# Foreword

Prostate cancer has become a worldwide problem, not only in the developed world but in developing countries as well. As the population ages worldwide and other diseases become less frequent causes of premature death, prostate cancer, which rapidly increases in frequency with age, will present a growing public health problem. Prostate cancer is a complex and heterogeneous disease. The ratio of deaths to new cases is one of the lowest of any of the major internal organ solid tumors. It is well known that most men die with, rather than of, prostate cancer, a paradox that has long stymied widespread understanding and the easy development of consensus about the management of this disease.

Fortunately, clinical and basic research in the past 20 years have provided important tools that have enormously facilitated our understanding of prostate cancer, the ability to predict the course of the disease and the outcomes of various treatments. Today we can add to the standard clinical factors (stage, grade, PSA and biopsy results) the burgeoning technology of medical imaging (especially magnetic resonance imaging) and the more recent molecular characterizations that could greatly enhance our ability to identify the threat posed by the cancer in any given patient. Further characterization of prostate cancer seems highly likely over the next decade with the expanding use of genomic analysis. The worldwide effort to characterize the prostate cancer genome will prove enormously fruitful and markedly increase our ability to discriminate between potentially lethal and indolent prostate cancers.

The biomarker prostate specific antigen (PSA) has revolutionized our understanding and ability to manage this disease. While PSA testing has proved the source of enormous debate over the last decade, it is clear that PSA is the best biomarker available in oncology. Recent studies have shown that a man's PSA levels in his 40s, 50s, and 60s strongly predict the likelihood that he will ever develop advanced prostate cancer or die of the disease. Nevertheless, controversy swirls around the optimum protocol for PSA testing, the age of onset of testing, and the cost benefit of screening for prostate cancer. Epidemiological data show that in countries where screening has been widely used, mortality from prostate cancer has been declining steadily and rapidly. Today, in the United States, the age-specific mortality rate from prostate cancer has fallen by nearly 50 % over the last 15 years.

The treatment of prostate cancer is also undergoing revolutionary changes. Technology has expanded the surgical options for radical prostatectomy, which now include robotic and free-hand laparoscopic as well as open retropubic and perineal techniques. Radiation therapy has also benefited from a technological advance. Intensity-modulated radiation has allowed us to safely deliver doses as high as 86 Gy to the prostate, and image guidance promises to target the prostate more accurately, improving cancer control. Many centers have developed combinations of interstitial radiation (brachytherapy) with external beam radiation to deliver higher doses. Proponents of proton beam therapy argue that it offers an even greater therapeutic index, although there is little clinical data to support the contention.

For those with metastatic prostate cancer, this is indeed an exciting era. There are over 100 new drugs in the pipeline for commercial development in the United States alone. Phase III clinical trials have shown substantially increased survival with new drugs that target the androgen receptor, such as abiraterone and Medivation 3100. The first immunotherapy approved for use in human cancer was sipuleucel-T, approved for prostate cancer. Other exciting approaches

include immunomodulation with anti-CTLA4 antibodies and with monoclonal antibodies targeting B7x and other immunoinhibitory targets.

These and many other exciting developments in prostate cancer are addressed in detail in this remarkable new book edited by Ashutosh Tewari and an international team of associate editors. Every possible aspect of prostate cancer is covered by a recognized authority in the field. For those deeply interested in understanding this disease, especially clinical and laboratory investigators, and for physicians and surgeons who devote their careers to treating men with prostate cancer, this book is a major new addition to the field.

Peter T. Scardino

## Applied Prostatic Anatomy

### History of Prostatic Anatomy and Radical Prostatectomy

Contemporary anatomical insights beginning in the 1970s have driven the dramatic improvements in outcomes for men treated by surgical removal of the prostate. Before the 1980s, only the very hardy patient was able to tolerate the morbidity of attempted surgical cure of prostate cancer.

The operation was attended often by massive blood loss, certain impotence, and a high likelihood of permanent urinary incontinence. It was preferable therefore to opt for radiation therapy as primary treatment to avoid the morbidity of radical prostatectomy.

## Introduction

Two factors have changed urologists' attitudes to surgery for prostate cancer since 1980. The first was the work of Dr. Patrick Walsh who "discovered" the neurovascular bundle so key in potency preservation at prostatectomy [1, 2]. Walsh also recognized that bleeding occurred due to failure to control Santorini's plexus of dorsal penile veins. These two anatomical insights ushered in three improvements in prostatectomy outcomes [3].

Because the operative field was no longer immersed in blood, greater care in the precise dissection of the striated sphincter was possible. This meant that with care being taken in this step of the operation, most men would maintain urinary continence. The anatomic description of a discrete autonomic neural bundle running in a groove posterolateral to the prostate between rectum and prostate meant potency preservation was a surgical reality. The surgeon's ability to perform the operation now in a mainly bloodless field allowed a better oncological procedure with clean dissection in and around the fascial compartments of the prostate. This led to steady and steep decline in the positive pathological margin rate.

Dr. Whitmore quoted saying that surgery (before 1975) was unlikely to lead to cure and is also less quoted stating "There is no better way to cure prostate cancer that is confined to the prostate than its total removal" [4, 5]. Before the mid-1970s, most men presented with locally very advanced cancer or regularly with metastatic disease. Surgery was most unlikely to cure those men.

The advent in the 1980s of PSA allowed a lead time of around 9 years from localized to metastatic prostate cancer. In 2000, the arrival of telerobotic surgery [6] provided the prostatectomist with an unprecedented ×10 magnified 3-dimensional surgical field. These incremental advances in surgery, underpinned by anatomical insights, enabled urologists to offer a patient presenting with PSA-detected, localized prostate cancer an oncologically sound operation with a high likelihood of continence preservation and retention of erectile function. This is the desired "trifecta" of outcomes.

What was remarkable about Walsh's insights is that they were made not in the anatomy room dissecting cadavers but from observations made in the operating room to be later proven in the dissecting room.

## Contemporary Prostate Anatomy

In the early 2000s at The Royal Melbourne Hospital, we began a series of cadaveric anatomical dissections of the neurovascular bundle (NVB) [7]. Our interest in this subject was spurred by our skepticism of a hypothesis that a nerve graft could be applied to join the severed end of a divided

nerve [8]. There was no anatomic insight to justify this theory. In spite of this, grafting was undertaken with little long-term success in potency preservation. As we discovered, the neurovascular bundle is a complicated plexus of nerves and blood vessels. There are at least four and up to 16 discrete autonomic sympathetic and parasympathetic nerves in these bundles, contained in three or four separate fascial compartments. It became very clear from these dissections that the hypothesis that a single large somatic nerve would act as a conduit for autonomic nerve recovery was null. Before surgeons were aware of these structures, these nerves were simply excised. As these structures were now recognized, these nerves are injured today by thermal injury (diathermy) and/or traction.

In this chapter we will concentrate on three areas of prostatic anatomy:

1. The neurovascular bundle
2. The fascial layers surround the prostate
3. The urinary sphincter

An understanding of this anatomy will aid the surgeon in performing a surgery that minimizes harm to vital surrounding structures while optimizing chances of a cure of this disease. If urologists empowered by the functional anatomical insights can provide a safe surgery with few or no side effects, then the debilitating debate over treatment for prostate cancer could be moot.

## Neurovascular Bundle Anatomy

In 2003, we performed 12 cadaver dissections of adult male pelves. The age of these cadavers was 56–74 years old. Mathew Brooks, a medical student at the University of Melbourne, performed these dissections using loupes with ×6 magnification [7]. Four specimens were hemisected and eight were dissected en bloc. The original work of Walsh and Doncker [2] was on the fetus where the prostate and surrounds had not developed postpubertally. Most considered that there was a single nerve that ran in the prostatorectal groove. This was partly the thinking behind the sural nerve grafting hypothesis. The components of the NVB were traced from the bladder neck distally to target organs.

What we found was that there were branches to a number of different targets not simply the cavernous tissue. Branches to seminal vesicle, prostate, levator ani muscle, rectum, bladder, and erectile tissue of the penis were identified. The cavernosal nerves were traced as far distal as possible to the level of the prostatic apex and proximal urethra.

The pelvic plexus has two components, the sympathetics via the hypogastric nerve and the parasympathetics via $S_2$, $S_3$, and $S_4$ sacral foraminae (Fig. 1.1). The pelvic plexus is located retroperitoneally on the lateral surface of the rectum. A fascial layer (pararectal fascia) and 1–2 cm of perirectal adipose tissue separate the lateral surface of the rectum from the pelvic plexus. The fenestrated pelvic plexus is situated in a sagittal plane, with moderate variations in its size and position between dissections. It extends as far as 1.5 cm posterior to the dorsal edge of the rectum and 1 cm superior to the rectovesical pouch (pouch of Douglas) (Fig. 1.2). Gauging pelvic plexus size is difficult, with borders between it and its branches hard to define. However, generally, the pelvic plexus ranges from 3 to 5.5 cm long and 2.5 to 5 cm high. There is a quantitative relationship between the size and mass of neural tissue within the pelvic plexus and the number of nerve branches within its projections. The branches of the pelvic plexus form three major projections: (1) anterior, extending across the lateral surface of the seminal vesicle and the inferolateral surface of the bladder; (2) anteroinferior, extending to the prostatovesical junction and obliquely

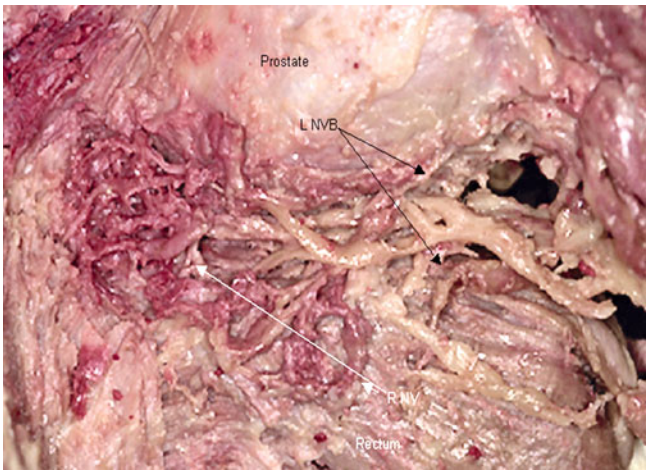

**Fig. 1.3** Left neurovascular bundle midprostate

along the lateral surface of the prostate; and (3) inferior, running between the rectum and the posterolateral surface of the prostate, forming the neural constituents of the NVB (Fig. 1.3).

The pelvic plexus is closely associated with branches of the inferior vesical vein and artery. These large vessels are predominantly in a sagittal plane that is superimposed on the lateral surface of the pelvic plexus. On removing investing adipose and connective tissues, these vascular and neural (pelvic plexus) structures generally lay in distinct separable layers posteriorly, only to converge at the level of the pelvic plexus projections.Illus3

In all 24 dissections, the plexus of nerves running within the NVB branch from the posteroinferior aspect of the pelvic plexus are 0.5–2 cm inferior to the level of the tip of the seminal vesicle. The number of macroscopic nerves present varies, with 6–16 noted. On branching from the pelvic plexus, these nerves are spread significantly, with up to 3 cm separating the anterior- and posterior-most nerves. The nerves located most anteriorly are intimately associated with the seminal vesicle, coursing along the posterolateral surface, while the nerves located posteriorly run dorsal to the posterolateral verge of the seminal vesicle (Fig. 1.4).

Generally, most of the NVB descends posteriorly to the seminal vesicle. The nerves converge en route to the midprostatic level, forming a more condensed NVB, only to diverge once again when approaching the prostatic apex (Fig. 1.5).

The nerves of the NVB are intimately associated with vessels branching from the inferior vesical vein and artery. As these vessels course distally toward the prostatic apex, numerous terminal branches are given off which, in most cases, mimic the course of the nerves.

The nerves running in the NVB innervate the corpora cavernosa, rectum, prostate, and levator ani musculature. The last three also receive a vascular supply from vessels coursing in the NVB. In 20 of the 24 dissections, a large vein

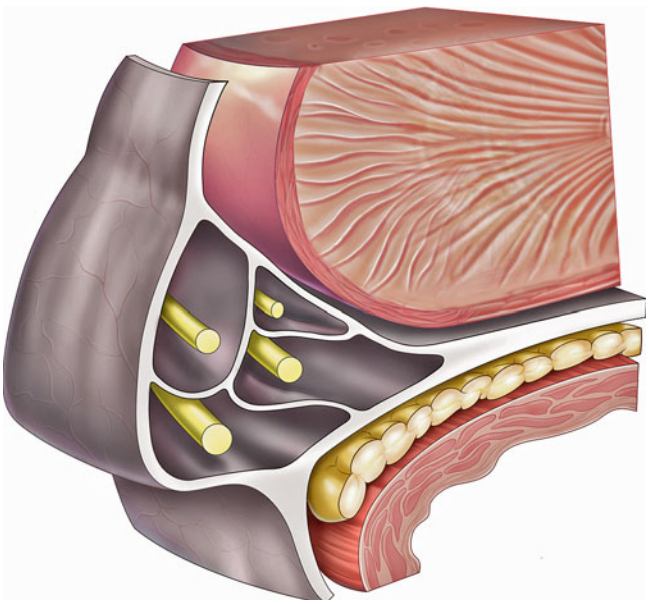

**Fig. 1.4** Fascial compartments of the left neurovascular bundle

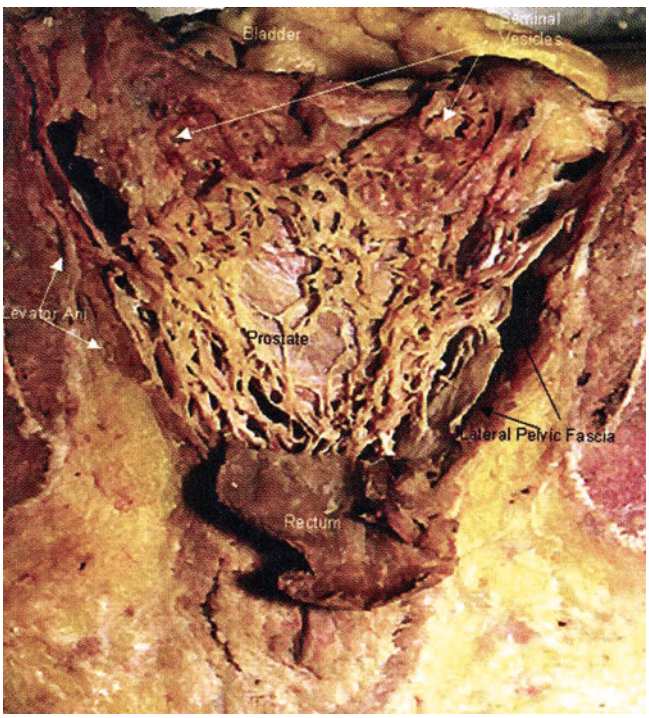

**Fig. 1.5** Posterior view of prostate and neural structures, rectum reflected downwards

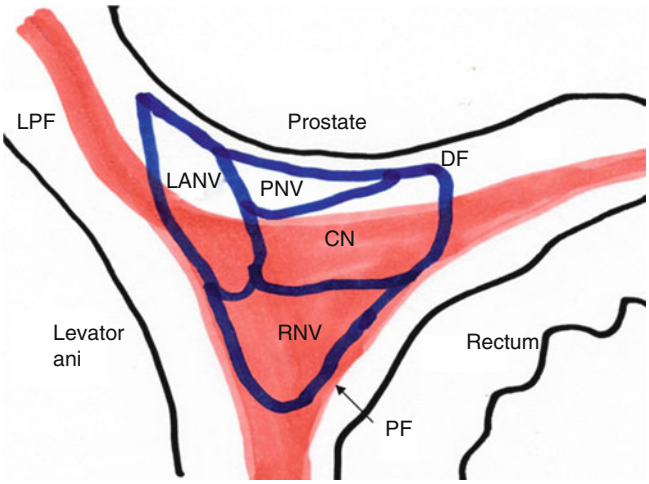
drained the rectum, piercing the pararectal fascia and entering the rectal musculature on its anterolateral surface at a variable level, ranging from midprostatic to prostatic apex. Artery and nerve branches supply the anterolateral wall of the rectum from the prostatic apex to midprostate level. Nerves running in the NVB pass through slit-like openings in the lateral pelvic fascia to innervate the superior and



- Rectal nerves posterior + posterolateral
- Levator ani nerves lateral
- Cavernous nerves + prostatic NVB medial

**Fig. 1.6** Functional organization of NVB

middle sections of the levator ani musculature. Many nerve and vascular branches pierce the lateral pelvic fascia distally to supply the inferior portion. The nerves innervating the posterior aspect of the prostate are intimately associated with capsular arteries and veins of the prostate (Fig. 1.5). These structures penetrate the prostatic capsule along its base, midportion, and apex.

The cavernosal nerves and several small vessels pierce the urogenital diaphragm posterolateral to the prostatic apex. At this level, the clearly visible cavernosal nerves divide into numerous small branches that descend along the posterolateral aspect of the membranous urethra before penetrating the posterior aspect of the corpora cavernosa.

The constituents of the NVB are organized into three functional compartments. The neurovascular supply to the rectum is generally in the posterior and posterolateral sections of the NVB, running within the leaves of Denonvilliers' and pararectal fasciae. The levator ani neurovascular supply is in the lateral section of the NVB, descending along and within the lateral pelvic fascia. The cavernosal nerves and the prostatic neurovascular supply descend along the posterolateral surface of the prostate, with the prostatic neurovascular supply most anterior. Part of this anterior compartment runs ventral to Denonvilliers' fascia. The functional organization of the NVB is not absolute and is less pronounced proximally at the levels of the seminal vesicles and the prostatic base (Fig. 1.6).

In addition to the nerves descending within the NVB, a scattering of nerves extends from the medial margin of the NVB to the prostatic midline. The deepest nerves (from an anterior aspect) innervate the anterior surface of the rectum at the level of the prostatic apex. The more superficial nerves descend posterior to the prostatic apex and merge laterally with the NVB.

## Fascial Architecture of the Prostate

We have shown from further dissections by Ben Dowdle et al. [9] and Emma Clarebrough the relevant fascial layers which ensheath the NVB. An understanding of the fascial investments of prostate rectum and levator ani is fundamental to the urologists' ability to perform nerve-sparing radical prostatectomy.

The key fascial layers surrounding the prostate are formed by a fusion or condensation of levator ani fascia, Denonvilliers' fascia, and prostatic fascia. The prostatic fascia varies from fused to the prostatic capsule or separates as a distinct layer.

These fascial layers condense posterior to the prostate where they form distinct fascial compartments. We have identified three or four compartments in which run the neurovascular components of the NVB. There are between 6 and 16 discrete nerves in these layers. Importantly for the surgeon, the neural supply of the cavernous tissue runs in a posteromedial sheath below a conduit supplying nerves to the prostate. Another more lateral and superiorly placed bundle supplies nerves to levator ani. Inferomedial are the rectal nerves. Thus, the nerves in the NVB closest to the prostate are the nerves going directly into the prostate. This means that even when the dissection of the prostate is widened into the NVB, there may not be damage to the nerve supply to cavernous tissue. This gives rise to the possibility of performing an "incremental" nerve-sparing technique. The majority of prostate cancers which penetrate through the capsule do so only by 3 mm. When a cancer truly invades into the NVB (an uncommon occurrence), it is unlikely that that man can be surgically cured of his cancer. There is also a cushion of adipose and fibrous tissue between the prostate and the NVB.

The NVB descends along the posterolateral border of the prostate. It extends laterally to the junction of the lateral pelvic fascia and pararectal fascia and posteriorly to the dorsal layer of Denonvilliers' fascia, which forms a fibrous sheath separating the prostatic capsule from the rectum. Laterally, it becomes continuous with the pararectal fascia posteriorly and the lateral pelvic fascia anteriorly. The pararectal fascia extends along the lateral surface of the rectum, while the lateral pelvic fascia separates the levator ani muscle from the prostate. At the prostatic midline, Denonvilliers' fascia exists as a single sheet and widens laterally to fuse with the fascias of the prostate and levator. This fusion of fascias is compartmentalized into three or four conduits, containing the functional nerves to their target organs. In Dowdle's dissections, 32 blocks of tissue were analyzed. In 18, the NVB had three distinct fascial compartments (Fig. 1.7). This shows staining of the prostate fascia nerves, vessels, muscle, and fat (Fig. 1.7).

Having identified these structures, we conducted further immunohistochemical studies to characterize both the function and the location of these nerves. The precise topography of these nerves has been contentious. There has been debate

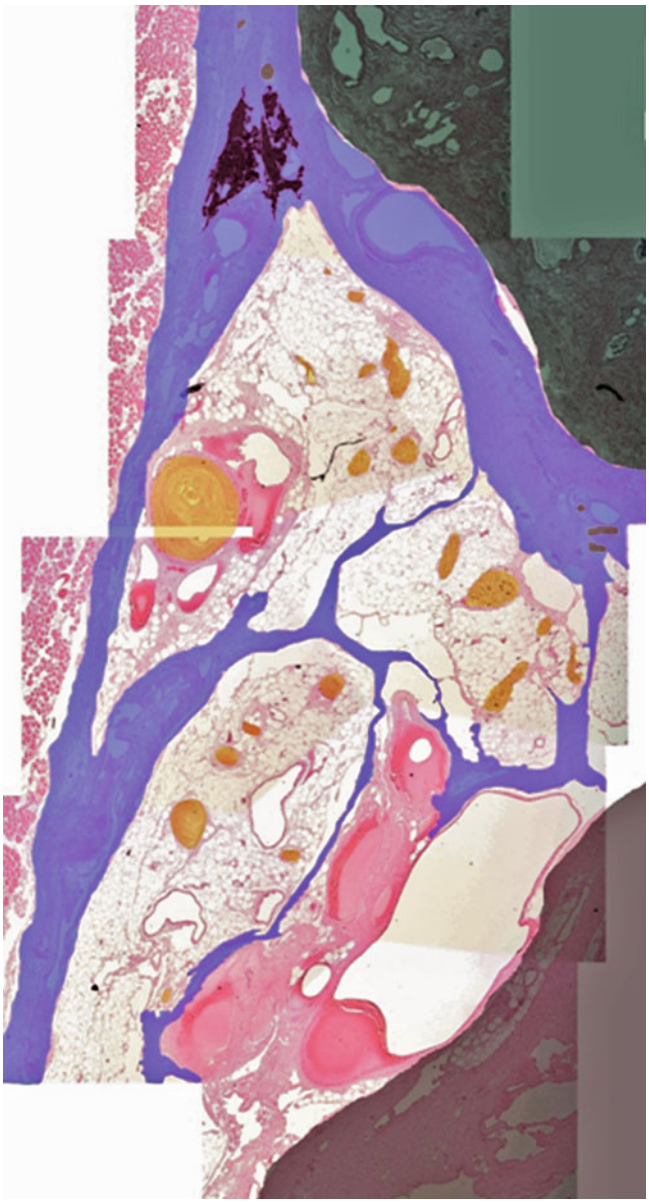


**Fig. 1.7** Connective tissue stain in *blue* of the neurovascular bundle fascial compartments. Prostate superomedial in *green*. Rectum posteromedial

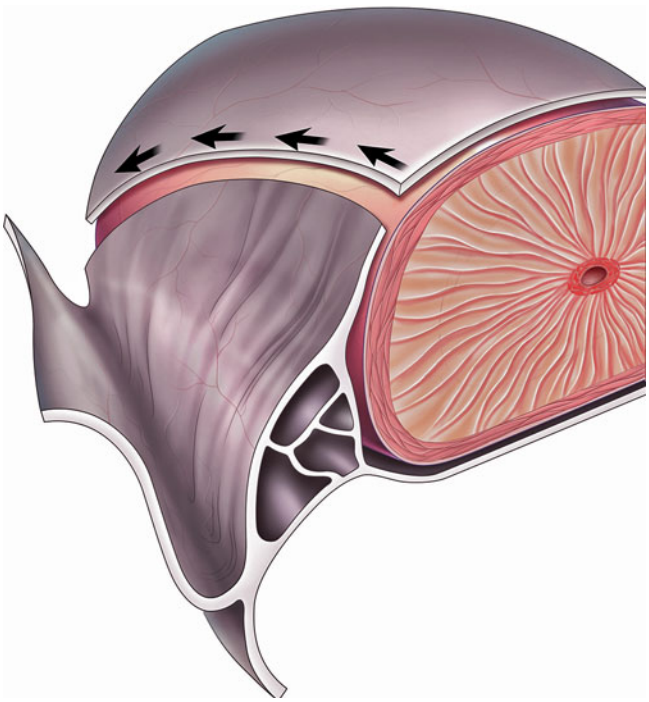

**Fig. 1.8** Line of fascial incision in nerve-sparing prostatectomy

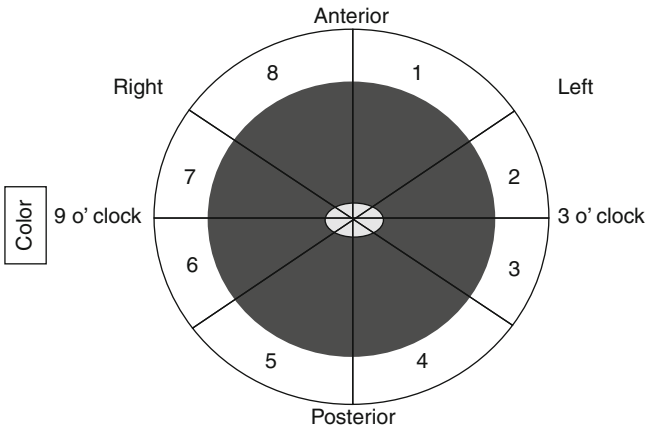

**Fig. 1.9** Distribution of nerve fibers and their positions around the circumference of the prostate

and discussion as to the most efficacious nerve-sparing surgical technique. This has led to the concept of high anterior release [10] (Fig. 1.8) of the anterior levator fascia to improve sexual function after prostatectomy. This hypothesis was proposed by Menon et al. [11–13] who pioneered telerobotic prostatectomy. He described the veil of Aphrodite incision, a high incision into the prostatic fascia to the capsule of the prostate to spare anteriorly placed nerves above the 3 and 9 o'clock position toward the prostatic apex. We have shown however that nerves in this position are nerves to the prostate not cavernous tissue. Nerves to cavernous tissue are predominantly below these o'clock levels. This high-release technique may be relevant in a practical sense. If the fascia is released high, then the effect of traction on these delicate autonomic nerves may be mitigated.

In our studies of the functional architecture of the NVB, we used several stains. To localize the parasympathetics, an antibody against nNos was used. nNos, a 150-kDa protein, is found in parasympathetic nerves and catalyzes the formation of the potent vasodilator nitric oxide (NO). NO is the mediator involved in the physiology of erection. Sympathetic nerves were characterized by tyrosine hydroxylase, an enzyme in the norepinephrine production pathway. Stained slides were analyzed for nerve counts according to fiber number type and position. The analysis allocated nerves in eight around the clock sectors (Fig. 1.9) (Table 1.2). Somatic

**Table 1.1** Distribution of total nerve fibers expressed as number and percentage of total fibers at each level

| Position | Parasympathetic | Sympathetic | Somatic | Combined |
|---|---|---|---|---|
| Base | | | | |
| Total, *n* (%)[a] | 111 (43.3) | 99 (38.7) | 46 (18) | 256 (100) |
| Total above 3–9 o'clock, *n* (%)[a] | 10 (4) | 39 (15.2) | 21 (8.2) | 70 (27.4) |
| Midprostate | | | | |
| Total, *n* (%) | 144 (44.7) | 125 (38.8) | 53 (16.5) | 322 (100) |
| Total above 3–9 o'clock, *n* (%)[a] | 18 (5) | 45 (14) | 24 (7.5) | 87 (26.5) |
| Apex | | | | |
| Total, *n* (%) | 100 (45.5) | 86 (39.1) | 34 (15.5) | 220 (100) |
| Total above 3–9 o'clock, *n* (%)[a] | 15 (6.8) | 34 (15.5) | 16 (7.3) | 65 (29.6) |

[a]Nerve fibers in sectors 1, 2, 7, and 8

**Table 1.2** Functional nerve distribution in anterolateral sectors as a percentage of fibers in sectors 1, 2, 7, and 8

| Position | Parasympathetic | Sympathetic | Somatic |
|---|---|---|---|
| Prostate base | 14.3 | 55.7 | 30 |
| Midprostate | 18.8 | 53 | 28.2 |
| Prostate apex | 23.1 | 52.3 | 18.6 |

nerves were identified on standard hematoxylin and eosin staining. A connective tissue stain was used to differentiate the fascial conduits. The distribution of the nerve fibers is shown in Table 1.1 and their positions around the circumference of the prostate in Table 1.2.

The present study has characterized the periprostatic nerves, including the cavernous nerves, by immunohistochemical analysis of sympathetic and parasympathetic nerves. We confirmed that autonomic nerve fibers were present on the anterolateral aspects of the prostate between the prostate and lateral prostatic fascia; however, only a small proportion of these were parasympathetic nerves likely to be of functional relevance. At the midprostate level, only 18.8 % of the nerves found on the anterior aspect of the prostate were parasympathetic nerves, 68 % being found in the previously defined NVB posterolateral to the prostate. Most of the nerve fibers found on the anterolateral regions examined were sympathetic in nature. The sympathetic nerves contribute significant innervations to the prostatic stroma and are responsible for innervations to the vascular structures in the region. As such, they may extend outside the typical NVB, which is predominantly parasympathetic by immunohistochemical characterization. The external urethral sphincter located immediately distal to prostatic apex receives input from the autonomic sympathetic nerves. The sympathetics may course over the anterior aspects of the prostate to provide innervations to the anterior external urethral sphincter.

