enhances evaporation in a liquid-vapor system. The rectified diffusion and heat transfer have been known and studied in mechanical and chemical engineering.

**Bubble collapse** When the bubble is compressed, oscillates, or loses its mass by diffusion or phase change, it contracts to a very small size and sometimes disappear. Bubble collapse indicates the contraction of a bubble and does not necessarily indicate its disappearance.

## Definition of the Subject

A volcano consists of solids, liquids, gases, and intermediate materials of any two of these phases. Mechanical and thermo-dynamical interactions of these phases are essential in generating a variety of volcanic activities. In particular, the gas phase is mechanically distinct from the other phases and plays important roles in the dynamic phenomena of volcanoes. When we work on volcanic activities, we are almost certainly confronted with physics problems associated with bubbles.

The roles of bubbles in volcanic activities have been investigated mainly in three aspects. Firstly, the nucleation, growth, and expansion of bubbles is considered to be the

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Table 1

List of important variables and constants

Notation	Unit	Definition
$C_{eq}$	–	Equilibrium volatile concentration (weight fraction) in the liquid
$c_l$	$m\ s^{-1}$	Sound speed in the liquid
$c_{pg}$	$J\ kg^{-1}\ K^{-1}$	Heat capacity of the gas at constant pressure
$c_{pl}$	$J\ kg^{-1}\ K^{-1}$	Heat capacity of the liquid at constant pressure
$K_g$	Pa	Effective bulk modulus of the bubble
$K_l$	Pa	Bulk modulus of the liquid
$L$	$J\ kg^{-1}$	Latent heat
$p_g$	Pa	Pressure in the bubble
$p_g$	Pa	Pressure in the liquid far from the bubble
$R$	m	Bubble radius
$S$	m	Outer radius of the cellular bubble
$T$	K	Temperature
$U$	$m\ s^{-1}$	Translational velocity of the bubble
$\gamma$	–	Specific heat ratio
$\eta_l$	Pa s	Liquid viscosity
$\kappa_{gl}$	$m^2\ s^{-1}$	Diffusivity of the volatile in the liquid
$\kappa_T$	$m^2\ s^{-1}$	Thermal diffusivity in the bubble
$\kappa_{Tl}$	$m^2\ s^{-1}$	Thermal diffusivity in the liquid
$\tilde{\mu}$	Pa	Effective stiffness of the magma chamber
$\mu_l$	Pa	Shear elasticity of the liquid
$\rho_l$	$kg\ m^{-3}$	Liquid density
$\Sigma$	$m\ s^{-1}$	Surface tension
$\sigma_\infty$	Pa	Ambient stress change given to the magma chamber
$\tau$	s	Maxwell relaxation time
$\omega$	$rad\ s^{-1}$	Angular frequency

main force that brings the magma to the surface [62,88]. Secondly, a single bubble, if it is sufficiently large, may generate seismic waves when it rapidly expands or accelerates in the volcanic conduit [11,35,81,95], and may generate acoustic waves in the air when it oscillates or bursts at the magma surface [36,82,95,96]. Thirdly, the existence of bubbles can significantly reduce the sound velocity [16,42] and increase the attenuation and dispersion of the waves [15,30,44]. This effect is considered to be relevant to many spectral features of seismic waves and air-waves associated with volcanic activities [3,10,22,45].

Studies on bubble dynamics relevant to the volcanology are spread over many research fields and cannot be covered by a single paper. Good review papers and textbooks have already been published on bubble phenomena in sound fields [61,70,73,74] and on the nucleation and

growth of bubbles in magma [62]. In this paper, we discuss several bubble dynamics phenomena selected from a particular point of view that the bubbly fluid works as an impulse generator. Here the term impulse means a pressure increase, either static or transient, which can generate any observable signal (e. g. earthquakes, ground deformations, airwaves, and an eruption itself). Especially, we focus on the processes that the impulse is excited by nonlinear coupling between the internal processes of a bubbly fluid and an external perturbation. The importance of these processes have recently become noticed as a possible triggering mechanism of eruptions, earthquakes, and inflation of a volcano [57,64]. Although it is generally considered that stress perturbation caused by preceding events is important, exact mechanisms to generate a pressure increase, which is required to trigger the subsequent events, are yet under discussion. In the first place, factors controlling single bubble dynamics are summarized as the elementary processes in the bubbly fluid. Then two distinct liquid-bubble systems are considered, both of which are included in a volcano. The one is a body of bubbly magma confined in an elastic chamber, where elasticity of the chamber, melt viscosity, and gas diffusion are important. The other is a hydrothermal system, where bubble oscillation, evaporation, and heat transfer are important.

## Introduction

### Elementary Processes in Single-Bubble Dynamics

Radial motion of a single bubble interacting with ambient pressure perturbation is the elementary process controlling behaviors of the liquid-bubble mixtures. Although it appears quite simple, it contains various mechanisms in plenty. The great variety of behaviors of a single bubble has attracted many scientists, among whom is Leonardo da Vinci [76]. Nowadays, knowledge of the single bubble dynamics is used and studies are continued in many academic and industrial areas such as mechanical engineering, chemical engineering, medical science, and earth science.

Factors which may control the radial motion of a bubble are the pressure difference inside and outside the bubble, inertia and stress associated with the deformation of the surrounding liquid, propagation of pressure waves, heat and mass transport, phase transition at the bubble wall, chemical reactions, relative translational motion between the bubble and the liquid, and so on. Because including all these mechanisms at the same time in order to calculate the behavior of a bubble is unrealistic, we need to make adequate simplification and assumptions. Each mechanism has its own characteristic time scale in

## Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Table 2

### List of characteristic times

Notation	Equation	Definition
$\tau_c$	(2)	Inertia-controlled bubble collapse
$\tau_g$	(25)	Mass diffusion in the liquid around the bubble
$\tau_T$	(24)	Thermal diffusion in the bubble
$\tau_v <$	(11)	Viscosity-controlled bubble expansion
$\omega_o$	(9)	Natural frequency of a bubble

which the effect is dominant (Table 2), and its own effect on the bubble dynamics. Knowing the individual time scales and features is important when we want to understand and simulate a certain phenomenon correctly and efficiently. A brief review of some representative mechanisms with linearized analyses are presented in Sect. “**Elementary Processes in a Single-Bubble Dynamics**” for this purpose. Based on the results, geophysical phenomena and proposed models are discussed in the latter sections.

### Bubbly Magma in an Elastic Rock as a Pressure Source

We consider a body of bubbly magma confined in an elastic rock. Pressure perturbations to the system are caused by a change of tectonic stress due to local earthquakes, surface unloading by dome collapse, passing seismic waves from a near or distant source, or depressurization of the chamber by degassing or magma leakage. Dynamic response of the system may be relevant to subsequent activities of the volcano as follows.

Nishimura [64] investigated pressure re-equilibration between the bubbles, the melt, and the surrounding elastic medium. It is assumed that the pressure of the system is suddenly decreased. After re-equilibration, the original magma pressure is partially or completely recovered or even exceeded, depending on the size of the bubbles, stiffness of the elastic container, and the confining pressure. His model is used to explain rapid pressurization of a magma chamber triggered by the lava-dome collapse at Soufriere Hills Volcano [97], and pressure recovery in magma filling the chamber after explosive degassing to continue activities at Popocatepetl Volcano [12]. Shimomura et al. [87] extended the formulation of [64] to calculate the time profile of the pressure recovery after sudden decompression. They showed that the time scale of the pressure recovery is strongly controlled by the system parameters, which include stiffness of the elastic container, bubble number density, diffusivity of the volatile in the melt, ambient pressure, and properties of the melt.

Chouet et al. [13] also calculated the time profile assuming the system parameters for Popocatepetl Volcano, and compared the results with a particular source time function of a very-long-period seismic signal. Furthermore, in the same year, Lensky et al. [53] independently developed a mathematically equivalent model considering magma with CO<sub>2</sub> bubbles in mantle rock. They interpreted the results as a possible pressurization mechanism to initiate dikes in mantle which allow the fast transport of magma. There are in fact quite a few documented cases in which eruptions were triggered by local tectonic earthquakes (e.g. [47,68]) and wave propagation from a distant earthquake (e.g. [6,54]). Recently, Manga and Brodsky [57] have given a comprehensive review on the phenomena and possible mechanisms. Brodsky et al. [6] investigated the possibility that a strain wave from a distant earthquake can increase the pressure in bubbly magma by rectified diffusion, which is the mechanism by which volatiles are pumped into a bubble by cyclic expansion and contraction. However, it has turned out that the mechanism by itself can cause a negligibly small pressure increase [6,29]. Several other mechanisms for long-range triggering have been proposed, which include pressure increase from rising bubbles [55], sub-critical crack growth [7], and fracture unclipping [8].

### Acoustic Bubbles in Hydrothermal Systems

A hydrothermal system is another major source of pressure increase, long-period volcano seismic events [46], and triggered seismicity [57,89]. Behaviors of a single bubble and liquid-bubble mixtures in a hydrothermal system are quite different from those in a magmatic system, mainly because of the water viscosity which is less than that of magma by several orders of magnitude. We introduce several phenomena which are particular to the hydrothermal systems in Sect. “**Acoustic Bubbles in Hydrothermal Systems**”.

Geysers activity is well known for intermittent activity of hot-water effusion. The effusion process looks quite similar to volcanic eruptions, and some geysers are characterized by regular intervals of time and duration, which are also recognized in particular types of eruptions and seismic activities. Consequently, the geysers have been widely studied using seismological and geophysical techniques, as well as field observations, not only for clarifying the mechanism of the geysers but also for understanding the volcanic activities (e.g., [39,40,43,65]). Kedar et al. [39,40] conducted a unique experiment at Old Faithful Geyser, Yellowstone. They measured pressure within the geyser’s water column simultaneously with seismic measurements

on the surface. The data demonstrated that the tremor observed at Old Faithful results from impulsive events in the geyser. The impulsive events were modeled by a collapse of a spherical bubble by cooling that occurred when the water column reached a critical temperature. Their data are reviewed in Sect. “Acoustic Bubbles in Hydrothermal Systems” in relation to other studies on the dynamics of gas and vapor bubbles.

## Elementary Processes in a Single-Bubble Dynamics

### Equation of Motion for the Bubble Radius

Motion of a bubble is in fact a fluid dynamical problem for the liquid surrounding the bubble. The simplest model describing the behavior of a bubble is based on three assumptions:

- (1) The bubble is spherical,
- (2) The liquid is incompressible, and
- (3) The motion is radial.

Using the basic equations of fluid mechanics, which are the continuity equation and the momentum equation, and the force balance at the bubble surface, the first equation of motion for the bubble radius was obtained by Rayleigh [80]:

$$\rho_l \left( R\ddot{R} + \frac{3}{2}\dot{R}^2 \right) = p(R) - p_1, \quad (1)$$

where  $R$  is the bubble radius,  $\rho_l$  is the liquid density,  $p(R)$  is the pressure in the liquid at the bubble surface, and  $p_1$  is the pressure in the liquid at a large distance from the bubble. Using Eq. (1), Rayleigh [80] solved the problem of the collapse of an empty cavity in a large body of liquid at a constant  $p_1$  and showed the characteristic collapse time is

$$\tau_c = R_o \sqrt{\rho_l / p_1}. \quad (2)$$

The time  $\tau_c$  is called the Rayleigh collapse time and is one of the most important time scales in the bubble dynamics.

Plesset [69] extended Eq. (1) including the effects of surface tension and time-dependent pressure field, and Proitsky [71] included the effect of viscosity. The generalized Rayleigh equation for bubble dynamics is known as the Rayleigh–Plesset equation. liquid viscosity and surface tension. The generalized Rayleigh equation for bubble dynamics is called the Rayleigh–Plesset equation [70]:

$$\rho_l \left( R\ddot{R} + \frac{3}{2}\dot{R}^2 \right) = p_g - p_1 - 4\eta_l \frac{\dot{R}}{R} - \frac{2\Sigma}{R}, \quad (3)$$

where  $\eta_l$  is the liquid viscosity, and  $\Sigma$  is the surface tension. Equation (3) is valid for a Newtonian liquid under

conditions of negligible mass exchange at the bubble surface. A further generalized equation to which these two restrictions do not apply is [72]:

$$\begin{aligned} \rho_l \left( R\dot{u}_l + \frac{3}{2}u_l^2 \right) - J \left[ 2u_l + J \left( \frac{1}{\rho_g} - \frac{1}{\rho_l} \right) \right] \\ = p_g - p_1 + \int_R^\infty \frac{3\tau_{rr}}{r} dr - \frac{2\Sigma}{R}, \quad (4) \end{aligned}$$

where  $u_l$  is the radial liquid velocity at the bubble surface,  $J = \rho_l(u_l - \dot{R})$  is the outgoing mass flux through the bubble wall,  $\rho_g$  is the density of the gas in the bubble, and  $\tau_{rr}$  is the normal radial stress. When the interfacial mass flux  $J$  vanishes,  $u_l = \dot{R}$  as in the left-hand side of the original Eq. (3).

While the above equations consider a single bubble in an infinite melt, magmatic systems often contain bubbles with some finite spacing. Cellular models of packing which include a finite volume of melt in interaction with each bubble have been employed for closely spaced bubbles [79]. When the elementary cell is represented by a sphere with an outer radius of  $S$ , the equation corresponding to (3) is [76]:

$$\begin{aligned} \rho_l \left[ R\ddot{R} \left( 1 - \frac{R}{S} \right) + \frac{3}{2}\dot{R}^2 \left( 1 - \frac{4R}{3S} + \frac{1}{3}\frac{R^4}{S^4} \right) \right] \\ = p_g - p_1 - 4\eta_l \frac{\dot{R}}{R} \left( 1 - \frac{R^3}{S^3} \right) - \frac{2\Sigma}{R}. \quad (5) \end{aligned}$$

Equation (5) agrees with Eq. (3) for  $S \rightarrow \infty$ .

When there is no transport of heat or mass between the liquid and the bubble, the pressure in the bubble is determined by the instantaneous bubble radius alone. Using the ideal gas approximation, we have

$$p_g R^{3\gamma} = p_{g_o} R_o^{3\gamma}, \quad (6)$$

where  $\gamma$  is the specific heat ratio, and the subscript  $o$  indicates the equilibrium value of the variable. Substituting Eq. (6) into Eq. (3) for  $p_g$  and linearizing the equation, we obtain a damped oscillator equation:

$$\ddot{X} + 2b_v \dot{X} + \omega_o^2 X = -\frac{p'_1}{\rho_l R_o^2}, \quad (7)$$

$$b_v = \frac{2\eta_l}{\rho_l R_o^2}, \quad (8)$$

$$\omega_o = \frac{1}{R_o} \sqrt{\frac{3\gamma p_{g_o} - 2\Sigma/R_o}{\rho_l}}, \quad (9)$$

where  $X$  and  $p'_1$  are defined by  $R = R_o(1 + X)$  and  $p_1 = p_{g_o} - 2\Sigma/R_o + p'_1$ , respectively. Equation (7) is useful to see the characteristic behaviors of a bubble and their time scales. The resonant frequency of the bubble is

$\omega_o$  ( $\text{rad s}^{-1}$ ). When the second term in the left-hand side of Eq. (7) dominates the first one in the time scale of the resonant oscillation, namely when  $\omega_o < b_v$ , the resonant oscillation is damped. In the case of a gas bubble with a radius of  $10^{-3}$  m in magma ( $\rho_l = 2500 \text{ kg m}^{-3}$ ) at 10 MPa ( $p_{go} - 2\Sigma/R_o = 10^7 \text{ Pa}$ ), the frequency ( $\omega_o/(2\pi)$ ) is about 20 kHz. The oscillation is damped when the viscosity is larger than 160 Pa s. This viscosity is relatively small for magma. According to these estimations, we see that the free oscillation of a bubble in magma is possible in the limited cases that the viscosity is small and the bubble is large. We also see that the bubble oscillation is easily excited in water which has a viscosity about  $10^{-3}$  Pa s.

### Liquid Rheology

The shear rheology of the liquid surrounding the bubble is one of the controlling factors for the bubble dynamics. According to experimental results, magma has viscoelastic nature, which is the most simply represented by a linear Maxwell model [99]. Then the normal radial stress  $\tau_{rr}$  in Eq. (4) is related to the corresponding strain rate  $\dot{e}_{rr}$  by

$$\tau_{rr} = \mu_1 \int_0^t \exp\left(-\frac{t-t'}{\tau}\right) \dot{e}_{rr} dt', \quad (10)$$

where  $\mu_1$  is the shear elasticity and  $\tau$  is the relaxation time. In the limit of  $t \ll \tau$ , the Maxwell relation (10) is reduced to a linear elastic stress-strain relation as  $\tau_{rr} = \mu_1 e_{rr}$ . While in the limit of  $t \gg \tau$ , it is reduced to a Newtonian viscous relation, that is a linear stress-strain rate relation as  $\tau_{rr} = \mu_1 \tau \dot{e}_{rr}$ , where  $\mu_1 \tau$  corresponds to the Newtonian viscosity  $\eta_1$ .

Fogler and Goddard [21] first used the viscoelastic relation (10) in the generalized Rayleigh–Plesset Eq. (4) without mass flux, and demonstrated that the influence of the viscoelastic effects on the radial motion of a bubble is characterized by a dimensionless parameter called the Deborah number  $De = \tau/\tau_c$ , which compares the relaxation time  $\tau$  and Rayleigh collapse time  $\tau_c$  defined in Eq. (2): the influence is large when  $\tau \gg \tau_c$ . Extending the formulation by Fogler and Goddard [21] to a cellular bubble, Ichihara [28] investigated its characteristic behaviors in magmatic conditions. It is shown that the elastic oscillation of a bubble, which occurs in the case of  $\tau \gg \tau_c$ , is in a frequency of order of MHz and with very small displacement of the bubble wall because of the large shear modulus of the magma.

Change of the bubble radius in magma is mainly controlled by the viscosity except in magma with very small viscosity in which the bubble oscillation is possible. Therefore, in most of the studies for bubble growth in magma,

effects of liquid inertia and viscoelasticity are not considered, and Eq. (3) or (5) for a Newtonian fluid is used, neglecting the left-hand side terms representing the inertia [2,62,79,88]. Barclay et al. [2] analytically solved the problem of the viscosity-controlled bubble expansion for instantaneous decompression, and showed the characteristic expansion time is

$$\tau_v = \frac{4\eta_1}{3p_l}, \quad (11)$$

where  $p_l$  is the pressure in the liquid. The time  $\tau_v$  is one of the most important time scales of the bubble dynamics in magma [2,30], while the Rayleigh collapse time  $\tau_c$ , which is controlled by the inertia, is important in low-viscosity fluids including hydrothermal systems.

Definition of the viscous expansion time corresponding to Eq. (11) is different depending on which problems and literature are being referenced. The time scale of the entire expansion of a bubble for instantaneous decompression is represented by Eq. (11) using the reduced pressure for  $p_l$  [2]. Volumetric oscillation of a bubble in an acoustic field is prevented by the viscous resistance if the period is shorter than  $\tau_v$ , in this case with the initial static pressure for  $p_l$  [30]. When the bubble expansion is driven by a constant gas pressure, which occurs at the initial stage of diffusion-drive gas expansion when the gas is efficiently supplied from the liquid, the bubble grows approximately as  $R \sim R_o \exp[t\Delta p/(4\eta_1)]$  [62,93], where  $\Delta p$  is the pressure difference. In this case,  $\tau_v = 4\eta_1/\Delta p$ . The last case is discussed again later in the section of mass transport.

### Liquid Compressibility

The effect of liquid compressibility on radial motion of a bubble was first considered in connection with underwater explosions [14,41]. Liquid compressibility allows energy transport as a pressure wave so that it causes radiation damping. Noting that the effect is considerable in the case of a violent oscillation or collapse of a bubble, several mathematical approaches were proposed to include the effect in the equation of bubble radius. According to mathematical and numerical studies by Prosperetti and Lezzi [78], which compared the proposed equations, the following Keller's equation [41] is widely accepted as the most adequate form.

$$\begin{aligned} \rho_l \left[ \left(1 - \frac{\dot{R}}{c_l}\right) R \ddot{R} + \frac{3}{2} \left(1 - \frac{\dot{R}}{3c_l}\right) \dot{R}^2 \right] \\ = \left(1 + \frac{\dot{R}}{c_l} + \frac{R}{c_l} \frac{d}{dt}\right) \left(p_g - p_l - 4\eta_1 \frac{\dot{R}}{R} - \frac{2\Sigma}{R}\right), \end{aligned} \quad (12)$$

where  $c_l$  is the sound speed in the liquid. Although Prosperetti and Lezzi [78] further proposed to use the liquid enthalpy at the bubble wall instead of the pressure for the best accuracy, Eq. (12) is generally used in the literature.

Comparing Eqs. (12) and (3), we can see that the correction terms due to the liquid compressibility have the order of  $\dot{R}/c_l$ . It means that the correction is considerable only when the bubble wall velocity becomes as large as the sound speed of the liquid. By applying  $[1 + (\dot{R}/c_l) + (R/c_l)d/dt]^{-1}$  to both sides of Eq. (12) and linearizing the equation, Prosperetti [75] derived the acoustic damping coefficient, which corresponds to  $b_v$  in Eq. (8) for the viscous damping, as  $b_{ac}$ :

$$b_{ac} = \frac{\omega^2 R_o}{2c_l}, \quad (13)$$

where  $\omega$  is the angular frequency of the oscillation. The acoustic damping is more significant when the bubble is larger and the oscillation frequency is higher.

Effects of liquid compressibility on bubble dynamics in a highly viscous liquid are not understood comprehensively. Derivation of Eq. (12) and related studies were performed thinking of liquids with ordinary viscosities like water. Therefore, the Reynolds number  $Re = \rho_l R_o c_l / \eta_l$  was presupposed to be large. On the other hand, the viscosity of magma can be large enough to make  $Re$  very small. In this case, the same mathematical approximation is not necessarily applicable. Yamada et al. [100] pointed out this problem and solved the equations including the viscous force associated with the volumetric strain rate. Although the equation of motion for the bubble radius appears not to be affected by the compressibility when the system is initially hydrostatic, the velocity field around the bubble is different from the incompressible solution, even if the wall velocity is much smaller than the acoustic velocity.

There is argument whether the equation of radial motion of a bubble surrounded by a finite volume of liquid needs correction terms for the compressibility. However, it seems to be negligible in magma, which is evaluated as follows [28]. In the case that the bubble is surrounded by an elastic shell, contribution of the compressibility to the bubble expansion is  $\delta_c R = R_o (p_g - p_l) (1 - R_o^3/S_o^3)^{-1} (3K_l)^{-1}$ , where  $K_l$  is the bulk modulus of the liquid, which is the reciprocal of the compressibility [48]. We can evaluate  $\delta_c R/R_o < 10^{-3}$ , because  $K_l \sim 10^{10} - 10^{11}$  Pa for magma [99], the realistic pressure difference,  $p_g - p_l$  is not much larger than  $10^7$  Pa, and the volume fraction of the bubbles,  $R_o^3/S_o^3$ , is reasonably assumed to be smaller than the close-packing limit ( $\sim 0.74$ ). The change of  $p_g$  due to  $\delta_c R$  is  $\delta_c p_g/p_{go} \sim -3\delta_c R/R_o$ , which is also in the same or-

der. When the shell deforms viscously, displacement due to non-volumetric deformation grows, while that from the volumetric deformation remains in the same order.

### Heat and Mass Transport

Each equation of motion for the bubble radius includes  $p_g$ , which is the pressure of the gas in the bubble, as we see in Eqs. (3), (5), and (12). Equation (6) is available to calculate  $p_g$  only for an adiabatic process. In fact, when a bubble expands, the pressure and temperature in the bubble decreases. Then heat and volatile components flow into the bubble from the surrounding liquid. The opposite occurs when a bubble shrinks. The internal processes which control  $p_g$  are schematically shown in Fig. 1. These transport effects are essential in most of actual systems including magmatic and hydrothermal systems.

Growth of a bubble by the mass diffusion in an over-saturated liquid is one of the fundamental problems. Based on purely dimensional considerations, an approximate growth law is given by

$$R\dot{R} = \frac{\kappa_{gl}\rho_l(C_o - C_{eq})}{\rho_g}, \quad (14)$$

where  $\kappa_{gl}$  is the diffusivity of the volatile in the liquid,  $C_o$  is the dissolved volatile concentration at a large distance from the bubble, and  $C_{eq}$  is the equilibrium concentration at the given pressure [62,70]. From Eq. (14) we find that, asymptotically,  $R \sim \sqrt{2\kappa_{gl}\rho_l(C_o - C_{eq})t/\rho_g}$ . This expression is not valid at  $t \rightarrow 0$  making  $\dot{R} \rightarrow \infty$ . In the initial stage, the diffusion is very efficient and the bubble growth is controlled by viscous resistance [62,93]. In this stage,  $R \sim R_o \exp[t\Delta p/(4\eta_l)]$  as discussed in the section of liquid rheology. The approximate time of the transition from the viscosity-controlled exponential solution to the diffusion-controlled square-root solution is found by

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 1

The internal heat and mass transport processes which control pressure change and energy loss associated with the bubble oscillation

Navon and Lyakhovskiy [62] to be

$$\tau_{\text{vd}} \sim [-15 - 10 \log(Pe)] \eta_l / \Delta p, \quad (15)$$

where  $Pe = \Delta p R_o^2 \eta_l^{-1} \kappa_{\text{gl}}^{-1}$  is the Pecret number that compares the time scales of viscous expansion and diffusion. It is noted that Eq. (15) is validated for  $Pe < 10^{-2}$ , that is for relatively large viscosity and small bubble radius [62]. If we consider  $\Delta p \sim 10^6$  Pa and  $\kappa_{\text{gl}} \sim 10^{-11} \text{ m}^2 \text{ s}^{-1}$ , this condition is satisfied when  $R_o^2 \eta_l^{-1} < 10^{-19}$ , that is  $\eta_l > 10^7$  Pa s when  $R_o \sim 10^{-6}$  m, and  $\eta_l > 10^9$  Pa s when  $R_o \sim 10^{-5}$  m. Then the corresponding times are  $\tau_{\text{vd}} > 50$  s and  $\tau_{\text{vd}} > 5000$  s, respectively. Lensky et al. [51] have suggested that the change of the characteristic behavior of the bubble expansion over the time scale  $\tau_{\text{vd}}$  generates a non-linear response of the liquid-bubble mixture to the pressure perturbation, which may cause amplification of a pressure wave. Coupling of effects of viscosity and diffusion on the bubble expansion also occurs through the material properties, because magma viscosity and water diffusivity are strongly influenced by the amount of dissolved water, which is the major volatile component in magma [4,50].

Matsumoto and Takemura [59] numerically solved a complete set of equations for the radial dynamics of a bubble including the conservation equation for mass, momentum, and energy in the bubble, heat and mass diffusion in the liquid, and heat and mass exchange between the gas and the liquid by diffusion and evaporation/condensation. Except in extremely rapid phenomena as the cases they treated, approximation of a spatially uniform pressure in the bubble is adequate [75]. With this approximation, the computational load is considerably reduced [9,38,63].

It is necessary to consider non-uniform temperature distribution and compositions, in order to quantify the amounts of energy exchange between the bubble and liquid and energy loss associated with the non-equilibrium process. Time scales required to recover uniform temperature and composition in the bubble are controlled by diffusion processes and are much longer than that to attain uniform pressure, which is controlled by the pressure wave propagation in the bubble. Assuming representative values of the thermal diffusivity,  $\kappa_T \sim 10^{-5} \text{ (m}^2 \text{ s}^{-1}\text{)}$ , and the inter-diffusivity of the components in the gas phase,  $\kappa_{\text{gi}} \sim 10^{-7} \text{ (m}^2 \text{ s}^{-1}\text{)}$  [38], development of thermal and material diffusion layers all over the bubble with radius of  $10^{-3}$  m takes  $\sim 0.1$  s and  $\sim 10$  s, respectively. The time range of 0.1–10 s is exactly what studies on seismoacoustic phenomena in volcanology are mainly concerned with. It takes an even longer amount of time to recover uniform concentration of volatile components in the liquid around

the bubble. Therefore approximation of uniform temperature and compositions are not always adequate. Again we introduce results from the linearized theory for a periodic acoustic field. The bulk modulus of a bubble,  $K_g$ , is defined as:

$$K_g = -\frac{R}{3} \frac{\partial p_g}{\partial R}, \quad (16)$$

which is generally a complex number. The elasticity and the energy loss associated with volumetric change of a bubble are represented by the real and imaginary parts of  $K_g$ , respectively. Then the damping factor and the resonant frequency for the bubble oscillation, which correspond to Eqs. (8) and (9), respectively, are [75]:

$$b_t = \frac{3\text{Im}(K_g)}{2\rho_l \omega R_o^2} \quad (17)$$

$$\omega_o = \frac{1}{R_o} \sqrt{\frac{3\text{Re}(K_g) - 2\Sigma/R_o}{\rho_l}}. \quad (18)$$

In the case of an adiabatic process for an ideal gas, where Eq. (6) holds,  $K_g = \gamma p_{g0}$  and Eq. (18) agree with Eq. (9). While in the case of an isothermal process,  $K_g = p_{g0}$ . In these two extreme conditions,  $\text{Im}(K_g) = 0$  and there is no thermal damping.

In order to include the effect of non-uniform temperature distribution in the bubble, we have to solve the energy equation with the continuity of temperature at the bubble surface. Assuming that the pressure in the bubble is uniform, the temperature at the bubble wall is constant, which is supported by the large heat capacity of the liquid compared with that of the gas, and the pressure perturbation is periodic ( $\propto e^{i\omega t}$ ), the effective bulk modulus,  $K_g$ , is represented as [75]:

$$\frac{p_{g0}}{K_g} = \frac{1}{\gamma} - \frac{3(\gamma-1)}{\gamma} i\chi \left[ \sqrt{\frac{i}{\chi}} \coth \left( \sqrt{\frac{i}{\chi}} \right) - 1 \right], \quad (19)$$

$$\chi = \frac{\kappa_T}{\omega R^2}. \quad (20)$$

When the mass transfer is controlled by the diffusion of the volatile component in the liquid phase, the diffusion equation in the liquid and the equilibrium condition at the bubble surface are added. Then the effective bulk modulus which includes both the heat and mass transport is

$$\frac{p_{g0}}{K_g} = \frac{1}{\gamma} - \frac{3(\gamma-1)}{\gamma} i\chi \left[ \sqrt{\frac{i}{\chi}} \coth \left( \sqrt{\frac{i}{\chi}} \right) - 1 \right] - 3A_g \sqrt{\alpha_g} i\chi \left( \sqrt{\frac{i}{\chi}} + \sqrt{\alpha_g} \right), \quad (21)$$

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 2

The relevant range of the dimensionless parameters representing the effect of the volatile transfer in the magmatic system is shown as the gray area. The parameter  $A_g$  and  $\alpha_g$  are defined in Eqs. (22) and (23), respectively. The temperature ( $T$ ) and the volatile diffusivity ( $\kappa_{gl}$ ) are assumed as shown in the legend, and the pressure is varied from 0.1 to 100 MPa. The open crosses are the corresponding parameters for a vapor-bubble system,  $A_v$  and  $\alpha_T$  given in Eqs. (27) and (28), respectively. The temperature is varied from 380 K to 500 K and the pressure is the saturation pressure at each temperature. (Modified from Fig. 1 in [30])

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 3

The effective bulk modulus of a gas bubble with heat and mass diffusion (calculated by Eq. (21)) as a function of the dimensionless frequency. The real and the imaginary parts are presented in a and b, respectively. The thick broken lines indicate no diffusion and include only thermal effects (which is calculated by Eq. (19)). (Fig. 2 in [30])

$$A_g = \frac{\rho_l p_{go}}{\rho_{go}} \frac{\partial C_{eq}}{\partial p}, \tag{22}$$

$$\alpha_g = \frac{\kappa_{gl}}{\kappa_T}, \tag{23}$$

where  $C_{eq}$  is the saturation concentration at  $p_{go}$  [30]. Equation (21) has the last term in addition to Eq. (19), which represents the effect of the mass transfer. The dimensionless parameter,  $A_g$ , represents the ratio of the volatile mass going into the gas phase from a unit volume of the liquid phase by decompression to the mass change in a unit volume of the gas phase due to expansion.

Figure 2 shows the relevant range of the dimensionless parameters,  $A_g$  and  $\alpha_g$ , for an  $H_2O$  bubble in magma [30]. As temperature decreases or pressure increases,  $A_g$  decreases (Fig. 2) because of the following two reasons. With decreasing temperature,  $\rho_{go}^{-1}$  decreases. In the case of magma,  $C_{eq}(p)$  is approximately proportional to  $\sqrt{p}$  [26] so that  $\partial C_{eq}/\partial p$  decreases with increasing pressure.

The effective bulk modulus of a bubble for some selected values of the parameters in the range is presented in Fig. 3 [30]. The thick broken lines in the figure are obtained by Eq. (19), which includes only the heat transport. In this case, the real part approaches the isothermal bulk modulus and the adiabatic one in the low and high frequencies, respectively. The mass transport makes the bubble stiffness ( $Re(K_g)$ ) smaller, which is the more significant in the lower frequency regime. It is because the bubble has

more time to take in and out the volatile from the liquid in a cycle of the pressure perturbation. The imaginary part for each parameter set has a local peak around

$$\omega \sim \tau_T^{-1} = 15\kappa_T R_o^{-2}, \tag{24}$$

which is the characteristic frequency of the energy loss due to heat transfer. In the case of  $R_o = 10^{-3}$  (m) and  $\kappa_T = 4 \times 10^{-6}$  (m<sup>2</sup> s<sup>-1</sup>), which is the value for H<sub>2</sub>O at 10 MPa and 1273 K [5], the corresponding frequency ( $\omega/(2\pi)$ ) is 9.5 Hz. The imaginary part of  $K_g$  including the diffusion effect has another peak at the characteristic frequency of the energy loss due to the mass transport. The frequency is approximately represented by

$$\omega \sim \tau_g^{-1} = 9\alpha_g \kappa_T A_g^2 R_o^{-2}, \tag{25}$$

which is usually smaller than  $\tau_T^{-1}$  [30]. It is noted that the above model assumes a single bubble in an infinite liquid. When the oscillation period is very long, interaction of the diffusion layers of the adjacent bubbles has to be considered [15].

When the mechanism of the mass exchange between the liquid and the bubble is the evaporation/condensation at the bubble wall, the latent heat plays an important role. Then the thermal diffusion equation in the liquid and the balance between the heat flux through the bubble surface and generation of the latent heat should be added [19,24]. The corresponding bulk modulus of the bubble is represented as [24]:

$$\frac{p_{go}}{K_g} = \frac{1}{\gamma} - \frac{3(\gamma - 1)}{\gamma} \left(1 - \frac{c_{pg} T_o}{L}\right)^2 i\chi \left[ \sqrt{\frac{i}{\chi}} \coth \left( \sqrt{\frac{i}{\chi}} - 1 \right) - 3A_v \sqrt{\alpha_T} i\chi \left( \sqrt{\frac{i}{\chi}} + \sqrt{\alpha_T} \right) \right], \tag{26}$$

$$A_v = \frac{\rho_l c_{pl} T_o p_{go}}{(\rho_{go} L)^2}, \tag{27}$$

$$\alpha_T = \frac{\kappa_{Tl}}{\kappa_T}, \tag{28}$$

where  $c_{pg}$  and  $c_{pl}$  are the heat capacity at constant pressure in the gas and the liquid phases, respectively,  $L$  is the latent heat, and  $\kappa_{Tl}$  is the thermal diffusivity in the liquid. In obtaining Eq. (26), the Clausius-Clapeyron relation:  $(dp/dT)_{sat} = L\rho_g/T$ , and thermodynamic relations for an ideal gas are used.

Equation (26) has the same form as Eq. (21) except  $c_{pg} T_o/L$ . This difference is due to the temperature change at the bubble wall. The dimensionless parameter,  $A_v$ , corresponds to  $A_g$  and has a similar physical meaning, which

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 4

The effective bulk modulus of a vapor bubble with thermal and evaporation effects (calculated by Eq. (26)) as a function of the dimensionless frequency. The real and the imaginary parts are presented in a and b, respectively. The thick broken lines indicate no evaporation and include only thermal effects (which is calculated by Eq. (19))

represents the ratio of the mass going through a phase change in a unit volume of the liquid phase to the mass change in a unit volume of the gas phase due to expansion. Although the equation is similar, the possible range of the parameter is different (Fig. 2). As a result, the frequency dependence of  $K_g$  is also different as is shown in Fig. 4. Comparing the figure with Fig. 3, we can see that the energy loss of the vapor bubble due to the phase change is significant in a frequency range higher than that due to diffusion. The frequency range is comparable to that of the heat transfer, but the amount of energy loss is much larger. The vapor bubble loses its elasticity, which is represented by  $Re(K_g)$ , in the lower frequency as well.

Under the action of the sound field, there is a net transport of heat into the bubble by a non-linear process called the rectified heat transfer [98]. In the evaporation/condensation system, the order of the non-linear effect is so large that it affects the amplitude and damping of the oscillation in the linear regime [24]. Equation (26) does not include the effect. Some works investigating the effect of rectified diffusion process in triggering an eruption or an earthquake are introduced in the later sections.

### Translational Motion

So far we have neglected the translational motion of a bubble relative to the liquid. The translational motion is considered to be negligible when the translational displacement is smaller than the diffusion layer in the liquid surrounding the bubble. In an acoustic field with frequency  $\omega$ , this condition is represented by  $U/\omega < \sqrt{\kappa/\omega}$ , where  $U$  is the translational speed and  $\kappa$  is the relevant diffusivity. The translational velocity of a spherical bubble driven by buoyancy is estimated by  $U = k\rho_l R_o^2 g \eta_l^{-1}$ , where  $g$  is the gravitational acceleration. Although  $k = 1/3$  for a pure liquid,  $k = 2/9$  is used for most of actual liquid, which is not perfectly pure, because the pro-surface components concentrate on the bubble surface to make the surface less mobile [49]. These approximations hold for relatively slow velocity, which satisfies  $Re_t = 2\rho_l R_o U \eta_l^{-1} \leq 1$ . Then the condition in which the translational motion has a minor effect on the heat and mass transfer is

$$\omega > \frac{R^4}{\kappa} \left( \frac{k\rho_l g}{\eta_l} \right)^2. \quad (29)$$

Assuming  $k = 2/9$ ,  $R = 10^{-3}$  (m),  $\kappa = \kappa_{gl} = 10^{-11}$  ( $\text{m}^2 \text{s}^{-1}$ ),  $\rho_l = 2500$  ( $\text{kg m}^{-3}$ ),  $\eta_l = 10^5$  (Pa s) for a magma-H<sub>2</sub>O system,  $\omega > 3 \times 10^{-4}$  ( $\text{rad s}^{-1}$ ) and  $U = 6 \times 10^{-6}$  ( $\text{m s}^{-1}$ ). For a water-vapor system, on the other hand, we assume  $k = 1/3$ ,  $\kappa = \kappa_{Tl} = 10^{-7}$ ,  $\rho_l = 1000$ ,  $\eta_l = 10^{-3}$ . Then, if  $R = 10^{-5}$ ,  $\omega > 1$  and  $U = 3 \times 10^{-4}$ , and if  $R = 10^{-4}$ ,  $\omega > 10^4$  and  $U = 3 \times 10^{-2}$ . According to these estimations, we can see that the translational motion is negligible for most cases with magma except basalt, which has relatively small viscosity ( $\eta_l < 10^2$ ) and large diffusivity ( $\kappa_{gl} \sim 10^{-9}$ ), while it is considerable in hydrothermal systems, except for very small bubbles and the time scale is very short. As an example, the effect on the thermal collapse of a vapor bubble is introduced later.

Another effect of the translational motion is its mechanical coupling with the radial motion. Because a bubble has to move the surrounding liquid in order to make itself move, it is subject to the inertial force of the liquid, which depends on its volume [49]. Therefore when the bubble volume changes, the force also changes. By this consideration, an equation of the translational motion of the bubble is approximately represented as [101]:

$$\dot{U} = -\frac{3}{R} \dot{R}U + 2g - \frac{3}{4} \frac{C_D}{R} |U|U, \quad (30)$$

where  $C_D$  is the non-dimensional drag coefficient, which is given as a function of  $Re_t$ . From the first term in the right-hand side, we see that the translational motion is decelerated by the bubble expansion. Although it had been

theoretically recognized for long time, it was quantitatively justified by experiments recently [66]. On the other hand, the effect of the translational motion on the radial motion is represented by the term,  $\rho U^2/2$ . This term can usually be neglected [37,66] except in cases with very strong oscillation [17].

### Bubbly Magma in an Elastic Rock as a Pressure Source

#### Model Overview

Here we consider a magma chamber filled with compressible viscous melt and numerous tiny H<sub>2</sub>O gas bubbles

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 5

Schematic illustrations of a cell model [79], b an elementary cell, and c a chamber surrounded by an elastic medium. The chamber is filled with compressible viscous melt and numerous tiny spherical gas bubbles. Magma is represented by a combination of many elementary cells.  $R$  and  $S$  is the radius of the elementary cell and gas bubble, respectively, and  $V_0 + \delta V$  is the volume of the chamber. (Modified from Fig. 1 in [87])

(Fig. 5) [79,87]. The magma chamber is confined in an elastic rock. When perturbation is given to the system, pressure may increase by interaction of the elastic deformation of the chamber, expansion of the bubbles, and gas diffusion from the melt to the bubble. Recently, the process has been discussed in the literature in relation to the observed volcanic phenomena [6,13,29,53,64,87,97], which are presented in the introduction.

The melt and bubbles are expressed by the cell model [79], in which multiple spherical bubbles of a constant radius are uniformly packed. Each bubble is surrounded by a finite volume of the melt, represented by an elementary cell. The elementary cell is spherical, in which a single gas bubble is located at the center. It is assumed there is no interaction between neighboring elementary cells such that all gas bubbles grow in the same manner. This simplification enables us to examine bubble growth processes in the entire chamber by studying the growth of just a single bubble, which is represented by Eq. (5).

The main mechanism for increasing the pressure is diffusion of the volatile. It is the slowest process of the bubble dynamics as is described in the previous section. It is certainly longer than the period of resonant oscillation of the individual bubbles so that the inertia terms in Eq. (5) are neglected. It is also longer than the time scale of the heat transport within the bubble as is shown in Fig. 3 so that we may assume uniform and constant temperature within the bubble. Then the mathematical model for the elementary cell consists of three equations, which represent the radial motion of the bubble, volatile diffusion in the melt, and ideal gas approximation, respectively, and three boundary conditions, which are phase equilibrium and mass flux at the bubble surface and no mass flux at the external boundary of the cell element.

**Interaction Between Melt and Elastic Medium**

The volumetric change of the bubbles and the melt due to the pressure change is compensated by the elastic deformation of the chamber. Here we consider the initial pres-

sure and stress conditions in relation to the physical process which brings about the condition, since the relations have not always been mentioned clearly in previous literature. We assume quasi-static deformation of the chamber, where the pressure of the melt is balanced by the elastic stress applied by the wall of the chamber. The volumetric change can be caused by (a) pressure change within the chamber and (b) stress change in the surrounding rock (Fig. 6). Each process is individually represented by

$$p_1 - p_o = \bar{\mu}_p \delta V_p / V_o, \tag{31}$$

$$-\sigma_\infty = \bar{\mu}_e \delta V_e / V_o, \tag{32}$$

where  $V_o$  is the initial equilibrium volume of the chamber,  $\sigma_\infty$  is the ambient stress change,  $\delta V_p$  and  $\delta V_e$  are the volumetric change due to (a) and (b), respectively, and  $\bar{\mu}_p$  and  $\bar{\mu}_e$  are the corresponding effective stiffness of the wall. Each effective stiffness depends on the elasticity of the rock, the geometry of the chamber, and the applied stress field. For the simplicity, we approximate  $\bar{\mu}_p = \bar{\mu}_e = \bar{\mu}$ . Then the total volumetric change,  $\delta V$ , is given by

$$p_1 - p_o - \sigma_\infty = \bar{\mu} \delta V / V_o. \tag{33}$$

The two perturbations which cause the volumetric change have not been clearly distinguished in previous literature. The mathematical treatment by [87] assumed that  $p_1 - p_o = -\Delta p$  is given at  $t = 0$ . They considered that this pressure drop is caused by a decrease of the ambient stress field by a certain amount, say  $\sigma_\infty = -\Delta\sigma$ . On the other hand, the assumption of [13] is that the pressures in all of the bubbles, the melt, and the rock are lower by  $\Delta p$  than the saturation pressure for the dissolved volatile concentration at  $t = 0$ . Strictly speaking, the consequent processes are different depending on what causes the pressure perturbation. If the pressure drop of  $\Delta p$  occurred first within the chamber, that is  $p_1 - p_o = -\Delta p$  and  $\sigma_\infty = 0$ , the chamber would initially shrink according to Eq. (33). If it is caused by an ambient stress drop first, that is  $p_1 - p_o = 0$  and  $\sigma_\infty < 0$ . Then the chamber would ini-

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 6  
 Mathematical representation for the interaction of melt pressure  $p_1$ , stress in the ambient rock  $\sigma_\infty$ , and volume change of the chamber,  $\delta V$ . Volume change due to internal overpressure  $p_1 - p_o$  and that due to external stress is considered separately

tially expand. In either case, the initial response is almost instantaneous, which is controlled by elasticity of the rock and compressibility of the melt. The major deformation occurs later and is controlled by volumetric change of the bubbles.

**Response to Sudden Decompression and Characteristic Time for Pressure Recovery**

There are three important parameters to characterize the response of the system to the pressure drop which are useful for comparing the model and the field observations. The first one is the re-equilibrated pressure  $p_f$ . The second is the final bubble radius,  $R_f$ . The third is the characteristic time of the recovery process,  $T_{\text{growth}}$ .

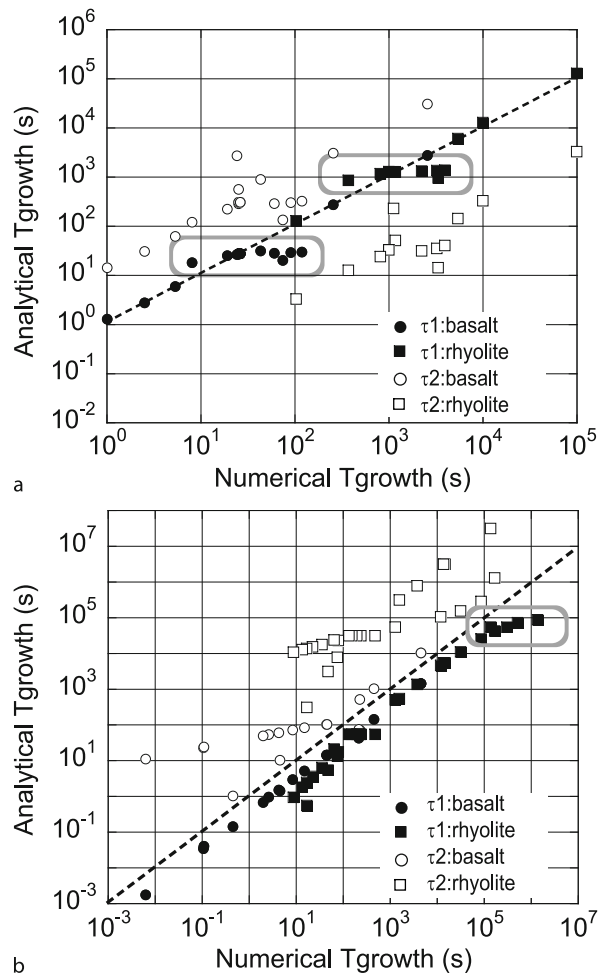

The first and the second are calculated by consideration of the equilibrium condition alone and can be calculated semi-analytically [64]. On the other hand,  $T_{\text{growth}}$  is determined by numerical calculation of the set of equations described above. Shimomura et al. [87] investigated the recovery processes and presented that  $T_{\text{growth}}$  depends on the stiffness of the chamber ( $\bar{\mu}$ ), initial bubble radius ( $R_o$ ), number density of the bubbles ( $N$ ), volatile diffusivity in the melt ( $\kappa_{\text{gl}}$ ), initial pressure ( $p_o$ ), the pressure drop ( $\Delta p$ ), and the melt properties in a complicated manner.

The corresponding study for the bubble growth in an open space, where the pressure is constant regardless of the bubble expansion, was presented by Prousevitch et al. [79]. They assumed an initially supersaturated condition, in which both  $p_{\text{lo}}$  and  $p_{\text{go}}$  are lower than the saturation pressure of the volatile dissolved in the melt. They investigated the final bubble radius and the time to reach it, which correspond to  $R_f$  and  $T_{\text{growth}}$ , respectively. They also presented effects of initial bubble radius ( $R_o$ ), number density of the bubbles ( $N$ ), volatile diffusivity in the melt ( $\kappa_{\text{gl}}$ ), initial pressure ( $p_o$ ), and initial super-saturation.

A simple theory to estimate the time scale of re-equilibration is useful to compare the model with observations, but has not been determined yet. Here we test two hypotheses.

1. The recovery time is comparable with the time scale in which the diffusion layer develops over the entire shell, that is  $\tau_1 = (S_f - R_f)^2 / \kappa_{\text{gl}}$ .
2. Based on a dimensional analysis of the simplified diffusion Eq. (14), Lensky et al. [53] proposed  $\tau_2 = (R_f^2 / \kappa_{\text{gl}})(\rho_{\text{gf}} / \rho_l)(C_o - C_f)^{-1}$ , where  $\rho_{\text{gf}}$  and  $C_f$  are the final gas density in the bubble and the volatile concentration remained in the melt, both of which are functions of  $p_f$ . They obtained this equation based on the approximation that the quasi-static mass flux through the interface is  $(C_o - C_{\text{eq}}(p_g)) / R$ .

The re-equilibration times,  $T_{\text{growth}}$ , obtained by Shimomura et al. [87] and Prousevitch et al. [79] are compared with the above models in Fig. 7. Comparing  $T_{\text{growth}} - \tau_1$  (black symbols) and  $T_{\text{growth}} - \tau_2$  (white symbols), we see that the general trend of  $T_{\text{growth}}$  is better estimated by  $\tau_1$  than by  $\tau_2$  in both confined and open systems. However, it should also be noted that  $\tau_1$  still has systematic errors which are indicated by gray frames. The errors are more dominant in the confined system (Fig. 7a). It is indicated

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 7  
 Numerical results of the pressure recovery time for magma in an elastic rock **a** and the bubble growth time in an open system **b** for various system parameters are compared with analytical approximations:  $\tau_1$  is the time scale of mass diffusion across the final shell thickness,  $\tau_2$  is approximation by [53]. Agreement between the numerical results and  $\tau_1$  is better, but some systematic discrepancy remains, as indicated by gray frames. The numerical results for **a** are from [87], and those for **b** are from [79]

that the simple estimation does not include all the factors relevant to the re-equilibration time and it is not necessarily applicable to the wider range of the parameters.

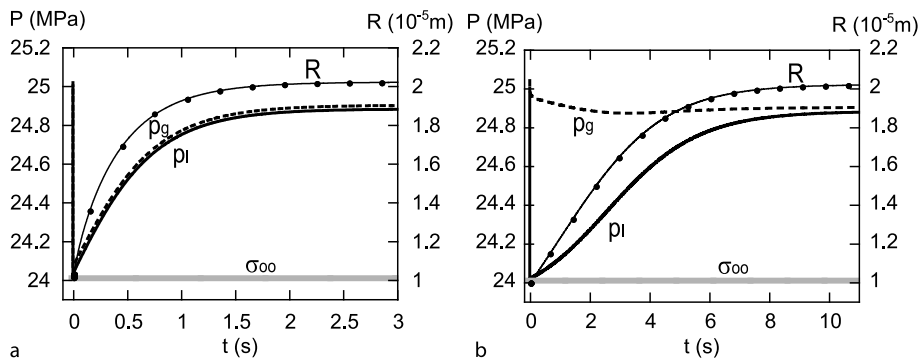

**Re-equilibration Processes**

Here we discuss different re-equilibration processes depending on the cause of the pressure drop and the relevant initial conditions. Three representative solutions are presented in Figs. 8–10. They are obtained for the standard basaltic system [87], but only viscosity is varied from 50 Pa s for (a) to 10<sup>6</sup> Pa s for (b).

Figure 8 is the case in which the stress drop occurs in the ambient rock first. It is generated by, for example, surface unloading by dome collapse [97] and stress change after a local earthquake. The condition is represented by  $\sigma_\infty = -\Delta\sigma$  at  $t \geq 0$  while  $p_l = p_g - 2\Sigma/R_o = p_o$  at  $t = 0$ . According to Eq. (33), the chamber expands in-

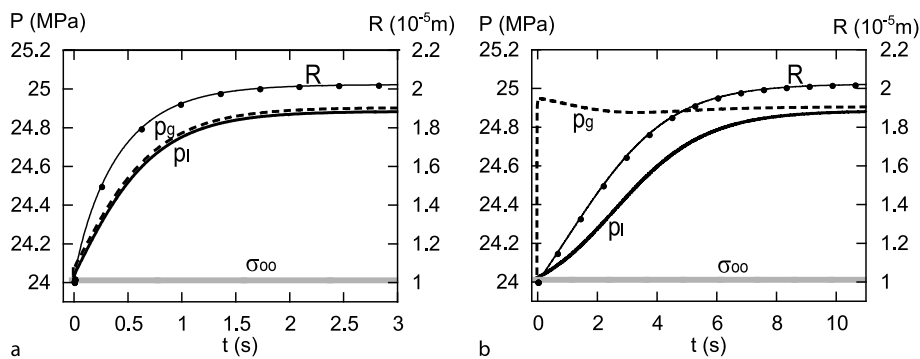

stantaneously, and  $p_l$  drops by  $\Delta p$ . Then the initial condition assumed by [64,87] is attained. Response of  $p_g$  is not instantaneous [62]. Due to the difference between  $p_g$  and  $p_l$ , the bubble expands according to Eq. (5) to decrease  $p_g$ . Then the difference between  $p_g$  and the equilibrium pressure for the volatile concentration in the melt occurs to make the volatile flow into the bubble to re-increase  $p_g$ . As the bubbles grow, the entire volume of the magma ( $\delta V$ ) increases to enlarge the chamber elastically. Then the elastic stress  $\bar{\mu}\delta V/V_o$  increases  $p_l$  according to Eq. (33). The re-equilibration proceeds in this way [87].

Figure 9 is the case in which the pressure in the bubble as well as those in the melt and the ambient rock is lower than the saturation pressure for the initial volatile concentration in the melt at  $t = 0$ . This condition occurs if bubbles are mixed with the supersaturated melt instantaneously, or if the bubbles are kept in the supersaturated mixture without interaction and suddenly allows the dif-

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 8

Pressure recovery in a bubbly magma in an elastic chamber after sudden unloading  $\sigma_\infty = -1$  MPa. The initial condition is  $p_l = p_g - 2\Sigma/R = 25$  MPa and  $R = 10^{-5}$  m. The bubble radius on the right axis is plotted with a line and points. The stress and pressures on the left axis are plotted with a solid line for  $p_l$ , a dotted line for  $p_g$ , and gray line for  $\sigma_\infty$ . The system parameters are  $\kappa_{gl} = 10^{-8} \text{ m}^2 \text{ s}^{-1}$ , the bubble number density is  $10^{11} \text{ m}^{-3}$ , and  $\eta_l = 50 \text{ Pa s}$  for a and  $10^6 \text{ Pa s}$  for b. The others are the same as those for the basaltic system by [87]

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 9

Similar to Fig. 8, but the initial condition is  $\sigma_\infty = p_l - p_o = p_g - 2\Sigma/R - p_o = -1$  MPa, with  $p_o = 25$  MPa

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 10  
 Similar to Fig. 8, but the initial condition is  $\sigma_\infty = 0$  and  $p_l - p_o = p_g - 2\Sigma/R - p_o = -1$  MPa, with  $p_o = 25$  MPa

fusion. Mathematically, the initial condition is equivalent to those assumed by [13] and [79]. The condition is represented by  $p_l - p_o = p_g - 2\Sigma/R_o - p_o = \sigma_\infty = -\Delta p$  at  $t \geq 0$ . Diffusion of the volatile into the bubble starts, which increases  $p_g$  first. Then  $p_g - p_l$  expands the bubble and the chamber to increase  $p_l$  in the same way as the previous case. Practically, the difference between Fig. 8 and Fig. 9 occurs only during a very short period in the beginning, and the subsequent increase of the pressure and volume of the chamber may look the same from outside.

Figure 10 is the case in which the pressure drop occurs in the melt and in the bubble, while the stress in the ambient rock is unchanged. The condition is represented by  $p_l - p_o = p_g - 2\Sigma/R_o - p_o = -\Delta p$  and  $\sigma_\infty = 0$ . Although the assumed initial condition is rather imaginary, this case is presented in order to demonstrate how the response can be different depending on the way the system is decompressed. In fact, it is more realistic that  $p_l$  drops first, while  $p_g$  remains at the initial value. This situation may occur by small leakage of the melt from the system. In this case, the melt pressure just recovers almost instantaneously, because the container compresses the melt according to Eq. (33) and bubbles also compress the melt. No other significant change is expected. On the other hand, if both  $p_l$  and  $p_g$  drop, as in Fig. 10, the pressure still recovers rapidly, but bubbles are compressed. Because the mechanical balance of the bubble and the melt is attained with  $p_g - 2\Sigma/R = p_l$  according to Eq. (5),  $p_g$  has to become larger when  $R$  decreases. Then  $p_g$  exceeds the equilibrium pressure for the volatile in the melt to make the volatile dissolve into the melt.

**Rectified Diffusion**

So far, we discussed responses of the system to a stepwise pressure drop. When the perturbation is caused by a seis-

mic wave from an external source, the system is subject to a cyclic disturbance. Rectified diffusion is a mechanism which can push dissolved volatiles into bubbles in a sound field. Bubbles take in more volatiles during expansion than they discharge during contraction, mainly because of the following two non-linear effects [18,27]. Firstly, the interface is larger during expansion than during contraction. Secondly, radial bubble expansion tangentially stretches the diffusion layer and sharpens the radial gradient of the volatile concentration in the diffusion layer, so that the volatile flux into the bubble is enhanced.

Brodsky et al. [6] discussed the possible pressure increase of a bubbly magma confined in an elastic rock by this mechanism. Using the solution by Hsieh and Plesset [27] for a periodic system, they considered that, even though the net pressure changes are determined by the pre-existing oversaturation, the rectified diffusion accelerates the pressure increase and may break the balance which had been stabilized the system prior to the oscillation. Ichihara and Brodsky [29] improved the solution by including resorption of gas as the pressure increase and development of the diffusion layer around the bubble in a self-consistent way. It is then shown that rectified diffusion is not faster than the ordinary diffusion and its contribution to the net pressure change is at the most  $2 \times 10^{-9}$  of the initial pressure regardless of the pre-existing oversaturation.

**Acoustic Bubbles in Hydrothermal Systems**

**Pressure Impulses Generated in a Geyser**

Here we consider a mixture of water and vapor bubbles, in which we expect effects of bubble oscillations and evaporation.

Kedar et al. [39,40] conducted field experiments at Old Faithful Geyser, Yellowstone. They measured pressure

**Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 11**  
 Simultaneous pressure records (through a high-pass filter at 1 Hz) and seismic traces at Old Faithful geyser, Yellowstone. The geyser's eruptions are 2–5 min long with the interval between them ranging from 30–100 min. The figure shows a 30 s data about 27 min after the previous eruption and about 52 min before the next eruption. The conduit of the geyser is 22 m deep, where the bottom sensor was located. The bottom, middle and top sensors were connected 3 m apart. The seismic station was located at  $\sim 25$  m from the geyser. The data show a direct correspondence between the pressure pulses and the seismic signals that follow them. (Fig. 3 in [39])

within the geyser's water column simultaneously with seismic measurements on the surface. The data show a distinct cause-and-effect relationship between the impulsive pressure source and the impulse response of the rock surrounding the water column. In addition, the pressure pulse, which is strongest at the top transducer, strongly attenuates downward. Considering that the pulse is generated by the oscillation of a single bubble, they compared one selected signal with a solution of the equation of motion for the bubble radius (Eq. (3)). In order to fit the measured oscillation with a reasonable bubble radius, they had to assume a very small ambient pressure to lower the frequency, and a very large viscosity to increase the damping. For  $R_o = 0.055$  m, for example, they used  $p_{go} = 0.02$  MPa, with which Eq. (9) gives the resonant frequency close to the observation:  $\sim 20$  Hz. The viscosity was assumed as  $\eta_l = 40$  Pa s, which is larger than the actual value by more than four orders. They compared the damping coefficient with those from radiation and heat transfer, though these effects were not included in the calculation of Eq. (3), and concluded that mechanisms other than acoustic, thermal, or viscous damping are required to explain the strong damping observed.

We have already introduced the damping coefficient  $b_t$  with the evaporation effect in Eq. (17) with Eq. (26). Then, assuming the similar bubble radius and frequency ranges as [40], let us see the damping coefficient by evaporation in comparison with the other coefficients, which are for viscous, acoustic and thermal damping, represented by Eqs. (8), (13), and (17) with Eq. (19), respectively. Their values are compared in Fig. 12b, assuming  $p_{go} = 0.13$  MPa (the saturation pressure at 380 K). We can see that the evaporation effect significantly increases the damping and dominates the other damping mechanisms in the frequency range of the geyser oscillation. The evaporation effect also decreases  $\text{Re}(K_g)$  (Fig. 12a) in the range. It is thus suggested that the evaporation effect is significant for the bubble dynamics in the hydrothermal system.

### Inertial and Thermal Collapse of a Bubble

When we heat water in a kettle, we hear strong intermittent pulses before boiling starts. The phenomenon is explained in terms of the bubble dynamics as follows [1]. In the first regime (which initiates above approximately

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 12  
 The bubble elasticity (a) and damping factors (b) for a single vapor bubble with radius 0.055 m at 380 K, 0.13 MPa (saturation pressure)

40 °C), small bubbles form slowly out of dissolved air in the liquid, rising silently to the surface as they break off the side of the vessel. At higher temperature (~ 70 °C), vapor bubbles start to nucleate at various sites at the heated bottom surface of the container. Vapor bubbles are different from the air bubbles in that their formation and collapse (at the bottom of the vessel) occurs explosively, producing pressure impulses that traverse the liquid and cause much of the sound we hear. In the third stage (between 90 °C and 100 °C), vapor bubbles grow, coalesce, and survive their ascent through the liquid. Bursting of vapor bubbles at the top surface is considered to be the sound source in this regime. Finally, the transition to full boil is characterized by large bubble formation throughout the bulk of the liquid.

We consider whether and how the impulse generation by the bubble collapse occurs in a geyser, where water that is already boiling is injected and cooled from the surface [43]. The collapse (or growth) of a bubble is classified into two modes: the inertia mode, which is controlled by the liquid inertia and driven by the pressure difference between the liquid and the bubble, and the thermal mode, which is controlled by the heat transfer and driven by the temperature difference [20,103]. The former is more violent than the latter and is responsible for the impulse generation.

Based on theoretical and experimental studies, Florschuetz and Chao [20] proposed that the relative importance of the inertia and the heat transfer is evaluated by a dimensionless parameter,  $B$ , defined by

$$Ja = \frac{\rho_l c_{pl}(T_{sat}(p_{l0}) - T_o)}{\rho_{go} L}, \tag{34}$$

$$B = Ja^2 \frac{K_{Tl}}{R_o} \sqrt{\frac{\rho_l}{p_{l0} - p_{sat}(T_o)}}, \tag{35}$$

where  $T_{sat}(p_{l0})$  is the saturation temperature for the ambient pressure ( $p_{l0}$ ) and  $p_{sat}(T_o)$  is the saturation pressure for the system temperature ( $T_o$ ). The dimensionless parameter  $Ja$  is called the Jacob number, which represents the degree of subcooling. Figure 13 displays their calculation results, which clearly shows that for  $B \geq 0.3$ , the collapse rate is dominated by liquid inertia effect, while for  $B \leq 0.03$  it is much slower and is recognized as the thermal mode. For an intermediate value of  $B$ , oscillation is observed.

In these works [20,77], it is often assumed that the pressure in the bubble is initially equal to the saturation pressure of the subcooled liquid, that is  $p_{go} = p_{sat}(T_o)$ , which is less than the ambient pressure ( $p_{l0}$ ) [20,77]. Experimentally, it is achieved by preparing for a thermally equilibrium water-vapor system at a low pressure and suddenly increasing the system pressure to  $p_{l0}$  [20]. Then the initial collapse is relatively violent and continues by inertia until the vapor heating at the bubble wall increases the vapor pressure above the ambient pressure to such an extent that the liquid is momentarily brought to rest and its motion actually reverses before the vapor pressure again falls below the system pressure [20,77]. Although the oscillation is difficult to see on the radius change curves in Fig. 13 for small  $B$ , the beginning inertia controlled stage is evidenced by that all the curves start along the inertia curve.

On the other hand, in case that a bubble suddenly enters cold water,  $p_{go} = p_{l0} > p_{sat}(T_o)$  while temperature in the bubble  $T_{go}$  is larger than  $T_o$  and is close to  $T_{sat}(p_{go})$ . Then the collapse begins in the gentle mode controlled by the heat transfer. It can turn into the inertia mode only if the rate of heat transport and condensation to decrease the vapor pressure is so large that inward motion of the surrounding liquid cannot follow. Prosperetti and Hao [77] presented that relative translational motion between the bubble and the liquid significantly increases the rate of heat transport and accelerates the bubble collapse. Furthermore, they pointed out the coupling effect between the translational and the radial motions. As Eq. (30) suggests, the decreasing bubble radius ( $\dot{R} < 0$ ) works to accelerate the translational motion. Although the drag force

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 13  
 Variation of wall temperature and radius during collapse of water vapor bubbles.  $B_{sat}$  is the dimensionless parameter given by Eq. (35), which determines relative importance of the liquid inertia and the heat transfer (Fig. 3 in [20])

( $\propto C_D R^{-1} |U|U$ ) increases as  $R$  decreases and  $U$  increases, there are cases in which the contribution of the first term is so large as to make  $\dot{U} > 0$ . Then the collapse and the translational motion of the bubble accelerate each other [77].

**Rectified Heat Transfer**

In the same way as the rectified diffusion discussed in the previous section, rectified heat transfer works for a vapor bubble in an acoustic field [24,98]. When the bubble is compressed, some vapor condenses, the surface temperature rises, and heat is conducted away into the adjacent liquid. When the bubble expands during the following half cycle, evaporation causes a temperature drop of the bubble surface, with a consequent heat flux from the liquid. The imbalance of the heat flux and the interface area between the compression phase and the expansion phase causes the net energy flux into the bubble.

Sturtevant et al. [89] investigated the effect of rectified diffusion on pressure increase in a hydrothermal system, as a possible mechanism for triggered seismicity by a distant earthquake. They modeled the system as a two-component H<sub>2</sub>O-CO<sub>2</sub> system, and considered rectified mass diffusion. As is mentioned in the previous section, the net pressure change due to rectified mass diffusion is very small, if it is evaluated in a self-consistent way [29].

Although rectified heat transfer has a similar mechanism as the rectified mass transfer, it is much more in-

tense since the thermal diffusivity of liquids typically exceeds the mass diffusivity by two orders of magnitude [77]. It can grow a vapor bubble quickly within several cycles of oscillation at the beginning (Fig. 14), and thus can be effective even with low-frequency pressure waves. Moreover the effect is reinforced by the coupling effect of the bubble growth and translational motion [25], and coupling of evaporation and diffusion of another gas component [38]. The net energy flux into the bubble increases the temperature in the bubble, which may change the liquid static pressure [24]. It is noted that numerical results in the literature cannot be directly used to estimate the pressure increase, because they were obtained for an open system in which the bubble continues to grow instead of increasing system pressure. However, it might be worth while to re-evaluate effects of rectified processes in a hydrothermal system taking account of these recent results.

**Non-linear Oscillation of a Spherical Cloud of Bubbles**

Oscillation of a group of bubbles generates particular signals as well as oscillation of a single bubble. The presence of bubbles can lower the acoustic speed of the fluid by an order of magnitude [16,42], if the liquid viscosity is small enough [30,31]. Therefore, there is a sharp impedance contrast between a region of bubbly liquid and a region of pure liquid. The boundary of a bubble cloud acts like an elastic boundary that traps acoustic energy in the bub-

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 14  
 Growth of a vapor bubble by rectified heat transfer. Bubble radius normalized by the linear resonant radius  $R_r = 2.71$  mm versus time for saturate water at 1 atm. The sound frequency is 1 kHz and the amplitude is attached to each profile (Fig. 4 in [24])

Pressure Impulses Generated by Bubbles Interacting with Ambient Perturbation, Figure 15  
 Change of bubble radius (blue lines) and pressure (red lines) in a spherical cloud of bubbles after a sudden pressure rise. The initial pressure and temperature are  $3 \times 10^4$  Pa, 293 K, radii of the bubble and the cloud are  $2.5 \times 10^{-4}$  m and  $3 \times 10^{-2}$ , the void fraction is 3%, and the pressure rise is  $2.4 \times 10^4$  Pa. Values at the center (a) and at a half the radius from the center (b) are presented in dimensionless form (a unit of the dimensionless time corresponds to  $\sim$  ms). (Modified from Fig. 9 in [67])

bly region so that the bubble cloud has characteristic frequency of resonance [56,67,102]. Chouet [10] considered that it is the mechanism for the harmonic oscillations observed at volcanoes having relatively low-viscosity magma. He showed the typical values for the oscillation in the few Hz range may be generated by a columnar bubble cloud with void fraction of 1%,  $\sim 100$  m in length, and  $\sim 1$  m in

radius in a bubble-free magma with  $\sim 5$  m in radius. The radius of each bubble is assumed as  $10^{-3}$  m, which has its own resonance frequency at 8.9 kHz [10].