At the apex, the absolute number of the parasympathetic fibers above the 3–9 o'clock junction increased slightly. This is consistent with studies that show the cavernous nerves ascending to assume a higher position distal to the apex. Takenaka and Tewari [13, 14] claimed the cavernous nerves assume a higher 2–10 o'clock positioning at the apex. The present study did not confirm these findings. However, careful apical dissection and ligation of the dorsal venous complex are of critical importance for preserving the neural anatomy.

The anteriorly placed parasympathetic nerve fibers are likely to be destined for innervations of the prostatic stroma and not the corpora cavernosa of the penis. This observation is supported by two pieces of evidence. First, the total number of visible nerve fibers was smaller at the prostatic apex as compared to the base. This decrease in the number of fibers has been reported previously and may be related to a significant proportion of nerves penetrating the prostate and other structures, including seminal vesicles, levator ani, and rectum. In the fresh cadavers included in our study, 134 nerve fibers were located at the base compared to 115 at the apex. Of these, the absolute number of parasympathetic nerves found on the anterior half of the prostate at the apex was eight, further supporting this hypothesis. With our connective tissue stains, we have shown the functional conduits of the NVB.

An important contribution to our understanding of the composition of the neurovascular bundle has been made by Takanaka's group [13]. They describe how the parasympathetic contribution joins the pelvic plexus around midprostate similar to our original findings in Brooks' dissections [7]. The major component of the NVB above midprostate is thus sympathetic and may not be as relevant in erectile function. Might it not therefore be more important to concentrate nerve-sparing surgical attention more distally to the apex? There have been suggestions that care in dissection around the tips of the seminal vesicles is mandatory in preservation or erectogenic nerve supply. If parasympathetic nerves make their major contribution to the NVB at midprostate and below, then seminal vesicle tip dissection/preservation seems less relevant.

## Functional Anatomic Characterization of the Neurovascular Bundle

As stated previously in this chapter, the past 20 years have realized remarkable outcome improvements in return of erectile function following radical prostatectomy. These improvements have come as a result of an understanding of the origin and course of the nerves to cavernous tissue. Prior to these anatomic insights, the nerves were mostly cut and left in place. In spite of much greater care in dissection and sparing or absence of heat application via diathermy, some previously potent men lose erectile function after surgery. One of the causes of this complication is excessive traction on these nerves that occurs during dissection occasioning partial or permanent neuropraxia. Alternatively, because the course number and location of these nerves may vary, is there a way of visualizing these nerves in situ to prevent injury to them?

We designed a series of animal experiments using a rat model injecting nerve dye tracers to establish an effective in vivo method of nerve visualization to optimize nerve-sparing surgery. Other technologies such as optical coherence tomography (OCT), transrectal ultrasound, and electrical stimulation have been tried with limited effect.

The discovery of axonal flow by Weiss in 1948 [15] revolutionized neuroanatomical knowledge. Specific effective dye tracers have been developed. We used three different tracers, Fluoro-Gold, Fast Blue, and Alexa Fluor, in this study by Anna Taylor, a medical student at The Royal Melbourne Hospital[16].

Effectiveness of cell labeling and the potential for neurotoxicity were assessed. In total, 63 rats were injected into the penis with three different dye tracers. Immunofluorescence testing in vivo was done as well as in vitro postmortem sectioning of the cavernous nerves and pelvic ganglia stained to assess dye uptake. Potency of the rats to determine toxicity of the dyes on nerve function was assessed.

All dyes successfully demonstrated retrograde nerve tracing in the cavernous nerve and major pelvic ganglion. With an immunofluorescence probe, the cavernous nerves could be visualized in vivo with all three tracers. The Fluoro-Gold tracer was the most easily seen (Fig. 1.10). Nerves could be seen with minimal dissection to remove superficial fat and fascia. Fluoro-Gold was a very sensitive dye labeling specific cavernous nerves clearly and specifically. There was no neurotoxicity evident with any dye.

This immunofluorescence dye injection approach may have surgical utility, allowing a surgeon to identify erectogenic nerves in real time and spare accordingly these functionally relevant nerves.

**Fig. 1.10** Fluoro-Gold staining of cavernous nerve in rat model

Future efforts to improve postoperative erectile function may also include intraoperative cooling as described originally by Ahlering [17] and the use of topical or systemic neuroprotective drugs.

## Anatomy of Male Urinary Continence

### The Prostate and the Urinary Sphincter

There are several reasons why a clear anatomic insight into the composition and physiological function of the male urethral sphincter remained arcane to many practicing urologists. This writer remembers well that whenever this topic was the subject of a tutorial or lecture, a soporific state ensued. Favorite questions of the writer to his urology trainees today are “Why do men develop temporary stress incontinence after radical prostatectomy?” and “What continence components are damaged by the removal of the prostate?”

Kouratim [18] has written a very clear and practical summation of current concepts.

1. The reasons for confusion are several:
2. Poor cadaver gross dissections.
3. Findings from fetal dissections have been applied to the postpubertal adult. The effect of testosterone on prostatic growth produces profound changes to the anatomic relationships of the prostate to its surrounding structures.

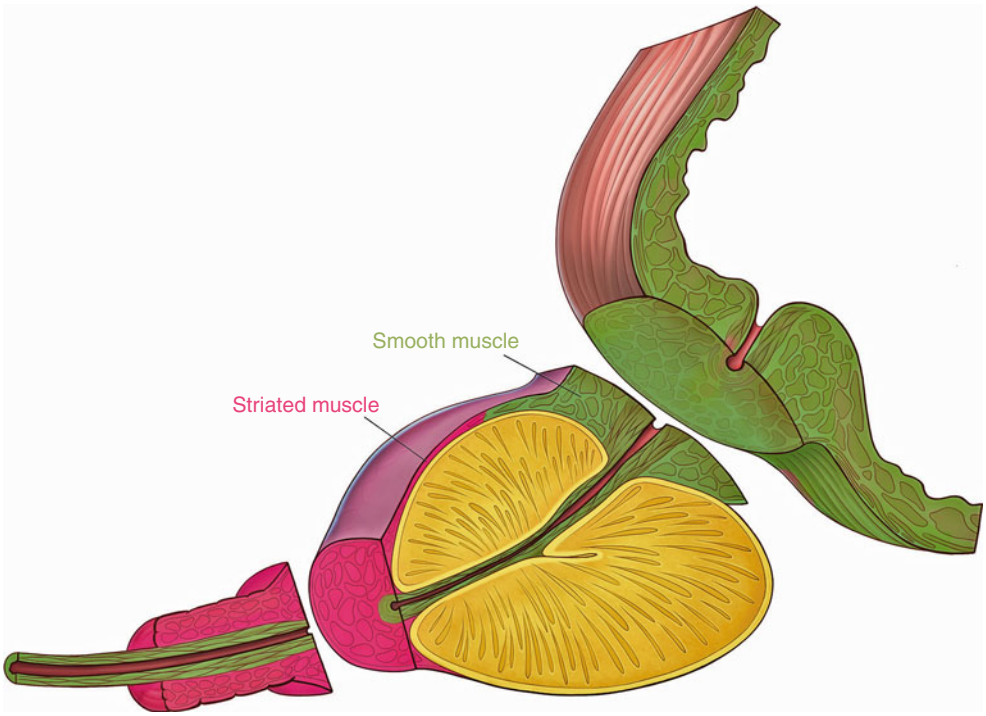

**Fig. 1.11** Smooth muscle (*green*) and striated muscle (*red*) components of the urethral sphincteric mechanism

4. There has been a lack of consensus as to individual anatomic terminology.
5. Many of the original and important anatomic texts were published in German and French and were thus unread by English-speaking surgeons.

The sphincter is composed of two functional muscular components. These are morphologically related but functionally independent.

1. *Smooth muscle*: the inner layer, which runs from bladder neck through the prostate to the membranous urethra and provides "passive" continence
2. *Skeletal muscle*: the outer rhabdo sphincter, which maintains "active" continence

Kouratim describes the urethral sphincter as a complex, in a cylindrical form around the urethra from bladder neck to distal membranous urethra. The outer component is the striated muscle thickest around the membranous urethra. It does not form a complete cylinder around the urethra but is horseshoe shaped. The fibers fold anteriorly around the urethra and unite posteriorly in a central fibrous tendon behind the urethra. The striated muscle extends over the prostate anteriorly and blends proximal to the prostatic apex with the smooth muscle and glands of the anterior zone of the prostate. This finding is sometimes reported by the pathologist following prostatectomy.

## Function of the Smooth Muscle Sphincter

The smooth muscle of the urethra acts to maintain passive continence. No conscious effort is needed for a male to be continent at rest. The smooth muscle is not a sufficient sphincter to maintain continence when intra-abdominal pressure rises with active movement, standing, walking, and coughing.

The smooth muscle of this sphincteric component works by contraction of the circular muscle fibers casing the bladder neck and urethra. Clearly, the entire length of this smooth muscle is not needed to maintain passive control as after both transurethral prostatectomy and radical prostatectomy, a length of this muscle is removed. Generally, men after radical prostatectomy can maintain urinary control at rest, lying in bed, but not when they move. However, as Myers has stated, a certain length of smooth muscle urethral sphincter is required [19]. He cautions great care in apical prostatic dissection for this reason (Fig. 1.11).

## Function of the Striated Sphincter

There has been a recent advocacy for restoration of the posterior urethral plate after prostatectomy [20]. Understanding the anatomy of the posterior prostatic fascial aponeurosis where Denonvilliers' layer fuses with the tendinous junction of the horseshoe striated muscle posterior to the prostatic apex and with muscle, we as surgeons recognize as rectourethralis. Restoration of this plate posteriorly after prostate excision may aid in restoration of continence by proving a platform for contacting circular striated muscle to compress the urethra anteroposteriorly. The attachment of the posterior muscle to the median tendon results in compression of the anterior urethral wall on this fibrous raphe on raising intra-abdominal pressure. Denonvilliers' fascia and rectourethralis form this rigid plate against which the urethral lumen is

flattened. This contraction constitutes active and short-lived voluntary continence mechanism illustrated by the voluntary interruption of the urinary stream. This active and forceful contraction is mediated by fast- and slow-twitch striated muscle fibers. This was originally reported by Denny-Brown who observed that this contraction could only be maintained for a few seconds [21].

As summarized by Kouratim, there are two functionally independent components of sphincteric urinary continence, the inner urethral smooth muscle for passive control and the outer striated skeletal muscle for active control. Finally, the shape of the prostatic apex varies significantly. This has been well described by Myers [22, 23]. "This can influence the length of urethra emerging at the apex. The apex may overlap the urethral sphincter circumferentially, symmetrically bilaterally, asymmetrically unilaterally, anteriorly only, or end above the sphincter." The practical instruction here for the prostatectomist is that great care in each apical dissection is required to maintain the integrity of both muscular sphincteric parts to optimize the likelihood of early return of control. A precise reason for the almost-inevitable short-term stress incontinence followed by a return-to-complete continence later eludes this writer. It may be that the division of the anterior ligamentous supports and some loss of rhabdosphincter muscle proximally that suspend the prostatourethral apical tissue cause this usually temporary surgical side effect.

## Prostate Embryology

### The Prostate Gland

The prostate is part of the accessory sex gland system in human males that synthesizes and secretes both organic and inorganic components of the seminal plasma. Prostatic secretions are believed to be important for spermatozoa survival in the female reproductive tract, although they are not necessary for conception, as sperm retrieved directly from the testis or epididymis can be used to successfully fertilize oocytes. Contraction of the smooth muscle stroma may play a role in semen expulsion during ejaculation, while simultaneous closure of the internal urethral sphincter prevents retrograde flow into the bladder. The internal urethral sphincter may also contribute to male urinary continence. Although the presence of a prostate is universal in mammals, its gross anatomical structure differs markedly between species. In man, it is a compact gland that extends from the bladder neck proximally to the external urethral sphincter complex at its distal apex.

### Gland Structure

Postsexual maturation and in the absence of pathology, the prostate approximates an inverted pyramid in shape, with a broad base, anterior, posterolateral and posterior surfaces, and a tapering apex. The gland is enclosed by a thin capsule, approximately 0.5 mm in diameter that is composed of collagen, elastin, and smooth muscle. At the base of the prostate, the outer longitudinal detrusor fibers of the bladder wall fuse with the fibromusclar fibers of capsule, with no true capsule identifiable separating prostate glands from bladder neck muscle. Similarly, the prostate capsule is deficient at the apex, and normal glands are commonly observed to extend into the sphincter complex. The bulk of the glandular tissue is situated posteriorly and laterally, with the anterior one third being composed of fibromuscular stroma. The urethra, approximately 3 cm in length and lined by transitional epithelium, runs the entire length of the prostate gland, situated closer to the anterior surface. At its midpoint, the urethra angles approximately 35–40° anteriorly, dividing the urethra into proximal (preprostatic) and distal (prostatic) segments. At the bladder neck, the inner longitudinal and middle circular detrusor muscle fibers project distally to surround the preprostatic urethra. Thickening of the circular fibers in this area forms the internal urethral sphincter, which is incomplete anteriorly, with the lateral projections inserting into the anterior fibromuscular stroma on either side. Arising from the posterior wall of the urethra and projecting into the lumen is the urethral crest, which runs the length of the prostatic uretha, giving it a crescentic appearance on cross section. The urethral crest broadens at the point of angulation to form the colliculus seminalis or verumontanum and to taper inferiorly at the prostatic apex. Projecting posteriorly and cephaladly from the verumontanum in the midline is the prostatic utricle, a blind ending pouch measuring approximately 4–7 mm in length that is believed to be a vestigial remnant of the paramesonephric system. The ejaculatory ducts which are formed by the union of the seminal vesicles and the vasa enter the prostate at its base posteriorly and course through the prostate in a plane parallel and slightly posterior to the postprostatic segment of the urethra to open on either side of the utricular opening. On either side of the urethral crest are shallow recesses termed the prostatic sinuses, which receive the ductal openings of glandular elements, 95 % of which lie in the distal urethra.

### Zonal Anatomy

Although the cut surface of a disease-free prostate is fairly homogenous, it has long being recognized that there are distinct regions within the gland that differ in the patterning of their acini and susceptibility to disease. Over the last 100 years, a number of different models of gland organization have been proposed; the most widely accepted model currently is that elaborated by Dr. McNeal based on serial sectioning of a large number of prostates removed at radical

prostatectomy [24]. Four discrete glandular zones are described based on the location of their ductal openings within the urethra with reference to the verumontanum. Most prostatic glands reside in the peripheral zone, which makes up approximately 75 % of glandular elements and occupies most of the posterior and lateral aspects of the gland. Peripheral zone ducts arise in a double row from the floor of the prostatic sinuses bilaterally, extending the whole length of the postprostatic urethra at approximately 2 mm intervals, with main ducts extending posteriolaterally and minor ducts more anteriorly. Subsidiary ducts arise at regular intervals along the course of the main duct, branching at an angle of approximately 15°, and extend only a short distance before giving rise to groups of acini. Ducts of the central zone, which accounts for approximately 25 % of glandular elements, originate circumferentially around the openings of the ejaculatory ducts and the convex surface of the verumontanum. These ducts then branch directly toward the base, parallel to and surrounding the ejaculatory ducts, forming a conical wedge of tissue, separated from the peripheral zone by a narrow band of stroma. Ducts of the transition zone arise at the junction of the proximal and distal urethral segments and course beneath the preprostatic sphincter to arborize on its posterior and lateral surfaces toward the bladder neck, with the most medial fibers penetrating into the internal prostatic sphincter. In the normal prostate, the transition zone accounts for 5–10 % of glandular elements and is separated from other glandular elements by a discrete fibromuscular band. The periurethral glands comprise less than 1 % of glandular elements. These rudimentary glands are scattered along the length of the proximal urethral segment and extend between fibers of the longitudinal smooth muscle to be contained wholly within the preprostatic sphincter. The anterior zone is composed primarily of fibromuscular stroma and extends from the bladder neck to the striated sphincter in direct continuity with the prostatic capsule.

## Microscopic Appearance

The architectural arrangement of the prostate befits its function, with a distensible glandular system capable of acting as a reservoir for secretions embedded in a smooth muscular stroma and capable of expelling those secretions during ejaculation. In the normal prostate, approximately 70 % of the prostate is composed of secretory glands, with the fibromuscular stroma accounting for the remainder. The glands themselves are tubuloalveolar, extend out to the prostatic capsule, and have a relatively simple branching pattern, with acini distributed uniformly along the course of the main duct [25]. Both acini and ducts are secretory and are lined by simple cuboidal or columnar epithelium. These cells are terminally differentiated, with a low proliferative index and contain abundant secretory granules. These cells stain positive for PSA, acid phosphatase, and the androgen receptor, express cytokeratins 8 and 18, and are attached to the underlying basement membrane via integrin receptors. Sandwiched between the basolateral surface of secretory epithelium and the basement membrane are basal cells, which are small and flattened with scant cytoplasm. These cells comprise less than 10 % of prostate epithelial cells and are distinguished immunohistochemically from secretory cells by staining negative for PSA and the androgen receptor, but positive for cytokeratins 4, 14, and 15. In man, the basal cell layer forms a nearly continuous layer between the basement membrane and secretory cells. Although they themselves have a low rate of proliferation, they are believed to be the progenitors of the rapidly dividing transient proliferating cells which replace secretory epithelium lost through attrition. The basal cell layer is also the proposed location of prostate stem cells, a population of single cells that can completely reconstitute all tissue elements of the normal gland. Scattered between secretory epithelium both within acini and ducts are neuroendocrine cells which express neural markers such as chromogranin A, neuron-specific enolase, and synaptophysin. Both the origin and function of these cells remain obscure, although a role in the paracrine regulation of prostate growth, differentiation, and secretory activity has been suggested. The stroma is composed of fibrillar collagen, elastin, and smooth muscle.

The microscopic appearance of glands in the central zone is distinct from that found in the peripheral and transitional zones. Peripheral zone glands are small (0.15–0.3 mm in diameter) with a simple almost rounded contour, with prominent undulations in the acinar wall, and are embedded in a loosely arranged matrix of smooth muscle. Secretory cells have small basal nuclei, pale cytoplasm, and a smooth luminal border. In contrast, central zone glands and ducts measure up to 6 mm in diameter, with polygonal acini arranged in clusters around a central draining duct. Secretory cells have larger nuclei, irregularly arranged in a darker, more granular-appearing cytoplasm. The luminal surface is noticeably irregular, with individual cells projecting into the lumen. The ratio of epithelium to stroma is higher in the central zone compared to the peripheral zone, although the stroma is denser and composed of compact smooth muscle bundles. Transitional zone glands resemble those of the peripheral zone but are embedded in compact, interweaving smooth muscle bundles.

## Embryonic Development

The normal development of the human prostate gland is incompletely understood, with most insights derived from fetal dissections or the study of organ development in other

species, in particular rodents. In man, its development spans almost two decades, from initial organogenesis in the first trimester to maturation during puberty. Its development is intimately related to other organs of the lower genitourinary system, which occurs in two phases, a sexually indifferent stage, which is common to both male and female fetuses, and a sexually determined phase that is dependent upon fetal genotype. In general, three distinct processes are involved in the generation of a branched glandular network – initiation, growth, and termination – which may be independently regulated. In addition, particularly for sexual glands, separate phases of development occur with the generation of rudimentary gland structure during embryonic development, a postnatal quiescent phase, and the reemergence of cell proliferation and branching during puberty to achieve a mature gland structure.

## Sexually Indifferent Development

The prostate gland develops predominantly from the urogenital sinus (UGS), the anterior division of the cloaca, with a small contribution from the mesonephric or Wolffian system [26]. The cloaca itself is formed by expansion of the caudal end of the primitive gut tube and is clearly identifiable during the third week of development. It is separated from the chorionic cavity by the cloacal membrane. During weeks 4–6 of development, the cloaca is divided by the ingrowth of a mesoderm partition in the coronal plane, separating the anterior urogenital sinus that will form the lower genitourinary tract in both sexes from the rectum posteriorly. This urorectal septum is a coalescence of three separate mesodermal folds, the superior fold of Tourneaux which projects caudally from above and the two folds of Rathke which originate laterally and project inwards to fuse in the midline. At its most caudal end, the urorectal septum fuses with the cloacal membrane at the site of the future perineum, similarly dividing it into the anterior urogenital and posterior anal membranes. The UGS is situated in the midline and is composed of two layers, an epithelial layer derived from endoderm and a mesenchymal layer derived from mesoderm. Viewed sagitally, the urogenital sinus assumes a short wine-glass appearance, with an expanded superior portion that will form most of the bladder, a narrow neck at the level of the true pelvis which in males gives rise to the prostatic and membranous urethra, and an inferior expansion termed the definitive urogenital sinus, from which the distal urethra and external genitalia is derived.

The mesonephric ducts first appear as paired condensations within the intermediate mesoderm of the thoracic region, related ventrally and medially to the developing tubules of the intermediate kidney, the mesonephros. Through a combination of cell proliferation and cell migration, the distal tips project caudally to fuse with the lateral aspects of the cloaca and then canalize to form a true duct. On approximately day 28, ureteric buds sprout from the distal portion of the buds, which invade the metanephric blastema to form the definitive kidney. At the same time, as the cloaca is being divided by the urogenital septum, the portion of the mesonephric duct distal to the ureteric buds begins to become incorporated into the presumptive bladder through a process of extrophy which affects the leading superior edge to much greater extent than the trailing inferior edge, which fuses with its contralateral counterpart in the midline. This results in the migration of the narrow mouths of the mesonephric ducts to open into the pelvic urethra at the level of the verumontanum and incorporation of the distal ureters into the bladder wall to attain their normal adult position at the posterolateral corners of the trigone. The mesonephric ducts give rise to the seminal vesicles at the level of the bladder neck in a process that is similar to that regulating prostate gland development, with the more distal ducts continuing as the common ejaculatory ducts that open into the floor of the urethra at the level of the verumontanum. The paramesonephric ducts arise by the growth and invagination of coelomic epithelium just lateral to the mesonephric system during the 6th week of development. Similar to the mesonephric system, the distal tips project caudally to open into the pelvic urethra just medial to the openings of the mesonephric ducts.

## Sexual Determination and Initiation

The primary genetic determinant of male-type patterning is the presence of SRY (Sex-determining region of the Y chromosome), which is usually located on the short arm of the Y chromosome [26]. The gene encodes a HMG-box transcription factor, and its expression in indifferent gonads in the 7th week leads to the differentiation of medullary sex cord cells into pre-Sertoli cells and, ultimately, the formation of a testis. Pre-Sertoli cells secrete anti-Mullerian hormone (AMH), which actively causes rapid regression of the paramesonephric duct system between weeks 8 and 10, with the most distal end persisting in the male fetus as the prostatic utricle. Similarly, in response to SRY expression in pre-Sertoli cells, during weeks 9–10, mesenchymal cells in the gonadal ridge differentiate into Leydig cells. Leydig cells synthesize and secrete testosterone, initially under the influence of chorionic gonadotropin produced by the placenta and later by LHRH secreted by the pituitary. The production of testosterone promotes survival of the mesonephric ducts with persistence of the distal ends as vasa deferentia and ejaculatory ducts.

Initiation begins with the specification of particular cell clusters for tube development, distinguishing them from surrounding cells that are destined to form other tissues.

For prostate organogenesis this involves the commitment of specific epithelial cells of the urogenital sinus to a prostate epithelial cell lineage and is marked by the expression of a specific cassette of androgen-dependent genes. The visible correlate of this molecular-mediated event is the development of solid cords of epithelial cells that will ultimately form glandular ducts that project from the urethra into the surrounding urogenital mesenchyme just caudal to the bladder neck at about the 10th week. Although this may occur in a number of ways, in mammals, invagination appears to be a predominant mechanism, whereby the initial tube forms by the ingrowth of cells perpendicular to the plane of the parent epithelium. These projections are symmetrical bilaterally with buds originating in groups in a ventral, lateral, and dorsal direction from the pelvic UGS, where they are surrounded by compact mesenchyme. These ductal origins remain constant into adult life and are a point of differentiation between zones in contemporary descriptions of gland structure. The distinctive patterning of glands in the central zone has led to the suggestion that precursor buds maybe of Wolffian rather than urogenital sinus epithelial origin. As the fetus develops, these cellular cords elongate and divide in a program of branching morphogenesis to form the rudimentary cellular structure of the glandular system [27]. At approximately the same time, the seminal vesicles bud from the distal mesonephric duct near its attachment to the pelvic uretha, which then comprises the common ejaculatory duct.

## Branching Morphogenesis and Cytodifferentiation

Branching morphogenesis is a fundamental biological program that is responsible for the patterning of tubuloalveolar networks. Although in certain species or organs, particular mechanisms of growth predominate, various aspects of network formation and its regulation are conserved from Drosophila to mammals [28]. The requirement to form an interconnected network of hollow tubes is important to the genesis of many organs, from the bronchoalveolar system of the lungs to the nephrons of the kidney, and is a feature in the formation of many exocrine glands, including salivary, mammary, and prostate glands. Formation of a tubuloalveolar network is advantageous to the function of a gland by providing a greater surface area for secretion of glandular plasma, as well as increasing storage capacity.

In order to understand the processes involved in branching morphogenesis, it is useful to review the end structure that the program is trying to attain. The essential characteristic of a tube is of a hollow lumen surrounded by a circumferential lining or epithelium. Adjacent epithelial cells maintain close cell-cell contact and adhesion through specialized junctions that link cells, provide structural support, and act as barrier function to prevent the movement of ions, fluid, and macromolecules between compartments. In mammalian epithelia, these roles are fulfilled by the tight and adherens junctions, as well as the desmosome. Epithelial cells also have a distinct apicobasal polarity, with the apical surface facing the lumen and the basal surface interacting with a basal layer of epithelium or a basement membrane. Tight junctions are important in the maintenance of cell polarity, as they prevent the diffusion of cell membrane proteins and lipids between compartments.

Depending of the system studied, the network may have a lumen ab initio, in which case cells must maintain their polarity during subsequent development, or grow initially as solid cellular cords that then become canalized. The growth phase is marked by tube elongation and elaboration. Tubes may grow by a number of mechanisms, such as elongation of individual cells or their rearrangement to increase tube length, recruitment of new cells, or by division of existing epithelia. Network elaboration through branching is important to allow the network to maximize the occupancy of a specified three-dimensional space. Although the finally achieved pattern is frequently bewilderingly complex, recent studies in both mammalian lung and kidney indicate that these arrangements are explained by the regular repetition of a small number of simple branch patterns. The final phase of the process is termination, whereby both tube elongation and branching are switched off when the network has achieved the desired size.

Branching morphogenesis begins when the elongating prostate epithelial buds make contact with the condensed urogenital mesenchyme that lies external to the periurethral smooth muscle. Multiple branch points occur at regular intervals, with a pattern that differs between zones. As branching morphogenesis continues proximally, distal ductal cells undergo differentiation to a prostate epithelial phenotype, with similar differentiation of surrounding mesenchymal cells to a smooth muscle. From 20 to 30 weeks, the primitive gland acini are represented by simple, solid cellular buds at the end of ducts, and by as early as week 13, prostate secretory activity may be discerned. Differences in epithelial cell shape are noted in these buds, with columnar-type epithelium noted in the basal region, with more spindle-shaped cells toward the center. Toward term, the acinotubular system becomes more elaborate.

## Regulation of Development

### Molecular Control of Development

A limited repertoire of transcription factors (such as the Hox and NK family of homeobox genes) and secreted signaling molecules (such as SHH, FGF-10, and BMPs) have been identified that have highly conserved roles in cell specification

and developmental patterning [29]. Expression of these factors occurs in a temporally and spatially restricted manner to promote (or inhibit) cell determination, initiation, branching morphogenesis, and differentiation in a number of different branched networks, including the developing prostate gland. For example, one of the first indications of prostate epithelial cell specification in the urogenital sinus epithelium is the expression of the homeobox transcription factor Nkx3.1 in response to circulating androgens [30]. A detailed description of the complex interplay between the various signaling cascades involved is outside the remit of this chapter, and interested readers are referred to an excellent recent review of the subject [31].

### Inductive Role of Urogenital Sinus Mesenchyme

It has been recognized for many years that a specific interaction between primitive stromal cells and corresponding primitive epithelial cells is important in the development of many organ systems. In general, it has been shown that mesenchyme induces and patterns epithelial development in that certain epithelia will only develop in the presence of a specific mesenchyme. In addition, this interaction is reciprocal, and the specified epithelium induces and patterns specific mesenchymal differentiation.

Many of the early insights into the role of stromal-epithelial interactions in prostate development were based on elegant tissue recombination experiments performed by Dr. Cunha and colleagues [32]. In early work, they showed that the presence of both urogenital mesenchyme and sinus epithelium is required for prostate development, as coimplantation of both tissue results in the successful gland formation, whereas implantation of either tissue alone does not. In the same system, they also demonstrated a specific requirement for urogenital mesenchyme, as mesenchymal tissue isolated from other organ sites failed to induce prostate gland development. To demonstrate the inductive power of urogenital mesenchyme in instructing epithelial differentiation, they then showed that coculture with urogenital sinus mesenchyme was sufficient to override the developmental programming of both embryonic and adult bladder epithelial (which is also of urogenital sinus origin) and result in the formation of prostate glandular formation. Confirming the reciprocal nature of this interaction, they have also shown that developing prostate epithelium induces smooth muscle differentiation of primitive urogenital mesenchyme. Overall, these results suggest that prostate development is spatially restricted by the distribution of prostate-inducing urogenital mesenchyme surrounding the urogenital sinus; however, the developmental cues that trigger the formation of the inductive mesenchyme and limit its spatial distribution have yet to be determined. Interestingly, although the factors that mediate the mesenchymal induction of prostate development have yet to be completely elucidated, they appear to be conserved between species, as heterospecific tissue recombination experiments result in successful prostate development.

### Role of Androgens

Testosterone is produced by the fetal testis from about the 8th week and presages male sexual differentiation of the urogenital system. Determination of prostate cell identity and initiation of branching morphogenesis from the prostate anlagen are critically dependent upon the presence of androgens [31]. In the absence of androgens, the urogenital sinus forms the female urethra and lower portion of the vagina. Although the main androgen secreted by the testes is testosterone, in peripheral certain tissues, including the urogenital sinus, testosterone is converted to the more potent dihydrotestosterone by the action of 5 alpha-reductase. Testosterone mediates its cellular action by binding to the androgen receptor, which translocates to the nucleus where it regulates the transcription of a particular gene cassette. Mice lacking a functional androgen receptor fail to initiate branching morphogenesis, and in humans, both inactivating androgen receptor mutations and androgen insufficiency lead to prostate agenesis. Conversely, exposure of female urogenital sinuses to testosterone induces prostate branching, and female virilizing syndromes such as congenital adrenal hyperplasia result in increased accessory sex gland formation. In mice with mutations in 5 alpha-reductase that prevent the generation of dihydrotestosterone, prostate bud initiation still occurs, but duct development and branching morphogenesis are severely inhibited, indicating that testosterone is sufficient for gland initiation; conversion to the more potent DHT is necessary for full organogenesis. Interestingly the absolute requirement of branching morphogenesis for androgens is temporally restricted, as androgen ablation once the process is underway reduces the frequency of new branching but does not prevent further branching from occurring.

Immunohistochemical studies indicate that in the urogenital sinus, the androgen receptor is expressed in both the developing stroma and epithelium during branching morphogenesis, however with different temporal patterns. Whereas the androgen receptor is highly expressed in UGS mesenchyme before and during prostate morphogenesis, epithelial expression is discerned only after budding and branching have begun, suggesting independent roles in prostate gland development. Indeed, analysis of heterotypic recombinants of wild type and testicular feminization mice which harbor germline inactivating mutations in the androgen receptor indicates that stromal AR expression, but not epithelial AR expression, is necessary for prostate organogenesis. AR expression in the epithelium is however required for the expression of AR-dependent secretory proteins. These observations are supported by the reported phenotype of prostate epithelial AR knockout mice, where prostate glands

clearly form but with a smaller gland size associated with stunted cytodifferentiation of the prostate epithelium. Other steroids, such as estrogens and retinoids, although not necessary for prostate development, may modulate the expression of specific genes through imprinting to affect the growth potential of the fetal prostate as well as susceptibility to disease in later life.

The mechanism whereby testosterone acting upon the stromal compartment gives rise to branching morphogenesis and epithelial cell differentiation is essentially unknown, although two theories have been popularized; the andromedin and smooth muscle hypotheses, which are not necessarily mutually exclusive.

### The Andromedin Hypothesis

The andromedin hypothesis proposes that androgens act upon androgen receptor expressing cells in the stromal compartment to stimulate the production of growth factors or cell surface molecules that act upon prostate epithelial cells in a paracrine manner to regulate their growth and differentiation, although androgen repression of a growth inhibitor would be equally valid. Given that the activated androgen receptor acts as a transcription factor, in the most facile system, expression of the putative growth factor would be directly regulated by androgen binding. These characteristics therefore define a putative andromedin:

- Expression directly regulated by androgens
- Expressed by cells in the mesenchyme/stroma
- Present in the androgen target tissues
- Acts as a paracrine regulator of epithelia

Over the last decade, a number of different molecules have been identified that fulfill these criteria to a greater or lesser degree. For example, the small peptide growth factors FGF7 and FGF10 have been shown to promote prostate epithelial growth and induce branching morphogenesis in tissue culture [33, 34]. Both growth factors are synthesized by stromal cells and act by interacting with their cognate receptor FGFR2iiib, the expression of which is restricted to the epithelial compartment. Interestingly, prostate gland formation in FGF10 knockout mice is severely compromised, with only a reduced number of small prostate epithelial buds being formed. However, FGF10 expression is not regulated by androgens, whereas FGF7 knockout mice, expression of which is at least weakly stimulated by androgens, are not reported to demonstrate and deficit in prostate gland formation. These observations suggest FGF10 is important to the process of branching morphogenesis independent of androgens, whereas any putative andromedin activity of FGF7 is largely redundant. Similarly, other small peptide growth factors have been shown to promote or inhibit growth, branching, or ductal tips (TGF-beta, BMP4, BMP7), although these again fail to fulfill the assumptions of the hypothesis.

### The Smooth Muscle Hypothesis

An alternative mechanism to the andromedin hypothesis to explain the regulation of prostate epithelial growth by androgens through an effect on stromal cells has come from detailed histological analysis of tissue distribution in the developing rat prostate anlagen [34]. This theory proposes that the inductive capacity of the urogenital mesenchyme is regulated by the presence or absence of a smooth muscle layer that acts as a physical barrier between stromal cells and the developing epithelium. In early fetal life, a thin discontinuous smooth muscle layer is observed in both sexes; however, in female rat this develops into a broad continuous sheet that conceivably isolates the primitive epithelium from the inductive effects of the stroma. In male rats however, this layer remains incomplete, and epithelial buds are observed to grow out into the mesenchyme through these gaps where they undergo branching morphogenesis. Prostate epithelial buds form before the smooth muscle layer forms indicating that induction is independent of this event; however, its main effect may be in limiting subsequent ductal growth and branching. It has been shown that the extent and thickness of this smooth muscle layer are negatively regulated by androgens, and it is one possible mechanism for explaining the critical time window for the effect of androgens on prostate development. The smooth muscle hypothesis is not incompatible with the presence of andromedin(s), as it is easy to imagine that the smooth muscle layer may act as a barrier to the diffusion of paracrine growth signals or the interaction of cell surface molecules between compartments. In addition, it is conceivable that the formation of the smooth muscle layer is itself regulated by andromedins.

### Postnatal Development

The postnatal development of the prostate is dependent upon ambient circulating levels of sex hormones. At birth, the prostate gland is composed mainly of connective tissue with a relatively small proportion of smooth muscle [35]. The prostate gland is small, with a measured volume of approximately 1 cc. Glandular ducts end blindly near the periphery, with the precursors of adult gland alveoli represented only by terminal duct buds. The ducts themselves are lined by cuboidal or low columnar cells and in many areas appear as solid cords of cells. Squamous metaplasia is common, particularly in the terminal parts of the prostatic ducts usually in response to exposure to high levels of circulating estrogens toward the end of term. Over the long period from birth to prepuberty, the prostate changes little. With the fall in maternal estrogens, squamous metaplasia disappears. Extensive hyperplasia is noted in the ducts, with obliteration of the lumen in many areas, with pseudoacinar formation. The end buds themselves remain small in size but gradually increase in patency. The lining epithelium is mainly short columnar cells but are not mature secretory cells. Prostate volume

changes little over this time period, a little less than doubling up to 10 years of age. The onset of puberty, with its associated surge in testosterone production, is marked by a phase of rapid growth of the prostate gland with dynamic changes in the internal architecture. Gland volume increases up to 10 cc in as little as 6–12 months. As the hyperplastic epithelium of the terminal end buds thins out into a single layer of cells, the diameter of the acini increases. The height of the columnar epithelium lining the acini increases and the nuclei become more basally located, attaining the appearance of mature secretory epithelium.

# Molecular Biology and Prostate Cancer

2

Greg L. Shaw and David E. Neal

## Introduction to Molecular Biology

Molecular biology is the study of the structure and activity of macromolecules essential to life such as nucleic acids and proteins. Over the past decade, progress in molecular biology has been rapid with advances in our understanding of the genome and cancer biology, computer power for bioinformatics, and development of novel techniques and equipment. This has changed molecular biology from being mainly limited to the study of particular candidate molecules to routine unbiased genome/expressome-wide analyses. Using this new technology, many novel candidate targets for prostate cancer (PCa) therapy have been identified. High-throughput screening allows rapid identification of candidate drugs, which have in vitro effects and which can go on to clinical testing.

For instance, the drug PLX4032 is the first to be specifically designed, based on the results of genome-wide association studies (GWAS). GWAS involves examination of the entire genome, and by comparing cases with control DNA, short sequences of bases, variation within which is associated with disease (short nucleotide polymorphisms or SNPs), can be identified. In melanoma, a subset of patients with a particular gene mutation (polymorphism) resulting in a single amino acid replacement in BRAF, a well-known cancer kinase target, was identified [1]. PLX4032 selectively inhibits the mutated form. Clinical testing showed that 80 % of patients with the V600E mutation had a response, which is remarkable for a patient group in whom treatment was largely futile [2]. Figure 2.1 illustrates the remarkable treatment response seen in a subset of patients.

In PCa, one focus has been to look for SNP variations predisposing to cancer. In a recent review of the current literature on SNPs associated with prostate cancer in Caucasians, 30 PCa risk-associated SNPs were identified. These SNPs have been shown to have moderate effects on risk of developing prostate cancer with odds ratios generally less than two. Surprisingly, most of the SNP variations associated with disease are found in the noncoding regions on the chromosome between genes (introns); it is speculated that these SNPs affect the tissue specific control of expression of coding genes [4].

## Pathways of Translational Research in Prostate Cancer Research

High-throughput drug testing means that with identification of a drug target, design of drugs to inhibit that particular target along with testing of panels of thousands of candidate inhibitor drugs can proceed rapidly. Preclinical work in PCa usually involves culture of the cell lines described in Table 2.1. Should cytotoxicity be demonstrated in cells, animal studies usually precede clinical studies. This approach has produced a large number of candidate drugs that are at various stages in clinical development, a selection of which are summarized in Table 2.2. The main delays and blocks in drug development are mostly related to delays in progress to studies in man.

The majority of PCa animal work is carried out with rodents, particularly mice. In dogs (the only other animal than humans to commonly develop spontaneous PCa), it takes too long before cancer develops to be practical. Previously, rat models such as Noble and Dunning models were used. Nowadays, most work is done using mouse models [5]. Transgenic mice models such as the TRAMP (transgenic adenocarcinoma mouse prostate) model utilize a promoter to overexpress the SV40 early oncogenes to induce

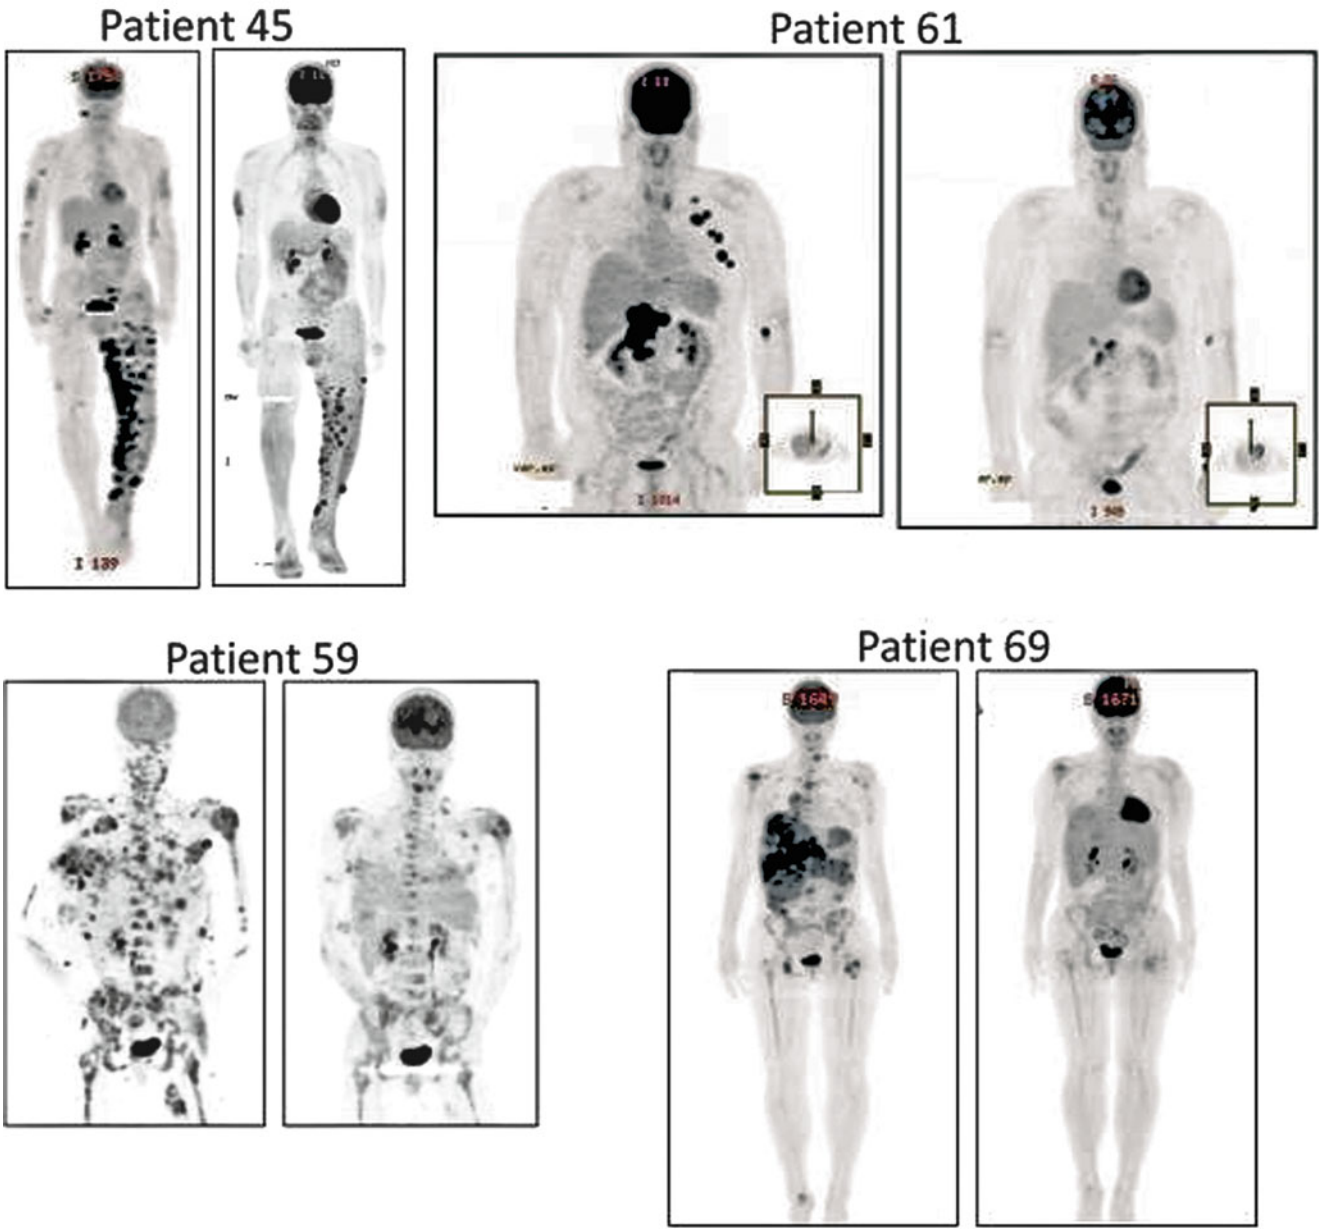

**Fig. 2.1** Representative PET scans for patients taken pre-dose and following 2 weeks of dosing with PLX4032. Each of these image pairs demonstrates significant reduction in FDG uptake following PLX4032 treatment. Note that tumor regressions were later documented for each of these patients: best responses were 70 % for patient 45, 70 % for patient 59, 68 % for patient 61, and 37 % for patient 69 (Reproduced with permission Nature Publishing Group. Bollag et al. [3])

progressive disease from epithelial hyperplasia or prostatic intraepithelial neoplasia (PIN) to adenocarcinoma and development of metastases. Knockout mice have specific genes deleted from the germ line. For example, knockout heterozygotes for *PTEN* (see below) develop PIN, while homozygotes develop invasive prostate adenocarcinoma [6]. Use of germ line knockout models is limited in that all cells in the animal have the deletion. It is not possible to attribute the phenotype solely to changes in the prostate epithelial cells. Conditional gene knockout, whereby gene function can be turned off using an inducible system such as Cre/Lox recombination, allows study of deletions that would be fatal in the germ line.

Xenograft models involve the transplantation of cell lines into immune-deficient animals. The cells used for these experiments are derived from established PCs meaning that study of transformation to cancer is limited in these models [7].

With the ability to analyze biochemical abnormalities present in the cancer of a particular patient and availability of novel agents targeting specific molecules/pathways, personalized

**Table 2.1** Derivation and basic characteristics of prostate cancer cell lines

| Tissue of origin | Cell line | PSA expression | Androgen receptor expression |
|---|---|---|---|
| Prostate | CWR22 | Y | Y |

| Liver metastases | LuCaP 23.12 | Y | Y |

oncological treatment becomes feasible. For example, trastuzumab in addition to standard chemotherapy results in improved survival in the 30 % of patients with HER-2 positive breast cancer [8]. In one clinical trial in PCa, a biopsy of a metastatic lesion is taken and the level of androgen receptor activity quantified; those with high levels of AR activity are treated with the antiandrogen nilutamide, while those with low AR activity are treated with the anti-Src agent dasatinib (NCT00918385). Because of the heterogeneity of PCas and the ability of tumor cells to adapt to altered cellular conditions, combination therapy is of great interest in PCa, and synergistic drug effects are sought.

## Cellular Processes of Importance in PCa

### Survival/Apoptotic Regulators: PI3K/Akt/mTOR/PTEN

Key to mediating the effects of receptor signaling is the PI3K-Akt pathway. When activated by phosphorylation through tyrosine kinase activity at the receptor complex, PI3Ks promote the transfer of a phosphate group onto PIP2 (phosphatidylinositol-4,5 bisphosphate) to generate PIP3 (phosphatidylinositol-3,4,5 trisphosphate). In turn, PIP3 promotes activation of Akt by phosphorylation. Downstream targets of Akt, such as mTOR (mammalian target of Rapamycin), control critical processes such as growth, proliferation, apoptosis, nutrient response, glucose homeostasis, and DNA repair.

*PTEN* (phosphatase and tensin homolog) is a tumor suppressor gene (TSG) which codes for a lipid phosphatase that governs activity of the PI3K-Akt pathway by converting PIP3 to PIP2 [9]. *PTEN* knockout mice develop PIN and prostate adenocarcinoma [6]. *PTEN* deletion is also a marker of poor prognosis in humans and is frequently deleted in PCa and is expressed at low levels in 85 % of primary PCa [10].

There is accumulating evidence that the PI3K-Akt pathway contributes to CRPC by activating the androgen receptor and other androgen responsive genes [11]. PI3K/Akt/mTOR signaling is upregulated in 30–50 % of CaPs providing the rationale for targeting the PI3K/Akt pathway [12]. Inhibition of PI3K using agents such as wortmannin and LY294002 has been stifled by significant toxicity despite positive preclinical results [13]. This has led to the development of agents targeting mTOR, the downstream effector of this pathway. Rapamycin (also known as sirolimus) is the inhibitor of mTOR used in transplantation from which mTOR derives its name. In PCa, cell line and xenograft therapeutic potential has been shown when mTOR inhibitors are used in combination with Taxanes [13]. One small study using rapamycin in a small sample of patients demonstrated some antitumor activity [14]. Use of combined TKI and mTOR inhibition may negate unwanted activation of Akt in response to mTOR inhibition (Table 2.2).

Akt inhibitors such as perifosine are in development, and despite encouraging preclinical data, early clinical trial data suggest very limited activity in CRPC [15]. Celecoxib is a COX-2 inhibitor which also inhibits activation of Akt by phosphorylation in PCa cells and may be chemopreventative for PCa [16]. Further trials such as the MRC STAMPEDE trial will clarify the role of celecoxib in treating advanced PCa (Table 2.2).

**Table 2.2** Summary of the translational impact of molecular biology in prostate cancer in terms of recruitment into clinical trials based on preclinical results

| Target | | TKI/AB | Trial | Setting | Results |
|---|---|---|---|---|---|
| Histone deacetylase | | Vorinostat | NCT00330161 | CRPC monotherapy | Not yet available |
| | | | NCT00589472 | Presurgery with hormones | Not yet available |
| | | Panobinostat | NCT00667862 | CRPC monotherapy | Not yet available |
| | | | NCT00663832 | CRPC with prednisolone and docetaxel | Not yet available |
| | | | NCT00878436 | CRPC with bicalutamide | Not yet available |
| Clusterin | | OGX-011 | NCT00258388 | CRPC | Increased median overall survival vs docetaxel/prednisolone |
| mTOR | | RAD-001 | NCT00636090 | mCaP | Not yet available |
| | | Temsirolimus | NCT01020305 | CRPC | Not yet available |
| AKT | | Perifosine | NCT00060437 | mCRPC | Limited activity |
| | | | NCT00058214 | Recurrent PCa | Limited activity |
| | | Celecoxib | NCT00136487 | Biochemical recurrence | Slowed PSA velocity in 90, 25 % PSA response |
| Neuroendocrine differentiation | IL-6 | Octreotide | NCT00166725 | Advanced PCa | Not yet available |
| | | Sandostatin | NCT00510224 | Advanced PCa | Not yet available |
| | | CNTO 328 | NCT00433446 | mCaP | Not yet available |
| | | | NCT00401765 | | |
| Tyrosine kinase | EGFR | Gefitinib | NCT00241475 | CRPC | No activity |
| | | | NCT00265070 | Biochemical recurrence | |
| | | | NCT00025116 | | |
| | | | NCT00635856 | | |
| | HER-2,3,4 | Pertuzumab | NCT00058539 | Combination with docetaxel | >50 % PSA response |
| | VEGFR | Aflibercept Sunitinib, Bevacizumab | NCT00672594, NCT00329043 | Presurgery | Not yet available |
| | | | NCT00631527 | With radiotherapy | |
| | | | NCT00879619 | CRPC first line | |
| | | | NCT00137436 | | |
| | | | NCT00676650 | | |
| | | | NCT00550810 | CRPC second line | |
| | PDGFR | Imatinib | NCT00500110 | mCRPC with docetaxel | Several trials stopped early limited activity and toxicity |
| | | | NCT00861471 | | |
| | | | NCT00038194 | | |
| | | | NCT00251225 | | |
| | FGFR | TK1258 | NCT00831792 | CRPC | Not yet available |
| | IGF-1R | Figitumumab | NCT00313781 | Comb with prednisolone and docetaxel | Not yet available |
| | | *Cixutumumab* | NCT00683475 | 2nd line after docetaxel | Not yet available |
| | | | NCT00769795 | Presurgery, with hormones | Not yet available |
| | | | NCT00520481 | CRPC primary monotherapy | Not yet available |
| | | | NCT01026623 | mCaP with temsirolimus | Not yet available |
| Bone metastases | RANKL | Denosumab | NCT00321620 | mCaP | Not yet available |
| | Endothelin A | Atrasentan | NCT00036543 | CRPC monotherapy | Delayed disease progression |
| | | | NCT00134056 | CRPC combi with docetaxel and prednisolone | Not yet available |
| | | Zibotentan | NCT00626548 | Localized CRPC monotherapy | Not yet available |
| | | | NCT00554229 | Asymptomatic mCaP | Not yet available |
| | | | NCT00617669 | mCRPC with docetaxel | Not yet available |
| | SRC | Dasatinib | NCT00744497 | CRPC combi with docetaxel | Not yet available |
| | | Saracatinib | NCT00558272 | mCaP monotherapy versus zoledronic acid | Not yet available |

**Table 2.2** (continued)

| Target | | TKI/AB | Trial | Setting | Results |
|---|---|---|---|---|---|
| Microtubules | | Ixabepilone | NCT00331344 | mCRPC with mitroxantrone | 31 % PSA response |
| DNA damage repair | PARP | ABT-888 | NCT01085422 | mCaP with temozolomide | Not yet available |
| | | Olaparib | NCT01078662 | Patients with BRCA mutation | Not yet available |

*mCaP* metastatic prostate cancer, *PSA* response = decrease in PSA to less than 50 % of baseline

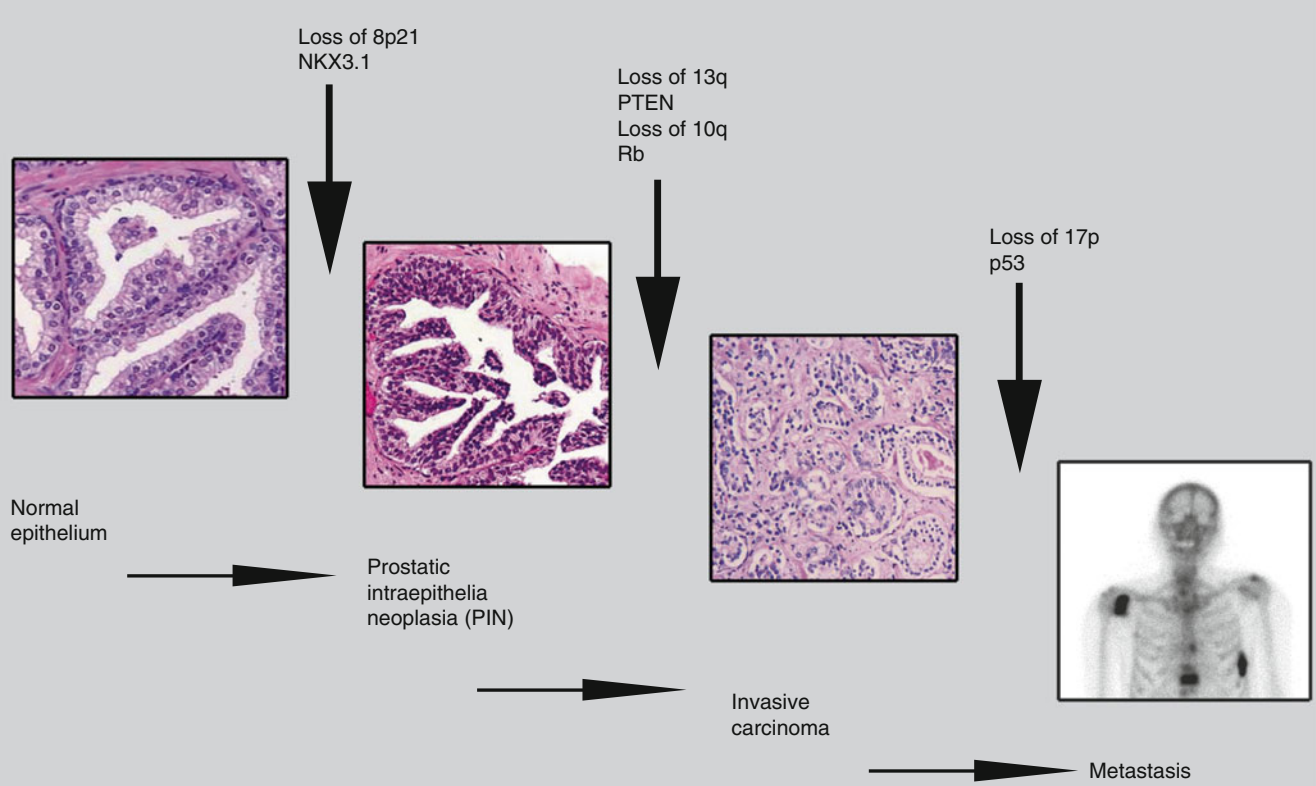

**Fig. 2.2** Pathway for progression in human prostate cancer. Loss of particular chromosomal regions with loss of function of candidate TSGs is associated with stepwise progression from normal epithelium to metastatic prostate cancer

## NKX3.1

The transcription factor NKX3.1 is a putative TSG in PCa. Loss of NKX3.1 protein expression is a common finding in human PCa and PIN. Expression of NKX3.1 precedes formation of the prostatic bud at the urogenital sinus by 2 days and is expressed in the areas where the buds appear suggesting a role in differentiation of the urogenital sinus to form the prostate gland during embryogenesis. Targeted gene disruption of NKX3.1 results in abnormal prostate duct morphology. NKX3.1 mutant mice develop PIN-like lesions that closely resemble human PIN, perhaps due to haploinsufficiency (where loss of a gene copy from one chromosome results in a decrease in the amount of gene product, enough to affect the organisms phenotype, rather than loss of both copies where the gene product is completely absent) [17].

PIN (which is thought to be a precursor to PCa) and early prostate cancer are associated with loss of specific regions of the short arm of chromosome 8 (8p) in up to 80 % of cases [18]. This leads to the hypothesis that this region might encode for a TSG, the loss of which promotes carcinogenesis. This region codes for NKX3.1 and no other known TSGs suggesting that NKX3.1 is an important TSG in early PCa [19].

Loss of chromosome 10q is also frequently seen in prostate cancer [20]. This loss is seen in early prostate cancer more commonly than PIN. *PTEN* maps to 10q23. It is thought that sequential loss of TSGs results in development of cancer that behaves in a progressively more aggressive fashion leading to invasion and metastasis when key TSGs are lost. Later mutations frequently seen in advanced PCa are loss of 13q (which contains the retinoblastoma TSG) and later 17p (which contains p53). Progression of the cancer toward increasingly aggressive behavior corresponds to loss of particular TSGs. This can be represented graphically in a so-called Vogelgram, after Vogelstein the geneticist who popularized the type of diagram shown in Fig. 2.2 [21].