Omta [67] conducted numerical calculation for oscillation of a spherical cloud of bubbles with relatively large amplitude. Figure 15 shows one of his results, in which the cloud oscillation was excited by an external pressure in-

crease. Three cycles of the oscillation are presented. We can see high-frequency strong pulsation at the center of the bubble cloud (Fig. 15a). It is explained as follows [67]. The pressure perturbation is amplified and sharpened toward the center of the cloud because of the spherical geometry. Then the bubbles are excited at their resonance frequency.

The strong pulsation is observed only near the center in a spherical bubble cloud (Fig. 15). If a bubble cloud is hemispherical with its cross section attached on a solid wall, the pulsation generated at the center of the hemisphere may strongly hit the wall [86]. Generation of strong high-frequency pulses by a bubble cloud interacting with a pressure perturbation with lower frequencies is actually observed in experiments and now the phenomenon is going to be applied to medical treatment under controlled condition [33,60]. Similar mechanisms may work in a hydrothermal system, in which a low-frequency perturbation generates strong pressure impulses hitting the walls to be observed as seismic waves. In fact pressure oscillations in the bubble cloud (Fig. 15) and in the geyser (Fig. 11) have quite similar features, though their time scales are different by three orders of magnitude.

### Future Directions

We have summarized theoretical bases of the bubble dynamics, mainly based on radial motion equations of a single bubble. These theories have been established and verified by experiments for simple systems. For volcanic systems, these theories have mainly been applied to the nucleation and growth of bubbles in magma. This subject takes an important role of volcanology, though it is not included in this review paper. By comparing the theory with observation of bubbles left in natural volcanic rock [58,94] and re-producing the process by laboratory experiments [23, 52,90], researchers have determined physical parameters of the volcanic processes, which are the temperature, pressure, volatile saturation, ascent rate, and so on. The bubble dynamics theories have also been applied to explain geophysical observations, as we have reviewed several possible mechanisms of bubbles that generate pressure impulses. However, determining the effects or even existence of bubbles is more difficult in these phenomena than in the bubble growth problems, because direct observation of bubbles and re-production of the process in a laboratory are more difficult. Here we discuss how we can go forward to confirm the models and apply them to determine useful physical parameters.

It would be effective to focus on relatively simple volcanic phenomena in which the bubble dynamics theory

appears to work. Especially, for some volcanoes which erupt frequently, data taken by modern geophysical methods are being accumulated and the phenomenological cause-and-result relations between an eruption and pressure impulses before and during the eruption are well documented. For example, at Stromboli Volcano all the sequences of the repetitive small eruptions and a few proximal explosions have been taken by multi-parameter monitoring systems [84,85]. Geophysical data taken close to active craters at Sakurajima, Suwanosejima, and Semeru volcanoes have revealed common features in the pressure change before and during an explosion [32]. At Sakurajima Volcano, behaviors of a shallow gas pocket are discussed in the sequences of seismic and explosion events based on analyses of seismic data [91,92]. It might be possible and useful to have a common backbone model for these eruptions, based on which we can explain the particular detail of each case as a result of different parameters of the system.

The bubble dynamics theory which is used in the models needs to be updated, too. Responses of a bubbly fluid are sensitive to the system parameters, which determine possibilities, features, and time scales of the individual mechanisms, as are shown in the text. Although many models assume uniform system for simplicity, the natural system is considered to be non-uniform. In other words, regions having different physical parameters may coexist. Interaction of these subsystems may enhance the characteristic response, but may diminish with one another, or generate completely different effects. The inhomogeneities and their interactions may occur in various scales and manners. For example, in Sect. “**Bubbly Magma in an Elastic Rock as a Pressure Source**”, behaviors of a single uniform magma body in an elastic rock have been discussed. In the real system, the bubble size and the chemical composition are likely to be non-uniform within a small region and/or over the entire magma body. If the system is large, the hydrostatic pressure gradient is significant. Moreover, if there are multiple magma containers which have different physical parameters, each magma body will respond to the pressure perturbation differently, and pressure gradient may be generated between the two adjacent containers. Developing a model including these subscale interactions may be a subject of modern multi-scale multi-physics studies.

Laboratory experiments using analogous materials are useful in verifying and improving the models. In the procedure to construct a model system, we frequently find factors which are important in the real system but have been neglected in the idealized mathematical model. Although there may be some processes which can be realized in the

nature more easily, and there always be a scaling problem, experiments will give us more concrete idea about the mechanism of the models. Although most of the previous analogue experiments are designed to be compared with geological and petrological observations, there are some which investigate generation of pressure impulses by bubbles and are intended to explain seismic and/or acoustic observations [34,35,83]. According to the results and implications obtained by these preceding works, laboratory studies in this direction are promising.

It is also important to connect geophysical observation and geological data to understand the bubble dynamics phenomena in volcanology. Compared with other geophysical processes which occur in the earth, there is larger possibility that the source of activity appears to the surface after relatively short time. The geological samples (e.g., pyroclasts during eruptions and volcanic gasses) can inform us physical and chemical properties of the materials generating pressure impulses, and would make useful constraints on the model. On the other hand, these constraints can be tested and verified by geophysical signals of seismic, geodetic and acoustic measurements when the models are established.

By combining these theoretical, experimental, geophysical, and geological approaches, we will get better understanding on the processes which generate volcanic activities.

### Acknowledgments

### Glossary

**Climate models** They are mathematical representations of the Earth system, in which physical and biogeochemical processes are described numerically. Climate models can be of a global scale or focus on a sub-region (regional climate model).

**Downscaling** Dynamical and statistical techniques to interpret global climatic changes in specific regions.

**IPCC emission scenario** Description of possible developments of the socio-economic system expressed in terms of emissions into the atmosphere.

**Projection** Simulation of possible climatic changes in the future, dependent on emission scenarios, land-use changes and natural variability in the climate system.

**Validation** Comparison of observed data against model result for quality assessment of the model.

### Definition of the Subject

A variety of observations demonstrates that during the last decades the climate has changed. As reported by the *Intergovernmental Panel on Climate Change* (IPCC, 2001, 2007), a mean increase of temperature by 0.09 K per decade was observed globally from 1951 to 1989. Up to now, 2007, this trend has continued. Europe experienced an extraordinary heat wave in summer 2003, with daily mean temperatures being about 10° warmer locally than the long term mean. The increase of temperature varies depending on the region and season.

The temperature change seems to be accompanied by changes in several meteorological and hydrological quantities, like number and duration of heat waves, frost periods, storminess or monthly mean precipitation. In Germany, for example, winter precipitation has increased in parts by more than 30% within the last four decades. In addition, very intense precipitation was observed in summer 2002 in parts of the Elbe drainage basin, which faced a severe flooding.

It can be expected that extreme weather situations will occur more often in a warming world. Therefore, a growing demand from decision-makers and the general public for detailed information on possible future climate development is evident, worldwide. The quantification of risks associated with changing climates is a prerequisite for the formulation and implementation of realistic adaptation and mitigation strategies [1].

Global climate models (GCM) have been developed to study the Earth's climate system in the past and future. Unfortunately, even today, global climate models provide information only at a relatively coarse spatial scale, which is often not suitable for regional climate change assessments. To fill this gap, two different principles to transfer the information from a global model to the region of interest have been developed accordingly: statistical downscaling and dynamical downscaling. Statistical downscaling techniques connect the climate change signal provided by the GCM with observations from measurement stations in the region to achieve higher resolved climate change signals.

Dynamical downscaling uses high resolution three-dimensional regional climate models (RCM), which are nested into GCMs. RCMs are similar to numerical weather forecasting models, which are taken into account non-linear processes in the climate system. The results of both downscaling methods depend on both the quality of the global and regional models. In the following, the focus will be on dynamical downscaling, in order to be able to also detect more easily new extremes, which have not been observed so far, and to take into account possible feedback mechanisms, which might appear under climate change conditions, and which influence the extent of regional climatic changes. Regional feedback mechanisms are, for example, snow-albedo/temperature feedbacks or soil moisture-temperature feedbacks. If snow melts the reflectivity of the surface changes from bright (white snow) to dark (vegetation or soil). This enhances the absorption of incoming radiation and leads to warming of the surface, which in turn accelerates the snow melt nearby. Evaporation from soils and vegetation increases with temperature and decreases soil moisture. Drier soils evaporate less,

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 1  
The physical climate system

so that cooling due to evaporation is decreasing, which in turn increases temperatures regionally.

### Introduction

The climate on Earth varies from region to region, and is characterized by sequences of weather events. These events are determined by the atmospheric flow, established through a wide range of interacting scales. The interacting scales cover large-scale features of the order of thousands to hundreds of km, mostly determined by the distribution of the continents and oceans, solar radiation and the composition of the atmosphere, regional features of the order of a few hundred km to a few km, forced through complex topography and vegetation distribution, and small scale features, like convection. The description of the Earth's climate needs to consider all scales, respectively. Therefore global climate models (GCMs) have been developed. They are mathematical representations of the Earth system (Fig. 1), in which physical and biogeochemical processes are described numerically to simulate the climate system as realistically as possible. Today GCMs develop into Earth system models (ESM), which are not only coupled atmosphere-ocean general circulation models (AOGCM), but also take into account some biogeochemical feedbacks, like the carbon cycle or dynamical

vegetation. They are the most advanced numerical tools for climate modeling and describe changes due to large scale forcing.

Increasing greenhouse gas (GHG) concentration, changing aerosol composition and load as well as land surface changes are influencing the climate of the Earth, globally and regionally. Therefore the demands for fine scale regional climate information were growing and in response to this the development of regional climate models started about 20 years ago. It is obvious that the simulations of regional climate changes requires the simulations of processes from global to local scales, so that very high resolution AOGCMs with grid sizes of about 10 km could be seen as the best solution. However, until today the horizontal resolution is still relatively coarse (100 to 250 km grid size) due to limitations in computer resources. Hence AOGCMs cannot provide regional details.

To overcome the deficiency two different approaches are used: statistical downscaling and dynamical downscaling. Both translate the information from the global model to the region of interest. Statistical downscaling techniques connect the climate change signal provided by the GCM with observations from measurement stations in the region to achieve higher resolved climate change signals. Dynamical downscaling uses high resolution three-dimensional regional climate models (RCM), which are

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 2  
Nesting technique

nested into GCMs (Fig. 2). RCMs are similar to numerical weather prediction models, in which non-linear processes in the climate system are taken into account. The results of both methods depend on both the quality of the global and regional models. In the following, the focus will be on dynamical downscaling, to be able to detect more easily new extremes, which have not been observed so far, and to take into account possible feedback mechanisms, which might appear under climate change conditions, like the snow-albedo/temperature feedback or the soil moisture-temperature feedback.

Regional climate models are limited area models. They only cover the area of interest, which can be resolved to a much higher degree than GCMs. Therefore RCMs describe the effects of regional and small scale processes within the simulation domain and are connected to the global flow using the nesting technique. This technique was developed to get higher resolution climate information on regional scales, and it is very similar to the nesting procedure in NWP. For initialization and at the lateral boundaries the GCM, in which the RCM is nested, provides information about the state of the atmosphere and the surface conditions. Usually atmospheric fields like wind, pressure, temperature and humidity are provided as well as sea surface temperatures [14,17]. Soil temperature and soil moisture are initialized once, but calculated within the RCMs during the simulation.

The development of regional climate models started in the USA. Filippo Giorgi at NCAR was the first one running the MM4 model in a so-called climate mode [10],

which means simulations longer than a few days, as it was common for numerical weather prediction (NWP). For many years RCMs were applied to simulations covering one month. The extension of NWP models to month-long simulations required changes in the formulation of physical processes which were taken into account within the model. In NWP models processes acting on time scales longer than weeks are not important and so not included.

The development of longer-term climate simulations happened very fast and simultaneously in several modeling centers of the world. In the early 1990s, the first multi-year simulations were carried out by Giorgi et al. [11,12], whereas Jones et al. [21,22] and McGregor et al. [27] succeeded in ten-year simulations. Nowadays regional climate simulations stretch from several decades, first achieved by Machenhauer et al. [25], up to more than a century in transient climate change mode [20]. Currently RCMs are widely used for regional climate studies for almost all regions of the world, with horizontal grid spacing ranging from more than 100 km to 10 km. A more detailed overview can be found in Giorgi [9] and for example in [7] focusing on regional climate modeling in the Arctic.

The basic features of RCMs will be explained in Sect. “**Basic Features and Model Characteristics**” and examples of applications will be presented in Sect. “**Validation**”, climate scenarios in Sect. “**IPCC-Scenarios**”, and examples of applications in Sects. “**Regional Climate Change**” and “**Regional Extremes**”. A discussion of future perspectives and concluding remarks follow in Sect. “**Future Directions**”.

## Basic Features and Model Characteristics

Until today, most RCMs are three-dimensional hydrostatic circulation models, solving the discretized primitive equations of the atmospheric motion. Summaries of model characteristics can be found in many publications, e. g. Jacob et al. [18,19]. As an example for the development and characteristics of many RCMs, the standard set-up of REMO, the regional climate model developed and used at the Max-Planck-Institute for Meteorology is described in more detail below.

The development of REMO started in 1994 utilizing the existing NWP model (EM) of the German Weather Service DWD [26]. Additionally, the physical parametrization package of the general circulation model ECHAM4 [33] has been implemented. During the last decade it could be shown in several applications that the combination of the EM dynamical core plus the ECHAM4 physical parametrization scheme is able to realistically reproduce regional climatic features and therefore became the standard setup.

The atmospheric prognostic variables of REMO are the horizontal wind components, surface pressure, temperature and specific humidity, as well as cloud liquid water. The temporal integration is accomplished by a leap-frog scheme with semi-implicit correction and time filtering after Asselin [2]. REMO is a grid box model, with grid box centers defined on a rotated latitude–longitude coordinate system. For horizontal discretization the model uses a spherical Arakawa-C grid in which all variables except the wind components are defined in the center of the respective grid box. In the vertical, a hybrid vertical coordinate system is applied [35]. Details about the physical parameterizations can be found in Jacob 2001 [16], but will not be explained here in more detail, since they vary slightly from RCM to RCM (see for example [18,19]).

The resolution of the horizontal grids in RCMs varies from about 100 km to 10 km and has increased constantly. For many years  $1/2^\circ$  grid size could be seen as a standard horizontal resolution, which was used in many experiments, even for model inter-comparison studies (e. g. [4,18,25,32]).

REMO uses horizontal grids with  $1/12^\circ$ ,  $1/6^\circ$  or  $1/2^\circ$ , corresponding to horizontal resolutions of about 10 km, 18 km and 55 km. In the vertical 20 to 40 levels are applied.

Applying the nesting technique for regional climate models requires large scale atmospheric flow fields to *drive* the RCMs at their lateral boundaries. These fields can be derived from different sources depending on the application. Regional climate simulations require climate change information from AOGCMs, whereas the simulations of

the last decades are driven by global analyzes of observations. The analyzes consist of observations, which have been interpolated in space and time using global models. They can be interpreted as the best available representation of the observed atmospheric flow conditions; however, systematic biases cannot be excluded due to the utilization of numerical models for interpolation. In regional climate modeling the use of driving data from analyzes or re-analyzes products are referred to as simulations with perfect boundary conditions (PBC). These experiments have the clear advantage to be directly comparable to observations for the actual time periods and they build the basis for model validation experiments.

In all cases, the relaxation scheme according to Davies [5] is applied in REMO, meaning that the prognostic variables are adjusted towards the large-scale forcing in a lateral sponge zone of 8 grid boxes. Within this zone the influence of the lateral boundary conditions decreases exponentially towards the inner model domain.

At the lower boundary, RCMs are determined through the interaction with the land surface and, over sea, by the sea surface temperature (SST) and sea ice distribution. The SST can either be interpolated from the large-scale forcing or from observational datasets, or it can be calculated online by a regional ocean model coupled to the RCM, e. g. [23]. The same is true for the sea ice extent, which can as a further option also be diagnosed from the SST. The land surface with its ongoing changes plays a major role in the climate system. Therefore, in all RCMs the exchange between surface and atmosphere is realized by the implementation of a land surface scheme [30]. Generally, one surface grid box can either be covered by water, sea ice or land or can include fractions of land and water areas, all characterized by their own roughness length and albedo. The land fraction of the surface can be covered by bare soil or by vegetation of different type. Depending on the complexity of the land surface scheme the exchange between the atmosphere and the underlying surface is realized through turbulent surface fluxes and the surface radiation flux, which are calculated separately for each fraction and weighted averages of the fluxes are used within the lowest atmospheric model level. Physical properties of the soil and vegetation control the exchange of heat, moisture and momentum over land. In REMO these properties include for example the surface roughness length, the soil field capacity, the water holding capacity of the vegetation, the background albedo, the fractional vegetation cover and the leaf area index (LAI). Some of these parameters strongly depend on the physiological state of the vegetation and are variable between the growing and the dormancy season [31].

There are two options to use the nesting technique. Within the one-way mode a GCM drives a RCM at the lateral boundaries, but no information is given back to the GCM. This method is the standard one used until today in regional climate modeling. It is relatively easy to implement and allows the use of RCMs without running a GCM. The RCM adds information on scales smaller than the driving GCM (e. g. topographical forcing), but is strongly dependent on the superimposed large scale flow. Hence RCMs cannot correct large scale flows originating from GCMs, which might have large errors. However, Giorgi et al. [13], showed that some modulation of the large scale flow is possible within the RCM simulation, stimulated by regional scale forcing.

In the two-way mode, both models GCM and RCM run simultaneously and the RCM feeds back information to the GCM every GCM time step. This method has recently been established for regional climate modeling studies [24]; it has the clear advantage that the atmospheric flow generated within the RCM domain can modulate the large scale flow in areas with strong energetic input from the surface to the atmosphere (e. g. the maritime continent).

If RCM experiments are carried out with high horizontal resolution, like 10 or 20 km, it can be required to use the so-called double nesting technique to avoid mismatch in scales along the lateral boundaries due to the coarse resolution of the driving GCMs. Double nesting means that first a RCM simulation will be carried out with a relatively coarse resolution to generate lateral boundary conditions for further nesting. For REMO, sometimes a sequence of nests is calculated [20].

Finally there are two independent options to run a regional climate model with PBC: the forecast mode and the climate mode. In climate mode the RCM simulation is initialized once from analyzes, and then it is continuously calculated forward in time, driven by regularly up-dated lateral boundaries. In forecast mode, a sequence of short runs (e. g. 30 hours), each initialized every 30 hours from analyzes, is carried out. The forecast mode has the advantage to force the RCM flow to be very close to the observed one, but it has the disadvantage to suppress mesoscale flow features. These mesoscale processes can be excited within the RCM domain by land–sea contrasts or topography and are too small to be taken into account in the GCM.

## Validation

The quality of the RCM simulations depends strongly on the performance of the driving model due to the one-way nesting procedure. Therefore, it is extremely important

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 3

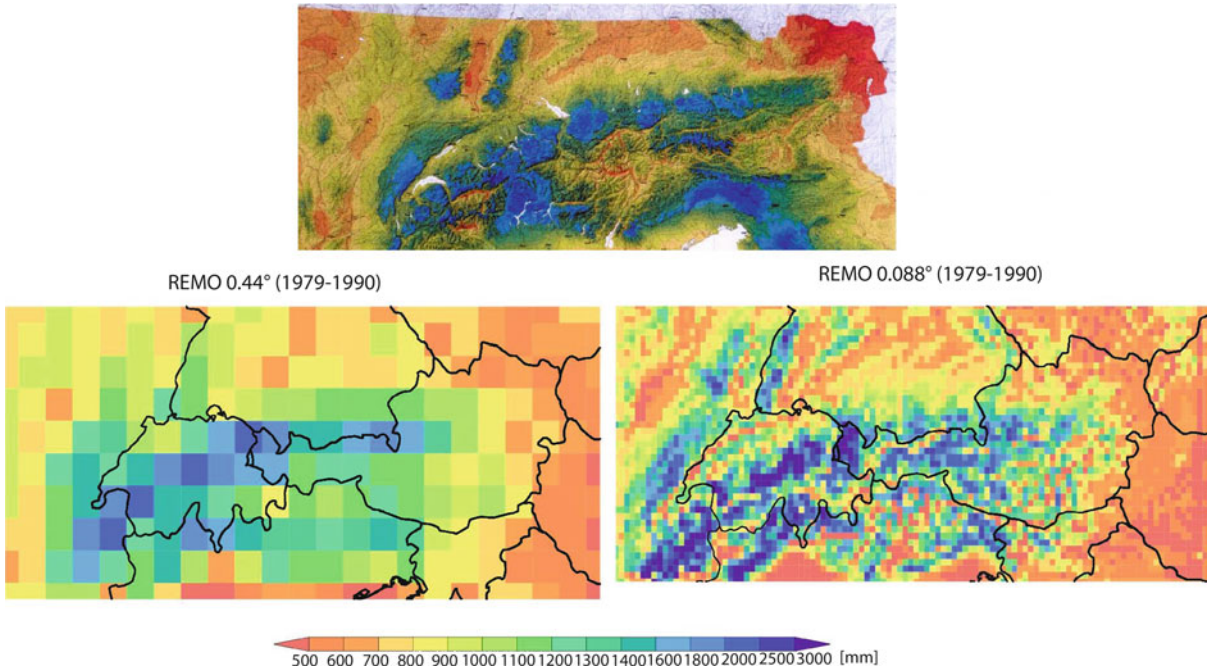

**Time series of the global mean near surface air temperature (K): observed (black), from reanalyzes (red), and from the MPI global climate model simulations (green)**

to validate the driving large scale fields before applying RCMs. The model quality, however, can only be judged in comparison with independent observations. Therefore, time periods of the past are simulated and the model results are compared against measurements before the models are used for climate change studies. These comparisons are also part of model development and testing.

As an example, Fig. 3 shows time series of observed and simulated global mean near surface temperatures for the period 1860 to 2000. The simulated results from the global coupled climate model ECHAM5/MPI-OM (Max-Planck-Institute for Meteorology) are in good agreement with ERA40 data, but about  $0.5^\circ$  warmer than the reconstructed observations. The observed increase during the last decades is clearly visible.

As for GCMs, the model quality of RCMs needs to be analyzed. Therefore RCMs are nested into re-analyzed data, which can be seen as close to reality as possible (see above). The results of the RCM simulations of the last decades are compared against independent observations, means as well as extremes are considered. As an example, simulated precipitation climatologies calculated with REMO with two different horizontal grid sizes are compared against observations [8].

The total amount of precipitation and the horizontal pattern are much better resolved using the very high horizontal resolution of about 10 km (Fig. 4). Regional maxima, like the one in the Black Forest, and minima, like in the central valleys of the Alps, are detectable. However, the resolution is still too coarse for climate change studies in individual alpine valleys. The 50 km grid is much finer than standard GCM grids (about 150 to 250 km), but is still

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 4  
 Annual total precipitation (mm), observed (1971–1990, upper panel) and simulated with about 50 km grid size (left) and 10 km grid size (right)

Changes in global mean near surface air temperature as calculated by several GCMs under seven emissions scenarios until 2100

insufficient for studying regional details if the regions are too small.

### IPCC-Scenarios

The investigation of possible future climate changes requires information about possible changes in the *drivers* of climate change. So-called *drivers* are for example, amount and distribution of aerosols and green house gases (GHG) in the atmosphere, which depend directly on natural and man-made emissions. The IPCC emissions scenarios (Fig. 5) follow so-called story lines, describing possible developments of the socioeconomic system [29].

The emissions are directly used within GCMs and RCMs and they initiate changes in global and regional climates through numerous non-linear feedback mechanisms. As an example, Fig. 6 shows possible developments of global mean near surface temperatures calculated by several models for different scenarios.

The global mean changes in near surface temperature until 2050 is about 1.5°C, whereas until the end of the century a wide spread appears from 1.5°C to 5.5°C.

### Regional Climate Change

In order to achieve information about the probability, e. g. for the intensification of the hydrological cycle over Europe, several models from different European climate research institutes are used, as it was done in the EU project PRUDENCE [4].

Following the climate change scenario A2 projecting a strong future increase of greenhouse gases until the year 2100 (IPCC, 2001) and a subsequent global mean temperature increase of about 3.5°, numerous simulations were conducted within PRUDENCE [19]. An analysis of their results for different river catchments [15] shows significant differences between the projected changes over northern and central Europe for the time period 2070–2100 compared to the current climate (1961–1990, Fig. 7).

For the Baltic Sea catchment, a precipitation increase of about +10% for the annual mean is projected, with the largest increase of up to +40% in winter, while a slight reduction of precipitation is calculated for the late summer. Evapotranspiration will increase during the entire year with a maximum increase in winter. These rises in precipitation and evapotranspiration would lead to an increase of river discharge into the Baltic Sea of more than 20% in winter and early spring. Here, the seasonal distribution of discharge is largely influenced by the onset of spring snowmelt.

For the catchments of Rhine, Elbe and Danube, a different change in the water balance components is projected. While the annual mean precipitation will remain almost unchanged, it will increase in late winter (January–March) and decrease significantly in summer. The evapotranspiration will rise during the entire year, except for the summer, with a maximum increase in winter. These changes lead to a large reduction of 10 to 20% in the annual mean discharge (Fig. 8). Especially for the Danube,

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 7  
 Simulated and observed river run-off (precipitation P – evaporation E) for 1961 to 1990 [15] in the Baltic Sea, Danube, Elbe and Rhine catchments

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 8  
 Simulated and observed change in river run-off (precipitation P – evaporation E) for the period 2071 to 2100 compared to 1961 to 1990 [15]. Baltic Sea, Danube, Elbe and Rhine catchments

the projected summer drying has a strong impact on the discharge that is reduced up to 20% throughout the year except for the late winter (February/March) when the increased winter precipitation causes a discharge increase of about 10%. These projected changes in the mean discharge will have significant impacts on water availability and usability in the affected regions.

Under climate change conditions not only the absolute amounts of precipitation may change but also the precipitation intensities, i. e. the amount of precipitation within a certain time period. The simulation of precipitation intensities or extreme precipitation events requires however a considerably higher resolution than the A2 results pre-

sented above so that for example the influence of the topography of the Alps on the formation of precipitation over the Rhine catchment could be adequately calculated. High resolution RCM results show that the global warming until 2050 will lead to an increase of high precipitation events over the Alpine part of the Rhine catchment, especially in summer. This climate change signal becomes clearly visible in the Pre-Alps, but a similar trend is also seen in the high resolution simulations over large parts of Europe.

A major breakthrough was possible with the regional climate change simulations on 10 km grid scale. Within a co-operation with the national environmental

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 9  
Changes in annual mean near surface temperature (°C) from 1950 to 2100 for three different IPCC SRES scenarios

agency (UBA), REMO was used for a control simulation from 1950 to 2000 and three transient runs for the IPCC SRES scenarios A2, A1B and B1. The simulation domain covers Germany, Austria and Switzerland [20]. As an example the most important results for Germany at the end of this century are summarized as follows:

The simulated annual mean near surface temperature is increasing up to 3.5°C depending on the emission scenario (Fig. 9). The regional pattern of temperature changes shows that the south and southeast warm more than all other areas in the simulation domain. The warming is associated with a decrease of precipitation amount in wide areas of Germany during summer and an increase of precipitation in south and southwest regions during the winter (Fig. 10). The winter precipitation is mostly rain and less precipitation falls as snow.

### Regional Extremes

The calculated rapid and strong changes of climate parameters can have severe impacts on humans and the environment. As an example, REMO results for the Rhine basin are presented for a B2 scenario until 2050. Between 1960 and 2050 the near surface temperature will rise by about 3°C and the number of summer days and hot days will increase (Fig. 11). In addition, the number of periods with summer days, this is the period of consecutive days with a daily maximum temperature above 25°C (not shown), will be higher in the future decades. Winter temperature also increases, leading to a decrease in frost and ice days.

The investigation of probability distribution functions for temperature and precipitation using the 10 km horizontal resolutions simulations for Germany shows possible monthly mean temperature of more than 30°C for July and >10°C for January appearing in the Rhine valley under the assumption of A1B scenario until the end of this century. In addition, possible increases in monthly mean precipitations are projected for A1B until 2100 in the area of Leipzig (Elbe drainage basin) for January as well as for July (Bülow, Ph D thesis, in preparation).

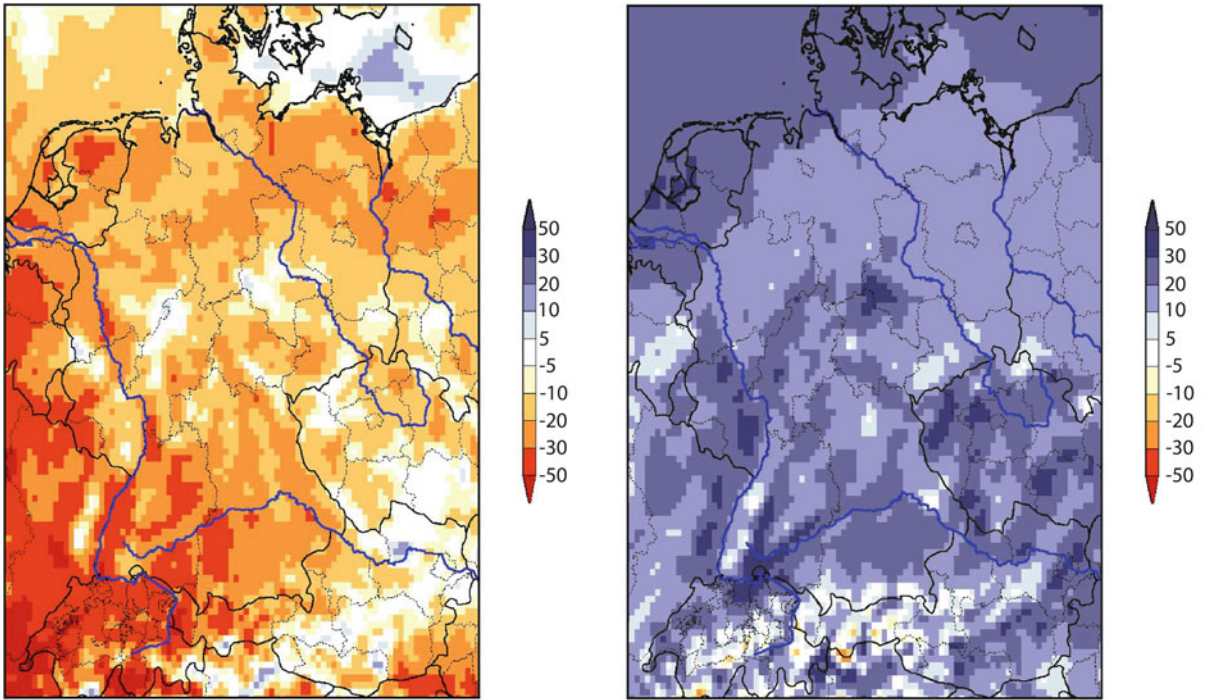

The projected changes in extremes are coherent with findings of Schär et al. [34] who studied the occurrence of summer heat waves in Europe today and in the future. He showed that the summer 2003 heat wave was extraordinary but can appear much more often in the future.

Another robust finding is the increase of heavy precipitation events in summer, which goes together with a decrease in monthly mean summer precipitation in central Europe [3]. Such short-term, strong convective summer precipitation events have the potential of causing damages, e. g. for agriculture, but also in cities, when sewage systems might be flooded.

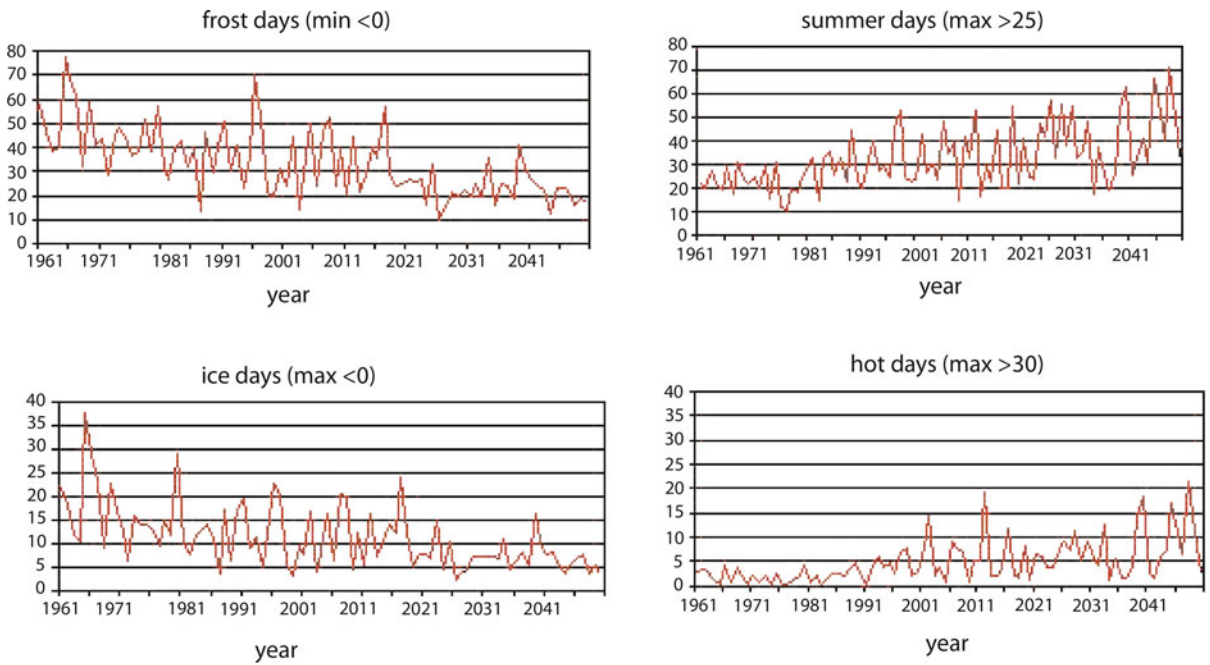

### Future Directions

Regional climate modeling has made major progress during the last decades and it could be shown that the added value lies mainly in the provision of details in space and time, which is demanded for impact assessments as well as by the public. RCMs are ready for operational use as powerful tools to simulate regional climatic features and their

Regional Climate Models: Linking Global Climate Change to Local Impacts, Figure 10

 REMO B2 scenario for the Rhine catchment: frost days (*upper left*), ice days (*lower left*), summer days (*upper right*) and hot days (*lower right*)

changes in all regions of the world, for time periods from today until the end of this century.

Now, further research on regional climate changes should focus on the reliability in projected regional and local climate change pattern. This can be done by ensemble calculations of GCMs-RCMs, which are also needed for the establishment of probability distribution functions to analyze extreme situations. Here special focus will be on the use of RCMs for regional climate prediction for the next 10 to 30 years, for which it is unclear if weather and climate extremes may change, where it might happen and if regions will face extreme situations in the future, in which this never happened before. The dissemination of regional climate “change information” can efficiently be done with the establishment of climate information systems in individual regions of the World.

The use of RCMs as intelligent interpolators of observed data in data sparse regions need to be proven, but RCMs have a great potential for this. In addition, the added value of RCMs compared to GCMs needs to be proven by applying the two-way nesting technique. In mountainous regions like the Alps an impact on the large scale flow can be expected.

The extension of regional climate models (RCM) to regional system models (RSM) is a major challenge for the next years. The coupling to regional ocean models, land use and hydrological models has recently started. Along with this the carbon and nitrogen cycles will be implemented on a regional scale. This allows a much better simulation of additional regional feedbacks as mentioned in Sect. “**Definition of the Subject**”, which might have the potential to modulate the regional climate signal projected by GCMs for the region of interest.

Finally, it must be stated that along with improvements of RCMs, the development of GCMs has to be continued. Their performance in individual regions can be quite poor and an improvement is urgently needed. Here RCMs can deliver important information about regional climatic details and help advancing global climate change simulations.

## Acknowledgments

I like to thank the REMO-grooup at the Max Planck Institute for Meteorology for their enthusiastic support.

### Glossary

**Numerical methods** Processes in nature are often described by partial differential equations. Finding solutions to those equations is at the heart of many studies aiming at the explanation of observed data. Simulations of realistic physical processes requires generally the use of numerical methods – a special branch of applied mathematics – that approximate the partial differential equations and allows solving them on computers. Examples are the finite-difference, finite-element, or finite-volume methods.

**Spectral elements** The spectral element method is an extension of the finite element method that makes use of specific basis functions describing the solutions inside each element. These basis functions (e. g., Chebyshev or Legendre polynomials) allow the interpolation of functions exactly at certain collocation points. This is often termed spectral accuracy.

**Discontinuous Galerkin method** The discontinuous Galerkin method is a flavor of the finite-element method that allows discontinuous behavior of the spatial or temporal fields at the element boundaries. The discontinuities – that might be small in the case of continuous physical fields such as seismic waves – then define so-called Riemann problems that can be handled using

the concepts from finite-volume techniques. Therefore, the approximate solution is updated via numerical fluxes across the element boundaries.

**Parallel algorithms** All modern supercomputers make use of parallel architectures. This means that a large number of processors are performing (different) tasks on different data at the same time. Numerical algorithms need to be adapted to these hardware architectures by using specific programming paradigms (e. g., the message passing interface MPI). The computational efficiency of such algorithms strongly depends on the specific parallel nature of the problem to be solved, and the requirement for inter-processor communication.

**Grid generation** Most numerical methods are based on the calculation of the solutions at a large set of points (grids) that are either static or depend on time (adaptive grids). These grids often need to be adapted to the specific geometrical properties of the objects to be modeled (volcano, reservoir, globe). Grids may be designed to follow domain boundaries and internal surfaces. Before specific numerical solvers are employed the grid points are usually connected to form triangles or rectangles in 2D or hexahedra or tetrahedra in 3D.

### Definition of the Subject

Seismology is the science that aims at understanding the Earth's interior and its seismic sources from measurements of vibrations of the solid Earth. The resulting images of the physical properties of internal structures and the spatio-temporal behavior of earthquake rupture processes are prerequisites to understanding the dynamic evolution of our planet and the physics of earthquakes. One of the key ingredients to obtain these images is the calculation of synthetic (or theoretical) seismograms for given earthquake sources and internal structures. These synthetic seismograms can then be compared quantitatively with observations and acceptable models be searched for using the theory of inverse problems. The methodologies to calculate synthetic seismograms have evolved dramatically over the past decades in parallel with the evolution of computational resources and the ever increasing volumes of permanent seismic observations in global and regional seismic networks, volcano monitoring networks, and experimental campaigns. Today it is a tremendous challenge to extract an optimal amount of information from seismograms. The imaging process is still primarily carried out using ray theory or extensions thereof not fully taking into account the complex scattering processes that are occurring in nature.

To model seismic observations in their full complexity we need to be able to simulate wave propagation through 3D structures with constitutive relations that account for anisotropic elasticity, attenuation, porous media as well as complex internal interfaces such as layer boundaries or fault systems. This implies that numerical methods have to be employed that solve the underlying partial differential equations on computational grids. The high-frequency oscillatory nature of seismic wave fields makes this an expensive endeavor as far as computational resources are concerned. As seismic waves are propagating hundreds of wavelengths through scattering media, the required accuracy of the numerical approximations has to be of the highest possible order. Despite the fact that the physics of wave propagation is well understood, only recently computational algorithms are becoming available that allow us to accurately simulate wave propagation on many scales such as reservoirs, volcanoes, sedimentary basins, continents, and whole planets.

In addition to the imaging problem for subsurface structure and earthquake sources, the possibilities for 3D wave simulations have opened a new route to forecasting strong ground motions following large earthquakes in seismically active regions. In the absence of any hope to deterministically predict earthquakes, the calculation of earthquake scenarios in regions with sufficiently well known crustal structures and fault locations will play an important role in mitigating damage particularly due to potentially amplifying local velocity structures. However, to be able to employ the advanced 3D simulation technology in an efficient way, and to make use of the fast advance of supercomputing infrastructure, a paradigm shift in the concept of wave simulation software is necessary: The Earth science community has to build soft infrastructures that enable massive use of those simulation tools on the available high-performance computing infrastructure.

In this paper we want to present the state of the art of computational wave propagation and point to necessary developments in the coming years, particularly in connection with finding efficient ways to generate computational grids for models with complex topography, faults, and the combined simulation of soil and structures.

## Introduction

We first illustrate the evolution of methodologies to calculate and model aspects of seismic observations for the case of global wave propagation. Seismology can look back at almost 50 years of systematic observations of earthquake induced teleseismic ground motions with the standardized

global seismic and regional networks. The digital revolution in the past decades has altered the recording culture such that now seismometers are recording ground motions permanently rather than in trigger-mode, observations are becoming available in near-real time, and – because of the required sampling rates – the daily amount of observations automatically sent to the data centers is gigantic. If we take a qualitative look at a seismic observation (Fig. 1) we can illustrate what it takes to model either part or the whole information contained in such physical measurements.

In Fig. 1 a seismogram observed using a broadband seismometer (station WET in Germany) is shown. Globally observed seismograms following large earthquakes contain frequencies up to 1 Hz (P-wave motions) down to periods of around one hour (eigenmodes of the Earth) in which case modeling is carried out in the frequency domain. Seismograms of the kind shown in Fig. 1 contain many types of information. For large earthquakes the first part of the seismogram (inlet) contains valuable information on the spatio-temporal evolution of the earthquake rupture on a finite-size fault. A model of the fault slip history is a prerequisite to model the complete wave form of seismograms as the whole seismogram is affected by it unless severe low-pass filtering is applied. Information on the global seismic velocity structure is contained in the arrival times of numerous body-wave phases (here only P- and S-wave arrivals are indicated) and in the dispersive behavior of the surface waves (here the onset of the low-frequency Love waves is indicated). Further information is contained in the characteristics of the coda to body wave phases indicative of scattering in various parts of the Earth (see [62] for an account of modern observational seismology).

Adding a temporal and spatial scale to the above qualitative discussion reveals some important insight what it takes to simulate wave propagation on a planetary scale using grid-based numerical methods. Given the maximum frequency of around 1 Hz (P-waves) and 0.2 Hz (S-waves) the minimum wavelength in the Earth is expected to be  $O(\text{km})$ , requiring  $O(100 \text{ m})$  type grid spacing at least in the crustal part of the Earth leading to  $O(10^{12})$  necessary grid points (or volume elements) for accurate numerical simulations. This would lead to memory requirements  $O(100 \text{ TByte})$  that are today possible on some of the world's largest supercomputers. The message here is that despite the rapid evolution of computational power, the complete modeling of teleseismic observations using approaches such as spectral elements (e. g., [63,64]) requiring tremendous numbers of calculations to constrain structure and sources will remain a grand challenge for some

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 1

Transverse velocity seismogram of the M8.3 Tokachi-Oki earthquake near Hokkaido observed at station WET in Germany with a broadband seismometer. The total seismogram length is one hour. Arrival times of body wave phases (P, S) and the onset of transversely polarized surface (Love) waves are indicated

time to come. However, in many cases it is not necessary or not even desirable to simulate or model the whole seismogram, i. e. the complete observed frequency band. If we lower the cutoff frequency to 0.1 Hz (period 10 s), the required memory drops down to  $O(100 \text{ GByte})$ . Such calculations can be done today on PC-clusters that can be inexpensively assembled and run on an institutional level (e. g., [8]). In addition, it means that the massive use of such forward simulations for imaging purposes and phenomenological investigations of wavefield effects is around the corner. This does not only apply to wave propagation or imaging on a planetary scale but in the same way to problems in volcanology, regional seismology, and exploration geophysics.

An illustration of global wave simulations using the finite difference method (e. g., [14,54,55,58,109,110,114]) is shown in Fig. 2 (more details on the methodologies are given in Sect. “The Evolution of Numerical Methods and Grids”). The snapshot of the radial component of motion at a time when the direct P-wave has almost crossed the Earth reveals the tremendous complexity the wave field exhibits even in the case of a spherically symmetric Earth model (PREM, [37]). The wavefield with a dominant period of ca. 15 seconds also highlights the short wavelengths that need to be propagated over very large distances. This is the special requirement for computational wave propagation that is quite different in other fields of compu-

tational Earth Sciences. While the theory of linear elastic wave propagation is well understood and most numerical methods have been applied to it in various forms, the accuracy requirements are so high that – particularly when models with complex geometrical features need to be modeled – there are still open questions as to what works best. One of the main goals of this paper is to highlight the need to focus on the grid generation process for various types of computational grid cells (e. g., rectangular, triangular in 2D, and hexahedral and tetrahedral in 3D) and the interface to appropriate highly accurate solvers for wave propagation problems.

As mentioned above computational modeling of strong ground motions following large earthquakes (see Fig. 3 for an illustration) is expected to play an increasingly important role in producing realistic estimates of shaking hazard. There are several problems that are currently unsolved: (1) to achieve frequencies that are interesting for earthquake engineers in connection with structural damage the near surface velocity structure needs to be known and frequencies beyond 5 Hz need to be calculated. In most cases this structure is not well known (on top of the uncertainties of the lower basin structures) and the required frequencies demand extremely large computational models. (2) In addition to structural uncertainties, there are strong dependencies on the particular earthquake rupture process that influence the observed ground

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 2

Snapshot of wave propagation inside the Earth approx. 25 minutes after an earthquake occurs at the top part of the model. The radial component of motion is shown (blue and red denote positive and negative velocity, resp.). The simulation was carried out using an axi-symmetric approximation to the wave equation [55,58] and high-order finite-differences. Motion is allowed in the radial and horizontal directions. This corresponds to the P-SV case in 2D cartesian calculations. Therefore the wavefield contains both P- and S-waves and phase conversions

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 3

Snapshot (horizontal component) for a simulation of the M5.9 Roermond earthquake in the Cologne Basin in 1992 [38]. The 3D sedimentary basin (maximum depth 2 km) leads to strong amplification and prolongation of the shaking duration that correlates well with basin depth. Systematic calculations may help mitigating earthquake induced damage

motions. This suggests that many 3D calculations should be carried out for any characteristic earthquake of interest, to account for such variations (e. g., Wang et al. 2006). (3)

The large velocity variations (e. g., 300 m/s up to 8 km/s) require locally varying grid densities which is difficult to achieve with some of the classical numerical methods in use (e. g. finite differences). Some of the potential routes are developed below.

In summary, computational simulation of 3D wave propagation will be more and more a central tool for seismology with application in imaging problems, earthquake rupture problems, questions of shaking hazard, volcano seismology and planetary seismology. In the following we briefly review the history of the application of numerical methods to wave propagation problems and the evolution of computational grids. The increasing complexity of models in terms of geometrical features and range of physical properties imposes the use of novel methodologies that go far beyond the initial approximations based on finite differences.

### The Evolution of Numerical Methods and Grids

In this section we give a brief history of the application of numerical methods to the problem of seismic wave propagation. Such a review can not be complete, certainly gives a limited perspective, and only some key references are given. One of the points we would like to highlight is the evolution of the computational grids that are being employed for wave propagation problems and the consequences on the numerical methods of choice now and in the future.

Why do we need numerical approximations to elastic wave propagation problems at all? It is remarkable what we learned about the Earth without them! In the first decades in seismology, modeling of seismic observations was restricted to the calculation of ray-theoretical travel times in spherically symmetric Earth models (e. g., [13,16]). With the advent of computing machines these approaches could be extended to 2D and 3D media leading to ray-theoretical tomography and the images of the Earth's interior that we know today (e. g., [115]). The analytical solution of wave propagation in spherical coordinates naturally leads to spherical harmonics and the possible quasi-analytical solution of wave propagation problems in spherically symmetric media using normal modes. As this methodology leads to complete waveforms the term "waveform inversion" was coined for fitting the waveforms of surface waves by correcting the phase differences for surface waves at particular frequencies (e. g., [118]). This allowed the recovery of seismic velocity models particularly of crust and upper mantle (surface wave tomography). A similar approach in Cartesian layered geometry led to complete solutions of the wave

equation in cylindrical coordinates through the summation of Bessel functions, the reflectivity method [46]. This method was later extended to spherical media through the Earth-flattening transformation [85]. Recently, ray-theory was extended allowing the incorporation of finite-frequency effects (e. g., [84]). The impact on the imaging process is still being debated.

Most of these methods are still today extremely valuable in providing first estimates of 2D or 3D effects and are important for the use in standard seismic processing due to their computational efficiency. Nevertheless, with the tremendous improvements of the quality of seismic observations we strive today to extract much more information on Earth's structure and sources from recorded waveforms. As waveforms are in most places strongly affected by 3D structural variations the application of numerical methods that solve "directly" the partial differential equations descriptive of wave propagation becomes mandatory. This necessity was recognized early on and the developments of numerical wave propagation began in the sixties of the 20th century.

### Numerical Methods Applied to Wave Propagation Problems

The finite-difference technique was the first numerical method to be intensively applied to the wave propagation problem (e. g., [1,6,61,77,82,83,88,89,116,117]). The partial differentials in the wave equation are replaced by finite differences leading to an extrapolation scheme in time that can either be implicit or explicit. The analysis of such simple numerical schemes led to concepts that are central to basically all numerical solutions of wave propagation problems. First, the discretization in space and time introduces a scale into the problem with the consequence that the numerical scheme becomes dispersive. This numerical dispersion – for the originally non-dispersive problem of purely elastic wave propagation – has the consequence that for long propagation distances wave pulses are no longer stable but disperse. The consequence is, that in any simulation one has to ascertain that enough grid points per wavelength are employed so that numerical dispersion is reduced sufficiently. Finding numerical schemes that minimize these effects has been at the heart of any new methodology ever since. Second, the so-called CFL criterion [24] that follows from the same theoretical analysis of the numerical scheme basically relates a "grid velocity" – the ratio between the space and time increments  $dx$  and  $dt$ , respectively – to the largest physical velocity  $c$  in the model. In order to have a stable calculation, this ratio has to be smaller than a constant  $\varepsilon$  that depends on the specific scheme and

the space dimension

$$c \frac{dt}{dx} \leq \varepsilon. \quad (1)$$

This simple relationship has important consequences: When the grid spacing  $dx$  must be small, because of model areas with low seismic velocities, then the time step  $dt$  has to be made smaller accordingly leading to an overall increase in the number of time steps and thus overall computational requirements. In addition, the early implementations were based on regular rectangular grids, implying that large parts of the model were carrying out unnecessary calculations. As shown below local time-stepping and local accuracy are important ingredients in efficient modern algorithms.

The fairly inaccurate low order spatial finite-difference schemes were later extended to high-order operators [26,48,49,50,51,56,76,103]. Nevertheless, the required number of grid points per wavelength was still large, particularly for long propagation distances. This has led to the introduction of pseudo-spectral schemes, "pseudo" because only the calculations of the derivatives were done in the spectral domain, but the wave equation was still solved in the space-time domain with a time-extrapolation scheme based on finite differences [10,45,47,67]). The advantage of the calculation of derivatives in the spectral domain is at hand: The Fourier theorem tells us that by multiplying the spectrum with  $ik$ ,  $i$  being the imaginary unit and  $k$  the wavenumber, we obtain an *exact* derivative (exact to numerical precision) on a regular set of grid points. This sounds attractive. However, there are always two sides to the coin. The calculation requires FFTs to be carried out extensively and the original "local" scheme becomes a "global" scheme. This implies that the derivative at a particular point in the computational grid becomes dependent on any other point in the grid. This turns out to be computationally inefficient, in particular on parallel hardware. In addition, the Fourier approximations imply periodicity which makes the implementation of boundary conditions (like the free surface, or absorbing boundary conditions) difficult.

By replacing the basis functions (Fourier series) in the classical pseudo-spectral method with Chebyshev polynomials that are defined in a limited domain  $(-1,1)$  the problem with the implementation of boundary problems found an elegant solution (e. g., [66,107,108]). However, through the irregular spacing of the Chebyshev collocation points (grid densification at the domain boundaries, see section below) new problems arose with the consequence that this approach was not much further pursued except in combination with a multi-domain approach in which the field

variables exchange their values at the domain boundaries (e. g., [108]).

So far, the numerical solutions described are all based on the *strong* form of the wave equation. The finite-element method is another main scheme that found immediate applications to wave propagation problems (e. g., [79]). Finite element schemes are based on solving the *weak* form of the wave equation. This implies that the space- and time-dependent fields are replaced by weighted sums of basis (also called trial) functions defined inside elements. The main advantage of finite element schemes is that elements can have arbitrary shape (e. g., triangular, trapezoidal, hexahedral, tetrahedral, etc.). Depending on the polynomial order chosen inside the elements the spatial accuracy can be as desired. The time-extrapolation schemes are usually based on standard finite differences. There are several reasons why finite-element schemes were less widely used in the field of wave propagation. First, in the process a large system matrix needs to be assembled and must be inverted. Matrix inversion in principle requires global communication and is therefore not optimal on parallel hardware. Second, in comparison with the finite-element method, finite-difference schemes are more easily coded and implemented due to their algorithmic simplicity.

A tremendous step forward was the introduction of basis functions inside the elements that have spectral accuracy, e. g., Chebyshev or Legendre polynomials [11,15,39,40,65,86,90,98]. The so-called spectral element scheme became particularly attractive with the discovery that – by using Legendre polynomials – the matrices that required inversion became diagonal [65]. This implies that the scheme does no longer need global communication, it is a local scheme in which extrapolation to the next time step can be naturally parallelized. With the extension of this scheme to spherical grids using the cubed-sphere discretization [63,64] this scheme is today the method of choice on many scales unless highly complex models need to be initiated.

Most numerical schemes for wave propagation problems were based on regular, regular stretched, or hexahedral grids. The numerical solution to unstructured grids had much less attention, despite the fact that highly complex models with large structural heterogeneities seem to be more readily described with unstructured point clouds. Attempts were made to apply finite volume schemes to this problem [31], and other concepts (like natural neighbor coordinates [7] to find numerical operators that are applicable on unstructured grids [72,73,78]). These approaches were unfortunately not accurate enough to be relevant for 3D problems. Recently, a new flavor of nu-

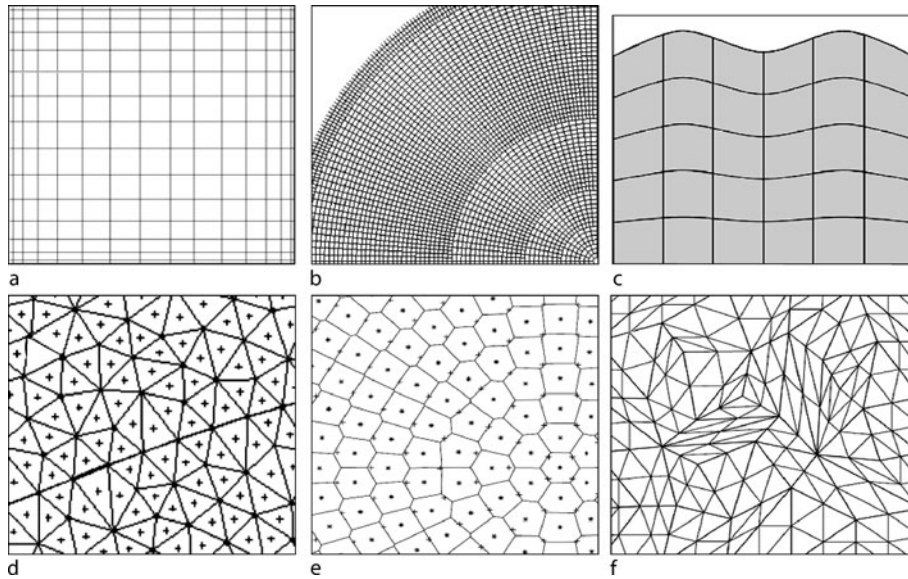

merical method found application to wave propagation on triangular or tetrahedral grids. This combination of a discontinuous Galerkin method with ideas from finite volume schemes [33,70] allows for the first time arbitrary accuracy in space and time on unstructured grids. While the numerical solution on tetrahedral grids remains computationally slower, there is a tremendous advantage in generating computational grids for complex Earth models. Details on this novel scheme are given below.

Before presenting two schemes (spectral elements and the discontinuous Galerkin method) and some applications in more detail we want to review the evolution of grids used in wave propagation problems.

### Grids for Wave Propagation Problems

The history of grid types used for problems in computational wave propagation is tightly linked to the evolution of numerical algorithms and available computational resources. The latter in the sense that – as motivated in the introduction – even today realistic simulations of wave propagation are still computationally expensive. This implies that it is not sufficient to apply stable and simple numerical schemes and just use enough grid points per wavelength and/or extremely fine grids for geometrically complex models. Optimal mathematical algorithms that minimize the computational effort are still sought for as the recent developments show that are outlined in the following sections.

In Fig. 4 a number of different computational grids in two space dimensions is illustrated. The simple-most equally-spaced regular finite-difference grid is only of practical use in situations without strong material discontinuities. With the introduction of the pseudospectral method based on Chebyshev polynomials grids as shown in Fig. 4a grids appeared that are denser near the domain boundaries and coarse in the interior. While this enabled a much more efficient implementation of boundary conditions the ratio between the size of the largest to the smallest cell depends on the overall number of grid points per dimension and can be very large. This leads to very small time steps, that can in some way be compensated by grid stretching [9] but overall the problem remains. An elegant way of allowing grids to be of more practical shape is by stretching the grids using analytical functions (Fig. 4c, this basically corresponds to a coordinate transformation, e. g., [50,107]). By doing this either smooth surface topography or smoothly varying internal interfaces can be followed by the grid allowing a more efficient simulation of geometrical features compared to a blocky representation on standard finite difference grids.

Examples of 2D grids used for wave propagation simulations. **a** Chebyshev grid with grid densification near the domain boundaries. **b** Multidomain finite-difference grid in regular spherical coordinates. **c** Stretched regular finite-difference grid that allows following smoothly varying interface or surface boundaries. **d** Triangular staggered grid following an interface that allows finite-difference type operators. **e** Unstructured grid with associated Voronoi cells for calculations using the finite-volume method. **f** Triangular cells for finite-element type calculations. See text for details and references

The problem of global wave propagation using spherical coordinates (here in the two-dimensional, axi-symmetric approximation) nicely illustrates the necessity to have spatially varying grid density (e. g., [42,43,53,59,89,109]). The grid shown in Fig. 4b demonstrates that in spherical coordinates a regular discretization leads to grid distances that get smaller and smaller towards the center of the Earth. This is in contrast to what is required to efficiently model the Earth's velocity structure: Velocities are small near the surface (requiring high grid density) and increase towards the center of the Earth (requiring low grid density). One way of adjusting is by re-gridding the mesh every now and then, in this case doubling the grid spacing appropriately. This is possible, yet it requires interpolation at the domain boundaries that slightly degrades the accuracy of the scheme.

The problems with grid density and complex surfaces cry for the use of so-called unstructured grids. Let us define an unstructured grid as an initial set of points (a point cloud), each point characterized by its spatial coordinates. We wish to solve our partial differential equations on this point set. It is clear that – with appropriate grid generation software – it is fairly easy to generate such grids that obey exactly any given geometrical constraints be it in connection with surfaces or velocity models (i. e., varying grid density). It is important to note that such point clouds can-

not be represented by 2D or 3D matrices as is the case for regular or regular stretched grid types. This has important consequences for the parallelization of numerical schemes. The first step after defining a point set is to use concepts from computational geometry to handle the previously unconnected points. This is done through the idea of Voronoi cells, that uniquely define triangles and their neighbors (Delauney triangulation). In Fig. 4d an example is shown for a triangular grid that follows an internal interface [72]. For finite-difference type operators on triangular grids a grid-staggering makes sense. Therefore, velocities would be defined in the center of triangles and stresses at the triangle vertices. Voronoi cells (Fig. 4e) can be used as volumetric elements for finite volume schemes [31,73]. For finite-element schemes triangular elements (Fig. 4f, e. g., [70]) with appropriate triangular shape functions are quite standard but have not found wide applications in seismology.

If the grid spacing of a regular finite-difference grid scheme in 3D would have to be halved this would result in an overall increase of computation time by a factor of 8 (a factor 2 per space dimension and another factor 2 because of the necessary halving of the time step). This simply means that the accuracy of a specific numerical scheme and the saving in memory or computation time is much more relevant in three dimensions. The evolu-

tion of grids in three dimensions is illustrated with examples in Fig. 5. A geometrical feature that needs to be modeled correctly particularly in volcanic environments is the free surface. With standard regular-spaced finite-difference schemes only a stair-step representation of the surface is possible (Fig. 5a, e. g., [87,92]). While the specific numerical implementation is stable and converges to the correct solution a tremendous number of grid points is necessary to achieve high accuracy.

Chebyshev grids and regular grids were applied to the problem of wave propagation in spherical sections (Fig. 5b, e. g., [52,57]). The advantage of solving the problem in spherical coordinates is the natural orthogonal coordinate system that facilitates the implementation of boundary conditions. However, due to the nature of spherical coordinates the physical domain should be close to the equator and geographical models have to be rotated accordingly. A highly successful concept for wave propagation in spherical media was possible through the adoption of the cubed-sphere approach in combination with spectral-elements (Fig. 5c, [63,64]). The cubed-sphere discretization is based on hexahedral grids. Towards the center of the Earth the grid spacing is altered to keep the number of elements per wavelength approximately constant.

Computational grids for wave propagation based on tetrahedra (Fig. 5d,e) are only recently being used for seismic wave propagation in combination with appropriate numerical algorithms such as finite volumes [34] or discontinuous Galerkin (e. g., [70]). The main advantage is that the grid generation process is greatly facilitated when using tetrahedra compared to hexahedra. Generating point clouds that follow internal velocity structures and connecting them to tetrahedra are straight forward and efficient mathematical computations. However, as described in more detail below, tetrahedral grids require more involved computations and are thus less efficient than hexahedral grids. Complex hexahedral grids – even for combined modeling of structure and soil (Fig. 5f) are possible but – at least at present – require a large amount of manual interaction during the grid generation process. It is likely that the combination of both grid types (tetrahedral in complex regions, hexahedral in less complex regions) will play an important role in future developments.

In the following we would like to present two of the most competitive schemes presently under development, (1) the spectral element method and (2) the discontinuous Galerkin approach combined with finite-volume flux schemes. The aim is to particularly illustrate the role of the grid generation process and the pros and cons of the specific methodologies.

### 3D Wave Propagation on Hexahedral Grids: Soil-Structure Interactions

We briefly present the spectral element method (SEM) based on Lagrange polynomials, focusing only on its main features and on its implementation for the solution of the elasto-dynamic equations. The SEM can be regarded as a generalization of the finite element method (FEM) based on the use of high order piecewise polynomial functions. The crucial aspect of the method is the capability of providing an arbitrary increase in spatial accuracy simply enhancing the algebraic degree of these functions (the spectral degree SD). On practical ground, this operation is completely transparent to the users, who limit themselves to choosing the spectral degree at runtime, leaving to the computational code the task of building up suitable quadrature points for integration and new degrees of freedom. Obviously, the increasing spectral degree implies raising the required computational effort.

On the other hand, one can also play on the grid refinement to improve the accuracy of the numerical solution, thus following the standard finite element approach. Spectral elements are therefore a so-called “ $h-p$ ” method, where “ $h$ ” refers to the grid size and “ $p$ ” to the degree of polynomials. Referring to Faccioli et al. [40], Komatitsch and Vilotte [65], Chaljub et al. [15] for further details, we briefly remind in the sequel the key features of the spectral element method adopted. We start from the wave equation for the displacement  $\mathbf{u}$ :

$$\rho \frac{\partial \mathbf{u}^2}{\partial t^2} = \text{div } \sigma_{ij}(\mathbf{u}) + f, \quad i, j = 1 \dots d (d = 2, 3) \quad (2)$$

where  $t$  is the time,  $\rho = \rho(x)$  the material density,  $f = f(x, t)$  a known body force distribution and  $\sigma_{ij}$  the stress tensor. Introducing Hooke’s law:

$$\sigma_{ij}(\mathbf{u}) = \lambda \text{div } \mathbf{u} \delta_{ij} + 2\mu \varepsilon_{ij}(\mathbf{u}), \quad (3)$$

where

$$\varepsilon_{ij}(\mathbf{u}) = \frac{1}{2} \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \quad (4)$$

is the strain tensor,  $\lambda$  and  $\mu$  are the Lamé coefficients, and  $\delta_{ij}$  is the Kronecker symbol, i. e.  $\delta_{ij} = 1$  if  $i = j$  and  $\delta_{ij} = 0$ , otherwise.

As in the FEM approach, the dynamic equilibrium problem for the medium can be stated in the weak, or variational form, through the principle of virtual work [121] and through a suitable discretization procedure that depends on the numerical approach adopted, can be written as an ordinary differential equations system with respect

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 5

Examples of 3D grids. **a** Stair-step representation of a complex free surface with finite-difference cells. **b** Chebyshev grid in spherical coordinates for a spherical section. **c** Cubed sphere grid used for spectral-element and multi-domain Chebyshev calculations. **d** Tetrahedral grid of the Matterhorn. **e** Tetrahedral grid of the Earth's interior with the grid density tied to the velocity model. **f** Hexahedral grid of bridge structure and subsurface structure for spectral-element calculations. to time:

$$[M] \ddot{\mathbf{U}}(t) + [K] \mathbf{U}(t) = \mathbf{F}(t) + \mathbf{T}(t) \quad (5)$$

with matrices  $[M]$  and  $[K]$ , respectively the mass and stiffness matrices, and vectors  $\mathbf{F}$  and  $\mathbf{T}$  representing the contributions of external forces and traction conditions, respectively. In our SE approach,  $\mathbf{U}$  denotes the displacement vector at the Gauss–Lobatto–Legendre (GLL) nodes, that correspond to the zeroes of the first derivatives of Legendre polynomial of degree  $N$ . The advancement of the numerical solution in time is provided by the explicit 2nd order leap-frog scheme. This scheme is conditionally stable and must satisfy the well known and already mentioned Courant–Friedrichs–Levy (CFL) condition. The key features of the SE discretization are described in the following.

Like in the FEM standard technique, the computational domain may be split into quadrilaterals in 2D or hexahedra in 3D, both the local distribution of grid points within the single element and the global mesh of all the grid points in the domain must be assigned. Many of these grid points are shared amongst several spectral elements. Each spectral element is obtained by a mapping of a master element through a suitable transformation and all computations are performed on the master element. Research is in progress regarding the introduction of triangular spec-

tral elements [80]. The nodes within the element where displacements and spatial derivatives are computed, on which volume integrals are evaluated, are not necessarily equally spaced (similar to the Chebyshev approach in pseudospectral methods mentioned above). The interpolation of the solution within the element is done by Lagrange polynomials of suitable degree. The integration in space is done through Gauss–Lobatto–Legendre quadrature formula.

Thanks to this numerical strategy, the exponential accuracy of the method is ensured and the computational effort minimized, since the mass matrix results to be diagonal. The spectral element (SE) approach developed by Faccioli et al. [40] has been recently implemented in the computational code GeoELSE (GeoElasticity by Spectral Elements) [93,102,120] for 2D/3D wave propagation analysis. The most recent version of the code includes: (i) the capability of dealing with fully unstructured computational domains, (ii) the parallel architecture, and (iii) visco-plastic constitutive behavior [30]. The mesh can be created through an external software (e.g., CUBIT [25]) and the mesh partitioning is handled by METIS [81].

### Hexahedral Grids

As already mentioned in the SEM here presented the computational domain is decomposed into a family of non

overlapping quadrilaterals in 2D or hexahedra in 3D. The grid discretization should be suitable to accurately propagate up to certain frequencies. Obviously, owing to the strong difference of the mechanical properties between soft-soil and stiff-soil (or building construction material) and to the different geometrical details as well, the grid refinement needed in the various parts of the model varies substantially. Therefore, a highly unstructured mesh is needed to minimize the number of elements. While 3D unstructured tetrahedral meshes can be achieved quite easily with commercial or non commercial software, the creation of a 3D non structured hexahedra mesh is still recognized as a challenging problem. In the following paragraph we provide state of the art results concerning the mesh creation.

### Grid Generation

Hexahedral grids have more severe restrictions in meshing efficiently. This is basically related to the intrinsic difficulty that arises from the mapping of the computational domain with this particular element. As a consequence automatic procedures have difficulty capturing specific boundaries, create poor quality elements, the assigned size is difficult to be preserved and the generation process is usually much slower compared to the tetrahedral mesh generation algorithms. On the other hand the advantages of hexahedral meshes are usually related to the lower computational cost of the wave propagation solutions with respect to the one based on triangular meshes or hexahedral structured grids (like in the finite difference method).

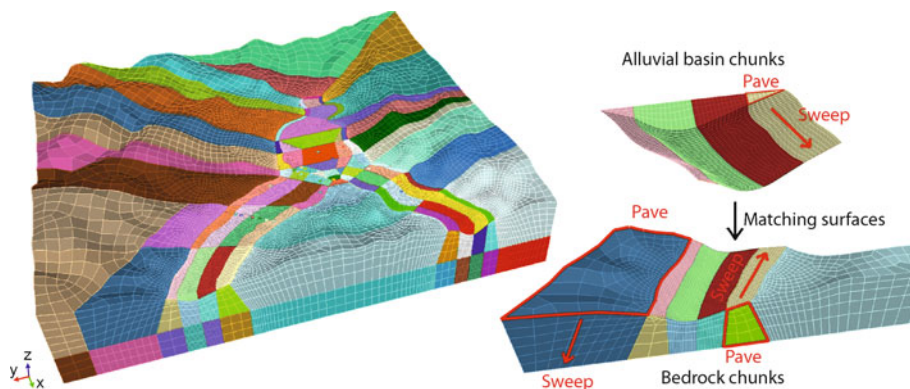

Nevertheless certain problems can be addressed reasonably well with specific solutions. A quite typical case

in earthquake seismology is the study of the alluvial basin response under seismic excitation. In handling this problem, a first strategy is to try to “honor” the interface between the sediment (soft soil) and the bedrock (stiff soil). The two materials are divided by a physical interface and the jump in the mechanical properties is strictly preserved. The major drawback of this approach is that usually it requires strong skills from the user to build-up the mesh and a significant amount of working time (Fig. 6). Given that the “honoring approach” is not always feasible in a reasonable time (or with a reasonable effort) a second strategy is worth to be mentioned: The so called “not honoring” procedure. In this second case the mesh is refined in proximity of the area where the soft deposit are localized but the elements do not respect the interface. On a practical ground the mechanical properties are assigned node by node and the sharp jump is smoothed through the Lagrange interpolation polynomial and substituted with smeared interfaces (Fig. 7). At the present time it is still strongly under debate if it is worth to honor or not the physical interfaces.