## p53 and Cell-Cycle Regulation

Protein 53 (p53) is encoded by the *TP53* gene in humans and regulates the cell cycle and functions as a tumor suppressor. p53 suppresses carcinogenesis by activating DNA repair proteins when DNA has sustained damage, inducing growth arrest by holding the cell cycle at the G1/S regulation point, allowing DNA repair proteins to fix the damage. It can also initiate apoptosis, if DNA damage proves to be irreparable. p53 mutations are uncommon in early PCa, while in metastatic tumors, loss of p53 is frequently seen [22]. Preclinical work proceeds to attempt to discover compounds that exploit the p53 pathway by either seeking targets and compounds that cause cell death in cells with *TP53* mutations or by looking for activators of the p53 response which do not act by causing DNA damage [23].

MDM2 regulates p53 activity by promoting its degradation and limiting its transcriptional activity and is upregulated frequently in PCa [24]. This can lead to deregulated p53 activity in PCa. It may be possible to inhibit this interaction therapeutically. Small molecular MDM2 inhibitors, such as nutlin-3, have shown promise when used in LNCaP xenografts [25]. This drug also suppresses androgen receptor signaling [26]. Antisense MDM2 oligonucleotides have been shown to enhance the cytotoxic effect of androgen deprivation and radiation in PCa cell lines [27].

## Telomerase

Telomerase is an enzyme which adds repeated sequences of DNA (TTAGGG in humans) to the ends of chromosomes forming telomeres which play a critical role in the maintenance of genomic stability [28]. During replication, in which the end sequences of the chromosomes are most vulnerable to loss, only the telomeres capping the ends of the chromosomes are lost without adverse effect to the organism. Telomerase is composed of a ribonucleoprotein complex with RNA template and human telomerase reverse transcriptase (coded by the *hTERT* gene) components. In adults, telomerase expression is confined to germ line and regenerating tissues [29]. Activation of telomerase to maintain telomeres is required for self-renewal and proliferative expansion of a number of cell types, including stem cells, activated lymphocytes, and cancerous cells. Human telomerase is not usually active in benign mature tissues but is highly active in more than 85 % of primary cancers [29].

In cell lines and mouse xenografts, androgen deprivation leads to a decrease in *hTERT* expression, followed by a decrease in telomerase activity, which can be reversed by androgen administration demonstrating that the *hTERT* gene is regulated by androgens in human PCa cells [30]. The androgen-mediated repression of *hTERT* is abrogated in LNCaP cells which expresses a mutant AR (T877A), a mutation frequently occurring in PCa in vivo [31]. This suggests a possible mechanism of aberrant *hTERT* activity causing increased telomerase activity in PCa.

Telomerase inhibition in mouse xenograft models of PCa has been shown to lower PSA expression and increased fibrosis and apoptosis in telomerase inhibitor-treated cancers [18]. Using specific surface markers, cancer stem cells from several PCa cell lines with increased telomerase activity have been identified. Imetelstat sodium (GRN163L) is a new telomerase antagonist that is currently in phase II clinical trials for hematological and lung malignancies. When treated with GRN163L, PCa cell lines showed shortening of telomere length to a length comparable to non-stem cell cancer cells [32].

## Chaperones, Heat Shock Proteins, and Clusterin

Chaperones are proteins that assist the non-covalent folding or unfolding and the assembly or disassembly of other macromolecular structures and prevention of unwanted protein aggregation. Some of these chaperones are heat shock proteins (HSPs). HSPs are expressed when cells are exposed to elevated temperatures or other stress [33]. HSP60, HSP70, and HSP90 (the most widely studied HSPs) refer to families of heat shock proteins of 60, 70, and 90 kDa in size, respectively.

HSP 90 is vital in stabilizing the androgen receptor preventing its degradation. HSP 90 binding is ATP dependent. Small molecule inhibitors of histone deacetylase (HDAC) such as vorinostat and panobinostat can also result in the loss of HSP90 ATP-binding activity through acetylation resulting in degradation of the androgen receptor in PCa cell lines [34]. HDAC inhibitors block the AR-mediated transcriptional activation of many genes, including the *TMPRSS2* gene [35] (Table 2.2).

Gamitrinibs are a class of small molecules that inhibit the HSP 90 that is found within mitochondria (namely, TRAP-1). Systemic administration of Gamitrinibs to xenograft-bearing mice is well tolerated and inhibits tumor growth [36]. TRAP-1 is highly expressed in both high-grade human PCa lesions and mouse models of PCa but not in benign or normal prostate tissue. Treatment with Gamitrinibs results in PCa cell death but not death of benign prostate cells [37].

Clusterin (apolipoprotein J) is a 75–80 kDa, stress-induced chaperone protein associated with the clearance of cellular debris and apoptosis [38]. Clusterin overexpression is demonstrated in PCs at low levels in hormone-naïve tissue but significantly increased levels after castration [39]. Clusterin levels correlate to grade of PCa and may predict biochemical recurrence following radical prostatectomy [40] (Table 2.2).

## Autophagy (or Autophagocytosis)

Autophagy is a process whereby the cells' own components are broken down and the resulting elements are recycled. It has an important homeostatic function, maintaining protein and organelle quality control and preventing the accumulation of polyubiquitinated and aggregated proteins [41].

Various mechanisms of autophagy have been described, but all involve the degradation of intracellular components via the lysosome. The process of autophagy and its role in PCa are far from clear. Autophagy may halt the progression of some cancers [42]. The context in which autophagy occurs determines whether it enables cells to survive or enhances their death and depends upon the type of stimulus, nutrient availability, organism development, and apoptotic status.

Autophagy is the subject of much interest at present in the pathogenesis as well as the treatment of cancer [43]. Central to regulation of autophagy are the PI3K/Akt/mTOR pathway, members of the Bcl-2 family, p53, and death-associated protein kinases (DAPK) . Prostate cancer cells show impaired autophagy, due to either loss of the essential autophagy gene *beclin1* or activation of mTOR through the PI3K/Akt pathway [44].

## Cancer Cell Metabolism

Cancer cells metabolize glucose predominately by glycolysis rather than oxidative phosphorylation. This is known as the "Warburg effect" [45]. Cancer cells often have glycolytic rates that are up to 200 times higher than those of their normal tissues of origin even if oxygen is plentiful. Anaerobic glycolysis generates only 2 ATP molecules per molecule of glucose, whereas oxidative phosphorylation yields 36 ATP molecules. The cancer cells' environment is relatively hostile with limited blood supply, oxygen, and nutrient availability. This coupled with the cancer cells deranged autophagy, high metabolic demand, and inefficient glucose metabolism renders them frail, particularly where glucose metabolism is concerned. Inhibition of glycolysis through drugs such as 2-deoxyglucose (2DG) or oxamate exploits this fragility. Recently, 2DG has been shown to induce cytotoxicity in PCa-3 and LNCaP cells [46]. When 2DG is combined with metformin in LNCaP cells, synergistic induction of apoptosis results [47]. In a recent small clinical study 2DG, 5/6 patients had positron emission tomography (PET)-detectable decrease in tumor signal using the marker fludeoxyglucose (FDG) suggesting a need for further study [48]. Work using LNCaP xenografts has demonstrated an effect on survival resulting from no carbohydrate ketogenic diet which has an effect on IGF and insulin levels [49].

## Neuroendocrine Differentiation

Neuroendocrine (NE) cells are found in benign and malignant tissue. They are characterized by expression of the NE markers chromogranin A (ChrA) and neuron-specific enolase (NSE) and their particular neuron-like morphology which includes the presence of dendrites. They are found to varying degrees in PCa. Focal NE differentiation represents a common feature of PCa occurring in 30–100 % of the cases [50]. Pure NE cell PCa is very rare (<0.1 %) but exceptionally aggressive (35 % 2 year survival rate) [51].

NE cancer cells seem to be important in determining the rate of growth of prostate cancer cells. Work using mouse xenografts and transgenic mice has shown that tumor progression is more rapid when the number of cells with NE characteristics is increased [52]. Implantation of mouse NE prostate tumor in the flank of one side of castrated immunodeficient mice promotes growth of human PCa cell line tumor implanted in the opposite side. NE tumor cells also promote metastasis of LNCaP cell line xenografts [33]. This suggests that the NE component of the developing PCa produces factors able to stimulate growth. Factors produced by the NE cells which may be responsible for this effect include peptides, hormones, and growth factors. They also produce survivin, which inhibits apoptosis of cancer cells, and VEGF which stimulates the neighboring prostate cancer epithelial cells [53].

It is thought that blocking NE function and or NE differentiation might prolong the period of androgen sensitivity [34]. Somatostatin antagonists have been shown to inhibit tumor growth in preclinical models [35]. Interleukin 6 (IL-6) is a cytokine implicated in stimulating neuroendocrine differentiation. IL-6 inhibition has shown interesting results on tumor progression in preclinical models [54] (Table 2.2).

## Splice Variants of the Androgen Receptor

It is known that several alternative splice forms of the androgen receptor exist and that these variants have different structures and different levels of constitutional activity [55]. Overexpression of abnormal splice variants has been shown to be associated with more rapid disease recurrence after radical prostatectomy [56]. Abnormal splice variants are not expressed in normal prostate epithelium and rarely in primary PCa. It is thought that constitutively active splice variants of the androgen receptor play a role in the development of castrate-resistant growth in PCa [57].

## Microtubules and Chemotherapy

Microtubules are polymers of tubulin that form part of the cytoskeleton (see Fig. 2.3). They have a diameter of 25 nm

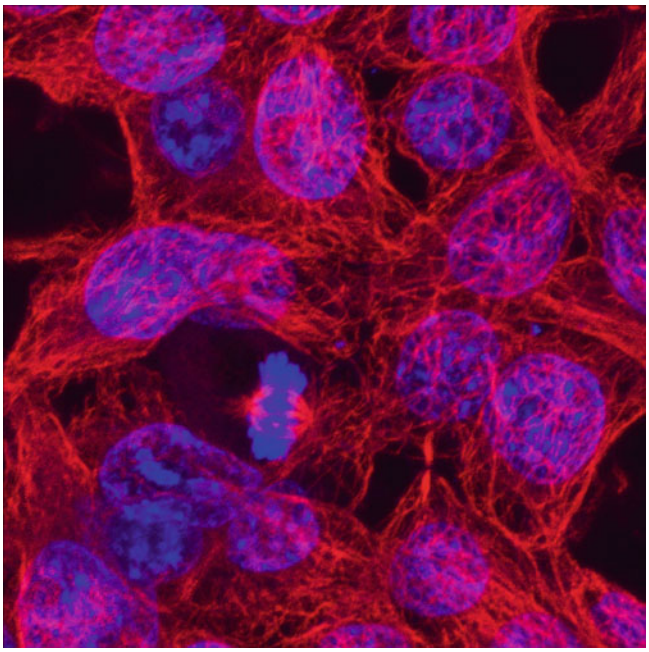

**Fig. 2.3** Human embryonic kidney HEK293 cells stained for alpha-tubulin (*red*) and DNA (*blue*). The mitotic cell to the lower left side of the center of the picture (with the condensed, "sausage-like" DNA) is easily seen. All other cells are in interphase (Reproduced with kind permission from Joana Borlido)

and length varying from 200 nm to 25 μm and are involved in many cellular processes including mitosis, cytokinesis, and vesicular transport [58].

Mitoxantrone is a type II topoisomerase inhibitor that disrupts DNA synthesis and repair. It was the first-line chemotherapeutic agent for CRPC until two clinical trials demonstrated a small but significant improvement in survival with the taxane Docetaxel [59, 60].The taxanes were initially isolated from plants of the genus Taxus (yews) and are now synthesized artificially. Taxanes include paclitaxel (Bristol-Myers Squibb), docetaxel (Sanofi-Aventis), and cabazitaxel (Sanofi-Aventis). Docetaxel is the standard of care in CRPC in men who have good performance status. The principal mechanism of the taxane class of drugs is disruption of microtubule function by binding to the β-tubulin subunit thereby inhibiting cell division.

Cabazitaxel is a novel taxane drug. It has been shown to double median progression-free survival from 1.4 to 2.8 months when compared with mitoxantrone therapy after failed docetaxel chemotherapy in a recent phase three trial [61].

Resistance to taxane chemotherapy is thought to occur due to the effects of ATP-binding cassette transporters (ABC-transporter) [62]. ABC-B1 (also known as P-glycoprotein or MDR-1) is responsible for the majority of systemic clearance of Docetaxel and is expressed in many normal tissues including liver, endothelial cells of the blood-brain barrier, and hematopoietic cells where it prevents toxicity by controlling distribution of the drug [63]. Hepatic ABC-B1 transports docetaxel into the biliary duct for clearance. Expression of ABC-B1 in CaPs is associated with high Gleason grade tumors which are chemoresistant and have a poor prognosis [64]. Polymorphism of the ABC-B1 gene rather than merely level of expression is linked with docetaxel-induced toxicity and overall survival [65].

A new class of microtubule stabilizers is the epothilones (Ixabepilone—Bristol-Myers Squibb, Sagopilone—Bayer, and Patupilone—Novartis). These drugs have a distinct mechanism of action to the taxanes and low susceptibility to drug resistance [66] (Table 2.2).

### DNA Damage Repair

DNA is damaged frequently during metabolic activity (producing reactive oxygen species) and through the effects of environmental factors such as radiation, chemical, and viruses. It is estimated that between 1,000 and 1,000,000 molecular lesions occur per cell per day [67]. While this only constitutes a small proportion of the genomes six billion bases (approx) it is important that this damage is repaired fully and rapidly in order to prevent carcinogenic mutation. A large number of enzymes with specific mechanisms to identify or repair DNA are described. When a cell's DNA is damaged beyond repair, the cell either undergoes apoptosis or enters a state of permanent dormancy called senescence. Occasionally, the DNA repair mechanism fails, and a mutation develops which renders the control of a cell's growth and proliferation uncontrolled. This mutation may provide the cell with a growth/survival advantage leading to development of cancer. A number of checkpoints in the cell cycle exist to ensure that cells with excessive damage to their DNA do not replicate.

Inherited mutations that effect DNA repair genes are associated with cancer, for example, the BRCA1 and BRCA2 mutations. Poly(ADP-ribose)polymerase-1 (PARP-1) is a protein that is important for repairing single-strand breaks. Several forms of cancer are more dependent on PARP than regular cells, making PARP an attractive target for chemotherapeutic cancer therapy (Table 2.2). In addition, radiotherapy causes DNA damage, and radiosensitization of tumors using PARP inhibitors holds some promise [68].

## Signaling Pathways of Importance in PCa

### Tyrosine Kinases

Kinase enzymes are a family of around 500 enzymes in the human that catalyze the transfer of a phosphoryl group from a nucleotide triphosphate donor (e.g., ATP) to an acceptor

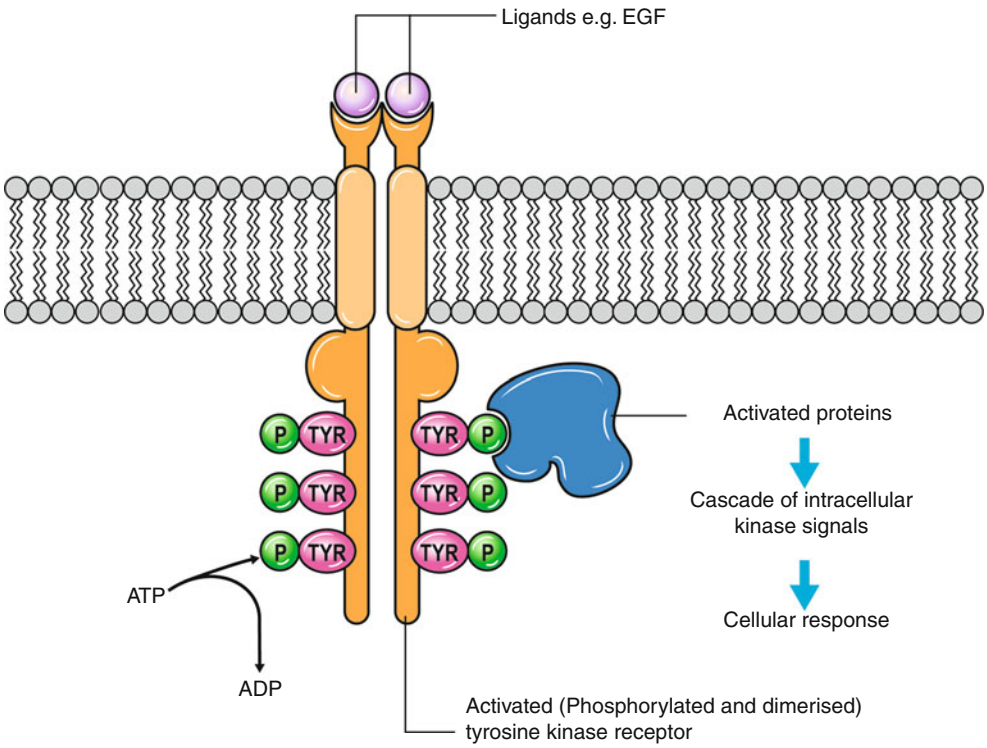

**Fig. 2.4** Cartoon depicting the mechanism by which receptor tyrosine kinases are activated. Ligand binding to the receptor causes dimerization. Phosphorylation of the tyrosine moieties is catalyzed by the receptor itself and results in activation of a cascade of kinase proteins which bring about the cellular response to ligand binding

molecule. More specifically, tyrosine kinases phosphorylate tyrosine moieties; other kinases phosphorylate serine/threonine residues and are named accordingly. Tyrosine kinases control mitogenic signals in human cells, while other kinases are involved with other intracellular signals. Phosphorylation of the target tyrosine moiety brings about a change in the structure and function of the target protein leading to signal transduction effecting a wide range of cellular activity including enzyme activity, subcellular localization, and interaction between molecules.

Receptor tyrosine kinases such as epidermal growth factor receptor (EGFR), vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), and fibroblast growth factor receptor (FGFR) are membrane bound and function in transmembrane signaling. Binding of ligand to tyrosine kinase receptor usually results in *dimerization* of two monomeric receptor kinases. Other tyrosine receptor kinases (e.g., the PDGFR) can form heterodimers with other similar but not identical kinases of the same subfamily, allowing a highly varied response to the extracellular signal. The active tyrosine kinase phosphorylates specific target proteins, which are often enzymes themselves. Figure 2.4 demonstrates the mechanism by which tyrosine kinases are activated. Mechanisms by which receptor tyrosine kinases are implicated in oncogenesis include gene mutation, chromosome translocation, or overexpression, all of which result in increased kinase activity with uncontrolled, ligand independent stimulation of growth of the cancer cells [69]. Tyrosine kinase inhibition has not proven effective as monotherapy in prostate cancer, and current focus is on use in combination with other treatment modalities (Table 2.2).

### Vascular Endothelial Growth Factor Receptor (VEGFR)

As a tumor grows, it requires development of a blood supply brought about by a number of factors, which are known to be of importance in PCa. These include VEGF, which signals through VEGF receptors VEGFR1 and 2. In the TRAMP mouse model, overexpression of VEGFR, especially VEGFR 2, has been linked to tumor progression. It is also overexpressed in human PCa. In castrate-resistant PCa, increased plasma VEGF correlates with poor prognosis and disease progression [70]. Three drugs targeting VEGF signaling have shown promise in clinical trials. Aflibercept is a fusion of the extracellular portion of the VEGFR with an immunoglobulin. Sunitinib is a multitarget tyrosine kinase inhibitor (TKI) with activity at the VEGFR. Bevacizumab is a monoclonal antibody directed against VEGF-A (Table 2.2).

### Endothelial Growth Factor Receptor (EGFR) Family

The confusingly named ErbB family of receptor tyrosine kinases includes EGFR (ErbB1), HER2 (ErbB2), HER3 (ErbB3), and HER4 (ErbB4). Both EGFR and ErbB2 have important roles in cell growth, differentiation, and motility mediated by downstream signaling pathways such as PI3K/Akt. In humans, overexpression of EGFR is an indicator of poor prognosis in PCa [71]. It is highly expressed in primary

PCa and metastases [72]. Overexpression is associated with progression from androgen dependent to independent disease [73].

Therapeutic agents with anti-EGFR activity include monoclonal antibodies and small-molecule tyrosine kinase inhibitors (TKIs). Erlotinib and gefitinib are TKIs which act primarily at EGFR. Gefitinib has been shown to suppress growth of PCa cell lines and in PCa cell line xenografts, where it also slows the rate of metastasis [74] (Table 2.2).

The role of HER-2 is far from clear in PCa. HER-2 overexpression is seen in 20 % of hormone-naive PCs and 67 % of hormone-treated tumors [75]. Despite this, trastuzumab, a monoclonal antibody against HER-2, has not thus far been proven to be of any benefit in CRPC [76]. Activation of HER-2 receptor by tyrosine phosphorylation (rather than HER-2 overexpression itself) has been implicated based on preclinical data, as a mechanism of castrate-resistant growth in PCa [77]. Lapatinib and PD168393 are TKIs, which have activity at EGFR and HER-2 receptors. PD168393 has been shown to potentiate the effect of taxane chemotherapy in castrate-resistant prostate cancer cell lines [78].

HER2 is an orphan receptor, and dimerization with HER3 has been shown to stimulate androgen-dependent signaling in the absence of androgen [79]. Pertuzumab is an antibody which inhibits dimerization of HER-2 with HER-3 or HER-4 is in clinical trials (Table 2.2). Agents to inhibit HER-3, which is necessary for EGFR and HER-2 signaling and is felt to have a role interacting with PI3K/Akt signaling, are in development.

### Platelet-Derived Growth Factor Receptor (PDGFR)

PDGFR is important in autocrine stimulation of tumor cells, regulation of stromal fibroblasts, as well as tumor angiogenesis [80]. Upon PDGF binding, the alpha and beta receptor subunits dimerize; these dimerized receptors have been shown to be expressed in the majority of metastatic (80 %) and even more primary (88 %) PCa tumors. The high level of PDGFR expression in both primary and metastatic PCa implies that it might be a suitable target for early treatment [81]. SU101 is a potent inhibitor of the PDGFR and has been trialed in a phase two study (Table 2.2).

Imatinib (Novartis) is an inhibitor of PDGFR as well as BCR-ABL tyrosine kinase. Clinical trials of imatinib for PCa showed limited efficacy with significant toxicity necessitating early closure of trials (Table 2.2). In mouse models of metastatic PCa, a synergistic effect between paclitaxel and imatinib has been demonstrated [82].

### FGFR (Fibroblast Growth Factor Receptor)

This receptor family consists of four receptors FGFR1, FGFR2, FGFR3, and FGFR4. Several of the 22 ligands for the FGFRs are overexpressed in PCa [83]. Stimulation of the FGFRs results in a wide variety of effects resulting in mitogenic, regulatory, morphological, and endocrine effects. They are "promiscuous" in that their actions exert multiple actions on multiple cell types [84]. One important function of FGF1 and FGF2 is the promotion of endothelial cell proliferation and the physical organization of endothelial cells into tube-like structures in angiogenesis. FGF1 and FGF2 are more potent angiogenic factors than VEGF or PDGF [85]. FGF signaling through activation of FGFR1-4 leads to downstream signaling of multiple pathways including MAPK and PI3K pathways. FGFR4 overexpression is strongly associated with high-grade disease and decreased survival [86]. Interference of FGF signaling in PCa cell lines using small interfering RNA molecules (siRNA) to target FGFR4 in PCa causes impairment of invasion and proliferation [87]. SU5402, a TKI which inhibits FGFR, has been used to decrease LNCaP xenograft tumor growth [88]. TK1258 (aka CHIR258) is the first TKI targeting FGFR activity to be studied in patients (Table 2.2).

### IGF-1R (Insulin-Like Growth Factor 1 Receptor)

The insulin-like growth factor pathway involves two growth factors IGF-1 and -2 and two transmembrane receptors (IGF-1R and IGF-2R). IGFs stimulate proliferation and differentiation and inhibit apoptosis. IGF-1 is the most potent natural activator of the Akt signaling pathway. Elevated levels of IGF-1 have been linked with PCa risk as well as aggressive cancer phenotype [89]. IGF-1R, IGF-1, and IGF-2 have been reported as being overexpressed in primary PCa, with increased levels in advanced disease [90]. Preclinical work on cell lines has implicated IGF-1 activity in castrate resistance and invasiveness [91, 92]. The human antibody IMC-A12 against IGF-1R has been shown to enhance the antitumor effects of castration and cytotoxic drugs in prostate xenograft models providing rationale for clinical trials targeting the IGF-R axis [93, 94]. Figitumumab and cixutumumab are humanized monoclonal antibodies against IGF-1R and are currently in clinical trials (Table 2.2).

## Biomarkers in PCa

### Alpha-Methylacyl-CoA Racemase (AMACR)

This biomarker was identified by comparison of cDNA from PCa and benign prostate tissue [95]. This resulted in the identification of P504S, which was selectively overexpressed in PCa with minimal expression in benign prostate tissue and non-prostate tissue. Immunohistochemical staining using rabbit monoclonal antibodies generated against P504S showed positive staining in PCa and negative staining in benign prostate tissue. The full-length 1,621 base pair sequence for P504S was cloned and found to encode human

AMACR (Genbank accession number 4204097), an enzyme with a key role in the metabolism of fatty acids and bile acid intermediates. Besides being produced in PCa tissue, the enzyme is encoded by a gene located in a region (5p13.3) that contains polymorphisms associated with PCa [96]. A meta-analysis of microarray data showed with high confidence that AMACR is upregulated in PCa [97]. The role of AMACR in PCa is unclear. Men who consume diets rich in dairy products and red meat are at increased risk for developing PCa, while these foods are the major dietary sources of the branched-chain fatty acid substrates of AMACR [98] suggesting that AMACR along with dietary factors might be important in PCa progression. Use of AMACR to identify aggressive tumors is limited. Recently, decreased AMACR expression has been shown to predict biochemical recurrence after radical prostatectomy and death due to PCa [99].

Currently, staining for AMACR is used to assist the histopathologist in distinguishing benign from malignant tissue on H&E staining of biopsies. It is particularly useful in diagnosing the small clusters of malignant cells that may either represent an under-sampled cancer or a very small focus of cancer. False positives do occur with HGPIN and occasionally benign prostate tissue. Four studies have evaluated the accuracy of immunohistochemistry using AMACR to identify PCa. Overall, they show sensitivities that range from 82 to 100 % and specificities ranging from 79 to 100 % [100].

Other applications of AMACR have been explored. Circulating concentrations of AMACR mRNA in serum and urine have been measured by reverse transcription-PCR analysis [101]. Increased concentrations of autoantibodies to AMACR were able to distinguish PCa patients from healthy individuals in the PSA interval of 4–10 g/L with a sensitivity of 62 % and a specificity of 72 % [102]. Studies to fully elucidate the potential uses of AMACR as a biomarker for PCa are in progress.

### Fusion Genes *TMPRSS2-ETS*

A fusion gene is a hybrid gene formed from two previously separate genes. It can occur as the result of a translocation, deletion, or chromosomal inversion. Often, fusion genes are oncogenic, where fusion produces a gene product with a new or different function from the two fusion partners or where fusion of a proto-oncogene to a promoter renders it oncogenic [103].

The *TMPRSS2* gene encodes the enzyme transmembrane protease, serine 2 which is a serine protease [104]. The biological function of this gene is unknown. Groundbreaking work by Tomlins et al. identified the recurrent fusion of the *TMPRSS2* to ETS (E twenty-six) family transcription factor genes. *TMPRSS2* is fused to *ERG* and *ETV1* in 55 and 27 % of PCa specimens, respectively[189]. *TMPRSS2* gene expression is governed by androgens in the prostate. ETS families are proto-oncogenes, and it has been postulated that fusion of *TMPRSS2* with an ETS proto-oncogene leads to increased expression of ETS in response to androgen.

The *TMPRSS2* and *ERG* oncogenes are situated on chromosome 21 and are very close. Fusion usually results from a deletion of the intervening short polynucleotide sequence. Figure 2.5 demonstrates the mechanism by which the fusion protein is formed and functions. There are approx 20 different variants of *TMPRSS-ERG* [61]. Study of *TMPRSS2*-ETS fusion products demonstrates the heterogeneity of PCs. Study of multifocal tumors revealed different fusion products in different tumors and different foci from the same tumor perhaps indicating that multifocal tumors develop from different origins [105, 106].

Attempts to utilize *TMPRSS2-ERG* detection to aid diagnosis using RT-PCR and southern blotting had a specificity of 93 % but was limited by a sensitivity of only 37 % [107]. *TMPRSS2* expression might also be of use as a prognostic marker having been found to correlate with PSA level, pathological stage, and Gleason score [108]. Cohort studies looking at PCa patients treated conservatively showed that *TMPRSS2*:*ERG* gene fusions were associated with a poor prognosis [109]. Recent work has linked *TMPRSS2*:*ERG* detection with recurrence after radical prostatectomy [110]. *TMPRSS2*:*ERG* status does not appear to predict response to hormone therapy despite apparent androgen-dependent *TMPRSS2* expression [111].

## Bone Homeostasis and the Molecular Biology of Metastatic PCa

Bone homeostasis is important in prostate cancer for a number of reasons. Firstly, metastasis to bone is the commonest site of progression of PCa, particularly the lumbosacral vertebrae. Bone metastases, despite appearing to be sclerotic on imaging, are characterized by increased bone turnover with increased osteoclastic activity [112]. Secondly, weakened bone at the site of metastasis may fracture, and either this or formation of bulky tumor with inherent inflammation in the vertebrae may lead to spinal cord compression which is severely disabling. Thirdly, castration (medical or surgical) for prostate cancer results in osteoporosis in a proportion of men for whom bisphosphonate therapy is indicated [113]. For these reasons, there is much interest in better elucidating the molecular mechanisms underpinning bone health in prostate cancer.

### RANKL (Receptor Activator for Nuclear Factor κ-B Ligand)

RANKL is important in bone metabolism. It binds to RANK to stimulate osteoclast proliferation and differentiation and

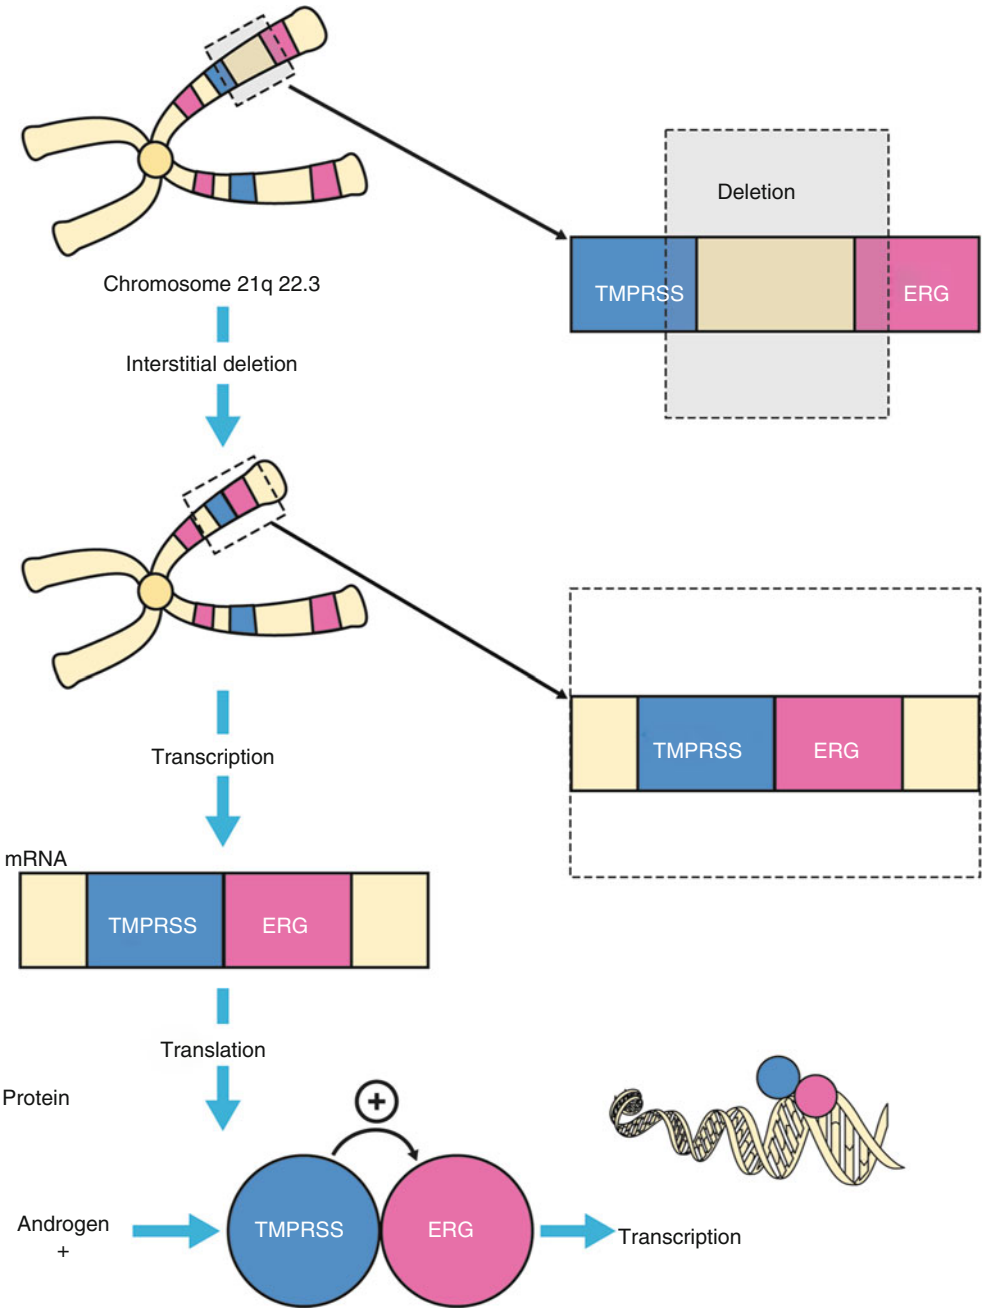

**Fig. 2.5** Mechanism of formation and consequences of *TMPRSS-ERG* gene fusion. An interstitial deletion at the short arm of chromosome 21 results in apposition of two genes *TMPRSS-2* and *ERG*. Transcription of the resultant DNA sequence into mRNA and translation of this into a sequence of amino acids generate a fusion protein composed of the *TMPRSS-2* and *ERG* gene products. The *TMPRSS-2* product is androgen responsive. The *ERG* product is a transcription factor. Activation of the *TMPRSS-2* moiety results in activation of the *ERG* transcription factor with consequent changes in target gene expression

inhibits apoptosis promoting bone resorption. Denosumab is a humanized monoclonal antibody against RANKL which limits bone resorption thereby and has been shown to reduce markers of bone turnover in patients with metastases from PCa [114] (Table 2.2).

## The Endothelins (ETs)

The ETs are a family of three peptides: ET-1, -2, and, -3. ET-1 mediates the osteoblastic response of bone to metastatic PCa leading to increased bone deposition in sclerotic bone lesions. ET-1 production is stimulated by osteoblasts, which are in turn stimulated by ET-1 in a cyclical fashion. ET-1 preferentially binds to the receptor ET-A, while ET-1 binding to ET-B has antagonistic effects. Thus, the differential expression and activation of ET-A and ET-B receptors in tissues determines the effect of the ET-1 [115]. ET-1 activates ET-A triggering several signaling pathways resulting in cellular growth and mitogenesis [116]. ET-1 also inhibits apoptosis via activation of PI3-K and Akt pathways. When ET-A receptor antagonist is applied to cells, the anti-apoptotic effects of ET-1 are reversed, implicating the ET-1/ET-A interaction as important in progression of PCa metastases in bone.

Atrasentan and zibotentan are highly selective inhibitors of the ET-A receptor currently being trialled (Table 2.2).

### Bisphosphonates (also called disphosphonates)

Bisphosphonates, such as zoledronic acid, palmidronate, and clodronate, inhibit resorption of bone by osteoclasts. They act by inhibiting activation of enzymes that utilize pyrophosphate (with which bisphosphonates are very similar structurally) [117]. Preclinical work suggests that bisphosphonates may play a role in immunomodulation and control of angiogenesis and have an antitumoral synergistic interaction with taxanes [118]. Bisphosphonates are increasingly used alongside specific anticancer treatments to prevent skeletal complications [119]. Zoledronic acid has been shown in a randomized trial to reduce skeletal-related events in PCa patients with metastases [120]. Zoledronic acid does not have a role in preventing metastasis [121].

### Src Family Kinases (SFKs)

Src was the first member of this family of tyrosine kinases to be identified. SFKs are proto-oncogenic and are not receptor bound. They interact with cytosolic, nuclear, and membrane proteins and modify these proteins by phosphorylating tyrosine residues to control migration, proliferation, adhesion, and differentiation. SFKs are involved in the downstream signal transduction of many receptors including EGFR, PDGFR, and VEGFR. SFKs are overexpressed in PCa cell lines and tissues, and inhibition of Src limits cell line proliferation [122]. Reduced cancer cell proliferation, invasion, and migration are seen following Src inhibition in mice models with increased survival [123]. Src/SFK inhibition therefore represents a potentially useful therapeutic strategy for patients with various stages of PCa.

Dasatinib is an agent with anti-Src activity. Trials in PCa using Dasatinib as a single agent failed to produce significant PSA responses; however, decreases in markers of bone turnover like alkaline phosphatase and urinary *N*-telopeptide were seen providing evidence of biological activity [122]. Other SRC inhibitors include saracatinib and bosutinib which both also have activity at another tyrosine kinase—Bcr-Abl. They have shown anti-PCa activity in preclinical studies and have been shown to block the RANKL stimulatory pathway in osteoclasts [124] (Table 2.2).

#### Conclusion

Significant investment in research into PCa is now yielding dividends in a better understanding of the molecular pathology of this disease. Early application of such research to human tissue samples is also making the findings more relevant to the disease itself. Human studies are a priority to confirm preclinical findings in terms of identifying new biomarkers and improving treatment of PCa. In order to take this forward, academic clinicians in urology, pathology, and medical oncology need to work together if we are to see the benefits that should come from this research over the next decade.

# 3 Endocrine Mechanisms, Androgen Receptor and Carcinogenesis, and Hormone Escape

Kaustubh Datta and Donald J. Tindall

## Endocrine Mechanisms

Androgens are essential for prostatic development, growth, and function. They also regulate many physiological processes such as the development and maintenance of the immune and neural systems, determining gender-specific phenotypes associated with the male reproductive system and secondary male traits [1]. A connection between androgens and prostate cancer came with observations that eunuchs do not develop prostate cancer and that men who use androgens as anabolic agents or therapeutics develop prostate cancer at a higher rate [1, 2]. Although population-based case-control studies have failed to establish a clear association between prostate cancer risk and circulating sex hormones, a somewhat weak association between higher circulating testosterone and high-risk ethnic or racial groups has been observed [1]. Indeed, the best evidence for an androgen axis in prostate cancer is the significant clinical response that has been observed in patients with advanced-stage prostate cancer upon androgen ablation. This observation was first documented by Charles Huggins and Clarence Hodges in their landmark study in 1941 [3], which earned them the Nobel Prize in medicine in 1972.

The biosynthesis of androgen is a two-step process [4]. Testosterone, which is the main circulating form of androgen in men, is synthesized predominantly (95 %) by the leydig cells of the testes under the control of luteinizing hormone (LH), which is secreted by the anterior pituitary in a pulsatile manner. The secretion of LH is controlled by luteinizing hormone-releasing hormone (LHRH) or gonadotropin-releasing hormone (GnRH) of the hypothalamus. LH binds to its receptor on the membrane of Leydig cells and initiates a G-protein coupled signaling cascade and activation of adenylate cyclase. This event leads to increased intracellular formation of 3′5′-cyclic monophosphate (cAMP) and activation of protein kinase A. In the following, cholesterol is transferred to the inner mitochondrial membrane where P450scc/CYP11A1 converts cholesterol to pregnenolone. Pregnenolone is further converted to progesterone in the smooth endoplasmic reticulum by 3β-hydroxysteroid dehydrogenase (3β-HSD). In the next step, 17α-hydroxylase/C17-20 lyase (CYP17) converts progesterone to androstenedione, which is finally metabolized to testosterone by type 3 17β-hydroxysteroid dehydrogenase (17β-HSD3) [4]. High serum testosterone levels constitute a negative feedback mechanism by inhibiting LHRH release, thereby maintaining an optimum physiological concentration (Fig. 3.1).

A minor part of circulating testosterone (5–20 %) is synthesized by the adrenal glands along with androstenedione and dehydroepiandrosterone (DHEA), which also can be converted to testosterone in the prostate. All these androgens from the adrenal gland are secreted under the control of adrenocorticotropic hormone from the anterior pituitary, which is regulated by the corticotrophin-releasing factor from the hypothalamus [2, 4].

Serum testosterone exists as a complex with sex hormone-binding globulin (SHBG), albumin, and corticosteroid-binding globulin and, therefore, is not readily available as a free form. Only 2–3 % of total testosterone in circulation remains as free and available to target tissues [2].

Testosterone, which is taken up into prostate cells by passive diffusion, is converted into 5α-dihydrotestosterone (DHT) by 5-α-reductase enzymes. DHT (Fig. 3.2) has a higher affinity for the AR compared to testosterone and also dissociates more slowly from the AR [2]. It protects AR more efficiently than testosterone from proteolytic degradation and is, therefore, the primary androgen for AR-mediated growth and survival of normal, hyperplastic, and malignant prostate tissues. There are three isoforms of 5-α-reductases [1]. Isoform I expression increases in PCa relative to normal

prostate and BPH. Type II isoform is prevalent in prostate, seminal vesicles, and epididymis. It is also important for the growth of prostate cancer. Finasteride, which is a specific type II inhibitor, has been shown to significantly decrease the incidence of prostate cancer in the recent prostate cancer prevention trial (PCPT) [5]. Similar result was also observed in another recent trial known as reduction by dutasteride of prostate cancer events (REDUCE) where dutasteride, a 5-α-reductase inhibitor for both isoform I and II, was used [6–8]. Type III is detected mainly in castration-resistant

prostate cancer with insignificant expression in normal adult organs and, therefore, is suspected to play a role in the growth and progression of castration-resistant PCa. Epidemiologic evidence shows an elevated activity of 5-α-reductases among white and black men compared with men of Asian origin, suggesting a role in the increased incidence rates of PCa in these ethnic groups.

## Androgen Receptor and Prostate Carcinogenesis

### Androgen Receptor

Androgens act as intracellular ligands for the androgen receptor (AR) functioning as a transcription factor and transcribing a number of genes responsible for cell differentiation, proliferation, and survival. AR is expressed in all human organs apart from the spleen and bone marrow [9]. Loss or partial loss of AR function during male development leads to a condition termed androgen insensitivity syndrome (AIS) that is characterized by a female phenotype [10]. The androgen/AR axis regulates the expression of a number of prostatic enzymes that are secreted into the seminal fluid [9]. The best characterized among these include PSA, kallikrein 2, and prostatic acid phosphatase. There are also other androgen regulated genes involved in lipogenesis, cell cycle regulation, and cell survival [11]. The growth and survival of prostate luminal epithelial cells in the normal prostate are regulated by a paracrine effect of many growth factors secreted by the prostate stromal cells under the influence of the stromal androgen/AR signaling axis.

AR is a member of the steroid/thyroid receptor superfamily, in which all the members share basic structural and functional homology [9, 12–14]. AR in its unliganded state remains in the cytoplasm as a part of large heterocomplex. Several heat shock proteins, co-chaperones, and tetratricopeptide repeat proteins constitute this heterocomplex, which protect AR protein from irreversible aggregation and degradation [15]. These proteins also help keep the ligand-binding domain (LBD) of AR in a relatively stable, partially unfolded, and inactive state with a high affinity for androgen thereby prevents the premature activation of AR in the absence of androgen.

Androgen activates AR by binding to its C-terminal ligand-binding domain and inducing a conformational change in AR structure, which has several implications in its function. One such effect is the unmasking of the bipartite nuclear localization signal (NLS) sequences of AR, which facilitates entry of AR protein into the nucleus [16]. The NLS sequences of AR reside in the DNA-binding-domain (DBD) and hinge region (amino acids 625–671) and LBD (amino acid 722–805). Another remarkable AR conformation change upon ligand binding, which is crucial for AR function, takes place with intramolecular interactions between the AR N-terminal transactivation domain and the C-terminal LBD [17]. An FXXLF (F = phenylalanine, L = leucine, and X = any amino acid) motif in the AR N-terminal activation domain (NTD) facilitates this interaction as it specifically recognizes the activation function 2 (AF2) domain of the AR C-terminus. The N/C interaction prevents inappropriate coactivator interaction with AR before it binds to the AR responsive elements (AREs) of target genes.

Binding of the AR homodimer to a specific ARE of a gene involves cooperation between the AR DBD and LBD [9]. The DNA-binding domain of AR, like other nuclear receptor superfamily members, consists of two zinc fingers that provide the structural basis required for ARE recognition. The consensus ARE consists of a pair of 6 bp palindromic core sequence (5′-AGAACA-3′) separated by a spacer of three nucleotides. The second zinc finger loop enhances AR-DNA binding through interaction with the first loop. Sequences outside the DNA-binding domain also play a role in AR-DNA binding. In addition to canonical AREs, several noncanonical AR binding sites have been described [18]. AR binds with lower affinity to those noncanonical AR binding sites when compared to canonical AREs.

The AR NTD is highly disordered and possesses a molten-globular conformation [13, 19]. It contains activation function 1 (AF1), which promotes strong transcriptional activity [20]. Two major transactivation units present in AF1 are known as transactivation unit 1 (TAU1) (amino acids 142–485) and transactivation unit 5 (TAU5) (amino acids 351–528). TAU1 is considered the major transactivation domain that binds to basal transcription factors [19], transcriptional coactivators, and heat shock proteins [20]. The FxxLF motif also belongs to the AF1 domain and promotes the N/C interaction. The TAU5 region of AF1 is responsible for ligand-independent AR activity in castration-resistant prostate cancer cells. A WxxLF motif within TAU5 is sufficient to induce this ligand-independent activity [21].

Two polymorphic trinucleotide repeat segments within the AR NTD encode polyglutamine (amino acids ~58–78, nucleotide sequence CAG) and polyglycine tracts (amino acids ~449–472), which influence AR activity by regulating the N/C interaction [20]. Shortened trinucleotide repeat stretches result in increased AR activity and may be associated with prostate cancer predisposition [22].

A number of posttranslational modifications of AR can influence its function. One of the major posttranslational modifications of AR is phosphorylation. Most of the AR phosphorylation sites reside in the NTD [23]. AR phosphorylation has been related to growth and progression of prostate cancer under androgen-depleted conditions. Ubiquitination (both poly- and mono-), acetylation, and sumoylation are other important posttranslational modifications of AR and have been linked to the development and progression of prostate cancer [24–26].

Several coregulators interact with AR and enhance (coactivators) or reduce (co-repressors) AR transcriptional activity [27–31]. Coregulators modulate the chromatin structure surrounding the ARE, facilitating the DNA occupancy of the AR, and recruiting the basal transcriptional machinery such as RNA polymerase II. Coregulators can also promote AR posttranslational modifications, thereby modulating androgen/AR binding affinity, AR expression, AR stability, and AR nuclear translocation, thus making the AR competent for gene transcription [28]. Over 200 coregulators have been detected that exhibit a wide range of functions including histone acetyltransferases (HATs), histone deacetylases (HDACs), histone methyltransferases and demethylases, and protein scaffolds.

Co-repressor proteins usually possess a specific motif known as the co-repressor/nuclear receptor (CoRNR) box or LXXX IXXX I/L motif. This motif binds to the hydrophobic pocket of the ligand-binding domain and competes with co-activator binding to the AR [32]. Selective androgen receptor modulators (SARMs) function as antagonists by recruiting the N-CoR complex.

Recently, a mechanism for AR function independent of its transcriptional activity has been demonstrated. This non-genomic event is very rapid and activates signaling cascades such as the Src/Raf1/ERK, PI3K-AKT, and IL-6-STAT3 pathways located at the lipid rafts of the cell membrane [33, 34]. The functional significance of these non-genomic AR activities in prostate cancer remains unclear.

## AR Function in Androgen-Dependent Prostate Cancer

A majority of prostate tumors are dependent on androgen at initial diagnosis [14, 35, 36]. AR in prostate cancer cells promotes cellular proliferation. AR regulates the expression of cell cycle genes such as Skp2, cyclin D1, cycline A, p21, and p27 [11, 37, 38] and the activities of CDK2 and Rb, thereby facilitating cell cycle progression at the G1/S-phase [11]. Collaborating transcription factors such as GATA2 and Oct1 by binding to the AR are also important for androgen-induced cell proliferation [18]. Another proposed mechanism by which the AR regulates prostate cancer cell proliferation is through its role as a licensing factor for DNA replication [39, 40].

AR is also important for survival of prostate cancer cells. AR upregulates the cellular Fas/FasL-associated death domain protein-like inhibitory protein (FLIP), which inhibits the death receptor-mediated activation (FAS ligand and TRAIL) of procaspase-8 and procaspase-10 [41–43]. The androgen/AR axis also inhibits the p53 pathway in an indirect way, thereby influencing cell survival. Expression of the apoptotic regulator Caspase-2, which is a direct target of AR, is inhibited by androgen in prostate cancer cells.

In prostate cancer, AR controls angiogenic growth by regulating the synthesis of vascular endothelial growth factor-A (VEGF-A), the major angiogenic growth factor [44, 45].

A bioinformatics approach known as cancer outlier profile analysis (COPA) together with standard genomic techniques identified recurrent gene fusions of the 5′ untranslated region of the TMPRSS2 gene to ETS transcription factors (ERG or ETV1) in over half of all human prostate cancers [46]. Importantly, since the TMPRSS2 promoter contains an ARE, androgens can regulate the expression of the fused gene under the control of the AR. Moreover, the AR has been demonstrated to facilitate the fusion of these genes in an androgen-dependent manner. Cooperativity between the aberrant expression of ETS fusion genes and other signaling pathways, e.g., the PI3 kinase-AKT pathway, is evident in prostate cancer [47, 48].

## Hormone Escape

Due to the overwhelming effect of AR in the pathogenesis of prostate cancer, androgen ablation by pharmacotherapeutic or surgical means is the primary choice of therapy for advanced (locally extensive or metastatic) prostate cancer. Various pharmacological agents such as gonadotropin-releasing hormone (GnRH) agonists or antagonists, which block testosterone synthesis via the pituitary axis, are widely used in the clinic as a means of androgen ablation therapy [49, 50]. Also, 5-α-reductase inhibitors such as finasteride and dutasteride, as well as competitive inhibitors of androgen binding to AR (flutamide, nilutamide, and bicalutamide), are used extensively in the clinic.

Nonetheless, after a period of regression in response to these therapies, these tumors eventually recur as a highly aggressive and castration-resistant prostate cancer (CRPC) [14, 35, 49, 51–54]. The median survival time for men with CRPC is between 18 and 24 months. Interestingly, the AR still remains an essential transcription factor in CRPC, since inhibiting AR expression or function disrupts the growth of castration-resistant prostate cancer cells [55–57]. Mechanisms for AR reactivation in patients with prostate cancer after hormonal manipulation include AR gene amplification, AR mutations, increased AR mRNA and protein levels, increased nuclear localization of AR, altered expression of AR-associated coregulators, and cross talk between different signal transduction pathways [52, 53].

## AR Gene Amplification

AR copy number is amplified in metastatic and castration-resistant tumors [58]. The overall frequency of AR amplification occurs in a minority of patients (~20–30 %)

and, therefore, cannot be the sole mechanism of progression to castration-resistant disease.

### Increased AR Transcription and Protein Stability

Increased AR levels due to the increase rate of AR transcription or increased stability of AR protein plays a causal role in the transition from hormone-dependent to CRPC by sensitizing prostate cancer cells to low levels of androgen [59] or even anti-androgen.

### AR Mutations

Gain of function mutations of AR in both the NTD and LBD are linked to CRPC. However, AR mutations are rare. AR mutations in the ligand binding pocket create a more sensitive AR that can respond to low concentrations of androgens and make the AR more promiscuous to other steroid hormones such as estrogen, hydrocortisone, weak androgen precursors, and even therapeutic anti-androgens [60].

### Aberrant Expression of AR Coregulators

Altered expression of AR coactivators promote activation of AR by reducing its requirement for androgen in castration-resistant prostate cancer [61]. Coactivators such as p300, FHL2, TIF2, SRC1, TIP60, and BAG-1L are present at increased levels in the tissue specimens from castration-resistant prostate tumors [28, 29, 62, 63]. Interestingly, expression of several of these coregulators depends either directly or indirectly on AR activity, suggesting a feedforward loop for aberrant AR activity in castration-resistant prostate cancer. Increased expression of SRC-1 is associated with ligand-independent activation of AR by IL-6. Enhanced levels of p300 can activate the expression of AR target genes and AR-mediated cell proliferation in the absence of androgens or in the presence of anti-androgens [64]. In castration-resistant cells, p300-mediated AR activity depends on IL6/MAPK signaling axis. Coactivators such as CBP, ARA54, and ARA70 can potentiate AR activity in the presence of anti-androgens such as hydroxyflutamide and, thus, may contribute to anti-androgen withdrawal syndrome. Co-repressors such as N-CoR and SMRT are also decreased in the castration-resistant stage and, therefore, contribute to increased AR activity.

### AR Cross Talk with Growth Factor Pathways

The insulin-like growth factor-1 (IGF-1)/IGF-1 receptor (IGF-1R) axis is important in regulating cell proliferation, survival, and transformation [65]. Androgens induce the expression of both the IGF-1 and IGF-1R expression in prostate cancer cells [65, 66]. Interestingly, IGF-1R signaling also promotes AR activation through phosphorylation of the AR at serine 210 and 790, especially during hormone ablation [67]. Therefore, AR and IGF-1R pathways are engaged in a positive feedback loop in prostate cancer cells. Epidermal growth factor (EGF), keratinocyte growth factor (KGF), Interleukin-6 (IL-6), HER-2/ErbB2, oncostatin (OSM), and ligands also enhance the activity of the AR or its coactivators in castration-resistant prostate cancer cells via cAMP-dependent protein kinase A (PKA) [50, 68–70]. Growth factor pathways also activate PI3K-AKT, JAK/STAT, and NFκB pathways, which promote posttranslational modifications of the AR, thereby facilitating AR stability and DNA-binding [71–75].

### Intraprostatic Generation of Androgens

Recurrent prostate tumors may synthesize their own testicular androgens from adrenal androgens or cholesterol, thereby reactivating AR through a cell autonomous mechanism [76]. This is achieved due to the ability of castration-resistant prostate cells to express genes encoding many steroidogenic enzymes such as FASN, CYP17A1, HSD3B1, HSD17B3, CYP19A1, and UBT2B17 [77].

### Constitutively Active AR Splice Variants

The N-terminal transactivation domain (NTD) of AR plays a major role in AR-mediated gene expression in the castration-resistant state [78]. The WxxLF motif in the TAU5 domain is important for the transcription-activating function of the NTD of the AR [21]. One of the mechanisms by which CRPC cells circumvent androgen ablation is by synthesizing splice variants of AR, which lack the ligand-binding domain and retain the AR NTD [79]. In the absence of the LBD, the NTD drives constitutive transcriptional activity. Splice variants lacking the LBD are expressed in tissues isolated from patients with CRPC [80].

#### Conclusion

The AR signaling axis is distinct in prostate cancer and induces the expression of specific genes responsible of cancer cell proliferation, survival, and metastasis. Therefore, the AR axis is a target for therapeutic intervention during locally advanced prostate cancer. Several agents, which block the synthesis and activation of androgen, either by inhibiting the hypothalamus-pituitary axis or by inhibiting the conversion to DHT from testosterone, are currently used in clinics for treating prostate cancer. Anti-androgens, which compete with androgen for

binding to the ligand-binding domain of AR, are also therapeutic agents for treating prostate cancer. Androgen receptor is also important for the progression of prostate cancer to the castration-resistant state [49]. Several mechanisms have been postulated for the transactivation of AR in this stage of prostate cancer. Therefore, the AR remains a potential therapeutic target in castration-resistant prostate cancer, and new therapeutic approaches to inhibit AR are needed. Development of second-generation antiandrogens with higher AR binding ability or drugs that specifically inhibit the constitutively activated AR splice variants may lead to novel therapies for castration-resistant prostate cancer.

# Molecular Mechanisms of Castrate Resistant Prostate Cancer

4

Francois Lamoureux, Amina Zoubeidi, and Martin E. Gleave

## Introduction

Cancer has replaced heart disease as the leading cause of death in North America – nearly half will develop cancer, and one in four will die from the disease [1]. Prostate cancer (PCa) is the most common male cancer in North America and 2nd leading cause of cancer deaths, but even more importantly, its incidence and mortality will double by 2020 based on current incidence trends. PCa represents 1 % of all death and 13 % of death by cancer [2]. While many gains have been made in early detection and treatment of localized PCa, many men still die of recurrent or metastatic disease. Androgen ablation remains the most effective therapy for patients with advanced disease. While ~80 % of patients initially respond, most patients progress to castrate resistant prostate cancer (CRPC) metastatic disease after 18–36 months [3–15]. Androgen ablation precipitates apoptosis in subpopulations of PCa cells, but despite high initial response rates, remissions are temporary because surviving tumor cells usually recur with a castrate resistant phenotype [15, 16]. CRPC progression is a complex process by which cells acquire the ability to both survive and proliferate in the absence of androgens and involves variable combinations of clonal selection [17], the reactivation of the androgen receptor axis [18], as well as adaptive upregulation of anti-apoptotic genes [19–25], alternative growth factor pathways [26–32], and cytoprotective chaperone networks [22, 33]. Clinically, CRPC is defined as biochemical and/or radiographic progression despite castrate levels of serum testosterone (<50 ng/ml) [34]. Biochemical progression is defined as two consecutive increases in prostate-specific antigen (PSA) above a minimal value of 5 ng/ml. Usually, progression occurs following cessation of treatment with androgen blockers for 4–6 weeks.

Many strategies used to kill cancer cells, including androgen ablation or docetaxel chemotherapy, induce a treatment-resistant phenotype [35, 36]. Hence, PCa, like most cancers, progresses and recurs after hormone and chemotherapy to a lethally resistant stage. This development of therapeutic resistance is the underlying basis for most cancer deaths and results from multiple, stepwise changes in DNA structure and gene expression – a Darwinian interplay of genetic and epigenetic factors, arising in part from selective pressures of treatment. This highly dynamic process cannot be attributed to singular genetic events, involving instead cumulative changes in gene expression that facilitate escape from normal regulatory control of cell growth and survival. Improved understanding of the molecular basis underlying metastasis and resistance to ADT or chemotherapy will facilitate to design new therapeutic strategies to inhibit the emergence of this CRPC phenotype.