Finally, we highlight the fact that meshing software (e.g., CUBIT [25]) is available that seems to be extremely promising and potentially very powerful for the creation of geophysical and seismic engineering unstructured hexahedral meshes. Further very interesting mesh generation procedures based on hexahedral are under investigation [99].

### Scale Problem with Structure and Soil

In engineering practice one of the most common approaches to design buildings under seismic load is the imposition of an acceleration time history to the structure,

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 6

3D numerical model used for the simulations of ESG06 “Grenoble Benchmark”. “Honoring” technique: The computational domain is subdivided into small chunks and each one is meshed starting from the alluvial basin down to the bedrock. For simplicity only the spectral elements are shown without GLL nodes

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 7

3D numerical model used for the simulations of ESG06 “Grenoble Benchmark”. “Not Honoring” technique: The computational domain is meshed with a coarse mesh and then refined twice approximately in the area where the alluvial basin is located

basically acting like an external load. An excellent example of this technique can be found in recent publications (e. g., [68,69]) and in the study of the so-called “urban-seismology”, recently presented by Fernandez-Ares et al., [44]. In this case the goal is to understand how the presence of an entire city can modify the incident wave-field. Due to the size of the simulation and the number of buildings, the latter are modeled as single degrees of freedom oscillators. The interaction between soil and structure is preserved but the buildings are simplified. For important structure (e. g.: Historical buildings, world heritage buildings, hospitals,

schools, theaters, railway and highways) it is worth to provide an ad-hoc analysis capable to take into account the full complexity of the phenomena.

Here we present an example of a fully coupled modeling (Fig. 8): A railway bridge and its geotechnical-topographical surroundings. The Acquasanta bridge on the Genoa-Ovada railway, North Italy, is located in the Genoa district and represents a typical structure the ancestor of which can be traced back to the Roman “Pont du Gard”. This structural type did not change significantly along the centuries, thanks to the excellent design achieved no less

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 8

3D model of Acquasanta bridge and the surrounding geological configuration. The investigated area is 2 km in length, 1.75 km in width and 0.86 km in depth. The model was designed to propagate waves up to 5 Hz with a  $SD = 3$  (Order 4) and has 38,569 hexahedral elements and 1,075,276 grid points. The contact between calcareous schists (brown color) and serpentine rocks (green color) is modeled with two sub-vertical faults (red-line). Cyan color represents the alluvial and weathered deposits

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 9  
 Snapshots of the modulus of the displacement vector and the magnified deformed shape of the bridge (in mm)

than 1900 years ago. The Acquasanta bridge structure is remarkable both for the site features and the local geological and geomorphological conditions. The foundations of several of the piers rest on weak rock; moreover, some instability problems have been detected in the past on the valley slope towards Ovada.

Several simulations have been performed with GeoELSE, in order to evaluate the influence of seismic site effects on the dynamic response of the Acquasanta bridge. A fully coupled 3D soil-structure model was designed: The grid is characterized by a “subvertical fault” between calcareous schists and serpentine rocks. This is in accordance with available data, even if further investigations in future should identify more in detail the tectonic structure of the area. The geometry of weathered materials overlaying the calcareous schists on the Ovada side has been assumed according to available information. The dimension of hexahedral elements ranges some tens of centimeters to about 1000 m. With such a model, the problem can be handled in its 3D complexity and we can exam-

ine the following aspects that are usually analyzed under restrictive and simplified assumptions: (i) soil-structure interaction, (ii) topographic amplification, (iii) soft soil amplification (caused by the superficial alluvium deposit shown in cyan), (iv) subvertical fault (red line) between the schists, on the Ovada side, and serpentine rock, on the Genoa side. For excitation a shear plane wave ( $x$ -direction) was used (Ricker wavelet,  $f_{max} = 3$  Hz,  $t_0 = 1.0$  s, and amplitude = 1 mm) propagating vertically from the bottom (red elements in Fig. 8).

In Fig. 9 we present some snapshots of the modulus of the displacement vector and the magnified deformed shape of the bridge. It is worth to note that at  $T = 2$  s the motion of the bridge is almost in-plane (direction  $x$ ), while at  $T = 4$  s is clearly evident how the coupling between the in-plane and out-plane ( $y$ -direction) motion starts to be important.

The study of the soil-structure interaction problem could be easily enhanced (i) improving the input excitation of the model here presented and (ii) taking into ac-

count complex constitutive behavior both from the soil and the structure side. The former is already available in GeoELSE thanks to the recent implementation [41,93] of the domain reduction method (DRM), a methodology that divides the original problem into two simpler ones [4,119], to overcome the problem of multiple physical scales that is created by a seismic source located some kilometers away from the structure with typical element size of the order of meters and located over a relatively small area (less than 1 km<sup>2</sup>) on soft deposit. The latter still needs to be improved because of the lack of a complete tool capable to handle in 3D non linear soil behavior, non-linear structural behavior and the presence of the water, that play a crucial role in the failure of buildings. Partial response to this problem can be found in the recent work of Bonilla et al. [5] and in the visco-plastic rheology recently introduced in GeoELSE [30].

### 3D Wave Propagation on Tetrahedral Grids: Application to Volcanology

As indicated above, the simulation of a complete, highly accurate wave field in realistic media with complex geometry is still a great challenge. Therefore, in the last years a new, highly flexible and powerful simulation method has been developed that combines the Discontinuous Galerkin (DG) Method with a time integration method using Arbitrary high order DERivatives (ADER) of the approximation polynomials. The unique property of this numerical scheme is, that it achieves arbitrarily high approximation order for the solution of the governing seismic wave equation in space and time on structured and unstructured meshes in two and three space dimensions.

Originally, this new ADER-DG approach [32,35] was introduced for general linear hyperbolic equation systems with constant coefficients or for linear systems with variable coefficients in conservative form. Then, the extension to non-conservative systems with variable coefficients and source terms and its particular application to the simulation of seismic waves on unstructured triangular meshes in two space dimensions was presented [70]. And finally, the further extension of this approach to three-dimensional tetrahedral meshes has been achieved [33]. Furthermore, the accurate treatment of viscoelastic attenuation, anisotropy and poroelasticity has been included to handle more complex rheologies [28,29,71]. The governing system of the three-dimensional seismic wave equations is hereby formulated in velocity-stress and leads to the hyperbolic system of the form

$$\frac{\partial \mathbf{Q}_p}{\partial t} + A_{pq} \frac{\partial \mathbf{Q}_q}{\partial \xi} + B_{pq} \frac{\partial \mathbf{Q}_q}{\partial \eta} + C_{pq} \frac{\partial \mathbf{Q}_q}{\partial \zeta} = S_p, \quad (6)$$

where the vector  $\mathbf{Q}$  of unknowns contains the six stress and the three velocity components and  $S$  is the source term. The Jacobian matrices  $A$ ,  $B$  and  $C$  include the material values as explained in detail in [33,70].

### The ADER-DG Method: Basic Concepts

The ADER-DG method is based on the combination of the ADER time integration approach [113], originally developed in the finite volume (FV) framework [96,97,111] and the Discontinuous Galerkin finite element method [18,19,20,21,22,23,91]. As described in detail in [33] in the ADER-DG approach the solution is approximated inside each tetrahedron by a linear combination of space-dependent polynomial basis functions and time-dependent degrees of freedom as expressed through

$$(\mathbf{Q}_h)_p(\xi, \eta, \zeta, t) = \hat{\mathbf{Q}}_{pl}(t) \Phi_l(\xi, \eta, \zeta), \quad (7)$$

where the basis functions  $\Phi_l$  form an orthogonal basis and are defined on the canonical reference tetrahedron. The unknown solution inside each element is then approximated by a polynomial, whose coefficients – the degrees of freedom  $\hat{\mathbf{Q}}_{pl}$  – are advanced in time. Hereby, the solution can be discontinuous across the element interfaces, which allows the incorporation of the well-established ideas of numerical flux functions from the finite volume framework [75,112]. To define a suitable flux over the element surfaces, so-called Generalized Riemann Problems (GRP) are solved at the element interfaces. The GRP solution provides simultaneously a numerical flux function as well as a time-integration method. The main idea is a Taylor expansion in time in which all time derivatives are replaced by space derivatives using the so-called Cauchy–Kovalevski procedure which makes recursive use of the governing differential Eq. (6). The numerical solution of Eq. (6) can thus be advanced by one time step without intermediate stages as typical e. g. for classical Runge–Kutta time stepping schemes. Due to the ADER time integration technique the same approximation order in space and time is achieved automatically. Furthermore, the projection of the elements in physical space onto a canonical reference element allows for an efficient implementation, as many computations of three-dimensional integrals can be carried out analytically beforehand. Based on a numerical convergence analysis this new scheme provides arbitrary high order accuracy on unstructured meshes. Moreover, due to the choice of the basis functions in Eq. (7) for the piecewise polynomial approximation [23], the ADER-DG method shows even spectral convergence.

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 10

Tetrahedral mesh for the model of the volcano Merapi. The zone of interest, such as the free surface topography and the volcano's interior are discretized by a fine mesh, whereas the spatial mesh is gradually coarsened towards the model boundaries

### Grid Generation: Unstructured Triangulations and Tetrahedralization

Both tetrahedral and hexahedral elements are effectively used to discretize three-dimensional computational domains and model wave propagation with finite element type methods. Tetrahedra can be the right choice because of the robustness when meshing any general shape. Hexahedra can be the element of choice due to their ability to provide more efficiency and accuracy in the computational process. Furthermore, techniques for automatic mesh generation, gradual mesh refinement and coarsening are generally much more robust for tetrahedral meshes in comparison to hexahedral meshes. Straightforward tetrahedral refinement schemes, based on longest-edge division, as well as the extension to adaptive refinement or coarsening procedures of a refined mesh exist [3,12]. In addition, parallel strategies for refinement and coarsening of tetrahedral meshes have been developed [27].

Less attention has been given to the modification of hexahedral meshes. Methods using iterative octrees have been proposed [74,95], but these methods often result in nonconformal elements that cannot be accommodated by some solvers. Lately also conformal refinement and coarsening strategies for hexahedral meshes have been proposed [2]. Other techniques insert non-hexahedral elements that result in hybrid meshes that need special solvers that can handle different mesh topologies. Commonly, the geometrical problems in geosciences arise through rough surface topography, as shown for the Merapi volcano in Fig. 10, and internal material boundaries of complex shape that lead to wedges and overturned or discontinuous surfaces due to folding and faulting. However, once the geometry of the problem is defined by the help of modern computer aided design (CAD) software,

the meshing process using tetrahedral elements is automatic and stable. After the mesh generation process, the mesh vertices, the connectivity matrix and particular information about boundary surfaces are typically imported to a solver.

The computational possibilities and algorithmic flexibility of a particular solver using the ADER-DG approach for tetrahedral meshes are presented in the following.

### Local Accuracy: $p$ -Adaptation

In many large scale applications the computational domain is much larger than the particular zone of interest. Often such an enlarged domain is chosen to avoid effects from the boundaries that can pollute the seismic wave field with possible, spurious reflections. Therefore, a greater number of elements has to be used to discretize the domain describing the entire model. However, in most cases the high order accuracy is only required in a restricted area of the computational domain and it is desirable to choose the accuracy that locally varies in space. This means, that it must be possible to vary the degree  $p$  of the approximation polynomials locally from one element to the other [36]. As the ADER-DG method uses a hierarchical order of the basis functions to construct the approximation polynomials, the corresponding polynomial coefficients, i. e. the degrees of freedom, for a lower order polynomial are always a subset of those of a higher-order one. Therefore, the computation of fluxes between elements of different approximation orders can be carried out by using only the necessary part of the flux matrices.

Furthermore, the direct coupling of the time and space accuracy via the ADER approach automatically leads to a local adaptation also in time accuracy, which often is referred to as  $p_t$ -adaptivity. In general, the distribution of the

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 11

The local degree  $p$  of the approximation polynomial depends on the insphere radius of each tetrahedral element and is given in color code. Close to the surface topography an approximation polynomial of degree  $p = 5$  (blue) is used, whereas in depth the degree is reduced to  $p = 4$  (green) and  $p = 3$  (yellow)

degree  $p$  might be connected to the mesh size  $h$ , i. e. the radius of the inscribed sphere of a tetrahedral element. In particular, the local degree  $p$  can be coupled to the mesh size  $h$  via the relations

$$p = p_{\min} + (p_{\max} - p_{\min}) \left( \frac{h - h_{\min}}{h_{\max} - h_{\min}} \right)^r, \quad (8)$$

$$p = p_{\max} - (p_{\max} - p_{\min}) \left( \frac{h - h_{\min}}{h_{\max} - h_{\min}} \right)^r, \quad (9)$$

where the choice of the power  $r$  determines the shape of the  $p$ -distribution. Note, that depending on the choice of the first term and the sign the degree  $p$  can increase as in Eq. (8) or decrease as in Eq. (9) with increasing  $h$ , starting from a minimum degree  $p_{\min}$  up to a maximum degree  $p_{\max}$ . This provides additional flexibility for the distribution of  $p$  inside the computational domain. An example of a  $p$ -distribution for the volcano Merapi is given in Fig. 11.

Here the idea is to resolve the slowly propagating surface waves with high accuracy, whereas the waves propagating towards the absorbing model boundaries pass through a zone of low spatial resolution. This approach leads to numerical damping due to an amplitude decay that reduces possible boundary reflections. Furthermore, the computational cost is reduced significantly due to the strongly reduced number of total degrees of freedom in the model.

### Local Time Stepping: $\Delta t$ -Adaptation

Geometrically complex computational domains or spatial resolution requirements often lead to meshes with small or even degenerate elements. Therefore, the time step for explicit numerical schemes is restricted by the ratio of the size  $h$  of the smallest element and the corresponding maximum wave speed in this element. For global time stepping schemes all elements are updated with this extremely restrictive time step length leading to a large amount of iterations. With the ADER-DG approach, time accurate local time stepping can be used, such that each element is updated by its own, optimal time step [36]. Local time-stepping was used in combination with the finite-difference method [42,106].

An element can be updated to the next time level if its actual time level and its local time step  $\Delta t$  fulfill the following condition with respect to all neighboring tetrahedra  $n$ :

$$t + \Delta t \leq \min(t_n + \Delta t_n). \quad (10)$$

Figure 12 is visualizing the evolution of four elements (I, II, III and IV) in time using the suggested local time stepping scheme. A loop cycles over all elements and checks for each element, if condition (10) is fulfilled. At the initial state all elements are at the same time level, however, element II and IV fulfill condition (10) and therefore can be updated. In the next cycle, these elements are already advanced in time (grey shaded) in cycle 1. Now elements I and IV fulfill condition (10) and can be updated to their next local time level in cycle 2. This procedure continues and it is obvious, that the small element IV has to be updated more frequently than the others. A synchronization to a common global time level is only necessary, when data output at a particular time level is required as shown in Fig. 12.

Information exchange between elements across interfaces appears when numerical fluxes are calculated. These fluxes depend on the length of the local time interval over which a flux is integrated and the corresponding element is evolved in time. Therefore, when the update criterion (10) is fulfilled for an element, the flux between the element itself and its neighbor  $n$  has to be computed over the local time interval:

$$\tau_n = [\max(t, t_n), \min(t + \Delta t, t_n + \Delta t_n)]. \quad (11)$$

As example, the element III fulfills the update criterion (10) in cycle 5 (see Fig. 12). Therefore, when computing the fluxes only the remaining part of the flux given by the intervals in Eq. (11) has to be calculated. The other flux contribution was already computed by the neighbors II and IV during their previous local updates. These flux

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 12

Visualization of the local time stepping scheme. The actual local time level  $t$  is at the top of the *gray shaded* area with numbers indicating the cycle, in which the update was done. *Dotted lines* indicate the local time step length  $\Delta t$  with which an element is updated

contributions have been accumulated and were stored into a memory variable and therefore just have to be added.

Note that e. g. element IV reaches the output time after 10 cycles and 9 local updates, which for a global time stepping scheme would require  $9 \times 4 = 36$  updates for the all four elements. With the proposed local time stepping scheme only 16 updates are necessary to reach the same output time with all elements as indicated by the final number of grey shaded space time elements in Fig. 12.

Comparing these numbers leads to a speedup factor of 2.25. For strongly heterogeneous models and local time step lengths this factor can become even more pronounced. However, due to the asynchronous update of elements that might be spatially very close to each other the mesh partitioning for parallel computations becomes an important and difficult issue. Achieving a satisfying load balancing is a non-trivial task and still poses some unresolved problems as explained in the following.

### Mesh Partitioning and Load Balancing

For large scale applications it is essential to design a parallel code that can be run on massively parallel supercomputing facilities. Therefore, the load balancing is an important issue to use the available computational resources efficiently. For global time stepping schemes without  $p$ -adaptation standard mesh partitioning as done e. g. by METIS [60] is sufficient to get satisfying load balancing. The unstructured tetrahedral mesh is partitioned into subdomains that contain an equal or at least very similar number of elements as shown in Fig. 13. Therefore, each processor has to carry out a similar amount of calculations. However, if  $p$ -adaptation is applied, the partitioning is more sophisticated as one subdomain might have many elements of high order polynomials whereas another might have the same number of elements but with lower order polynomials. Therefore, the parallel efficiency is re-

stricted by the processor with the highest work load. However, this problem can usually be solved by weighted partitioning algorithms, e. g. METIS.

In the case of local time stepping, mesh partitioning is becoming a much more difficult task. One solution is to divide the computational domain into a number of zones, that usually contain a geometrical body or a geological zone that typically is meshed individually with a particular mesh spacing  $h$  and contains a dominant polynomial order. Then each of these zones is partitioned separately into subdomains of approximately equal numbers of elements. Then each processor receives a subdomain of each zone, which requires a similar amount of computational work as shown in Fig. 13. In particular, the equal distribution of tetrahedra with different sizes is essential in combination with the local time stepping technique. Only if each processor receives subdomains with a similar amount of small and large elements, the work load is balanced. The large elements have to be updated less frequently than the smaller elements and therefore are computationally cheaper. Note, that the separately partitioned and afterwards merged zones lead to non-connected subdomains for each processor (see Fig. 13). This increases the number of element surfaces between subdomains of different processors and therefore increases the communication required. However, communication is typically low as the degrees of freedom have to be exchanged only once per time step and only for tetrahedra that have an interface at the boundary between subdomains. Therefore, the improvements due to the new load balancing approach are dominant and outweigh the increase in communication.

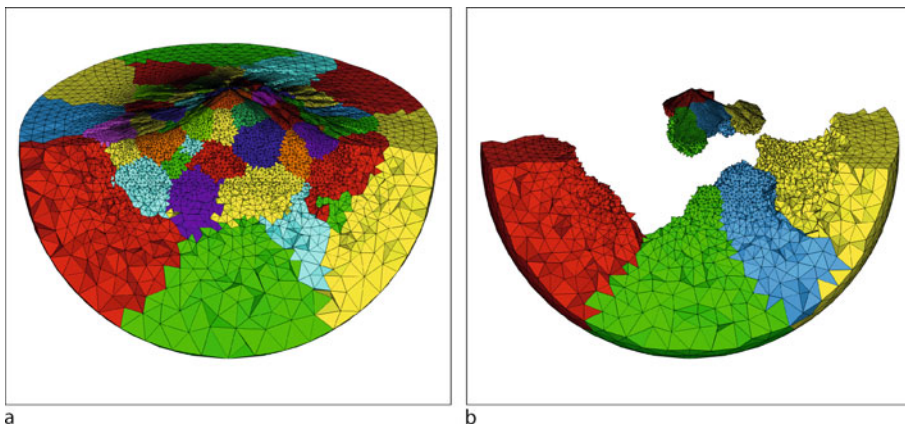

However, care has to be taken as the distribution of the polynomial degree  $p$  or the seismic velocity structure

might influence the efficiency of this grouped partitioning technique. A profound and thorough mesh partitioning method is still a pending task as the combination of local time stepping and  $p$ -adaptivity requires a new weighting strategy of the computational cost for each tetrahedral element considering also the asynchronous element update. The automatic partitioning of unstructured meshes with such heterogeneous properties together with the constraint of keeping the subdomains as compact as possible to avoid further increase of communication is still subject to future work.

In Fig. 13 an example of a grouped partition of the tetrahedral mesh is shown for 4 processors. Two non-connected subdomains indicated by the same color are assigned to each processor including small – and therefore computationally expensive – tetrahedra that are updated frequently due to their small time step, and much larger elements that typically are cheap due to their large time step. This way, the work load often is balanced sufficiently well over the different processors.

#### Relevance of High Performance Computing: Application to Merapi Volcano

In recent years the development of the ADER-DG algorithm including the high order numerical approximation in space and time, the mesh generation, mesh adaptation, parameterization, and data visualization created the basis of an efficient and highly accurate seismic simulation tool. Realistic large scale applications and their specific requirements will further guide these developments. On the other hand, the study and incorporation of geophysical processes that govern seismic wave propagation insures,

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 13

Standard partitioning of the computational domain (left) and an example of 4 subdomains grouped together for more efficient local time stepping

that the simulation technology matches the needs and addresses latest challenges in modern computational seismology. Hereby, the accurate modeling of different source mechanisms as well as the correct treatment of realistic material properties like anelasticity, viscoplasticity, porosity and highly heterogeneous, scattering media will play an important role.

However, only the combination of this state-of-the-art simulation technology with the most powerful supercomputing facilities actually available can provide excellent conditions to achieve scientific progress for realistic, large scale applications. This combination of modern technologies will substantially contribute to resolve current problems, not only in numerical seismology, but will also influence other disciplines. The phenomenon of acoustic, elastic or seismic wave propagation is encountered in many different fields. Beginning with the classical geophysical sciences seismology, oceanography, and volcanology such waves also appear in environmental geophysics, atmospheric physics, fluid dynamics, exploration geophysics, aerospace engineering or even medicine.

With the rapid development of modern computer technology and the development of new highly accurate simulation algorithms computer modeling just started to herald a new era in many applied sciences. The 3D wave propagation simulations in realistic media require a substantial amount of computation time even on large parallel computers. Extremely powerful national supercomputers already allow us to run simulations with unrivaled accuracy and resolution. However, using the extremely high accuracy and flexibility of new simulation methods on such massively parallel machines the professional support of experts in supercomputing is absolutely essential. Only professional porting, specific CPU-time and storage optimizations of current software with respect to continuously changing compilers, operating systems, hardware ar-

chitectures or simply personnel, will ensure the lifetime of new simulation technologies accompanied by ongoing improvements and further developments. Additionally, the expertise and support in the visualization of scientific results using technologies of Virtual Reality for full 3D models not only enhances the value of simulation results but will support data interpretation and awake great interest in the new technology within a wide research community.

As an example, volcano monitoring plays an increasingly important role in hazard estimation in many densely populated areas in the world. Highly accurate computer modeling today is a key issue to understand the processes and driving forces that can lead to dome building, eruptions or pyroclastic flows. However, data of seismic observations at volcanoes are often very difficult to interpret. Inverting for the source mechanism, i. e. seismic moment tensor inversion, or just locating an exact source position is often impossible due to the strongly scattered wave field caused by an extremely heterogeneous material distribution inside the volcano. Furthermore, the rough topography alone can affect the wave field by its strongly scattering properties as shown in Fig. 14.

Therefore, it is fundamental to understand the effects of topography and scattering media and their influence on the seismic wave field. A systematic study of a large number of scenarios computed by highly accurate simulation methods to provide reliable synthetic data sets is necessary to test the capabilities of currently used inversion tools. Slight changes in parameters like the source position, the source mechanism or the elastic and geometric properties of the medium can then reveal the limits of such tools and provide more precise bounds of their applicability in volcano seismology.

Finally, the implementation of the ADER-DG method is still much more expensive than other state-of-the-art implementations of existing methods. However, a fair

Seismic Wave Propagation in Media with Complex Geometries, Simulation of, Figure 14

Snapshots of the seismic wave field after an explosive event close to the summit of Merapi volcano. The free surface topography introduces strong scattering of the waves making it extremely difficult to invert for the seismic source mechanism or the exact source location

comparison between accuracy and computational cost is still a pending task. The main reason for the CPU-time difference is the much larger number of tetrahedral elements than hexahedra that have to be used to cover the same volume. Furthermore, due to the choice of the basis functions, the flux computations are expensive, as the matrix-matrix multiplications involved are not sparse.

However, the ADER-DG method is currently implemented on hexahedral meshes to make fair comparisons possible. Preliminary tests show, that the change of mesh topology from tetrahedra to hexahedra significantly reduces the computational cost. However, final results are subject to future investigations.

### Discussion and Future Directions

As indicated in the introduction and highlighted in the previous sections, computational tools for wave propagation problems are getting increasingly sophisticated to meet the needs of current scientific problems. We are far away from simple finite-difference time schemes that are solving problems on regular grids on serial computers in which case the particular programming approach did not affect dramatically the overall performance. Today, competitive algorithms are results of years of partly highly professional coding. Implementations on high-performance computing hardware requires in-depth knowledge of parallel algorithms, profiling, and many technical aspects of modern computations. To make complex scientific software available to other researchers requires implementation and testing on many different (parallel) platforms. This may involve parallelization using different programming paradigms (e. g., the combination of OpenMP and MPI on nodes of shared memory machines), and interoperability on heterogeneous computational GRIDs.

This has dramatic consequences particularly for young researchers in the Earth Sciences who want to use advanced computational tools to model observations. While in the early days a finite-difference type algorithm could be understood, coded, implemented and tested in a few weeks, this is no longer possible. In addition, standard curricula do not offer training in computational methods allowing them to efficiently write and test codes. This suggests that at least for some, well-defined computational problems verified and professionally engineered scientific software solutions should be provided to the community and also professionally extended and maintained in close collaboration with scientists. In seismology we are in a quite fortunate situation. In contrast to many other fields of physical sciences, our constitutive relations (e. g., stress-strain) are fairly well understood, and – as indicated

in this paper – numerical solutions for 3D problems and their implementation on parallel hardware are well advanced. Another argument for stable tested “community”-codes for wave propagation is the fact that advancement in many scientific problems (e. g., imaging the Earth’s interior, quantifying earthquake-induced shaking hazard) relies on zillions of forward modeling runs with only slight variations of the internal velocity models.

As far as technical developments are concerned, the efficient initialization of complex 3D models on computational grids is still a great challenge. Realistic models may be composed of complex topography, families of overlapping fault surfaces, discontinuous interfaces, and varying rheologies (e. g., elastic, anisotropic, viscoelastic, viscoplastic, porous). This may require the combination of tetrahedral and hexahedral grid in models with strongly varying degree of complexity. Ideally, standards for Earth models (and synthetic data) formats should be established by the communities that allow easy exchange and multiple use of models with different simulation tools (e. g., wave propagation, deformation, earthquake rupture). In addition, the rapid developments towards PetaFlop computing opens new questions about the scalability and efficient parallelization of current and future algorithms.

As the forward problem of wave propagation is at the core of the seismic imaging problem for both source and Earth’s structure, in the near future we will see the incorporation of 3D simulation technology into the imaging process. Provided that the background seismic velocity models are fairly well known (e. g., reservoirs, global Earth, sedimentary basins), adjoint methods provide a powerful analytical tool to (1) relate model deficiencies to misfit in observations and (2) quantify the sensitivities to specific aspects of the observations (e. g., [100,104,105]). As the core of the adjoint calculations is the seismic forward problem, the challenge is the actual application to real data and the appropriate parametrizations of the model and the data that optimize the data fitting process.

In summary, while we look back at (and forward to) exciting developments in computational seismology, a paradigm shift in the conception of one of the central tools of seismology – the calculation of 3D synthetic seismograms – is necessary. To extract a maximum amount of information from our high-quality observations scientists should have access to high-quality simulation tools. It is time to accept that “*software is infrastructure*” and provide the means to professionally develop and maintain community codes and model libraries at least for basic Earth science problems and specific focus regions. Developments are one the way along those lines in the SPICE project (Seismic Wave Propagation and Imaging in Complex Me-

dia, a European Network [101]), the Southern California Earthquake Center (SCEC [94]) and the CIG Project (Computational infrastructure in geodynamics [17]).

### Acknowledgments

We would like to acknowledge partial support towards this research from: The European Human Resources and Mobility Program (SPICE-Network), the German Research Foundation (Emmy Noether-Programme), the Bavarian Government (KOHNIWIHR, graduate college THESIS, BaCaTec), and MunichRe. We would also like to thank J. Tromp supporting MS's visit to CalTech. We also thank two anonymous reviewers for constructive comments on the manuscript.

### Glossary

**Attenuation factor  $Q^{-1}$**  A measure of attenuation characteristics of a medium caused by intrinsic absorption and scattering loss. The former means the transfer of vibration energy into heat and the latter means the transfer of vibration energy from the direct wave to coda waves caused by scattering due to medium heterogeneity.

**Coda waves** Wave trains that follow the arrival of the direct S-wave phase are called S-coda waves or simply coda waves. Coda waves are interpreted as a superposition of S waves scattered by distributed heterogeneities. Wave trains between direct P and S wave arrivals are called P-coda waves.

**Coda attenuation factor  $Q_C^{-1}$**  This parameter characterizes the amplitude decay of S coda of a local earthquake with the lapse time increasing based on the S-to-S single scattering. The coda duration shortens for a larger coda attenuation factor.

**Envelope broadening** The source duration time of a microearthquake is short; however, the apparent duration time of the S-wave seismogram increases with the travel distance increasing because of diffraction and scattering by medium heterogeneities. This phenomenon is called envelope broadening.

**Radiative transfer theory** A phenomenological theory that describes scattering process of wave energy in a scattering medium on the basis of causality, geomet-

rical spreading and the energy conservation. It neglects the interference of waves but focuses on the intensity only. This theory admits various types of scattering patterns. It is often applied to model the energy propagation of high-frequency seismic-waves in heterogeneous Earth media.

**Random media** A mathematical model for media whose parameters are described by random functions of space coordinates. The stochastic properties of the ensemble of random media are characterized by their autocorrelation function or the power spectral density function.

**Scattering coefficient  $g$**  A measure of the scattering power in a unit solid angle at a certain direction by a unit volume of heterogeneous media for the incidence of unit energy flux density. The average of  $g$  over the solid angle gives the total scattering coefficient  $g_0$ , of which the reciprocal gives the mean free path. This quantity characterizes the coda excitation and the scattering loss in the heterogeneous media.

### Definition of the Subject

The structure of the solid Earth was extensively studied by using seismic waves such as travel time analysis based on Snell's law, dispersion analysis of surface waves, and spectral analysis of free oscillation, where the notion of a horizontally stratified structure or a spherical shell structure prevailed among the geophysical community. This means the acceptance of the dominance of gravity in geodynamic process. Velocity tomography revealed that the solid Earth structure is three-dimensionally inhomogeneous with various ranges of scales; however, the resolution of velocity tomography is much coarser than the wavelength of seismic waves. In 1970s, the existence of distributed inhomogeneities having the order of the wavelength of seismic waves was recognized from the observation of coda waves of local earthquakes, which are long-lasting wave trains following the direct S-wave arrival in high-frequency seismograms. Here, we use "high-frequency" for frequency higher than about 1 Hz. The long duration time of coda waves can be interpreted as a direct evidence of wide-angle scattering caused by distributed small-scale heterogeneities since the source duration time is generally very short. S-wave seismograms of microearthquakes show broadened envelopes with travel distance increasing. This envelope broadening phenomenon is also an evidence of scattering around the forward direction due to random velocity inhomogeneities.

Since then, focusing on the frequency dependence of seismogram envelopes, geophysicists have extensively

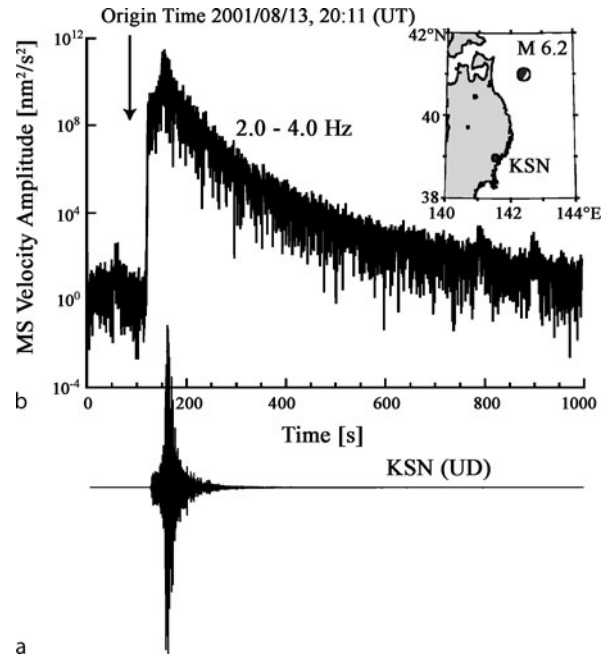

studied the scattering process of high-frequency seismic waves in relation to the spectral structure of velocity inhomogeneities, where the statistical characterization of the medium inhomogeneity is inevitable. The radiative transfer theory and the stochastic Markov approximation have been developed as mathematical tools for the analyzes of seismogram envelopes. The strength of scattering and/or the spectral structure of random inhomogeneity have been measured in various regions of the solid Earth. The scattering approach is found to be also useful for detecting temporal changes in the crustal medium associated with earthquake occurrences. Thus, scattering of high-frequency seismic waves in the heterogeneous Earth medium is important for understanding the physical structure and the geodynamic process reflecting the evolution of the solid Earth.

## Introduction

### Coda Waves

The high-frequency seismogram of a local earthquake has a long tail after the direct S-coda arrival. The tail portion of seismogram is called “S-coda waves” or simply “coda”. As an example, Fig. 1a and b show the raw seismogram and the band-pass filtered mean square (MS) trace of an earthquake of magnitude (M) 6.1, respectively. We note that the mean square wave envelope, which is the running mean of the squared trace with characteristic time of a few times the center period, is proportional to the time trace of the wave energy density. The coda wave oscillation lasts more than several hundreds of seconds. The duration of coda waves measured from the P-wave onset until when the coda amplitude decreases to the microseism’s level has been used as a quick measure of the earthquake magnitude from a single station observation since the 1960s. Having a motivation to extract the source spectrum of a large earthquake from clipped seismograms, Aki [1] first studied the characteristics of coda waves as scattered waves. Coda envelopes of a local earthquake have a smoothly decaying common curve with lapse time increasing irrespective of epicentral distances and the source radiation pattern. Aki and Chouet [4] interpreted coda waves as single back-scattered S-waves due to heterogeneities randomly distributed in the lithosphere. Their model based on the radar equation for the same location of a source and a receiver can be written as follows.

Point-like isotropic scatterers characterized by total scattering cross-section  $\sigma_0$  are randomly and homogeneously distributed with number density  $n$  in a 3-D medium with background wave velocity  $V_0$ . The scattering power per unit volume is characterized by the total scatter-

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 1  
**a** Seismogram of a local earthquake of M 6.2 in northeastern Honshu, Japan recorded by F-net, NIED. **b** Bandpass-filtered MS envelope (Courtesy of T. Maeda)

ing coefficient  $g_0 = n\sigma_0$ , of which the reciprocal gives the mean free path. When the total wave energy  $W$  is impulsively radiated from a point source at time  $t = 0$ , the wave energy density of singly back-scattered waves at the source location is written as

$$E^{\text{SB}}(t) \approx \frac{Wg_0}{2\pi V_0^2 t^2} e^{-Q_C^{-1} 2\pi ft} \quad (1)$$

since the interference of scattered waves can be neglected because of the random distribution of scatterers. The inverse square of lapse time means geometrical spreading in a 3-D space. Here, an exponential damping term with coda attenuation factor  $Q_C^{-1}$  is introduced to represent phenomenological attenuation effect. This simple formula has been widely used for measurements of  $g_0$  and  $Q_C^{-1}$  for S-waves in the world since the 1980s. Reported  $g_0$ -values are of the order of  $0.01 \text{ km}^{-1}$  for 1–30 Hz and  $Q_C^{-1}$  values are about  $10^{-2}$  at 1 Hz and decrease to about  $10^{-3}$  at 20 Hz in the lithosphere [74].

### Envelope Broadening of S-Seismogram

There is another evidence of scattering due to random inhomogeneity in high-frequency seismograms. Observed S-seismograms of a microearthquake have broadened en-

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 2  
Envelope broadening shown in horizontal component seismograms of a microearthquake with M 4.0 in Japan recorded by Hi-net, NIED, where the abscissa is reduced travel time with move-out velocity 7 km/s (Courtesy of T. Takahashi)

velopes around their peaks after the direct arrivals. As shown by an example in Fig. 2, the apparent duration time of the S-seismogram just after the direct S-arrival increases with increasing travel distance. It is more than ten seconds at distances larger than 100 km, where the source duration time is less than one second for an earthquake of M 4.0. Sato [70] called this phenomenon observed in an island arc as “envelope broadening”, and Atkinson [6] reported similar phenomenon in a continent. For P-waves of teleseismic events, broadening of the vertical component envelope [35] and the excitation in the transverse component amplitude [52] have been used as a measure of lithospheric heterogeneity. These phenomena can be interpreted by multiple scattering within a narrow angle around the global ray direction due to random velocity inhomogeneities. When the wavelength is much shorter than the characteristic scale of the random velocity inhomogeneity, the scattering process of waves can be repre-

sented by successive ray bending processes, where scattering angles are statistically controlled by the spectrum of random velocity inhomogeneity. At a given distance from the source, a small number of rays with large scattering angles arrive long after the direct ray.

## Radiative Transfer Theory for a Scattering Medium

### Radiative Transfer Integral Equation for the Isotropic Scattering Process

Disregarding wave interference and focusing on wave power, the radiative transfer theory [8] treats the propagation of wave energy in a scattering medium. Wu [85] first introduced the radiative transfer theory for the stationary state in the synthesis of seismogram envelopes. The non-stationary multiple isotropic scattering process in 1-D was solved by Hemmer [24] and that in 2-D was solved by Shang and Gao [77]. Later, Zeng et al. [92] formulated the time-dependent multiple isotropic scattering process in 3-D as an extension of the single backscattering model [4] as follows.

In a 3-D scattering medium characterized by background velocity  $V_0$  and total scattering coefficient  $g_0$ , when the total wave energy  $W$  is impulsively radiated isotropically from a source at the origin, the multiple isotropic scattering process is written by the following integral equation for energy density:

$$E(\mathbf{x}, t) = WG_E(\mathbf{x}, t) + g_0 V_0 \cdot \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} G_E(\mathbf{x} - \mathbf{x}', t - t') E(\mathbf{x}', t') d\mathbf{x}' dt', \quad (2)$$

where the convolution integral in the second term means the propagation of energy from the last scattering point  $\mathbf{x}'$  to a receiver at  $\mathbf{x}$ . The first term is the ballistic term that means the direct propagation of energy from the source with scattering loss,  $G_E(\mathbf{x}, t) = \delta(t - r/V_0) \exp(-g_0 V_0 t) / (4\pi V_0 r^2)$ , where  $r = |\mathbf{x}|$ . The solution is written as [92]

$$E(\mathbf{x}, t) = WG_E(\mathbf{x}, t) + \frac{Wg_0 e^{-g_0 V_0 t}}{4\pi r^2} \frac{r}{V_0 t} \cdot \ln \left[ \frac{V_0 t + r}{V_0 t - r} \right] H \left( t - \frac{r}{V_0} \right) + Wg_0^2 V_0^2 \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} d\omega dk e^{-i\omega t - ikr} \cdot \frac{ik}{2\pi r} \frac{\bar{G}_E(-k, -i\omega)^3}{1 - g_0 V_0 \bar{G}_E(-k, -i\omega)}, \quad (3)$$

where  $\bar{G}_E(k, s) = (1/kV_0) \tan^{-1} kV_0/(s + g_0V_0)$  is the Fourier–Laplace transform of  $G_E$  with respect to coordinate and time, respectively. The second term represents the single scattering process (see Sato [67]), which has a logarithmic divergence at the direct arrival  $t = r/V_0$  and decreases according to the inverse square of lapse time at long lapse times as  $Wg_0/(2\pi V_0^2 t^2)$ . The third term representing multiple scattering converges to a diffusion solution with lapse time increasing as

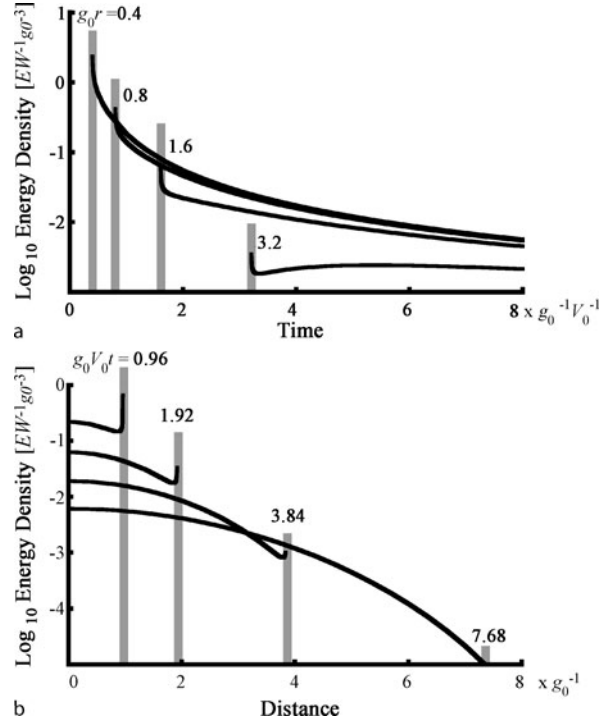

$$E^{\text{Dif.}}(\mathbf{x}, t) = W \left( \frac{3g_0}{4\pi V_0 t} \right)^{3/2} e^{-\frac{3g_0 r^2}{4V_0 t}} H(t), \quad (4)$$

where the factor  $V_0/(3g_0)$  is the diffusivity. Later, Paaschens [54] proposed an approximation as

$$E^{\text{Paa.}}(\mathbf{x}, t) \approx W G_E(\mathbf{x}, t) + \frac{W e^{-g_0 V_0 t}}{(4\pi V_0 t / (3g_0))^{3/2}} \cdot \left( 1 - \frac{r^2}{V_0^2 t^2} \right)^{\frac{1}{8}} M \left( g_0 V_0 t \left( 1 - \frac{r^2}{V_0^2 t^2} \right)^{\frac{3}{4}} \right) \cdot H \left( t - \frac{r}{V_0} \right), \quad (5)$$

where  $M(x) \approx e^x \sqrt{1 + 2.026/x}$ . The error of this approximation is of the order of 2% outside the ballistic peak and its tail for  $g_0 V_0 t < 6$  and  $2 < g_0 r < 4$ .

Figure 3 shows spatiotemporal variations in energy density in a scattering medium theoretically predicted by the approximation solution (5) for instantaneous spherical source radiation at the origin. Scattered energy density is shown by a black curve, where the ballistic term is shown by a vertical gray line. At a small distance from the source compared with the mean free path  $1/g_0$ , the energy density decreases rapidly after the direct arrival as predicted by the single scattering term; however, the decay rate becomes smaller due to multiple scattering according to the power of lapse time  $t^{-3/2}$  at long lapse times. At a long distance, for example at  $r = 3.2/g_0$ , the energy density has an additional diffusion peak. The spatial distribution of scattered energy density is uniform around the source at a short lapse time compared with the mean free time  $1/g_0 V_0$ ; however, it converges to a Gaussian curve at a long lapse time as theoretically predicted by the diffusion solution (4), for example at  $t = 7.48/g_0 V_0$ . There is no violation of causality since no signal exists beyond the ballistic peak. The smooth spatial distribution of scattered energy density around the source location gives the physical basis of the coda normalization method for measure-

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 3 a Temporal change and b spatial variation of energy density in an isotropic-scattering medium for a point source radiation. Each black curve shows the scattering contribution predicted by the Paaschens approximation and each vertical gray line shows a ballistic term

ments of S-wave attenuation and site amplification factors (e. g. [3,56,89]).

Gusev and Abubakirov [21] and Hoshiba [27] numerically solved the radiative transfer equation for the isotropic scattering process by using the Monte Carlo method. Yoshimoto [88] numerically simulated envelopes in scattering media of which the background velocity decreases with depth. He found the concentration of scattered energy near the surface because of seismic ray bending.

Nonisotropic radiation from a source can be easily introduced in the radiative transfer equation. Sato et al. [75] analytically solved the case of double couple source radiation: the energy density theoretically predicted faithfully reflects the source radiation pattern near the direct arrival; however, the azimuthal dependence diminishes with increasing lapse time. It qualitatively agrees with the observed radiation pattern independence of coda amplitudes at long lapse times. Their solution has been used in the envelope inversion of strong motion records for the spatial distribution of high-frequency wave energy radiation from an earthquake fault (e. g. [47]).

### Measurements of Total Scattering Coefficient and Attenuation

For the practical application of the radiative transfer theory to observed seismograms, it is necessary to introduce intrinsic absorption  $Q_{\text{Int}}^{-1}$  by multiplying an exponential temporal decay factor  $\exp[-Q_{\text{Int}}^{-1}2\pi ft]$  to the resultant energy density. By using the solution (3) of the radiative transfer theory for the isotropic scattering model, total scattering coefficient  $g_0$  and intrinsic absorption factor  $Q_{\text{Int}}^{-1}$  of the S-wave have been measured. Reported  $g_0$  values in the lithosphere are of the order of  $10^{-2} \text{ km}^{-1}$  for frequencies from 1 to 30 Hz as plotted in Fig. 4.

From the observed lapse time dependence of  $Q_{\text{C}}^{-1}$ , Gusev [20] quantitatively explained the decrease of  $g_0$  with depth. Lee et al. [40] analyzed coda envelopes of regional earthquakes before and after the ScS arrival around 900s in lapse time from the origin time based on the numerically simulated envelopes for the PREM model, which is characterized by depth-dependent background velocity and total attenuation for S-waves. They reported lower  $g_0$  values in 4s and 10s period bands in the upper and lower mantle compared with those in the lithosphere as illustrated in Fig. 4.

Hoshiba et al. [28] and Fehler et al. [10] developed a method to measure simultaneously  $g_0$  and  $Q_{\text{Int}}^{-1}$  values for the S-wave from the whole S-envelope analysis based on the synthetic envelope derived from the radiative

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 4 Total scattering coefficient of S-waves in the Earth. Measurements in the mantle [40] are added to lithospheric inhomogeneity [74]

transfer theory. Their multiple lapse-time window analysis method has been widely used in the world. Estimated scattering loss  $g_0 V_0/\omega$  decreases with frequency; however, intrinsic absorption  $Q_{\text{Int}}^{-1}$  is rather insensitive to frequency. Estimated seismic albedo  $B \equiv g_0 V_0/(\omega Q_{\text{Int}}^{-1} + g_0 V_0)$ , the ratio of scattering loss to the total attenuation, of S-waves in the lithosphere widely distribute from 0.2 to 0.8 for 1–6 Hz, but they are limited between 0.2 and 0.5 for 6–20 Hz.

Total scattering cross-section and number density of scatterers appear jointly as the total scattering coefficient in theoretical models; however, Matsumoto [44] proposed a method to separate them from the temporal variation of the semblance coefficient of coda waves recorded by a seismic array. Analyzing data obtained in the aftershock area of the 2000 western Tottori earthquake, Japan, he estimated  $n = 0.03 \text{ km}^{-3}$  and  $g_0 = 0.001 \text{ km}^{-1}$  at 20 Hz.

It should be noted that lunar seismograms have coda durations exceeding one hour. Applying the diffusion model for the explanation of spindle-like envelopes of lunar-quakes, Dainty and Toksöz [9] estimated  $g_0$  to be as large as  $0.05\text{--}0.5 \text{ km}^{-1}$  at 0.45 Hz.

### Wave Envelopes in Random Media and Statistical Characterization

#### Statistical Characterization of Random Media

As revealed from tomography analyses (e. g. [93]), velocity structure is three-dimensionally inhomogeneous especially in the lithosphere. Well log data show typical samples of the shallow crust. Figure 5a shows well log data of P- and S-wave velocities and mass density obtained in Kyushu, Japan [80], where wave velocities and mass density are measured in a borehole by using ultrasonic waves and gamma rays, respectively. These well log data clearly show random fluctuation with short wavelengths. As a natural consequence, we imagine random inhomogeneities widely distributed in the solid Earth medium.

By using computer power, wave propagation in random media has been numerically studied extensively. Using finite difference simulations of waves in random media, Frankel and Clayton [14] first examined the relation between coda excitation and scattering loss and the spectrum of random inhomogeneity. On the basis of numerical simulations, Frankel and Wennerberg [15] proposed the energy flux model that has a uniform distribution of scattered energy behind the direct waves for the analysis of high-frequency seismogram envelopes. Using a boundary integral method for the simulation of waves in a medium containing many cavities, Yomogida and Benites [87] examined a relation between coda attenuation and the distribution of cavities.

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 5  
**a** Well log data at the YT-2 site, Kyushu, Japan. **b** Power spectral density function of the fractional fluctuation of P-wave velocity log. **c** Scattergram of P-wave velocity and mass density. Reproduced from [80]

There is an alternative approach to treat statistically randomly inhomogeneous media. The wave-velocity is written as  $V(\mathbf{x}) = V_0 \{1 + \xi(\mathbf{x})\}$ , where  $V_0$  is the average velocity and fractional fluctuation  $\xi(\mathbf{x})$  is a homogeneous and isotropic random function of space coordinate  $\mathbf{x}$ . We imagine an ensemble of random media  $\{\xi\}$ , which is statistically characterized by the autocorrelation function (ACF)  $R(\mathbf{x}) \equiv \langle \xi(\mathbf{x} + \mathbf{x}') \xi(\mathbf{x}') \rangle$ , where angular brackets mean the ensemble average. The MS fractional fluctuation  $\varepsilon^2 \equiv R(0)$  and the correlation distance  $a$  are key parameters. The Fourier transform of ACF gives the power spectral density function (PSDF)  $P$ . The PSDF of the P-wave velocity fractional fluctuation of well log data shows a power-law characteristic at large wavenumbers as illustrated in Fig. 5b. P-wave velocity and mass density show a good correlation as shown in Fig. 5c. The statistical view is useful for representing geological data, too (e. g. [18,26]).

### Scattering Coefficient Based on the Born Approximation

When the medium inhomogeneity is small  $|\xi| \ll 1$ , scalar wave  $\phi$  is governed by the following wave equation:

$$\left(\Delta - \frac{1}{V_0^2} \partial_t^2\right) \phi + \frac{2}{V_0^2} \xi(\mathbf{x}) \partial_t^2 \phi = 0. \quad (6)$$

Velocity inhomogeneity is supposed to localize in a volume around the origin, of which the dimension is chosen to be much larger than  $a$ . For the incidence of a plane wave of unit amplitude at angular frequency  $\omega$  as  $e^{i(k_0 \mathbf{e}_z x - \omega t)}$ , where  $\mathbf{e}_z$  is the unit vector to the  $z$  direction, we calculate the spherically outgoing scattered waves due to a localized inhomogeneity by using the Born approximation as  $\phi^1(\mathbf{x}, t) = -k_0^2 e^{i(k_0 r - \omega t)} \tilde{\xi}(k_0 \mathbf{e}_r - k_0 \mathbf{e}_z) / (2\pi r)$ , where the tilde means the Fourier transform with respect to coordinates in 3-D space and  $\mathbf{e}_r$  is a radial unit vector (e. g. [74]). According to Aki and Chouet [4], the scattering coefficient defined as the scattering power in a unit solid angle at certain direction by a unit volume of random inhomogeneous media for the incidence of unit energy flux density is statistically written by using its PSDF as

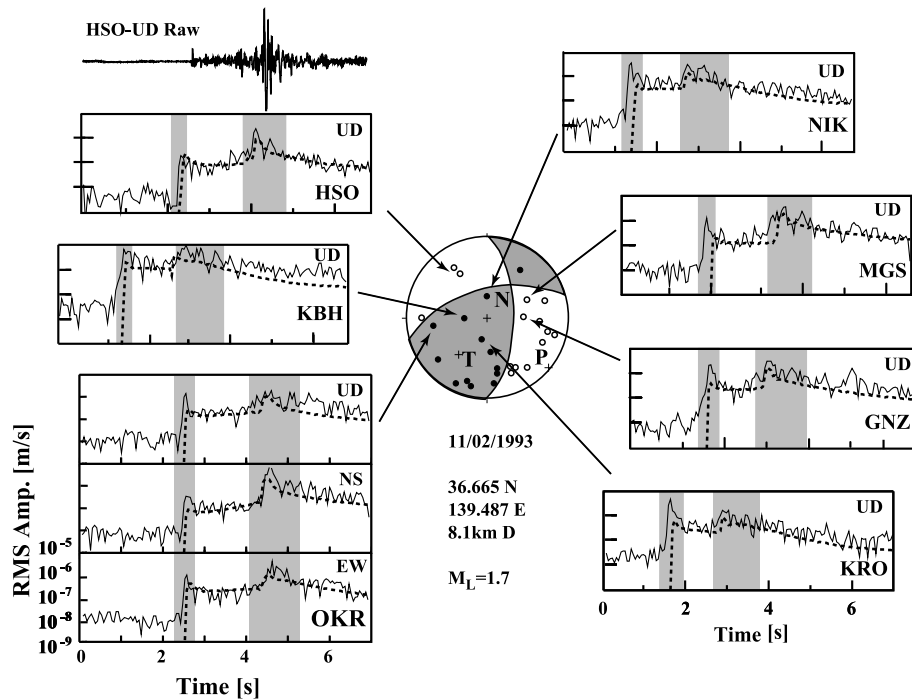

$$g(\psi; \omega) = \frac{k_0^4}{\pi} P(k_0 \mathbf{e}_r - k_0 \mathbf{e}_z) = \frac{k_0^4}{\pi} P\left(2k_0 \sin \frac{\psi}{2}\right), \quad (7)$$

where  $\psi$  is the scattering angle measured from the  $z$  direction. This functional form means anisotropic scattering depending on frequency. In general, scattering near around the forward direction becomes larger with increasing wavenumber in random media.

### Radiative Transfer Theory with Scattering Coefficients Calculated by the Born Approximation

Extending the above formulation to vector wave propagation in random elastic media, we can define scattering coefficients for different scattering modes as PP, PS, SP, and SS. For the case of random elastic media characterized by an exponential ACF with  $\varepsilon = 10\%$  and  $a = 2$  km, Sato [68] synthesized three-component seismogram envelopes of a microearthquake of M 3 as a superposition of polarized scattered waves' power at a finite distance from a point shear dislocation source. That is the single scattering approximation of the radiative transfer theory with scattering coefficients calculated by the Born approximation. The SS scattering mode dominates in S coda, and pseudo P and S waves are produced even at a receiver on the null direction of the source radiation. By using a von Kármán-type ACF for describing random elastic media, Sato [71] estimated parameters  $\kappa = 0.35$ ,  $\varepsilon = 8.4\%$  and  $a = 2.1$  km from observed frequency dependence of S-wave attenuation and  $g_0$ , where the parameter  $\kappa$  controls the role-off of PSDF at large wavenumbers. Extending the above vector wave envelope synthesis to include mode conversions at the free surface, Yoshimoto et al. [90]

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 6

RMS envelopes of a microearthquake in the shallow crust, Nikko in northern Kanto, Japan. *Fine curves* and *broken curves* are observed and best-fit synthesized envelopes, respectively, where *shades* show time windows used for the estimation of the source radiation energy. The trace on the *top left* shows a raw seismogram. Reproduced from [90]

analyzed three-component seismogram envelopes of microearthquakes in the shallow crust in Nikko, northern Kanto, Japan. A raw seismogram is shown at the top-left of Fig. 6 as an example. Fine curves in Fig. 6 are logarithmic plots of observed root mean square (RMS) envelopes in the 2–16 Hz band. Broken curves are best-fit theoretical envelopes for random elastic media characterized by an exponential ACF with  $\varepsilon = 5.7\%$  and  $a = 400$  m. We find that the fitness is good not only for S coda but also for P coda.

Wave theory in random media predicts that the scattering coefficient has a large lobe in the forward direction in higher frequencies. Gusev and Abubakirov [22] used the Monte Carlo method to simulate envelopes for the multiple nonisotropic scattering process. There have been mathematical developments to derive the radiative transfer equation for multiple nonisotropic scattering from the stochastic averaging of the wave equation in random media (e. g. [13,29,41,64]). Przybilla et al. [58] showed an excellent coincidence of vector envelopes calculated from finite difference simulation in 2-D random elastic media and those synthesized by the radiative transfer theory with scattering amplitudes derived from the Born approximation and the wandering effect of travel time.

### Interference of Scattered Waves

The interference effect is neglected in conventional studies of wave scattering in random media; however, it becomes important for a specific case even in random media. When randomness is strong enough to produce multiple scattering, coda wave intensity at a receiver near a source is enhanced compared to the prediction of conventional radiative transfer theory. Margerin et al. [42] showed that a spot of backscattering enhancement stabilizes in a sphere of radius half a wavelength centered at the source after a transient regime. The enhancement persists in time and should be observable as long as a coda is measurable. From field experiment of seismic waves in a shallow volcanic structure Larose et al. [39] reported the existence of weak localization, where the size of enhancement spot was one wavelength and the estimated mean-free path was 200 m for seismic waves around 20 Hz.

### Envelope Broadening of a High-Frequency Seismogram

#### Markov Approximation for Parabolic Wave Equation

For the study of light propagation through the upper atmosphere and/or acoustic sound propagation through in-

ternal waves in oceans, various stochastic methods have been developed in the fields of physics. One of the most attractive methods for explaining the wave envelope around the direct arrival is the Markov approximation for the parabolic wave equation, which is an extension of the phase screen method or the split step Fourier method (e. g. [29,63]). This method is found to be applicable to seismogram envelopes. We imagine an elastic medium composed of a homogeneous half space  $z < 0$  and an inhomogeneous half space  $z > 0$ , where the inhomogeneity is supposed to be small ( $\varepsilon^2 \ll 1$ ) and the randomness is statistically homogeneous and isotropic. When the wavelength is smaller than the correlation distance  $a$ , we may neglect conversion scattering between P and S waves. Then, we can describe the principal characteristics of vector wave propagation by using potentials. For the incidence of plane P-wavelet to the  $z$  direction from the homogeneous zone, scalar potential is written as a superposition of harmonic waves of angular frequency  $\omega$  as  $\phi = \int_{-\infty}^{\infty} (2\pi i k_0)^{-1} U(\mathbf{x}_{\perp}, z, \omega) e^{ik_0 z - i\omega t} d\omega$  for  $z > 0$ , where  $\mathbf{x}_{\perp} = (x, y)$  on the transverse plane. Neglecting the second derivative with respect to  $z$ , we have the parabolic-type equation for  $U$  as

$$2ik_0 \partial_z U + (\partial_x^2 + \partial_y^2) U - 2k_0^2 \xi(\mathbf{x}) U = 0. \tag{8}$$

We define the two-frequency mutual coherence function (TFMCF) of field  $U$  between two different locations on the transverse plane at a distance  $z$  and different angular frequencies at  $\omega'$  and  $\omega''$  as  $\Gamma_2(\mathbf{x}_{\perp c}, \mathbf{x}_{\perp d}, z, \omega_c, \omega_d) \equiv \langle U(\mathbf{x}'_{\perp}, z, \omega') U(\mathbf{x}''_{\perp}, z, \omega'')^* \rangle$ , where  $\omega_c$  and  $\omega_d$  are center-of-mass and difference angular frequencies, respectively. In the case of quasi-monochromatic waves  $|\omega_d| \ll |\omega_c|$ , using causality and neglecting back scattering, we derive the master equation for TFMCF. This derivation is called the Markov approximation. For the  $i$ th component, the intensity is defined as the ensemble average of the square of displacement  $\langle \partial_i \phi \partial_i \phi^* \rangle = 1/(2\pi) \int_{-\infty}^{\infty} \widehat{I}_i^P d\omega_c$ . The integrand is the intensity spectral density (ISD)  $\widehat{I}_i^P$ , which means the time trace of MS amplitude in a band having the central angular frequency  $\omega_c$ .

**Vector Envelopes for a Gaussian ACF**

The case of a Gaussian ACF  $R(\mathbf{x}) = \text{Exp}(-r^2/a^2)$  is mathematically tractable. For the initial condition  $\widehat{I}_x^P = \widehat{I}_y^P = 0$  and  $\widehat{I}_z^P = \delta(t - z/V_0)$  at  $z = 0$ , ISDs are analyti-

cally written as [72]

$$\begin{aligned} \widehat{I}_{x0}^P(z, t, \omega_c) &= \widehat{I}_{y0}^P(z, t, \omega_c) \\ &= 2(V_0/z)(t - z/V_0) \cdot \widehat{I}_0^R(z, t, \omega_c) \\ \widehat{I}_{z0}^P(z, t, \omega_c) &= [1 - 4(V_0/z)(t - z/V_0)] \\ &\quad \cdot \widehat{I}_0^R(z, t, \omega_c), \end{aligned} \tag{9}$$

where subscript “0” means ISD without the wandering effect. The reference ISD is a solution for scalar waves for the initial condition  $\Gamma_2(\mathbf{x}_{\perp}, z = 0) = 1$  [82]:

$$\widehat{I}_0^R(z, t, \omega_c) = \frac{1}{t_M} \frac{\pi}{8} \vartheta_1' \left( 0, e^{-\frac{\pi^2}{4} \frac{(t-z/V_0)^2}{t_M}} \right) \cdot H \left( t - \frac{z}{V_0} \right), \tag{10}$$

where  $t_M = \sqrt{\pi} \varepsilon^2 z^2 / (2V_0 a)$  is the characteristic time and function  $\vartheta_1'$  is the derivative of the elliptic theta function of the first kind. Function  $\widehat{I}_0^R$  shows a broadened envelope having a delayed peak and a smoothly decaying tail as illustrated by a chained curve in Fig. 7, where solid and broken curves show three-component ISDs  $\widehat{I}_{0z}^P$  and  $\widehat{I}_{x0}^P (= \widehat{I}_{y0}^P)$ , respectively, for  $V_0 t_M / z = 0.05$  as an example. All the three component envelopes have broadened traces; however, the peak height of the transverse component is smaller than that of the longitudinal component and the peak delay of the transverse component is larger than that

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 7 Chained curve shows the reference ISD without the wandering effect in 3-D random elastic media characterized by a Gaussian ACF for the incidence of a plane P-wavelet. Solid and broken curves show three-component ISDs without the wandering effect for  $V_0 t_M / z = 0.05$ . Reproduced from [72]

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 8  
Synthesized vector envelopes in random media characterized by a Gaussian ACF for radiation of P wavelet and S wavelet with a polarization to the  $x$ -axis from a point source. Reproduced from [73]

of the longitudinal component. When  $\varepsilon^2 z/a \ll 1$ , the peak height of  $\widehat{I}_{z0}^P$  approximately decays according to the square of travel distance and the peak ratio of the transverse component to longitudinal component is proportional to  $\varepsilon^2 z/a$ . ISDs  $\widehat{I}_x^P$ ,  $\widehat{I}_y^P$ , and  $\widehat{I}_z^P$  can be calculated by using the convolution of (9) with the travel-time wandering effect  $\exp[-(V_0 t - z_0)^2 / 2\sqrt{\pi}\varepsilon^2 a z] V_0 / \sqrt{2\pi\sqrt{\pi}\varepsilon^2 a z}$  in time domain. For 2-D cases, the validity of the Markov approximation was numerically confirmed by a comparison with the finite difference simulations [11,36].

The above synthesis can be simply extended to S wave envelopes. Extension from plane wave incidence to impulsive radiation from a point source is also possible [73]. Figure 8 shows simulated three-component RMS envelopes along the  $z$  axis for a point source radiation, where random media are characterized by average P and S wave velocities, 6 km/s and 3.46 km/s, respectively, and a Gaussian ACF with  $\varepsilon = 5\%$  and  $a = 5$  km. We assume that P-wavelet radiation is isotropic and S-wavelet radiation is axially symmetric around the  $y$  axis with polarization to the  $x$  axis, where the ratio of S to P-wave source energy is chosen to be 23.3. Envelope broadening is common to both P and S waves in the syntheses. Excitation of the

transverse component for P-waves and that of the radial component for S-waves are prominent. The appearance of scattered S-waves having long duration in synthesized envelopes at large travel distances qualitatively well explains observed characteristics shown in Fig. 2.

### Randomness in the Lithosphere

Applying the envelope broadening model to S-wave seismograms recorded in Kanto, Japan, Sato [70] estimated the ratio  $\varepsilon^2/a \approx 10^{-3} \text{ km}^{-1}$  with the assumption of a Gaussian ACF and S-wave attenuation  $Q^{-1} = 0.014 f^{-1}$ . Saito et al. [66] studied the case of a von Kármán-type random media having a power-law spectrum at large wavenumbers, which are more appropriate for the real Earth inhomogeneity. The resultant envelope shows frequency dependence, which is controlled by the roll-off of the PSDF. Analyzing the hypocentral-distance dependence and frequency dependence of S-wave seismogram envelopes in northern Honshu, Japan for 2–32 Hz, Saito et al. [66] estimated parameters of von Kármán-type ACF as  $\kappa = 0.6$  and  $\varepsilon^{2.2}/a \approx 10^{-3.6} \text{ km}^{-1}$  with  $Q^{-1} = 0.009 f^{-1}$ . It means the PSDF decreases as wavenumber to the power of  $-4.2$ . Petukhin and Gusev [55] averaged S-wave seismogram envelopes of small earthquakes recorded in Kamchatka and compared the shapes with those numerically calculated for various types of random media. They concluded that random media whose PSDF decreases as the wavenumber to the power of  $-3.5$  to  $-4$  are appropriate.

### Spatial Variation of Scattering Characteristics

#### Scattering Coefficient and Active Faults

Precisely examining coda envelopes of local earthquakes against lapse time measured from the origin time, we find temporal fluctuations around the smoothly decaying master curve. We may interpret that swellings and dips around the master curve are caused by stronger and weaker scatterers, respectively, distributed in the subsurface. By using a single isotropic scattering model, Nishigami [48] proposed an inversion scheme from coda envelopes of local earthquakes recorded at multiple stations for estimating the spatial variation of the scattering coefficient. Applying this inversion scheme to coda records obtained in central California, Nishigami [49] mapped the distribution of relative scattering coefficient in the shallow crust as in Fig. 9. A good correlation is found between sub-parallel active faults and relatively stronger scattering zones marked by larger circles, where some large circles are caused by topographic roughness. He also suggested that segment bound-

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 9  
**Distribution of relative scattering coefficient at a depth of 0–5 km in central California revealed from the coda envelope inversion. Circles with larger diameter indicate stronger scattering and solid lines represent active faults. Reproduced with permission from [49]**

aries of the San Andreas Fault are characterized by relatively stronger scattering.

Stacking forward scattered energy in the coda of teleseismic P waves observed by a local seismographic network, Revenaugh [59] proposed a Kirchhoff coda migration method, which puts a focus on small-angle scattering from the forward direction. He made a map of P-wave scatterers in the upper mantle beneath southern California. Between depths of 50 km and 200 km, the southern flank of the slab subducting beneath the Transverse Ranges was marked by strong scattering. Using the same method, Revenaugh [60,61] estimated geographic variation of the statistical significance of scattering potential in the upper crust in California, where the scattering potential is a measure of the likelihood that scattering strength locally exceeds the regional mean. In the region surrounding the 1992 Landers earthquake of M 7.3, he found a noticeable tendency for aftershocks to cluster in regions of strong scattering potential.

There were more precise mappings of scattering coefficient. Slant-stacking records of 12 explosions in the Awaji island, Japan registered by a dense seismic array for a 6–10 Hz band, Matsumoto et al. [45] mapped the spatial distribution of PP signal scatterers. The resultant distribution

of scatterers shows higher strengths beneath the initiation point of the mainshock rupture and in the southwestern part of the fault plane of the 1995 Kobe earthquake (M 7.2). Analyzing precisely aftershock records of the 2000 western Tottori earthquake (M 7.3), Japan registered by a dense seismic network, Asano and Hasegawa [5] found strong scattering along and around the fault zone of 20 km in length.

### Coda Attenuation and Deformation Zone

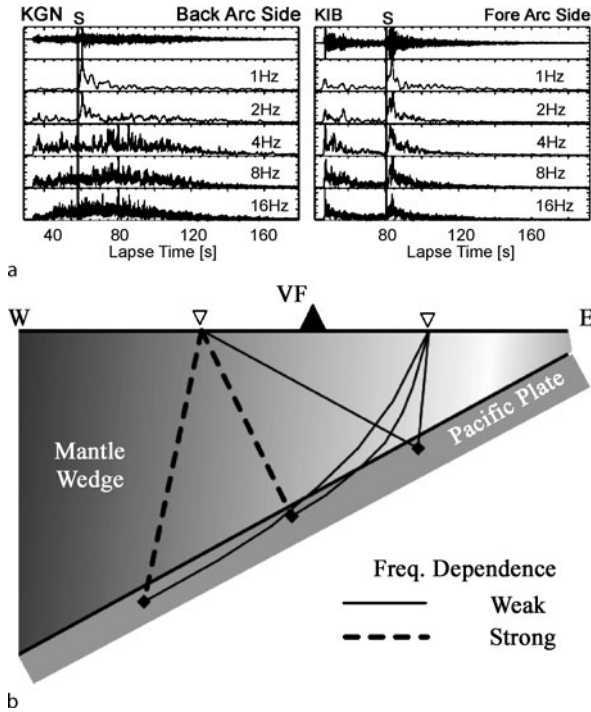

Regional variation of coda attenuation  $Q_c^{-1}$  has been measured from the decay gradient of coda amplitude envelopes of small earthquakes in various areas in the world. Jin and Aki [31] made a map of  $Q_c^{-1}$  at 1 Hz in China. They reported that  $Q_c^{-1}$  is as large as 0.01 in Tibet at the active continental collision. They found that large historical earthquakes took place in large  $Q_c^{-1}$  regions. Jin and Aki [33] made precise analysis of  $Q_c^{-1}$  for 1–32 Hz in Japan. They found significant spatial variation up to a factor of 3 for the lower frequency bands, as well as its strong frequency dependence. They found conspicuous large  $Q_c^{-1}$  for 1–4 Hz in a narrow belt from Niigata towards the south-west to the Biwa lake along the Japan Sea coast, which coincides with a high-deformation rate zone revealed from the GPS observation. For frequency bands 4–16 Hz (2–4 Hz in Kyushu), large  $Q_c^{-1}$  areas agree with volcanic and geothermal areas.

### Attenuation and Volcanoes

Yoshimoto et al. [91] studied the spatial variation of MS amplitude of S-coda at a fixed lapse time across the volcanic front in northeastern Honshu, Japan: S-coda energy is uniformly distributed in the fore-arc side, whereas an exponential decrease with horizontal offset to the west from the volcanic front was found in the back-arc side. The decay rate increases with increasing frequency. They interpreted this variation by a diffusion-absorption model, where the intrinsic absorption factor of S-wave  $Q_{\text{Int}}^{-1} = 0.02$  at a frequency of 10 Hz beneath the back-arc side, which is about twice as large as those reported for the fore-arc side.

### Scattering and Volcanoes

Medium heterogeneity is strong beneath volcanoes. Applying the diffusion model to seismogram envelopes beneath Merapi volcanoes, Friedrich and Wegler [16] estimated the total scattering coefficient as large as  $5 \text{ km}^{-1}$  as shown in Fig. 4. Nishimura et al. [50] applied an envelope inversion method based on the isotropic scatter-

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 10 **a** Seismogram envelopes observed in the back-arc side and fore-arc side in Kanto-Tokai, Japan and **b** a schematic illustration of seismic rays. Reproduced from [53]

ing model for PP and PS scattering to artificial explosion records obtained in Jemez volcanic field, New Mexico. They found that the mid-crust under most of the region is fairly transparent but that the lower crust is heterogeneous. The strongest scattering occurs at shallow depths beneath the center of the caldera, where the medium is highly heterogeneous.

Obara and Sato [53] analyzed S-wave envelopes of microearthquakes in Kanto-Tokai, Japan, where the Pacific plate is subducting from east to west, to examine regional differences in their envelope broadening. As shown by examples in Fig. 10a, envelope broadening is typically stronger for higher frequencies in records at stations on the back-arc side of the volcanic front but weaker and frequency independent in records on the fore-arc side. These regional differences in the envelope broadening mean that PSDF of velocity inhomogeneity is rich in short-wavelength components in the mantle wedge on the back-arc side and poor on the fore-arc side as schematically illustrated in Fig. 10b. Takahashi et al. [83] precisely examined how the peak delay from the S-wave onset depends on the ray path in northern Japan. They found that peak delays observed in the back-arc side of the volcanic front

are larger for rays which propagate beneath Quaternary volcanoes (see Fig. 11b and d); however, peak delays for rays which propagate between Quaternary volcanoes are as short as those observed in the fore-arc side (see Fig. 11a, c, and e). Large peak delay suggests strong scattering due to medium inhomogeneity. That is, the structure beneath Quaternary volcanoes is not only characterized by low velocity and large intrinsic absorption revealed from tomography studies but also by strong inhomogeneity.

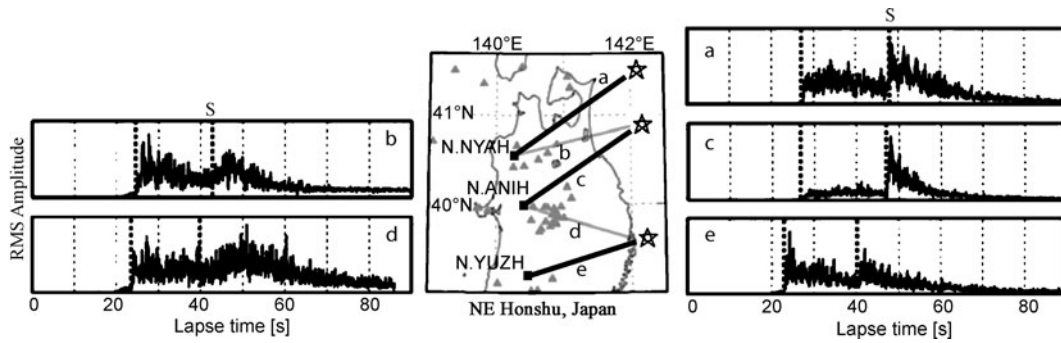

### Nonisotropic Random Medium Oceanic Slab

If random media are statistically nonisotropic, scattering contribution depends on the propagation direction. Saito [65] studied the envelope broadening in nonisotropic random media based on the Markov approximation. His simulations show that the envelope of scalar wavelet propagating in parallel to the longer correlation direction has longer duration compared to that with the shorter correlation direction. The effective envelope broadening in the elongated direction shows the wave trap phenomenon of nonisotropic random media.

An intensity anomaly is observed on the eastern seaboard of northern Japan for deep earthquakes. The waveform records in the region of high intensity show a low-frequency ( $f < 0.25$  Hz) onset for both P and S waves, followed by large-amplitude high-frequency ( $f > 2$  Hz) later arrivals with long coda. A simple subduction zone model comprising a high-velocity plate with low attenuation cannot explain quantitatively these observed facts. Furumura and Kennett [17] proposed a scattering slab model that the nonisotropic random structure in the Pacific plate works as a wave-guide for high-frequency seismic waves. Their preferred random medium is characterized by a von Kármán-type ACF with elongated correlation distance of about 10 km parallel to the plate margin and much shorter correlation length of about 0.5 km in thickness and  $\varepsilon$  of about 2%. They clearly demonstrated the scattering waveguide effects and frequency selectivity for seismic waves traveling through the Pacific plate by using 3-D numerical simulations.

### Lateral Variation of Lithospheric Heterogeneity

Korn [34] developed the energy flux model [15] appropriate for the wave front of teleseismic P and P-coda waves propagating through a scattering layer. During the propagation the primary wave loses energy due to scattering and intrinsic absorption, then the scattered energy appears as coda energy behind the wave front. From the analysis of vertical component trace envelopes observed in the world, Korn [35] found strong scattering at island arcs

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 11  
 Path dependence of RMS envelopes (16–32 Hz) in northeastern Honshu, Japan, where stars and triangles indicate earthquake epicenters and Quaternary volcanoes, respectively. Ray paths b and d travel beneath Quaternary volcanoes (triangles), and a, c, and e travel between Quaternary volcanoes. Reproduced from [83]

Seismic Waves in Heterogeneous Earth, Scattering of, Figure 12  
 Plots of the square root of the relative partition of wave energy into the transverse component (1–2 Hz) by a diameter of the circle revealed from the teleseismic P-waves. Reproduced from [37]

and smaller scattering on stable continental areas like Australia. Nishimura et al. [52] analyzed the energy partition of teleseismic P and P-coda into the transverse component to evaluate the lithospheric heterogeneity in the western Pacific region. They showed the presence of strong heterogeneity in and around the tectonically active regions. Kubanza et al. [37] systematically characterized the medium heterogeneity of the lithosphere by analyzing the partition of P-wave energy into the transverse component for 0.5–4 Hz. They found significant regional differences as shown in Fig. 12. The energy partition to the transverse component is small at stations on stable continents while

the partition is large at stations in tectonically active regions such as island arcs or collision zones.

**Random Inhomogeneity in the Lithosphere and Mantle**

Records of earthquakes registered by arrays of seismographs are useful for the statistical measurement of the Earth inhomogeneity. Aki [2] first analyzed teleseismic P-waves centered on about 0.6 Hz registered by a seismic array in Montana for the quantification of the lithospheric inhomogeneity. Measuring transverse correlation functions of teleseismic P-waves arriving from near ver-

tical incidence, he found a positive correlation between log-amplitude and phase fluctuations as theoretically predicted for a Gaussian ACF. From plots of the ratio of RMS log-amplitude to RMS phase fluctuations against the correlation between log-amplitude and phase fluctuations, he estimated the thickness of the inhomogeneous lithosphere to be 60 km,  $a = 10$  km, and  $\varepsilon = 4\%$ . Flatté and Wu [12] measured the transverse correlation of log-amplitude and phase fluctuations of teleseismic P-wave beams with 2 Hz center frequency recorded at NORSAR. They also introduced the new concept of angular correlation functions, which are based on measurements of two rays with different incident angles. They proposed a model for lithospheric and asthenospheric inhomogeneities that consists of two overlapping layers: the upper layer extending from the surface to about the 200 km depth has a white PSDF, however, the lower layer extending from 15 to 250 km has poor amplitude in the short wavelength spectrum. There are more small-scale inhomogeneities near the surface compared with the deeper portions.

The radiative transfer theory with scattering coefficients calculated from the Born approximation was also used for the study of mantle inhomogeneity. Analyzing stacked P and P coda envelopes of teleseismic ( $>10^\circ$ ) events at 1 Hz, Shearer and Earle [79] concluded that most scattering occurs in the lithosphere and upper mantle, but that some lower mantle scattering is likely required. They estimated  $\varepsilon$  to be 3–4% and  $a = 4$  km in the upper mantle and 0.5% and 8 km in the lower mantle. Analyzing envelopes of precursors to PKP, Margerin and Nolet [43] found that inhomogeneity can not be restricted to the D'' layer and a small inhomogeneity spread over the whole lower mantle. They proposed a von Kármán ACF of  $\kappa = 0$  for random media, which has a power law PSDF rich in short wavelengths compared with an exponential ACF. They mentioned that  $\varepsilon$  of 0.1–0.2% in the whole lower mantle is enough to explain the observation even though correlation distance is irresolvable because of the limited range of observations.

### Imaging of Subsurface Heterogeneity

There have been developments in deterministic imaging of medium inhomogeneity from the analysis of array records of P-coda waves. When the structures of interest are characterized by laterally variable stratification, the receiver-function technique [38] is useful since it is based on the deconvolution of the horizontal component trace in the radial direction by the vertical component trace for measuring the Ps conversion depth. On the other hand, scattering from localized volume inhomogeneity is most read-

ily treated by using the Born approximation. Analyzing array records of teleseismic P coda in central Oregon by using the Born approximation for both forward scattered waves and backscattered free-surface reflected waves, Rondenay et al. [62] successfully imaged the precise structure of the Cascadia subduction zone, which is consistent with the consequences of prograde metamorphic reactions occurring within the oceanic crust. Analyzing array records of P coda waves of regional earthquakes at Izu-Oshima volcano, which erupted in 1986, Mikada et al. [46] deterministically imaged PP and PS scatterers on the basis of diffraction tomography. They interpreted a cloud of scatterers centered at about 10 km depth beneath the volcano crater as a primary magma reservoir and smaller and shallower patches of high scattering strength with sub-magma reservoirs.

### Temporal Change in the Earth Medium Structure

There were reports on the temporal changes in the Earth medium structure revealed from the analyses of scattered waves. One is coda amplitude envelope analysis, which gives information about the change in intrinsic absorption and scattering strength of the crustal heterogeneity. Another is coda phase interferometry, which offers information about the change in background velocity.

### Change in Coda Characteristics

Monitoring coda envelopes of local earthquakes, Gusev and Lemzikov [23] reported temporal change in  $Q_c^{-1}$  before and after the 1971 Ust-Kamchatsk earthquake (M 7.8), and Jin and Aki [30] reported temporal change in  $Q_c^{-1}$  associated with the 1976 Tangshan earthquake (M 7.8) in China. Their observation attracted the interest of geophysicists to the temporal variation of coda characteristics because of a potential for monitoring the stress accumulation process preceding an earthquake occurrence. Analyzing high-frequency seismograms recorded at Riverside, California for 55 years, Jin and Aki [32] found a temporal variability in  $Q_c^{-1}$  at about 1.6 Hz having a positive correlation with the seismic  $b$ -value calculated for  $M > 3$  earthquakes within a 180 km radius. The seismic  $b$ -value is a measure of the ratio between the numbers of small to large earthquakes; smaller  $b$ -values mean that there are relatively fewer small earthquakes compared to the number of larger ones. They interpreted these changes in  $Q_c^{-1}$  and the  $b$ -value by creep fractures in the ductile part of the lithosphere. Hiramatsu [25] precisely examined the temporal variation in  $Q_c^{-1}$  and  $b$ -value for 10 years before and after the 1995 Hyogo-ken Nanbu earthquake (M 7.2) in Japan. At frequencies between 1.5 and 4.0 Hz the tempo-

ral variation in  $Q_c^{-1}$  increased after the mainshock occurrence, where the variation in  $b$ -value was opposite.

Sato [69] analyzed the relation between coda duration time and earthquake magnitude of small earthquakes before and after an M 6.8 earthquake in central Japan. He found that coda durations were anomalously longer than usual for 16 months before the earthquake occurrence. From 24-year observation of coda at 0.5 Hz in Kamchatka Gusev [19] reported prominent anomalies in coda level residual from the mean coda excitation level at 100s lapse time associated with two M 8 earthquakes and a volcanic eruption.

Sawazaki et al. [76] measured the temporal variation of the spectral ratio of coda waves registered on the ground surface to that at the bottom of a borehole of 100 m depth in Japan, which experienced strong ground motion of several hundred gals. They reported a sudden drop of the site amplification factor caused by earthquake strong motion and gradual recovery for a few years approaching to the original ratio. They suggested crack formation and ground water movement for explaining the site factor weakening observed.

### Coda Interferometry

Pairs of earthquakes with almost identical focal mechanisms are called earthquake doublets. The cross-correlation function of earthquake doublet records allow us to detect differences in the background velocity of the Earth medium that took place in between the pair of earthquakes. Applying the phase spectral analysis to coda wave records of earthquake doublets before and after the 1979 Coyote earthquake of M 5.9 in California, Poupinet et al. [57] found that the coda wave arrivals for some stations are progressively delayed for the second earthquake in the doublet. They interpreted systematic variation along the coda as a decrease of background S-wave velocity by 0.2% in an oblong region 5–10 km in radius at the south end of the aftershock zone. Applying the phase spectral analysis to records of repeated artificial explosions, Nishimura et al. [51] found that the average seismic velocity of the crust in the frequency range of 3–6 Hz decreased by about 1% around the focal region of an M 6.1 earthquake at Iwate volcano in northeastern Honshu, Japan in 1998. They interpreted this velocity drop by the dilatation caused by the M 6.1 earthquake with stress sensitivity of the velocity change  $(\delta V/V)/\delta\sigma$  of the order of  $0.1 \text{ MPa}^{-1}$ . From the set of successive artificial explosion experiments, they observed gradual recovery of the seismic velocity towards its original value over the next four years. While interferometry detected a change in velocity of the order of

1%, it was unidentifiable from travel time analysis of first arrivals. Using coda waves is superior to direct waves since coda waves volumetrically sample the Earth medium.

Snieder et al. [81] demonstrated detection of the non-linear dependence of the seismic velocity in granite on temperature and the associated acoustic emissions from the interference measurement of coda waves in rock samples as a laboratory experiment. They named this method “coda interferometry” and proposed to use it for detecting the presence of temporal changes in the medium, or in diagnostic mode. There is an idea to retrieve the Green function from the stacked cross-correlation function (CCF) of multiple scattered waves or microseisms at a pair of stations on condition that the propagation directions of those waves are randomly isotropic. Stacking CCFs of coda waves at several pairs of stations for regional earthquakes in Mexico, Campillo and Paul [7] estimated the surface wave velocity between each station pair from the peak delay. The idea was extended for monitoring the temporal change in the crustal structure. Wegler and Sens-Schönfelder [84] computed the ACF of microseisms recorded at a site in the vicinity of the source region of the 2004 Mid-Niigata earthquake (M 6.6) in Japan for three months. They detected a sudden decrease of relative seismic velocity in the crust of 0.6% at the occurrence of the earthquake from the temporal variation of stacked ACFs.

### Future Directions

In addition to classic parameterization as a layered structure with sharp edges and smooth velocity perturbation, we introduced new approaches using scattered waves that reflect solid Earth heterogeneity. For high-frequency seismograms of earthquakes, envelope characteristics such as the excitation level and the decay gradient of coda envelopes and the envelope broadening of the direct wavelet are useful for the study of small-scale inhomogeneities. The lithospheric inhomogeneity is phenomenologically well characterized by the scattering coefficient and coda attenuation factor as a function of frequency. Furthermore, the power spectral density function of random velocity inhomogeneity is estimated from the frequency dependence of high-frequency seismogram envelopes of local earthquakes or the array analysis of teleseismic waves. The radiative transfer theory with scattering coefficients calculated from the Born approximation and the Markov approximation for the parabolic wave equation are useful mathematical tools for the analyses.

Scattering characteristics are found to vary spatially reflecting seismotectonic settings. It will be necessary for us to make a classification of seismogram-envelope patterns

in various regions in the world under different tectonic conditions. It is interesting to model how such a variation of medium inhomogeneity was created through the geodynamic process. Compared to the lithospheric inhomogeneity, there were insufficient numbers of studies on the mantle inhomogeneity. It will be necessary to map the distribution of inhomogeneities deep in the mantle, which is useful for the study of the evolution of the planet Earth.

For mathematical simplicity; however, most approaches assume homogeneity and isotropy of randomness and a constant background velocity, which are somewhat different from reality. It will be necessary to mathematically develop the envelope synthesis in inhomogeneous media that are a superposition of small-scale random inhomogeneities and a gradually varying background velocity. As revealed from the ray path dependence of S-wave envelope broadening, randomness varies from place to place. It is also necessary to develop the envelope synthesis for random media having spatially varying statistical parameters. In addition, it is important to examine how conversion scattering between P and S waves contributes to form spindle-like envelopes in highly scattering media as shown in high-frequency seismograms observed in volcanoes and on the Moon.

For further understanding, there are monographs that treat the discussed subjects as follows: Sato and Fehler [74] review seismological observation and mathematical models; Shapiro and Hubral [78] put special focus on wave propagation through stratified random media; Goff and Holliger [18] summarize the crustal heterogeneity; Wu and Maupin [86] compile recent developments in mathematical modeling of wave propagation in inhomogeneous media; Chandrasekhar [8] is a classic text for radiative transfer theory; Ishimaru [29] and Rytov et al. [63] offer advanced mathematical tools for the study of wave propagation in random media.

### Glossary

**Bayesian analysis** A model estimation technique that accounts for incomplete knowledge. Bayes' theorem is a mathematical formulation of how an a priori estimate of the probability of an event can be updated, if a new information becomes available.

**Critical earthquake concept** The occurrence of large earthquakes may be described in terms of statistical physics and thermodynamics. In this view, an earthquake can be interpreted as a critical phase transition in a system with many degrees of freedom. The preparatory process is characterized by acceleration of the seismic moment release and growth of the spatial correlation length as in the percolation model. This interpretation of earthquake occurrence is referred to as the critical earthquake process.

**Earthquake forecast/prediction** The forecast or prediction of an earthquake is a statement about time, hypocenter location, magnitude, and probability of occurrence of an individual future event within reasonable error ranges.

**Fault model** A fault model calculates the evolution of slip, stress, and related quantities on a fault segment or a fault region. The range of fault models varies from

conceptual models of cellular automaton or slider-block type to detailed models for particular faults.

**Probability** A quantitative measure of the likelihood for an outcome of a random process. In the case of repeating a random experiment a large number of times (e. g. flipping a coin), the probability is the relative frequency of a possible outcome (e. g. head). A different view of probability is used in the → Bayesian analysis.

**Seismic hazard** The probability that a given magnitude (or peak ground acceleration) is exceeded in a seismic source zone within a pre-defined time interval, e. g. 50 years, is denoted as the seismic hazard.

### Self-organized criticality

Self-organized criticality (SOC) as introduced by Bak [2] is the ability of a system to organize itself in the vicinity of a critical point independently of values of physical parameters of the system and initial conditions. Self-organized critical systems are characterized by various power law distributions. Examples include models of sandpiles and forest-fires.

### Definition of the Subject

The most fundamental question in earthquake science is whether earthquake prediction is possible. Related issues include the following: Can a prediction of earthquakes solely based on the emergence of seismicity patterns be reliable? In other words, is there a single or several “magic” parameters, which become anomalous prior to a large earthquake? Are pure observational methods without specific physical understanding, like the pattern recognition approach of Keilis–Borok and co-workers [41], sufficient? Taking into account that earthquakes are monitored continuously only for about 100 years and the best available data sets (“earthquake catalogs”) cover only a few decades, it seems questionable to forecast earthquakes solely on the basis of observed seismicity patterns. This is because large earthquakes have recurrence periods of decades to centuries; consequently, data sets for most regions include less than ten large events making a reliable statistical testing questionable.

In the studies discussed here, the goal is not to forecast individual earthquakes. Instead, we aim at developing a combined approach based on numerical modeling and data analysis in order to understand seismicity and the emergence of patterns in the occurrence of earthquakes. The discussion and interpretation of seismicity in terms of statistical physics leads to the concept of “critical states”, i. e. states in the seismic cycle with an increased probability for abrupt changes involving large earthquakes. A more general goal of this work is to provide perspectives for

the understanding of the relevant mechanisms and to give outlines for developments related to time-dependent seismic hazard.

## Introduction

Several empirical relationships for the occurrence of seismicity are well-known. The most common one is probably the Gutenberg–Richter law [30] for the relation between frequency and magnitude of earthquakes in a large seismically active region,

$$\log N = a - bM, \quad (1)$$

where  $N$  is the frequency of earthquakes with magnitude equal to or greater than  $M$ ;  $a$  is a measure of the overall seismicity level in the region and the  $b$  value determines the relation between large and small earthquakes. The Gutenberg–Richter law provides an important constraint for the design of physical models and serves as a key ingredient for seismic hazard estimations. Statistical relations for the temporal occurrence of large events are less well known, because the corresponding data records are too short.

Several additional problems exist in the understanding and interpretation of observed seismicity patterns. First, it is important to decide whether an observed pattern has a physical origin or is an artifact, arising for example from inhomogeneous reporting or from man-made seismicity like quarry blasts or explosions [69]. Second, the non-artificial events have to be analyzed with respect to their underlying mechanisms. This leads to an inverse problem with a non-unique solution, which can be illustrated for the most pronounced observed temporal pattern associated with aftershocks. It is empirically known that the earthquake rate  $\dot{N}$  after a large event at time  $t_M$  follows the Omori–Utsu law [49,67]

$$\dot{N} = \frac{K}{(c + t - t_M)^p}, \quad (2)$$

where  $t$  is the time,  $K$  and  $c$  are constants, and the Omori exponent  $p$  is close to unity. In particular, aftershocks are an almost universal phenomenon; that is, they are observed nearly after each mainshock. The underlying mechanisms leading to aftershocks are, however, unknown. Various physical models have been designed to explain aftershock occurrence following Eq. (2). These models include viscoelasticity [32], pore fluid flow [46], damage rheology [9,57], and rate-state friction [24]. The question which mechanism or combination of mechanisms is relevant in a given fault zone remains open. Detailed comparisons of observed and modeled seismicity with respect to

the aftershock rate, the duration of aftershock sequences, the dependence on the mainshock size, and other features are necessary to address this problem. Additionally, results from lab experiments on rupture dynamics and satellite observations of deformation provide important information for the design of such models.

Apart from aftershock activity, other seismicity patterns are occasionally associated with observations, including foreshocks [39], seismic quiescence [34,72,78], and accelerating moment release [17,38]. These patterns have been documented in several cases before large earthquakes. They occur, however, far less frequently than aftershocks. For example, foreshocks are known to precede only 20–30% of large earthquakes [71]. Therefore, their predictive power is questionable. Moreover, it is not clear whether these patterns can be attributed to physical processes or to random fluctuations in the highly sparse and noisy earthquake catalogs. This problem can be addressed by using fault models which simulate long and complete earthquake sequences over thousands of years. If the models capture the main features of the underlying physics, the occurrence of seismicity patterns can be studied with reasonable statistics. The main ingredients of such models are the geometry of a fault region, empirically known constitutive laws, spatial heterogeneities, and stress and displacement functions following dislocation theory [20,47]. In order to allow for detailed studies of the relations between the imposed mechanisms and the observed seismicity functions, it is important that the number of adjustable parameters is limited.

It is emphasized that these models do not aim to reproduce an observed earthquake catalog in detail. Instead, the main goal is to address questions like: Why is the Parkfield segment of the San Andreas fault characterized by relatively regular occurrence of earthquakes with magnitude  $M \approx 6$ , while on the San Jacinto fault in California the properties of earthquake occurrence are more irregular? Basic models for seismicity are mainly based on one or more solid blocks, which are driven by a plate over a sliding surface. The plate and the blocks are connected with springs. This model can generate stick-slip events considered to represent earthquakes. The slider-block models can produce a wide range of complexity, beginning with a single block model leading to periodic occurrence of events of uniform size, and progressing to an array of connected blocks [18] leading to complex sequences of events with variable size. In order to reduce the computational effort cellular automata are commonly used [42,48]. Mathematically, these models include maps instead of differential equations; physically, this corresponds to instantaneously occurring slip events, neglecting inertia effects.

The main ingredients of slider-block and cellular automaton models are (1) external driving (plate motion), and (2) sudden local change of system parameters (stress), when a critical value (material strength) is reached, followed by an avalanche of block slips (stress drop and coseismic stress transfer during an earthquake). While the first process lasts for years to several hundred years, the second occurs on a time scale of a few seconds. The simplest model including these features has been formulated by Reid [52] and is known as *Reid's elastic rebound theory*; in terms of slider-block models, this corresponds to a single block model with constant plate velocity. Accounting for spatial heterogeneity and fault segmentation, many interacting blocks, or fault segments, have to be considered. This leads to a spatiotemporal stress field instead of a single stress value. In general, the material strength will also become space-dependent. Such a model framework can be treated with the methodology of statistical physics similar to the Ising model or percolation models [43]. In this context, large earthquakes are associated with second-order phase transitions [2,59,64]. The view of earthquakes as phase transitions in a system with many degrees of freedom and an underlying critical point, is hereinafter referred to as the “critical point concept”. The period before such a phase transition is expected to be characterized by a preparation process including development of power laws and growing spatial correlation length [14]. However, depending on the parameters of a model, different situations are conceivable: the system trajectory can enter the critical state and the critical point frequently (“supercritical”) or it may never become critical (“subcritical”). A case of special interest is the class of models [2] showing *self-organized criticality* (SOC), which have their origin in a simple cellular automaton model for a sandpile [3]. In this case the system drives itself permanently to the vicinity of the critical point with almost scale-free characteristics. Consequently, each small event can grow into a large earthquake with some probability [28].

Long simulations of earthquake activity can be used to calculate statistical features like the recurrence time distribution of large earthquakes and the frequency-size distribution with high precision. Despite the scaling behavior (Eq. (1)) in the earthquake magnitudes for small and intermediate earthquakes, which is observed for many sets of model parameters, clear deviations become visible for large magnitudes. Such deviations are known from real catalogs, but their statistical significance is not clear in all cases. The model simulations suggest that deviations from scaling for strong earthquakes can be attributed to physical properties. One important property is the spatial disorder of brittle parameters of the fault. The presence

of strong heterogeneities suppresses system-wide events with some probability, whereas such events can evolve more easily on smooth faults. The degree of quenched (time-independent) spatial heterogeneity turns out to be a key parameter for statistical and dynamical properties of seismicity [5,12,80]. This includes the temporal regularity of mainshock occurrence, various properties of the stress and displacement fields, and a spontaneous mode-switching between different dynamical regimes without changing parameters. The degree of heterogeneity can act as a tuning parameter that allows for a continuous change of the model dynamics between the end-member cases of supercritical and subcritical behavior. Such a dependence, which is observed also for other parameters, can be visualized in phase diagrams similar to the phase diagram for the different aggregate states of water [22,79,80]. For increasing complexity of a model, the number of axes of the phase diagram, representing the relevant model parameters, will increase. The above mentioned question of distinguishing different faults like the Parkfield segment and the San Jacinto fault can be rephrased as the problem of assigning the faults to different regions in such a diagram. An important step in this direction is the physical modeling of observed seismicity patterns, including universal patterns like aftershocks (Eq. (2)), common fluctuations like foreshocks and the acceleration of seismic energy release before large earthquakes. The latter phenomenon which sometimes occurs over large regions including more than one fault, can be interpreted in terms of the approach towards a critical point. This view is supported by an observational study of the growth of the spatial correlation length which is a different aspect of the same underlying physics [73,75,76,77].

The establishment of relationships between model parameters and observational features may be used to tune the model towards a specific fault zone, and use the tuned fault model for practical applications of seismic hazard estimations. Toward this end the recurrence time distribution of large earthquakes is needed. Since observational data records are often short and noisy, the use of Bayesian probability theory is helpful for the estimation of uncertain model parameters, and the incorporation of various types of observational data in seismic hazard estimations. The Parkfield segment, as one of the best monitored seismically-active regions, serves as an excellent natural laboratory for such a case study. A discussed example illustrates how partially known parameters like the stress drop and the seismic hazard can be estimated by combining numerical models and observational data [74].

In Section “**Modeling Seismicity in Real Fault Regions**”, the physical fault model used for the discussed studies is described. Results from numerical simulations

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 1  
Sketch of the fault model framework

are presented in Sect. “Results”. A summary is given in Sect. “Summary and Conclusions”.

### Modeling Seismicity in Real Fault Regions

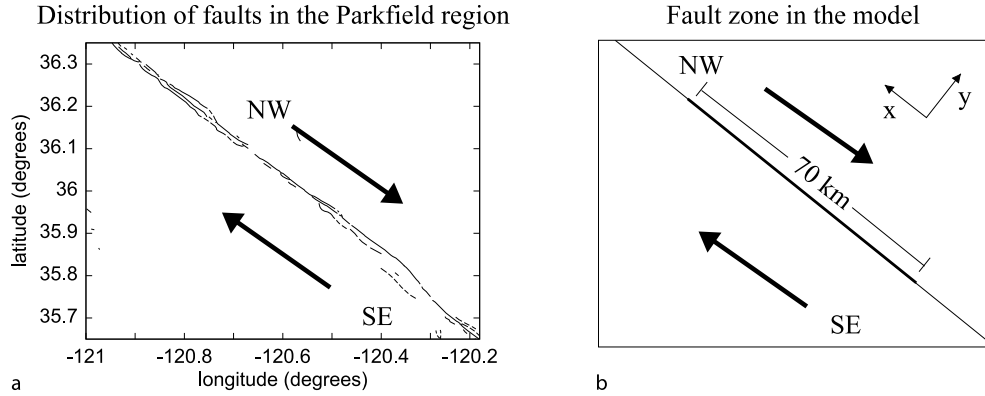

Numerous frameworks have been used to simulate seismicity (see e.g. [6,9,10,18,32,37,48] and references therein). These include slider-block models, cellular automata, “inherently discrete” fault models where the discreteness is an inherent feature of the imposed physics, and continuum models. In this section we illustrate how a fault model (Fig. 1) can be adjusted in order to simulate seismicity of a real fault region, e.g. the Parkfield segment of the San Andreas fault in California.

### Fault Geometry and Model Framework

A first constraint for a specific model is to represent the geometry of the fault segment. As shown in Fig. 2, the region of Parkfield is characterized by a distribution of fault segments, which have generally the same orientation. It is therefore reasonable to map these segments in the model on a plane intersecting the surface at a straight line from SE to NW. The dimensions of the fault segment for modeling (Fig. 1) are chosen to be 70 km in length and 17.5 km in depth. As discussed in [10], this geometry corresponds approximately to the San Andreas fault near Parkfield. The entire fault is an infinite half-plane, but the brittle processes are calculated on the above rectangular section referred to below as the computational grid. The computational grid is discretized to  $128 \times 32$  cells of uniform size, where stress and slip are calculated. The size of the cells is

not related here to observations; rather it depends on the magnitude range under consideration and the computational effort. The failure of a single cell defines the lowest magnitude. A higher resolution of the grid with same overall dimensions increases the magnitude range, because the magnitude is calculated from the slip of all cells during an earthquake. Following Ben-Zion and Rice [10], the material surrounding the fault is assumed to be a homogeneous elastic half space, which is characterized by elastic parameters and a related Green’s function:

1. The elastic properties are expressed by the Lamé constants  $\lambda$  and  $\mu$ , which connect stress and strain in Hooke’s law. For many rocks, these constants are almost equal; therefore we use  $\lambda = \mu$  with  $\mu$  being the rigidity. An elastic solid with this property is called a *Poisson solid*. Because the strain is dimensionless,  $\mu$  has the same dimension as the stress. In the present study, we use  $\mu = 30$  GPa.
2. The (static) Green’s function  $G(\vec{y}_1, \vec{y}_2)$  defines the static response of the half space at a position  $\vec{y}_1$  to a displacement at  $\vec{y}_2$ , which may arise from (coseismic) slip or (aseismic) creep motion. Due to the discretization of the fault plane into computational cells, we use the Green’s function for static dislocations on rectangular fault patches of width  $dx$  and height  $dz$ , which is given in [20] and [47]. The main difference between this Green’s function and the nearest-neighbor interaction of most slider-block models and cellular automata is the infinite-range interaction following a decay according to  $1/r^3$ , where  $r$  is the distance between source cell and receiver point.

**a** Distribution of faults in the Parkfield (California) region; **b** fault region in the model

### Interseismic Processes

The motion of the tectonic plates, indicated in Fig. 2, is responsible for the build-up of stress in the fault zone. Geodetic measurements of surface displacements provide estimates of the velocity of the plates. For the San Andreas fault, a value of  $v_{pl} = 35$  mm/year as a long-term average [55] is widely accepted and is adopted for the model. The displacement  $du$  in the regions surrounding the grid during a time period  $\Delta t$  is simply  $du = v_{pl} \cdot \Delta t$ . While the average slip rate  $\dot{u}$  is independent of the location of a cell, the stress rate  $\dot{\tau}$  depends on space. The assumption that the computational grid is embedded in a half-plane which undergoes constant creep, implies that cells at the boundaries of the grid experience higher load than cells in the center of the grid. The Green's function  $G(i, j; k, l)$  defines the interaction of points  $(i, j)$  and  $(k, l)$  in the medium. In particular, the stress response at a position  $(i, j)$  to a static change of the displacement field  $du(k, l)$  is given by

$$d\tau(i, j) = - \sum_{(k, l) \in \text{half space}} G(i, j; k, l) \cdot du(k, l), \quad (3)$$

where the minus sign stems from the fact that forward (right-lateral) slip of regions around a locked fault segment is equivalent to back (left-lateral) slip of the locked fault segment. Taking into account that

$$\sum_{(k, l) \in \text{half space}} G(i, j; k, l) = 0, \quad (4)$$

Eq. (3) can be written as

$$\tau(i, j; t) = - \sum_{(k, l) \in \text{half space}} G(i, j; k, l) \cdot [u(k, l; t) - v_{pl}t], \quad (5)$$

where  $u(k, l; t)$  is the total displacement at position  $(k, l)$  and time  $t$  since the start of the simulation. Because the surrounding regions sustain stable sliding,  $u(k, l; t) = v_{pl}t$  for  $(k, l) \notin \text{grid}$ , the slip deficit outside the fault region vanishes and it is sufficient to perform the summation on the computational grid:

$$\tau(i, j; t) = \sum_{(k, l) \in \text{grid}} G(i, j; k, l) \cdot [v_{pl}t - u(k, l; t)]. \quad (6)$$

Equation (6) can be decomposed to a part for the tectonic loading and a residual part for slip on the computational grid. The tectonic loading follows the formula

$$\tau_{\text{load}}(i, j; t) = \gamma(i, j) \cdot t \quad (7)$$

with a space-dependent but time-independent loading rate

$$\gamma(i, j) = v_{pl} \cdot \sum_{(k, l) \in \text{grid}} G(i, j; k, l). \quad (8)$$

The build-up of stress may be reduced by aseismic creep motion, which is implemented by a local constitutive law corresponding to lab-based dislocation creep [5]:

$$\dot{u}_{\text{creep}}(i, j; t) = c(i, j) \cdot \tau^3(i, j; t) \quad (9)$$

with space dependent but time-independent creep coefficients  $c(i, j)$ .

### Friction and Coseismic Stress Transfer; Quasidynamic Approach

It is widely accepted that earthquakes on large faults are due to frictional processes on pre-existing structures. The friction is therefore an important empirical ingredient of a fault model [56]. Numerous laboratory experiments

have been carried out to characterize frictional behavior of different materials (see e.g. [19]). An important finding is that the friction coefficient defined as the ratio of shear stress  $\tau_{\text{shear}}$  and compressional normal stress  $\tau_{\text{normal}}$ ,  $\mu_f = \tau_{\text{shear}}/\tau_{\text{normal}}$  at the initiation of slip is approximately constant for many materials; the value of  $\mu_f$  lies between 0.6 and 0.85. This observation, known as *Byerlee's law*, is related to the Coulomb failure criterion [16] for the Coulomb stress CS,

$$CS = \tau_{\text{shear}} - \mu_f \tau_{\text{normal}}. \quad (10)$$

The Coulomb stress depends on a plane where shear stress and normal stress are calculated. Neglecting cohesion, the Coulomb criterion for brittle failure is

$$CS \geq \tau_0, \quad (11)$$

which for  $CS = 0$  is Byerlee's law.

The North-American plate and the Pacific plate move in opposite directions along the fault plane having strike-slip motion. The absence of normal and thrust faulting reduces the problem to a one-dimensional motion: all parts of the fault move along the fault direction. The stress state of the fault is fully determined by the shear stress  $\tau_{xy}$  in the coordinates given in Fig. 2b. Slip is initiated if  $\tau_{xy}$  exceeds  $\mu_f \tau_{yy}$ . This quantity, which is called the static strength  $\tau_s$  is constant in time if  $\mu_f$  is assumed to be constant. Note that the normal stress on a planar fault in a homogeneous solid does not change [1]. The shear stress  $\tau_{xy}$  will be denoted simply by  $\tau$ . In this notation, the failure criterion Eq. (11) reduces to

$$\tau \geq \tau_s. \quad (12)$$

When a cell  $(k, l)$  fails, the stress drops in this cell to the arrest stress  $\tau_a$ :

$$\tau(k, l) \rightarrow \tau_a, \quad (13)$$

where the value  $\tau_a$  maybe space-dependent. The stress change produces a corresponding slip

$$du(k, l) = \frac{\tau(k, l) - \tau_a}{G(k, l; k, l)} \quad (14)$$

with the self-stiffness  $G(k, l; k, l)$  of cell  $(k, l)$ .

The observational effect of dynamic weakening includes also a strength drop from the static strength to a lower dynamic strength:

$$\tau_s \rightarrow \tau_d. \quad (15)$$

In particular, slipping material becomes weaker during rupture and recovers to the static level at the end of the

rupture. This approximation of the strength evolution is known as static-kinetic friction.

The values  $\tau_s$ ,  $\tau_d$ , and  $\tau_a$  are connected by the dynamic overshoot coefficient  $D$ :

$$D = \frac{\tau_s - \tau_a}{\tau_s - \tau_d}, \quad (16)$$

or alternatively by the dynamic weakening coefficient  $\varepsilon$ :

$$\varepsilon = 1 - \frac{\tau_d}{\tau_s}. \quad (17)$$

Following [10] we use in most simulations  $D = 1.25$ .

The redistribution of the stress release  $\Delta\tau(k, l) = \tau(k, l) - \tau_a$  from cell  $(k, l)$  to a point  $(i, j)$  at time  $t$  is

$$d\tau(i, j; t) = G(i, j; k, l) \cdot \delta\left(t - \frac{r(i, j; k, l)}{v_s}\right) \cdot \frac{\Delta\tau(k, l)}{G(k, l; k, l)}, \quad (18)$$

where  $\delta(x)$  denotes the  $\delta$ -function, which is 1 for  $x = 0$  and 0 else;  $v_s$  is the shear-wave velocity, and  $r(i, j; k, l)$  is the distance between source cell  $(k, l)$  and receiver position  $(i, j)$ . That is, regions far from the slipping cell receive their stress portion later than regions close to the slipping cell. The value of  $v_s$  is assumed to be constant. Each "stress transfer event" associated with Eq. (18) gives a transfer of a stress  $d\tau$  from a source cell  $(k, l)$  to a receiver cell  $(i, j)$  at time  $t$ . This time-dependent stress transfer is called the *quasidynamic* approach in contrast to the *quasistatic* approach used in most similar models.

The evolution of stress and strength in a failing cell is shown schematically in Fig. 3. When the slip is initiated, both the stress and the strength drop. Due to coseismic stress transfer during the event, the cell may slip several times before the earthquake is terminated and instantaneous healing takes place in all cells. The piecewise constant failure envelope (dashed line) indicates static-kinetic friction. A model version with gradual healing was employed by [79]. A review of analytical results associated with the basic model in the context of a large universality class is given in ► [Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of.](#)

We note that the Green's function leads to an infinite interaction range. Using open boundary conditions with respect to the computational grid, the stress release from a slipping cell is not conserved on the grid, but on the infinite half plane.

## Data

The model produces two types of data, earthquake catalogs and histories of stress and displacement fields. As demon-

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 3  
Pictorial evolution of stress (solid line) and strength (dashed line) of a hypocenter cell in the quasidynamic approach

strated below, all parameters of the model have physical dimensions and can therefore be compared directly with real data, where they are available. This is in contrast to most of the slider-block and cellular automaton models.

Earthquake catalogs include values of the earthquake time, hypocenter, and size. The time of an earthquake is the time of the first slip; the hypocenter is determined by the position of the corresponding cell along strike and depth. The size of an event can be described by different measures: The rupture area  $A$  is the total area, which slipped during an earthquake. The potency

$$P = \int u(A)dA \quad (19)$$

measures [7] the total slip during the event and is related to the seismic moment  $m_0$  by the rigidity:  $m_0 = \mu P$ . The (moment) magnitude  $M$  can be calculated from the potency [10] using

$$M = (2/3) \log_{10}(P) + 3.6, \quad (20)$$

where  $P$  is given in  $\text{cm} \cdot \text{km}^2$ .

## Results

Numerous simulations of the model described in the previous section have been performed. Firstly, simulations have been examined with respect to the spatiotemporal propagation of stress during single earthquakes (“rupture histories”). Then, long deformation histories have been simulated in order to search in a large fraction of the parameter space for relationships between input parameters and observed seismicity features. In this section, a selection of key results is presented and discussed in relation to critical states of seismicity.

## Rupture Histories

We compare qualitatively rupture histories of large earthquakes for three end-member cases in parameter space:

- (1) a smooth fault,
- (2) a rough fault, and
- (3) a fault without dynamic weakening ( $\tau_d = \tau_s$  or  $D \rightarrow \infty$  in Eq. (16)).

Following [5], we vary the degree of quenched spatial disorder for a particular realization by introducing barriers of high stress drop  $\tau_s - \tau_a$  in an environment of low stress drop.

The observation that smooth faults show a more regular earthquake occurrence than rough faults, can be explained by the ability of the stress field to synchronize on certain fault patches. On a disordered fault, this type of synchronization is unlikely. Figure 4a shows the stress field (normalized between 0 and 1) immediately before a large earthquake on a smooth fault. The most striking feature is the emergence of clearly defined patches with highly loaded boundaries. During rupture evolution, these patches rupture almost in series until the fault is nearly unloaded (see Fig. 4b–f). A different situation is shown in Fig. 5, corresponding to a rough fault with creep coefficients  $c(i, j)$  (Eq. (9)) that increase with depth leading to a brittle-ductile transition zone as in [5] and [80]. Here the stress field in the brittle regime is irregular without obvious pattern formation. Similar behavior is found in a case where dynamic weakening is switched off ( $D \rightarrow \infty$ ); in other words, the material heals instantaneously. Figure 6 shows the stress field in this case. In analytical studies, it has been shown that this corresponds exactly to a critical point in a phase diagram spanned by the stress dissipation and dynamic weakening [22,27]. Observational results indicate [68] that irregular slip histories and power

Snapshots of rupture evolution for a system-wide event on a smooth fault without creep motion.  $t$  denotes the time after the rupture initiation (given in units of the total earthquake duration  $t_{EQ}$ ). The white circle is the hypocenter of the event. The figure shows the dimensionless stress state  $\hat{\tau} = \frac{\tau - \tau_a}{\tau_s - \tau_a}$  of the cells. **a**  $t/t_{EQ} = 1/6$ ; **b**  $t/t_{EQ} = 2/6$ ; **c**  $t/t_{EQ} = 3/6$ ; **d**  $t/t_{EQ} = 4/6$ ; **e**  $t/t_{EQ} = 5/6$ ; **f**  $t/t_{EQ} = 1$

law frequency-size distributions are associated with geometrically disordered fault structures, while characteristic earthquake statistics and overall regular ruptures are found on mature fault with large total displacements.

Although the stress field shows a complex evolution during a simulation, the presence or absence of characteristic length scales indicating the relation to a critical point is easily detected. From an observational point of view, the stress field is not accessible. The evolution of the displacement field may be estimated, e. g. from seismic and geodetic data using slip inversion techniques. Because of the high uncertainties in the calculated slip histories, a quantitative comparison of the simulated data with “natural” data is questionable. However, general features of the quasidynamic ruptures are quite realistic, e. g. the irregular patterns in Fig. 5 resemble the rupture of the Chi–Chi (Taiwan) earthquake on September 21, 1999 ( $M_w = 7.6$ ) [58].

Later we will show that the frequency-size distribution of earthquakes can serve to some extent as a proxy for the degree of disorder of the stress field. Ben-Zion et al. [12]

discuss additional seismicity functions that may be used as surrogate variables for the stress.

### Frequency–Size Distributions

The frequency-size (FS) distribution is one of the most important characteristics of observed seismicity. For worldwide seismicity, this distribution is given by the Gutenberg–Richter law (Eq. (1)). Figure 7 shows the FS distribution of California seismicity from 1970 to 2004. Here we use the non-cumulative version of Eq. (1), where  $N$  is the number of earthquakes with magnitude between  $M$  and  $M + dM$  with a magnitude bin  $dM = 0.1$ .

For individual fault zones the FS distribution can deviate from Eq. (1), especially for high magnitudes. Examples are given in Fig. 8, which shows the FS distribution of the Parkfield segment (Fig. 8a) and for the San Jacinto fault (Fig. 8b) in California for a time span of 45 years. The distribution of the Parkfield segment consists of two parts: A scaling regime for  $2.2 \leq M \leq 4.5$  and a “bump” for  $4.5 < M \leq 6.0$ . For the San Jacinto fault, the scaling range

 Same as Fig. 4 for a strongly disordered fault with a brittle-ductile transition at about 15 km depth. **a**  $t/t_{EQ} = 1/6$ ; **b**  $t/t_{EQ} = 2/6$ ; **c**  $t/t_{EQ} = 3/6$ ; **d**  $t/t_{EQ} = 4/6$ ; **e**  $t/t_{EQ} = 5/6$ ; **f**  $t/t_{EQ} = 1$

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 6  
 Same as Fig. 4a for a fault without dynamic weakening ( $\tau_d = \tau_s$ ) corresponding to a dynamic overshoot coefficient  $D \rightarrow \infty$  (Eq. (16))

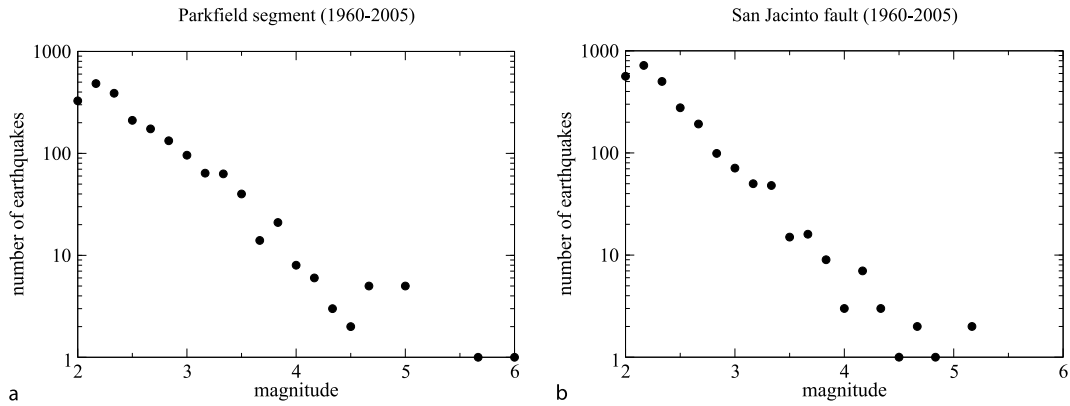

is observed for almost all events ( $2.2 \leq M \leq 5.0$ ). The decrease for  $M \approx 2$  in both plots is probably due to catalog incompleteness.

The FS distribution as shown in Fig. 8a is called the characteristic earthquake distribution, because of the increased probability for the occurrence of large (“characteristic”) events compared to the prediction of the Gutenberg–Richter relation. The latter is an exponential dis-

nitudes [66]. The Gutenberg–Richter relation is “scale-free” because a power law distribution indicates the absence of a characteristic scale of the earthquake size [64]. In terms of critical point processes, the absence of a characteristic length scale indicates that the system is close to the critical point. In this state, earthquakes of all magnitudes can occur, or each small rupture can grow into a large one. Therefore, the frequency-size distribution can serve as a proxy for the current state of a system in relation to a critical point.

The FS distribution in a model can be tuned by varying the mean stress  $\langle \tau \rangle$  on the fault, where  $\langle \rangle$  denotes the spatial average. This can be achieved, for instance, by varying brittle properties, e.g. in terms of the dynamic overshoot coefficient  $D$  (Eq. (16)), or by introducing dissipation [31,79]. Figure 9 shows FS distributions for two different values of  $D$ :  $D = 5/4$  (Fig. 9a) and a higher value  $D = 5/3$  (Fig. 9b). While Fig. 9a follows a characteristic

earthquake behavior similar to the Parkfield case (Fig. 8a), Fig. 9b resembles the shape of the FS distribution of the San Jacinto fault (Fig. 8b).

As an outcome, three cases can be distinguished by means of a critical mean stress  $\tau_{\text{crit}}$ :

1. subcritical fault ( $\langle \tau \rangle < \tau_{\text{crit}}$ ): the mean stress on the fault is too small to produce large events. The system is always far from the critical point. The FS distribution is a truncated Gutenberg–Richter law.
2. supercritical fault ( $\langle \tau \rangle > \tau_{\text{crit}}$ ): the mean stress is high and produces frequently large events. After a large earthquake (critical point), the stress level is low (system is far from the critical point) and recovers slowly (approaches the critical point). The FS distribution is a characteristic earthquake distribution.
3. critical fault ( $\langle \tau \rangle \approx \tau_{\text{crit}}$ ): the system is always close to the critical point with scale-free characteristics. The FS

Phase diagram for the frequency-size distribution (GR=Gutenberg-Richter distribution, CE=characteristic earthquake distribution) spanned by the degree of quenched spatial disorder and the dynamic weakening represented by  $\varepsilon$ . The upper left corner corresponds exactly to a critical point [22,27] and results in scale-free characteristics as shown in Fig. 6

distribution is a Gutenberg-Richter law with a scaling range over all magnitudes.

If the FS distribution is plotted as a function of the model parameters, the result can be visualized by a phase diagram [22,31,79,80]. An example is provided in Fig. 10, which shows schematically the phase diagram spanned by the degree of quenched spatial disorder and  $1 - \varepsilon$  with the dynamic weakening coefficient  $\varepsilon$  (Eq. (17)). The phase diagram summarizes results from various studies, which demonstrate that the degree of spatial disorder of the stress drop acts as a tuning parameter for the FS distribution [5,36,80].

If the model is in the transition regime between Gutenberg-Richter statistics and characteristic earthquake behavior, the ability of the stress field to synchronize on parts of the fault can have additional impact on the dynamics of seismicity: for a model with small cells and high stress fluctuations along the cell boundaries arising from a high degree of spatial disorder, the system can undergo a spontaneous transition from an ordered state and characteristic behavior to a disordered state following Gutenberg-Richter statistics. Due to the high fluctuations in the stress field, there is some probability that a certain number of cells synchronize by chance, leading to an ordered behavior for some seismic cycles, until the order is destroyed, again resulting from stress fluctuations. This type of mode-switching behavior has been observed earlier in a mean-field model and a damage rheology model [11,22]. Figure 11a gives a corresponding earthquake sequence with spontaneous mode-switching behavior. Figure 11b shows a sequence calculated with a higher grid resolution ( $128 \times 50$  cells). The tendency to mode-switching is less pronounced, but still visible. In [79] it is shown that the emergence of such mode-switching depends both on the spatial range of interaction (given as the decay of the Green's function) and the discretization of the computational grid. In the less realistic model of [22], where the stress redistribution is governed by a constant (space-independent) Green's function, analytical expressions for persistence times have been calculated [27]. In [11] some evidence for mode-switching behavior in long seismic records based on paleoseismic and geologic data from the Dead Sea fault and other regions are discussed. However, the relevance of mode-switching to natural seismicity remains unclear due to the general lack of very long data records.

### Aftershocks and Foreshocks

The most pronounced temporal pattern in observed seismicity is the emergence of strongly clustered aftershock activity following a large earthquake. Apart from the Omori–Utsu law (Eq. (2)), it is widely accepted that aftershocks are characterized by the following properties:

1. The aftershock rate scales with the mainshock size [51].
2. Aftershocks occur predominantly around the edges of the ruptured fault segments [66].
3. Båth's law [4]: The magnitude of the largest aftershock is usually about one unit smaller than the mainshock magnitude.

Deviations from the Omori–Utsu law, especially for rough faults, are discussed in [45]. While aftershocks are observed after almost all large earthquakes, foreshocks occur less frequent [71]. As a consequence, much less is known about the properties of these events. Kagan and Knopoff [40] and Jones and Molnar [39] propose a power law increase of activity according to an “inverse” Omori–Utsu law.

Figure 12a shows an example for the aftershock sequence following the  $M7.3$  Landers earthquake in California on June 28, 1992. An earthquake of similar size generated by the model is given in Fig. 12b. The absence of aftershocks in the simulation is clearly visible. The reason for the lack of aftershocks is the unloading of the fault resulting from the mainshock: When a large fraction of the fault has ruptured, the stress in this region will be close to the arrest stress after the event. Consequently, the seismicity rate will be almost zero until the stress field has recovered to a moderate level.

Discussions for likely mechanisms of aftershocks are given in [9] and [81]. A common feature is the presence of rapid postseismic stress which generates aftershock activity. In [32], for instance, postseismic stress has been attributed to a viscoelastic relaxation process following the mainshock. In the work discussed here, continuous creep displacement following Eq. (9) is assumed. Additionally, the computational grid is divided by aseismic barriers from the free surface to depth into several seismically active fault segments. As shown in [81], this modification results in a concentration of stress in the aseismic regions during rupture and, subsequently in a release of stress after the event according to the coupled creep

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 13  
 Earthquakes before and after a mainshock with  $M = 6.8$  in the modified model

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 14

Earthquake rate as a function of time for the model with seismic and aseismic regions. The calculation is based on a simulation with 200,000 earthquakes covering about 5000 years; the earthquake rates are averaged over about 300 mainshocks. A fit of the Omori-Utsu law (Eq. (2)) with  $p = 1$  is denoted as a solid line. The dashed line gives the estimated background level of seismicity

process. This stress release triggers aftershock sequences obeying the Omori-Utsu law (Eq. (2)). A typical aftershock sequence after a  $M_{6.8}$  event is shown in Fig. 13. In agreement with Båth's law, the strongest aftershock has the magnitude  $M = 5.5$  in this sequence. The sequence shows also the effect of secondary aftershocks, namely aftershocks of aftershocks [61]. The stacked earthquake rate as a function of the time after the mainshock is given in Fig. 14. In this case, where the barriers are characterized by creep coefficients higher by a factor of  $10^5$  than in the other patches, a realistic Omori exponent of  $p = 1$  is found.

Aftershock sequences like in Fig. 13 emerge after all large events in the extended model. In contrast, there is generally no clear foreshock signal visible in single sequences. However, stacking many sequences together unveils a slight increase of the earthquakes rate prior to a mainshock supporting the observation of accelerating foreshock activity. An explanation of these events can be given in the following way: Between two mainshocks the stress field organizes itself towards a critical state, where the next large earthquake can occur. This critical state is characterized by a disordered stress field and the absence of a typical length scale, where earthquakes of all sizes can occur [12]. The mainshock may occur immediately or after some small to moderate events. The latter case can be considered as a single earthquake, which is interrupted in the beginning. This phenomenon of delayed rupture propagation has also provided a successful explanation of foreshocks and aftershocks in a cellular automaton model [33,35].

The hypothesis that foreshocks occur in the critical point and belong, in principle, to the mainshock, can be verified by means of the findings from Subsect. "Frequency-Size Distributions". In particular, the frequency-size distribution in the critical point (or close to the

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 15

Frequency-magnitude distributions of all earthquakes, foreshocks and aftershocks. Foreshocks and aftershocks are defined as earthquakes occurring within one month before and after an earthquake with  $M \geq 6$

critical point) is expected to show scale-free statistics. If an overall smooth fault model following characteristic earthquake statistics is studied over a long time period, the approach of the critical point should be seen in terms of a change of the frequency-size distribution towards Gutenberg-Richter behavior [12]. This change of frequency-size statistics is indeed observed in the model (Fig. 15) and supports the validity of the critical point concept [82].

### Accelerating Moment Release

In the previous section, it has been argued that large earthquakes are associated with a critical point and the prepa-

ration process is characterized by increasing disorder of the stress field and increasing tendency for scale-free characteristics in the frequency-size distribution. Further support for critical point dynamics has been provided by the observational finding of [17] that the cumulative Benioff strain  $\Sigma \Omega(t)$  follows a power law time-to-failure relation prior to the *M*7.1 Loma Prieta earthquake on October 17, 1989:

$$\Sigma \Omega(t) = \sum_{i=1}^{N(t)} \sqrt{E_i} = A - B(t_f - t)^m \tag{21}$$

Here,  $E_i$  is the energy release of earthquake  $i$ ,  $N(t)$  is the number of earthquakes before time  $t$ ;  $t_f$  is the failure time and  $A$ ,  $B$ , and  $m > 0$  are constants. Similar studies for numerous seismically active regions followed (see [8,77] and references therein).

The time-to-failure relation Eq. (21) has been explained by [54] and [60] from the viewpoint of renormalization theory and by [8] and [65] in terms of damage rheology. Similar to the findings about foreshocks, the time-to-failure pattern is not universal. Therefore, a stacking procedure is adopted in order to obtain robust results on the validity of Eq. (21) in the model. This is not straightforward, since the interval of accelerating moment release is not known a priori and the duration of a whole seismic cycle, as an upper limit, is not constant. To normalize the time interval for the stacking, the potency release (Eq. (19)) is computed as a function of the (normalized) stress level (Fig. 16). Taking into account that the stress level increases almost linearly during a large fraction of

the seismic cycle, the stress level axis in Fig. 16 can effectively be replaced by the time axis leading to a power law dependence of the potency release on time. The best fit is provided with an exponent  $s = -1.5$ . Transforming the potency release to the cumulative Benioff strain (Eq. (21)), results in an exponent  $m = 0.25$  in Eq. (21). This finding is based on a simulation over 5000 years; the exponent is in good agreement with the theoretical work [53], that derives  $m = 0.25$  for a spinodal model, and the analytical result of  $m = 0.3$  in the damage mechanics model [8]. An observational study of California seismicity finds  $m$  between 0.1 and 0.55 [15].

### Interevent Times

In recent studies it has been shown that the distribution of interevent times can be described by a universal law. In particular, the distributions from different tectonic environments, different spatial scales (from worldwide to local seismicity) and different magnitude ranges collapse if the time  $\Delta t$  is rescaled with the rate  $R_{xy}$  of seismic occurrence in a region denoted by  $(x, y)$  [21]. Such rescaling leads to

$$D_{xy}(\Delta t) = R_{xy} \cdot f(R_{xy} \Delta t), \tag{22}$$

where  $D_{xy}$  is the probability density for the interevent time  $\Delta t$ , and  $f$  can be expressed by a generalized gamma distribution

$$f(\theta) = C \frac{1}{\theta^{\gamma-1}} \exp\left(-\frac{\theta^\delta}{B}\right). \tag{23}$$

The parameters  $C$ ,  $\gamma$ ,  $\delta$ , and  $B$  have been determined by a fit to several observational catalogs [21].

In Fig. 17 we compare  $D_{xy}(\Delta t)$  from Eq. (22) with two earthquake catalogs: (1) The ANSS catalog of California (catalog ranges are given in the caption), and (2) the model catalog. Due to the universality of Eq. (22) with respect to different spatial scales, the comparison of the model simulating a single fault of 70 km length with a region of hundreds of kilometers including several faults in California does not require coarse graining the ANSS catalog. In the region where the interevent times are calculated, we find a remarkable agreement of the three curves. For small values of  $\Delta t$ , Eq. (22) deviates from the California data; for high values the model has a slightly better correspondence with the observational data than Eq. (22). Thus the results generally support the recent findings of [21].

The degree of temporal clustering of earthquakes can be estimated by the coefficient of variation  $CV$  of the interevent time distribution.

$$CV = \sigma/\mu, \tag{24}$$

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 16  
**Mean potency release (Eq. (19)) as a function of the stress level. The stress level is normalized to the maximum (max) and minimum (min) observed stress**

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 17

The normalized interevent time distribution of the model simulations (black dots) compared with the result of [21] and the distribution of earthquakes in California (ANSS catalog of  $M \geq 3$  earthquakes occurred between 1970 and 2004 within  $29^\circ$  and  $43^\circ$  latitude and  $-113^\circ$  and  $-123^\circ$  longitude)

where  $\sigma$  is the standard deviation and  $\mu$  the mean value of the interevent time distribution. Values of  $CV > 1$  denote clustered activity, while  $CV < 1$  represents quasiperiodic occurrence of events. The case  $CV = 1$  corresponds to a random Poisson process. The studies of [5] and [80] have found that the clustering properties of the large events depend on the degree of quenched spatial disorder of the fault. Figure 18 shows that  $CV$  as a function of the lower magnitude cutoff has a characteristic shape. The values of  $CV$  are higher than 1 (clustered) for small and intermediate earthquakes ( $M \leq 5.4$ ) and smaller than 1 (quasiperiodic) for larger earthquakes. This corresponds to the case of a low degree of disorder in [80], because the brittle cells which participate in an earthquake have no significant spatial disorder. We note that this behavior resembles the seismicity on the Parkfield segment of the San Andreas fault, which is characterized by a quasiperiodic occurrence of mainshocks. Based on the analysis of 37 earthquake sequences, an estimation of  $CV \approx 0.5$  has been found for multiple tectonic environments [26].

A different behavior is observed on the San Jacinto fault in California, where the largest events occur less regularly and have overall smaller magnitudes. As discussed in [5] and [80], this can be modeled by imposing higher degrees of disorder leading to a broader range of spatial size scales, e. g. by using a higher number of near-vertical barriers. While barriers provide a simple and physically motivated way to tune the degree of disorder, other types of heterogeneities may work as well, as long as they are

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 18

The temporal earthquake occurrence quantified by the coefficient of variation as a function of the lower magnitude cutoff. Values larger than 1 indicate clustering, whereas lower values point to quasiperiodic behavior

able to produce strong enough fluctuations of the stress field. As an example, we mention fractal distributions of the stress drop, which can be tuned easily by changing the fractal dimension [63,80].

### Recurrence Times of Large Earthquakes

While interevent times are waiting times between successive earthquakes in a given catalog, recurrence times are defined as waiting times between two successive *large* events, typically in the magnitude range  $6 \leq M \leq 9$ , depending on the region. For example, on the Parkfield segment of the San Andreas fault seven  $\sim M6$  earthquakes occurred between 1857 and 2004 with recurrence times  $T_1 = 24$  years,  $T_2 = 20$  years,  $T_3 = 21$  years,  $T_4 = 12$  years,  $T_5 = 32$  years, and  $T_6 = 38$  years.

The distribution of recurrence times of large earthquakes is crucial for the calculation of seismic hazard. Due to a lack of observational data, this distribution is unknown for real fault systems. Commonly used distributions are based on extreme value statistics and on models for catastrophic failure. These include the lognormal distribution [50], the Brownian passage time distribution [44], and the Gumbel distribution [29]. All distributions are characterized by a maximum for a certain recurrence time followed by an asymptotic decay. The Brownian passage time distribution and the lognormal distribution have been used by the Working Group on California Earthquake Probabilities [70], e. g. for calculating earthquake probabilities in the San Francisco Bay area.

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 19

**a** Approximated probability density function of the recurrence time distribution of large earthquakes ( $M > 6.2$ ) for a simulated earthquake catalog and fit with a truncated Gamma distribution; **b** A posteriori distribution  $P(\Delta\tau|T_1, \dots, T_N)$  of stress drop  $\Delta\tau$  calculated with Bayes' theorem (Eq. (25))

Figure 19a shows the probability density function (pdf) of the recurrence times of earthquakes with magnitude  $M > 6.2$  in a realization of the numerical model for the Parkfield region [74]. Since we focus on long time-scales, we use here a minimal model without aseismic creep and strong spatial heterogeneities. This model leads to characteristic earthquake statistics and quasiperiodic occurrence of large events, and can therefore serve as a model framework for large earthquakes on the Parkfield segment. However, quantities which are only poorly known from empirical data, e.g. the stress drop, have to be chosen in order to perform a numerical simulation. Starting with an imposed uniform a priori distribution  $P(\Delta\tau)$  of stress drops between a lower bound  $\Delta\tau_{\min}$  and an upper bound  $\Delta\tau_{\max}$ , an a posteriori distribution  $P(\Delta\tau|T_1, \dots, T_N)$  can be estimated using observational recurrence times  $T_1, \dots, T_N$  from Parkfield and Bayes' theorem [13],

$$P(\Delta\tau|T_1, \dots, T_N) = \frac{P(T_1, \dots, T_N|\Delta\tau)P(\Delta\tau)}{\sum_{s=\Delta\tau_{\min}}^{\Delta\tau_{\max}} P(T_1, \dots, T_N|s)P(s)}, \quad (25)$$

with the likelihood function

$$P(T_1, \dots, T_N|\Delta\tau) = \prod_{i=1}^N f(T_i|\Delta\tau). \quad (26)$$

The function  $f(T_i|\Delta\tau)$  denotes the pdf of recurrence times simulated with a model stress drop  $\Delta\tau$ . To get an analytic expression of this function, it is fitted by a Gamma distribution  $f(t) = \beta^{-1}(\Gamma(\gamma))^{-1}(\frac{t-\mu}{\beta})^{\gamma-1} \exp(-\frac{t-\mu}{\beta})$  with

the location parameter  $\mu$ , the shape parameter  $\gamma \equiv 2.0$  and the scale parameter  $\beta$  (with  $x \geq \mu$ ;  $\gamma, \beta > 0$ ). For an example see Fig. 19a. In [74] it is shown that the mean value  $\mu_t$  and the standard deviation  $\sigma_t$  of the fits in this model are related to the average stress drop of a large earthquake  $\Delta\tau$  by the simple empirical relations

$$\begin{aligned} \mu_t(\Delta\tau) &= 9.7 \cdot \Delta\tau \\ \sigma_t(\Delta\tau) &= 1.8 \cdot \Delta\tau^2 - 6.8 \cdot \Delta\tau + 11.7 \end{aligned} \quad (27)$$

with  $\mu_t, \sigma_t$  in years and  $\Delta\tau$  in MPa. Using this approximation in combination with six observational recurrence times from  $\sim M6$  earthquakes on the Parkfield segment, we find the a posteriori distribution of stress drops shown in Fig. 19b. The position where this distribution reaches the maximum,  $\Delta\tau = (3.04 \pm 0.27)$  MPa, is the most representative value of the stress drop of  $\sim M6$  Parkfield events.