This chapter will describe molecular and cellular mechanisms involved in CRPC progression and metastases, focusing on pathways that are currently targeted for treatment including the AR axis, growth factors and their receptors in survival pathways (IGF, IL-6, EGF), anti-apoptotic proteins such as Bcl-2 or molecular chaperones, and, finally, the influence of the microenvironment and the bone metastasis.

## Androgen Receptor Pathway in CRPC

The androgen receptor (AR) plays a critical role in the development of male reproductive organs [37, 38]. In normal development, androgens are primarily required for differentiation and growth. By contrast, during the

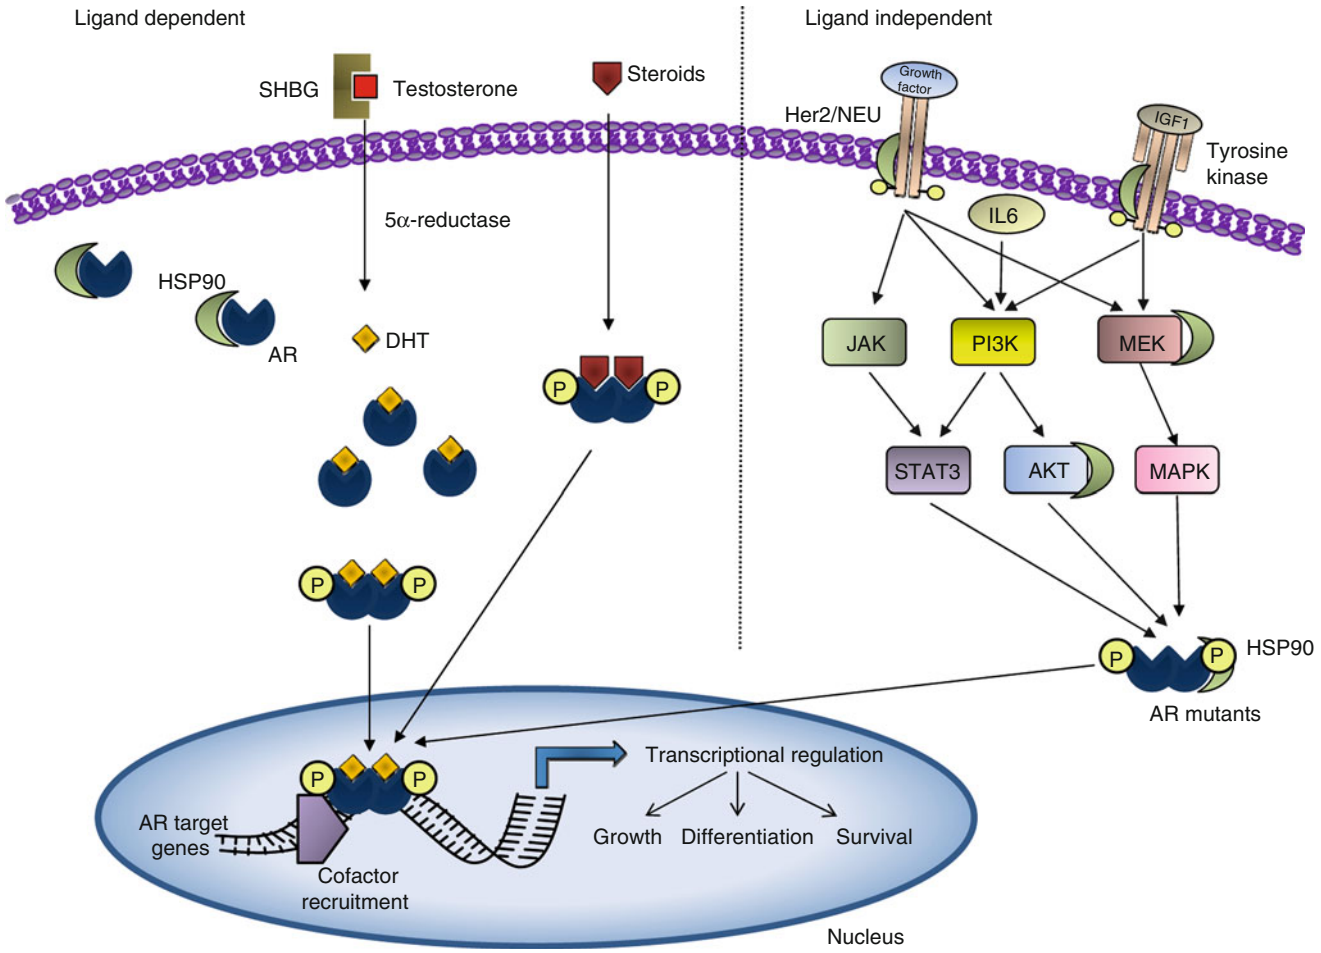

**Fig. 4.1** AR signaling in CRPC. Ligand-dependent pathway takes place through DHT or steroids stimulation of AR, while multiple signaling pathways, including PI3K and MAPK, stimulate and allow tumor cells to survive without androgens. These both ways (ligand dependent or ligand independent) induce cell proliferation, differentiation, migration, and survival. *AR* androgen receptor, *Hsp90* heat-shock protein 90, *IGF-1* insulin-like growth factor, *IL-6* interleukin 6, *SHBG* sex hormone-binding globulin, *DHT* dihydrostestosterone

development of PCa, androgen becomes a growth and survival factor for tumor cells.

Upon androgen binding, AR is phosphorylated and forms a dimer that translocates to the nucleus, where it binds to its specific DNA consensus site, termed androgen response element (ARE), on the promoter and enhancer regions of androgen-regulated genes, such as PSA, to initiate transcription. The transcriptional activity of AR is mediated by co-regulators (coactivators and corepressors) [39, 40] that, following androgen binding to AR, are assembled in a dynamic way at different ARE along the genome. The best recognized coactivators are the histone acetylases, such as p300 [41, 42] and the p160 SRC (steroid receptor coactivator) family [43–45]. These coactivators drive transcription by remodeling chromatin via histone acetylation and by recruiting RNA polymerase to the promoter.

As PCa initially progresses as an androgen-dependent, castrate sensitive tumor, androgen ablation therapy (i.e., surgical or medical castration) is highly effective in advanced stage of the disease. But this effect is short-lived, because castrate resistant subpopulations eventually emerge, resulting in treatment-resistant metastasis and mortality. Interestingly and despite ongoing growth post-castration, over 80 % of CRPC cases express AR and androgen-responsive genes, indicating that the AR axis remains activated, despite castration levels of testicular androgens. Three mechanisms have been postulated to account for aberrant AR activation in CRPC tumors: (1) activation of AR by nonsteroids such as growth factors and cytokines via multiple deregulated kinase signaling pathways; (2) amplification or overexpression of AR and its coactivators or chaperones, which sensitizes cells toward low levels of androgen; and (3) intratumoral steroidogenesis. These three mechanisms are not mutually exclusive and indeed likely work in concert to induce CRPC (Fig. 4.1).

## Nonsteroidal Activation of AR Via Kinase Signaling Pathways

The phosphorylation of the N-terminal domain (NTD) of the AR has been postulated as an underlying mechanism for a ligand-independent activation of AR by nonsteroidal agonists such as cyclic adenosine monophosphate (AMP)/protein kinase A (PKA), interleukin (IL)-6, and epidermal growth factor (EGF) [46–51]. Recently, splice variants of the AR that lack the ligand binding domain (LBD) have been reported in prostate cancer cell lines (LNCaP and 22Rv1) and also in CRPC patients [52–54]. These mutants are constitutively active and would not be inhibited by current therapies. Indeed, in vitro phosphorylation and activation of AR by serine/threonine kinases like the extracellular-signal regulated kinase (ERK) [28, 55], AKT [56], PKA [48, 57], and PKC [58] have been reported. IL-6 and EGF phosphorylate coactivators SRC-1 and SRC-2, respectively, which indirectly leads to activation of AR in CRPC [47, 50]. While serine/threonine kinases are direct modulators of AR and its transcriptional machinery, they are not the immediate effectors of growth factors or cytokines. Indeed, IL-6 and EGF both activate tyrosine kinases in PCa [59, 60] and induce AR phosphorylation on tyrosine (pTyr) via SRC and activated Cdc42-associated kinase (Ack) 1 [61–63].

Epidermal growth factor (EGF) has long been postulated to play a role in the regulation of AR transcriptional activity, especially under androgen-depleted conditions. However, the mechanisms by which growth factors modulate AR activity are not well understood. Though, several studies indicate it may be mediated by direct phosphorylation of AR or its cofactors through a kinase cascade involving tyrosine and serine/threonine kinases. Recently, Ack1 and SRC were demonstrated to phosphorylate AR, identifying the molecular basis for interplay between Ack1/AR and Src/AR signaling in PCa progression [61, 63]. Activated Ack1 phosphorylates AR on $Tyr^{267}$ [63] while SRC phosphorylates AR only on $Tyr^{534}$ [61, 62]. Recruitment of Ack1/AR complex at AREs results in androgen-induced gene expression in the absence of androgen with androgen-independent progression of prostate xenografts. EGF leads to AR phosphorylation on $Tyr^{267}$ via Ack1 and $Tyr^{534}$ via SRC [63]. Surprisingly, a small molecule inhibitor dasatinib targeting SRC and Ack1 activity abrogated EGF inducing AR phosphorylation on $Tyr^{534}$ but not EGF inducing AR phosphorylation on $Tyr^{267}$.

## Molecular Chaperones in Treatment Resistance and AR Stability

Molecular chaperones, including heat-shock proteins (Hsps) (described below), help cells cope with stress and act as genetic buffers stabilizing the phenotype of various cells at times of environmental stress. They enhance the Darwinian fitness of cells during transformation, progression, and treatment resistance [64]. Molecular chaperones are transcriptionally activated by heat-shock factor (HSF-1) and are involved in processes of folding, trafficking, and transcriptional activation of most steroid receptors, including AR. In the absence of ligand, AR is predominately cytoplasmic, maintained in an inactive but highly responsive state by a large dynamic heterocomplex composed of Hsp90 and Hsp70 and co-chaperones like FKBP52. Ligand binding leads to a conformational change in the AR and dissociation from the large Hsp90/Hsp70 complex. Subsequently, AR becomes associated with Hsp27, translocates to the nucleus, interacts with coactivators, and transcriptionally activates target genes [65, 66]. Dissociation of the AR-chaperone complex after ligand binding is viewed as a general regulatory mechanism of AR signaling [67]. Molecular chaperones remain important players in the events downstream of receptor activation and throughout the life cycle of the AR. For example, Hsp90 and Hsp27 inhibitors destabilize AR and increase its proteasomal degradation, thereby decreasing AR-regulated genes [66, 68]. Recent findings point out the importance of co-chaperones on AR activation. Hence, FKBP52, a co-chaperone, has shown to regulate AR transcriptional activity [69, 70], and FKBP52 knockout mice exhibited obvious defects in male reproductive tissue and prostate development [69, 70].

## Intratumoral Androgen Synthesis

Current androgen ablation strategies aim to inhibit gonadal androgen production. However, low circulating, and reasonably high intraprostatic, levels of androgens persist, in part due to peripheral conversion of adrenal steroids. Recent findings suggest that CRPC acquires the ability to synthesize androgen from cholesterol or adrenal precursors thereby creating an intracrine signaling system. Intratumoral steroidogenesis associated with overexpression of key enzymes including CYP17 can cause resistance to castration [71–73]. Cytochrome p450c17 (CYP17) catalyzes 2 essential reactions in androgen biosynthesis, including 17α-hydroxylation of $C_{21}$ steroids and cleavage of the $C_{17,20}$ bond of $C_{21}$ steroids [74]. These reactions are key in the biosynthesis of DHEA and androstenedione, precursors of testosterone and estradiol. Interestingly, Locke et al. demonstrated that cholesterol and its derivatives can be converted to androgens in prostate tumor cells through a series of well-characterized stepwise enzymatic events [72]. While androgen synthesis is often described in terms of the classical steroidogenic pathway through DHEA and testosterone, a recently described "backdoor pathway" can serve as an alternative synthesis pathway utilizing progesterone as the primary steroidal precursor of DHT, thereby bypassing T as an intermediate [74]. This evidence suggests that de novo androgen synthesis is one of the mechanisms leading to PCa progression following castration.

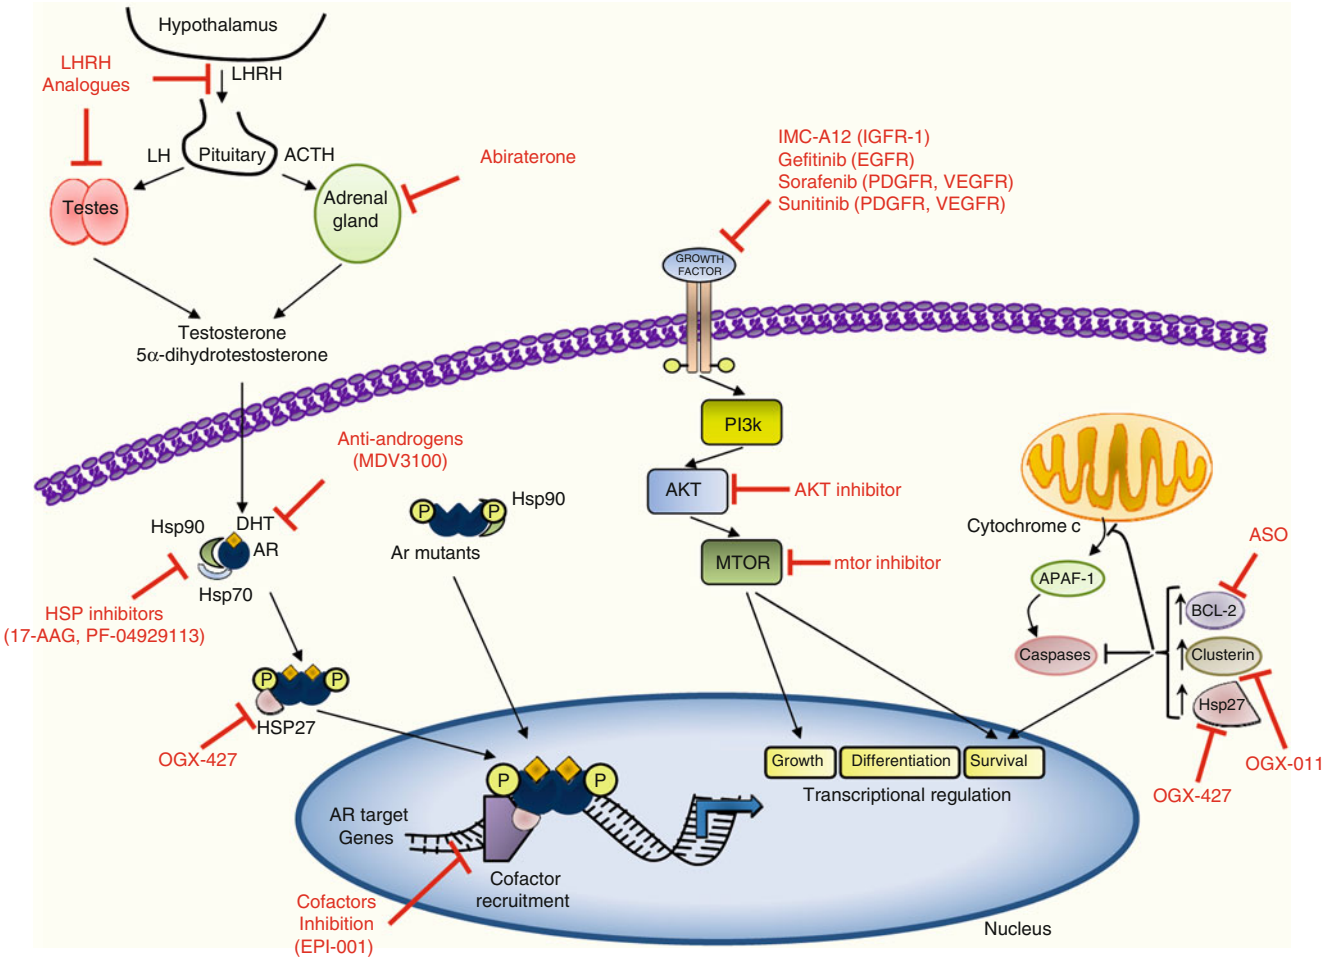

**Fig. 4.2** Molecular targets for the treatment of CRPC. *AR* androgen receptor, *BCl-2* B-cell lymphoma 2, *Hsp* heat-shock protein, *IGFR-1* insulin-like growth factor-1 receptor, *EGFR* epidermal growth factor receptor, *PDGFR* platelet-derived growth factor receptor, *VEGFR* vascular endothelial growth factor receptor, *mTOR* mammalian target of rapamycin, *LH* luteinizing hormone, *ACTH* adenocorticotropic hormone, *LHRH* luteinising hormone releasing hormone, *DHT* dihydrostestosterone, *ASO* antisense oligonucleotide

## Targeting Androgen Receptor Axis

Despite the failure of androgen blockage trials using nonsteroidal antiandrogens such as flutamide or bicalutamide, CRPC tumors are not uniformly hormone refractory and remain sensitive to therapies directed against the AR axis. Hence, several new classes of AR-targeting agents and molecules that destabilize AR are now in clinical development, including more potent AR antagonists (e.g., MDV3100), inhibitors of steroidogenesis (e.g., abiraterone, TAK700), and Hsp inhibitors (e.g., OGX-427, several Hsp90 inhibitors) (Fig. 4.2).

### Second-Generation Antiandrogens

MDV3100 is a second-generation, more potent nonsteroidal antiandrogen, rationally designed utilizing the AR crystal structure, modeling, and cell-based screening. Since bicalutamide has partial agonist activity in LNCaP cells that overexpress AR, candidate compounds were screened for pure antagonist activity in these cells. MDV3100 binds LBD of AR in cells with tenfold higher affinity than bicalutamide in competition studies and inhibits PSA secretion at tenfold lower concentrations. Preclinical studies showed that MDV3100 inhibits growth of castration-resistant xenografts [75]. Unlike bicalutamide, MDV3100 impairs AR nuclear translocation and blocks DNA binding [75]. Data from phase I/II trial suggest that MDV3100 treatment correlated with declining PSA, reduced circulating tumor cells, and radiographic disease stabilization [76]. Importantly, MDV3100 was active in both pre- and post-chemotherapy-treated patients [76], and it is currently in phase III trial in both pre- and post-chemotherapy-treated patients.

### CYP17 Inhibitors

Given its critical role in androgen biosynthesis, CYP17 has generated interest as a relevant biological target for CRPC. Several novel therapeutic entities that selectively inhibit

CYP17 are currently under clinical evaluation for CRPC. Abiraterone acetate is a highly potent, selective, irreversible inhibitor of CYP17.35, suppressing conversion of pregnenolone to DHEA and progesterone to androstenedione in the testes and adrenal glands. Abiraterone also appears to suppress de novo androgen production in prostate tumors, as evidenced by inhibition of CRPC growth in xenograft models devoid of testicular and adrenal androgens [73].

In phase I and II clinical studies of abiraterone acetate, 50–60 % of chemotherapy-naïve patients had a decline in PSA by 50 %, and the median time to PSA progression was about 230 days [77, 78]. Importantly, 20–30 % of patients had a 90 % PSA decline that was associated with a patient subgroup that had near complete radiological responses, normalization of CTC count, and PSA progression-free survival lasting longer than 1 year. Antitumor activity was reported at all doses from 250 to 2,000 mg daily, but 1,000 mg once daily was selected for phase II development due to a plateau in the feedback-driven increase of steroids upstream of CYP17 at 750, 1,000, and 2,000 mg daily [79]. Phase II studies reported significant antitumor activity in chemotherapy-treated patients, with a time to PSA progression of about 170 days, suggesting that docetaxel-treated CRPC remained hormone dependent [80, 81]. A phase III study comparing placebo to abiraterone in post-chemotherapy CRPC patients demonstrated a 4-month gain in overall survival from 12 to 16 months, supporting approval of abiraterone for this indication in 2011 [82].

### Chaperones Inhibitors

Inhibition of chaperones involved in AR stabilization is another promising approach to treat CRPC. Among these chaperones, targeting Hsp27 using antisense OGX-427 and Hsp90 using small molecule inhibitors have been used to disrupt AR axis and to delay CRPC, as described below (*3. survival regulation*; *c. cytoprotective molecular chaperones*).

## Growth Factors and Their Receptors

Development and progression of PCa involve a complex interplay of many growth factor-signaling pathways, including EGF, FGF, IGF, IL-6, and TGF, that collectively regulate cell differentiation, proliferation, migration, and survival [83, 84].

### EGF

Epidermal growth factor receptor (EGFR) and its ligands EGF, TGF-α, HB-EGF, and amphiregulin have been reported to correlate with high-grade PCa [83–88]. EGFR ligands are powerful mitogens for epithelial cells and fibroblasts that induce a sequence of events to increase the transcription activity of the pro-oncogene c-fos [89]. TGF-α, EGF, and EGFR are often overexpressed in PCa [90]. Several studies report high expression of EGFR associated with low expression of TGF-α in androgen-dependent tumors. However, in metastatic CRPC, co-expression of EGFR and TGF-α was found in the epithelial compartment [91]. These data suggest paracrine regulation of tumor growth during androgen-dependent stage, with autocrine regulation upon progression to androgen independence [91]. Tso et al. demonstrated that androgen suppression induces expression of EGFR in androgen-dependent LNCaP cells [92]. Furthermore, high expression of EGFR in androgen-independent PC-3 and DU145 cells correlates with autocrine activation [93]. The ability of tumor cells to auto-activate themselves could play a role in the androgen-independent tumor growth, because enabling tumor cells release critical growth factors for the cell proliferation and survival post-castration.

Activation of EGFR stimulates several mitotic cascades including MAPK, PI3K/Akt, nuclear factor kappa-β (NF-κB), phospholipase Cγ (PCγ), or Shc signaling pathways, all involved in cell proliferation, survival, motility, and invasion [84, 94, 95]. While this highlights EGFR as a therapeutic target in CRPC, unfortunately, EGFR inhibitors like gefitinib (250 mg or 500 mg) did not show any clinical activity in a randomized phase II study including 40 patients with CRPC [96].

### FGF

Fibroblast growth factors (FGF) are a family over 22 identified proteins secreted by the fibroblasts. The FGF family is involved in a many varied biological processes including embryogenesis, angiogenesis, and carcinogenesis [97–103] and is considered a key paracrine mediator of proliferation by stimulating mitosis of prostate stromal and epithelial cells [104–106]. The homeostatic balance of interactions between stromal and epithelial compartments is critical for prostate development and can lead to neoplastic transformation. In PCa, some members of the FGF family are involved in growth and survival of epithelial tumor cells by inducing Bcl-2 expression [107]. FGFR2IIIb is reported to be frequently lost or spliced to FGFR2IIIc isoform in epithelial cells during carcinogenesis [108, 109]. FGF8 can bind FGFR2IIIc, expressed in tumor cells suggesting an autocrine loop controlling the growth [110]. FGFR1 kinase is normally found in stromal cells and often expressed in prostate tumors [108, 111, 112]. The cooperation between the loss of FGFR2 and the ectopic expression of FGFR1 induces high-grade prostatic intraepithelial neoplasia (PIN) in mice [113]. Avecedo et al. reported that activation of FGFR1 induced the progression to adenocarcinoma involving the epithelial-mesenchymal transition [101]. This process is reversible after inactivation of FGFR1.

Additionally, FGF10 is reported to increase the expression of the epithelial AR leading to the formation of mutifocal PIN or adenocarcinoma [102]. All these data suggest that the FGF10/FGFR1 axis is a potential therapeutic target in the treatment of castrate sensitive or castrate refractory prostate cancer. Furthermore, FGF8 is reported to be frequently expressed in bone metastases of human prostate cancer and increases tumor progression in an in vivo intratibial PC-3 model of prostate cancer [114].

## IGF

The insulin-like growth factor (IGF) axis regulates cell growth, proliferation, survival, and metabolism through activation of the IGF-1 receptor (IGF-1R) tyrosine kinase and the mannose-6-phosphate receptor (IGF-IIR) [115–120]. Signaling proteins activated downstream of IGF-1R include extracellular signal-related kinase (ERK)/mitogen-activated protein kinase (MAPK), phosphate-inositol 3-kinase (PI3K), and Akt. IGF-1 signaling promotes tumorigenesis in a variety of human cancers [116]. Patients with PCa have higher serum IGF-1 levels, and the majority express high levels of IGF-1R [121–124]. IGF-1 is considered to be one of the most potent mitogens in PCa cells in vitro [121, 122]. Overexpression or activation of IGF-1R increases proliferation of transformed cells, activating many signaling pathways that converge to phosphorylate the pro-apoptotic protein BAD and block apoptosis. The transcription factor ELK is another endpoint of IGF-1 signaling, via that MAP kinase pathway. IGF-1 increases the expression of Hsp27 mRNA levels and induces Hsp27 protein phosphorylation. Many humanized antibodies or small molecules targeting IGF-1R are in early clinical development in CRPC such as CP-751,871, IMC-A12, or NVP-AEW541 [125–129]. However, cross-activity between IGF-1R and insulin receptor can induce toxicity and increased glucose.

In plasma or biological fluids, IGFs bind insulin-like growth factor binding proteins (IGFBPs) that are particularly involved in the tumor progression in PCa by modulating IGF/IGF-R biological activities [130–132]. IGFBPs are a family of six circulating proteins that bind IGF-1 and IGF-II and regulate IGF distribution, function, and activity [133, 134]. IGFBP-2, IGFBP-3, IGFBP-4, IGFBP-5, and IGFBP-6 are expressed in prostatic tissues and cell lines [135–139]. IGFBP-2 and IGFBP-5 are increased after castration in Shionogi and LNCaP models [140] and correlate with poor prognosis [135, 139]. Overexpression of IGFBP-5 in LNCaP cells increased cell proliferation in an IGF-1-dependent manner via PI3K and Akt/PKB activations and potentiates the anti-apoptotic effect of IGF-1 [29]. Knockdown of IGFBP-5 inhibited proliferation and tumor progression to CRPC [29, 141, 142]. IGFBP-2 levels also increase threefold in Shionogi and LNCaP models, as well as in human prostate tumors following androgen ablation [32, 140, 143]. Knockdown IGFBP-2 induces apoptosis and delays CRPC in LNCaP xenografts. All these data identify an important role for IGFBP-2 and IGFBP-5 in cell survival by potentiating the anti-apoptotic effect of IGF-1 and accelerating CRPC progression. Knockdown of IGFBP-2 and IGFBP-5 using the ASO OGX-225 promoted apoptosis and sensitized tumor to chemotherapy in preclinical models of human prostate, breast, bladder, and glioma cancers [144]. OGX-225 has completed preclinical pharmacology and is being evaluated for clinical trials.

## TGF-Beta

Under physiological conditions, TGF-beta inhibits prostate epithelial cell proliferation induced by EGF or FGF2 [145, 146]. In PCa, expression of TGF and their receptors are regulated by androgens. Consequently, androgen suppression increases expression of TGF-beta and betaglycans in human PCa cells to induce apoptosis [147]. The sensitivity of tumor cells to TGF-beta is correlated with the tumor aggressiveness [148]. In PCa, studies using human samples correlate loss of TGF-beta type II receptor (TBRII) with higher tumor grade [149–151]. TBRII transduces signals for TGF-beta in many pathways including growth inhibition, apoptosis, and differentiation [152–154]. Furthermore, TGF-beta I modulates cell adhesion, angiogenesis, and invasion in PCa [155]. High expression of TGF-beta I in bone can function as an autocrine-paracrine modulator of bone invasion in PCa [155] and has been implicated to play a paracrine role in CRPC progression [156].

## IL-6

Interleukin-6 is a pleiotropic cytokine that plays a central role in host defense mechanisms by regulating immune response and hematopoiesis and induces either differentiation or growth of a variety of cells. IL-6 modulates growth and differentiation of many cancers and is associated with poor prognosis in lymphoma, ovarian, and prostate cancer [157]. There is evidence that IL-6 is involved in development of CRPC [158–160]. Multiple studies demonstrate that IL-6 is elevated in sera of patients with metastatic PCa and IL-6 levels correlate with tumor burden, serum PSA levels, and metastatic burden [158, 159]. IL-6 functions as a paracrine growth factor in androgen-sensitive PCa cells (LNCaP) and as an autocrine growth factor in androgen-insensitive human PCa cells DU145 and PC-3 [161]. IL-6 induces neuroendocrine (NE) differentiation in LNCaP cells [60, 162, 163].