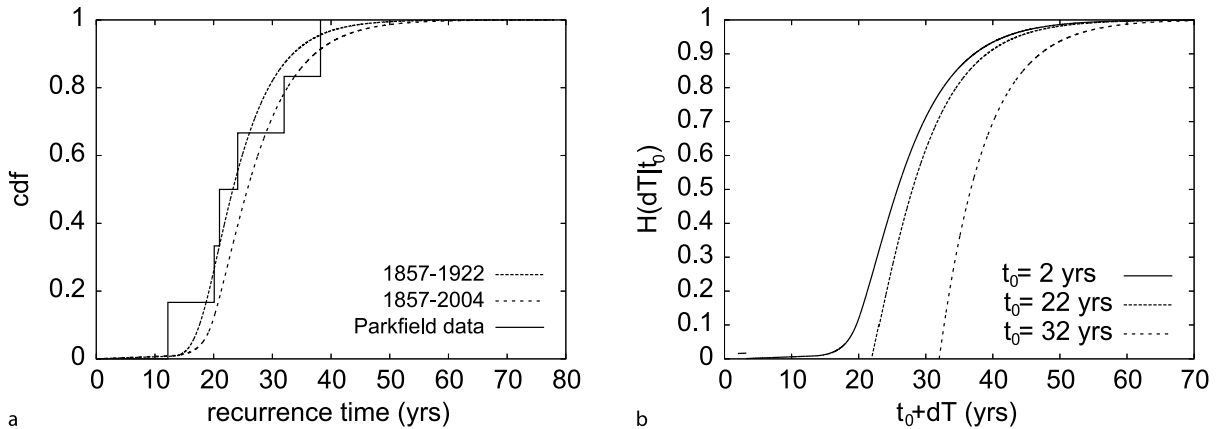

The cumulative probability density function (cdf) of recurrence times based on Eq. (26) and the observational data can now be calculated by

$$C(t) = \int_0^t \int_{\Delta\tau_{\min}}^{\Delta\tau_{\max}} f(t'|\Delta\tau)P(\Delta\tau|T_1, \dots, T_N)d\Delta\tau dt'. \quad (28)$$

The hazard function

$$H(\Delta t|t_0) = \frac{C(t_0 + \Delta t) - C(t_0)}{1 - C(t_0)} \quad (29)$$

is the conditional probability that the next large earthquake occurs in the interval  $[t_0; t_0 + \Delta t]$  given the time  $t_0$  since the last large event. Results for two choices of observational data (corresponding to two different observa-

Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space, Figure 20

**a** Cumulative recurrence time distribution  $C(t)$  (Eq. (28)) for (1) the Bayesian approach with three data points: long-dashed line; (2) the Bayesian approach with six data points: short-dashed line. The solid line denotes the cdf of the six Parkfield recurrence times; **b** Hazard function  $H(t_0|\Delta T)$  (Eq. (29)) based on the six observational recurrence times between 1857 and 2004 a as a function of  $dT$  for different values of  $t_0$

tional periods) in comparison to the Parkfield cdf are given in Fig. 20a. The hazard function for three fixed values of  $t_0$  and varying  $\Delta t$  is given in Fig 20b.

This approach enables us to calculate the most likely occurrence time of the next (post 2004) Parkfield earthquake by picking the maximum of the (non-cumulative) recurrence time distribution (inner integral in Eq. (28)) after taking all Parkfield earthquakes (1857–2004) into account. Based on the analysis done so far, we may forecast the next  $\sim M6$  Parkfield earthquake to occur in May 2027. The error associated with one standard deviation of the pdf is 7.7 years. We note, however, that the probability for the occurrence of a  $\sim M6$  earthquake between May 2026 and May 2028 is only about 14%.

## Summary and Conclusions

The present review deals with the analysis, the understanding and the interpretation of seismicity patterns with a special focus on the critical point concept for large earthquakes. Both physical modeling and data analysis are discussed. This study aims at practical applications to model data from real fault zones. A point of particular interest is the detection of phenomena prior to large earthquakes and their relevance for a possible prediction of these events. Despite numerous reports on anomalous precursory seismicity changes [62], there is no precursor in sight which obeys a degree of universality that would make it practically useful. It is, therefore, important to study less frequent precursory phenomena by means of long model simulations.

Toward this goal, we discuss a numerical model which is on one hand reasonably physical, and on the other hand simple enough that it allows to obtain some analytical results and perform long simulations. The basic version of the model consists of a segmented two-dimensional strike-slip fault in a three-dimensional elastic half space and is inherently discrete because of the abrupt transition from static to kinetic friction [10]. This paper and ► [Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of](#) summarize a large body of analytical and numerical results associated with the model.

The results of the simulations indicate an overall good agreement of the synthetic seismicity with natural earthquake activity, with respect to frequency-size distributions and various features of earthquake sequences. The degree of spatial heterogeneity on the fault, which is implemented by means of space-dependent rheological properties, has important effects on the resulting catalogs. Smooth faults are associated with the characteristic earthquake statistics, regular occurrence of mainshocks and overall smooth stress fields. On the other hand, rough faults generate scale-free Gutenberg–Richter statistics, irregular mainshock occurrence, and overall rough stress fields. A closer look at the disorder of the stress field shows, however, that even on a smooth fault a gradual roughening takes place when the next large earthquake is approached [12,82]. This is reflected in the frequency-size distribution which evolves towards the Gutenberg–Richter law and other changes of seismicity. The results can be used to establish relations between the proximity of a state on a fault to a critical point, the (unobservable)

stress field, and the (observable) seismicity functions. Furthermore, it is demonstrated that the concept of “self-organized criticality” can be folded back to criticality associated with tuning parameters [12,31]. We note that phase diagrams with different dynamic regimes as functions of tuning parameters, in addition to criticality, provide a general and rich description of seismicity. Accelerating seismic release, growing spatial correlation length, changes of frequency-size statistics and evolution of other seismicity parameters may be used to track the approach to criticality [73,75,76,77].

### Future Directions

We have demonstrated that numerical fault models are valuable for understanding the underlying mechanisms of observed seismicity patterns, as well as for practical estimates of future seismic hazard. The latter requires model realizations that are tuned to a specific fault zone by assimilating available observational results and their uncertainties. In a case study, the seismic hazard in the Parkfield region has been estimated by combining such a tuned model with few observational data. The use of Bayesian analysis allows us to construct a flexible hazard model for this region which can, in general, incorporate statistical and non-statistical data (e. g. from paleoseismology and geodesy) to improve and update the estimations of the seismic hazard. This approach is particularly promising for less-well monitored regions, and especially for low-seismicity regions like those in central Europe.

Modification of the stress transfer calculations to account for a statistical preference of earthquake propagation direction on a given fault section, e. g. [6,25], can improve the estimates of seismic hazard associated with large faults. It is also possible to extend the discussed framework to other geohazards with even smaller amount of observational data, e. g. the occurrence of landslides. Since the fault model deals with coupled physical processes leading to interacting earthquakes, a challenging future direction will be the design of a more general model for interacting geohazards including earthquakes on different faults as well as landslides triggered by earthquakes, and perhaps tsunamis initiated by (submarine) earthquakes or landslides.

### Acknowledgments

We thank Jürgen Kurths, James R. Rice, Frank Scherbaum, Karin Dahmen, Donald L. Turcotte, and many others for useful discussions. GZ and MH acknowledge support from the collaborative research center “Complex Non-

linear Processes” (SFB 555) of the German Research Society (DFG). SH acknowledges support from the DFG-project SCHE280/14 and the EU-project SAFER. YBZ acknowledges support from the National Science Foundation, the United States Geological Survey, and the Southern California Earthquake Center. GZ and YBZ thank the Kavli Institute for Theoretical Physics, UC Santa Barbara, for hospitality during a 2005 program on Friction, Fracture and Earthquake Physics, and partial support based on NSF grant PHY99-0794. We thank James R. Holliday, Vladimir Keilis-Borok and Willie Lee for providing comments on the paper.

## Glossary

**Chaos** Chaos occurs in dynamical systems with two ingredients: (i) nonlinear recurrent re-injection of the dynamics into a finite domain in phase space and (ii) exponential sensitivity of the trajectories in phase space to initial conditions.

**Continuous phase transitions** If there is a finite discontinuity in the first derivative of the thermodynamic potential, then the phase transition is termed first-order. During such a transition, a system either absorbs or releases a fixed amount of latent heat (e.g. the freezing/melting of water/ice). If the first derivative is continuous but higher derivatives are discontinuous or infinite, then the phase transition is called continuous, of the second kind, or critical. Examples include the critical point of the liquid–gas transition, the Curie point of the ferromagnetic transition, or the superfluid transition [127,235].

**Critical exponents** Near the critical point, various thermodynamic quantities diverge as power laws with associated critical exponents. In equilibrium systems, there are scaling relations that connect some of the critical exponents of different thermodynamic quantities [32,127,203,216,235].

**Critical phenomena** Phenomena observed in systems that undergo a continuous phase transition. They are characterized by scale invariance: the statistical properties of a system at one scale are related to those at another scale only through the ratio of the two scales

and not through any one of the two scales individually. The scale invariance is a result of fluctuations and correlations at all scales, which prevents the system from being separable in the large scale limit at the critical point [32,203,235].

**Declustering** In studies of seismicity, declustering traditionally refers to the deterministic identification of fore-, main- and aftershocks in sequences (or clusters) of earthquakes clustered in time and space. Recent, more sophisticated techniques, e.g. stochastic declustering, assign to earthquakes probabilities of being triggered or spontaneous.

## Dynamical scaling and exponents

Non-equilibrium critical phase transitions are also characterized by scale invariance, scaling functions and critical exponents. Furthermore, some evidence supports the claim that universality classes also exist for non-equilibrium phase transitions (e.g. the directed percolation and the Manna universality class in sandpile models), although a complete classification of classes is lacking and may in fact not exist at all. Much interest has recently focused on directed percolation, which, as the most common universality class of absorbing state phase transitions, is expected to occur in many physical, chemical and biological systems [85,135,203].

**Finite size scaling** If a thermodynamic or other quantity is investigated at the critical point under a change of the system size, the scaling behavior of the quantity with respect to the system size is known as finite size scaling [32]. The quantity may refer to a thermodynamic quantity such as the free energy or it may refer to an entire probability distribution function. At criticality, the sole length scale in a finite system is the upper cut-off  $s_c$ , which diverges in the thermodynamic limit  $L \rightarrow \infty$ . Assuming a lower cut-off  $s_0 \ll s_c$ , a finite size scaling ansatz for the distribution  $P(s; s_c)$  of the observable variable  $s$ , which depends on the upper cut-off  $s_c$  is then given by:

$$P(s; s_c) = a s^{-\tau} G(s/s_c) \quad \text{for } s, s_c \gg s_0, \quad (1)$$

where the parameter  $a$  is a non-universal metric factor,  $\tau$  is a universal (critical) exponent, and  $G$  is a universal scaling function that decays sufficiently fast for  $s \gg s_c$  [32,36]. Pruessner [163] provides a simple yet instructive and concise introduction to scaling theory and how to find associated exponents. System-specific corrections appear to sub-leading order.

**Fractal** A deterministic or stochastic mathematical object that is defined by its exact or statistical self-similar-

ity at all scales. Informally, it often refers to a rough or fragmented geometrical shape which can be subdivided into parts which look approximately the same as the original shape. A fractal is too irregular to be described by Euclidean geometry and has a fractal dimension that is larger than its topological dimension but less than the dimension of the space it occupies.

**Mean-Field** An effective or average interaction field designed to approximately replace the interactions from many bodies by one effective interaction which is constant in time and space, neglecting fluctuations.

**Mechanisms for power laws** Power laws may be the hallmark of critical phenomena, but there are a host of other mechanisms that can lead to power laws (see Chapter 14 of [203] for a list of power law mechanisms as well as [37,143]). Observations of scale invariant statistics therefore do not necessarily imply SOC, of course. Power laws express the existence of a symmetry (scale invariance) and there are many mechanisms by which a symmetry can be obtained or restored.

**Non-equilibrium phase transitions** In contrast to systems at equilibrium, non-equilibrium phase transitions involve dynamics, energy input and dissipation. Detailed balance is violated and no known equivalent of the partition function exists, from which all thermodynamic quantities of interest derive in equilibrium. Examples of non-equilibrium phase transitions include absorbing state phase transitions, reaction-diffusion models, and morphological transitions of growing surfaces [85,135].

**Phase transitions** In (equilibrium) statistical mechanics, a phase transition occurs when there is a singularity in the free energy or one of its derivatives. Examples include the freezing of water, the transition from ferromagnetic to paramagnetic behavior in magnets, and the transition from a normal conductor to a superconductor [127,235].

**Renormalization group theory** A mathematical theory built on the idea that the critical point can be mapped onto a fixed point of a suitably chosen transformation on the system's Hamiltonian. It provides a foundation for understanding scaling and universality and provides tools for calculating exponents and scaling functions. Renormalization group theory provides the basis for our understanding of critical phenomena [32,216,235]. It has been extended to non-Hamiltonian systems and provides a general framework for constructing theories of the macro-world from the microscopic description.

**Self-organized criticality (SOC)** Despite two decades of research since its inception by [13] and the ambitious

claim by [11] that, as a mechanism for the ubiquitous power laws in Nature, SOC was “How Nature Works”, a commonly accepted definition along with necessary and sufficient conditions for SOC is still lacking [93,163,203]. A less rigorous definition may be the following: Self-organized criticality refers to a non-equilibrium, critical and marginally stable steady-state, which is attained spontaneously and without (explicit) tuning of parameters. It is characterized by power law event distributions and fractal geometry (in some cases) and may be expected in slowly driven, interaction-dominated threshold systems [93]. Some authors additionally require that temporal and/or spatial correlations decay algebraically (e. g. [84], but see [163]). Definitions in the literature range from broad (simply the absence of characteristic length scales in non-equilibrium systems) to narrow (the criticality is due to an underlying continuous phase transition with all of its expected properties) (see, e. g., [162] for evidence that precipitation is an instance of the latter definition of SOC in which a non-linear feedback of the order parameter on the control parameter turns a critical phase transition into a self-organized one attracting the dynamics [198]).

**Spinodal decomposition** In contrast to the slow process of phase separation via nucleation and slow growth of a new phase in a material inside the metastable region near a first-order phase transition, spinodal decomposition is a non-equilibrium, rapid and critical-like dynamical process of phase separation that occurs quickly and throughout the material. It needs to be induced by rapidly quenching the material to reach a sub-area (sometimes a line) of the unstable region of the phase diagram which is characterized by a negative derivative of the free energy.

**Statistical physics** is the set of concepts and mathematical techniques allowing one to derive the large-scale laws of a physical system from the specification of the relevant microscopic elements and of their interactions.

**Turbulence** In fluid mechanics, turbulence refers to a regime in which the dynamics of the flow involves many interacting degrees of freedom, and is very complex with intermittent velocity bursts leading to anomalous scaling laws describing the energy transfer from injection at large scales to dissipation at small scales.

**Universality** In systems with little or no frozen disorder, equilibrium continuous phase transitions fall into a small set of universality classes that are characterized by the same critical exponents and by certain scal-

ing functions that become identical near the critical point. The class depends only on the dimension of the space and the dimension of the order parameter. For instance, the critical point of the liquid–gas transition falls into the same universality class as the 3D Ising model. Even some phase transitions occurring in high-energy physics are expected to belong to the Ising class. Universality justifies the development and study of extremely simplified models (caricatures) of Nature, since the behavior of the system at the critical point can nevertheless be captured (in some cases exactly). However, non-universal features remain even at the critical point but are less important, e. g. amplitudes of fluctuations or system-specific corrections to scaling that appear at sub-leading order [32,216,235,239].

### Definition of the Subject

A fundamental challenge in many scientific disciplines concerns upscaling, that is, of determining the regularities and laws of evolution at some large scale from those known at a lower scale: biology (from molecules to cells, from cells to organs); neurobiology (from neurons to brain function), psychology (from brain to emotions, from evolution to understanding), ecology (from species to the global web of ecological interactions), condensed matter physics (from atoms and molecules to organized phases such as solid, liquid, gas, and intermediate structures), social sciences (from individual humans to social groups and to society), economics (from producers and consumers to the whole economy), finance (from investors to the global financial markets), Internet (from e-pages to the world wide web 2.0), semantics (from letters and words to sentences and meaning), and so on. Earthquake physics is no exception, with the challenge of understanding the transition from the laboratory scale (or even the microscopic and atomic scale) to the scale of fault networks and large earthquakes.

Statistical physics has had a remarkably successful track record in addressing the upscaling problem in physics. While the macroscopic laws of thermodynamics have been established in the 19th century, their microscopic underpinning were elaborated in the early 20th century by Boltzmann and followers, building the magnificent edifice of statistical physics. Statistical physics can be defined as the set of concepts and mathematical techniques allowing one to derive the large-scale laws of a physical system from the specification of the relevant microscopic elements and of their interactions. Dealing with huge ensembles of elements (atoms, molecules) of the order of the Avogadro number ( $\simeq 6 \cdot 10^{23}$ ), statistical physics uses the

mathematical tools of probability theory combined with other relevant fields of physics to calculate the macroscopic properties of large populations.

One of the greatest achievement of statistical physics was the development of the renormalization group analysis, to construct a theory of interacting fields and of critical phase transitions. The renormalization group is a perfect example of how statistical physics addresses the micro-macro upscaling problem. It decomposes a problem of finding the macroscopic behavior of a large number of interacting parts into a succession of simpler problems with a decreasing number of interacting parts, whose effective properties vary with the scale of observation. The renormalization group thus follows the proverb “divide to conquer” by organizing the description of a system scale-by-scale. It is particularly adapted to critical phenomena and to systems close to being scale-invariant. The renormalization group translates into mathematical language the concept that the overall behavior of a system is the aggregation of an ensemble of arbitrarily defined sub-systems, with each sub-system defined by the aggregation of sub-subsystems, and so on [203].

It is important to stress that up to now the term “statistical” has different meanings in statistical physics and in statistical seismology, a field that has developed as a marriage between probability theory, statistics and the part of seismology concerned with empirical patterns of earthquake occurrences [225] (but not with physics). Statistical seismology uses stochastic models of seismicity, which are already effective large-scale representation of the dynamical organization. In contrast, a statistical physics approach to earthquake strives to derive these statistical models or other descriptions from the knowledge of the microscopic laws of friction, damage, rupture, rock-water interactions, mechano-chemistry and so on, at the microscopic scales [200,201]. In other words, what is often missing in statistical seismology is the physics to underpin the stochastic model on physically-based laws, e. g. rate-and-state friction [55].

The previously mentioned successes of statistical physics promote the hope that a similar program can be developed for other fields, including seismology. The successes have been more limited, due to the much more complex interplay between mechanisms, interactions and scales found in these out-of-equilibrium systems. This short essay provides a subjective entry to understand some of the different attempts, underlining the few successes, the problems and open questions. Rather than providing an exhaustive review, we mention what we believe to be important topics and have especially included recent work.

## Introduction

Much of the recent interest of the statistical physics community has focused on applying scaling techniques, which are common tools in the study of critical phenomena, to the statistics of inter-event recurrence times or waiting times [14,40,41,42,43,44,46,48,134]. However, the debate over the relevance of critical phenomena to earthquakes stretches back as far as 30 years [7,11,12,47,61,84,93,104,106,109,114,147,151,178,192,193,194,202,203,207,223], ► **Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of** and ► **Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space**. The current debate on recurrence statistics is thus the latest tack in an evolving string of arguments with a long history. As discussed below, many of the claims made in the recent articles on recurrence statistics have either been challenged, refuted or explained by previously known facts about earthquake statistics [132,133,145,176,177,230]. As will be discussed below, this debate in the literature is important because of the potential consequences for understanding earthquakes, but it needs to be pursued with rigorous scientific arguments accessible to both the seismological and the statistical physics communities.

The debate would almost certainly benefit significantly from testing hypotheses with simulations to establish null hypotheses and benchmarks: seismicity patterns are sufficiently stochastic and earthquake catalogs contain a sufficient amount of observational uncertainties so as to make inference difficult. It is often not straightforward to predict the signal of well-known statistical features such as clustering in new data analysis techniques. Therefore, testing the purported claims by realistic simulations of earthquake catalogs can provide a strong benchmark against which the claims can be evaluated. This view and the corresponding criticism of many studies has been put forward and defended for a long time by Kagan [111].

Such a model-dependent approach may be at odds with the philosophy of a so-called “model-free” analysis, which the community of statistical physicists claim to take in their analysis. For instance, network theory-based approaches, space-time window-based finite size scaling, box-covering methods and other techniques used in the study of critical and fractal phenomena are said to be “model-free” because no assumptions about seismicity are supposedly made at the outset. By using model-free analysis techniques, the often uncertain and sometimes clearly wrong assumptions of flawed models and resulting biased results are meant to be circumvented.

However, as is almost always the case in statistical hypothesis testing, the less assumptions are made about the test, the less powerful the test statistic. More importantly, seismicity is sufficiently stochastic so that well-known features may appear as novel in new analysis methods. Furthermore, to convince the seismological community of new data analysis techniques, the methods need to be tested on established knowledge and show the improvement over traditional methods. These types of initial tests are rarely performed by the statistical physics community.

In the next Sect. “**Concepts and Computational Tools**”, we present a summary of some of the concepts and computational tools that have been developed in attempts to apply statistical physics approaches to seismology. Then, Sect. “**Competing Mechanisms and Models**” summarizes the leading theoretical physical models of the space-time organization of earthquakes. Section “**Empirical Studies of Seismicity Inspired by Statistical Physics**” presents a general discussion and several examples of the new metrics proposed by statistical physicists, underlining their strengths and weaknesses. Section “**Future Directions**” briefly outlines expected developments.

## Concepts and Computational Tools

### Renormalization, Scaling and the Role of Small Earthquakes in Models of Triggered Seismicity

A common theme in many of the empirical relations in seismology (and in those employed in seismicity models) is the lack of a dominating scale. Many natural phenomena can be approached by the traditional reductionist approach to isolate a process at a particular scale. For example, the waves of an ocean can be described quite accurately by a theory that entirely ignores the fact that the liquid is made out of individual molecules. Indeed, the success of most practical theories in physics depends on isolating a scale [234], although since this recognition, much progress has been made in developing a holistic approach for processes that do not fall into this class. Given current observational evidence, earthquakes seem to belong to the set of processes characterized by a lack of one dominating length scale: fluctuations of many or perhaps a wide continuum of sizes seem to be important and are in no way diminished – even when one is interested solely in large-scale descriptions [206].

The traditional reductionist approach in seismology, which, for instance, attempted to separate large (main) shocks from small (fore- or after-) shocks, is slowly giving way to the holistic approach, in which all earthquakes are created equal and seismicity is characterized by fluctuations of all sizes. This gradual shift is supported, on

a conceptual and qualitative level, by the vision of critical phenomena. A particularly strong model of the interactions between earthquakes has emerged in the concept of triggering, which places all earthquakes on the same footing: each earthquake can trigger its own events, which in turn can trigger their own events, and so on, according to the same probability distributions, and the resulting seismicity can be viewed as the superposed cascades of triggered earthquakes that cluster in space and time [77,117,149,150].

From this point of view, it is natural that small earthquakes are important to the overall spatio-temporal patterns of seismicity. Indeed, the scaling of aftershock productivity with mainshock magnitude suggests that small earthquakes are cumulatively as important for the triggered seismicity budget as rarer but larger events [60,76,82]. The importance of small earthquakes has also been documented in, e.g., [73,138,141].

But earthquake catalogs do not contain information (by definition) about the smallest, unobserved events, which we know to exist from acoustic emission experiments and earthquakes recorded in mines. To guarantee a finite seismicity budget, Sornette and Werner argued [209] for the existence of a smallest triggering earthquake, akin to a “ultra-violet cut-off” in quantum field theory, below which earthquakes do not trigger other events. Introducing a formalism which distinguishes between the detection threshold and the smallest triggering earthquake, Sornette and Werner placed constraints on its size by using a simplified version of the popular Epidemic-Type Aftershock Sequence (ETAS) Model [149], a powerful model of triggered seismicity based on empirical statistics, and by using observed aftershock sequences. Sornette and Werner [210] also considered the branching structure of one complete cascade of triggered events, deriving an apparent branching ratio and the apparent number of untriggered events, which are observed when only the structure above the detection threshold is known. As a result of our inability to observe the entire branching structure, inferred clustering parameters are significantly biased and difficult to interpret in geophysical terms. Second, separating triggered from untriggered events, commonly known as declustering, also strongly depends on the threshold, so that it cannot even in theory constitute a physically sound method.

Sornette and Werner [210] also found that a simplified, averaged version of the ETAS model can be renormalized onto itself, with effective clustering parameters, under a change of the threshold. Saichev and Sornette [175] confirmed these results for the stochastic number statistics of the model using a rigorous approach in terms of generat-

ing probability functions, but also showed that the temporal statistics could not be renormalized. Furthermore, it can be shown (see Chapter 4 of [229]) that the conditional intensity function of the ETAS model, the mathematical object which uniquely defines the model, cannot be renormalized onto itself under a change of magnitude threshold. It is not a fixed-point of the renormalization process operating via magnitude coarse-graining. The functional form of the model must change under a change in the detection threshold [175]. In other words, if earthquakes occur according to an ETAS model above some cut-off  $m_0$ , then earthquakes above  $m_d$  cannot be described by the ETAS model in a mathematically exact way. Although in practice, the ETAS model provides an excellent fit.

The issue of how to deal with small earthquakes is thus reminiscent of the decades of efforts that have been invested in physics to deal with the famous ultra-violet cut-off problem, eventually solved by the so-called “renormalization” theory of Feynmann, Schwinger and Tomonaga. In the 1960s and 1970s, this method of renormalization was extended into the “renormalization group” (in fact a semi-group in the strict mathematical sense) for the theory of critical phenomena (see glossary), which we also mention in Sect. “Competing Mechanisms and Models”. It is fair to say that there has been limited success in developing a multi-scale description of the physics of earthquakes and, in particular, in addressing the upscaling problem and the impact of the many small earthquakes.

One tantalizing approach, not yet really understood in terms of all its consequences and predictions, is the variant of the ETAS model proposed by Vere-Jones [224], which has the remarkable property of being bi-scale invariant under a transformation involving time and magnitudes. One of the modifications brought in by [224] is to assume that the distribution of the daughter magnitudes is dependent on the mother magnitude  $m_i$  through a modification of the Gutenberg–Richter distribution of triggered earthquake magnitudes by a term of the form  $\exp(-\delta|m - m_i|)$ , where  $\delta > 0$  quantifies the distance to the standard Gutenberg–Richter distribution. Remarkably, Saichev and Sornette [174], who studied the Vere-Jones model, found that, due to the superposition of the many magnitude distributions of each earthquake in the cascades of triggered events, the resulting distribution of magnitudes over a stationary catalog is a pure Gutenberg–Richter law. Thus, there might be hidden characteristic scales in the physics of triggering that are not revealed by the standard observable one-point statistical distributions. Simulation and parameter estimation algorithms for the Vere-Jones model are not yet available. If and when these algorithms become available, the study of this bi-scale in-

variant branching model may be a strong alternative to the ETAS model, as this model is exactly scale invariant with neither ultra-violet nor infra-red cut-offs.

Nevertheless, being empirically based, these stochastic point process models lack a genuine microscopic physical foundation. The underlying physics is not explicitly addressed and only captured effectively by empirical statistics, even at the smallest scales. The physical processes and their renormalization are missing in this approach.

### Universality

Universality, as defined in the glossary, justifies the development and study of extremely simplified models (caricatures) of Nature, since the behavior of a studied system at the critical point can nevertheless be captured by toy models (in some cases exactly). For instance, the liquid–gas transition, the ferromagnetic to paramagnetic transition, and the behavior of binary alloys, all apparently different systems, can be described successfully by an extremely simplified picture of Nature (the Ising model) because of universality. The hope that a similar principle holds for earthquakes (and other non-equilibrium systems) underpins many of the models and tools inspired by statistical physics that have been applied to seismicity, to bring about the “much coveted revolution beyond reductionism” [17,67].

Speaking loosely, the appearance of power laws in many toy models is often interpreted as a kind of universal behavior. The strict interpretation of universality classes, however, requires that critical exponents along with scaling functions are identical for different systems. It is interesting to note that slight changes in the sand-pile model already induce new universality classes, so that even within a group of toy models, the promise of universality is not, strictly, fulfilled [13,98,136].

A lively debate in seismology concerns the universality of, on one hand, the frequency-size distribution of earthquake magnitudes (e.g. [47,61,91,108,111,232]), and, on the other hand, the universality of the exponent of the Gutenberg–Richter distribution (e.g. [25,184,212,233]). A spatio-temporally varying critical exponent is not traditionally part of the standard critical phenomena repertoire, although analytical and numerical results based on a simple earthquake model on a fault showed a possible spontaneous switching between Gutenberg–Richter and characteristic earthquake behavior associated with a non-equilibrium phase transition [24,47,61], ► [Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of](#) and ► [Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space](#). Another

possible mechanism for the coexistence of and intermittent shifts between different regimes (Gutenberg–Richter scaling and characteristic earthquakes) stems from the competition between several interacting faults which give rise to long intervals of activity in some regions followed by similarly long intervals of quiescence [129,213,214]. Both careful empirical investigations of seismicity parameters and theoretical progress on heterogeneous, spatially extended critical phenomena may help elucidate the controversy.

### Intermittent Periodicity and Chaos

As part of the conquest of chaos theory in the 70s and 80s [58,139], its concepts and methods were invariably also applied to seismicity. Huang and Turcotte [87,88] modeled the interaction between two faults by two sliding blocks that are driven by a plate through springs, coupled to one another via another spring and endowed with a velocity-weakening friction law. The dynamical evolution of the blocks showed chaotic behavior and period-doubling (the Feigenbaum route to chaos [58]). Huang and Turcotte [87,88] suggested that the interaction of the Parkfield segment with the southern San Andreas fault may be governed by the kind of chaotic behavior they observed in their model: the lighter block slipped quasi-periodically for several times until both slipped together. Their study explained that apparent quasi-periodicity of earthquakes on fault segments may be a result of chaotic interactions between many fault segments, thereby providing a warning that the extrapolations of quasi-periodic models are not to be trusted (e.g. [15,75] and references therein). However, it is doubtful that models with just a few degrees of freedom can go a long way towards providing deeper physical insights, or predictive tools. One needs to turn to models with a large number of degrees of freedom, for which turbulence appears as the leading paradigm of complexity.

### Turbulence

A drastically different approach has been favored by Yan Kagan [104,106,109,114], who described seismicity as the “turbulence of solids” – attesting to the far greater problems in earthquake seismology than the theory of critical phenomena promises to solve. While renormalization group methods and scaling theory have contributed immensely to the study of turbulence [63], the problem of turbulence involves significant additional complications. First, loosely speaking, renormalization group theory helps predict global behavior by coarse-graining over degrees of freedom, which is essentially a bottom–up ap-

proach. In turbulence, the enstrophy acts bottom-up, but the energy cascades top down. Secondly, there is a significant spatial and topological aspect to turbulence, for instance involving topological defects, such as filament structures, which are crucial to the dynamical evolution of the system. The existence of the two cascades (top-down and bottom-up) as well as the influence of the dissipation scale all the way within the so-called inertial range makes turbulence the most important problem still unsolved in classical Physics. The importance of addressing the issue of the interplay between the top-down and bottom-up cascades in earthquake toy models has been outlined by [65, 66, 236, 237].

The analogous problem for seismicity lies in the complex fault network, which constrains seismicity through its weak structures but also grows and evolves because of earthquakes redistributing stresses and rupturing fresh surfaces. The statistical description of this tensorial and dynamical problem is only at its beginning [64, 99, 100, 101, 102, 103, 107, 116, 118, 119, 142, 213]. But it is likely to be a key aspect to the dynamical evolution of faults and seismicity. New physics and approaches are required to tackle the tensorial nature of the stress and strain fields and the complex topological structures of defects, from dislocations to joints and faults, as well as the many different physical processes operating from the atomic scale to the macro-scale [200, 201].

### Self-Organized Criticality

Self-organized criticality (SOC) refers to the spontaneous organization of a system driven from outside into a globally dynamical statistical stationary state, which is characterized by self-similar distributions of event sizes and sometimes fractal geometrical properties. SOC applies to the class of phenomena occurring in driven out-of-equilibrium systems made of many interactive components, which possess the following fundamental properties: 1) a highly non-linear behavior, 2) a very slow driving rate, 3) a globally stationary regime, characterized by stationary statistical properties, and 4) power-law distributions of event sizes and fractal geometrical properties. The crust obeys these four conditions, as first suggested by [12, 193], who proposed to understand the spatio-temporal complexity of earthquakes in this perspective.

The appeal of placing the study of earthquakes in the framework of critical phenomena may be summarized as follows. Power law distributions can be understood as a result of an underlying continuous phase transition into which the crust has organized itself [197, 211]. Applying

the methods of renormalization group theory may help calculate exponents and scaling functions and rationalize the spatio-temporal organization of seismicity along with its highly correlated structures. For instance, Sornette and Virieux [208] provided a theoretical framework which links the scaling laws exhibited by earthquakes at short times and plate tectonic deformations at large times. Perhaps earthquakes fall into a universality class which can be solved exactly and/or investigated in toy models. Moreover, studying the detailed and highly complicated microphysics involved in earthquakes may not lead to insights about the spatio-temporal organization, because, as a critical phenomenon, the traditional approach of separating length scales to describe systems is inadequate. On the other hand, as mentioned above, there is the possibility of a hierarchy of physical processes and scales which are inter-related [156, 157], for which the simplifying approach in terms of critical phenomena is likely to be insufficient.

As another reason for the importance of the topic, interesting consequences for the predictability of earthquakes might be derived, for instance by mapping earthquakes to a genuine critical point (the accelerating moment release hypothesis, e.g. [202, 207]) or by mapping earthquakes to SOC (e.g. [70, 147]). The latter mapping had led some to argue that earthquakes are inherently unpredictable. In the sandpile paradigm [13], there is little difference between small and large avalanches, and this led similarly to the concept that “large earthquakes are small earthquakes that did not stop,” hence their supposed lack of predictability. More than ten years after this contentious proposal, a majority of researchers, including most of the authors of this “impossibility claim,” recognize that there is some degree of predictability [83, 97]. Actually, the clarifications came from investigators of SOC, who recognized that the long-term organization of sandpiles [51, 52] and of toy models of earthquakes and fault networks [142, 213, 214] is characterized by long-range spatial and temporal correlations. Thus, large events may indeed be preceded by subtle long-range organizational structures, an idea at the basis of the accelerating moment release hypothesis. This idea is also underlying the pattern recognition method introduced by Gelfand et al. [69] and developed extensively by V. Keilis-Borok and his collaborators for earthquake predictions [122]. In addition, Huang et al. [89] showed that avalanche dynamics occurring within hierarchical geometric structures are characterized by significant precursory activity before large events; this provides a clear proof of the possible coexistence between critical-like precursors of large events and a long-term self-organized critical dynamical state.

In summary, self-organized criticality provides a general conceptual framework to articulate the search for a physical understanding of the large-scale and long-time statistical properties of the seismogenic process and of the predictability of earthquakes. Beyond this, it is of little help as many different mechanisms have been documented at the origin of SOC (see, e.g., chapter 15 in [203]). SOC is not a theory, it does not provide any specific calculation tools; it is a concept offering a broad classification of the kinds of dynamics that certain systems, including the Earth crust, seem to spontaneously select.

### Competing Mechanisms and Models

It should be noted at this point that the statistical physics approach to earthquake science is not limited to SOC. Over the years, several groups have proposed to apply the concepts and tools of statistical physics to understanding the multiscale dynamics of earthquake and fault systems. Various mechanisms drawn conceptually from statistical mechanics but not necessary even limited to critical (phase transition) phenomena have been proposed and are being pursued. Such approaches include the concept of the critical point earthquake related to accelerated moment release, network theory, percolation and fiber models as models for fracture, and many more, some of which can be found in [84,203,220,221].

In this section, we outline some of the major model classes which underpin distinct views on what are the dominating mechanisms to understand earthquakes and their space-time organization.

### Roots of Complexity in Seismicity: Dynamics or Heterogeneity?

The 1990s were characterized by vigorous discussions at the frontier between seismology and statistical physics aimed at understanding the origin of the observed complexity of the spatio-temporal patterns of earthquakes. The debate was centered on the question of whether space-time complexity can occur on a single homogeneous fault, solely as a result of the nonlinear dynamics [23,38,39,128,186,187,188,189], associated with the slip and velocity dependent friction law validated empirically in particular by [53,54,55,56]. Or, is the presence of quenched heterogeneity necessary [21,22,126,168]?

The rediscovery of the multi-slider-block-spring model of [31,33] led to a flurry of investigations by physicists [34,128,170], finding an enticing entry to this difficult field, in the hope of capturing the main empirical statistical properties of seismicity. It is now understood that complexity in the stress field, in co-seismic slips and

in sequences of earthquakes can emerge purely from the nonlinear laws. However, heterogeneity is probably the most important factor dominating the multi-scale complex nature of earthquakes and faulting [156,157,181,182]. It is also known to control the appearance of self-organized critical behavior in a class of models relevant to the crust [191,214].

### Critical Earthquakes

This section gives a brief history of the “critical earthquake” concept.

We trace the ancestor of the critical earthquake concept to Vere-Jones [223], who used a branching model to illustrate that rupture can proceed through a cascade of damage events. Allègre et al. [7] proposed what is in essence a percolation model of damage/rupture describing the state of the crust before an earthquake. They formulated the model using the language of real-space renormalization group, in order to emphasize the multi-scale nature of the underlying physics, and the incipient rupture as the approach to a critical percolation point. Their approach is actually a reformulation in the language of earthquakes of the real-space renormalization group approach to percolation developed by [165]. Chelidze [35] independently developed similar ideas. In the same spirit, Smalley et al. [192] proposed a renormalization group treatment of a multi-slider-block-spring model. Sornette and Sornette [194] took seriously the concept put forward by [7] and proposed to test it empirically by searching for the predicted critical precursors. Voight [227,228] was probably the first author to introduce the idea of a time-to-failure analysis quantified by a second order nonlinear ordinary differential equation. For certain values of the parameters, the solution of [227,228]’s time-to-failure equation takes the form of a finite time singularity (see [180] for a review and [204] for a mechanism based on the ETAS model). He proposed and did use it later to predict volcanic eruptions. The concept that earthquakes are somehow associated with critical phenomena was also underlying the research efforts of a part of the Russian school [120,222].

The empirical seed for the critical earthquake concept were the repeated observations that large earthquakes are sometimes preceded by an increase in the number of intermediate size events [29,59,92,96,121,123,131,144,164,217]. The relation between these intermediate events and the subsequent main event took a long time to be recognized because the precursory events occur over such a large area. Sykes and Jaumé [217] proposed a specific law  $\sim \exp[t/\tau]$  quantifying the acceleration of seismicity prior to large

earthquakes. Bufe and Varnes [30] proposed that the finite-time singularity law

$$\epsilon_{\text{Benioff}} \sim 1/(t_c - t)^m \quad (2)$$

is a better empirical model than the exponential law. In (2),  $\epsilon_{\text{Benioff}}$  is the cumulative Benioff strain,  $t_c$  is critical time of the occurrence of the target earthquake and  $m$  is a positive exponent. The fit with this law of the empirical Benioff strain calculated by summing the contribution of earthquakes in a given space-time window is supposed to provide the time  $t_c$  of the earthquake and thus constitutes a prediction. This expression (2) was justified by a mechanical model of material damage. It is important to understand that the law (2) can emerge as a consequence of a variety of mechanisms, as reviewed by [180].

One of these mechanisms has been coined the “critical earthquake” concept, first formulated by Sornette and Sammis [207], who proposed to reinterpret the formula (2) proposed by [30] and previous related works by generalizing them within the statistical physics framework. This concept views a large earthquake as a genuine critical point. Using the insight of critical points in rupture phenomena, Sornette and Sammis [207] proposed to enrich Eq. (2), now interpreted as a kind of diverging susceptibility in the sense of critical phenomena, by considering complex exponents (i. e. log-periodic corrections to scaling). These structures accommodate the possible presence of a hierarchy of characteristic scales, coexisting with power laws expressing the scale invariance associated with a critical phenomenon [199]. This was followed by several extensions [89,94,95,178]. Sornette [202] reviewed the concept of critical “ruptures” and earthquakes with application to prediction. Ike and Sornette [90] presented a simple dynamical mechanism to obtain finite-time singularities (in rupture in particular) decorated by complex exponents (log-periodicity). Bowman et al. [28, 153,154,242,243] proposed empirical tests of the critical earthquake concept. The early tests of [28] have been criticized by [74], while [226] commented on the lack of a formal statistical basis of the accelerating moment release model. This stresses the need for rigorous tests in the spirit of [166,167]. The debate is wide open, especially in view of the recent developments to improve the determination of the relevant spatio-temporal domain that should be used to perform the analyzes [26,27,124,130] (see [62] for a review).

### Spinodal Decomposition

Klein, Rundle and their collaborators have suggested a mean-field approach to the multi-slider-block-spring

model justified by the long-range nature of the elastic interactions between faults. This has led them to propose that the fluctuations of the strain and stress field associated with earthquakes are technically those occurring close to a spinodal line of an underlying first-order phase transition (see [125,169,172] and references therein). This conceptual view has inspired them to develop the “Pattern Informatics” technique, an empirical seismicity forecasting method based on the idea that changes in the seismicity rate are proxies for changes in the underlying stress [86, 218].

The fluctuations associated with a spinodal line are very similar to those observed in critical phenomena. It is thus very difficult if not impossible in principle to falsify this hypothesis against the critical earthquake hypothesis, since both are expected to present similar if not identical signatures. Perhaps, the appeal of the spinodal decomposition proposal has to be found at the theoretical level, from the fact that first-order phase transitions are more generic and robust than critical phenomena, for systems where heterogeneity and quenched randomness are not too large.

### Dynamics, Stress Interaction and Thermal Fluctuation Effects

Fisher et al. [24], Dahmen et al. [47], Ben-Zion et al. [61] and co-workers (see the reviews by ► [Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of](#) and ► [Seismicity, Critical States of: From Models to Practical Seismic Hazard Estimates Space](#)) have introduced a mean-field model (resulting from a uniform long-range Green function) of a single fault, whose dynamical organization is controlled by two control parameters,  $\epsilon$  which measures the dynamic stress weakening and  $c$  which is the deviation from stress conservation (due for instance to coupling with ductile layers). The point ( $\epsilon = 0$ ;  $c = 0$ ) is critical in the sense of a phase transition in statistical physics, with its associated scale invariant fluctuations described by power laws. Dynamic stress strengthening ( $\epsilon < 0$ ) leads to truncated Gutenberg–Richter power laws. Dynamic stress weakening ( $\epsilon > 0$ ) is either associated with a truncated Gutenberg–Richter power law for  $c > 0$  or with characteristic earthquakes decorating a truncated power law for  $c < 0$ . The coexistence of a characteristic earthquake regime with a power-law regime is particularly interesting as it suggests that they are not exclusive properties but may characterize the same underlying physics under slightly different conditions. This could provide a step towards explaining the variety of empirical observations in seismology [5,110,185,232].

Sornette et al. [214] have obtained similar conclusions using a quasi-static model in which faults grow and self-organize into optimal structures by repeated earthquakes. Depending on the value of dynamical stress drop (controlling the coupling strength between elements) relative to the amplitude of the frozen heterogeneity of the stress thresholds controlling the earthquake nucleation on each fault segment, a characteristic earthquake regime with a truncated power law is found for small heterogeneity or large stress drop while the power law SOC regime is recovered by large heterogeneity or small stress drop. The two approaches of [24,47,61] and ► **Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of** on the one hand and of [214] on the other hand can be reconciled conceptually by noting that the dynamic stress weakening of ► **Jerky Motion in Slowly Driven Magnetic and Earthquake Fault Systems, Physics of** controls the dynamical generated stress heterogeneity while the lack of stress conservation  $c$  controls the coupling strength. Fundamentally, the relevant control parameter is the degree of coupling between fault elements seen as threshold oscillators of relaxation versus the variance of the disorder in their spontaneous large earthquake recurrence times. Generically, power law statistics are expected to co-exist with synchronized behavior in a general phase diagram in the heterogeneity-coupling strength plane [152,214].

Let us finally mention a promising but challenging theoretical approach, which has the ambition to bridge the small-scale physics controlled by thermal nucleation of rupture to the large-scale organization of earthquakes and faults [155,205]. Partial success has been obtained with a remarkable prediction on the (“multifractal”) dependence of the Omori law exponent of aftershocks on the magnitude of the mainshock, verified by careful empirical analyzes on earthquakes in California, Japan and worldwide [158].

### Empirical Studies of Seismicity Inspired by Statistical Physics

*“False facts are highly injurious to the progress of science, for they often endure long; but false views, if supported by some evidence, do little harm, for everyone takes a salutary pleasure in proving their falseness.”*

Charles Darwin, in *The Origin of Man*, Chap. 6.

### Early Successes and Subsequent Challenges

A significant benefit of the statistical physics approach to seismology has been the introduction of novel techniques

to analyze the available empirical data sets, with the goal of obtaining new insights into the spatio-temporal organization of seismicity and of revealing novel regularities and laws that may guide the theoretical analysis.

A prominent forerunner is the application of the concept of fractals introduced by Mandelbrot [137] and of the measures of fractal dimensions to describe complex sets of earthquake epicenters, hypocenters and fault patterns. The use of fractals has constituted an epistemologic breakthrough in many fields, and not only in seismology. Indeed, before Mandelbrot, when dealing with most complex systems, one used to say: “this is too complicated for a quantitative analysis” and only qualitative descriptions were offered. After Mandelbrot, one could hear: “this is a fractal, with a fractal dimension equal to xxx!” By providing a new geometrical way of thinking about complex systems associated with novel metrics, Mandelbrot and his fractals have extended considerably the reach of quantitative science to many complex systems in all fields.

However, while there have been some attempts to use fractal dimensions as guidelines to infer the underlying organization processes, as for instance in [195,196], most of the initial reports have lost their early appeal [18,19,183,219] since the complexity of seismicity and faulting is much too great to be captured by scaling laws embodying solely a simple scale invariance symmetry. Among others, multifractal and adapted wavelet tools are needed to quantify this complexity, see for instance [68,146,156,157,159]. It should also be noted that few studies of the fractal dimensions of seismicity address the significant issues of errors, biases and incomplete records in earthquake catalogs – a notable exception being [115].

Since the beginning of the 21st century, a renewal of interest and efforts have burgeoned as groups of statistical physicists, interested in earthquakes as a potential instance of self-organized criticality (SOC), have claimed “novel”, “universal” and “robust” scaling laws from their analysis of the spatio-temporal organization of seismicity. The authors purport to have discovered universal and hitherto unknown features of earthquakes that give new insights into the dynamics of earthquakes and add to the evidence that earthquakes are self-organized critical. We now discuss a few of these recent studies to illustrate the existence of potential problems in the “statistical physics” approach. In a nutshell, we show that perhaps most of these “novel scaling laws” can be explained entirely by already known statistical seismicity laws. This claim has been defended by other experts of statistical seismology, the most vocal being perhaps Yan Kagan at UCLA [111].

The flurry of interest from physicists comes from their fascination with the self-similar properties exhibited by

seismicity (e. g. the Gutenberg–Richter power law of earthquake seismic moments, the Omori–Utsu law of the decay of aftershock rates after large earthquakes, the fractal and multifractal space-time organization of earthquakes and faults, etc.), together with the development of novel concepts and techniques that may provide new insights. But, and this is our main criticism based on several detailed examples discussed below, many of the new approaches and results do not stand close scrutiny. This failure is rooted in two short-comings: (i) the lack of testing of new methods on synthetic catalogs generated by benchmark models which are based on well-known statistical laws of seismicity, and (ii) the failure to consider earthquake catalog bias, incompleteness and errors. The latter may cause catalog artifacts to appear as genuine characteristics of earthquakes. Testing the results on a variety of catalogs and considering the influence of various catalog errors can help minimize their influence. The former short-coming often leads to the following scenario: authors fail to realize that a simpler null hypothesis could not be rejected, namely that their “discovery” could actually be explained by just a combination of basic statistical laws known to seismologists for decades.

The well-established laws of statistical seismicity that authors should consider before claiming for novelty include the following:

1. The Gutenberg–Richter law for the distribution of earthquake magnitudes with a  $b$ -value close to 1 (corresponding to an exponent  $\simeq 2/3$  for the probability density function of seismic moments),
2. The Omori–Utsu law for the decay of the rate of aftershocks following a mainshock,
3. The inverse Omori law for foreshocks,
4. The fact that aftershocks also trigger their own aftershocks and so on, and that aftershocks do not seem to exhibit any distinguishable physical properties,
5. The fact that the distribution of distances between mainshocks and aftershocks has a power law tail,
6. The fertility law (the fact that earthquakes of magnitude  $M$  trigger of the order of  $10^{aM}$  aftershocks with  $a \sim b \simeq 1$ ),
7. The fractal distribution of faults which are concentration centers for earthquakes.

This above non-exhaustive list selects “laws” which are arguably non-redundant, in the sense that it is likely not possible to derive one of these laws from the others (a possible exception is the inverse Omori law for foreshock, which can be derived from the direct Omori law for aftershocks in the context of the ETAS model [78,81]). Some

experts would argue that we should add to this list other claimed regularities, such as “Båth’s law” (see e. g. [190] for a recent discussion emphasizing the importance of this law), that states that the differences in magnitudes between mainshocks and their largest aftershocks are approximately constant, independent of the magnitudes of mainshocks [20]. However, Helmstetter and Sornette [79] and Saichev and Sornette [173] have shown that Bath’s law can be accurately recovered in ETAS-type models combining the first, second, fourth, and sixth laws stated above, with the assumption that any earthquake can trigger subsequent earthquakes.

### Entropy Method for the Distribution of Time Intervals Between Mainshocks

Mega et al. [140] used the “diffusion entropy” method to argue for a power-law distribution of time intervals between a large earthquake (the mainshock of a seismic sequence or cluster) and the next one. Helmstetter and Sornette [80] showed that all the “new” discoveries reported by [140] (including the supposedly new scaling) can be explained solely by Omori’s law for intra-cluster times, without correlation between clusters, thus debunking the claim for novelty.

### Scaling of the PDF of Waiting Times

Bak et al. [14] analyzed the scaling of the probability density function of waiting times between successive earthquakes in southern California as a function of “box size” or small regions in which subsequent earthquakes are considered. They found an approximate collapse of the pdfs for different seismic moment thresholds  $S$  and box sizes  $L$  which suggested the following scaling ansatz for the waiting times  $T$ :

$$T^\alpha P_{S,L}(T) = f(TS^{-b}L^{d_f}), \quad (3)$$

where  $b = 1$  is the Gutenberg–Richter exponent,  $d_f \simeq 1.2$  was claimed to be a spatial fractal dimension of seismicity (see [146] and [115] for more in-depth studies),  $\alpha = 1$  was identified as the exponent in the Omori law and  $f(\cdot)$  is a scaling function which was proposed to be roughly constant up to a constant (“kink”) beyond which it quickly decays. The scaling (3) was claimed to be a unified law for earthquakes that revealed a novel feature in the spatio-temporal organization of seismicity in that the Gutenberg–Richter, the Omori law and the spatial distribution of earthquakes were unified into a single picture that made no distinction between fore-, main- and aftershocks. The

scaling relations and critical exponents were claimed to be contained in the scaling ansatz. Corral [40,41,42,43] and others broadened the analysis to other regions of the world. Corral [41] proposed a slightly different scaling ansatz for a modified data analysis.

Early criticism came from Lindman et al. [132], who noted that synthetic data generated using a non-homogeneous Poisson process derived from Omori's law was able to reproduce some of the results of [14], indicating a rather trivial origin of the unified scaling law. Molchan [145] showed that, if at least two regions in the data set are independent, then, if a scaling relation were to hold exactly, this scaling function could only be exponential. All other functions could only result in approximate data collapses. Proponents of the unified scaling law, e. g. [44], argued that indeed all regions were correlated, as expected in systems near a critical point so that the assumption of independence between different regions should not hold. But Molchan [145] also showed that a simple Poisson cluster model (Poissonian mainshocks that trigger Omori-type aftershock sequences) could reproduce the short and long time limits of the observed statistics, indicating that the Omori law, the Gutenberg–Richter relationship and simple clustering were the sole ingredients necessary for the observed short and long time limit, and no spatial correlation was needed.

Saichev and Sornette [176,177] extended Molchan's arguments to show that the approximate data collapse of the waiting times could be explained completely by the Epidemic-Type Aftershock Sequence (ETAS) model of [149]. This provided further evidence that the apparent data collapse was only approximate. Remarkably, the theoretical predictions of the ETAS model seem to fit the observed data better than the phenomenological scaling function proposed by [41] to fit the data. Saichev and Sornette [176,177] thus showed that a benchmark model of seismicity was able to reproduce the apparent unified scaling law and that therefore the distribution of interevent times did not reveal new information beyond what was already known via statistical laws: The combination of the Gutenberg–Richter law, the Omori law, and the concept of clustering suffice to explain the apparent "universal" scaling of the waiting times.

Sornette et al. [215] developed an efficient numerical scheme to solve accurately the set of nonlinear integral equations derived previously in [177] and found a dramatic lack of power for the distribution of inter-event times to distinguish between quite different sets of parameters, casting doubt on the usefulness of this statistics for the specific purpose of identifying the clustering parameter (e. g. [72]).

### Scaling of the PDF of Distances Between Subsequent Earthquakes

Davidson and Paczuski [49] claimed evidence contradicting the theory of aftershock zone scaling in favor of scale-free statistics. Aftershock zone scaling refers to the scaling of the mainshock rupture length, along which most aftershocks occur, with the mainshock magnitude [112]. Davidson and Paczuski [49] suggested that the probability density function of spatial distances between successive earthquakes obeys finite size scaling with a novel dynamical scaling exponent, suggesting that the mainshock rupture length scale has no impact on the spatial distribution of aftershocks and that earthquakes are self-organized critical.

Werner and Sonette [230] debunked this claim by showing that (i) the purported power law scaling function is not universal as it breaks down in other regions of the world; (ii) the results obtained by [49] for southern California depend crucially on a single earthquake (the June 28, 1992, M7.3 Landers earthquake): without Landers and its aftershocks, the power law disappears; (iii) a model of clustered seismicity, with aftershock zone scaling explicitly built in, is able to reproduce the apparent power law, indicating that an apparent lack of scales in the data does not necessarily contradict aftershock zone scaling and the existence of scales associated with mainshock rupture length scales.

### The Network Approach

The recent boom in the statistical mechanics of network analysis has recently extended to applications well beyond physics (for reviews, see [6,16,57,148]). Earthquake seismology is no exception [1,2,3,4,8,9,10,160,161]. The resulting impact has been limited so far for several reasons.

A major concern is the assumption that earthquake catalogs as downloaded from the web are data sets fit for immediate analysis. References [82,113,229] and [231] present modern and complementary assessments of the many issues of incompleteness spoiling even the best catalogs. In particular, we should stress that magnitude determinations are surprisingly inaccurate, leading to large errors in seismic rate estimates [231]. Furthermore, there is no such thing as a complete catalog above a so-called magnitude of completeness, due to the fact that a non-negligible fraction of earthquakes are missed in the aftermath of previous earthquakes [82,113]. One should be concerned that analyses in terms of network metrics could be particularly sensitive to these defects. Nevertheless, Abe and Suzuki [1,2,3,4] applied metrics of network analysis to "raw" catalogs which included events well below the esti-

mated magnitude of completeness. As a result of neglecting to use a (reasonably) homogeneous and trustworthy data set, the results of their analysis may be severely biased, because the reliability of the inferred network structure is probably more sensitive than other metrics to the correct spatio-temporal ordering of the earthquake catalog. No serious study has yet been performed to quantify the usually serious impact of quality issues on the metrics used in network analysis. As a consequence, it is also not clear how to interpret the “success” of [160,161] in reproducing the “features” of Abe and Suzuki’s analysis on the synthetic seismicity generated by a spring-block model.

In addition, at best limited attempts have been made to interpret the results of the new network metrics using well-known, established facts in seismology. Many of the claimed novel features are probably very well understood – they are mostly related to scale-invariance and clustering of seismicity, facts documented for decades. The authors should always strive to show that the new metrics that they propose give results that cannot be explained by the standard laws in statistical seismology. Toward this end, there are well-defined benchmark models that incorporate these laws and that can generate synthetic catalogs on which the new metrics can be tested and compared.

A few exceptions are worth mentioning. Motivated by the long-standing and unresolved debate over “aftershock” identification, Baiesi and Paczusi [9,10] and Baiesi [8] provided a new metric for the correlations between earthquakes based on the space-time-magnitude nearest-neighbor distance between earthquakes. The authors compared their results with known statistical laws in seismology and with the predictions of the ETAS model, actually confirming both. While no new law has been unearthed here, such efforts are valuable to validate known laws and continue to test the possible limits. Zaliapin et al. [238] extended their study and investigated the theoretical properties of the metric and its ability to decluster catalogs (i. e., separate mainshocks from aftershocks). They concluded that aftershocks defined from this metric seem to be different from the rest of earthquakes. It will be interesting to see head-to-head comparisons with current state-of-the-art probabilistic declustering techniques that are based on empirical statistical laws and likelihood estimation [105, 240,241].

### Future Directions

The study of the statistical physics of earthquakes remains wide-open with many significant discoveries to be made. The promise of a holistic approach – one that emphasizes

the interactions between earthquakes and faults – is to be able to neglect some of the exceedingly complicated micro-physics when attempting to understand the large scale patterns of seismicity. The marriage between this conceptual approach, based on the successes of statistical physics, and seismology thus remains a highly important domain of research. In particular, statistical seismology needs to evolve into a genuine physically-based statistical physics of earthquakes.

The question of renormalizability of models of earthquake occurrence and the role of small earthquakes in the organization of seismicity is likely to remain an important topic. It connects with the problem of foreshocks and the predictability of large events from small ones and therefore has real and immediate practical applications as well as physical implications.

More detailed and rigorous empirical studies of the frequency-size statistics of earthquake seismic moments and how they relate to seismo-tectonic conditions are needed in order to help settle the controversy over the power-law versus the characteristic event regime, and the role of regime-switching and universality.

Spatially extended, dynamically evolving fault networks and their role in the generation of earthquakes are mostly ignored in the statistical physics approach to seismicity. Akin to the filaments in turbulence, these may provide key insights into the spatio-temporal organization of earthquakes. Novel methods combining information from seismology to faulting will be required (e. g., [71,159,195, 196,197]) to build a real understanding of the self-organization of the chicken-and-egg structures that earthquakes-faults constitute. Furthermore, a true physical approach requires understanding the spatio-temporal evolution of stresses, their role in earthquake nucleation via thermally activated processes, in the rupture propagation and in the physics of arrest, both involved in the generation of complex stress fields.

The important debate regarding statistical physics approaches to seismicity would benefit significantly from two points. Firstly, earthquake catalogs contain data uncertainties, biases and subtle incompleteness issues. Investigating their influence on the results of data analyses inspired by statistical physics increases the relevance of the results. Secondly, the authors should make links with the literature on statistical seismology which deals with similar questions. It is their task to show that the new metrics that they propose give results that cannot be explained by the standard laws in statistical seismology. For this, there are well-defined benchmark models that incorporate these laws and that can generate synthetic catalogs on which the new metrics can be tested.

## Glossary

**Atmospheric boundary layer** The Atmospheric Boundary Layer (ABL) is the lower part of the atmosphere which is directly influenced by the presence of the earth's surface. As such its major characteristics are turbulence and the diurnal cycle.

**Diurnal cycle** The depth of the dry atmospheric boundary layer (ABL) can vary over land between tens of meters during night up to kilometers during daytime (see Fig. 2). Over sea the depth is often typical a few hundred meters and rather constant on the time scale of a day.

**Turbulence** Turbulence in the atmospheric boundary layer is the three-dimensional, chaotic flow of air with time scales typically between a second and an hour. The corresponding length scales are from a millimeter up to the depth of the boundary layer (or more in the case of clouds). Turbulence in the ABL originates due to friction of the flow and heating (convection) at the surface.

## Definition of the Subject

In this article we deal with the single column modeling of the Atmospheric Boundary layer (ABL) and the complex interactions which may occur with the land surface. As such we review the major characteristics of the ABL over land, and summarize the basic parameterizations for the representation of atmospheric turbulence and the surface fluxes. The modeling principles are illustrated with the outcome of single-column models for a variety of conditions using field data and fine-scale model results. Our emphasis is on stable conditions which occur over land at night-time under clear skies. For readers not familiar with atmospheric turbulence and meteorological definitions, some background and basic definitions are also given.

## Introduction

The Atmospheric Boundary Layer (ABL) is generally characterized by turbulence. Because of its capability to mix air with different properties efficiently, the representation of turbulence is directly relevant for atmospheric and environmental modeling. For instance, turbulence directly impacts on the transfer of momentum, sensible heat, water vapor, ozone, and methane, among many other quantities, between the earth's surface and the atmosphere. Turbulence also defines the mixing of properties inside the atmospheric boundary layer, the transfer of quantities between the boundary layer and the clear or cloudy atmosphere aloft, and the mixing inside clouds.

Turbulence in the ABL is mainly due to the mechanical turbulence by vertical wind shear and turbulence by convection. Most of the atmosphere above the ABL is not turbulent, although turbulence can occur throughout the whole atmosphere. For instance, cumulus-type clouds, which may grow into thunderstorms, are always turbulent through convection produced by the heat released due to the condensation of water vapor. Turbulence can also occur in clear air above the ABL; most of this is produced in layers of strong vertical wind shear at the boundary between air masses (so-called 'Clear-Air Turbulence').

Because of the mixing capacity of turbulence, modeling atmospheric boundary layers is also relevant for many practical applications. For instance, chimney plumes are diluted and spread over larger volumes than they would be without turbulence. As such, strong local peaks of pollution are prevented and otherwise clean air is polluted. In practice turbulence may also cause engineering problems, because it shakes structures such as bridges, towers, and airplanes, causing failure of such systems in extreme cases. Turbulent fluctuations in the horizontal motions during

severe storms can be fatal to tall buildings or bridges, particularly if resonance (e. g., forcing of a system at its natural frequency) occurs.

The correct formulation of the overall effects by turbulence, either inside or outside the atmospheric boundary layer, is an essential part of atmospheric models dealing with the prediction and study of weather, climate and air quality. These models are based on solving the equations dealing with atmosphere behavior. With state-of-the-art computers, the number of grid points in atmospheric models is limited to a number of typically  $10^8$  or so. This implies that on the regional and global scale the atmospheric model equations are usually applied too fairly large ‘air boxes’. Such boxes are often in the order of ten to hundred kilometers wide and ten to a few hundred meters thick. In these large boxes, smaller scale motions make air parcels interact and mix. For example, if a hot parcel is located next to a cold parcel, turbulent motion at their boundaries will heat the cool and cool the hot parcel. Thus, a closure formulation is needed to reproduce mixing by the turbulent motions into the model-resolved scales using the equations for the larger-scale ‘mean’ motions. It is important to realize that the closure formulation needs to be expressed in terms of variables available in the modeling context. This is called a ‘parameterization’.

In this contribution we provide an overview of the modeling principles, the turbulent closures and parameterizations in use for of the atmospheric boundary layer, where we emphasize the modeling and parameterization of turbulence in the atmospheric boundary layer without clouds. Additionally we discuss the performance of models in current use [7,28], and we study the impact of the surface boundary condition over land [18].

## Background

Atmospheric models for the forecasting and study of weather, climate, and air quality are typically based on integration of the basic equations governing atmospheric behavior. These equations are the gas law, the equation of continuity (mass), the first law of thermodynamics (heat), the conservation equations for momentum (the so-called “Navier–Stokes equations”), and usually equations expressing the conservation of moisture, trace gases and air pollutants. At one extreme, atmospheric models may deal with the world’s climate and climate change; at the other, they may account for the behavior of local flows at coasts, in mountain-valley areas, or even deal with individual clouds. This all depends on the selected horizontal modeling domain and the available computing resources.

Since there is an enormous range of scales in atmospheric motion and turbulence, there is a need to separate the scales of atmospheric turbulence from larger-scale motions. Let  $C$  denote an atmospheric variable, such as specific humidity. Then  $\bar{C}$  represents a mean or “smoothed” value of  $C$ , typically taken on a horizontal scale of order 10 (or more) km and a corresponding time scale in the order of 10 min to one hour. A local or instantaneous value of  $C$  would differ from  $\bar{C}$ . Thus, we have

$$C = \bar{C} + c. \quad (1)$$

Here  $c$  represents the smaller-scale fluctuations. Note that we use lower case for the latter (often primes are used as well to indicate fluctuations). In principle, the fluctuations around the mean motion also reflect gravity waves and other smaller scale motions, in addition to turbulence. Gravity waves often co-exist with turbulence or are generated by turbulence. If the wind at the same time is weak, there may be no turbulence at all. Anyhow, if turbulence exists, it is usually more important for most atmospheric applications, because it mixes more efficiently than the other small-scale motions.

To make the mathematical handling of  $c$  tractable, it must satisfy the so-called “Reynolds postulates”. These require, for example, that  $\bar{c} = 0$  and that small- and larger-scale values must not be correlated. After a quantity has been averaged to create a larger-scale quantity, further averaging should produce no further changes, in order for this postulate to apply. The mean of the summation of two variables  $A$  and  $C$  will produce  $\overline{A \pm C} = \bar{A} \pm \bar{C}$ . A further condition is that a mean variable  $\bar{C}$  must be differentiable, since differentials show up in the atmospheric equations (see below). In practice, not all these conditions are rigorously satisfied. If the Reynolds postulates are fulfilled, then the averaging for the product of two variables provides

$$\overline{AC} = \bar{A}\bar{C} + \overline{ac}. \quad (2)$$

The second term at the right hand side of Eq. (2) is known as the turbulent covariance. Similarly, the turbulence variance of a quantity is given by  $\overline{C^2} - (\bar{C})^2$  (which is the square of the standard deviation).

If in Eq. (2), the variable  $A$  represents one of the velocity components ( $U, V, W$  in the  $x, y, z$  direction, respectively), then  $\bar{AC}$  is the total flux of  $C$  and the second term at the right hand side of Eq. (2) represents a turbulent flux of  $C$ . For instance,  $\overline{uc}$  and  $\overline{wc}$  are the horizontal and vertical turbulent fluxes of the variable  $C$ , respectively. Here  $u$  and  $w$  are the turbulent fluctuations of the horizontal and vertical velocities. Near the surface, the mean vertical wind  $\bar{W}$  is usually small, and thus the total vertical fluxes are normally dominated by the turbulent contributions.

## Atmospheric Boundary-Layer Structure

Turbulent fluctuations, variances and fluxes of variables are influenced by the vertical boundary-layer structure. Here the variation of temperature in the atmospheric boundary-layer plays an important role. Since pressure decreases with altitude, air parcels, which are forced to rise (sink), do expand (compress). According to the first law of thermodynamics, a rising (sinking) parcel will cool (warm) if there is no additional energy source such as condensation of water vapor. Then this is called a dry adiabatic process.

It can be shown that in the atmospheric boundary layer, the temperature ( $T$ ) variation with height for a dry adiabatic process is  $dT/dz = -g/C_p$  (here  $g$  is gravity constant and  $C_p$  is specific heat at constant pressure). The value for  $g/C_p$  is approximately 1 K per 100 m. An atmospheric layer which has such a temperature variation with height, is called neutral for dry air (at least when there is no convection arising from other levels). In that case  $\Theta = T + (g/C_p)z$  is constant, where  $\Theta$  is called the potential temperature (Note that the previous definition for potential temperature is not accurate above the boundary layer). Since air normally contains water vapor and because moist air is lighter than dry air, we have to correct for the influence of this on vertical motions. Consequently, a virtual potential temperature is defined as  $\Theta_v = \Theta(1 + 0.61q)$ , where  $q$  is the specific humidity (defined as the mass of water vapor per unit mass of moist air).

In a neutral layer with constant  $\Theta_v$ , vertical motions of moist (not saturated) air can maintain themselves. If the virtual potential temperature of the atmospheric layer increases with height, vertical displacements are suppressed. This is called a stable condition (or ‘inversion’). At the other hand, when the virtual potential temperature decreases with height, vertical fluctuations may be accelerated. Consequently this is called an unstable condition. Thus in considerations with turbulent fluctuations and atmospheric stability, we have to deal with the virtual potential temperature and not with the actual temperature. Similarly, the vertical flux of sensible heat is connected to turbulent fluctuations of (virtual) potential temperature; e. g. it reads as  $w\theta_v$  (in m K/s). The latter relates directly to the energy per time and unit area  $H$  by  $H = \rho C_p w\theta_v$  (in W/m<sup>2</sup>), where  $\rho$  is density of the air (in kg/m<sup>3</sup>).

Figure 1 (after [30]), provides the typical, idealized, mean vertical profiles for temperature  $T$ , potential temperature  $\Theta$ , specific humidity  $q$ , in addition to the horizontal wind  $M$  (defined by  $M^2 = U^2 + V^2$ ). These profiles apply for an atmospheric boundary layer over land in clear sky conditions in the afternoon and around midnight. Note

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 1  
Idealized vertical profiles of mean variables in the Atmospheric Boundary Layer over land in fair weather (after [30]). See text for additional information

that in the free atmosphere the horizontal wind is mostly a result of the acting of the larger scale pressure differences and the Coriolis force due to the rotation of the earth (but other effects may play a role as well). The resulting wind is known as the ‘geostrophic’ wind and indicated with  $G$  in Fig. 1 (see dashed line). In the daytime boundary layer the actual wind is smaller due to surface friction, while at clear nights the actual wind away from the surface may be substantially stronger than  $G$  due to inertial effects (resulting in the so-called ‘low level jet’).

The temporal variation of the mean boundary-layer profiles over land can be quite substantial due to the strong diurnal variation of solar incoming radiation and the nighttime cooling at the land surface. During daytime the turbulent boundary layer may grow to several kilometers into the non-turbulent ‘free atmosphere’ (indicated as FA in Fig. 1). At night the turbulent part of the stable boundary layer (SBL) may only extend up to a few hundred meters or less (the lowest dashed line in the lower figure). An idealized picture for the temporal variation of the boundary layer over land is given in Fig. 2 (after [30]).

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 2  
Idealized diurnal evolution of the Atmospheric Boundary Layer over land in fair weather (after [30])

Here the arrows with local time indications refer to the day and nighttime figures of Fig. 1.

Figure 1 also indicates that the boundary layer during daytime shows a three-layer structure: an unstable ‘surface layer (SL)’, a ‘well-mixed layer (ML)’ with rather uniform (virtual) potential temperature, and a stably-stratified ‘entrainment zone (EZ)’. In the latter zone, turbulence acts to exchange heat, momentum, water-vapor and trace gasses between the boundary layer and the free atmosphere. During nighttime, often the vertical structure of the previous day persists above the SBL. As such a ‘residual layer (RL)’ with sporadic turbulence (remaining from the previous day) can be identified as well as a ‘capping inversion (CI)’.

### Modeling Basics

The challenge of modeling the atmospheric boundary layer is the prediction of the temporal variation of the vertical and horizontal structures in response to the influence of the major processes acting in the atmosphere and at the earth’s surface. As such the governing equations have to be integrated. In practice, the variables are split into ‘mean’ larger-scale motions and smaller-scale fluctuations as in Eq. (1). Inserting this into the basic equations and after averaging this provides a set of equations for the behavior of the larger-scale (mean) variables. The larger-scale variables are then used explicitly in atmospheric models. This can be demonstrated as follows below.

The general character of any of the budget equations dealing with atmospheric motions is

$$\frac{DC}{Dt} = S_i . \quad (3a)$$

Here  $S_i$  represents the subsequent sources and sinks for the variable  $C$  (such as radiation or chemistry effects). The notation  $DC/Dt$  represents the total rate of change for the variable  $C$  by local changes ( $\partial/\partial t$ ), and changes transported with the fluid motion in the three directions. As such, we have

$$\frac{\partial C}{\partial t} + U \frac{\partial C}{\partial x} + V \frac{\partial C}{\partial y} + W \frac{\partial C}{\partial z} = S_i . \quad (3b)$$

Here  $U, V, W$  are the wind speeds in the three directions  $x, y, z$ , respectively.

If in the atmospheric motion each variable is split into a mean component and a fluctuation then (3b) provides after Reynolds-averaging, some algebraic manipulations and simplifying assumptions, a budget equation for the mean variable  $\bar{C}$ . This reads as

$$\begin{aligned} \frac{D\bar{C}}{Dt} &= \frac{\partial \bar{C}}{\partial t} + \bar{U} \frac{\partial \bar{C}}{\partial x} + \bar{V} \frac{\partial \bar{C}}{\partial y} + \bar{W} \frac{\partial \bar{C}}{\partial z} \\ &= \bar{S}_i - \frac{\partial \overline{u\bar{c}}}{\partial x} - \frac{\partial \overline{v\bar{c}}}{\partial y} - \frac{\partial \overline{w\bar{c}}}{\partial z} . \end{aligned} \quad (4)$$

We may note that in the derivation of (4), single terms representing fluctuations have disappeared (as above in Eq. (2)). However, terms involving the product of two fluctuations did remain.

Thus because the basic equations are nonlinear, the budget equations for the mean variables contain terms involving smaller-scale motions. The latter terms are of the form of a divergence of fluxes produced by such motions in the three directions and appear as the last three terms in Eq. (4). These motions are said to be sub-grid and consequently, closure formulations or parameterizations are

needed to introduce mixing by the smaller-scale, sub-grid, motions into the equations for the larger-scale motions (as resolved by the model). Note that additional terms may also appear in (4) when the source or sink term  $S_i$  incorporates nonlinear effects (such as in the case of chemistry).

The atmospheric model equations can also be applied on much smaller spatial and temporal scales than discussed here, for instance by using vertical and horizontal grid elements of 10 to 100 m, and time steps of seconds only. It is important to realize that in such cases a significant part of the turbulent fluctuations are resolved by the model equations. This type of modeling is nowadays known as ‘Large-eddy simulation (LES)’. This has become a powerful and popular tool in the last decade to study turbulence in clear and cloudy boundary layers under well-defined conditions. It is important to realize that in the case of LES the simplifying assumptions leading to Eq. (2) are normally not valid.

A special and simple form of Eq. (4) arises for horizontally homogeneous conditions. In such cases the terms including horizontal derivatives are negligible. If in addition the mean vertical wind is small and if there are no other sources and sinks, then (4) provides

$$\frac{\partial \bar{C}}{\partial t} = -\frac{\partial \bar{w}c}{\partial z}. \quad (5)$$

This equation is known as the one-dimensional, vertical diffusion equation. It shows that the local time rate of change for the mean of a variable (such as temperature or wind) at a certain height, is given by the divergence of the turbulent (corresponding heat or momentum) flux in the vertical direction. As such, information on the turbulent flux may produce a local forecast of the variation of a mean variable (but only under the simplifications mentioned).

Equation (5) can be seen as the basis of a single-column model where only local information of the atmosphere is relevant. However, normally the other terms in (4) are also relevant, in particular the terms with mean wind speed (the so-called ‘‘advection terms’’). This means that in general the budget equations for momentum, heat, and the various scalars are closely coupled in any atmospheric model. Still one can solve for the local time rate of change in a single column model once the advection terms are known from observations or other means. This approach is widely adopted to study atmospheric boundary layers in comparison with observations on a local scale.

Before we proceed with more detailed parameterizations for the fluxes in the boundary layer, let us deal with the derivation of the surface fluxes. These fluxes enter as boundary conditions when solving the budget equations for all the relevant mean variables (in any approach). It

is important to realize that near the surface, the average wind must vanish because the mean wind is zero at the earth’s surface. At the other hand, we know from observations that the fluxes of heat, momentum and trace gasses are nonzero. Consequently, it is convenient to model an ‘effective’ surface flux  $\bar{w}c_0$  of a conserved variable due to the combined effect of molecular diffusion and turbulence at the surface. This can be achieved by writing

$$\bar{w}c_0 = \beta_t w_t (C_0 - C_a). \quad (6)$$

Here  $C_0$ , and  $C_a$  are the values of the transported variable at the surface and in the air, respectively;  $\beta_t$  is a transfer coefficient, and  $w_t$  is an effective transport velocity representing the turbulence. For example, in near-neutral conditions the effective transport velocity is well represented by the well-known surface friction velocity  $u_{*0}$ . Then it can be shown that  $\beta_t = \kappa / \ln(z/z_0)$ , where  $\kappa$  is the ‘Von Karman’ constant (often specified as  $\kappa \cong 0.4$ ),  $z$  is the corresponding height of  $C_a$  in the lowest part of the boundary layer and  $z_0$  is the so-called surface roughness length for the variable  $C$ . We refer to the literature for a more detailed treatment (e. g., Beljaars and Holtslag [4]).

### Local Mixing Parameterization

To solve the budget Eq. (4) for all the mean atmospheric variables involved, the terms involving turbulent fluxes need to be parametrized. As mentioned before, this means that the fluxes need to be expressed in terms of available mean model quantities, both in the atmosphere and at the surface. Once this has been achieved, the atmospheric model equations can be integrated. Thus, starting with proper initial values, new values can be calculated for the following time step and so on.

The most frequently used parameterization for environmental and atmospheric models, is known as first-order closure or often also called  $K$ -theory. In this theory it is assumed that the flux  $\bar{w}c$  of a variable  $C$  in the vertical direction  $z$ , is down the vertical gradient of the mean concentration of  $C$  per unit mass. Thus

$$\bar{w}c = -K_c \frac{\partial \bar{C}}{\partial z}. \quad (7)$$

Here,  $K_c$  is known as the ‘eddy-diffusivity’ or mixing coefficient for the variable  $C$ . Similarly, the horizontal fluxes can be represented in terms of horizontal gradients. Note that the corresponding eddy-diffusivities typically are not constant, but that they generally depend on properties of the flow and the variable of interest. This also means that normally no analytic solutions are possible, not even for the simple case in which Eqs. (5) and (8) are combined.

We may note that the dimension of an eddy-diffusivity is a length scale  $\ell$  times a velocity scale. These are proportional to the products of effective eddy sizes and eddy velocities in the corresponding directions. Often a diagnostic expression is used for the eddy-diffusivity, on basis of what is called ‘mixing length theory’ (in analogy with molecular diffusion). The result reads as

$$K_c = \ell^2 S f(\text{Ri}) . \quad (8)$$

Here  $S$  is vertical wind shear (that is the variation of mean horizontal wind with height). Note that the combination  $\ell S$  in Eq. (9) has units of velocity. In Eq. (8),  $f(\text{Ri})$  denotes a functional dependence on local stability as represented by the gradient Richardson-number  $\text{Ri}$  defined by

$$\text{Ri} = \frac{g}{\Theta_v} \frac{\partial \overline{\Theta}_v / \partial z}{(\partial \overline{U} / \partial z)^2 + (\partial \overline{V} / \partial z)^2} . \quad (9)$$

Here  $g$  is the acceleration due to gravity, and  $\overline{\Theta}_v$  is the mean ‘virtual potential temperature’.

The specification of the length scale  $\ell$  is not at all straightforward, except near the surface where so-called ‘surface-layer similarity theory’ (see cited literature) provides that  $\ell \propto z$ . A frequently used form for  $\ell$  is:

$$\frac{1}{\ell} = \frac{1}{\kappa z} + \frac{1}{\lambda} . \quad (10)$$

Here  $\lambda$  is a turbulent length scale, which should be valid for the turbulence far above the surface. We note that the latter has a rather empirical nature and consequently there is no agreement on the specification of  $\lambda$  in the literature.

Equation (8) is a diagnostic equation, which indicates that the eddy-diffusivity may vary with height, wind speed, stability, et cetera. In combination with the flux parameterization of Eq. (7), it follows that the flux at a certain height depends on the local gradient of the mean variable involved. Consequently the approach is referred to as a ‘diagnostic local mixing approach’. Such an approach is mostly suitable for relatively homogeneous conditions with neutral and stable stratification, and is not so suitable for cases with convection (see non-local mixing parameterizations below).

### More Advanced Mixing Parameterizations

A physically realistic alternative to the diagnostic approach is to relate the eddy-diffusivity of Eq. (7) to the actual turbulent kinetic energy of the flow, by using the prognostic turbulent kinetic energy equation and an appropriate choice for the turbulent length scale. It is important to realize that the kinetic energy of atmospheric motion per unit of mass  $E$  is given by the half of the sum of

the velocities squared in the three directions (as in classic mechanics), e.g.  $E = (U^2 + V^2 + W^2)/2$ . Similar as with respect to Eq. (2), we can separate between the Mean Kinetic Energy  $\overline{E}$  of the mean atmospheric motions and the Turbulent Kinetic Energy (TKE or  $e$ ) of the smaller-scale fluctuating motions by turbulence. Thus  $e$  is given by  $e = (\overline{u^2} + \overline{v^2} + \overline{w^2})/2$ .

The prognostic equation for  $e$  reads in its basic form as:

$$\frac{De}{Dt} = -\overline{uw} \frac{\partial \overline{U}}{\partial z} - \overline{vw} \frac{\partial \overline{V}}{\partial z} + \frac{g}{\Theta_v} \overline{w\theta_v} + D - \varepsilon . \quad (11)$$

Here  $De/Dt$  is the total variation of  $e$  with time (the sum of local variations and those transported with the mean air motion). The two terms at the immediate right hand side of (11) represent the shear production of turbulence. These depend primarily on vertical variations of wind or, near the ground, on wind speed and surface roughness. The terms are almost always positive. The third term in Eq. (11) represents the rate of production or breakdown of turbulence by buoyancy effects (such as heat convection). It depends directly on density effects, which can be written in terms of the virtual potential temperature  $\overline{\Theta}_v$ , and its turbulent flux  $\overline{w\theta_v}$ . The term  $D$  in Eq. (11) represents divergence and pressure redistribution terms. These have a tendency to cancel near the surface. Finally, the term  $\varepsilon$  reflects the molecular dissipation of turbulence into heat and this term is always positive. In fact  $\varepsilon$  is typically proportional to  $e/\tau$ , where  $\tau$  is the characteristic time scale for the turbulent mixing process.

Using Eq. (11), turbulent kinetic energy can be calculated for given mean profiles when the corresponding fluxes are calculated using Eq. (7) for all fluxes involved. In this approach the diffusivities are typically calculated with equations of the form

$$K_c = \alpha_c \ell \sqrt{e} . \quad (12)$$

Here  $\alpha_c$  is a constant depending on the variable of interest. The length scale is typically calculated with a similar type of diagnostic equation as (10) provides. This approach is known as the ‘TKE-length scale approach’ and it is an example of so-called 1.5 order closure. Sometimes a prognostic equation is used for the length scale as well, but such an approach is more popular in engineering applications than in the atmospheric sciences.

It can be shown that Eq. (8) is a solution of (11) and (12) in stationary conditions and when other simplifications are made such as the neglect of the influences by advection and turbulence divergence in the TKE equation. A more advanced turbulence scheme is known as ‘second-order closure’. In such an approach, prognostic

equations are developed for the fluxes and variances themselves. Such equations have a very similar structure as Eq. (12) for kinetic energy. Unfortunately, new unknowns are present in these equations. These must be related to the other variables in the model equations, always involving assumptions. Thus, second-order closure involves many more than the original equations and is therefore computationally more time consuming ('expensive') than first-order and 1.5 order closure.

One may expect that a model with 1.5 or second-order closure would produce more realistic results than a model with a first order closure. However, in practice this is often not the case, because of complex model interactions and the difficulty of representing all the relevant details with sufficient accuracy (see also below). That is the reason why diagnostic approaches remain popular. Nevertheless, second order equations are useful to gain insight in the governing physics, and after simplification useful extensions of the basic parameterizations may be achieved.

We continue our discussion with mixing parameterizations which have been proposed for boundary-layers with strong atmospheric convection. In such cases, the turbulent flux of a conserved quantity is typically not proportional to the local gradient alone as predicted by Eq. (7). In fact, in a large part of the ABL the mean gradients are small in conditions with dry convection, in particular for potential temperature (see Fig. 1). Then the fluxes depend mostly on the mixing characteristics of the large eddies across the ABL. Theories are available, which have modified  $K$ -theory to allow for the influence of convection, for example by including additional terms at the right hand side of Eq. (8) For details we refer to the literature (e. g., Holtslag and Moeng [15]).

In the next sections we apply the modeling concepts above and compare their results with field observations. In addition we present results from model intercomparison studies, and illustrate the role of boundary conditions.

### Intercomparison of Single Column Models for Stable Conditions

Atmospheric models for weather and climate need to make an overall representation of the smaller-scale boundary-layer and near surface processes. This appears to be more successful during daytime (e. g. Ek and Holtslag [10]; Holtslag and Ek [17]) than during nighttime stable conditions over land. The modeling of the stable boundary layer over land is rather complex because of the many different physical processes which are "at work" in stable conditions [21]. These small-scale processes are: clear air radiation divergence, drainage flow, generation of grav-

ity waves and shear instabilities, fog and dew formation, the occurrence of a low-level jet and generation of discontinuous or intermittent turbulence [33]. In addition, the phenomenology of stable atmospheric boundary layers is quite diverse, e. g. shallow and deep boundary layers with continuous turbulence through most of their depth, and on the other hand boundary layers with intermittent turbulence or even laminar flow.

The small-scale processes influence the vertical and horizontal exchange of quantities between the surface and the atmosphere as well as the mixing in the atmosphere on a variety of scales. In addition, it is known that turbulent mixing in stratified flow has an inherent non-linear character and may, as such, trigger positive feedbacks. These positive feedbacks, in turn, may cause unexpected transitions between totally different SBL regimes (e. g. van de Wiel et al. [34]).

Figure 3 depicts the interactions between relevant processes in the stable boundary layer. The non-linear behavior of the system is seen in e. g. the surface sensible heat flux ( $H$ ). A sudden change of the surface temperature can result in 2 different impacts on  $H$ . First, in weakly stable conditions (with strong wind and sufficient turbulence), a surface temperature decrease will provide a larger heat flux since  $H$  is proportional to the temperature difference between the surface and the atmosphere. The larger heat flux from the atmosphere to the surface compensates for the stronger cooling. In contrast for stronger stably stratified conditions, a surface temperature decrease will provide a stronger stratification and inhibits turbulent mixing, and consequently  $H$  will decrease. This allows for even stronger surface cooling (positive feedback). Note that a similar diagram for the daytime boundary layer can be found in Ek and Holtslag [10].

Having in mind the above mentioned complexity, one should not be surprised that atmospheric models encounter large forecast errors for stable conditions [20,24]. One strategy to improve model performance is to provide different models the same forecasting task, and analyze which model descriptions are in favor for which atmospheric stability. Recently such an intercomparison of boundary-layer schemes for stable conditions was made within the GEWEX Atmospheric Boundary Layer Study ('GABLS'). This GEWEX project aims to improve the understanding and the representation of the atmospheric boundary layer in regional and large-scale climate models [14]. A rather simple case was selected as a benchmark to review the state of the art and to compare the skills of single column (1D) models [7] and Large-Eddy Simulation models [3]. In this case a stable boundary layer is driven by an imposed, uniform geostrophic wind, with

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 3 Interaction diagram for the processes and variables in the stable atmospheric boundary layer over land (after [26])

a specified constant surface-cooling rate over (homogeneous) ice. The case is initialized with  $\theta = 265$  K for  $0 < z < 100$  and a lapse rate of 1 K/100 m aloft.

It turns out that with the same initial conditions and model forcings, the models indicate a large range of results for the mean temperature and wind profiles. Figure 4 shows the mean profiles for several models after nine hours of constant surface cooling (sufficient to achieve a quasi-steady state). The variable results achieved are strongly related to the details of the boundary-layer mixing schemes [7]. An important finding is that the models in use at operational weather forecast and climate centers (as depicted at the left hand side of Fig. 4) typically allow for enhanced mixing resulting in too deep boundary layers, while the typical research models (at the right hand sides) show less mixing in more in agreement with the ‘Large Eddy Simulation’ results for this case [3].

Because of the enhanced mixing in weather and climate models, these models tend to show a too strong surface drag, too deep boundary layers, and an underestimation of the wind turning in the lower atmosphere [19]. At the other hand, by decreasing the mixing and surface drag, a direct impact on the atmospheric dynamics (‘Ekman

pumping’) is noted (e.g. Beljaars and Viterbo [5]). Consequently, cyclones may become too active, corresponding in too high extremes for wind and precipitation, etc.

### Modeling Boundary Layers over Land

To study the interactions of the ABL with the land surface we utilize the model by Duynkerke [9] with the extensions and modifications by Steeneveld et al. [28]. This model has been validated against tower observations at Cabauw, The Netherlands and later with CASES-99 field observations [1,28], and also participated in the GABLS model comparison in the previous section.

Instead of prescribing the surface temperature, and to enable interaction between the ABL and the land surface, the model is extended with a soil and a vegetation layer. The soil temperature evolution is calculated by solving the diffusion equation (using a grid spacing of 1 cm) and the heat flux  $G_h$  from the soil to vegetation is calculated by:

$$G_h - (1 - f_{veg})K^\downarrow = r_g(T_{veg} - T_{s0}). \quad (13)$$

In Eq. (13)  $K^\downarrow$  is the incoming shortwave (solar) radiation,  $T_{veg}$  represents the vegetation surface temperature,

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 4  
 Modeled potential temperature and wind profiles by an ensemble of column models (after 9 h). Grey areas indicate the ensemble of Large Eddy Simulation results [3]. Left panel shows the results for first order closure models and the right panel for higher order closure models (after [7])

and  $T_{s0}$  the soil temperature just below the vegetation. We use a vegetation fraction  $f_{veg} = 0.9$  and conductance  $r_g = 5.9 \text{ W m}^{-2} \text{ K}^{-1}$ , which are consistent with the observations of CASES99 [28]. Initial soil and surface temperatures are also taken from the CASES99 observations.

Subsequently, the evolution of  $T_{veg}$  is computed by solving the surface energy budget for the vegetation layer:

$$C_v \frac{\partial T_{veg}}{\partial t} = Q^* - G_h - H - L_v E. \quad (14)$$

Here  $C_v$  is the heat capacity of the vegetation layer per unit of area ( $C_v = 2000 \text{ J m}^{-2} \text{ K}^{-1}$ , van de Wiel [34]),  $Q^*$  is the net radiation,  $H$  is the sensible heat flux and  $L_v E$  the latent heat flux. The turbulent fluxes are calculated basically with the format of Eq. (6) above. Finally,  $Q^*$  is calculated by adopting the Garratt and Brost [12] radiation scheme. Note that Eqs. (13) and (14) provide a rather strong coupling of the atmosphere to the vegetated land surface for the current parameter setting which is found to be important [28].

Model forecasts have been compared with CASES-99 observations for contrasting diurnal cycles (i. e. for different wind speeds) for 23–26 Oct. 1999. Note that the model is only initialized once and that the total run comprises three full days. We distinguish between “radiative nights” with weak winds and small turbulent mixing, when radiative cooling dominates the SBL development. On the contrary, so-called “continuous turbulent” nights are characterized by strong winds. The final archetype is the so called “intermittently turbulent” night where turbulent episodes alternate with calm periods, when the radiative and turbulent forcings are of similar order of magnitude. Here we restrict ourselves to the results for surface fluxes, surface vegetation temperature, and vertical profiles of temperature and wind speed during nighttime. The diurnal cycle of the modeled net radiation  $Q^*$  (the balance of all incoming and outgoing short- and longwave radiative fluxes) agrees with the observations (not shown). Net radiation amounts typically  $Q^* = 400 \text{ Wm}^{-2}$  during daytime and  $Q^* = -70 \text{ Wm}^{-2}$  during nighttime.

The friction velocity ( $u_*$ ) shows a clear diurnal cycle:  $u_*$  is large during the day and small at night, which is in general well captured by the model (Fig. 5a). Looking in more detail we find that during weak winds (1st and 3rd night) the model tends to overestimate  $u_*$ . The model lacks a clear turbulence collapse as observed during the first (intermittent) night. In the period 24 Oct., 700 CDT – 25 Oct., 1700 CDT the model performs well, while during the last (radiative) night  $u_*$  is slightly too high until midnight but follows the collapse at the end of the night. The overall bias amounts to  $0.03 \text{ ms}^{-1}$  for the last night. Sodar observations show much smaller wind speeds at 200 m AGL (which is above the SBL during this night) than the imposed G. This may suggest that G was overestimated, and this consequently may explain the bias in  $u_*$ . In general it is known that models correctly predict  $u_*$  for strong winds, but overestimate  $u_*$  for weak winds [25,32].

The sensible heat flux differs substantially between day ( $\sim 250 \text{ Wm}^{-2}$  here) and night (between 0 and  $-60 \text{ Wm}^{-2}$  depending on the wind speed). In the first (intermittent) night, the modeled  $H = -14.1 \text{ Wm}^{-2}$  on average, while  $-9.1 \text{ Wm}^{-2}$  was observed. However, the model does not simulate the observed intermittent character of the surface fluxes (Fig. 5b). Some models with more resolution [23,36] were also able to reproduce intermittent turbulence. On the other hand, the models by Sharan and Gopalakrishnan [25] and Derbyshire [8] did not show any intermittency. This subject needs further investigation.

Just after the day-night transition to the intermittent night, the observed magnitude of  $H$  shows a clear maximum (see arrows in Fig. 5b), which is well reproduced

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 5 Modeled and observed (+) friction velocity (a), surface sensible heat flux (b), and surface vegetation temperature (c) for three diurnal cycles in CASES-99 (after [28])

by the model. This maximum is caused by a sudden reversal of the stratification near the surface due to longwave radiation emission during the day-night transition, and is maintained by residual turbulence of the convec-

tive boundary layer. This is an often observed *realistic feature* (e. g. during 11 of the 30 nights for CASES-99 and in FIFE observations shown by [6]). However, most modeling studies rarely show these minima. The reproduction of this detailed feature emphasizes the realism of the model outcome.

During the turbulent night (24–25 Oct.), the predicted  $H$  follows the observations. The specific minimum during the day-night transition (24 Oct., 1900 CDT) is present here as well. Radiative flux divergence dominates the last (radiative) night and the observed  $H$  is approximately zero. The model slightly overestimates the magnitude of  $H$  ( $-2.9 \text{ Wm}^{-2}$ ), mainly caused by an overestimation of  $u_*$ . This causes a weaker stratification and thus a larger magnitude of  $H$ . The second half of this night the model gives good results.

Reliable prediction of  $T_{\text{veg}}$  is a common problem for large-scale models. Some models show unphysical decoupling of the atmosphere from the surface resulting in so-called “runaway cooling” of  $T_{\text{veg}}$ . On the other hand, the pragmatic enhanced mixing approach which is commonly used for very stable conditions, leads to overestimation of  $T_{\text{veg}}$ . For both day- and nighttime  $T_{\text{veg}}$  is simulated in very good agreement with the data, despite the fact that we cover a broad range of stability (Fig. 5c).

We conclude that the present model generates surface fluxes which are in good agreement with observations, because of the detail in the description of the surface scheme, the soil heat flux and radiation physics (with high resolution). In general, the model is also able to estimate temperature and wind profiles (see results and discussion in Steeneveld et al. [28]). To examine the robustness of the results, we performed some sensitivity analysis on the initial conditions and model parameters. Disturbing the initial temperature (by 1 K), wind profiles (by 5%), soil temperature and vegetation temperature (both by 1 K) do not affect the results seriously. Also model re-initialization every 24 h (1400 CDT) with observed radiosonde information showed hardly any impact on the results (not shown).

### Impact of Land Surface Conditions on Model Results

Inspired by the result in the previous section that a coupling with the land surface is necessary to obtain satisfactory model results, we now analyze the difference in variability of model results during model intercomparisons, as function of the chosen boundary condition. At first we use the first-order closure model and vary the parameters in the turbulence scheme for stable conditions in a reasonable range to mimic the apparent variability among

boundary-layer models. As such first model runs are performed with a prescribed surface temperature as inspired by (but not identical to) the observations in CASES99 [22] and as described in the GABLS2 case description [31]. Subsequently, the model runs are repeated, but then using an interactive prognostic heat budget equation for the surface temperature (Eq. (14)).

To study the impacts of parameter values on the model results, reference runs are made for coupled and uncoupled cases with alternative permutations in some of the parameter settings for stable conditions. The parameter modifications are chosen such that they cover a realistic range in comparison with existing models of the stable boundary layer [7]. The local starting time in the model runs is 14.00 LT on October 22, 1999 (rather than 16.00 LT in the GABLS2 runs). The duration of all runs is 59 hours (so that the axis of all the figures indicates 14.00 until 73.00 h, covering a period of 2.5 diurnal cycles). In all model runs the roughness length for heat  $z_{\text{oh}}$  and momentum  $z_{\text{om}}$  (3 mm and 3 cm respectively), and the canopy resistance are constant, and the geostrophic wind is taken at a reference value of  $9.5 \text{ ms}^{-1}$  (as in Svensson and Holtslag [31]). The reference model set up has 50 logarithmically distributed layers and the first atmospheric model level is at 2 m.

The model results for all parameter permutations are presented for the sensible heat flux (Fig. 6). In the upper sub-frame of the figure (labeled a) the results achieved with the uncoupled model are given (using prescribed surface temperature). Overall the variety of results in the upper frame is comparable to the variety within the GABLS2 intercomparison study in stable conditions for the uncoupled models (see Svensson and Holtslag [31]). Thus we have a range of  $-15$  to  $-50 \text{ Wm}^{-2}$  for the sensible heat flux (at the end of the first night e. g. at the time of 30 h). The variability is a result of the range of parameters chosen above and the impact is apparently sufficient to mimic the different parameterizations for stable conditions in the models used within GABLS2.

Next we repeat all model runs and allow for surface feedback using Eqs. (13) and (14). The results for the sensible heat flux with the coupled model are given in the lower frame (Fig. 6b). Now we have a range of  $-10$  to  $-25 \text{ Wm}^{-2}$  (again the values apply for the end of the first night e. g. at the time of 30 h). Thus it appears that the variety of model results is *smaller* for the sensible heat flux in the coupled case. At the same time it appears that the variability appears to be somewhat larger for friction velocity and boundary-layer depth, which seems to be related to the larger variability in the near surface air temperature and wind speed.

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 6  
**Time series of an ensemble of model results for the sensible heat flux in a model intercomparison study with a prescribed surface temperatures, and b by solving the surface energy budget (after [18])**

During daytime the sensible heat fluxes are rather similar for all model runs within one category (either coupled or uncoupled), but the maximum values differ. In addition, due to the coupling the sensible heat fluxes show a more smooth behavior in the morning hours as compared with the uncoupled results. Thus, surface feedback is influencing the model results and is also able to compensate for some variation in the model parameter values. Note also that the variability in the friction velocities of the first night remains during the morning hours in the uncoupled runs, but not so much in the coupled case.

In Fig. 7 the surface temperatures are given as specified for the uncoupled case (the dashed line), and the temperatures as calculated in the various interactive model runs (various gray lines). It is seen that the latter ones are quite different from each other (in particular at night). It is also important to note that the surface temperature by the en-

Single Column Modeling of Atmospheric Boundary Layers and the Complex Interactions with the Land Surface, Figure 7  
**Time series of an ensemble of modeled surface temperature for coupled runs. Dash-dotted line: prescribed surface temperature in the uncoupled case (after [18])**

semble of coupled model runs is clearly different from the specified temperature in the uncoupled case. This impacts also on the absolute values and the range of air temperatures and the wind speeds.

Thus it is apparent that the treatment of the surface temperature impacts strongly on the outcome of the boundary-layer model results and their variety (see also Basu et al. [2]). By repeating the uncoupled model runs with a specified surface temperature as given by the ensemble mean value of the interactive runs, we achieve basically the same variety of model outputs for the potential temperature and wind as for the coupled cases. This confirms that in model evaluation studies the surface temperature should be taken consistent with the value of the geostrophic wind (although this may be model dependent).

## Summary

In this paper a summary is given of the basic approaches for the modeling and parameterization of turbulence in the atmospheric boundary layer. The treated approaches are in current use in regional and global-scale models for the forecasting and study of weather, climate and air quality. Here we have shown the results of such approaches by using single column models in comparison with field data and fine-scale model results. We have also studied the impact of the surface temperature condition on the variability of results by an atmospheric boundary-layer model. From the coupled model results we achieve that surface feedback can compensate for some of the variety introduced by

changing model parameters. Generally much work needs still to be done before we have a full understanding of the complexity of atmospheric turbulence and the interactions with the land surface. A better understanding of atmospheric turbulence hopefully also contributes to our capability in refining and unifying the turbulence parameterizations for modeling of the atmospheric boundary layer in response to the different type of surfaces which are found in reality.

### Acknowledgments

This contribution is a compilation of earlier works by the authors, in particular the works by Holtslag [13], Steeneveld et al. [28] and Holtslag et al. [18].

### Glossary

**Strombolian activity** Is a kind of volcanic activity consisting of discrete, intermittent ejections of gas and magma fragments. The height reached by the ejecta seldom exceeds a few hundred meters above the volcanic crater. They consist mostly of molten magma fragments that partially quench as they fly. Strombolian explosions are intermediate between small Hawaiian eruptions and stronger Plinian eruptions. This kind of activity takes its name from the Stromboli volcano (Southern Italy) famous for its perpetual activity consisting of repeated moderate explosions (usually about 10 every hours).

**Gas slug** A bubble whose diameter is close to the diameter of the conduit where it is flowing. The shape and the motion of the slug is largely controlled by the conduit walls.

**Modeling** A simplified representation of a system aimed at reproducing some of its features. Mathematical models describe a system through a set of variables related by analytical relations. When these relations are too complex to be solved exactly, they can be solved using approximate numerical methods. Actually these numerical techniques often involve the massive use of computers. An alternative kind of modeling (analogue

modeling) involves the use of versions of the system under study rescaled to fit spatial and temporal laboratory scales. Different materials are used to simulate original ones. For instance silicon oil is often used to simulate magma. The scaling relationships are rigorously stated in order to get physically meaningful results.

**Computational fluid dynamics** A set of mathematical, numerical and computational tools aimed at simulating complex fluid flows on computers. It developed simultaneously with computer science starting from the 1950s mostly with the aim of solving engineering problems. Today CFD spans a wider range of fields, from aeronautics to chemical engineering, to astrophysics to geophysics and much more. The most recent developments of CFD are related with the increase in computer performances and with the wider use of parallel computers.

**Diffuse interface theory** A molecular theory for describing the variation of the chemical composition across the interface on the basis of a rigorous thermodynamical approach. Starting from the definition of a free-energy function dependent on the chemical composition and its gradient, it is possible to compute all the chemical-physical properties of the interface. Beyond its physical meaning, this theory can be used also as a numerical tool for modeling of multiphase flows.

**Very-long-period events (VLP)** Seismic events recorded on active volcanoes and geothermal systems having a typical period of  $10^2$ – $10^0$  s. Their observation and study began during the 1990s, with the spreading of seismic broadband sensors and have shown to be one of the most powerful tools for investigating the geometries of volcanic conduits and the dynamics of volcanic eruptions. Until now they have been observed in tens of volcanoes with different eruptive styles such as: Aso (Japan), Erebus (Antarctica), Kilauea (Hawaii), Popocatepetl (Mexico), Sakurajima (Japan), Stromboli (Italy).

**Moment-tensor** Tensor representation of the force systems acting on seismic sources. It can be applied to common earthquake sources (rupturing faults) as well as to volcanic sources (fluid filled conduits). In the former case its trace is null, which from a physical point of view, means that there is no net volume change during common earthquakes. On the other hand in volcanic sources volumetric variations are very common and furthermore they are accompanied also by a single force component, related to the net acceleration of center of mass of the fluid filling the conduit.

## Definition of the Subject

Among the eruptive styles, the Strombolian activity is one of the more easy to study because of its repetitive behavior. For this reason large amount of data can be comfortably collected. Strombolian volcanoes are like natural laboratories repeating the same experiment (individual explosions) many times each day.

The development of quantitative models of eruptive dynamics is driven by the comparison of experimental observations and synthetic data obtained through mathematical, numerical or analogue modeling.

Since Strombolian activity offers a profuse amount of interesting seismic signals, during the last decades there has been growing attention on seismological techniques aimed at retrieving the conduit geometry and the eruption dynamics from the seismological recordings. One of these techniques, the source function inversion, is able to retrieve a summary of the forces acting on the volcanic conduit during the VLP event generation [5]. The comparison of observed source functions with synthetic ones, obtained through numerical modeling, allow us to put constraints on the proposed models.

Quantitative models, able to fit seismological observations, are a powerful tool for interpreting seismic recordings and therefor the seismological monitoring of active volcanoes.

## Introduction

In this paper we discuss the mechanism of generation of Very-Long-Period events related to Strombolian explosions. This eruptive style, occurring in many basaltic volcanoes worldwide, is characterized by the ascent and the bursting of large gas slugs. The mechanism of formation, ascent and explosion of bubbles and slugs and their relation to eruptive activity has been studied from a theoretical point of view and by means of analogue simulations. Here we introduce results from numerical simulations, focusing on the pressure variations induced on the conduit walls and responsible for the generation of seismic signals.

We will first illustrate the main features of the fluid dynamics related to Strombolian eruptive activity (Sect. “**Slug Flow and Strombolian Activity**”) and an overview of the numerical modeling (Sect. “**Numerical Modeling**”) Then we will show results obtained using simple conduit model (Sect. “**Bubble Ascent**”, Sect. “**Slug Ascent in a Vertical Pipe**” and Sect. “**Slug Ascent in a Pipe with a Flare**”) and we will compare the synthetic source functions with actual observations (Sect. “**Seismological Constraints on Numerical Models**”).

## Slug Flow and Strombolian Activity

A fundamental distinction can be made between eruptive regimes on the basis of the magma viscosity. In silicic systems, the magma viscosity ( $>10^5$  Pa s) is too high to allow an independent motion of gas bubbles [18]. They can only grow by diffusion processes and expand under the effects of pressure variations until fragmentation occurs. In basaltic magmas the viscosity ( $<10^3$  Pa s) allows independent motion of the gas bubbles leading to a different behavior with the possibility of bubble coalescence, splitting and turbulent fluid flow [11]. Theoretical laboratory and numerical studies have been published in order to understand the dynamics of Strombolian eruption in terms of gas/magma interaction [12,24].

The distinction between free bubble ascent and slug flow can be made using the ratio between the average bubble diameter  $d$  and the conduit diameter  $D$  [7]: the parameter  $\lambda$  (Table 1). Values of  $\lambda$  higher than 0.6 are related to slug flow. The range of behavior exhibited by slug flow depends on the physical properties of the fluids (density, viscosity, surface tension) and on the geometry of the conduit (diameter, shape, inclination). It is possible to define adimensional parameters for describing the particular flow regime (see Table 1). The Reynolds number is the ratio between inertial and viscous forces. Low values of  $Re$  are typical of laminar flows, while higher values are related to turbulent regimes. The Froude number  $Fr$  is the ratio between inertial and gravitational forces. The Eotvos number  $Eo$  is the ratio between buoyancy and surface tension effects. The values of  $Eo$  determines the bubble shape. High values of  $Eo$  are related to distorted bubble shapes, while lower values to sub-spherical shapes. The Morton number  $Mo$  has a similar meaning. The dimensionless inverse viscosity  $N_f$  assess the relative importance of viscous effects. Viscous flows are characterized by  $N_f < 2$  while inertial flows by  $N_f > 200$  [9].

The ascent of gas in a basaltic system has been studied both from a theoretical and an experimental point of view. Observations of basaltic systems have shown that usually the flow conditions are transitional between viscous dominated and inertia dominated systems [17]. This puts constraints on the parameter range to explore both in numerical and analogue modeling. The range of adimensional numbers for basaltic systems, summarized from [17] and [9] is reported in Table 2.

For a basaltic system with given physical properties another variable plays a fundamental role in determining the physics of the flow: the gas/magma volumetric ratio. Flows are characterized by a low ratio consist of isolated bubbles rising with minor interaction between them

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 1  
 Symbols used in the text

Symbol	Meaning
$d$	Average bubble diameter
$D$	Conduit diameter
$L$	Distance between the top of the bubble and the magma/air interface in the initial conditions.
$U$	Terminal slug velocity
$\lambda$	$\lambda = \frac{d}{D}$
$g$	Gravity
$\rho$	Liquid density
$\Delta\rho$	Difference between gas and liquid densities
$\mu$	Dynamic viscosity
$\nu$	Kinematic viscosity $\nu = \frac{\mu}{\rho}$
$\sigma$	Surface tension
$\gamma$	Isothermal expansion ratio
$Re$	Reynolds number $Re = \frac{Ud}{\nu}$
$Fr$	Froude number $Fr = \frac{U}{\sqrt{gD}} \sqrt{\frac{\rho}{\Delta\rho}}$
$Mo$	Morton number $Mo = \frac{g\mu^4\Delta\rho}{\rho^2\sigma^3}$
$Eo$	Eotvos number $Eo = \frac{\Delta\rho g D^2}{\sigma}$
$N_f$	Dimensionless inverse viscosity $N_f = \left(\frac{Eo^3}{Mo}\right)^{\frac{1}{4}}$

and the conduit walls (Fig. 1a). In this regime bubbles rise assuming a shape that depends on their size and on the magma viscosity. Surface tension effect depends on the size of the bubbles and the ascent velocity depends on both the bubble size and the magma viscosity. In the range allowed for basaltic systems, larger bubbles have shapes ranging from dimpled ellipsoidal cap to spherical cap, while smaller bubbles have shapes ranging from spherical to ellipsoidal [7]. For higher gas/magma ratios bubbles begin to interact and to coalesce forming gas slugs occupying most of the conduit diameter (Fig. 1b). The ascent of gas slugs is strongly controlled by the conduit walls. During their passage, the magma is completely mixed and the motion of smaller bubbles is dominated by the fluid vorticity released (in a transitional regime) in their wake. For even higher gas/magma ratios (Fig. 1c) the slugs co-

alesce forming an almost continuous (turbulent) gas flow at the center of the conduit, while walls remains wet with a magma film. The high velocity of the flow produces instabilities on the surface of the magma film pulling out small fragments carried away from the gas.

Bubbly flows are related to effusive and to moderate Hawaiian explosive activity. Each single bubble explodes at the magma/air interface ejecting small magma fragments resulting from the shattering of the liquid film around the bubble. The bubble is usually overpressurized because of surface tension, viscous and inertial effects [23]. Slug flows are related instead to intermittent Strombolian activity. Each slug exploding at the magma/air interface generates a jet of gas of short duration (from a few seconds to some tens of seconds) [24]. The main Strombolian explosion can be followed by minor bursts caused by the smaller bubbles trapped behind the slug wake. Annular flows are related to continuous lava fountains with the central gas jet carrying molten magma fragments [11].

The nature of the flow can change along the conduit because of the gas expansion due to the magmastatic pressure decrease. This expansion makes the gas/magma volumetric ratio increase along the conduit. At the base of the conduit, where the gas starts to evolve from the magma there is always a bubbly flow. As the pressure decreases the flow can change into slug flow. This can be made easier by an inclined conduit [4] and by constrictions [12] that force the bubbles to coalesce even at lower gas/magma ra-

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 2

Range of adimensional numbers for flows related to basaltic systems (from [17] and [9])

Parameter	Range
$Fr$	$0.1 \div 0.345$
$Re$	$5 \div 31^3$
$Eo$	$51^5 \div 71^7$
$Mo$	$51^5 \div 101^{10}$
$N_f$	$16 \div 5000$

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 1

Schematic representation of gas/magma flows in basaltic systems. **a** represents bubbly flow, **b** slug flow and **c** annular flow

tions than those required in a straight vertical conduit. The total gas flow can change in the conduit because of variations in the deep feeding system or because of non-linear instabilities due to the complex shape of the conduit system [11,12].

The expansion of bubbles and slugs is a fundamental factor to take into account when studying Strombolian activity [17]. Assuming a simple ideal isothermal state equation for the gas we get the relative volumetric change for a bubble rising in a magma with density  $\rho$ :

$$\frac{V_0}{V} = \frac{P_{\text{atm}} + \rho gh}{P_{\text{atm}}} \quad (1)$$

It is easy to show that the expansion ratio in the upper few hundreds of meters is more than one order of magnitude.

The flow regime can change also horizontally, for instance in a subvertical dike the flow rate can be higher on

one side, leading to a slug flow, and lower on the other side, leading to a bubbly flow. This explains the coexistence of effusive and Strombolian activity observed during some basaltic eruptions.

### Numerical Modeling

The aim of this work is to investigate the pressure variations induced by a gas bubble rising in a magma-filled volcanic conduit. This phenomenon has been also investigated by means of analogue laboratory models [9,10,12,17].

The major drawback of analogue modeling, in this context, is that it provides only a limited number of pressure time series: one for each sensor. Numerical modeling provides a different point of view giving the full set of scalar (density), vector (velocity) and tensor (pressure) quantities over the whole computational domain. This allows quantitative inferences on the flow regimes and on the elastodynamic wavefield generated (see Sect. “[Seismological Constraints on Numerical Models](#)”).

The modeling of two-phase systems as gas magma is not a simple task in computational fluid dynamics (CFD) [6]. Taking into account surface tension effects at the liquid-gas interface can be done in two different ways. The first consists in explicitly tracking the time evolution of the gas-liquid interface [22]. In situations involving complex flows with extensive occurrences of bubble coalescence and splitting, these methods show a rapid increase in computational effort. Another category of methods model the gas-liquid systems using the diffuse-interface theory. These methods consider two scalar fields, defining the relative local concentrations of the two components and a modified advection-diffusion equation for modeling the physical-chemical interaction between them. This is done using a thermodynamically consistent definition of a free-energy function that takes into account the phase equilibria. This approach leads to smooth interfaces where the concentration of one phase gradually decreases while the other increases. The thickness of these interfaces depends on the numerical method and on the surface tension value [25]. From a numerical point of view this problem can be faced using Lattice Boltzmann Methods (LBM) [20] or by classic CFD [6]. Here we use the latter. Some details about the numerical method are reported in the Appendices.

In our models we have not considered the mechanical interaction between the fluid phases and the elastic conduit walls. The exchange of linear momentum between them is a significant factor in the generation of seismic waves [3] in seismo-volcanic sources. However in

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Table 3  
Description and adimensional numbers for the six simulations presented in the text

Sim.	Description	Comp. domain (pts.)	$\lambda$	$\gamma$	$Re$	$\log(Mo)$	$Eo$	$Fr$	$N_f$
1A	Bubble ascent (low viscosity)	60 × 600	0.5	5	$1.93 \times 10^3$	0	$9 \times 10^4$	0.37	$5.19 \times 10^3$
1B	Bubble ascent (high viscosity)	60 × 600	0.5	5	$1.90 \times 10^2$	4	$9 \times 10^4$	0.36	$5.19 \times 10^2$
2A	Slug ascent in vertical pipe (low viscosity)	30 × 600	0.8	5	$1.82 \times 10^3$	0	$9 \times 10^4$	0.35	$5.19 \times 10^3$
2B	Slug ascent in vertical pipe (high viscosity)	30 × 600	0.8	5	$1.54 \times 10^2$	4	$9 \times 10^4$	0.30	$5.19 \times 10^2$
3A	Slug ascent in vertical pipe with a flare (low viscosity)	60 × 600	0.8	5.3	$1.83 \times 10^3$	0	$9 \times 10^4$	0.35	$5.19 \times 10^3$
3B	Slug ascent in vertical pipe with a flare (high viscosity)	60 × 600	0.8	5.3	$1.68 \times 10^2$	4	$9 \times 10^4$	0.32	$5.19 \times 10^2$

conduits having ratios between the linear dimension and thickness lower than  $10^1$ – $10^2$  the effect of the motion of the conduit walls does not affect significantly the fluid flow. Furthermore we show in Sect. “**Seismological Constraints on Numerical Models**” that we will not compare the result of the simulation directly with seismograms, but with an equivalent system of forces acting on the conduit walls.

In the following we present results of some elementary two-dimensional conduit models focusing on the slug flow regime which occurs during Strombolian activity. The numerical simulations generate snapshots of the physical quantities (composition, density, pressure and velocity) along all the point of the discretized computational domain. The effective computational domains for each simulation are showed in Table 3. In all the simulations we start from a static fluid with a bubble in the lower part of the conduit and a gas/magma interface in the upper part. The boundary conditions keeps a constant pressure value at the bottom and the top of the model. The no-slip boundary conditions are implemented along the conduit walls.

The adimensional numbers for each simulation are reported in Table 3. Velocities for determining  $Re$  and  $Fr$  are computed when the bubble/slug is moving in a steady state after a transient due to the initial conditions. These velocity values  $U$  are also used for normalizing times:

$$t^* = t \frac{U}{L}, \quad (2)$$

where  $L$  is the distance between the top of the bubble and the magma/air interface. So (2) represents a normalization for the virtual time the bubble needs to reach the surface in an ideal steady motion. We can also normalize distances:

$$x^* = x \frac{1}{D}, \quad (3)$$

where  $D$  is the conduit diameter. We can define then normalized velocities as:

$$v^* = \frac{\partial x^*}{\partial t^*}. \quad (4)$$

In our simulations we have also defined an isothermal expansion ratio  $\gamma$  which is the ratio between the bubble volume at the initial conditions and its volume at (simulated) atmospheric pressure.

### Bubble Ascent

We first consider the ascent of a single bubble in a vertical conduit. In the first simulation (1A in Table 3) the initial shape of the bubble is an ellipse (see Fig. 2). As the simulation evolves the bubble becomes unstable splitting into three smaller bubbles. The two smaller lateral bubbles are embedded in a symmetric vortex structure. As the flow evolves the symmetry is broken and a turbulent wake develops behind the largest bubble. This one rises with an almost steady velocity (Fig. 2 top) with a spherical cap shape. In the final part of the simulation, the bubble suffers an expansion that made the bubble accelerate ( $t > 0.8$ ) and causes the flow to become transitional toward the slug flow regime. Then the bubble reaches the surface and a curved liquid film develops above the bubble just before bursting. This phase is accompanied by a sudden deceleration of the bubble ascent ( $t > 1.0$ ). The pressure variations in the conduit are modest, with a lack of low frequency oscillations. Also the pressure transients generated by the bubble burst are limited (Fig. 3).

The adimensional number for this simulation (Table 3) is in a range related to transitional flow regimes typical of basaltic systems [9,17]. An increase of an order of magnitude of the viscosity (1B in Table 3) makes the flow still in the transitional regime (Table 3). The high values of

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 2

Ascent and bursting of a gas bubble (simulation 1A in Table 3). Time, height and velocity are normalized according to (2), (3) and (4)

the Eotvos number indicates that the surface tension effect is not relevant in the flow dynamics [7] in both cases.

### Slug Ascent in a Vertical Pipe

In these simulations (2A and 2B in Table 3) we model the ascent of a single slug in a vertical pipe. Again we start from an elliptical shape of the bubble. After an initial transient the typical slug shape develops (Fig. 4) and a turbulent wake appears behind the slug. As the slug rises it suffers a volume expansion. In the slug flow regime the liquid is pushed upward causing an overall increase of the hydrostatic pressure in the conduit. After the bursting of the slug the liquid film on the wall falls down to the original hydrostatic level. The slug expansion causes a significant acceleration of the liquid for  $t > 1.0$  (Fig. 4). The velocity drops as the slug reaches the bursting point and the liquid film develops.

The major feature in the pressure pattern is the slow ramp-like increase followed by a drop (Fig. 5). The increase reflects the rise of the hydrostatic head above the slug while the gradual decrease is related to the passage of the slug. The bursting of the slug generates a moderate pressure transient in the conduit (marker “T” in Fig. 5) and damped resonant oscillations in the uppermost part of the pipe, filled with gas (above norm. height 11 in Fig. 5).

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 3

Time series of pressure variations for simulation 1A. The represented pressure values are normalized by the external atmospheric pressure  $P_0$ . Each time series represents the recording of a virtual sensor located at the center of the conduit at the height of its first point (see scale on the left)

The simulated pressure pattern fits very well the observations of analogue modeling [9]. Both the pressure increase linked to the rise of the hydrostatic head and the pressure drop related to the passage of the slug are in good agreement. Together with these long period variations they observe also oscillatory pressure transients just before the slug approaches the surface and after the bursting. The simulations presented here lack this feature because of an intrinsic limit in the numerical method that does not model explicitly the interface (see Appendix).

The overall behavior of simulation 2B, where a tenfold increase of the liquid viscosity (Table 3) is very similar to 2A. The only remarkable difference is the lack of high frequency oscillations in the pressure (as the transient “T” in Fig. 5) due to the greater viscous damping effect.

### Slug Ascent in a Pipe with a Flare

In this set of simulations (3A and 3B in Table 3) we model again the ascent of a single slug in a pipe. However in this

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 4

Ascent and bursting of a single gas slug in a straight pipe (simulation 2A in Table 3)

case the width of the pipe doubles after a norm. height of 10. In the first part of the simulation, the behavior is similar to the one illustrated in Sect. “[Slug Ascent in a Vertical Pipe](#)”. As the slug nose enters in the flare (Fig. 6) it starts to expand rapidly making the fluid accelerate upward. The expansion of the slug in the flare is followed by its breakup because of the development of strong turbulence. The velocity of the top of the slug increases until the slug passes through the flare then it drops because of the change in the conduit diameter.

The pressure pattern shows a major difference, compared with simulation 2A (Fig. 7). As the slug passes

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 5

Time series of pressure variations for simulation 2A.  $T$  marks the most significant transient in the pressure patterns

through the flare there is a sudden pressure increase recorded along the whole conduit. The pressure then drops when the slug expansion has terminated. This strong pressure pulse is clearly related to the varying fluid flow regime as the slug enters the upper conduit and it deserves a closer analysis. In Fig. 8 we have represented the fluid dynamic regime during the slug expansion together with the related pressure variations. We observe that the pressure rises when most of the slug has passed through the flare. The strong acceleration induces turbulence both in the lower and the upper sections of the conduit. The upward acceleration first causes the disruption of the lower part of the slug leaving behind the main bubble a set of smaller ones, whose motion is driven by the fluid turbulence. When the slug has entered in the upper conduit it suffers another splitting due both to the induced vorticity and to the change in the boundary conditions. The behavior of the slug for  $t^* > 0.8$  is characterized by a flow regime with a smaller value of  $\lambda$  and so it is similar to the initial part ( $t^* < 0.2$ ) of simulation 1A.

Similar fluid dynamics behavior and pressure patterns have been observed in analogue simulations by [10]. In

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 6  
 Ascent and bursting of a single gas slug in a pipe with a flare (simulation 3A in Table 3)

particular, the breakup of the slug and the generation of a positive pressure pulse as it passes through the flare are observed in analogue models within a wide range of fluid viscosities and conduit widenings.

As in the previous case the simulation with higher liquid viscosity (3B in Table 3) shows a similar behavior. Higher viscosities reduce the fluid vorticity leading to less fragmented slugs.

**Seismological Constraints on Numerical Models**

Seismological data analysis is a powerful tool for putting constraints on the geometry and the dynamics of volcanic systems. Non-stationary fluid flow in volcanic conduits generates pressure variations on the conduit walls and then seismic waves propagating toward the Earth’s surface where they are recorded by seismometers. The frequency band of seismic signals recorded in volcanic areas spans a wide range: from the Ultra-Long-Period (ULP)

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 7  
 Time series of pressure variations for simulation 3A. E marks the entering of the slug in the upper conduit while B marks the bursting of the main bubble at the magma surface

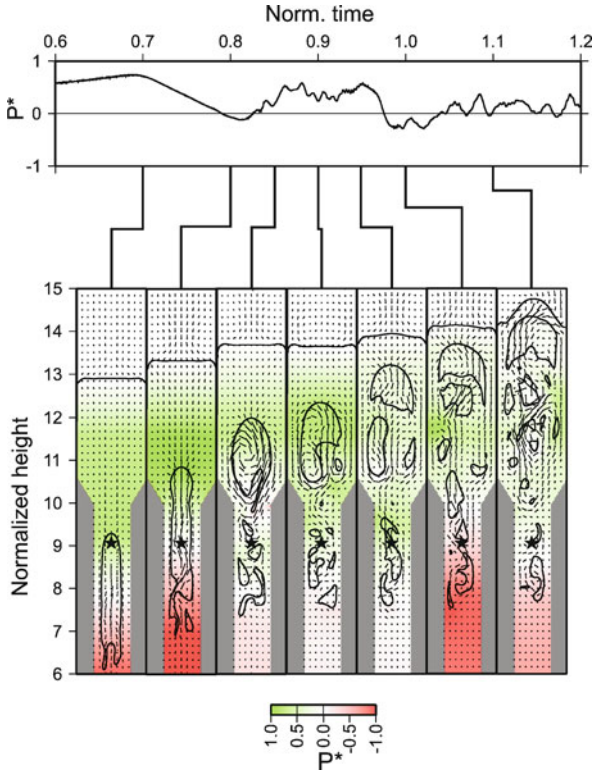

band ( $>10^2$  s), the Very-Long-Period (VLP) band ( $10^2-10^0$  s) and the Long-Period (LP) band ( $10^0-10^1$  s) [5].

From a formal point of view this can be expressed considering the elastodynamic field generated by a general extended source, whose external surface is  $\Sigma$ :

$$u_n(\mathbf{x}, t) = \iint_{\Sigma} [f_q * G_{np} + m_{pq} * G_{np,q}] d\Sigma, \quad (5)$$

where  $u_n(\mathbf{x}, t)$  is the  $n$ th component of the ground displacement recorded at the position  $\mathbf{x}$ ,  $f_q$  is the body-force distribution over  $\Sigma$ ,  $m_{pq}$  is the moment density tensor and  $G_{np}$  are the Green’s functions. In (5) we take into account all the details of the source dynamics. However the density of actual seismic networks is not sufficient for retrieving every minor feature of the seismic sources. Volcano monitoring networks usually have a limited extension ( $10^3-10^4$  m) and the wavelengths associated with ULP and VLP signals are higher. Therefore the analysis of such signals the seismic source (i. e. the part of the volcanic conduit responsible of seismic wave generation) can be represented

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 8

Detail of the conduit during the slug expansion phase. Each snapshot represents the normalized pressure variations (see the color scale on the bottom) and the local fluid velocity vectors. The thick contours are the bubble interfaces. The pressure values represented above are measured at the virtual sensor indicated by a black star in the snapshots

as a point [5]. Under the assumption of a point source we can express (5) as [5]:

$$u_n(\mathbf{x}, t) = F_q * G_{np} + M_{pq} * G_{np,q}, \quad (6)$$

where:

$$F_q = \iint_{\Sigma} f_q d\Sigma \quad (7)$$

and:

$$M_{pq} = \iint_{\Sigma} m_{pq} d\Sigma. \quad (8)$$

In common earthquake sources the single force component  $F_q$  is null. In volcanic sources, the acceleration of the center of mass of the fluid makes this component noteworthy.

The inversion of the recorder waveforms  $\mathbf{u}(\mathbf{x}, t)$ , after the numerical computation of the Green's functions  $\mathbf{G}$  allows the retrieval of the single force and moment tensor components of (6) [14].  $\mathbf{F}$  and  $\mathbf{M}$  are a synthesis of the force systems acting on volcanic conduits and then can be used for discriminating among numerical models on the basis of their fit with observations.

Numerical simulations provide the pressure tensor field  $\mathbf{P}$  over the whole computational domain. The pressure tensor can be used for computing the forces acting on each point of the conduit walls multiplying it for the unit vector normal to the wall  $\hat{\mathbf{n}}$ :

$$\mathbf{f} = \mathbf{P}\hat{\mathbf{n}}. \quad (9)$$

These values can be integrated numerically using an expression similar to (7) to get the single force component  $\mathbf{F}$ . Then using the definition of moment they can be used for retrieving also the equivalent moment tensor:

$$M_{pq} = \iint_{\Sigma} \left( f_q - \frac{F_q}{\Sigma} \right) r_p d\Sigma, \quad (10)$$

where  $\mathbf{r}$  is the arm formed by the force respect to an arbitrary origin  $\mathbf{O}$ .

In Fig. 9 we have represented the vertical force component and the moment tensor isotropic component (that is the trace  $M_{xx} + M_{zz}$ ) for the three simulations with lower liquid viscosity. The represented values are normalized.

In the first case (1A) we note the absence of significant signals. There are only minor oscillations related to fluid dynamics instability during the bubble ascent. The rise of a bubble smaller than the conduit dimension seems not to be able to generate VLP signals. Therefore a repetitive bursting of small bubbles at the magma/air interface can be responsible for the generation of continuous infrasonic and seismic tremor recorded in some basaltic volcanoes [16].

In the second case, again, the signal amplitudes are quite low. It is evident that there is an anticorrelation between the vertical force and the isotropic moment. The vertical acceleration of the slug ( $1.0 < t^* < 1.3$  in Fig. 4) causes a downward reaction force as well as an increase in the conduit pressure. The bursting ( $t^* > 1.3$ ) causes a downward acceleration of the liquid and a pressure decrease. A similar effect, although with a minor magnitude, is also evident in 1A (Fig. 9).

In the third case the signal amplitude increases dramatically, about five times higher than 2A. The slug entering in the upper, wider portion of the conduit is marked by a downward force and a positive moment. At the end of the expansion phase ( $t^* > 0.8$ ) there is a sudden inversion of the trends in both quantities, followed again by

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 9

Vertical force and isotropic component for simulations 1A, 2A and 3A of the moment tensor for simulations 1A, 2A and 3A (see Table 3)

a positive downward peak of the force and positive of the momentum ( $1.0 < t^* < 1.1$ ). This peak occurs when two pieces of the original slug coalesce again (Fig. 8) leading to a sudden, but limited in time, upward acceleration. In real cases the dynamics can be even more complex with multiple slugs or slug fragments entering in the upper conduit and interacting with each other. In this case during the main expansion phase, the lower conduit is filled almost exclusively with liquid (Fig. 6). If we suppose the simultaneous presence of many vertically aligned slugs in the lower conduit, then the pressure variations induced by the expansion of the topmost one would influence the lower ones in a complex non-linear mechanism still to investigate.

The signals presented in Fig. 9 need to be scaled to an actual time scale to be compared with real seismic signals source functions. In basaltic volcanoes the dimensions of the upper conduit is of the order of  $10^2$  m while the ascent velocities of the slugs are of the order of  $10^0$ – $10^1$  m/s. This gives a scaling factor of about  $10^1$ – $10^2$  s. Since the simulated transients have a normalized duration of about  $10^{-1}$  the actual simulated signals should have a characteristic period of  $10^0$ – $10^1$  s. These values are within the range of VLP and LP signals [5].

The patterns observed in simulation 3A (Fig. 9) closely matches the results obtained by [4] for the source function of VLP events at the Stromboli volcano. Thus this result, together with analogue simulations [10], strongly supports the hypothesis that VLP events at Stromboli are generated by the passage of a gas slug through a conduit widening and its subsequent expansion and bursting. The long ramp-like signals in both force and moment for  $t^* < 0.8$  in Fig. 9 has a characteristic period longer than the VLP signals recorded and analyzed by [4]. Recordings at Stromboli, using a seismic sensor with a wider frequency range [13] interestingly suggested in some seismic signals a similar ramp having a length of more than 60 s, compatible with our scaling. This long ramp is related to the slow and gradual increase in the magmatic head due to the continuous expansion of the ascending slug.

## Conclusions

The rapid expansion of the gas slugs in the uppermost part of the conduit plays a fundamental role, both in the eruptive dynamics and the seismic wave generation process. We have focused on the role of conduit geometry in the fluid dynamics of gas slug ascent and its implication in the generation of seismic signals. In one of the simulations (3A) we have shown that the system of forces acting on the conduit is able to generate seismic waves with a higher efficiency compared with other cases. This observation can be generalized to more complex geometry such as an alternating of widening and narrowing [10]. The passage of slugs can occur also in very complex conduits [17]. In this case it is possible that pressure transients are generated in different positions along the conduit.

## Future Directions

A deeper understanding of the relationship between slug ascent dynamics and seismic signals generation would require more advanced modeling techniques in various three-dimensional geometries, testing how the effect of changes in slug volumes and magma properties can affect the generation of seismic signals.

These studies are an important step toward more advanced seismic monitoring techniques of active basaltic volcanoes aimed at assigning in real time a volcanological meaning to variations in observed LP and VLP seismic signals.

## Appendix A – Fluid Dynamics of a Two-Phase System

### Definition of a Two-Phase System

A fluid two-phase system can be described using two scalar fields  $n_a$  and  $n_b$ , representing the local molar densities of the two components  $a$  and  $b$ . The actual local density  $\rho$  is then:

$$\rho = m_a n_a + m_b n_b, \quad (11)$$

where  $m_a$  and  $m_b$  are the molecular weight of the two phases. As it will be shown in the following, it is convenient to describe the system using an alternative representation based on the variables:

$$n = n_a + n_b, \quad (12)$$

and

$$\phi = n_a - n_b. \quad (13)$$

$\phi$  defines the local composition of the fluid. It can span the range  $[-n, +n]$  with the value  $-n$  representing a pure  $b$  composition and  $+n$  a pure  $a$  composition. The relation between  $n$ ,  $\phi$  and  $\rho$  is:

$$\rho = \frac{1}{2} [m_a (n + \phi) + m_b (n - \phi)]. \quad (14)$$

The values of  $m_a$  and  $m_b$  are set so that in reference conditions the value of  $n$  is always equal to 1. So for instance, if we consider pure water at ambient conditions  $m_w = 1000$  kg/mol.

### State Equation

We assume that pure phases obey to a simple isothermal ideal gas state equation like:

$$P = \rho c^2, \quad (15)$$

where  $P$  is the pressure and  $c$  is the sound speed. We assume that the pressure is zero in the reference state, so the state equation for the component  $a$  is:

$$P = m_a (n - 1) c_a^2. \quad (16)$$

A similar relation holds for  $b$ . Since along interfaces the composition varies continuously, we should define a state

equation for a mixture that satisfies two requirements: the state equation for pure phases must match (16) and the isobaric contours in the  $(\phi, n)$  plane must be straight lines. This second requirement follows from the consideration that diffusion processes between the components follows straight paths in this domain. In most of the actual Lattice Boltzmann literature, this question is not issued because the proposed implementations are almost isobaric ( $n \simeq 1$ ) [21,25,26]. A suitable choice for the state equation is then:

$$P(n, \phi) = \frac{1}{4} \left[ \Lambda + \sqrt{16m_a m_b c_a^2 c_b^2 (n - 1) + \Lambda^2} \right] \quad (17)$$

with:

$$\Lambda = m_a c_a^2 (n + \phi - 2) + m_b c_b^2 (n - \phi - 2). \quad (18)$$

In Fig. 11 an example contour plot of isobaric lines is shown. We can define another parameter  $\chi$  as:

$$\chi(n, \phi) = -1 + 2 \sqrt{\frac{(\phi + B)^2 + (n - B)^2}{(A + B)^2 + (A - B)^2}}, \quad (19)$$

where:

$$A = \frac{P(n, \phi)}{m_a c_a^2} + 1, \quad (20)$$

and

$$B = \frac{P(n, \phi)}{m_b c_b^2} + 1. \quad (21)$$

The actual meaning of  $\chi$  is shown in Fig. 10. It is the rescaled ratio of the distance between the points  $(\phi, n)$  and  $(-B, B)$  and the distance between the points  $(A, A)$  and  $(-B, B)$ . So  $\chi = -1$  along the line  $\phi = -n$  and  $\chi = 1$

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 10

Definition of  $\chi$ . See text for details

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 11

In the upper panel, isolines of  $\chi$  (red lines) and  $P$  (black lines) are represented in the  $(n, \phi)$  domain. In the lower panel isolines of  $n$  (black lines) and  $\phi$  (red lines) are represented in the  $(\chi, P)$  domain. These plots represent a two-phase system where  $m_a c_a^2 = 5$  and  $m_b c_b^2 = 1$

along  $\phi = n$ . In practice  $\chi$  is related to the local composition of the fluid. In Fig. 10 the relation between  $\phi, n, P$  and  $\chi$  is represented. This relation can be inverted and the system  $(\chi, P)$  can be used as well as the  $(\phi, n)$  coordinate system. In the following we show that the former is the best choice for describing chemical equilibria.

### Chemical Equilibria and the Diffuse Interface Theory

The chemical equilibrium between the two phases can be described using a physically consistent thermodynamic approach [2,8,26]. We define a Ginzburg–Landau free energy functional for an heterogeneous mixture as [15]:

$$\mathcal{F} = \int \left[ \psi(n, \phi) + \frac{\kappa_n}{2} (\nabla n)^2 + \frac{\kappa_\phi}{2} (\nabla \phi)^2 \right] dV, \quad (22)$$

where  $\kappa_n$  and  $\kappa_\phi$  are parameters related to the surface tension. The system reaches its final thermodynamical equilibrium making the free energy minimum.

We can rewrite (22) in the  $(\chi, P)$  representation:

$$\mathcal{F} = \int \left[ \psi(\chi, P) + \frac{\kappa_\chi}{2} (\nabla \chi)^2 \right] dV. \quad (23)$$

Note that we have set  $\kappa_P = 0$ . This implies that surface tension effects are independent of the absolute pressure. In this paper we set:

$$\psi(\chi, P) = \alpha \left( \frac{\chi^4}{4} - \frac{\chi^2}{2} \right) + P \ln \frac{P}{P_0}, \quad (24)$$

where  $P_0$  is an arbitrary reference pressure value. Using this definition of  $\psi$  we note that this function has two minima for  $\chi = \pm 1$ , corresponding to the two equilibrium compositions. Starting from an heterogeneous mixture, the system evolves by creating domains having a quite homogeneous composition separated by interfaces where the composition varies smoothly. The equilibrium is reached when the chemical potential:

$$\mu = \frac{\delta \mathcal{F}}{\delta \chi}, \quad (25)$$

is everywhere equal to zero [2,26]. So, in our case, using (23) and (24) we obtain the condition of chemical equilibrium for a plane interface orthogonal to the  $x$ -direction:

$$\mu = \frac{\partial \psi}{\partial \chi} - \kappa_\chi \frac{\partial^2 \chi}{\partial x^2}. \quad (26)$$

Assuming the boundary conditions  $\psi(x) = 0$  and  $\frac{\partial \chi}{\partial x} = 0$  for  $x = \pm \infty$  and  $\chi(0) = 0$ , the previous ODE can be integrated giving the expression of the spatial variation of the composition through an equilibrium interface:

$$\chi(x) = \tanh \left( \frac{2x}{\xi} \right), \quad (27)$$

where the interface thickness  $\xi$  is the width where the 96% of variation occurs. Its value is:

$$\xi = 2 \sqrt{-\frac{2\kappa_\chi}{\alpha}}. \quad (28)$$

On the basis of the definition of surface tension  $\sigma$  [25]:

$$\sigma = \int_{-\infty}^{+\infty} \mathcal{F}(x) dx, \quad (29)$$

we can write:

$$\sigma = \frac{2}{3} \sqrt{-2\alpha\kappa_\chi}. \quad (30)$$

Using (28) and (30) we can also retrieve useful inverse relations:

$$\alpha = 3 \frac{\sigma}{\xi}, \quad (31)$$

and

$$\kappa_\chi = \frac{3}{8} \sigma \xi. \quad (32)$$

We should emphasize that in real physical systems expression (27) describes an actual interface having a thickness whose order of magnitude is of molecular scale. In this work we use the diffuse interface theory as a numerical tool for modeling of two-phase systems. In other words, we use unphysical interfaces having a macroscopic thickness (usually  $10^{-3} \div 10^{-1} m$ ).