## Survival Regulation

### Bcl-2

Bcl-2 is an oncogene that contributes to neoplastic progression by enhancing tumor cell survival through inhibition of apoptosis [164]. In PCa, experimental and clinical observations strongly suggest that Bcl-2 plays a critical role in the progression to CRPC through inhibition of apoptotic cell death precipitated by androgen ablation [24, 165–170]. Moreover, Bcl-2 overexpression is also associated with survival in growth factor-deprived medium and resistance to heat-shock stress, several chemotherapies, and radiotherapy [23, 165, 168, 169, 171–175]. Intrinsic expression of Bcl-2 by PCa tissue may result in resistance to the effects of hormone manipulation because higher proportion of nonresponders or early relapsers to hormonal therapy occurred in patients strongly expressing Bcl-2 [176–178]. Tso et al. reported that an androgen-independent clone from androgen-dependent LNCaP cells was associated with decreased p53 and increased Bcl-2 expression [92]. Activation Bcl-2 inhibits p53-induced apoptosis without affecting cell proliferation [179]. Bcl-2 knockdown using ASOs synergistically enhanced the apoptotic triggers of androgen withdrawal or taxane chemotherapy in preclinical models [23, 24, 180–182]. These studies provided the preclinical proof of principle for the first phase I dose finding study of combined treatment with an Bcl-2 ASO (Genasense or oblimersen sodium) plus mitoxantrone in patients with metastatic CRPC [183] and a second phase I/II trial in combination with docetaxel [184]. Unfortunately, clinical studies in CRPC did not provide a clear signal of anticancer activity [185], putting future trials with this agent on hold. Issues persist about the dosing and regimen of this first-generation ASO and whether 6 days of 7 mg/kg/day treatment is enough to suppress target sufficiently.

### Cytoprotective Molecular Chaperones

Heat-shock proteins (HSPs) are a family of highly conserved proteins whose expression is induced by cell stressors such as hyperthermia, oxidative stress, and cytotoxic drugs [186–188]. HSPs have attracted attention as new therapeutic targets for cancer, especially since the discovery and characterization of geldanamycin as an inhibitor of Hsp90 [189, 190] and the targeting of *clusterin* [191], whose product has sHSP-like function.

#### Hsp27

Heat-shock protein 27 (Hsp27) is a 27-kDa molecular ATP-independent chaperone that forms oligomers during cell stress to inhibit protein precipitation and to regulate activity/degradation of certain client proteins [192]. The oligomerization status and chaperone activity of Hsp27 is regulated by stress-induced changes in phosphorylation involve three Ser residues catalyzed by p38 MAP kinase and other stress signaling pathways [193–196]. This phosphorylation is a reversible event modulating the oligomerization of Hsp27. Hsp27 sits as a "hub" at the center of many pathways regulating the response of a cell to stress and therapeutic stimuli. Similar to other chaperones, Hsp27 is a potent cell survival factor that contributes to thermotolerance [197]. Higher levels of Hsp27 are commonly detected in many cancers [188, 198, 199] including CaP [143, 200, 201], where it plays a role in cytoprotection, hormonal response, and molecular chaperoning. Hsp27 is highly overexpressed gene in castrate resistant LNCaP tumors in human CaP, and Hsp27 levels increase after hormone therapy to become highly expressed in CRPC [202].

Hsp27 interacts with many key apoptosis-associated proteins to regulate a cell's apoptotic rheostat through pathways involving both the intrinsic and extrinsic pathways. The intrinsic pathway functions primarily through intracellular death signals that trigger outer mitochondrial membrane permeabilization, leading to the release of cytochrome-c. Cytochrome-c interacts with Apaf-1 and caspase-9 to form the "apoptosome" which activates caspase-3, leading to an activation cascade of downstream caspases, the so-called "effectors" of cell death. The extrinsic pathway is activated through cell membrane associated proteins of the TNF receptor family (such as Fas, Trail-R1, Trail-R2, and others), which can trigger caspase-independent apoptosis or directly activate caspase-8, which leads to activation of the downstream effector caspases. Hsp27 prevents formation of the apoptosome, by either preventing release of mitochondrial cytochrome-c or directly sequestering cytochrome-c in the cytosol after mitochondrial release [203–205]. Also, Hsp27 may directly interact with and inhibit caspase-3 [206]. Hsp27 may also interfere with the extrinsic pathway by inhibiting Daxx, a mediator of Fas-induced caspase-independent apoptosis [207]. Hsp27 also inhibits apoptosis by decreasing reactive oxygen species within cells by increasing glutathione and reducing the toxic effect of oxidized proteins [208, 209]. In addition, Hsp27 can act early during a cell stress to stabilize and accelerate recovery of actin filaments, thus preventing disruption of the cytoskeleton [210, 211]. Hsp27 is also involved in regulation of the serine/threonine kinase AKT (protein kinase B), an important signaling molecule for cell survival and proliferation downstream of growth factor stimulation. Both MAPKAPK2 and Hsp27 are necessary for TGFβ-mediated increases in MMP-2 and cell invasion in human prostate cancer [210, 212, 213]. Finally, Hsp27 enhances NF-κB activity by facilitating proteasomal degradation of its main inhibitor I-κBα [214].

In addition to the above described generalized cancer mechanisms, Hsp27 also regulates ligand-activated AR and protein kinase D1 (PKD1) [66, 215]. Androgen-bound AR and PKD1 induce rapid Hsp27 phosphorylation on Ser(78) and Ser(82) residues that, in turn, enhance AR stability, shuttling, and transcriptional activity [66, 215]. Knockdown of Hsp27 using the Hsp27 inhibitor, OGX-427, decreases AR transcriptional activity, increases AR degradation via the proteasome, and induces apoptosis in AR-positive LNCaP cells [66]. In addition, Hsp27 expression and phosphorylation levels are correlated with IGF-1 signaling and CRPC progression [216]. IGF-1 induces Hsp27 phosphorylation via p90Rsk to promote CRPC progression. Hsp27 knockdown inhibits IGF-1-induced phosphorylation of p90Rsk and Akt destabilizing BAD/14.3.3 complexes, thereby inducing apoptosis [216].

This abbreviated summary illustrates that Hsp27 is associated with poor clinical prognosis and therapeutic resistance [22, 198, 217] highlighting that Hsp27 as a potential target for development of new therapies. Indeed, Hsp27 knockdown destabilizes BAD/14-3-3 complexes increasing apoptosis [216] and sensitizing cancer cells to hormone, chemo-, and radiotherapy [22, 202, 217]. Recently, inhibitors of Hsp-27 called triazol ribonucleosides (3-arylethynyltriazolyl ribonucleosides) were described to induce apoptosis in drug-resistant cancer cells [218]. Furthermore, others inhibitors such as biphenyl isoxazole KRIBB3 or p38 MAPK/MAPK-activated protein kinase 2 (MK2) inhibitors have been described to induce cell-cycle arrest and apoptosis [219] or to inhibit phosphorylation of Hsp27 at Ser78 and Ser82 by the MAPKAP kinase MK5 [220, 221]. Hsp27 knockdown with ASO (OGX-427) enhances apoptosis, sensitizes chemotherapy, and delays tumor progression in preclinical models [22]. OGX-427, a second-generation antisense inhibitor of Hsp27, has been tested in phase I/II clinical trials in many cancers, was well tolerated, and associated with decreased circulating tumor cells and reduced PSA levels in patients with CRPC [222]. OGX-427 is currently in phase II studies in CRPC.

## Hsp90

Hsp90 is a molecular chaperone that accounts for 1–2 % of all cellular proteins [223]. Hsp90 is a larger heat-shock ATPase-dependent chaperone [224] required for protein folding, maturation, and conformational stabilization of many "client" proteins, protecting them from degradation [225]. Its chaperone function involves a complex series of association with several co-chaperones including Hsp70, Hsp40, HOP, AHA1, and p23 [226]. Hsp90 interacts with more than 200 client proteins which some of them regulate proliferation and cell survival of tumor cells including growth factors receptors, cell-cycle regulators, and signaling kinases [64, 227, 228]. AR is a known client protein of Hsp90 [68, 229] that plays a key role in carcinogenesis and progression of CRPC. Thus, Hsp90 inhibitors like 17-AAG analogues are a rational approach to destabilize and disrupt nuclear localization of the AR in the treatment of CRPC [230]. For example, Lamoureux and al. demonstrated that Hsp90 inhibition using the novel inhibitor PF-04929113 inhibits LNCaP CRPC progression [229]. This activity is partially mediated by decreased AR levels, translocation, and activity. Her-2 is also one of the most important client proteins of Hsp90. Her-2 is often overexpressed in malignancies including PCa, inducing resistance to chemotherapy [231]. Several preclinical studies report a degradation of Her-2 after treatment with Hsp90 inhibitors (17-AAG, PF-04928473) [229, 232] supporting the therapeutic interest to target Hsp90 in PCa.

## Clusterin

Clusterin (CLU) is a stress-activated chaperone regulated by HSF1 that binds to a wide variety of biological ligands to potently inhibit stress-induced protein precipitation and stabilize protein conformations at times of cell stress [233–236]. While CLU is implicated in many physiological processes, its functional relationship to apoptosis has been studied most [237, 238]. In the prostate gland, CLU mRNA was originally cloned as "testosterone-repressed prostate message 2" (TRPM-2) from regressing rat prostate [239, 240], but CLU was reported as an apoptosis-associated gene protecting cells from apoptosis-inducing stressors, rather than as an androgen-repressed gene [33]. CLU expression increases following a diverse variety of stressors, including cytotoxic chemotherapy [21], radiation [241, 242], and androgen [33] or estrogen [243] withdrawal in hormone-dependent tumors.

CLU increases >threefold following androgen ablation and during CRPC progression. CLU is highly expressed in PCa specimens after neoadjuvant hormone therapy but low or absent in untreated low-grade tumors [33, 244]. Forced overexpression of CLU in LNCaP cells confers a hormone- and chemoresistant phenotype [21, 245]. Many reports document that CLU inhibits mitochondrial apoptosis, interacting with conformationally altered Bax to inhibit apoptosis in response to chemotherapeutic drugs [246]. In addition, CLU increases Akt phosphorylation levels and cell survival rates [247]. sCLU induces epithelial-mesenchymal transformation by increasing Smad2/3 stability and enhancing TGF-β-mediated Smad transcriptional activity [248]. CLU also promotes prostate cancer cell survival by increasing NF-kB nuclear transactivation, acting as a ubiquitin-binding protein that enhances COMMD1 and I-kB proteasomal degradation via interaction with E3 ligase family members. sCLU knockdown stabilized COMMD1 and I-kB, suppressing NF-kB translocation to the nucleus and suppressing NF-kB-regulated gene signatures [249].

This anti-apoptotic function for CLU results in broad-spectrum resistance to many anticancer therapies and

identifies it as a potential anticancer target. A CLU ASO inhibitor (OGX-011 or custirsen) has been developed that enhances cancer cell death after a variety of therapeutic stressors including hormone , radiation, and chemotherapy in preclinical models of prostate, lung, renal cell, urothelial, sarcoma, and breast cancers [21, 241, 244, 245, 250–258]. OGX-011 is a second-generation MOE gapmer ASO with prolonged tissue half-life of 7 days [250, 251]. Two Phase I trials evaluated OGX-011 given weekly by intravenous infusion as a single agent or in combination with docetaxel [259]. A novel presurgery study demonstrated that prostate tissue concentrations of OGX-011 increased with dose and tissue concentrations (>500 nM) associated with preclinical effect could be achieved. Moreover, >90 % dose-dependent decreases in prostate cancer cell CLU expression were also observed [191]. A randomized phase II trial of 82 chemotherapy-naïve patients compared docetaxel and prednisone with or without OGX-011. The OGX-011 group had a 6.9-month longer overall survival compared to docetaxel alone (16.9 months vs. 23.8 months), warranting further investigation with OGX-011 [260]. Phase III trials in CRPC began in 2010 (NCT01083615).

## Metastasis

Targeting the environment supporting metastatic growth is an expanding therapeutic strategy. Many biological processes promote site-specific osseous metastasis, such as extracellular matrix, angiogenesis, cell adhesions, and epithelial-mesenchymal transition (EMT). Underlying mechanisms and the therapeutic strategies targeting them will be discussed in this section (Fig. 4.3).

### Extracellular Matrix

Loss of cell adhesion is associated with degradation of extracellular matrix (ECM). Several proteolytic enzyme systems are involved in degradation of the ECM. Among them, urokinase plasminogen activator (uPA) and its receptors (uPAR) play an important role in tissue degradation, cell migration, angiogenesis, cancer invasion, and metastasis [261]. uPA is a member of the serine protease family and acts as a promoter of tumor progression in various human malignancies. Binding to uPAR, uPA converts the inactive zymogen, plasminogen, into the active serine protease, plasmin, which cleaves ECM components including laminin, fibronectin, vitronectin, fibrin, and collagen [262]. The uPA/uPAR system is associated with PCa metastasis. uPA and uPAR expression levels correlate with serum PSA levels and inversely correlate with overall survival in PCa [263]. Amplification of uPA gene is often found in CRPC metastatic lesions [264]. Moreover, uPA and uPAR are frequently overexpressed in tissues with high-grade primary tumors and lymph nodes metastasis and are related to PCa progression [265]. These results link uPA and uPAR to metastatic PCa and identify them as therapeutic targets to control metastasis and progression in CRPC.

### Angiogenesis

Angiogenesis is critically important for growth and metastatic development of tumors. Angiogenesis is regulated by a variety of factors, including growth factors, cytokines proteases, and adhesion molecules, released by tumor cells under stimuli such as hypoxia via the overexpression of hypoxia-inducible factor-1 (HIF1). Tumor cells also secrete factors involved in the activation of macrophages around the tumor, which are able to release other angiogenic factors and chemo-attractants to attract the endothelial cells [266]. Among the various angiogenic factors, vascular endothelial growth factor (VEGF) is the major angiogenic factor inducing migration and proliferation of endothelial cells by activating tyrosine kinase receptors VEGFR1 and VEGFR2. In PCa, the neo-angiogenesis density is correlated with the expression of VEGF and/or FGF [267].

Therapy targeting tumor neovasculature represents a promising area of research with more than 20 anti-angiogenic agents being evaluated in various phases of clinical trials [268]. Among the various angiogenic targets implicated in tumor angiogenesis, VEGF has evoked the most interest [269, 270]. While plasma VEGF levels are negative prognostic factors in CRPC [271], a phase III study of 1,020 patients using docetaxel/prednisone with and without the anti-VEGF monoclonal antibodies, bevacizumab, (CALGB 90401) reported no gain in overall survival.

Platelet-derived growth factor (PDGF) has also been linked to PCa bone metastasis and is expressed in 80 % of CRPC lesions [272]. Preclinical studies using imatinib mesylate (Gleevec®), a PDGF inhibitor, showed activity in prostate cancer cell lines, and a phase I trial of 21 patients with metastatic CRPC reported a 38 % PSA response rate [273]. However, a randomized phase II trial of imatinib and docetaxel in patients with CRPC showed increased toxicity without delaying progression. Sunitinib (Sutent®), vatalinib, and sorafenib (Nexavar®) are oral multi-targeted tyrosine kinase inhibitors that inhibit RAF kinase, VEGF receptor tyrosine kinase, and PDGF receptor, and are currently approved for treatment of metastatic renal cell carcinoma [274]. Unfortunately, phase II studies in CRPC [275–277] did not demonstrate consistent anticancer signals, and a phase III trial of sunitinib in docetaxel recurrent CRPC was closed early due to excessive toxicity and no survival benefit.

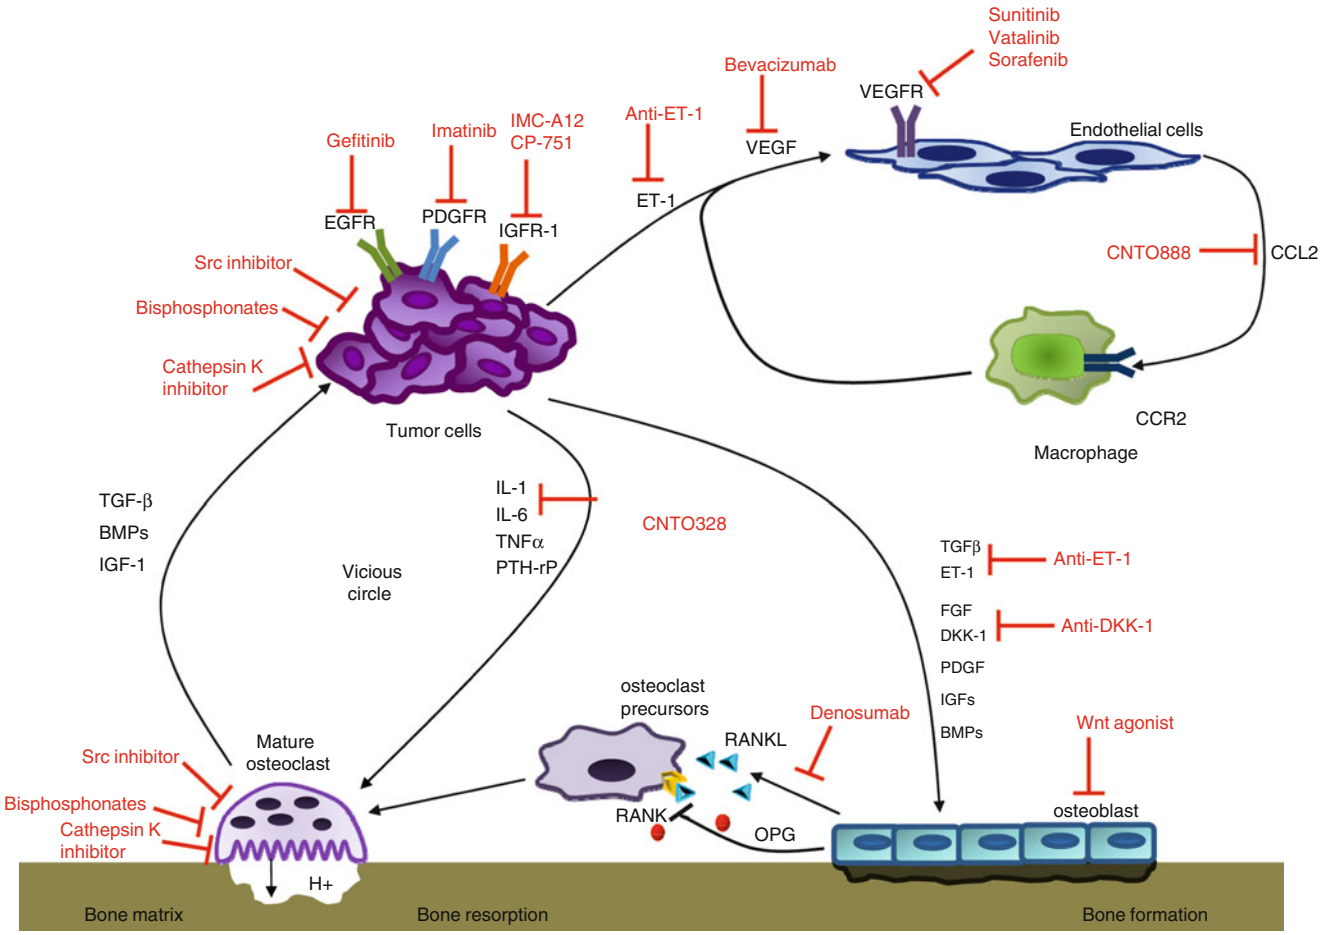

**Fig. 4.3** Therapeutic approaches in targeting bone metastasis in PCa. *IGF-1* insulin-like growth factor-1, *IGFR-1* IGF-1 receptor, *EGFR* epidermal growth factor receptor, *PDGFR* platelet-derived growth factor receptor, *VEGF* vascular endothelial growth factor, *VEGFR* VEGF receptor, *ET-1* endothelin 1, *TGF-β* transforming growth factor beta, *IL* interleukin, *TNFα* tumor necrosis factor alpha, *BMPs* bone morphogenetic proteins, *FGF* fibroblast growth factor, *DKK-1* Dickkopf-related protein 1, *OPG* osteoprotegerin, *RANK* receptor activator of NF-kB, *RANKL* RANK ligand, *PTH-rP* parathyroid hormone-related protein, *CCR2* chemokine (C-C motif) receptor 2, *CCL2* chemokine (C-C motif) ligand 2

Angiogenesis inhibitors have therefore been disappointing in CRPC to date.

## Cell Adhesion

Loss of cell adhesion increases migration, invasion, and, ultimately, vascular dissemination. In the prostate, the cadherin-catenin complex is a key regulator of cell-cell adhesion, whereas integrins mainly mediate cell-matrix adhesion. E-cadherin, β-catenin, and α-catenin are the best characterized in PCa to play important roles in cell-cell adhesion, in particular, post-androgen withdrawal. E-cadherin is attached intracellularly to the catin cytoskeleton via intracellular catenin. Beta-catenin, localized in the nucleus, induces cell proliferation and inhibits apoptosis, as well as the loss of E-cadherin expression, which is associated with EMT and resistance to hormone therapy.

Loss of E-cadherin leads to increased cell detachment and mobility [278, 279], whereas transfection of E-cadherin cDNA into invasive adenocarcinoma cells reverses this invasive phenotype [280, 281]. Indeed, E-cadherin is normally expressed in low-grade carcinomas, but its expression commonly decreases in high-grade cancers, bone metastasis, and poor prognosis [282–285]. However, McWilliam et al. found no correlation between E-cadherin expression and tumor progression or PCa death [286]. Interestingly, E-cadherin is re-expressed in metastatic CRPC [282], suggesting paracrine regulation from cells in the metastatic microenvironment. Rhodes et al. reported a correlation between low E-cadherin expression and PSA recurrence after radical prostatectomy, suggesting that the level of E-cadherin expression could be predictive of clinical outcome [287]. The results suggest that the loss of E-cadherin is important and can be considered as clinically relevant protein in the invasion-metastasis suppression, but it is not the only protein in the regulation of the metastatic cascade.

Beta-catenin is an adhesion molecule that binds E-cadherin via its intracytoplasmic domain to regulate signal transduction. Abnormal β-catenin expression is associated with poor prognosis in PCa [288] affecting the function of the cadherin-catenin complex. β-catenin can be mutated in PCa (<4 % of primary prostate tumors) [289], binding AR to enhance AR transcriptional activity and reduce effects of antiandrogen activity (i.e., bicalutamide) [289, 290].

Integrin expression, essential in the cell-matrix adhesion, varies between tumors, but overexpression of $\alpha_6$ and $\beta_3$ integrins was reported to increase invasion [291, 292] and plays an important role in the binding and migration processes at the metastatic site. Indeed, these integrins work together with matrix metalloproteinases (MMPs) to degrade the ECM and basement membrane [293] creating a breach in the membrane during invasion.

## Epithelial-Mesenchymal Transition

Malignant cells discard epithelial restraints and acquire invasive abilities that facilitate their dissemination to permissive microenvironments [294]. This epithelial-mesenchymal transition (EMT) is also a developmental program in which epithelial cells assume a mesenchymal phenotype during gastrulation and organogenesis, allowing single cell invasive movement away from the ectodermal layer [295]. Early carcinomas harboring oncogenic mutations (e.g., ras) are thought to undergo EMT as a result of contextual cell signaling responses to local tumor stromal signals in the inflammatory and hypoxic tumor microenviroment [296, 297]. EMT is activated by developmental transcriptional regulators, including Twist, Zeb1, and the Snail family transcription factors Snail and Slug [298]. These EMT transcription factors alter epithelial gene expression by repressing genes encoding epithelial junction complexes (e.g., E-cadherin) and cytokeratins and inducing expression of their mesenchymal counterparts, N-cadherin and vimentin. EMT is linked to metastatic progression and is associated with stem cell features and immunosuppression that collectively promote metastasis [299–301].

Several growth factors can induce EMT. IL-6 plays a central role in host defense mechanisms by regulating immune response and hematopoiesis and inducing differentiation or growth in a variety of cells. IL-6 induces neuroendocrine (NE) differentiation in LNCaP cells [60, 162, 163] and promotes EMT in breast cancer cells [302]. IL-6 overexpression in MCF-7 cells induces E-cadherin repression and increases vimentin, N-cadherin, Snail, and Twist [302]. IGF-1 induces EMT in epithelial PCa cells ($ARCaP_E$) [303, 304] and is associated with increased Zeb1, N-cadherin, and fibronectin expression [304]. Targeting Zeb1 by small interfering RNA (siRNA) in mesenchymal PCa cells $ARCaP_M$ [303, 304] abrogates IGF-1-induced cell migration and motility, induces upregulation of E-cadherin, and decreases N-cadherin and fibronectin. This suggests that IGF-1 induces EMT in $ARCaP_E$ cells via the IGF-1R-Erk-Zeb1 pathway [304].

TGF-β is a multifunctional cytokine that inhibits proliferation of normal prostate. Thus, targeting TGF-β signaling early in the tumorigenic process may mitigate its tumor suppressing activity and enable rapid tumor growth and metastasis in PCa [305]. CRPC and recurrent PCa frequently produce osteoblastic bone lesions stimulated by TGF-β released from the tumor microenvironment or bone matrix [306]. Interestingly, a strong correlation was found between elevated plasma TGF-β1 and PCa progression and metastasis in locally advanced disease patients [307]. Consequently, members of the TGF-β signaling family are being considered as predictive biomarkers and molecular targets for the prevention and treatment of metastatic PCa [308]. Indeed, elevated serum TGF-β is considered a poor prognosis marker [309, 310]. One mechanism by which TGF-β contributes to cancer progression is the induction of EMT. Upon TGF-β treatment, epithelial cells showed decreased expression of epithelial markers and enhanced expression of mesenchymal markers such as E-cadherin and vimentin, respectively [311]. TGF-β1 overexpression in the rat prostate carcinoma line resulted in enhanced primary tumor growth and both lung and lymph node metastasis after subcutaneous implantation. Targeting TGF-β1 with an antisense oligonucleotide inhibited primary tumor growth and metastasis [312]. Thus, TGF-β1 expression can enhance metastasis of rat prostate carcinoma cells. Mechanistically, TGF-β binds to cell surface receptors which in turn phosphorylate and activate Smad2 and/or Smad3. Smads then translocate to the nucleus and regulate gene transcription [313–315]. In advanced PCa, TGF-β enhances the metastatic ability of cells and provides a driving mechanism for high tumor vascularity [305]. TGF-β can also activate PI3K, MAPK, and p38 kinase signaling pathways in Smad-independent manner [316].

## Inflammation

Recently, inflammation has been functionally linked to metastasis [317]. Many inflammation-associated proteins, including tumor necrosis factor (TNF)-α interleukin-1 (IL-1), interleukin-6 (IL-6), interleukin-11 (IL-11), TGF-β, cyclooxygenase 2 (COX-2), NFκ, Stat3, stromal-derived factor-1 (SDF1), and hedgehog, facilitate PCa growth, tissue invasion, and, importantly, metastasis. Furthermore, inhibition of, for example, the COX-2 enzyme, which catalyzes the conversion of arachidonic acid to prostaglandins, has led to inhibition of tumor growth and suppression of metastasis in multiple cancers, including PCa [318]. Accordingly, inhibition of cancer-associated inflammation has emerged as a promising approach for treatment of metastatic PCa.

The nuclear transcription factor, NF-κB, is a key regulator of immune, inflammatory, and acute phase responses and has also been implicated in the control of cell proliferation and apoptosis [319]. It is overexpressed in many human cancers, including metastatic PCa [320, 321]. Stat3, which is both a cytoplasmic signaling molecule and a nuclear transcription factor, belongs to the seven-member Stat gene family of transcription factors. Recently, it has been reported that Stat3 is activated in PCa metastasis [322]. Hence, NF-κB and Stat3 may serve as potential targets for inhibition of metastatic progression of PCa. RTA 402, an NF-κB and Stat3 inhibitor, has demonstrated anticancer activity in preclinical studies and a recent clinical phase I pancreatic cancer trial [323]. This inhibitor is now moving into phase II trials. Moreover, several small molecule inhibitors for such targets are under preclinical development [324].

The chemokine stroma-derived factor, SDF-1/CXCL12, plays multiple roles in tumor pathogenesis, promoting PCa growth, enhancing angiogenesis, contributing to immune-suppressive networks within the tumor microenvironment, and facilitating tumor metastasis [325, 326]. The interaction of CXCL12 and its receptor CXCR4 leads to mitogen-activated protein kinase and phosphoinositide 3-kinase/Akt-mediated MMP-9 expression, migration, and invasion of PCa cells [327]. A wide variety of strategies, based on peptides (e.g., T22) [328], small molecules (e.g., AMD3100) [329], antibodies [330], and small interfering RNAs [331], have been used to target this pathway. Treatments in combination with current therapies seem to be especially promising in preclinical studies, and compounds are advancing into early stages of clinical development [332].

The hedgehog pathway has also been implicated in PCa development and metastasis [333]. The multi-transmembrane protein, patched (PTCH), is the receptor for various hedgehog ligands (Sonic, Indian, and Desert). In the absence of hedgehog, PTCH inhibits Smoothened (SMO), a G protein-coupled receptor protein encoded by the SMO gene of the hedgehog pathway [334]. When hedgehog binds to PTCH, SMO is disinhibited and initiates a signaling cascade that results in activation of GLI transcription factors and increased expression of target genes (including PTCH and GLI1). Inhibition of the hedgehog pathway induces apoptosis and decreases tumor invasiveness of PCa cells. For example, IPI-926 (Infinity Pharmaceuticals, Inc.), a small molecule inhibitor of the hedgehog-signaling pathway, has shown potent efficacy and specific inhibition of the hedgehog pathway in multiple preclinical animal cancer models. Currently, IPI-926 is in a clinical phase 1 trial for patients with advanced and/or metastatic solid tumors. GLI2 knockdown in preclinical models induces apoptosis, inhibits cancer growth, and chemosensitizes cells to chemotherapy in vitro and in vivo, providing preclinical proof of principle for CRPC [335]. The approach of regulating cancer-associated inflammation is a promising treatment strategy for a variety of tumors, including PCa.

## Site-Specific Bone Metastasis

Bone metastases represent 98 % of malignant bone tumors and are the most frequent metastases occurring in PCa. It estimated that 30–50 % of patients with PCa will develop bone metastases with the progression of the disease. Indeed, these bone lesions are often associated to pathological fractures, palpable mass, bone loss and/or formation, spinal cord compression, and severe bone pain [336].