### Cahn–Hilliard and Mass Conservation Equations

The time evolution under non-equilibrium conditions can be expressed by two Cahn–Hilliard equations [2,26]:

$$\frac{Dn}{Dt} = \Gamma \nabla^2 \mu_n, \quad (33)$$

$$\frac{D\phi}{Dt} = \Gamma \nabla^2 \mu_\phi. \quad (34)$$

These equations are similar to common advection-diffusion equations with  $\Gamma$  being a diffusion coefficient and the operator  $D/Dt$  the substantial derivative. The explicit expressions for the chemical potentials  $\mu_n$  and  $\mu_\phi$  are:

$$\mu_n = \frac{\delta \mathcal{F}}{\delta n} = \frac{\delta \mathcal{F}}{\delta \chi} \frac{\partial \chi}{\partial n} = \mu_\chi \frac{\partial \chi}{\partial n}, \quad (35)$$

$$\mu_\phi = \frac{\delta \mathcal{F}}{\delta \phi} = \frac{\delta \mathcal{F}}{\delta \chi} \frac{\partial \chi}{\partial \phi} = \mu_\chi \frac{\partial \chi}{\partial \phi}. \quad (36)$$

with:

$$\mu_\chi = \frac{\delta \mathcal{F}}{\delta \chi} = \alpha \chi (\chi^2 - 1) - \kappa_\chi \nabla^2 \chi. \quad (37)$$

Then the Cahn–Hilliard Eqs. (33) and (34) can be rewritten as:

$$\frac{D}{Dt} \begin{pmatrix} n \\ \phi \end{pmatrix} = \Gamma \nabla^2 \mu_\chi \begin{pmatrix} \frac{\partial \chi}{\partial n} \\ \frac{\partial \chi}{\partial \phi} \end{pmatrix} \quad (38)$$

On the basis of the definitions of  $n$  (12) and  $\phi$  (13), we can state that the previous equation expresses the mass transfer of components  $a$  and  $b$  because of chemical disequilibria. Since we are dealing with a compressible flow, we should obviously account for this in the mass balances. Then, following basic fluid dynamics [1], we can rewrite (38) in explicit form as:

$$\frac{\partial n}{\partial t} = -\mathbf{v} \nabla n - n \nabla \cdot \mathbf{v} + \frac{\partial \chi}{\partial n} \Gamma \nabla^2 \mu_\chi \quad (39)$$

$$\frac{\partial \phi}{\partial t} = -\mathbf{v} \nabla \phi - \phi \nabla \cdot \mathbf{v} + \frac{\partial \chi}{\partial \phi} \Gamma \nabla^2 \mu_\chi. \quad (40)$$

### Thermodynamic Pressure Tensor

It can be shown, from statistical mechanics that the pressure tensor can be obtained from (23) [8,15]:

$$P_{ij}^{th} = p_0 \delta_{ij} + \kappa_\chi \frac{\partial \chi}{\partial x_i} \frac{\partial \chi}{\partial x_j}, \quad (41)$$

where the isotropic component is:

$$p_0 = P \frac{\delta \mathcal{F}}{\delta P} + \chi \frac{\delta \mathcal{F}}{\delta \chi} - (\psi(\chi, P) + \frac{\kappa_\chi}{2} (\nabla \chi)^2). \quad (42)$$

so:

$$p_0 = P + \alpha \left( \frac{3}{4} \chi^4 - \frac{1}{2} \chi^2 \right) - \kappa_\chi (\nabla^2 \chi) - \frac{\kappa}{2} (\nabla \chi)^2 \quad (43)$$

The tensor  $\mathbf{P}^{th}$  describes the stresses induced by spatial variation in density and composition and has to be added to the viscous stress tensor  $\boldsymbol{\tau}$ .

### Conservation Equations

Let us now apply the results of the previous section for building a system of fluid dynamics equations suitable for a numerical implementation. Together with the mass conservation Eqs. (39) and (40) we need the conservation equation for the linear momentum [1]:

$$\rho \frac{d\mathbf{v}}{dt} = \nabla \cdot \mathbf{P} + \rho \mathbf{g}, \quad (44)$$

where  $\mathbf{P} = -\mathbf{P}^{th} + \boldsymbol{\tau}$  is the full pressure tensor of (41),  $\mathbf{g}$  is the gravity and  $\boldsymbol{\tau}$  is the viscous stress tensor that, for a Newtonian fluid is:

$$\tau_{ij} = \lambda e_{kk} \delta_{ij} + 2\mu e_{ij}, \quad (45)$$

with  $\lambda$  and  $\mu$  the bulk and shear viscosities and  $e_{ij}$  is the strain rate tensor expressed by:

$$e_{ij} = \frac{1}{2} \left( \frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right). \quad (46)$$

## Appendix B – Numerical Implementation

### Transformed Equations

A common problem in the numerical solution of the conservation Eqs. (33) and (34) is the output of values having no physical meaning (for instance negative densities for one of the components) with bad effects on the numerical stability of the code. This is due to the fact that both variables are defined over a limited range of values that are  $n \in [0, +\infty[$  and  $\phi \in [-n, +n]$ . These conditions are

not explicit in the conservation equations, but this problem can be overcome by making simple changes of variable:

$$n = e^l, \quad (47)$$

$$\phi = e^l \tanh q. \quad (48)$$

Using the new variable  $l$  instead of  $n$  the conservation Eq. (39) become:

$$\frac{\partial l}{\partial t} = -\mathbf{v} \cdot \nabla l - \nabla \cdot \mathbf{v} + \frac{1}{e^l} \left( \frac{\partial \chi}{\partial n} \right) \Gamma \nabla^2 \mu. \quad (49)$$

Substituting (48) in (40) we first obtain:

$$\begin{aligned} \frac{\partial q}{\partial t} = & -\mathbf{v} \cdot \nabla q - \frac{1}{2} \sinh 2q \left( \frac{\partial l}{\partial t} + \mathbf{v} \cdot \nabla l + \nabla \cdot \mathbf{v} \right) \\ & + \frac{1}{e^l} \cosh^2 q \left( \frac{\partial \chi}{\partial \phi} \right) \Gamma \nabla^2 \mu. \end{aligned} \quad (50)$$

Using (49) and some algebraic manipulation the previous expression become:

$$\begin{aligned} \frac{\partial q}{\partial t} = & -\mathbf{v} \cdot \nabla q - \frac{1}{e^l} \cosh q \left[ \frac{\partial \chi}{\partial n} \sinh q + \frac{\partial \chi}{\partial \phi} \cosh q \right] \\ & \cdot \Gamma \nabla^2 \mu \end{aligned} \quad (51)$$

### Boundary and Initial Conditions

Equations (49) and (51) have to be solved setting proper boundary and initial conditions.

The no-slip boundary condition, implemented along the conduit walls is:

$$\mathbf{v} = 0. \quad (52)$$

Another boundary condition is set along the walls:

$$\nabla \phi \cdot \mathbf{n} = 0. \quad (53)$$

This is the neutral wetting condition [25] and it is needed in order to avoid the wall to behave sticky respect to one of the phases.

At the conduit top and bottom conditions of constant pressure are implementer. On the top the pressure is kept to a reference atmospheric value, while at the bottom it is kept at the hydrostatic pressure value, computed on the initial conditions.

In the initial conditions we set  $\mathbf{v} = 0$  and the computational domain is composed of domains having a homogeneous composition separated by smooth interfaces,

close to the equilibrium solution of (27). At the top of the model a gas domain represents the atmosphere, while the remaining part of the conduit is filled with magma. A small elliptical gas bubble in hydrostatic equilibrium is placed in the lower part of the conduit. The details are specified for each set of simulations.

### Finite Difference Implementation

Equations (49), (51) and (44) are discretized on a regular grid and the differential equations are transformed in finite-difference equations [19]. Scalar, vector and tensor quantities are discretized on staggered grids [6] (Fig. 12). Scalar quantities ( $l$ ,  $q$ ,  $\mu$  and  $P_{ii}$ ) are defined at integer grid steps ( $x_i$ ,  $z_j$ ). Velocities are staggered half grid step along  $x$  and  $z$  directions, that is  $v_x$  is defined at  $(x_{i+1/2}, z_j)$  and  $v_z$  at  $(x_i, z_{j+1/2})$ . The deviatoric part of the pressure tensor  $P_{xz}$  is defined at grid points  $(x_{i+1/2}, z_{j+1/2})$ . This allows a second-order accuracy in the computation of spatial derivative.

We apply also a staggering in time. At the time step  $k$  we first solve (49) and (51). Then the current values of  $l$  and  $q$  are updated:

$$l_{i,j}^{(k)} = l_{i,j}^{(k-1)} + \frac{dl^{(k)}}{dt} \Delta t, \quad (54)$$

Slug Flow: Modeling in a Conduit and Associated Elastic Radiation, Figure 12

**Spatial scheme of the staggered grid used in the computation.** Circle represents the isotropic grid (density, composition and isotropic pressure), rightward triangles are the grids for  $v_x$  while downward triangles are for  $v_z$ . Squares are the grids used for discretizing  $P_{xz}$

$$q_{i,j}^{(k)} = q_{i,j}^{(k-1)} + \frac{dq}{dt}^{(k)} \Delta t. \quad (55)$$

Using these new values the full pressure tensor  $\mathbf{P}^{(k)}$  is computed using the discretized version of (41), (42) and (43). At the time step  $k + 1/2$  (44) is solved and the values of the local velocities are updated.

The computation of  $\frac{dl}{dt}^{(k)}$  and  $\frac{dq}{dt}^{(k)}$  requires the values of  $l^{(k-1)}$ ,  $q^{(k-1)}$  and  $v^{(k-1/2)}$ . On the other hand the computation of  $v^{(k+1/2)}$  requires the values of  $l^{(k)}$ ,  $q^{(k)}$  and  $v^{(k-1/2)}$ .

The time step  $\Delta t$  is chosen in order to satisfy a stability condition. Since we are dealing with isothermal flows with a very low Mach number, the condition can be expressed by:

$$\Delta x < \Delta t c_{\max}, \quad (56)$$

where  $c_{\max}$  is the highest sound speed among the two components. In our simulations we have set:

$$\Delta x = 6 \Delta t c_{\max}, \quad (57)$$

## Glossary

**Soliton** A class of nonlinear dispersive wave equations in (1+1) dimensions having a delicate balance between dispersion and nonlinearity admit localized solitary waves which under interaction retain their shapes and speeds asymptotically. Such waves are called solitons because of their particle like elastic collision property. The systems include Korteweg–de Vries, nonlinear Schrödinger, sine-Gordon and other nonlinear evolution equations. Certain (2+1) dimensional generalizations of these systems also admit soliton solutions of different types (plane solitons, algebraically decaying lump solitons and exponentially decaying dromions).

**Shallow and deep water waves** Considering surface gravity waves in an ocean of depth  $h$ , they are called shallow-water waves if  $h \ll \lambda$ , where  $\lambda$  is the wavelength (or from a practical point of view if  $h < 0.07\lambda$ ). In the linearized case, for shallow water waves the phase speed  $c = \sqrt{gh}$ , where  $g$  is the acceleration due to gravity. Water waves are classified as deep (practically) if  $h > 0.28\lambda$  and the corresponding wave speed is given by  $c = \sqrt{g/k}$ ,  $k = \frac{2\pi}{\lambda}$ .

**Tsunami** Tsunami is essentially a long wavelength water wave train, or a series of waves, generated in a body of water (mostly in oceans) that vertically displaces the water column. Earthquakes, landslides, volcanic eruptions, nuclear explosions and impact of cosmic bodies can generate tsunamis. Propagation of tsunamis is in many cases in the form of shallow wa-

ter waves and sometimes can be of the form of solitary waves/solitons. Tsunamis as they approach coastlines can rise enormously and savagely attack and inundate to cause devastating damage to life and property.

**Internal solitons** Gravity waves can exist not only as surface waves but also as waves at the interface between two fluids of different density. While solitons were first recognized on the surface of water, the commonest ones in oceans actually happen underneath, as internal oceanic waves propagating on the pycnocline (the interface between density layers). Such waves occur in many seas around the globe, prominent among them being the Andaman and Sulu seas.

**Rossby solitons** Rossby waves are typical examples of quasigeostrophic dynamical response of rotating fluid systems, where long waves between layers of the atmosphere as in the case of the Great Red Spot of Jupiter or in the barotropic atmosphere are formed and may be associated with solitonic structures.

**Bore solitons** The classic bore (also called mascaret, poroca and aeger) arises generally in funnel shaped estuaries that amplify incoming tides, tsunamis or storm surges, the rapid rise propagating upstream against the flow of the river feeding the estuary. The profile depends on the Froude number, a dimensionless ratio of inertial and gravitational effects. Slower bores can take on oscillatory profile with a leading dispersive shock-wave followed by a train of solitons.

## Definition of the Subject

Surface and internal gravity waves arising in various oceanographic conditions are natural sources where one can identify/observe the generation, formation and propagation of solitary waves and solitons. Unlike the standard progressive waves of linear dispersive type, solitary waves are localized structures with long wavelengths and finite energies and propagate without change of speed or form and are patently nonlinear entities. The earliest scientifically recorded observation of a solitary wave was made by John Scott Russel in August 1834 in the Union Canal connecting the Scottish cities of Glasgow and Edinburgh. The theoretical formulation of the underlying phenomenon was provided by Korteweg and de Vries in 1895 who deduced the now famous Korteweg–de Vries (KdV) equation admitting solitary wave solutions. With the insightful numerical and analytical investigations of Martin Kruskal and coworkers in the 1960s the KdV solitary waves have been shown to possess the remarkable property that under collision they pass through each other without change of shape or speed except for a phase shift and so they are

solitons. Since then a large class of soliton possessing nonlinear dispersive wave equations such as the sine-Gordon, modified KdV (MKdV) and nonlinear Schrödinger (NLS) equations occurring in a wide range of physical phenomena have been identified.

Several important oceanographic phenomena which correspond to nonlinear shallow water wave or deep water wave propagation have been identified/interpreted in terms of soliton propagation. These include tsunamis, especially earthquake induced ones like the 1960 Chilean or 2004 Indian Ocean earthquakes, internal solitary waves arising in stratified stable fluids such as the ones observed in Andaman or Sulu seas, Rossby waves including the Giant Red Spot of Jupiter and tidal bores occurring in estuaries of rivers. Detailed observations/laboratory experiments and theoretical formulations based on water wave equations resulting in the nonlinear evolution equations including KdV, Benjamin–Ono, Intermediate Long Wave (ILW), Kadomtsev–Petviashvili (KP), NLS, Davey–Stewartson (DS) and other equations clearly establish the relevance of soliton description in such oceanographic events.

## Introduction

Historically, the remarkable observation of John Scott Russel [1,2] of the solitary wave in the Union Canal connecting the cities of Edinburgh and Glasgow in the month of August 1834 may be considered as the precursor to the realization of solitons in many oceanographic phenomena. While riding on a horse back and observing the motion of boat drawn by a pair of horses which suddenly stopped but not so the mass of water it had set in motion, the wave (which he called the ‘Great Wave of Translation’) in the form of large solitary heap of water surged forward and travelled a long distance without *change of form or diminution of speed*. The wave observed by Scott Russel is nothing but a solitary wave having a remarkable staying power and a patently nonlinear entity. Korteweg and de Vries in 1895,

starting from the basic equations of hydrodynamics and considering unidirectional shallow water wave propagation in rectangular channels, deduced [3] the now ubiquitous KdV equation as the underlying nonlinear evolution equation. It is a third order nonlinear partial differential equation in (1+1) dimensions with a delicate balance between dispersion and nonlinearity. It admits elliptic function cnoidal wave solutions and in a limiting form exact solitary wave solution of the type observed by John Scott Russel thereby vindicating his observations and putting to rest all the controversies surrounding them.

It was the many faceted numerical and analytical study of Martin Kruskal and coworkers [4,5] which firmly established by 1967 that the KdV solitary waves have the further remarkable feature that they are solitons having elastic collision property (Fig. 1).

It was proved decisively that the KdV solitary waves on collision pass through each other except for a finite phase shift, thereby retaining their forms and speeds asymptotically as in the case of particle like elastic collisions. The inverse scattering transform (IST) formalism developed for this purpose clearly shows that the KdV equation is a completely integrable infinite dimensional nonlinear Hamiltonian system and that it admits multisoliton solutions [6,7,8,9]. Since then a large class of nonlinear dispersive wave equations such as the sine-Gordon (s-G), modified Korteweg–de Vries (MKdV), NLS, etc. equations in (1+1) dimensions modeling varied physical phenomena have also been shown to be completely integrable soliton systems [6,7,8,9]. Interesting (2+1) dimensional versions of these systems such as Kadomtsev–Petviashvili (KP), Davey–Stewartson (DS) and Nizhnik–Novikov–Veselov (NNV) equations have also been shown to be integrable systems admitting basic nonlinear excitations such as line (plane) solitons, algebraically decaying lump solitons and exponentially localized dromion solutions [7,8].

It should be noted that not all solitary waves are solitons while the converse is always true. An example of a solitary wave which is not a soliton is the one which oc-

Solitons, Tsunamis and Oceanographical Applications of, Figure 1

KdV equation: **a** One soliton solution (solitary wave) at a fixed time, say  $t = 0$ , **b** Two soliton solution (depicting elastic collision)

curs in double-well  $\lambda\phi^4$  wave equation which radiates energy on collision with another such wave. However even such solitary waves having finite energies are sometimes referred to as solitons in the condensed matter, particle physics and fluid dynamics literature because of their localized structure.

As noted above solitary waves and solitons are abundant in oceanographic phenomena, especially involving shallow water wave and deep water wave propagations. However, these events are large scale phenomena very often difficult to measure experimentally, rely mostly on satellite and other indirect observations and so controversies and differing interpretations do exist in ascribing exact solitonic or solitary wave properties to these phenomena. Yet it is generally realized that many of these events are closely identifiable with solitonic structures. Some of these observations deserve special attention.

### Tsunamis

When large scale earthquakes, especially of magnitude 8.0 in Richter scale and above, occur in seabeds at appropriate geological faults tsunamis are generated and can propagate over large distances as small amplitude and long wavelength structures when shallowness condition is satisfied. Though the tsunamis are hardly felt in the mid-sea, they take monstrous structures when they approach land masses due to conservation of energy. The powerful Chilean earthquake of 1960 [10] led to tsunamis which propagated for almost fifteen hours before striking Hawaii islands and a further seven hours later they struck the Japanese islands of Honshu and Hokkaido. More recently the devastating Sumatra–Andaman earthquake of 2004 in the Indian Ocean generated tsunamis which not only struck the coastlines of Asian countries including Indonesia, Thailand, India and Srilanka but propagated as far as Somalia and Kenya in Africa, killing more than a quarter million people. There is very good sense in ascribing soliton description to such tsunamis.

### Internal Solitons

Peculiar striations, visible on satellite photographs of the surface of the Andaman and Sulu seas in the far east (and in many other oceans around the globe), have been interpreted as secondary phenomena accompanying the passage of “internal solitons”. These are solitary wavelike distortions of the boundary layer between the warm upper layer of sea water and cold lower depths. These internal solitons are travelling ridges of warm water, extending hundreds of meters down below the thermal boundary, and carry enormous energy. Osborne and Burch [11]

investigated the underwater currents which were experienced by an oil rig in the Andaman sea, which was drilling at a depth of 3600 ft. One drilling rig was apparently spun through ninety degrees and moved one hundred feet by the passage of a soliton below.

### Rosby Waves and Solitons

Rosby waves [12] are long waves between layers of the atmosphere, created by the rotation of the planet. In particular, in the atmosphere of a rotating planet, a fluid particle is endowed with a certain rotation rate, determined by its latitude. Consequently its motion in the north-south direction is constrained by the conservation of angular momentum as in the case of internal waves where gravity inhibits the vertical motion of a density stratified fluid. There is an analogy between internal waves and Rossby waves under suitable conditions. The KdV equation has been proposed as a model for the evolution of Rossby solitons [13] and NLS equation for the evolution of Rossby wave packets. The Great Red Spot of the planet of Jupiter is often associated with a Rossby soliton.

### Bore Solitons

Rivers which flow to the open oceans are very often affected by tidal effects, tsunamis or storm surges. Tidal motions generate intensive water flows which can propagate upstream on tens of kilometers in the form of step-wise perturbation (hydraulic jumps) analogous to shock waves in acoustics. This phenomenon is known as a bore or mascaret (in French). Examples of such bores include the tidal bore of Seine river in France, Hooghly bore of the Ganges in India, the Amazon river bore in Brazil and Hangzhou bore in China. Bore disintegration into solitons is a possible phenomenon in such bores [14].

Besides these there are other possible oceanographic phenomena such as capillary wave solitons [15], resonant three-wave or four wave interaction solitons [16], etc., where also soliton picture is useful.

In this article we will first point out how in shallow channels the long wavelength wave propagation is described by KdV equation and its generalizations (Sect. “**Shallow Water Waves and KdV Type Equations**”). Then we will briefly point out how NLS family of equations arise naturally in the description of deep water waves (Sect. “**Deep Water Waves and NLS Type Equations**”). Based on these details, we will point how the soliton picture plays a very important role in the understanding of tsunami propagation (Sect. “**Tsunamis as Solitons**”), generation of internal solitons (Sect. “**Internal Solitons**”), formation of Rossby solitons (Sect. “**Rosby Solitons**”) and

disintegration of bores into solitons (Sect. “Bore Solitons”).

**Shallow Water Waves and KdV Type Equations**

Kortweg and de Vries [3] considered the wave phenomenon underlying the observations of Scott Russel from first principles of fluid dynamics and deduced the KdV equation to describe the unidirectional shallow water wave propagation in one dimension.

Consider the one-dimensional ( $x$ -direction) wave motion of an incompressible and inviscid fluid (water) in a shallow channel of height  $h$ , and of sufficient width with uniform cross-section leading to the formation of a solitary wave propagating under gravity. The effect of surface tension is assumed to be negligible. Let the length of the wave be  $l$  and the maximum value of its amplitude,  $\eta(x, t)$ , above the horizontal surface be  $a$  (see Fig. 2).

Then assuming  $a \ll h$  (shallow water) and  $h \ll l$  (long waves), one can introduce two natural small parameters into the problem  $\epsilon = a/h$  and  $\delta = h/l$ . Then the analysis proceeds as follows [3,6].

**Equation of Motion: KdV Equation**

The fluid motion can be described by the velocity vector  $V(x, y, t) = u(x, y, t)\mathbf{i} + v(x, y, t)\mathbf{j}$ , where  $\mathbf{i}$  and  $\mathbf{j}$  are the unit vectors along the horizontal and vertical directions, respectively. As the motion is irrotational, we have  $\nabla \times V = 0$ . Consequently, we can introduce the velocity potential  $\phi(x, y, t)$  by the relation  $V = \nabla\phi$ .

**Conservation of Density** The system obviously admits the conservation law for the mass density  $\rho(x, y, t)$  of the fluid,  $d\rho/dt = \rho_t + \nabla \cdot (\rho V) = 0$ . As  $\rho$  is a constant,

Solitons, Tsunamis and Oceanographical Applications of, Figure 2 One-dimensional wave motion in a shallow channel

we have  $\nabla \cdot V = 0$ . Consequently  $\phi$  obeys the Laplace equation

$$\nabla^2 \phi(x, y, t) = 0. \tag{1}$$

**Euler’s Equation** As the density of the fluid  $\rho = \rho_0 = \text{constant}$ , using Newton’s law for the rate of change of momentum, we can write  $dV/dt = \partial V/\partial t + (V \cdot \nabla)V = -\frac{1}{\rho_0} \nabla p - g\mathbf{j}$ , where  $p = p(x, y, t)$  is the pressure at the point  $(x, y)$  and  $g$  is the acceleration due to gravity, which is acting vertically downwards (here  $\mathbf{j}$  is the unit vector along the vertical direction). Since  $V = \nabla\phi$  we obtain (after one integration)

$$\phi_t + \frac{1}{2} (\nabla\phi)^2 + \frac{p}{\rho_0} + gy = 0. \tag{2}$$

**Boundary Conditions** The above two Eqs. (1) and (2) for the velocity potential  $\phi(x, y, t)$  of the fluid have to be supplemented by appropriate boundary conditions, by taking into account the fact (see Fig. 2) that (a) the horizontal bed at  $y = 0$  is hard and (b) the upper boundary  $y = y(x, t)$  is a free surface. As a result

(a) the vertical velocity at  $y = 0$  vanishes,  $v(x, 0, t) = 0$ , which implies

$$\phi_y(x, 0, t) = 0. \tag{3}$$

(b) As the upper boundary is free, let us specify it by  $y = h + \eta(x, t)$  (see Fig. 2). Then at the point  $x = x_1, y = y_1 \equiv y(x, t)$ , we can write  $\frac{dy_1}{dt} = \frac{\partial \eta}{\partial t} + \frac{\partial \eta}{\partial x} \frac{dx_1}{dt} = \eta_t + \eta_x u_1 = v_1$ . Since  $v_1 = \phi_{1y}, u_1 = \phi_{1x}$ , we obtain

$$\phi_{1y} = \eta_t + \eta_x \phi_{1x}. \tag{4}$$

(c) Similarly at  $y = y_1$ , the pressure  $p_1 = 0$ . Then from (2), it follows that

$$u_1 t + u_1 u_{1x} + v_1 v_{1x} + g\eta_x = 0. \tag{5}$$

Thus the motion of the surface of water wave is essentially specified by the Laplace Eq. (1) and Euler Eq. (2) along with one fixed boundary condition (3) and two variable nonlinear boundary conditions (4) and (5). One has to then solve the Laplace equation subject to these boundary conditions.

**Taylor Expansion of  $\phi(x, y, t)$  in  $y$**  Making use of the fact  $\delta = h/l \ll 1, h \ll l$ , we assume  $y (= h + \eta(x, t))$  to be small to introduce the Taylor expansion

$$\phi(x, y, t) = \sum_{n=0}^{\infty} y^n \phi_n(x, t). \tag{6}$$

Substituting the above series for  $\phi$  into the Laplace Eq. (1), solving recursively for  $\phi_n(x, t)$ 's and making use of the boundary condition (4),  $\phi_y(x, 0, t) = 0$ , one can show that

$$u_1 = \phi_{1x} = f - \frac{1}{2}y_1^2 f_{xx} + \text{higher order in } y_1, \quad (7)$$

$$v_1 = \phi_{1y} = -y_1 f_x + \frac{1}{6}y_1^3 f_{xxx} + \text{higher order in } y_1, \quad (8)$$

where  $f = \partial\phi_0/\partial x$ . We can then substitute these expressions into the nonlinear boundary conditions (4) and (5) to obtain equations for  $f$  and  $\eta$ .

**Introduction of Small Parameters  $\epsilon$  and  $\delta$**  So far the analysis has not taken into account fully the shallow nature of the channel ( $a/h = \epsilon \ll 1$ ) and the solitary nature of the wave ( $a/l = a/h \cdot h/l = \epsilon\delta \ll 1, \epsilon \ll 1, \delta \ll 1$ ), which are essential to realize the Scott Russel phenomenon. For this purpose one can stretch the independent and dependent variables in the above equations through appropriate scale changes, but retaining the overall form of the equations. To realize this one can introduce the natural scale changes

$$x = lx', \quad \eta = a\eta', \quad t = \frac{l}{c_0}t', \quad (9)$$

where  $c_0$  is a parameter to be determined. Then in order to retain the form of (7) and (8) we require

$$\begin{aligned} u_1 &= \epsilon c_0 u'_1, \quad v_1 = \epsilon \delta c_0 v'_1, \quad f = \epsilon c_0 f', \\ y_1 &= h + \eta(x, t) = h(1 + \epsilon \eta'(x', t')). \end{aligned} \quad (10)$$

Then

$$u'_1 = f' - \frac{1}{2}\delta^2(1 + \epsilon\eta')^2 f'_{x't'} = f' - \frac{1}{2}\delta^2 f'_{x't'}, \quad (11)$$

where we have omitted terms proportional to  $\delta^2\epsilon$  as small compared to terms of the order  $\delta^2$ . Similarly from (8), we obtain

$$v'_1 = -(1 + \epsilon\eta')f'_{x'} + \frac{1}{6}\delta^2 f'_{x't'}. \quad (12)$$

Now considering the nonlinear boundary condition (4) in the form  $v_1 = \eta_t + \eta_x u_1$ , it can be rewritten as

$$\eta'_{t'} + f'_{x'} + \epsilon\eta' f'_{x'} + \epsilon f' \eta'_{x'} - \frac{1}{6}\delta^2 f'_{x't'x'} = 0. \quad (13)$$

Similarly considering the other boundary condition (5) and making use of the above transformations, it can be rewritten, after neglecting terms of the order  $\epsilon^2\delta^2$ , as

$$f'_{t'} + \epsilon f' f'_{x'} + \frac{ga}{\epsilon c_0^2} \eta'_{x'} - \frac{1}{2}\delta^2 f'_{x't't'} = 0. \quad (14)$$

Now choosing the arbitrary parameter  $c_0$  as  $c_0^2 = gh$  so that  $\eta'_{x'}$  term is of order unity, (14) becomes

$$f'_{t'} + \eta'_{x'} + \epsilon f' f'_{x'} - \frac{1}{2}\delta^2 f'_{x't't'} = 0. \quad (15)$$

(Note that  $c_0 = \sqrt{gh}$  is nothing but the speed of the water wave in the linearized limit). Omitting the primes for convenience, the evolution equation for the amplitude of the wave and the function related to the velocity potential reads

$$\eta_t + f_x + \epsilon\eta f_x + \epsilon f \eta_x - \frac{1}{6}\delta^2 f_{xxx} = 0, \quad (16)$$

$$f_t + \eta_x + \epsilon f f_x - \frac{1}{2}\delta^2 f_{xxt} = 0. \quad (17)$$

Note that the small parameters  $\epsilon$  and  $\delta^2$  have occurred in a natural way in (16), (17).

**Perturbation Analysis** Since the parameters  $\epsilon$  and  $\delta^2$  are small in (16), (17), we can make a perturbation expansion of  $f$  in these parameters:

$$f = f^{(0)} + \epsilon f^{(1)} + \delta^2 f^{(2)} + \text{higher order terms}, \quad (18)$$

where  $f^{(i)}$ ,  $i = 0, 1, 2, \dots$  are functions of  $\eta$  and its spatial derivatives. Note that the above perturbation expansion is an asymptotic expansion. Substituting this into Eqs. (16) and (17) and regrouping and comparing different powers proportional to  $(\epsilon, \delta^2)$  and solving them successively one can obtain (see for example [6] for further details) in a self consistent way,

$$f^{(0)} = \eta, \quad f^{(1)} = -\frac{1}{4}\eta^2, \quad f^{(2)} = \frac{1}{3}\eta_{xx}. \quad (19)$$

Using these expressions into (18) and substituting it in (16) and (17), we ultimately obtain the KdV equation in the form

$$\eta_t + \eta_x + \frac{3}{2}\epsilon\eta\eta_x + \frac{\delta^2}{6}\eta_{xxx} = 0, \quad (20)$$

describing the unidirectional propagation of long wavelength shallow water waves.

### The Standard (Contemporary) Form of KdV Equation

Finally, changing to a moving frame of reference,  $\xi = x - t$ ,  $\tau = t$ , and introducing the new variables  $u = (3\epsilon/2\delta^2)\eta$ ,  $\tau' = (6/\delta^2)\tau$  and redefining the variables  $\tau'$  as  $t$  and  $\xi$  as  $x$ , we finally arrive at the ubiquitous form of the KdV equation as

$$u_t + 6uu_x + u_{xxx} = 0. \quad (21)$$

The Korteweg–de Vries Eq. (21) admits cnoidal wave solution and in the limiting case solitary wave solution as well. This form can be easily obtained [6,17] by looking for a wave solution of the form  $u = 2f(\xi)$ ,  $\xi = (x - ct)$ , and reducing the KdV equation into a third order nonlinear ordinary differential equation of the form

$$-c \frac{\partial f}{\partial \xi} + 12f \frac{\partial f}{\partial \xi} + \frac{\partial^3 f}{\partial \xi^3} = 0. \tag{22}$$

Integrating Eq. (22) twice and rearranging, we can obtain

$$\left(\frac{\partial f}{\partial \xi}\right)^2 = -4f^3 + cf^2 - 2df - 2b \equiv P(f), \tag{23}$$

where  $b$  and  $d$  are integration constants. Calling the three real roots of the cubic equation  $P(f) = 0$  as  $\alpha_1$ ,  $\alpha_2$  and  $\alpha_3$  such that

$$\left(\frac{\partial f}{\partial \xi}\right)^2 = -4(f - \alpha_1)(f - \alpha_2)(f - \alpha_3), \tag{24}$$

the solution can be expressed in terms of the Jacobian elliptic function as

$$f(\xi) = f(x - ct) = \alpha_3 - (\alpha_3 - \alpha_2) \operatorname{sn}^2 \left[ \sqrt{\alpha_3 - \alpha_1} (x - ct), m \right], \tag{25a}$$

where

$$(\alpha_1 + \alpha_2 + \alpha_3) = \frac{c}{4}, \quad m^2 = \frac{\alpha_3 - \alpha_2}{\alpha_3 - \alpha_1}, \quad \delta = \text{constant}. \tag{25b}$$

Here  $m$  is the modulus parameter of the Jacobian elliptic function. Eq. (25a) represents in fact the so called cnoidal wave (because of its elliptic function form). In the limiting case  $m = 1$ , the form (25a) reduces to

$$f = \alpha_2 + (\alpha_3 - \alpha_2) \operatorname{sech}^2 \left[ \sqrt{\alpha_3 - \alpha_1} (x - ct) \right]. \tag{26}$$

Choosing now  $\alpha_1 = 0$ ,  $\alpha_2 = 0$ , and using (25b) we have

$$f = \frac{c}{4} \operatorname{sech}^2 \left[ \frac{\sqrt{c}}{2} (x - ct) \right]. \tag{27}$$

Then the solitary wave solution to the KdV Eq. (21) can be written in the form

$$u(x, t) = \frac{c}{2} \operatorname{sech}^2 \frac{\sqrt{c}}{2} (x - ct + \delta), \quad \delta : \text{constant} \tag{28}$$

Note that the velocity of the solitary wave is directly proportional to the amplitude: larger the wave the higher is the speed. More importantly, the KdV solitary wave is

a soliton: it retains its shape and speed upon collision with another solitary wave of different amplitude, except for a phase shift, see Fig. 1 [6,7,8]. In fact for an arbitrary initial condition, the solution of the Cauchy initial value problem consists of  $N$ -number of solitons of different amplitudes in the background of small amplitude dispersive waves. All these results ultimately lead to the result that the KdV equation is a completely integrable, infinite dimensional, nonlinear Hamiltonian system. It possesses [6,7,8]

- (i) a Lax pair of linear differential operators and is solvable through the so called inverse scattering transform (IST) method,
- (ii) infinite number of conservation laws and associated infinite number of involutive integrals of motion,
- (iii)  $N$ -soliton solution,
- (iv) Hirota bilinear form,
- (v) Hamiltonian structure

and a host of other interesting properties (see for example [6,7,8,9]).

### KdV Related Integrable and Nonintegrable NLEEs

Depending on the actual physical situation, the derivation of the shallow water wave equation can be suitably modified to obtain other forms of nonlinear dispersive wave equations in (1+1) dimensions as well as in (2+1) dimensions relevant for the present context. Without going into the actual derivations, some of the important equations possessing solitary waves are listed below [6,7,8,9].

1. Boussinesq equation [7]

$$u_t + uu_x + g\eta_x - \frac{1}{3}h^2u_{txx} = 0, \tag{29a}$$

$$\eta_t + [u(h + \eta)]_x = 0 \tag{29b}$$

2. Benjamin–Bona–Mahoney (BBM) equation [18]

$$u_t + u_x + uu_x - u_{xxt} = 0 \tag{30}$$

3. Camassa–Holm equation [19]

$$u_t + 2\kappa u_x + 3uu_x - u_{xxt} = 3u_x u_{xx} + uu_{xxx} \tag{31}$$

4. Kadomtsev–Petviashvili (KP) equation [7]

$$(u_t + 6uu_x + u_{xxx})_x + 3\sigma^2 u_{yy} = 0 \tag{32}$$

( $\sigma^2 = -1$ : KP-I,  $\sigma^2 = +1$ : KP-II).

In the derivation of the above equations, generally the bottom of water column or fluid bed is assumed to be flat. However in realistic situations the water depth varies as a function of the horizontal coordinates. In this situation, one often encounters inhomogeneous forms of the above wave equations. Typical example is the variable coefficient KdV equation [14]:

$$u_t + f(x, t)uu_x + g(x, t)u_{xxx} = 0, \quad (33)$$

where  $f$  and  $g$  are functions of  $x, t$ . More general forms can also be deduced depending upon the actual situations, see for example [14].

### Deep Water Waves and NLS Type Equations

Deep water waves are strongly dispersive in contrast to the weakly dispersive nature of the shallow water waves (in the linear limit). Various authors (see for details [8]) have shown that nonlinear Schrödinger family of equations models the evolution of a packet of surface waves in this case. There are several oceanographic situations where such waves can arise [8]:

(i) A localized storm at sea can generate a wide spectrum of waves, which then propagates away from the source region in all horizontal directions. If the propagating waves have small amplitudes and encounter no wind away from the source region, these waves can eventually sort themselves into nearly one-dimensional packets of nearly monochromatic waves. For appropriately chosen scales, the underlying evolution of each of these packets can be shown to satisfy the nonlinear Schrödinger equation and its generalizations in (2+1) dimensions.

(ii) Nearly monochromatic, nearly one-dimensional waves can cover a broad range of surface waves in the sea that results due to a steady wind of long duration and fetch. Then the generalization of the NLS equation in (2+1) dimensions can describe the waves that result in when the wind stops.

In all the above situations one looks for the solution of the equations of motion (1)-(5) but generalized in three dimensions which consists mainly in the form of a small amplitude, nearly monochromatic, nearly one-dimensional wave train. Assuming that this wave train travels in the  $x$ -direction with a mean wave number  $\kappa = (k, l)$  with a characteristic amplitude ' $a$ ' of the disturbance and a characteristic variation  $\delta k$  in  $k$ , one can deduce the NLS equation in (2+1) dimensions under the following conditions:

- (i) small amplitudes such that  $\hat{\epsilon} = \epsilon\delta \equiv \kappa a \ll 1$
- (ii) slowly varying modulations,  $\frac{\delta k}{\kappa} \ll 1$

- (iii) nearly one dimensional waves,  $\frac{|l|}{k} \ll 1$
- (iv) balance of all three effects,  $\frac{\delta k}{\kappa} = \frac{|l|}{k} \approx O(\hat{\epsilon})$
- (v) for finite and deep water waves,  $(kh)^2 \gg \hat{\epsilon}$

In the lowest order approximation (linear approximation) of water waves, the prediction is that a localized initial state will generally evolve into wave packets with a dominant wave number  $\kappa$  and corresponding frequency  $\omega$ , given by the dispersion relation  $\omega = (g\kappa + \sigma\kappa^3)\tanh\kappa h$ ,  $\kappa = |\kappa| = \sqrt{k^2 + l^2}$  within which each wave propagates with the phase speed  $c = \omega/k$ , while the envelope propagates with the group velocity  $c_g = d\omega/d\kappa$ . After a sufficiently long time the wave packet tends to disperse around the dominant wave number.

This tendency for dispersion can be offset by cumulative nonlinear effects. In the absence of surface tension, the outcome for unidirectional waves can be shown to be describable by the NLS equation. If the surface wave in the lowest order is  $\phi \approx A \exp i(kx - \omega t) + c.c.$ , where  $\phi$  is the velocity potential, then to leading order the wave amplitude evolves as

$$i(A_t + c_g A_x) + \frac{1}{2}\lambda A_{xx} + \mu |A|^2 A = 0. \quad (34)$$

The coefficients here are given by

$$\begin{aligned} \lambda &= \frac{\partial^2 \omega}{\partial k^2}, \\ \mu &= -\frac{\omega k^2}{16S^4}(8C^2S^2 + g - 2T^2) \\ &\quad + \frac{\omega}{8C^2S^2} \frac{(2\omega C^2 + kc_g)^2}{(gh - c_g^2)}, \end{aligned} \quad (35)$$

where  $C = \cosh(kh)$ ,  $S = \sinh(kh)$ ,  $T = \frac{S}{C}$ . Equation (34) has been obtained originally by Zakharov in 1968 for deep water waves [20] and by Hasimoto and Ono for waves of finite depth in 1972 [21].

The NLS equation is also a soliton possessing integrable system and is solvable by the IST method [6,7,8,9]. For  $\lambda > 0$  (focusing case), the envelope solitary (soliton) wave solution (also called bright solitons in the optical physics context) is given by

$$A(x, t) = a \operatorname{sech} \gamma(x - c_g t) \exp(-i\Omega t), \quad (36)$$

where  $\mu a^2 = \lambda \gamma^2$ ,  $\Omega = +\frac{1}{2}\mu a^2$ .

When the effects of modulation in the transverse  $y$ -direction are taken into account, so that the wave amplitude is now given by  $A(x, y, t)$ , the NLS equation is replaced by the Benney-Roskes system [22] also popularly known as the Davey-Stewartson equations [23],

Solitons, Tsunamis and Oceanographical Applications of, Figure 3

Exponentially localized dromion solution of the Davey–Stewartson equation at a fixed time ( $t = 0$ ) for suitable choice of parameters

$$i(A_t + c_g A_x) + \frac{1}{2} \lambda A_{xx} + \frac{1}{2} \delta A_{yy} + \mu |A|^2 A + UA = 0, \tag{37a}$$

$$\alpha U_{xx} + U_{yy} + \beta (|A|^2)_{yy} = 0, \tag{37b}$$

where  $\delta = \frac{c_g}{k}$ ,  $\alpha = 1 - \left(\frac{c_g^2}{gh}\right)$ ,  $gh\beta = \frac{\omega}{8C^2g^2}(2\omega C^2 + kc_g)^2$ . Here  $U(x, y, t)$  is the wave induced mean flow. In the deep water wave limit,  $kh \rightarrow \infty$ , and  $U \rightarrow 0$ ,  $\beta \rightarrow 0$  and one has the nonintegrable (2+1) dimensional NLS equation. On the other hand in the shallow water limit, one has the integrable Davey–Stewartson (DS) equations. For details see [7,8]. The DS-I equation admits algebraically decaying lump solitons and exponentially decaying dromions [24] besides the standard line solitons for appropriate choices of parameters. A typical dromion solution of DS-I equation is shown in Fig. 3.

### Tsunamis as Solitons

The term ‘tsunami’ (tsu:harbour, nami:wave in Japanese) which was perhaps an unknown word even for scientists in countries such as India, Srilanka, Thailand, etc. till recently has become a house-hold word since that fateful morning of December 26, 2004. When a powerful earthquake of magnitude 9.1–9.3 on the Richter scale, epicentered off the coast of Sumatra, Indonesia, struck at 07:58:53, local time, described as the 2004 Indian Ocean earthquake or Sumatra–Andaman earthquake (Fig. 4), it triggered a series of devastating tsunamis as high as 30 meters that spread throughout the Indian Ocean killing about 275,000 people and inundating coastal communities across South and Southeast Asia, including parts of Indonesia, Srilanka, India and Thailand and even reaching as far as the east coast

Solitons, Tsunamis and Oceanographical Applications of, Figure 4

26 December 2004 Indian Ocean tsunami (adapted from the website [www.blogaid.org.uk](http://www.blogaid.org.uk) with the courtesy of Andy Budd)

of Africa [25]. The catastrophe is considered to be one of the deadliest disasters in modern history.

Since this earthquake and consequent tsunamis, several other earthquakes of smaller and larger magnitudes keep occurring off the coast of Indonesia. Even as late as July 17, 2006 an earthquake of magnitude 7.7 on the Richter scale struck off the town of Pandering at 15.19 local time and set off a tsunami of 2m high which had killed more than 300 people.

These tsunamis, which can become monstrous tidal waves when they approach coastline, are essentially triggered due to the sudden vertical rise of the seabed by several meters (when earthquake occurs) which displaces massive volume of water. The tsunamis behave very differently in deep water than in shallow water as pointed out below. By no means the tsunami of 2004 and later ones are exceptional; More than two hundred tsunamis have been recorded in scientific literature since ancient times. The most notable earlier one is the tsunami triggered by the powerful earthquake (9.6 magnitude) off southern Chile on May 22, 1960 [10] which traveled almost 22 hours before striking Japanese islands.

It is clear from the above events that the tsunami waves are fairly permanent and powerful ones, having the capacity to travel extraordinary distances without practically diminishing in size or speed. In this sense they seem to have considerable resemblance to shallow water nonlinear dispersive waves of KdV type, particularly solitary waves and solitons. It is then conceivable that tsunami dynamics has close connection with soliton dynamics.

### Basics of Tsunami Waves

As noted above tsunami waves of the type described above are essentially triggered by massive earthquakes which

lead to vertical displacement of a large volume of water. Other possible reasons also exist for the formation and propagation of tsunami waves: underwater nuclear explosion, larger meteorites falling into the sea, volcano explosions, rockslides, etc. But the most predominant cause of tsunamis appear to be large earthquakes as in the case of the Sumatra–Andaman earthquake of 2004. Then there are three major aspects associated with the tsunami dynamics [26]:

1. Generation of tsunamis
2. Propagation of tsunamis
3. Tsunami run up and inundation

There exist rather successful models to approach the generation aspects of tsunamis when they occur due to the earthquakes [27]. Using the available seismic data it is possible to reconstruct the permanent deformation of the sea bottom due to earthquakes and simple models have been developed (see for example, [28]). Similarly the tsunami run up and inundation problems [29] are extremely complex and they require detailed critical study from a practical point of view in order to save structures and lives when a tsunami strikes.

However, here we will be more concerned with the propagation of tsunami waves and their possible relation to wave propagation associated with nonlinear dispersive waves in shallow waters. In order to appreciate such a possible connection, we first look at the typical characteristic properties of tsunami waves as in the case of 2004 Indian Ocean tsunami waves or 1960 Chilean tsunamis.

### The Indian Ocean Tsunami of 2004

Considering the Indian Ocean 2004 tsunami, satellite observations after a couple of hours after the earthquake establish an amplitude of approximately 60 cms in the open ocean for the waves. The estimated typical wavelength is about 200 kms [30]. The maximum water depth  $h$  is between 1 and 4 kms. Consequently, one can identify in an average sense the following small parameters ( $\epsilon$  and  $\delta^2$ ) of roughly equal magnitude:

$$\epsilon = \frac{a}{h} \approx 10^{-4} \ll 1, \quad \delta^2 = \frac{h^2}{l^2} \approx 10^{-4} \ll 1 \quad (38)$$

As a consequence, it is possible that a nonlinear shallow water wave theory where dispersion (KdV equation) also plays an important role (as discussed in Sect. “**Shallow Water Waves and KdV Type Equations**”) has considerable relevance [26]. However, we also wish to point out here that there are other points of view: Constantin and Johnson [31] estimate  $\epsilon \approx 0.002$  and  $\delta \approx 0.04$

and conclude that for both nonlinearity and dispersion to become significant the quantity  $\delta\epsilon^{-3/2} \times \text{wavelength}$  estimated as 90,000 kms is too large and shallow water equations with variable depth (without dispersion) should be used. However, it appears that these estimates can vary over a rather wide range and with suitable estimates it is possible that the range of 10,000–20,000 kms could be also possible ranges and hence taking into account the fact that both the Indian Ocean 2004 and Chilean 1960 tsunamis have traveled over 10 hours or more (in certain directions) before encountering land mass appears to allow for the possibility of nonlinear dispersive waves as relevant features for the phenomena. Segur [32] has argued that in the 2004 tsunamis, the propagation distances from the epicenter of the earthquake to India, Srilanka, or Thailand were too short for KdV dynamics to develop. In the same way one can argue that the waves that hit Somalia and Kenya in the east coast of Africa (or as in the case of Chilean earthquake see also [32]) have traveled sufficiently long distance for KdV dynamics to become important [33]. In any case one can conclude that at least for long distance tsunami propagation solitary wave and soliton picture of KdV like equations become very relevant.

### Internal Solitons

For a long time seafarers passing through the Strait of Malacca on their journeys between India and the Far East have noticed that in the Andaman sea, between Nicobar islands and the north east coast of Sumatra, often bands of strongly increased surface roughness (rippings or bands of choppy water) occur [11,34]. Similar observations have been reported in other seas around the globe from time to time. In recent times there has been considerable progress in understanding these kind of observations in terms of internal solitons in the oceans [7]. These studies have been greatly facilitated by photographs taken from satellites and space-crafts orbiting the earth, for example by synthetic aperture radar (SAR) images of ERS-1/2 satellites [34,35].

Peculiar striations of 100 km long, separated by 6 to 15 km and grouped in packets of 4 to 8, visible on satellite photographs (see Fig. 5) of the surface of the Andaman and Sulu seas in the Far East, have been interpreted as secondary phenomena accompanying the passage of ‘internal solitons’, which are solitary wavelike distortions of the boundary layer between warm upper layer of sea water and cold lower depths. These internal solitons are traveling edges of warm water, extending hundreds of meters down below the thermal boundary [7]. They carry enormous energy with them which is perhaps the reason for unusually strong underwater currents experienced by deep-sea

Solitons, Tsunamis and Oceanographical Applications of, Figure 5

SAR image of a 200 km  $\times$  200 km large section of the Andaman Sea acquired by the ERS-2 satellite on April 15, 1996 showing sea surface manifestations of two internal solitary wave packets, see [34]. Figure reproduced from ESA website [www.earth.esa.int/workshops/ers97/papers/alpers3](http://www.earth.esa.int/workshops/ers97/papers/alpers3) with the courtesy of European Space Agency and W. Alpers

drilling rigs. Thus these internal solitons are potentially hazardous to sub-sea oil and gas explorations. The ability to predict them can improve substantially the cost effectiveness and safety of offshore drilling.

A systematic study of the underwater currents experienced by an oil rig in the Andaman sea which was drilling at a depth of 3600 ft was carried out by Osborne and Burch in 1980 [11]. They spent four days measuring underwater currents and temperatures. The striations seen on satellite photographs turned out to be kilometer-wide bands of extremely choppy water, stretching from horizon to horizon, followed by about two kilometers of water “as smooth as a millpond”. These bands of agitated water are called “tide rips”, they arose in packets of 4 to 8, spaced about 5 to 10 km apart (they reached the research vessel at approximately hourly intervals) and this pattern was repeated with the regularity of tidal phenomenon.

As described in [7], Osborne and Burch found that the amplitude of each succeeding soliton was less than the previous one, is precisely what is expected for solitons (note that the velocity of a solitary wave solution of KdV equation increases with amplitude, vide Eq. (22)). Thus if a number of solitons are generated together, then we expect them eventually to be arranged in an ordered sequence of decreasing amplitude. From the spacing between successive waves in a packet and the rate of separation calculated from the KdV equation, Osborne and Burch were able to estimate the distance the packet had traveled from its source and thus identify possible source regions [7]. They concluded that the solitons are generated by tidal currents off northern Sumatra or between the islands of the Nicobar chain that extends beyond it and that their observations have good general agreement with the predictions for internal solitons as given by the KdV equation. Numerous recent observations and predictions of solitons in the Andaman sea have clearly established that it is a site where extraordinarily large internal solitons are encountered [34,35].

Further, Apel and Holbrook [36] undertook a detailed study of internal waves in the Sulu sea. Satellite photographs had suggested that the source of these waves was near the southern end of the Sulu sea and their research ship followed one wave packet for more than 250 miles over a period of two days – an extraordinary coherent phenomenon [7]. These internal solitons travel at speeds of about 8 kilometers per hour (5 miles per hour), with amplitude of about 100 meters and wavelength of about 1700 meters.

Similar observations elsewhere have confirmed the presence of internal solitons in oceans including the strait of Messina, the strait of Gibraltar, off the western side of Baja California, the Gulf of California, the Archipelago of La Maddalena and the Georgia strait [7]. There has also been a number of experimental studies of internal solitons in laboratory tanks in the last few decades [37]. These experiments provide detailed quantitative information usually unavailable in the field conditions, and are also an efficient tool for verifying various theoretical models.

As a theoretical formulation of internal solitons [7], consider two incompressible, immiscible fluids, with densities  $\rho_1$  and  $\rho_2$  and depths  $h_1$  and  $h_2$  respectively such that the total depth  $h = h_1 + h_2$ . Let the lighter fluid of height  $h_1$  be lying over a heavier fluid of height  $h_2$ , in a constant gravitational field (Fig. 6). The lower fluid is assumed to rest on a horizontal impermeable bed, and the upper fluid is bounded by a free surface.

Then as in Sect. “Shallow Water Waves and KdV Type Equations”, we denote the characteristic amplitude

Solitons, Tsunamis and Oceanographical Applications of, Figure 6  
 Formation of internal soliton (note that under suitable conditions small amplitude surface soliton can also be formed)

of wave by ‘ $a$ ’ and the characteristic wavelength  $l = k^{-1}$ . Then the various nonlinear wave equations to describe the formation of internal solitons follow by suitable modification of the formulation in Sect. “Shallow Water Waves and KdV Type Equations”, assuming viscous effects to be negligible. Each of these equations is completely integrable and admits soliton solutions [7].

(a) **KdV equation (Eq. (21))** follows when

- (i) the waves are of long wavelength  $\delta = \frac{h}{l} \ll 1$ ,
- (ii) the amplitude of the waves are small,  $\epsilon = \frac{a}{h} \ll 1$ , and
- (iii) the two effects are comparable  $\delta^2 = O(\epsilon)$

(b) **Intermediate-Long-Wave (ILW) equation [38]**

$$u_t + u_x + 2uu_x + Tu_{xx} = 0, \tag{39}$$

where  $Tu$  is the singular integral operator

$$(Tf)(x) = \frac{1}{2l} \int_{-\infty}^{\infty} \coth \left\{ \frac{\pi}{2l}(y-x) \right\} f(y) dy \tag{40}$$

with  $\int_{-\infty}^{\infty}$  the Cauchy principal value integral is obtained under the assumption that

- (a) there is a thin (upper) layer,  $\epsilon = \frac{h_1}{h_2} \ll 1$ ,
- (b) the amplitude of the waves is small,  $a \ll h_1$ ,
- (c) the above two effects balance,  $\frac{a}{h_1} = O(\epsilon)$ ,
- (d) the characteristic wavelength is comparable to the total depth of the fluid,  $l = kh = O(1)$  and
- (e) the waves are long waves in comparison with the thin layer,  $kh_1 \ll 1$ .

(c) **Benjamin-Ono equation [39]**

$$u_t + 2uu_x + Hu_{xx} = 0, \tag{41}$$

where  $Hu$  is the Hilbert transform

$$(Hf)(x) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{f(y)}{y-x} dy, \tag{42}$$

is obtained under the assumption

- (a) there is a thin (upper) layer  $h_1 \ll h_2$ ,
- (b) the waves are long waves in comparison with the thin layer,  $kh_1 \ll 1$ ,
- (c) the waves are short in comparison with the total depth of the fluid,  $kh \gg 1$  and
- (d) the amplitude of the waves is small,  $a \ll h_1$ .

It may be noted that in the shallow water limit, as  $\delta \rightarrow 0$ , the ILW equation reduces to the KdV equation, while the Benjamin-Ono equation reduces to it in the deep water wave limit as  $\delta \rightarrow \infty$ . Each of these equations have their own ranges of validity and admit solitary wave and soliton solutions to represent internal solitons of the oceans.

**Rossby Solitons**

The atmospheric dynamics is an important subject of human concern as we live within the atmosphere and are continuously affected by the weather and its rather complex behavior. The motion of the atmosphere is intimately connected with that of the ocean with which it exchanges

Solitons, Tsunamis and Oceanographical Applications of, Figure 7

A coupled high/low pressure systems in the form of a Rossby soliton formed off the coast of California/Washington on Valentine's Day 2005. The low pressure front hovers over Los Angeles dumping 30 inches of rain on the city in two weeks. The high pressure system lingers off the coast of Washington state providing unseasonably warm and sunny weather. This particular Rossby soliton proved exceptionally stable because of its remarkable symmetry. In an accompanying animated gif in this website one can watch the very interesting phenomenon as the jet stream splits around the soliton suctioning warm wet air from the off the coast of Mexico to Arizona, leaving behind a welcome drenching of rain. The figure and caption have been adapted from the website [http://mathpost.la.asu.edu/~rubio/rossby\\_soliton/rs.html](http://mathpost.la.asu.edu/~rubio/rossby_soliton/rs.html) with the courtesy of the National Oceanic and Atmospheric Administration (NOAA) and Antonio Rubio

fluxes of momentum, heat and moisture [40]. Then the atmospheric dynamics is dominated by the rotation of the earth and the vertical density stratification of the surrounding medium, leading to newer effects. Similar effects are also present in other planetary dynamics as well.

In the atmosphere of a rotating planet, a fluid particle is endowed with a certain rotation rate (Coriolis frequency), determined by its latitude. Consequently its motion in the north-south direction is inhibited by conservation of angular momentum. The large scale atmospheric waves caused by the variation of the Coriolis frequency with latitude are called *Rossby waves*. In Sect. “**Internal Solitons**” we saw that KdV equation and its modifications model internal waves. Since there is a resemblance between internal waves and Rossby waves, it is expected that KdV like equations can model Rossby waves as well [8]. Under the simplest assumptions like long waves, incompressible fluid,  $\beta$ -plane approximations, etc. Benney [41] had derived the KdV equation as a model for Rossby

waves in the presence of east-west zonal flow. Boyd [42] had shown that long, weakly nonlinear, equatorial Rossby waves are governed either by KdV or MKdV equation. Recently it has been shown by using the eight years of Topex/Poseidon altimeter observations [43] that a detailed characterization of major components of Pacific dynamics confirms the presence of equatorial Rossby solitons.

Also observational and numerical studies of propagation of nonlinear Rossby wave packets in the barotropic atmosphere by Lee and Held [44,45] have established their presence, notably in the Northern Hemisphere as storm tracks, but more clearly in the Southern Hemisphere (see Fig. 7). They also found that the wavepackets both in the real atmosphere and in the numerical models behave like the envelope solitons of the nonlinear Schrödinger equation (Fig. 7).

An interesting application of KdV equation to describe Rossby waves is the conjecture of Maxworthy and Redekopp [46] that the planet Jupiter's Great Red Spot

might be a solitary Rossby wave. Photographs taken by the spacecraft Voyager of the cloud pattern show that the atmospheric motion on Jupiter is dominated by a number of east-west zonal currents, corresponding to the jet streams of the earth's atmosphere [8]. Several oval-shaped spots are also seen, including the prominent Great Red Spot in the southern hemisphere. The latter one has been seen approximately this latitude for hundreds of years and maintains its form despite interactions with other atmospheric objects. One possible explanation is that the Red Spot is a solitary wave/soliton of the KdV equation, deduced from the quasigeostrophic form of potential vorticity equation for an incompressible fluid. A second test of the model is the combined effect of interaction of the Red Spot and Hollow of the Jupiter atmosphere on the South Tropical Disturbance which occurred early in the 20th century and lasted several decades. Maxworthy and Redekopp [46] have interpreted this interaction as that of two soliton collision of KdV equation, with the required phase shift [6,7,8].

The above connection between the KdV solitary wave and the rotating planet may be seen more concretely by the following argument as detailed in [8]. One can start with the quasigeostrophic form of the potential vorticity equation for an incompressible fluid in the form

$$\left\{ \left( \frac{\partial}{\partial t} + v \frac{\partial}{\partial x} \right) + \epsilon \left( \frac{\partial \psi}{\partial y} \right) \left( \frac{\partial}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial}{\partial y} \right) \right\} \left\{ \mu^2 \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial}{\partial z} \left( K^2 \frac{\partial}{\partial z} \right) \right\} \psi + (\beta - U'') \frac{\partial \psi}{\partial x} = 0, \quad (43)$$

where  $x$ ,  $y$  and  $z$  represent the east, north and vertical directions, while the function  $U$  is related to the horizontal stream function  $\Phi$  as  $\Phi(x, y, z, t) = \int_y^y U(\eta) d\eta + \epsilon \psi(x, y, z, t)$  in terms of a zonal shear flow and a perturbation. In (43), in the  $\beta$ -plane approximation, the Coriolis parameter is given as  $f = 2\Omega \sin \theta_0 + \beta y$  and the function  $K(z)$  is given by  $K(z) = 2\Omega \sin \theta_0 l_2 / N(z) d$ , where  $N(z)$  is the Brunt-Väisälä frequency and  $l_2$  is the characteristic length scales in the north-south direction while  $d$  is the length scale in the vertical direction. Note that  $K$  compares the effects of rotation and density of variation. Then  $\mu = l_2 / l_1$  represents the ratio of the length scales in the north-south and east-west directions.

In the linear ( $\epsilon \rightarrow 0$ ), long wave ( $\mu \rightarrow 0$ ) limit, the potential function  $\psi$  has the form  $\psi = \sum_n A_n(x - c_n t) \phi_n(y) p_n(z)$ , where  $c_n$  is deduced by solving two related eigenvalue problems [8],  $(K^2 p_n')' + k_n^2 p_n = 0$ ,  $p_n(0) = p_n(1) = 0$  and  $\phi_n'' - k_n^2 \phi_n + [(\beta - U'') / (U - c_n)] \phi_n = 0$ ,

$\phi_n(y_s) = \phi_n(y_N) = 0$ . If the various modes are separable on a short time scale, one can then deduce an evolution equation for the individual modes, by eliminating secular terms at higher order in the expansion. Depending on the nature and existence of a stable density of stratification, which is characterized by the function  $N(z)$  mentioned above, either KdV or mKdV equation can be deduced for a given mode and thereby establishing the soliton connection in the present problem.

In spite of the complexity of the phenomenon underlying Rossby solitons there is clear evidence of the significance of solitonic picture.

### Bore Solitons

Rivers which flow into the open oceans are usually affected by tidal flows, tsunami or storm surge. For a typical estuary as one moves towards the mouth of the river, the depth increases and width decreases. When a tidal wave, tsunami or storm surge hits such an estuary, it can be seen as a hydraulic jump (step-wise perturbations like a shock-wave) in the water height and speed which will propagate upstream [47]. Far less dangerous but very similar is the bore (mascaret in French), a tidal wave which can propagate in a river for considerable distances.

Typical examples of bores occur in Seine river in France and the Hooghli river in West Bengal in India. A bore existed in the Seine river upto 1960 and disappeared when the river was dredged. The tide amplitude here is one of the largest in the world. The Hughli river is a branch of the Ganges that flows through Kolkata where a bore of 1m is present, essentially due to the shallowness of the river. Another interesting example is that at the time of the 1983 Japan sea tsunami, waves in the form of a bore ascended many rivers [48]. In some cases, bores had the form of one initial wave with a train of smaller waves and in other cases only a step with flat water surface behind was observed (Fig. 8). The Hangzhou bore in China is a tourist attraction. Other well known bores occur in the Amazon in Brazil and in Australia.

Another interesting situation where bore solitons were observed was in the International H<sub>2</sub>O Project (IHOP), as a density current (such as cold air from thunderstorm) intrudes into a fluid of lesser density that occurs beneath a low level inversion in the atmosphere. A spectacular bore and its evolution into a beautiful amplitude-ordered train of solitary waves were observed and sampled during the early morning of 20 June 2002 by the Leandre-II abroad the P-3 aircraft. The origin of this bore was traceable to a propagating cold outflow boundary from a mesoscale convective system in extreme western Kansas [49].

Solitons, Tsunamis and Oceanographical Applications of, Figure 8

Tidal bore at the mouth of the Araguari River in Brazil. The bore is undular with over 20 waves visible. (Adapted from the book "Gravity Currents in the Environment and the Laboratory" by John E. Simpson, Cambridge University Press with the courtesy of D.K. Lynch, John E. Simpson and Cambridge University Press)

In the process of propagation the bore undergoes dissipation, dispersive disintegration, enhancement due to decrease of the river width and depth, influence of nonlinear effects and so on. The profile depends on the Froude number which is a dimensionless ratio of inertial and gravitational effects. Theoretical models have been developed to study these effects based on KdV and its generalizations [14]. For example, bore disintegration into solitons in channel of constant parameters can be studied in signal coordinates in terms of the KdV like equation for the perturbation of water surface,

$$\eta_x + \frac{1}{c_0}(1 - \alpha\eta)\eta_t - \beta\eta_{ttt} = 0, \quad (44)$$

where  $c_0 = \sqrt{gh}$ ,  $\alpha = 3/2h$ ,  $\beta = h^2/6c_0^3$ ,  $h$  being the depth of the river, with the bore represented by a Heaviside step function as the boundary condition at  $x = 0$ . Other effects then can be incorporated into a variable KdV equation of the form (26).

### Future Directions

We have indicated a few of the most important oceanographical applications of solitons including tsunamis, internal solitons, Rossby solitons and bore solitons. There are other interesting phenomena like capillary wave solitons [15], resonant three and four wave interaction solitons [16], etc. which are also of considerable interest depending on whether the wave propagation corresponds to shallow, intermediate or deep waters. Whatever be the situation, it is clear that experimental observations as

well as their theoretical formulation and understandings are highly challenging complex nonlinear evolutionary problems. The main reason is that the phenomena are essentially large scale events and detailed experimental observations require considerable planning, funding, technology and manpower. Often satellite remote sensing measurements need to be carried out as in the case of internal solitons and Rossby solitons. Events like tsunami propagation are rare and time available for making careful measurements are limited and heavily dependent on satellite imaging, warning systems and after event measurements. Consequently developing and testing theoretical models are extremely hazardous and difficult. Yet the basic modeling in terms of solitary wave/soliton possessing nonlinear dispersive wave equations such as the KdV and NLS family of equations and their generalizations present fascinating possibilities to understand these large scale complex phenomena and opens up possibilities of prediction. Further understanding of such nonlinear evolution equations, both integrable and nonintegrable systems particularly in higher dimensions, can help to understand the various phenomena clearly and provide means of predicting events like tsunamis and damages which occur due to internal solitons and bores. Detailed experimental observations can also help in this regard. It is clear that what has been understood so far is only the qualitative aspects of these phenomena and much more intensive work is needed to understand the quantitative aspects to predict them.

### Glossary

**Submarine landslide** A gravitational mass failure feature on the seafloor.

**Slow earthquake** A discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking.

**GPS** The Global Positioning System consists of a constellation of at least 24 medium earth orbiting satellites transmitting two or more microwave frequencies for use in precise positioning.

**Seafloor geodesy** The application of geodetic methods (studies of the change in the shape of the earth's surface) applied to a submarine environment.

### Definition of the Subject

The term 'submarine landslide' encompasses a multitude of gravitational mass failure features at areal scales from square meters to thousands of square kilometers. Here, we concentrate on the large end of that spectrum, namely the submarine landslides that, when they move either in contained slip events or catastrophically, can generate surface

displacements equivalent to  $> M6$  earthquakes and/or hazardous tsunami.

The term 'slow earthquake' describes a discrete slip event that produces millimeter to meter-scale displacements identical to those produced during earthquakes but without the associated seismic shaking. Slow earthquakes, primarily associated with tectonic fault zones, have been recognized and studied with increasing frequency in the past decade largely due to the decreasing cost and proliferation of Global Positioning System (GPS) geodetic networks capable of detecting the ground motion [1,2,3]. Recently, one such GPS network on the south flank of Kilauea volcano, has recorded multiple slow earthquakes on the subaerial portion of a large landslide system that occurs primarily in the submarine environment [4,5,6]. Because the bathymetric charts surrounding the Hawaiian islands are littered with the remnants of massive, catastrophically emplaced submarine landslides (Fig. 1) it is natural to wonder if a slow-slipping submarine landslide is a precursory stage of one that will ultimately fail catastrophically.

We see two principal reasons why monitoring submarine landslides and slow earthquakes associated with them is important. First, because catastrophic failure of submarine landslides can cause tsunami they represent significant hazards to coastal zones. Understanding and monitoring how slow slip may lead to accelerated slip and catastrophic failure is, therefore, very important in terms of hazard mitigation. Second, submarine landslide systems can be some of the most active as well as spatially confined deforming areas on earth and so they represent excellent targets of study for furthering our understanding of the general fault failure process. For instance a pertinent question for which we do not yet have an answer is: are fault frictional properties homogeneous enough that the occurrence of slow earthquakes on a detachment fault plane underlying a landslide could relieve stress on the fault or do the slow earthquakes in one region load a neighboring seismogenic patch bringing it closer to a large sudden failure (i. e. an earthquake)?

While installation and operation of GPS networks on land is now relatively routine and somewhat inexpensive, the in situ monitoring of submarine landslide motion represents a significant technical challenge with accordingly higher costs. Submarine geodesy e. g. [7], however, is a nascent and rapidly evolving field with relative and absolute positioning techniques being intensely studied and developed. The near future is sure to see many advances in our monitoring and understanding of submarine landslides and slow earthquakes due to the application of submarine geodetic techniques.

## Introduction

### Submarine Landslides

The last 30 years have seen a dramatic increase in the recognition of submarine landslides world-wide, due largely to the increased prevalence and capability of swath and side-looking sonar mapping systems and systematic submarine mapping programs. For instance, the side-scan sonar mapping of the Hawaiian exclusive economic zone in the 1980s resulted in the discovery that massive submarine landslides are spatially distributed along the entire Hawaiian Ridge [8] (Fig. 1). These features are some of the largest landslides on the planet, with more than 70 attaining lengths greater than 20 km and some having lengths greater than 200 km and total volumes exceeding 5000 km<sup>3</sup>. Since then, submarine landslides associated with other volcanic islands e.g. [9,10,11], mid-ocean ridges [12], and continental margins [13] have also been studied. Of these, the slopes flanking volcanic islands, especially when they are in their steeper-sloped shield-building stage [14,15], tend to be particularly susceptible to landslide instability and so they have been the focus of much recent research in the Canary Islands [16,17] and

especially in the Hawaiian Islands [18,19,20,21,22,23]. For instance, most of the Hawaiian submarine landslides are thought to be inactive, except for those on the flanks of the Big Island e.g. [21].

The morphology of submarine landslide features is similar to their subaerial counterparts. In map view they generally exhibit lobate and hummocky bathymetry. In cross-section, a wedge-shaped region of deformed material thins down-slope and is underlain by a gently-sloping planar dislocation surface (sometimes referred to as a basal detachment or 'decollement') separating the deformed carapace from the underlying undeformed substratum (Fig. 2). An upslope extensional head-scarp region transitions into a contractional fold belt towards the toe. The normal faults in the upslope region typically intersect the surface at high angles (> 45 degrees) and are manifested as scalloped-shaped scarps at the head of the slide that separate regions of differentially tilted fault blocks; in the sub-surface they may continue at high angles until they intersect the basal decollement, or they may sole with depth either into the decollement or into another sub-horizontal slip-surface [24]. The contractional regions are characterized by folded and bulging layers, closed de-

pressions, and steep toes [20,21,25]. Moore et al. [8] separated the Hawaiian submarine landslides into two principal types: ‘slumps’ and ‘debris avalanches’. The slumps are wide (up to  $\sim 100$  km), deep-seated ( $\sim 10$  km thick), and have surface inclinations of up to 3 degrees while the debris avalanches are long (up to  $\sim 230$  km), shallowly-seated (50 m–2 km thick), and have surface slopes generally less than 3 degrees.

Concomitant with the mapping of the landslide features has been the increasing recognition that sudden submarine landslide movement can cause tsunamis with destructive implications for coastal societies e.g. [26]. A particularly well-known example of this scenario is the 1929 Grand Banks failure [27]. Moreover, in the 1990s alone workers have attributed at least 5 tsunami events to catastrophic landslide failure sources: (1) 1992 Flores Island, Indonesia [28]; (2) 1994 Mindoro, Phillipines [29]; (3) 1998 Papua New Guinea e.g. [30]; (4) Kocaeli, Turkey [31]; (5) 1999 Pentecost Island, Vanuatu [32]. In Hawaii, the  $M_w$  7.7 1975 Kalapana earthquake, most likely due to slip of the fault surface underlying an active submarine landslide [33,34,35], caused local loss of life and damage in Southern California.

From a hazards standpoint it is particularly important to understand how tsunamis are generated by submarine landslides because the propagation time between tsunami generation to runup is typically on the order of minutes. For instance, a catastrophic failure of the west side of the island of Hawaii would likely send tsunami waves around the Hawaiian islands that would reach the densely populated areas of Oahu’s Waikiki beaches in less than an hour and more likely  $\sim 30$  min (G. Fryer, personal communication, 2007). Simulating waves generated by a sudden, chaotic disturbance of the seafloor, as expected from a submarine landslide, is quite complicated e.g. [36,37] and not all workers agree on approaches or results. Murty [38], however, stressed that parameters such as slide angle, water depth, density, speed, duration of the slide are second order, while instantaneously displaced volume is likely the most important parameter controlling tsunami generation.

Despite the increasing awareness of their hazard, little is known about how submarine landslides actually move, largely because of the challenge of installing instruments and retrieving data from the submarine environment. Moore et al. [8] recognized that while slumps more likely move relatively slowly, debris avalanches could be deposited very rapidly based on, for instance, uphill flow of material in the distal portions of the landslide deposits. In agreement with this, the estimated downhill velocities from the 1929 Grand Banks event was 60–100 km/h [39]

whereas many studies have documented  $\sim 6$ –10 cm/yr horizontal and vertical velocities associated with a submarine landslide flanking the Island of Hawaii’s Kilauea volcano, the Hilina Slump [4,5,6,40,41,42]. Recently, GPS data from the Hilina Slump have elucidated that not only does the slump move at the above-stated, fairly smooth, background velocities, but also that the slump will occasionally deform in discrete accelerated cm-scale motions equivalent to  $M_6$  earthquakes but without the shaking [4,5,6]. These ‘slow earthquakes’ last hours and accommodate cm’s of ground displacement (Fig. 3). It is not currently known, however, how the occurrence of a slow earthquake in a submarine landslide system will affect its future movement by either making it more or less probable of failing catastrophically.

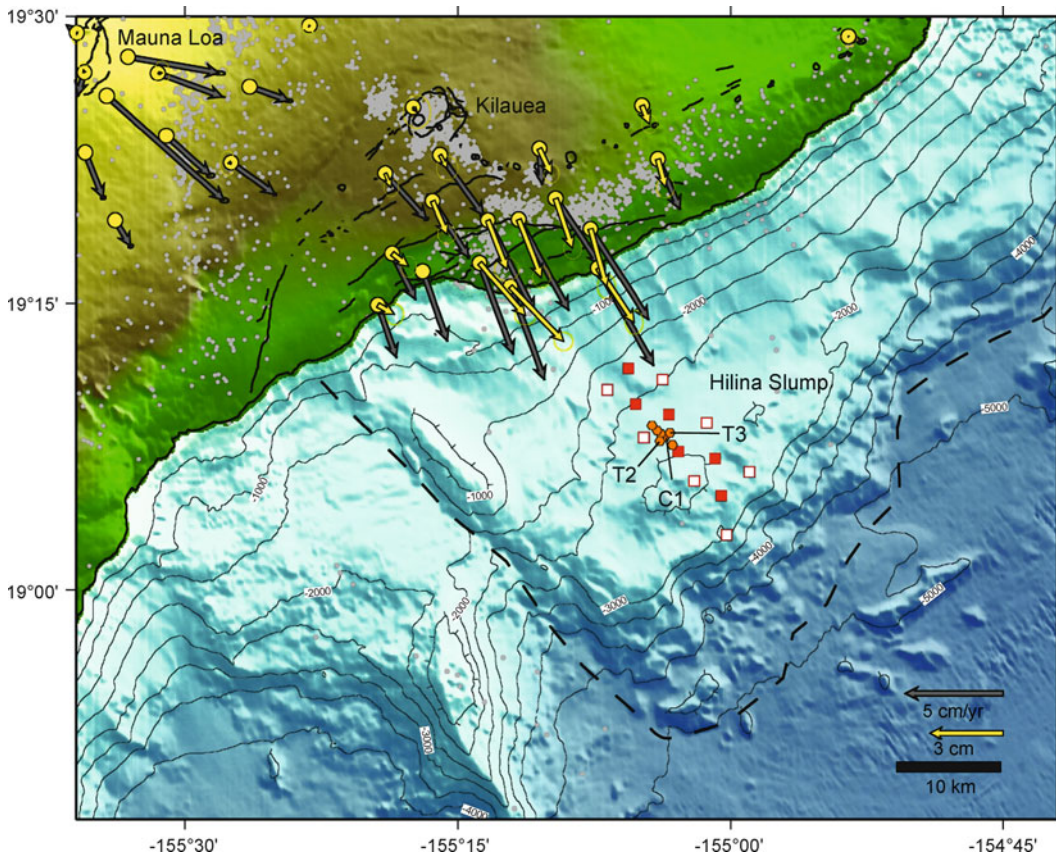

### Slow Earthquakes

The term ‘slow earthquake’ has been used to describe a variety of transient aseismic deformation phenomena including slow precursor events preceding large earthquakes [43,44,45,46,47,48], afterslip following earthquakes [49,50,51], variable fault creep rates [52,53,54,55], certain subduction zone thrust events with unusually long durations and large amplitude tsunamis for their size [56], and discrete fault-slip events that do not produce detectable seismic shaking but are accompanied by ground displacements very similar to those produced during earthquakes [1,2,3,4,5,6,57]. Hereafter, when we use ‘slow earthquake’ we will refer to this latter description although the term was first used in the modern literature to describe a slow precursor to the great Chilean 1960 earthquake [43].

In contrast to slow precursor events whose ground motions, like traditional earthquakes, are measured in seconds or minutes, slow earthquake (SE) displacements usually accrue over time periods ranging from hours to days and so they have been typically sensed with geodetic methods. In the last decade, the proliferation of continuous GPS (CGPS) networks has led to numerous SE observations and the discovery of some very rich behavior. In certain regions SEs have occurred with very regular periods [2,4,58], they are often associated with non-volcanic tremor [59,60] and, apparently, SEs follow very different scaling laws (moment vs. duration) than traditional earthquakes [61]. Explanations for SE slip behavior has varied to date. For subduction zones, the combination of deep ( $> 35$  km) SE sources and their association with tremor (a phenomenon initially thought to be caused by forced fluid flow [62] but more recently also explained in terms of shear failure [63,64]) led to one current hypothesis that SE

Grey dots are earthquakes from the HVO catalog for the period May 2004–2005

mechanics are controlled by water released during metamorphic phase changes at the interface between a subducting and overriding plate [65,66]. Other explanations have invoked rate- and state-variable frictional behavior to sug-

gest that SEs occur preferentially at transitions between velocity strengthening and weakening regimes on a fault plane [67,68,69] and that temporally varying climatic load changes could help explain SE periodicity [58].

Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, Figure 4

Time series of north component of motion for selected GPS stations. Offsets of 7 slow earthquakes are identified by yellow lines. Red dashed lines are magmatic diking events

Due, in part, to their large magnitude deformation signal and the high concentration of CGPS networks focused on them, subduction zones have dominantly been the location of the most SEs to date [1,2,57,59,70,71,72]. Recently, the CGPS network on Kilauea volcano's mobile south flank has recorded multiple SEs [4,5,6] (Fig. 4) and it is through the Kilauea events that SEs have come to be associated with submarine landslides.

### Monitoring Motion: Subaerial and Submarine Geodetic Methods

Not surprisingly, much more is known about the motion of subaerial than submarine landslides. Geodetic measurements on land combined with contemporaneous measurements of other properties (pore-water pressures, strength of materials, etc.) have allowed, in some cases, a very thorough understanding of how landslide motion is related to driving forces such as gravitational stresses and rainfall.

For instance, Baum and Reid [73] instrumented a slow-moving submarine landslide in Honolulu's Manoa valley with extensometers recording at 15 minute intervals and rain gauges and found a direct correlation between rain fall and deformation events. Similarly, Malet et al. [74] showed that GPS-measured surface velocities increased to as high as 20 cm/day following periods of higher rainfall during May 1999 at the Super-Sauze earthflow in the French Alps. At a slightly different scale, Hilley et al. [75] used InSAR to simultaneously map deformation of multiple landslides in California's Berkely Hills at  $\sim$  monthly intervals and found that landslide motion correlated with times of high precipitation and that during the 1997–1998 El Nino event displacement rates doubled from the background rate of  $\sim$  27–38 mm/year, albeit with a  $\sim$  3 month time lag between the onset of motion and the high precipitation.

Much of the current knowledge that we have about the motion of submarine landslides comes from their easier-to-monitor subaerial portions, such as at Kilauea's Hilina

slump (Fig. 3). In the case of the Hilina Slump, fully 3/4 of the feature resides offshore at depths greater than 2000 m and the deformation monitoring network is necessarily concentrated on the down-dropped blocks near the head-wall scarp of the entire system. Recently, however, submarine methods have started to provide geodetic information from the ocean floor itself e.g. [7], e.g. [76,77,78,79]. As these methods become more cost-effective and widespread they will surely yield much insight into submarine landslide kinematics and, eventually, be employed in operational hazard monitoring/mitigation scenarios.

Whether a network is solely subaerial, submarine, or some combination of the two, it is important to consider that monitoring strategies can vary substantially depending on the time duration of the expected signal, the desired threshold of detection, and the desired time latency for individual solutions. For instance, simple detection and warning of catastrophic landslide failure needs the most rapid solution latency but coarse detection thresholds (meter rather than millimeter level, for instance) are appropriate. Conversely, if the goal is to detect small, potentially precursory motions such as slow earthquakes, then detection threshold must be as sensitive as possible along with solution latency being low.

### Subaerial Geodesy: GPS

A multitude of geodetic techniques, from mechanically- to electromagnetically-based, are currently employed on landslides to measure motion caused by a range of deformational phenomena spanning opening of small surface cracks to the motion of kilometer sized blocks e.g. [74]. Data from Global Positioning System (GPS) networks has increasingly contributed to the library of observations associated with landslide motion. In particular, for submarine landslides that are large enough so that their motion causes earthquakes or slow earthquakes [4,6,80], a technique which is suitable for inter-station distances measured in kilometers is most appropriate and so below, we concentrate on the use of GPS with submarine landslides.

**GPS** GPS networks capable of sub-cm to mm-scale 3-dimensional ground motion detection are now deployed in many of Earth's most actively deforming zones (see for example, [http://sps.unavco.org/crustal\\_motion/dxdt/](http://sps.unavco.org/crustal_motion/dxdt/)) and readers are referred to thorough reviews of the general technique and its application for geodynamic studies [81,82,83].

Crustal motion GPS networks are usually divided into two types: those that record data continuously (CGPS) and those whose individual monuments are occupied less

frequently in survey mode (SGPS). Depending on a variety of factors including the modernity of the receiver, the bandwidth of telemetry networks (should they exist), and the storage capacity of the archival center, CGPS sampling rate generally varies between once every 30 and 1 s (though most modern receivers are capable of sampling at frequencies higher than 1 Hz). SGPS sampling is more varied though it usually comprises re-occupation of sites at intervals ranging from months to years with occupation times of hours to days and sampling rates similar to CGPS. Accordingly, SGPS networks are more useful for wider ranging spatial characterization of deformation phenomena rather than for the rapid detection of motion or for tracking temporal evolution during transient events.

High rates of sampling alone, however, do not guarantee that CGPS network positional solutions will achieve their highest precision and/or accuracy. Assuming that all sites within a CGPS network have stable monuments and high-grade geodetic antennae and dual frequency receivers, the most important components of its error budget for deformation monitoring are: (1) integer ambiguity resolution; (2) orbital estimation; (3) atmospheric delay estimation; (4) antenna multipath; (5) satellite constellation geometry, and (6) intra-network baseline length. For networks monitoring landslides with spatial scales on the order of kms or tens of kms, however, the baselines are short enough that errors scaling with baseline lengths are small contributors to the error budget. In addition, as absolute positioning in a global reference frame is not essential, precise orbital estimation is less important. For the other error sources, freely available software packages such as GAMIT, GIPSY, and BERNESE (<http://facility.unavco.org/software/processing/processing.html>), and precise orbit processing centers such as the IGS (International GNSS Service, <http://igs.cb.jpl.nasa.gov/>) or the Scripps Orbit and Permanent Array Center (SOPAC, <http://sopac.ucsd.edu/>) usually allow good enough mitigation of these errors so that daily GPS solutions have resolution on the order of 2–5 mm in the horizontal and  $\sim 2$ –3 times worse in the vertical e.g. [83]. This resolution rule-of-thumb, however, generally applies to post-processed data with occupation times exceeding  $\sim 6$ –8 h, use of precise orbits, and the best atmospheric estimation techniques e.g. [84]. Because of the hours-to-days delay needed for estimating various grades of precise orbits and the computational time needed to estimate all the parameters for all sites with this much data this standard rule-of-thumb cannot necessarily be applied to a real-time or near real-time solution.

**Real- and Near-Real Time GPS Processing** There are a variety of processing techniques that may be suitable

for real-time or near-real time monitoring applications for the subaerial counterparts to submarine landslides. For instance, the well-known real time kinematic (RTK) positioning technique frequently employed by the surveying community applies differential corrections sent via radio link between stations to yield site position estimates with cm-scale precision over baselines up to  $\sim 10$  km in real-time [85]. The technique works best for baseline distances less than  $\sim 10$  km typically, because the assumption of correlated errors between stations is not necessarily valid and differential corrections cannot be accurately applied for larger baselines. Thus, RTK may be a suitable monitoring technique if a more spatially contained portion of a landslide, such as a fault zone, is a particularly good indicator of motion for the overall larger unit.

It is the number of measurement epochs required to resolve the integer-cycle phase ambiguity inherent with GPS data, however, that is the principal factor limiting the temporal latency of high resolution GPS positioning solutions. Kinematic techniques typically require minutes worth of GPS data (when sampled at 1–30 s) in order to resolve integer ambiguities for initialization and reinitialization if a cycle slip or loss of phase lock occurs during measurement, although progress is being made on mitigating ionospheric effects and reducing time of integer ambiguity resolution e.g. [86]. Regardless, if GPS station locations are chosen with relatively good sky-view then loss of lock due to poor satellite visibility should be minimal.

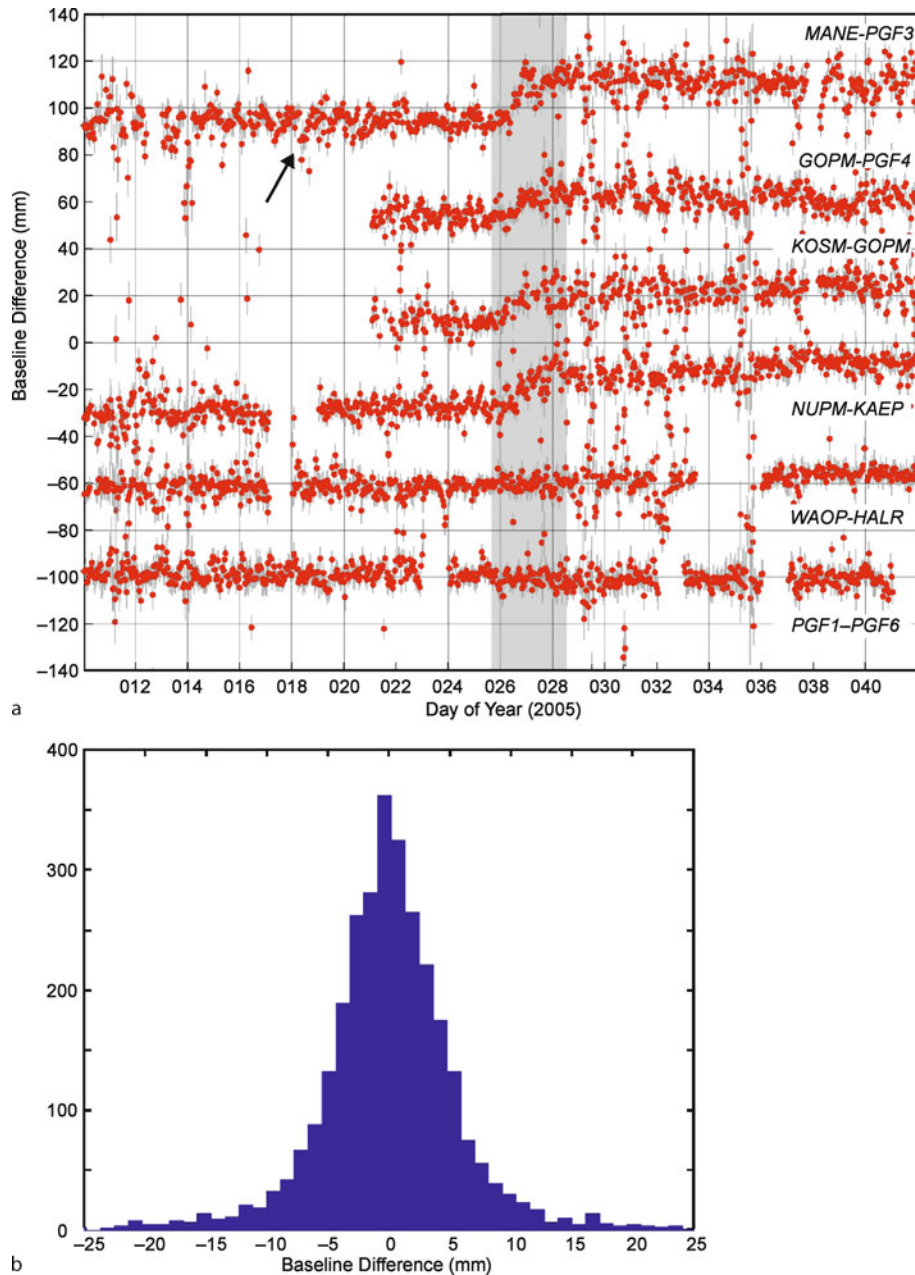

Recently, Bock et al. [87] developed a method of resolving integer ambiguities from a single epoch of dual frequency GPS phase and pseudo range data that provides independent epoch-by-epoch position estimates over baselines as large as  $\sim 40$  km. Their method allowed instantaneous positioning resolution of 1.5 cm in the horizontal and 7–8 times worse in the vertical coordinates. Langbein and Bock [88] applied the technique to determine offsets in positional time series due to slip events recorded by the Parkfield, California CGPS network which has similar spatial scales to a typical large submarine landslide. They found that offset sensitivity was  $\sim 5$  mm for a 2 s sampling window and this decreased to  $\sim 2$  mm when a 60 s window was used [88]. To the best of our knowledge this represents the current state-of-the art in terms of real-time detection of motion over spatial and temporal scales typical of submarine landslides.

At Kilauea, we have developed an automated *near* real-time processing strategy for our monitoring efforts at the Hilina Slump (Figs. 3 and 5) [89]. The CGPS data are telemetered hourly by radio modem back to the USGS Hawaii Volcano Observatory (HVO) where they are re-

trieved via FTP. We use a sliding window approach, collecting all data available within the most current two-hour period and performing a network solution using the PAGES [90] processing software. We use the 30 s, ionosphere free phase combination as the observable and use and hold fixed the IGS ultra-rapid orbits and apply the NGS antenna phase calibration patterns for each site [91]. We also apply the IERS standard solid Earth tide [92] and Schwiderski ocean tide loading corrections [93,94]. Every half hour we estimate a piece-wise, linear neutral atmosphere (troposphere) correction and one set of N–S and E–W neutral atmospheric gradient corrections for each site. We apply a ‘weak’ constraint of 10 cm to the atmospheric corrections based on examination of previous adjustments.

Figure 5a shows an example of baseline change time series from indicative stations derived from this approach and re-run in a simulated near real-time mode for the time period bracketing the slow earthquake from January 26–28, 2005 at Kilauea. Generally, the hourly baseline change noise levels are on the order of  $\pm 10$  mm, although because of some particularly large outliers, the standard deviation of the baseline changes (not including the time period of the SE) is closer to 20 mm (Fig. 5b). Some of the large excursions in the time series not associated with the SE are due to the high amplitude, strongly spatially and temporally varying atmospheric water vapor gradients often associated with tropical islands such as Hawaii e.g. [95]. For instance for the excursion in the MANE-PGF3 baseline in the middle of day 18 (Fig. 5a), the time series takes a sharp upward bend until the start of day 19 when it again begins to oscillate about its mean value from present days. This baseline change gradient is very similar to the onset of the SE near the beginning of day 26. It is clear from the remainder of the time series after day 27 that the  $\sim 25$  mm offset is permanent, however, and so indicative of a real deformation event.

In a real-time monitoring scenario, because of the 2 h temporal latency and the atmospheric noise levels on the order of 1/3 the maximum signal levels in the baseline change plots, it would probably require on the order of 12–24 h before this event could be definitively classified as a deformational event. This could certainly be useful to hazard mitigators for being aware that a slow event such as an SE was occurring, but not in the event of a rapidly accelerating catastrophic collapse where the detection and warning time must be on the order of minutes. For more rapid warning, more sophisticated filtering techniques could be employed (such as monument motion, and network-wide coherence assessment as described below for the Network Inverse Filter [96]) although regions

of large atmospheric gradient will always be hampered by low signal-to-noise ratios unless more sophisticated atmospheric mitigation techniques such as tomographic mapping [97] are employed in a real-time manner. Accord-

ingly, the small detection threshold levels of the epoch-by-epoch processing at Parkfield described above [88] must be taken in the context of the relatively low atmospheric delay environment present there.

## Submarine Geodesy

Subaerial geodetic methods have, until now, provided essentially the entirety of geodetic evidence for submarine landslide-related deformation including slow earthquakes. Our understanding of submarine landslide motion and slow earthquake mechanics stands to increase dramatically in the coming decade, however, owing to the rapidly advancing field of submarine geodesy which can now reliably provide in situ measurements of seafloor deformation. The submarine environment is particularly challenging for geodesy techniques especially if they require the propagation of energy across a medium (ocean water) that can exhibit highly spatially and temporally variable material properties.

**Direct Path and Indirect Acoustic Approach** One of the submarine geodesy techniques most frequently employed to date is direct path acoustic measurement of baseline length changes using acoustic transponders. This method has been used to make in situ observations of tectonic motions on the seafloor at the Juan de Fuca ridge where one study found cm-scale motion occurring over a period of a few days associated with an on-axis eruption [77] and another found no detectable motion over a period of a few years at a quiescent ridge segment [76]. By interrogating each other, pairs of instruments use two-way travel time measurements to constrain the inter-station distance. After correcting for variations in sound speed that result from changes in water temperature, salinity, pressure, and local tilt of the monument itself, these systems yield sub-cm precision for individual measurements. Operating frequencies typically range from 7.5 to 108 kHz and in deeper isothermal waters, the upward refraction of sound waves prevents signals from one transponder being received by the other at distances greater than  $\sim 1$  km [79]. Travel-time is determined simply by correlating the transmitted and received signals and picking the peak of the resultant correlogram. In quiet operating environments this can usually be done at the scale of  $\sim 5 \mu\text{s}$ , resulting in a  $\sim 4$  mm range error [7].

For the greater depth ranges, Sweeney et al. [79] devised an approach that allowed  $\pm 2$  cm resolution measurements for baselines up to 10 km at 2500–2600 m depths at a stable site on the Juan de Fuca plate. Sweeney et al. [79] suspended an acoustic interrogator hundreds of meters above the seafloor in a position acoustically visible to an array of seafloor-mounted instruments. In a manner similar to Spiess [98] they estimated the relative positions of the stations by moving the interrogator and collecting acoustic range data multiple locations.

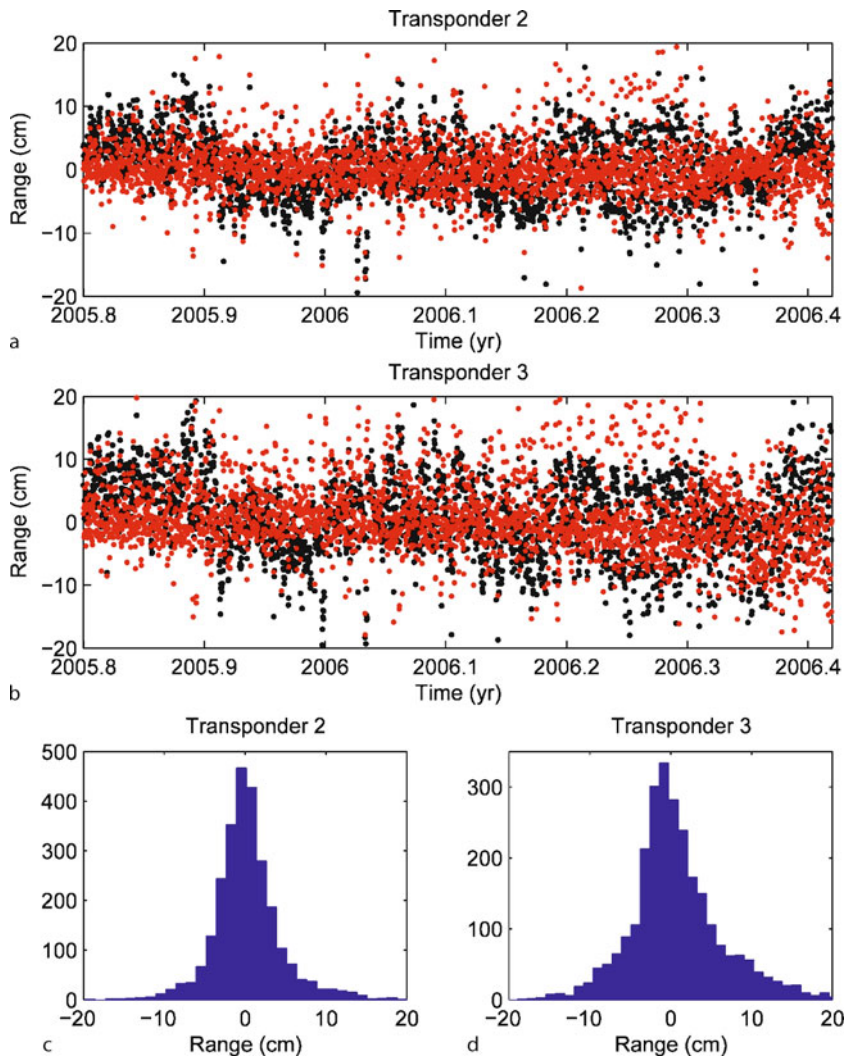

The focus of these initial deployments of the direct and indirect acoustic approach systems was on measuring annual tectonic rates, and not necessarily on capturing transient events such as SEs that occur over hours or days. Accordingly sampling rates in current seafloor geodesy projects typically do not exceed a few times per day, largely because providing adequate power to seafloor instruments is still financially prohibitive. However with cabled oceanographic observatories scheduled to come online in 2007–2010 (<http://www.neptunecanada.ca/>; <http://www.orionprogram.org/>) the power delivery problem could be solved at high priority seafloor sites.

From October, 2005 through June, 2006 we deployed seven 10 kHz Linkquest transponders mounted  $\sim 3$  m above steel tripods and spaced over a distance of  $\sim 3$  km on the Hilina Slump (Fig. 3). One of the goals of this pilot project was to evaluate the performance of the transponders for use in submarine landslide monitoring at significant depth; each unit operated at a depth between 2640 and 2690 m. Battery power restrictions for the  $\sim 8$  month duration of the project meant that the instruments ranged to one another 12 times per day.

In Fig. 6 we show range change time series from two transponder-pair baselines ( $\sim 530$  and 683 m respectively) for which data recovery was complete over the experiment's duration. For the other transponder pairs data recovery was not as complete because either: (1) the unit was knocked over by local mass-wasting events or (2) the baseline distance was too long and data dropouts occurred when the transponders lost sync with one another. The two way travel times were picked from the peak of the correlation function between the outgoing and received waveforms at one end of the baseline. The black dots in Fig. 6a and b show the raw measurements, while the red dots show the distance measurements corrected for the variations in sound speed due to temperature changes, which were measured by an external conductivity and temperature sensor mounted on the transponder frames. The raw time series show significant long-term trends due to temperature variations that are effectively removed using just the temperature measurements at the transponders. We did not correct for salinity variations because all of our conductivity sensors provided contaminated data due to clogging by the local mass wasting events.

For these baseline pairs which were oriented approximately perpendicular to the maximum expected motion of the Hilina Slump we expect essentially no motion for such short baselines and during such a short measurement period. At the  $1\sigma$  level individual measurement noise is  $\sim 4.1$  and 5.7 cm respectively, though it is clear that smaller, cm-scale changes would be detectable given a long

Submarine Landslides and Slow Earthquakes: Monitoring Motion with GPS and Seafloor Geodesy, Figure 6

enough time period. For instance, daily estimates of baseline length have approximately a 1 cm standard deviation. For rapid event detection, baseline changes would need to be on the order of 10 or more cm or measurement frequency would need to be increased.

**GPS-Acoustic Method** The acoustic measurements described above provide only relative measurements of baseline length changes; however, for submarine landslide monitoring efforts it may be desirable to place submarine and subaerial measurements in a single regional or global reference frame. Largely with the aim of furthering

seafloor active tectonics studies, a research group spearheaded by the late Fred Spiess conceived of, and have begun implementing integrated GPS and acoustic seafloor geodesy (GPS-A) studies, described in great detail by Spiess et al. [7] and references therein.

Briefly, GPS-A positions seafloor geodetic markers in a global reference frame by combining kinematic GPS positioning of a sea-surface platform (ship or buoy), precision underwater sound travel time measurement over km-scale path lengths, and a strategy for eliminating the large errors in travel time measurement arising from a spatially and temporally varying sound speed structure in the near

surface portion of the water column. The error mitigation strategy is based on the recognition that the location of the sea surface midpoint above the center of a triangle of seafloor transponders (themselves positioned via a near-bottom acoustic survey) is the point at which the three sea surface-to-seafloor travel times are identical and so, independent of sound speed.

Spieß et al. [7] reported repeatabilities of  $\pm 0.8$  cm and  $\pm 3.9$  cm in the north and east components, respectively, of seafloor measurements on the Juan de Fuca plate from 1994–1995. More recently, Gagnon et al. [78] reported velocities with  $\sim 5.5$  cm magnitudes and 0.6–0.8 cm  $1\sigma$  errors from surveys between 2001–2003 on the updip portion of the Nazca–South America subduction zone in the Peru trench.

**Optical Path Length** Zumberge [99] combined commercial subaerial surveying technology (an EDM) with an optical fiber strainmeter in order to devise a low-power, cost-effective system for the harsh seafloor operating environment. EDMs (electronic distance meters) typically can measure distances with 1–2 mm precision over several km by transmitting intensity modulated infra-red energy and measuring travel time from far away reflective surfaces. Zumberge [99] modified the EDM for seafloor geodesy by focusing the transmitted beam into the fiber's core and gathering the reflected light from the fiber's far-end into the EDM receiver optics.

The composite instrument comprises an optical fiber (enclosed in a hermetically sealed stainless steel casing) that stretches between two anchors, one 'active' and one 'passive', separated by several hundred meters on the seafloor. The active anchor houses the EDM and all supporting electronics and the passive anchor's purpose is to fix the fiber to the seafloor. In a test of their instrument, Zumberge et al. [100], report 1 mm scatter of distance measurements over a 500-m-long fiber during a 50 day long period.

One of the obvious advantages of the optical path length technique is the high precision, isolation from sea water-borne errors, and the continuous nature of the measurement. The disadvantage, however, is that the technique is limited to short baselines ( $< \sim 1$  km) and so the precise location of straining regions must be known a priori. Nonetheless, for monitoring purposes with very well-defined targets such as the headwall portion of an active landslide, the technique holds much promise.

**Pressure Sensor Vertical Deformation** Phillips et al. [40] recently developed a new technique that used pressure sensors in campaign-mode repeat surveys to mea-

sure vertical deformation rates of the seafloor at depths exceeding 2000 m at the offshore portion of the Hilina Slump. Depth and pressure are related to one another in a straightforward manner through the hydrostatic equation, though for measuring seafloor deformation rates at the cm/yr level many other reductions must be performed (Phillips et al. [40] – also her thesis). The pressure sensor method is technologically challenging, requires much ship time, and requires during each site visit both a geodetic monument and a pressure sensor (lowered from a ship) to be operating in close proximity to one another at depth on the seafloor. Because, in each revisit it was not practical to collocate the pressure sensor in a repeatable fashion on the benchmark, Phillips et al. [40] found it necessary to measure the vertical offset between the pressure sensor and the benchmark via acoustic ranging.

Important error sources for this technique are poor knowledge of  $\alpha$  the specific volume of the water column (the reciprocal of density) and the speed of sound in depth. Due to changing tides, secular and seasonal barometric changes it is also necessary to utilize a common, stable reference, such as mean sea level (MSL) which, in turn, requires estimation of the geopotential anomaly.

Ultimately, Phillips et al. [40] conclude that their data show significant vertical deformation ( $9 \pm 2.4$  cm/yr) in the mid-section of the HS and negligible deformation towards the outer bench (just inboard of the toe of the entire landslide feature). These data are consistent with dislocation models delimiting the potential amount ( $25.0\text{--}28.1 \pm 7.3$  cm/yr), spatial extent ( $24.8\text{--}27.0 \pm 0.5$  km seaward of Kilauea's East rift zone), and depth (7 km) of the principal slipping surface below the landslide. This is a significant advance not only because it represents the first data set that allows a glimpse of how strain is partitioned in a massive submarine landslide such as the Hilina Slump, but also because it represents an ongoing monitoring project at a submarine landslide, albeit at temporally sparse sampling rate.

## Data Analysis and Inversion

In addition to the challenge of acquiring geodetic data from submarine or even subaerial landslides is the added challenge of inferring sub-surface fault geometry and/or deformation processes, with attendant realistic error bounds on estimated parameters, from a data set of earth surface displacements. We identify two principal types of analysis modes: (1) process-based and (2) hazards-based. Process-based analysis focuses on deriving the most accurate and, if possible, complete assessment of the factors involved in the observed landslide motion. Hazards-based

analysis has two primary components: (a) rapid warning and (b) long-term hazards estimation. Rapid warning comprises, with the smallest temporal latency possible, providing information regarding the current state of the landslide system and how it relates to current, short- and long-term dangers to life and infrastructure. Long-term estimation comprises making probabilistic statements about the components and potential future behavior of the system and so temporal latency is not a limiting consideration.

For either of the two types of analysis modes, the first objective is to usually try to relate the measured displacements  $d$ , of monuments at the surface of the earth to the source parameters,  $m$ , of the buried feature causing the deformation (usually considered a fault) through  $G(m)$ , a model of the deformation process. For instance, one very common model formalism, the dislocation in an elastic half-space, is a non-linear problem whose model vector  $m$  contains 9 parameters describing the location, orientation, and relative displacement of the dislocation approximating a faulting source [101,102].

Determining the most likely components of  $m$  and associated errors falls under the wide category of geophysical inversion for which there are a multitude of techniques e. g. [103]. In addition to the computational power available and the total amount of time allotted to the inversion, the choice of inversion method depends upon the nature of the model (for instance, linear vs. non-linear), the number of parameters in  $m$ , and the computational cost associated with individual model realizations and misfit assessments. Furthermore, it must be decided if the goal of an inversion is to obtain a rapid solution (a solution that satisfies some predetermined misfit level), an optimal solution (i. e. one 'best-fitting' solution), or rather to probe parameter space as thoroughly as possible with the goal of estimating posterior probability densities for each of the parameters for their value as indicators of resolution and uncertainty e. g. [104]. For instance, the most robust inversion method possible is the direct or 'grid' search, where the misfit for every possible permutation of  $m$  in parameter space is calculated. For more complicated or non-linear  $G(m)$  however the computational cost associated with each forward model run can make a grid-search time prohibitive, even for a process-based analysis. For these types of more difficult problems, inversion based on Monte Carlo sampling, which collects pseudo-random samples from multidimensional parameter space as a proxy for the problem's true posterior probability density,  $\sigma(m)$ , has been found to be quite successful [105,106]. Indeed, it is common practice in the tectonic geodesy community to use the Okada model combined with some type

of Monte-Carlo method to derive parameters of earthquakes and slow earthquakes from surface displacements observed with GPS [80,104,107].

The recent evolution of the work on the SEs at Kilauea demonstrates how important the inversion results are to the overall analysis either from a process-based or long-term hazards-based perspective. In their initial recognition of the November 2000 SE, Cervelli et al. [5] used a simulated annealing optimization routine [80] and the Okada model to invert the GPS observations and conclude that the most likely dislocation source for the SE occurred on a gently landward-dipping thrust fault plane at 5–6 km depth. Combined with the fact that the SE post-dated by 9 days a burst of local rainfall of nearly 1 m and reasonable estimates of local hydrologic parameters, Cervelli et al. [5] suggested that the increased pore pressure due to deeply percolating rainwater triggered SE motion by inducing a  $\sim 2$  MPa pressure decrease of the effective normal stress on their preferred fault plane. Brooks et al. [4], however, showed from Gibbs Sampling inversion [104] results of GPS data on three additional SEs that posterior distributions of estimated fault parameters allow a wide family of equivalently plausible solutions, ranging from deeper seated decollement solutions at  $\sim 8$  km depth to the more shallow fault plane favored by Cervelli et al. [5] (Fig. 7). Moreover, they showed that the other SEs were not associated with anomalous rainfall. Segall et al. [6] then used the same inversion method of Cervelli et al. [5] for the GPS data of the additional SEs relocations of high-frequency earthquakes triggered by the January 2005 SE, seismicity rate theory [108], and Coulomb stress modeling [109] to conclude that the SE (and other similar events) likely occurred at a depth of  $\sim 8 \pm 1$  km on the main decollement plane below the Hilina Slump.

In this case, the crucial addition to the source inversion was the added constraint of the triggered microearthquakes which were relocated to depths near the decollement [6]. In their earthquake relocations, however, Segall et al. [6] did not use the full waveform data; rather, they used a double-difference-derived mapping with manual picks, assuming a 1D velocity model, between triggered events and previous high-precision relocations and tomography from elsewhere at Kilauea [110]. Two other studies, [111,112] performed high precision relocations using waveform cross correlation data and found different depths for the same cluster of events as Segall et al. [6]. Got and Okubo [111] suggested that their relocated events (including those triggered by the 1998 SE) do not illuminate a sub-horizontal fault plane but rather a deeper, steeply south-dipping reverse fault. Wolfe et al. [112] found that the triggered seismicity from the four SEs identified by

North-south cross-section of the Hilina Slump after Got and Okubo [111]. K, Kilauea. HS, Hilina slump. Black line below K is the seismic (solid) and aseismic (dashed) position of the decollement from Got and Okubo [111]. Two thicker black lines with green shaded area, are the family of geologically plausible dislocation solutions equivalently supported by inversion of GPS data. Yellow colored circles, locations of microearthquakes from HVO catalog for  $\pm 5$  days around each slow earthquake event

Brooks et al. [4] consistently relocates on distinct map-view clusters aligned in the direction of the SE displacements themselves and in a subhorizontal band with depths of  $\sim 5$  km. This is a solution consistent with Morgan et al. [21] who used seismic reflection data to identify moderately landward-dipping fault planes at similar depths. While the epicenters are well constrained in the Wolfe et al. [112] study, however, they were concerned that poor station geometry as well as near source velocity heterogeneity may bias the absolute depth of the relocations and the analyses may not be capable of distinguishing between shallow and deep fault zones. Thus, while the decollement is certainly the prime candidate on which a SE would occur (in agreement with the Segall et al. [6] suggestion), the analyses remain somewhat equivocal. This, in turn affects our best understanding of the most important hazard issue, the propensity of the decollement for a catastrophic failure. In order to more definitively answer these questions the above-mentioned research groups in conjunction with the Hawaiian Volcano Observatory of the US Geological Survey (the group charged with hazards analysis and mitigation for the region) have teamed up in a joint seismological and geodetic research project aimed at definitively constraining the depths of triggered seismicity, and, hopefully, the depth of SE sources in the region.

While the above example focuses mostly on process and long-term hazards assessment, recent developments focused on deriving the time-dependent history of slip during a deformation event could also potentially be used for automated real-time inversion and event detec-

tion [96,113]. The Network Inverse Filter (NIF) [96] is a recursive Kalman filter algorithm that operates on either processed position estimates or raw phase data (rather than derived displacement rates) from an entire network of geodetic stations, includes a stochastic description of local benchmark motion, and finds a non-parametric description of slip rate on a fault plane as a function of time. In current implementations, the NIF employs Green's functions relating slip to surface displacement computed from the analytical solutions for a dislocation in an elastic half-space [101] although there is no reason other deformation models could not be employed [113]. Application of the NIF to the 1999 Cascadia SE allowed McGuire and Segall [113], for instance, to determine that slip rate on the slipping fault plane took up to  $\sim 20$  days to reach its peak and that the southern portion of the fault had finished slipping before the northern portion began to slip. Cervelli et al. [5] and Segall et al. [6] also applied the NIF to the Kilauea SEs to derive source-time functions for the events. One caveat, however, is that the fault plane is not solved for by the NIF, rather, it must be known and held fixed a priori. For subduction zones with greater spatial geodetic coverage above the slipping portion of the fault this condition may be satisfied more satisfactorily than at submarine landslides.

#### Discussion: Slow Earthquake and Submarine Landslide Process

Largely because of CGPS subaerial measurements at Kilauea there are now a suite of observations of slow earth-

quakes related to submarine landslide motion. As it seems that SEs are a fairly general fault slip phenomenon, occurring at a variety of subduction zone locales globally, it stands to reason that SEs may be common to submarine landslide-related deformation, at least on the flanks of ocean island volcanoes. Clearly, as seafloor geodesy projects become more common we will learn if this is the case or not. It is also clear that the search for a theoretical understanding of the slow earthquake phenomena will be coupled to further understanding the motion of submarine landslides.

Currently, explanations for slow earthquake slip behavior focus on rock mechanic theory that follows an empirically derived rate- and state-variable frictional constitutive law based on laboratory experiments e. g. [114]. (The description below follows the summary and notation in Scholz [114]). The Dieterich–Ruina or ‘slowness’ law is expressed as:

$$\tau = [\mu_0 + a \ln(V/V_0) + b \ln(V_0\theta/\zeta)]\sigma,$$

where  $\tau$  is shear stress,  $\mu_0$  is the steady-state friction,  $\sigma$  is effective normal stress,  $V$  is slip velocity,  $V_0$  is a reference velocity,  $a$  and  $b$  are frictional material properties,  $\zeta$  is the critical slip distance and  $\theta$  is a state variable that evolves according to:

$$d\theta/dt = 1 - \theta V/\zeta.$$

The frictional stability of the system, then, depends on  $(a - b)$ , the velocity dependence of steady-state friction, defined:

$$a - b = \delta\mu/\delta(\ln(V)).$$

In the context of a simple spring-slider model approximating a slipping fault, the boundary between the stable and unstable frictional regimes will occur at a critical value of effective normal stress,  $\sigma_c$ , given by:

$$\sigma_c = k\zeta / (a - b),$$

where  $k$  is the stiffness. When  $(a - b) > 0$  the material is said to follow ‘velocity strengthening’ behavior and the system is stable – earthquakes cannot nucleate in this regime and earthquakes propagating into such regions will be abruptly terminated. When  $(a - b) < 0$  the material is said to follow ‘velocity weakening behavior and the system is unstable for  $\sigma \geq \sigma_c$  – earthquakes will nucleate in this regime. When  $\sigma \leq \sigma_c$  the system exhibits oscillatory behavior and is said to be ‘conditionally stable’, it is stable under quasi-static loading but requires a discrete velocity

perturbation in order for earthquakes to nucleate. Others interpret these relations slightly differently suggesting that nucleation occurs when matrix stiffness (scale and stress-rate dependent) drops to a critical value over a spatial scale large enough to promote rupture [68,115].

It may be in the boundary of this stability transition where slow earthquake slip behavior arises. For instance, a common observation of most of the subduction zone SEs is that they occur down-dip of the ‘locked’ zone or near the base of the seismogenic zone where earthquakes nucleate [1,57,58,69,71]. At these depths in subduction zones temperatures are close to the 450°C temperature at which feldspar starts to exhibit plastic behavior and so conditionally stable behavior would be expected [114], although it has recently been shown that transient oscillatory behavior may also arise naturally from system dynamics alone [116]. Faults in the conditionally stable regime, under steady-state loading, slip aseismically unless a perturbation to the system is large enough to push the fault across the stability boundary triggering an earthquake [117]. If the perturbation, however, is not quite large enough to push the fault across the stability regime then a period of stable sliding at increased velocity will occur (i. e. a slow earthquake) as the fault evolves back to steady-state [117]. It is not yet clear, however, how the explanations for subduction-zone related SEs may translate to the submarine landslide environment. While many subduction zone SEs apparently occur down-dip of the ‘locked’ zone where earthquakes nucleate along the subduction interface, at Kilauea, SEs apparently occur up-dip of the zone where the majority of earthquakes occur [4,6].

Recent studies have more explicitly focused on helping to explain SEs in terms of the rate- and state-variable formalism. For instance, Kato [67] used rate- and state friction to simulate the effect that ‘asperities’, velocity weakening regions surrounded by velocity strengthening regions, have on slip behavior and found that episodic SEs occur when the velocity-weakening patch size is close to the critical size of earthquake nucleation. Similarly, Liu and Rice [68] found that when they applied along-strike variations in the frictional  $(a - b)$  parameter in models of subduction zone processes, that SE-type transient deformation events emerged spontaneously near the down-dip end of the seismogenic zone. They suggested that the down-dip end of the seismogenic zone is likely to be in the conditionally stable boundary between unstable- and stable regimes and that this could allow the SE behavior. More recently, Lowry [58] employed further theoretical implications of rate- and state-variable friction under resonant loading conditions [115,118] to suggest that Earth’s response to climatic redistribution of atmospheric, hydro-

spheric, and cryospheric loads could lead to resonant fault slip behavior that could explain observed periodic slow earthquakes on the Cocos-North America plate boundary at Guerrero, Mexico.

Shibazaki and Shimamoto [119] recently proposed an alternate model of slow earthquakes that was motivated by laboratory experiments on the velocity dependence of frictional stability. They introduced a cutoff velocity to the rate-state formulation to mimic laboratory results where fault surfaces transition from velocity weakening at low sliding velocities to velocity strengthening at higher velocities. Implementing the laboratory values for these transitions reproduced the slip ( $10^{-7}$  m/s) and rupture propagation velocities (km/day) seen in subduction zone environments. Their model predicts a linear relationship between these two velocities that can in principle be inferred from high quality continuous geodetic measurements of slow earthquakes. This relationship may be an important way to relate observations of slow earthquakes to mechanical models, particularly in regions such as Kilauea where the fault planes are shallow enough ( $< 10$  km) to allow the details of the rupture to be resolved with high quality instrumentation. We note additionally that other recent model parameterizations [116] yield recurrence intervals and propagation velocities similar to observed events and Lowry [58] also suggested means of relating geodetic observations and model parameters.

Two additional factors that may modulate the frictional properties of faults in submarine landslide environments include local hydrologic and magmatic forces (in regions of active volcanism) [23]. For instance, the Nov. 2000 SE at Kilauea post-dated by 9 days an intense rain storm of nearly 1 m at the southeastern Big Island [5]. Cervelli et al. [5] estimated permeability using regionally appropriate hydrologic parameters for porosity and fault zone diffusivity and suggested that the 1 m of rain could have triggered SE motion by inducing a  $\sim 2$  MPa pressure decrease of the effective normal stress on a gently landward dipping fault at  $\sim 5$  km depth. Brooks et al. [4], however, showed that 3 other SEs at Kilauea were not preceded by anomalous rainfall and that other periods of anomalous rainfall were not accompanied by SEs. Additionally, prior to these events Iverson [23] was skeptical of rainfall triggers as he found from a rigid wedge analysis that, in order for ground water head gradients to be large enough to destabilize the Hilina Slump, implausibly large clay layers ( $\sim 200$  m thick) or very low hydraulic diffusivity ( $\sim 10^{-11}$  m<sup>2</sup>/s) needed to be present. Others, however, have found that magmatic injection-induced mechanical and thermal pressurization of fluids may help to explain Canary and Cape Verdes Islands flank instabilities [120].

Excess shear stresses exerted on a basal decollement because of rift zone magma injection have also been shown to be of sufficient magnitude to potentially cause slip [22,23]. Although others have suggested from geodetic observations of discrete dike events at Kilauea's rift zones that the dikes are injected passively, as a response to decollement slip, rather than as a trigger for it [121,122].

### Future Directions: Slow Earthquakes and Submarine Landslide Monitoring

It is clear that expanded seafloor geodetic monitoring of submarine landslides would be extremely important in bettering our understanding of both the slow earthquake process and the hazards associated with submarine landslides. For instance, at the Hilina Slump, it is not even known how much of submarine portion of the landslide actually displaces the seafloor during a slow earthquake. Given the logistical and financial challenges associated with seafloor geodesy, however, it is reasonable to ask if it is worth it to society to monitor submarine landslides. In the Hawaiian Islands, for instance, one compilation suggests that there have been at least 6 tsunami-generating landslide events in the past 300 000 years [123]. For comparison, the average 50 000 year recurrence interval for such events is 1 to 2 orders of magnitude larger than typical earthquake recurrence intervals in Southern California where substantial resources are focused on earthquake-cycle related monitoring (<http://www.wgcep.org/>). As discussed above, however, landslide-generated tsunami can be quite damaging both locally and regionally. One study simulated  $\sim 30$  m wave heights reaching the California coast within 6 h of a massive collapse of the Hilina Slump at Kilauea [124]. Clearly minimizing the impact of such an event would be of societal benefit.

Continuous submarine landslide deformation monitoring, although expensive, is not out of the realm of possibility, as costs for seafloor geodetic instrumentation are decreasing. In the coming years, in order to make continuous monitoring efforts more feasible, research will likely focus on two major technical challenges: (1) instrument power delivery and (2) data transmission. While cabling a network via seafloor pathways is certainly one way of satisfying both requirements, cabling may not be the best long-term solution for a number of reasons. First, the costs of large cable lengths and laying them on the seafloor is often measured in the millions of dollars. Second, especially for submarine landslides, the seafloor across which the cable need be lain can be very rough and cable failure can be a quite common occurrence. Third, if cable runs are long then annual maintenance efforts and cost can also be quite

high. Accordingly, techniques such as acoustic data transmission [125] and local power generation via a buoy, for instance, will be critical.

### Acknowledgments

We thank the Hawaiian Volcano Observatory of the US Geological Survey, in particular Asta Miklius, Maurice Sako, and Kevan Kamibayashi, for their collaboration and efforts in operating the CGPS network at Kilauea. We thank Paul Segall of Stanford University for sharing GPS data from this network. We thank Matt Gould and Nick Witzell of WHOI for engineering support. We thank Capt. Rick Myer and the crew of the R/V Kilo Moana for their help in deploying and retrieving the extensometers. We thank Mark Schenewerk for help with implementing PAGES. We thank Katie Phillips and Dave Chadwell for helpful discussion and sharing a manuscript in preparation. We thank Cecily Wolfe and Gerard Fryer for stimulating discussion. In particular we thank J. Moore, T. Lowry, and D. Chadwell for thorough and insightful reviews which improved this contribution. This research was supported by the Geophysics and Geochemistry programs of the US National Science Foundation, grants from School of Ocean and Earth Science and Technology at the University of Hawaii, and a grant from the Deep Ocean Exploration Institute of the Woods Hole Oceanographic Institution.

## Glossary

**CO<sub>2</sub>** Carbon dioxide is the predominant greenhouse gas. Anthropogenic CO<sub>2</sub> emissions are created largely by the combustion of fossil fuels.

**CGCM** Coupled general circulation model, a climate model which combines the atmospheric and oceanic systems.

**GCM** General circulation model, a term commonly used to describe climate models maintained at large research centers.

**GHG** GHG is a greenhouse gas such as CO<sub>2</sub> and methane. These gases contribute to global warming by capturing some of the outgoing infrared radiation before it leaves the atmosphere.

**GT** Gigaton, a common measure of carbon storage in the global carbon cycle. A GT is a billion metric tons.

**IPCC** The Intergovernmental Panel on Climate Change was formed in 1988 by the World Meteorological Organization and the United Nations Environmental Program. It reports research on climate change. Their assessments are closely watched because of the requirement for unanimous approval by all participating delegates.

## Definition of the Subject

System dynamics is a methodology for studying and managing complex systems which change over time. The method uses computer modeling to focus our attention on the information feedback loops that give rise to the dynamic behavior. Computer simulation is particularly useful when it helps us understand the impact of time delays and nonlinearities in the system. A variety of modeling methods can aid the manager of complex systems. Coyle (p. 2 in [3]) puts the system dynamics approach in perspective when he describes it as that “branch of control theory which deals with socio-economic systems, and that branch of management science which deals with problems of controllability.” The emphasis on controllability can be traced to the early work of Jay Forrester [9] and his background in control engineering [10]. Coyle highlighted controllability again in the following, highly pragmatic definition:

*System dynamics is a method of analyzing problems in which time is an important factor, and which involve the study of how a system can be defended against, or made to benefit from, the shocks which fall upon it from the out-side world.*

The emphasis on controllability is important as it directs our attention to understanding and managing the system, not to the goal of forecasting the future state of the system. Making point predictions is the objective of some modeling methods, but system dynamics models are used to improve our understanding of the general patterns of dynamic behavior. System dynamics has been widely used in business, public policy and energy and environmental policy making. This article describes applications to energy and environmental systems.

## Introduction

System dynamics has been used extensively in the study of environmental and energy systems. This article describes some of these applications, paying particular attention to the problem of global climate change. The applications were selected to illustrate the power of the method in promoting an interdisciplinary understanding of complex problems.

The applications to environmental and energy systems are similar to applications to other systems described in this encyclopedia. They usually begin with the recognition of a dynamic pattern that represents a problem. System dynamics is based on the premise that we can improve our understanding of the dynamic behavior by the construction and testing of computer simulation models. The

models are especially helpful when they illuminate the key feedbacks that give rise to the problematic behavior.

System dynamics is explained in the core article in this volume, in the early texts by Forrester [9], Coyle [3] and Richardson [18] and in more recent texts on strategy by Warren [22] and by Morecroft [17]. The most comprehensive explanation is provided in the text on business dynamics by Sterman [19]. Applications to environmental systems are explained in the text by Ford [7]. The most widely read application to the environment is undoubtedly *The Limits to Growth* [16]. Collections of environmental applications appear in special issues of the *System Dynamics Review* [11,20].

The models are normally implemented with visual software such as Stella (<http://www.iseesystems.com>), Vensim (<http://www.vensim.com/>) or Powersim (<http://www.powersim.com/>). These programs use stock and flow icons to help one see where the accumulations of the system take place. They also help one to see the information feedback in the simulated system. The programs use numerical methods to show the dynamic behavior of the simulated system. The examples selected for this article make use of the Stella and Vensim software.

This article begins with textbook examples of environmental resources in the western US. The management of water levels at Mono Lake in Northern California is the first example. It shows a hydrological model to simulate the decline in lake levels due to water exported out of the basin. The second example involves the declining salmon population in the Tucannon River in Eastern Washington. These examples demonstrate the clarity of the approach, and they illustrate the potential for interdisciplinary modeling.

The article then turns to the topic of climate change and global warming. The focus is on the global carbon cycle and the growing concentration of carbon dioxide (CO<sub>2</sub>) in the atmosphere. A wide variety of models have been used to improve our understanding of the climate system and the importance of anthropogenic CO<sub>2</sub> emissions. Examples of system dynamics models are presented to show how they can improve our understanding and provide a platform for interdisciplinary analysis.

System dynamics has also been widely applied in the study of energy problems, especially problems in the electric power industry. The final section describes two applications to electric power. The first involved the financial problems of regulated electric utilities in the US during the 1970s. It demonstrates the usefulness of the method in promoting an interdisciplinary understanding of the utilities' financial problems. The second study dealt with the CO<sub>2</sub> emissions in the large electricity system in the West-

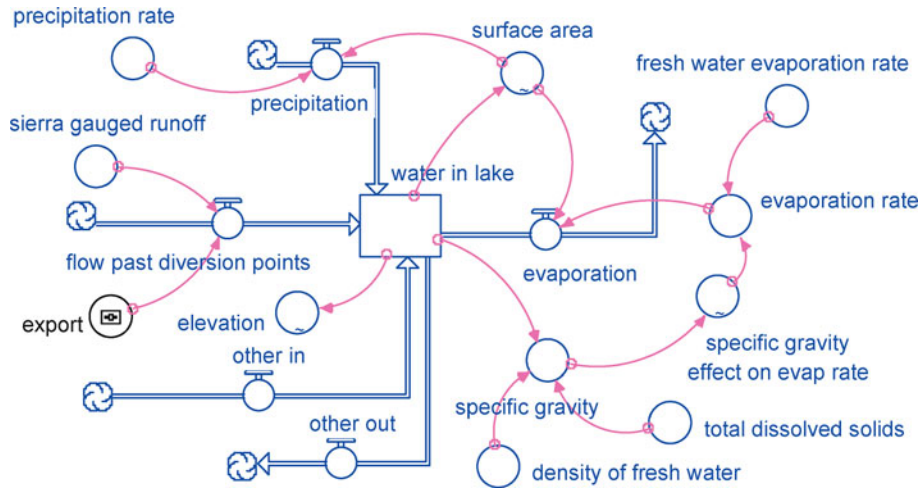

ern USA and Canada. It demonstrated how the power industry could lead the way in reducing CO<sub>2</sub> emissions in the decades following the implementation of a market in carbon allowances.

### The Model of Mono Lake

Mono Lake is an ancient inland sea on the east side of the Sierra Nevada Mountains in California. Microscopic algae thrive in its saline waters, and the algae support huge populations of brine flies and brine shrimp which can, under the right conditions, provide a virtually limitless food supply for migratory and nesting birds. Starting in 1941, stream flows toward Mono Lake were diverted into the aqueduct for export to Los Angeles. The large export deprived the lake of the historical flows, and the volume shrunk over the next four decades. By 1980, the lake's volume was cut approximately in half, and its salinity nearly doubled. Higher salinity levels posed risks to the ecosystem, and environmental scientists feared for the future of the lake ecosystem. Various groups filed suit in the 1970s to limit exports, and the California Supreme Court ruled in 1983 that public trust doctrine mandated a reconsideration of the management of the waters of the Mono Basin. That reconsideration led to a long-term plan to limit exports until the lake's elevation would return to safer levels.

Figure 1 shows a system dynamics model to simulate water flows and storage in the Mono Basin. The goal was to understand the pattern of decline over four decades and to study the responsiveness of the lake to a change in export policy. The model is implemented with the Stella software, and Fig. 1 shows how the model appears when using the software. A single stock variable is used to represent the storage in the basin. The main flow into the lake is the flow from gauged streams that bring runoff from the Sierra to the lake. The aqueduct system diverts a portion of this flow south to Los Angeles, and the flow allowed past the diversion points is the main flow into the lake. The main outflow is the evaporation. It depends on the surface area of the lake and the evaporation rate. The surface area depends in a nonlinear way on the volume of water in the lake. Figure 1 shows that this model follows the standard, system dynamics practice of using familiar names to convey the meaning of the variables in the model. (These particular names match the terms used by water managers and hydrological models of the basin.)

Figure 2 shows the simulated decline in the lake if exports were allowed to continue at high levels for 50 years. The lake would decline from 6374 to around 6342 feet above sea level, a value which is designated as a hypothetical danger level for this simulation. The long, gradual

System Dynamics Models of Environment, Energy and Climate Change, Figure 2  
 Simulated decline in Mono Lake elevation if historical export were allowed to continue until the year 2040

decline is a match of projections by the other hydrological models used in the management plan for the basin. The lake will continue to fall until the area has been reduced sufficiently to create an evaporation which will lead to a balance of the flows in and out of the basin.

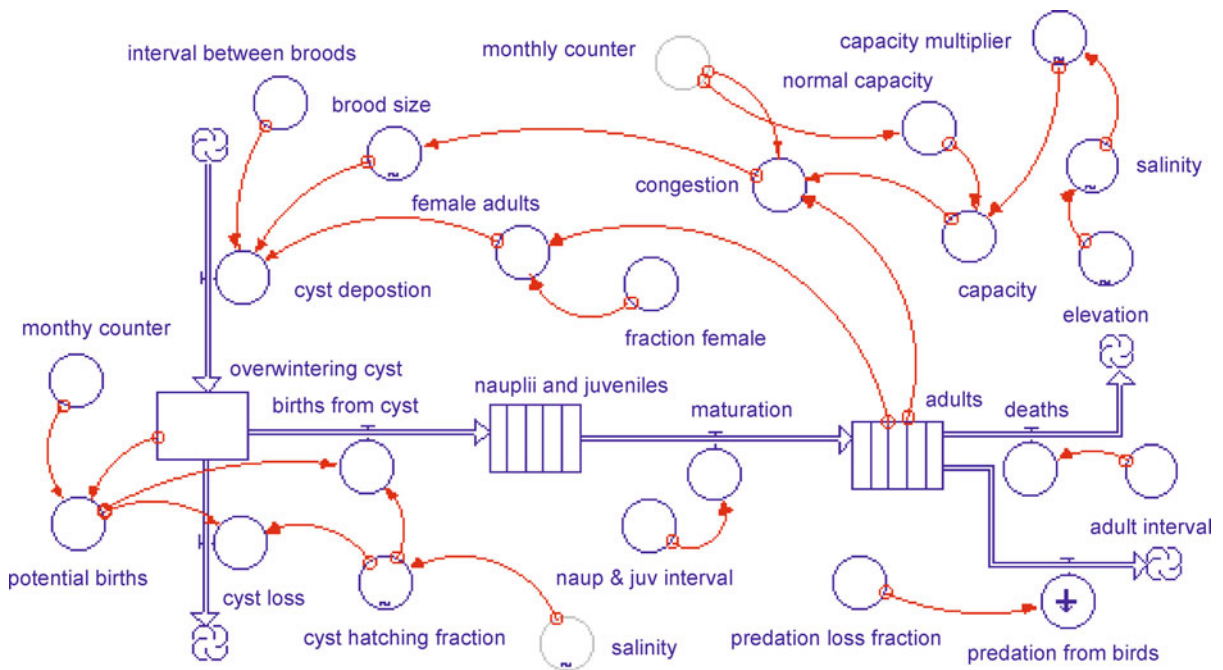

Figure 3 shows the simulated responsiveness of the lake to a change in export. The export is cut to zero midway through the simulation, and the elevation increases rapidly in the ensuing decade. The simulation reveals an immediate and rapid response, indicating that there is little downward momentum associated with the hydrology of the basin. This responsiveness is highly relevant to the management plan. When the lake falls to a dan-

gerous level, the export could be reduced, and the lake would climb to higher elevations within a few years after the change in policy. This rapid response supports the “wait and see” argument by those who advocated waiting for full signs of a dangerous salinity before changing export policy.<sup>1</sup> But there is far more than hydrology at work in this system. The waters of Mono Lake support a complex ecosystem which may or may not recover as quickly as the lake elevation. To explore the larger system requires

<sup>1</sup>“Wait and see” may be supported by an analysis of the hydrology of the basin, but it does not necessarily make sense when considering the long delays in the political and managerial process to change water export.

System Dynamics Models of Environment, Energy and Climate Change, Figure 3  
 Simulated recovery of Mono Lake elevation if export is set to zero for the second half of the simulation

System Dynamics Models of Environment, Energy and Climate Change, Figure 4  
 Stella model of the brine shrimp population of Mono Lake

an interdisciplinary model, one that looks at both hydrology and population biology.

Figure 4 shows a model of the population of brine shrimp that live in Mono Lake. The life cycle begins when the adult females deposit cysts in the summer. A stock is assigned to the overwintering cysts. The nauplii and juvenile phases are combined into a second stock, and the maturation leads to a new population of adults in the fol-

lowing summer. The model operates in months and is simulated over a long time interval to show the population response to long-term changes in elevation and in salinity. The model shows the population's response to changes in lake elevation, so one can learn about the delays in the population's response to the changes in lake elevation. Since the shrimp life cycle is 12 months, one would expect the population to rebound rapidly after the increase in ele-

vation and the reduction in salinity. The model confirms that the shrimp population would increase rapidly in the years following the elimination of water export from the basin.

The Mono Lake models are textbook models [7]. They demonstrate the clarity that the system dynamics approach brings to the modeling of environmental systems. The stock and flow icons help one see the structure of the system, and the long variable names help one appreciate the individual relationships. The simulation results help one understand the downward momentum in the system. In this particular case, there is no significant downward momentum associated with either the hydrological dynamics or the population dynamics.

The model in Fig. 1 allows for a system dynamics portrayal of the type of calculations commonly performed by hydrologists. Compared to the previous methods in hydrology, system dynamics adds clarity and ease of experimentation. The population model in Fig. 4 is a system dynamics version of the type of modeling commonly performed by population biologists. System dynamics adds clarity and ease of experimentation in this discipline as well.

The main theme of this article is that system dynamics offers the opportunity for interdisciplinary modeling and exploration. The Mono Lake case illustrates this opportunity with the combination of the hydrological and biological models that allows one to simulate management policies that control export based on the size of the brine shrimp population. The new model is no longer strictly hydrology nor strictly population biology; it is an interdisciplinary combination of both. And by using stock and flow symbols that are easily recognized by experts from many fields of study, the system dynamics enables quick transfer of knowledge. The ability to combine perspectives from different disciplines is one of the most useful aspects of the system dynamics approach to environmental and energy systems. This point is illustrated further with each of the remaining examples in the article.

### The Model of the Salmon in the Tucannon River

The next example involves the decline in salmon populations in the Snake and Columbia River system of the Pacific Northwest. By the end of the 1990s, the salmon had disappeared from 40% of their historical breeding ranges despite a public and private investment of more than \$1 billion. The annual salmon and steelhead runs had dwindled to less than a quarter of the runs from one hundred years ago. Figure 5 shows a system dynamics model one of the salmon runs, the population of Spring Chinook

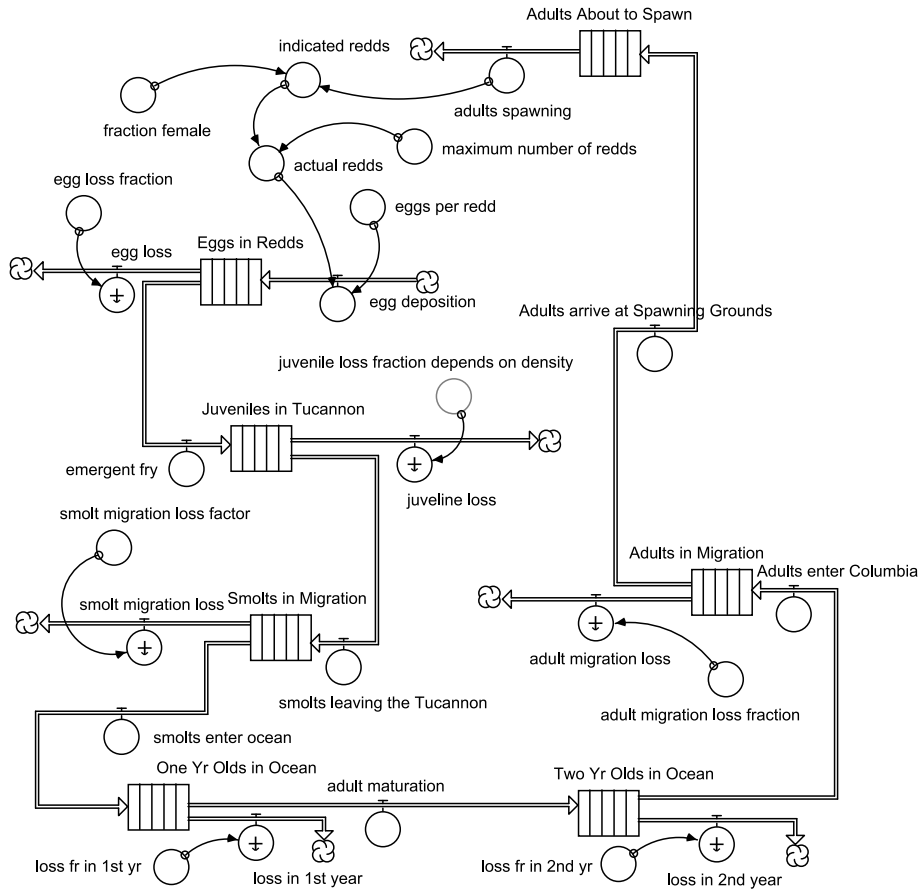

System Dynamics Models of Environment, Energy and Climate Change, Table 1  
Inputs to simulate the salmon population under pre-development conditions

Months in each phase		Population parameters	
Adults ready to spawn	1	fraction female	50%
eggs in redds	6	eggs per redd	3,900
juveniles in Tucannon	12	egg loss fraction	50%
smolts in migration	1	smolt migration loss factor	90%
one yr olds in ocean	12	loss fr for first yr	35%