The discovery by two different groups in 1997 of receptor activator of nuclear factor κB (NF-κB) (RANK) [337] and RANK ligand (RANKL) [338, 339] and decoy receptors osteoprotegerin (OPG) [340, 341] have allowed a better knowledge of the molecular mechanisms involved in the regulation of bone remodeling. In bone, OPG and RANKL are expressed by osteoblasts and bone marrow stromal cells whereas RANK is found at the surface of mature osteoclasts and osteoclast precursors. The binding of RANKL to RANK on pre-osteoclasts induces their differentiation, maturation, and activation leading to bone resorption. Therefore, RANKL is an essential mediator of osteoclast formation, function, and survival, whereas OPG, a decoy receptor for RANKL, operates as a real competitor of RANK/RANKL interaction and prevents this latter to interact with RANK. Consequently, OPG inhibits the osteoclastic differentiation and activation, leading to protection against bone loss.

Metastatic development within bone relies on a "vicious cycle" between bone resorption and tumor proliferation [342, 343]. Bone pathology from metastases is associated with altered expression of cytokines involved in the regulation of bone remodeling, including OPG, RANK, and RANKL (RANK Ligand), all members of the TNF (tumor necrosis factor)/TNF receptor superfamilies. Indeed, tumors in bone environment produce factors such as parathyroid hormone-related peptide (PTH-rP), which increases RANKL production by osteoblasts or by bone marrow stromal cells promoting differentiation, activation, and maturation of pre-osteoclasts into mature osteoclasts. Tumor cells also secrete various factors such as interleukin (IL)-6, IL-11, TNF-α, IL-1α, colony stimulating factor-1, or macrophage inflammatory protein-1α activating osteoclasts, which degrade the bone matrix. Bone matrix also store and release growth factors (e.g., IGF-1, TGF-beta) or chemo-attractants (e.g., SDF-1) to attract tumor cells and stimulate osteoblast proliferation [344–346]. Predominantly produced by stromal cells or osteoblasts, RANKL may be produced by tumor cells themselves increasing osteoclast activity and leading to excess bone loss [347–350].

The discovery in the past few years of this OPG/RANK/RANKL triad and its role in pathophysiology of skeletal metastasis has led to promising therapeutic targets [351–354]. For example, as OPG blocks the RANK/RANKL interaction, it represents a potent antiresorptive molecule to use in degradative bone pathologies by tumors [340, 343, 346, 355–357]. Furthermore, denosumab, a human monoclonal antibody that neutralizes RANKL in the tumor-bone microenvironment, inhibits osteoclastogenesis and bone degradation associated with prostate and other cancers. Randomized clinical studies of denosumab in metastatic PCa and elevated bone marker uNTX levels have shown promising results in normalizing uNTX more frequently than bisphosphonates [358]. Double-blind randomized phase 3 clinical trial is ongoing in CRPC patients with detected bone metastasis (e.g., ClinicalTrials. Gov Identifier: NCT00286091).

Endothelins (ETs), especially ET-1, and their receptors, ET-AR and ET-BR, are often overexpressed in tumor playing a role in tumor cell proliferation, angiogenesis [359], as well as osteoblasts proliferation increasing bone density in PCa bone metastasis [360, 361]. Several antagonists of ET-AR, including atrasentan and ZD4054, exhibited promising phase II results in CRPC [362]. Unfortunately, several phase III trials of atrasentan and ZD4054, either alone or in combination with docetaxel, were negative, and further targeting of this axis is unlikely.

Others important pathways in bone metastasis include Src, cathepsin K, RANKL, and WNT pathways. SRC expression is correlated with tumor progression and metastasis [363], and SRC inhibitors currently in clinical trials include saracatinib (AZD0530: phase II trial; NCT00558272) and dasatinib (phase III trial; NCT00744497). Cathepsin K is a key enzyme involved in osteoclastic bone resorption and bone matrix degradation [364]. Cathepsin K is often expressed in cancers with high tendency to metastasize to bone including PCa [365]. Several inhibitors of cathepsin K were developed including L006235 or odanacatib (MK-0822). Odanacatib is in clinical development [366] and showed reduced urinary NTx bone marker after 4 weeks in a randomized phase II study in metastatic breast cancer [367]. Wnt pathway is a major signaling pathway in osteoblasts and is regulated by soluble antagonists including DKK-1. DKK-1 increases RANKL/OPG ratio enhancing osteoclastogenesis. In a recent study, DKK-1-neutralizing antibodies increased the number of osteoblasts, reduced number of mature TRAP-positive osteoclast, reestablished the bone mineral density, and decreased the tumor volume in treated mice in myeloma model [368] indicating that targeting Wnt/DKK1 pathway is a rational therapeutic strategy for bone metastasis by regulating osteoblastogenesis and osteoclastogenesis.

*Christine Galustian and Oussama Elhage contributed equally.*

## Prostate Cancer and the Immune System

The concept that cancer can be eliminated by the immune system has been put forward over 100 years ago [1]. At this time, it was already thought that immune effector cells can recognize cancer cells as non-self and can eliminate them in the same way as viral or microbial pathogens. Both the innate immune system and the adaptive immune system have a major role in the control of tumor cell growth. The innate immune system consists of nonantigen-specific cells including macrophages, dendritic cells, neutrophils, natural killer cells, gamma delta T cells, and complement. The adaptive immune system consists of cells such as antigen-specific cytotoxic and helper T cells and antibody-producing B cells which can obtain a memory phenotype against specific antigenic challenge. The result is the ability of the different immune cell types to recognize cancer cells as foreign [2]. Antigens produced by tumor cells are known to be recognized by T cells and B cells, and both tumor antigen-specific T cells and antibodies against tumor antigens can be detected in patients with cancers such as melanoma, ovarian cancer, colorectal carcinoma, and hepatocellular cell carcinoma [3, 4]. Tumor-related antigens fall into a number of types including unique patient or shared tumor-specific antigens, antigens which are in both tumors and normal tissues, and antigens derived from tumor-associated viruses. In prostate cancer, a number of antigens are expressed which can be used for prostate cancer diagnosis or monitoring and some viruses are also thought to be associated with prostate cancer pathogenesis (Table 5.1).

Tumor elimination is initiated by the initial recruitment of immune cells including either neutrophils, monocytes, and macrophages to the site of the tumor, normally through the presence of acute or chronic proinflammatory signals which are produced by normal or tumor cells reacting to the tumor microenvironment [13, 14]. These cells release cytokines and chemokines such as IL-8 and IL-6 which will attract T cells and NK cells to the sites of the tumor. Inflamed endothelium in these areas also expresses E-selectin, which will recruit cells such as T and B lymphocytes and neutrophils which express carbohydrate ligands such as Lewis x and sialyl Lewis X. Once T cells and NK cells enter tumor lesions, they will secrete other chemokines and cytokines such as interferon gamma and IL-2 and IL-12 for further recruitment of T cells, NK cells, B cells, and Dendritic cells – the latter cells are critical in taking up antigens for presentation to helper T cells in the lymph nodes for creation of antigen-specific T cells and for creation of an antibody response against the tumor antigens. B cells also take up antigen for processing either through T cells or independently and can process antigen for antibody production. During the last stages of the elimination phase, tumor-specific CD4 helper and CD8

**Table 5.1** Tumor associated and viral antigens in Prostate Cancer

| Type of tumor-associated antigens | Example in prostate |
|---|---|
| Unique point mutation-specific tumor antigens | Spas-1 [5] |
| Tumor-specific antigens | Cancer–testis antigens, for example, NY-ESO1 [6] |
| Overexpressed antigens (greater expression in tumor vs. normal tissue) | GAD1 [7], CARM-1 [8], PSMA [9], PSA [10], Dickkopf-1 [11] |
| Viral antigens | Epstein bar virus and human papiloma virus 18 [12] |

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_5, © Springer-Verlag London 2013

cytotoxic T lymphocytes from the lymph nodes and tumor-specific antibodies infiltrate the lesion to eliminate the tumor cells, with some antibodies acting through ADCC (antibody-dependent cellular cytotoxicity) via Fc receptors on NK cells.

## Immunoediting

The concept of tumor elimination by the immune system has been superseded by a new hypothesis, known as *immunoediting* [15] which is relevant in many cancers including prostate cancer. In this hypothesis, there is the initial phase described above where the immune system can recognize and actively react and eliminate tumor cells appearing within a normal tissue environment; however, there are two further phases known as equilibrium and escape.

In the equilibrium phase, there is a balance between the destruction of tumor cells by the immune system and the proliferation of new tumor cells in the lesion. The new cells formed are eliminated in due course, but the immune system cannot eliminate the lesion completely. In prostate cancer and breast cancer, this phase may last for many years with either a minimal residual tumor volume obtained after surgery or radiotherapy or with small tumors that are nonpalpable and therefore not detectable [16]. Although reasons for this equilibrium state are as yet unclear, the coexistence of tumor cells with immune cells has been observed in a number of animal models.

The third stage of the hypothesis is known as *escape*. In this phase, cells may be growing at a rapid or slow rate, but are now able to evade the immune system by one or more of a number of techniques. These include the production of factors to prevent attack or masking of the cell surface by a loss or alteration of surface antigens such as MHC molecules, or the ability to move away from the site of capture (metastasis). Such cells that are growing in the presence of an ongoing immune response have either grown to resist the immune system by selective pressure or have an inherent or induced genetic predisposition to evade recognition or to inhibit the effector cells that they encounter.

## Factors that Cause Immunosuppression in Prostate Cancer

There are a number of immunosuppressive factors that the tumor cells themselves or the cells or stroma of the tumor microenvironment are able to produce to enable to continue existence of a cancer population. The microenvironment of the cancerous prostate has been shown to be very immunosuppressive, and prostate cancer cells are frequently poorly immunogenic, that is, unable to give rise to an immune response.

### Suppressive Immune Cell Populations Within the Prostate Tumor Environment

Although the infiltration of functionally active lymphocytes into tumor lesions is a favorable state for elimination of the tumor cells, in high-grade prostate cancer, immune infiltrates of CD3+ T cells are significantly diminished [17]. Also, immune infiltrates have been shown to frequently consist of anergic or suppressive T cell populations such as CD4+CD25+FOXP3+ regulatory T cells (known as Tregs) and also a rarer CD8+CD25+FOXP3+ population [18]. Both these cell types suppress both T cell proliferation and activity and NK function. Other suppressor populations appearing in the infiltrate are myeloid suppressor cells – these are immature myeloid cells which are either resident in the tissue or migrate there through recruitment, but have a suppressor function against dendritic cells, T cells, and NK cells in the tissue. The phenotype of these cells is not well characterized, but is thought to consist of Cd33+CD11b positive cells. The suppressive cells are either recruited into the tumor lesion by chemokines secreted by the tumor itself, or they are formed from active nonsuppressive effector cell populations through the functions of cytokines secreted from the tumor or stromal tissue [19]. For example, prostate cancer cells and the cells of their surrounding environment such as fibroblasts can secrete TGF beta, IL-2, and IL-10 which can actively induce the production of Tregs and myeloid suppressor cells. Although Tregs can naturally occur in the immune system, they are of thymic origin, and therefore as the thymus is absent or atrophied in old age, the Tregs of prostate cancer patients (who are diagnosed later in life) are thought to be induced in the tumor environment itself. The molecule indoleamine 2,3-dioxygenase (IDO) secreted by myeloid suppressor cells and by fibroblasts and other stromal components also suppresses T cell and NK cell function.

### Suppressive Stroma-Associated Proteins in the Prostate Cancer Environment

A number of suppressive prostate-associated proteins have also been discovered, for example, fibroblast-associated protein (FAP-1) and ps20 [20, 21]. These proteins are secreted in the normal prostate microenvironment, but higher levels are associated with cancer progression with the proteins being expressed by the tumor cells in addition to the stromal cells. Their inhibitory functions have not been well

characterized, but they can inhibit proliferation and function of effector T cells and NK cells.

### Complement Regulatory Proteins

Complement attack of tumor cells can happen through direct antibody involvement or through ADCC mechanisms, as described previously. The inhibition of complement by tumor cells is an evasive mechanism, which attenuates the effects of antibodies toward tumor antigens and also may reduce the efficacy of antibody therapies such as Herceptin [22]. Membrane-bound complement regulatory proteins such as CD46, CD59, CD55, and CD97 (a receptor for CD55) are known to be expressed frequently on tumor cell populations [23, 24], and the receptors CD55 and CD97 are upregulated in prostate cancer biopsies from primary and metastatic disease and in patients with prostate intraepithelial neoplasia (PIN) compared to biopsies from normal prostate [25].

### Loss of Antigenic Proteins

MHC class I antigens are expressed on almost all human-nucleated cells and play a vital part in the antiviral and antitumor immune response by their ability to present intracellular protein-derived peptides to antigen-specific cytotoxic T lymphocytes (CTLs). In many cancers, including prostate cancer, there is a dramatic loss of MHC class I antigen with tumor progression, and 100 % of prostate metastases have no class I-expressing cells [26] Also, in one study, expression of class 1 protein, corresponding to an HLA-A genotype, has been shown to be partially or completely lost in approximately 90 % of the tumors examined: However, only 8 % of these patients also had a deletion of the HLA-A1 and HLA-A2 alleles – so that the loss of expression is mostly at the translational level [27]. Upregulation of expression of MHC class I protein on the cell surface is possible with some immunotherapeutic, chemotherapeutic, and radiotherapy regimens. For example, interferon gamma upregulates MHC class I expression on prostate cancer TRAMP-C1 MHC class I negative tumors [28]. Radiotherapy upregulates a number of cell surface molecules including MHC class I and FAS (CD95) that make tumor cells more susceptible to T cell-mediated immune attack [29]. Chemotherapeutic drugs such as 5-Aza-2′-deoxycitidine also increase expression of class I on a number of tumor cell lines including those of prostate cancer [30].

### Expression of Inhibitory Receptors

Tumor cells can also be eliminated by their lack of expression of MHC class I antigens which are monitored by NK cells through the missing self-hypothesis [31]. However, this hypothesis has also been modified on the discovery of families of inhibitory receptors on NK cells and their corresponding ligands on tumor cells [32, 33]. Such families of receptors including the KIR [32, 34] and LILR receptors [35–38] (which were originally discovered in myeloid cell populations such as monocytes and dendritic cells) and their ligands including nonclassical MHC molecules such as HLA-G [37, 39–41] and HLA-E [42] can promote potent immunosuppressive functions, and tumor cells commonly express these ligands in prostate cancer.

## Immunotherapy Strategies

Various ways to exploit the immune system to treat prostate cancer are being tried clinically. Either employing a whole tumor cell or part of its components is usually used to elicit a specific immune response. Below is a range of immunotherapy strategies.

### Cell-Based Immunotherapy

The concept of cell-based immunotherapy is to expose a whole tumor cell to the immune system to evoke a response to multiple antigens, thus acting as a vaccine. The allogeneic tumor cells are introduced into the patient where these cells can attract antigen-presenting cells (APCs) to the site of introduction. The introduced cells are destroyed and taken up by APCs, which present the antigen to T cells and activate T cell cytotoxic activity toward tumor cells in the patient. Dranoff et al. examined the immunogenicity of irradiated melanoma cells in mouse models [43]. Retroviral gene transfer of some cytokines into the tumor cells was used to enhance the immunogenicity of the tumor cells. Irradiated transduced vaccine tumor cells were injected. A high level of CD4+ and CD8+ T cell immune responses was observed. The GM-CSF attracts antigen-presenting cells to the injection site. Other cytokines did not show similar antitumor activity [43]. The treatment works by recruiting antigen-presenting cells (APC) such as dendritic cells to injection sites. The vaccine cells are lysed, and the debris are taken up by APC, resulting in TH1 and TH2 cell activation which activates cytotoxic cell tumor lysis.

The whole cell allogeneic immunotherapy treatment has been developed further and has used prostate cancer cell lines including the hormone-sensitive cell line LNCaP and hormone-resistant cell line PC3. In a phase II trial studying the effect of this type of treatment, dendritic cells and macrophages in addition to eosinophils were present at site of intradermal injection confirming the ability of the transduced cells to secrete GM-CSF in vivo [44]. Several patients mounted LNCaP and PC3 reactive antibodies. There is a

possible correlation between the antibody titre and time from vaccination. This treatment strategy exposes multiple tumor antigens to potentiate the antitumor immune response.

## Antigen-Based Immunotherapy

This strategy focuses on one antigen to evoke an antitumor immune response.

Various tumor-associated antigens (TAA) have been studied for this type of treatment. Three of them have been targeted. Prostatic-specific antigen (PSA) is a glycoprotein and a serine protease enzyme secreted by the epithelial cells of the prostate gland. Another antigen is prostate acid phosphatase (PAP), which is expressed in vast majority of prostate cancer cells. The third antigen is prostate-specific membrane antigen (PSMA). The selected antigen can be carried and introduced to its target using various mechanisms including a virus vector or DNA plasmid or using one of the host's own antigen-presenting cells as a vehicle. These methods are discussed in more detail below.

### Viruses as Antigen-Carrying Vector-Based Immunotherapy

A vaccine is used as a vehicle for the targeted antigen. The most commonly used vector is vaccinia virus as prime vaccine and fowlpox virus as booster vaccine (PROSTVAC VF). This vaccine has a DNA plasmid-encoding PSA, in addition to costimulatory molecules (lymphocyte function-associated antigen 3 LFA3, CD80, and intracellular adhesion molecule 1 (ICAM1)). All three molecules form the triad of costimulatory molecules (TRICOM) and are designed to synergistically enhance T cell proliferation [45]. The viral vector is injected intradermally infecting epithelial cells which eventually die with cell debris including the PSA as antigen which is taken up by antigen-presenting cells (APC) and present it to CD4+ and CD8+ which leads to immune responses against PSA-producing cancer cells. The immune response can be limited by antibody responses to the viral protein rather than the encoded antigen. This type of treatment is effective if cancer is caused by viruses (HBV, HPV) as the vaccine would be used as a preventive measure.

Virus-based vaccine strategy is limited to the small number of virus options that can be used; in addition, there is the need for a repeated booster dose. The immune response can be dual in effect, one against the viral vector which the undesirable but sometimes inevitable response and the other one against the target antigen carried in the vector virus which the desirable response. Plasmid DNA-based vaccines aim to avoid the disadvantages of having a carrier viral vector and use plasmid to carry the genetic code for the desired antigen to generate an antigen-specific T cell response. A plasmid vector is used to encode an antigen sequence, for example, PAP, and is injected intradermally with or without GM-CSF [46, 47] to elicit the desired immune response.

### Antigen-Presenting Cell-Laden-with-Antigen-Based Immunotherapy

In this type of approach, the antigen is loaded onto autologous APC. A recently Food and Drug Administration (FDA) approved treatment (Sipuleucel-T, Dendreon) is composed of autologous APCs which are loaded with PAP fused with GM-CSF [48]. This fusion protein is called PA2024 and is designed to help with antigen presentation by upregulating costimulatory molecules. The treatment starts by isolating the patient's dendritic cells (DC) by leukapheresis. Then, the cells are incubated with the fusion protein for 40 h. The cells take up the protein. The product is then injected intravenously into patient. GM-CSF mediates PAP presentation. The elicited immune response includes activation of CD4+ and CD8+.

## Antibody-Based Immunotherapy

The preferred antigen for this type of approach is PSMA, which is a transmembrane glycoprotein. It has an internalization motif which makes it ideal target for monoclonal antibodies [49]. An anti-PSMA antibody has been developed in the mouse and is deimmunized (J591). The antibody is labeled with a radioisotope $^{177}$lutetium. The antibody aims to bind the target prostate cancer cells where the radioisotope gamma emissions induce cell death [49, 50].

Another antibody used in immunotherapy is anti-CTLA-4. This is a monoclonal antibody also known as MDX-010 or Ipilimumab. This antibody targets the immune system rather than the tumor. CTLA-4 (Cutaneous lymphocyte antigen-4) is an immunoregulatory molecule on T cells which competes with CD28 on T cells to bind to B7.1 and B7.2 antigens and thus regulates T cell activation. The deficiency of CTLA-4 results in lymphoproliferative disorders [51], and the immune suppressive function of Tregs depends on CTLA-4 [52]. Inhibition of Treg activity by anti-CTLA4 can therefore potentiate anti-tumour immunity by activation of T cells [53, 54].

## Conventional Treatment and Immunology

Conventional prostate cancer treatment modalities such as hormone, radiotherapy, and chemotherapy alter the immune system.

Androgen ablation may boost the antitumor immune response. CD4+ number in the prostate gland increases after treatment with antiandrogen, expansion of naïve T cells, increase in effector T cell response, and production of prostate-associated antibodies. All indicate that androgen deprivation may facilitate a favorable antitumor environment [55]. Radiation treatment has similar effect on immune system. Hurwitz et al. found that in 13 prostate cancer patients treated with radiotherapy, there was increased number of CD8+ and NK cells in addition to higher level of heat shock protein

(HSP) 27 level. HSP27 acts as immunomodulator and has a role in activating cytotoxic T cells [56]. Another protein (HMGB1) is released by radiotherapy-treated dying cells; Apetoh et al. found that HMGB1 is the primary ligand for TLR4 which activates dendritic cells and provoke T cell response. The combination of these conventional treatment modalities with the new immunotherapeutic modalities is being explored in various trials [57].

## Clinical Trials in Prostate Cancer Immunotherapy

### Cell-Based Immunotherapy

#### GVAX

The GVAX platform involves injecting tumor cells to provoke immune response, thus presenting to the immune system a cocktail of antigens, which increases the likelihood of a tumor-specific immune response [43]. The tumor cells are genetically modified to secrete GM-CSF. Two cultured allogenic prostate cancer cell lines are used, PC3 and LNCaP. Cell lines are genetically modified to encode the GM-CSF gene and are irradiated to prevent proliferation.

The initial dose escalating study recruited 80 hormone refractory metastatic prostate cancer patients. Symptomatic patients were excluded from the study. Five dose levels were used. Patients divided into three different groups: low-dose, moderate-dose, and high-dose groups. Treatment ranges from once every 28, 14, and once, and it lasted for 6 months; doses started at $100 \times 10^6$ cells. The study was stopped prematurely due to disease progression in 90 % of patients in addition to adverse events in 2 %. However, it did record that the antibody response was proportional to dose and was highest for the high-dose group (89 %) and lowest for the low-dose group (43 %). The median survival was 35 months (high dose), 20 months (moderate dose), and 23 months (low dose) groups, respectively. PSA stabilized in 19 % of patients. The study couldn't determine a maximum tolerable dose [54].

In a phase III trial by the same group, GVAX was compared to docetaxel and prednisolone treatment for castrate resistant metastatic prostate cancer patients. Six hundred and twenty six patients were recruited from more than 100 centers in North America and Europe. GVAX was given in 13 doses every 2 weeks and then as maintenance doses for a total of 6 months. The study was prematurely terminated as it showed the futility of achieving the primary end point of increased overall survival. The survival analysis showed no superiority in survival of GVAX over the chemotherapy arm [58].

Another phase III trial comparing GVAX in combination with docetaxel was carried out with patients in the control arm receiving docetaxel and prednisolone. The study aimed at recruiting 600 castrate resistant prostate cancer patients; however, it was terminated following recruiting 408 patients due to high death rate in the treatment arm and survival advantage in the control arm [59].

### Antigen-Based Immunotherapy

#### PROSTVAC

Prostatic-specific antigen (PSA) is at target for immunotherapy as it is exclusively expressed in the prostatic epithelial cells. Vaccinia virus elicits humoral and cell-mediated responses, and a recombinant form of vaccinia virus encoding PSA (rV-PSA) is used to enhance the immunogenicity of PSA-producing cells and subsequently cell lysis. In a clinical trial of 33 men with prostate cancer recurrence after radical prostatectomy or radiotherapy, rV-PSA was given on three monthly dose basis. A PSA-specific T cell response was present in five patients in whom PSA blood level stabilized for up to 21 months posttreatment. IgG and IgM humoral response was observed in one patient only [60].

In a phase II randomized trial, rV-PSA was used as a prime vaccine with fowlpox virus encoding PSA as a boost vaccine (rF-PSA). Sixty-four patients were recruited with organ-confined prostate cancer with biochemical failure after local radical treatment of surgery or radiotherapy. An increase of absolute measure of PSA above 2 ng/ml after surgery or three consecutive increases after radiotherapy constituted biochemical failure. Neoadjuvant chemotherapy or hormonal treatment was given for 6 months prior to enrolling into the study. All participants had negative bone scans and no evidence of locally advanced disease. Patients were assigned to three treatment arms, one to receive 3rF-PSA vaccine alone, another to receive multiple doses of 3rF-PSA vaccine followed by one dose of rV-PSA, and a third arm to receive multiple doses of rV-PSA followed by single dose 3rF-PSA. The study did not have a control arm with conventional treatment. The results showed no objective biochemical response, with 45 % of patients showing no PSA progression and 78 % free of clinical progression at 19 months with no difference between the treatment arms. The immunologic response did not show increases in anti-PSA antibody, but there was an increase in PSA-induced T cell proliferation [61].

Another phase II trial evaluated the effectiveness of rV-PSA [62]; however, this group used a different T cell costimulatory molecule (B7.1) and IL-2. In addition, granulocyte-macrophage colony-stimulating factor (GM-CSF) was given to enhance dendritic cell recruitment. This treatment regime was compared to antiandrogen (nilutamide) treatment. A total of 42 hormone refractory metastatic-free prostate cancer patients were randomized to receive prime/boost strategy (rV-PSA, rF-PSA); however, the treatment continued rF-PSA boost on a monthly basis till disease recurrence contrary to the four doses regime in the previous trial. The antiandrogen treatment arm received nilutamide orally on

daily basis till disease recurrence. A crossover of 12 patients from the vaccine to the antiandrogen arm and 8 patients from the antiandrogen to the vaccine arm was observed. There was no difference in time to treatment failure for the vaccine arm (9.9 months) and nilutamide arm (7.6 months). Time to treatment failure for combined therapy was 13.9 months (vaccine then nilutamide) extending the overall treatment to 25.9 months and 5.2 months (nilutamide then vaccine) with total treatment of 15.9 months. PSA-specific T cell response was observed in varying degrees in the vaccine treatment arm. In the vaccine arm, 13 patients had decrease in their PSA velocity compared to 16 in the nilutamide arm. It is notable that sequential treatment with hormone following vaccine showed improved clinical outcome, but no conclusion can be drawn, as there is potential selection bias as patients receiving additional treatment had less aggressive disease.

The largest trial to assess PROSTVAC-VF randomized 125 patients from 43 centers in the United States (US) in 2:1 randomization ratio to achieve 80 % study power [63]. In the vaccine arm, the treatment regime included one priming dose of rV-PSA-TRICOM and six boosts of rF-PSA-TRICOM in addition to GM-CSF adjunct treatment. The control arm received empty vaccinia vector and empty fowlpox vector boosts in an identical regime as to the treatment arm. Patients who had minimally symptomatic castration-resistant metastatic prostate cancer (mCRPC) were eligible for the study. Progression-free survival were similar in both arms; however, at 3 years, the overall survival for the treatment group was better (30 %) compared to the control group (17 %), lengthening the survival by 8.5 months. The immunological studies did not detect humoral response to PSA vaccine. This well-designed study failed to find a correlation between treatment arm and progression. However, clinically, it did show the improvement in overall survival in the relatively small group of patients [63].

### DNA Vaccine

A dose escalating trial assessing the toxicity of pTVG-HP a plasmid DNA-encoding prostate acid phosphatase (PAP) has been conducted. Twenty-two patients were treated with escalating dose of intradermal injection of the vaccine with GM-CSF as adjuvant treatment for six times over 14 days interval. The trial confirmed treatment safety. Fourteen percent of patients developed PAP-specific IFNγ secreting CD8+ T cells. There was no significant clinical response; however, PSA doubling time was increased in some patients [64].

## Antibody-Based Immunotherapy

### Ipilimumab

A phase III double blind randomized controlled trial compared ipilimumab to placebo, in castrate resistant metastatic prostate cancer who are receiving radiotherapy. The study by Bristol Myers Squibb is ongoing and aims at recruiting 800 patients and is expected to conclude in 2012 (Trial number NCT00861614).

### Radioisotope Ab

A phase I study looked at anti-prostate-specific membrane antigen (PSMA) which was a murine deimmunized antibody (J591). It was attached to the radiometal $^{177}$Lu (lutetium-177). This study recruited 35 castrate resistant prostate cancer patients. All received the treatment up to 3 doses. The results showed that myelosuppression occurred with higher doses. There was no anti-J591 antibody development, and all sites of metastasis took up the radio-labeled antibody. PSA stabilization was observed in almost half of patients. This study confirmed excellent targeting ability of anti-PSMA [49].

A phase II randomized trial by Weil Cornell University is ongoing and is recruiting 140 patients into two arms. A monoclonal anti-PSMA (murine deimmunized J591) labeled with $^{177}$Lu is being used in the treatment arm, and $^{111}$In-J591 is being used in the control arm. $^{111}$In is a weak radioactive label that does not kill cancer cells. The study is recruiting patients who were previously treated with surgery or radiotherapy and have biochemical recurrence but not metastasis (NCT00859781).

Another trial by the same group is assessing the suitability of monoclonal antibody treatment of $^{177}$Lu-J591 and is recruiting patients with castrate resistant metastatic prostate cancer (NCT00195039).

A third trial is assessing the toxicity of radiolabeled monoclonal anti-PSMA treatment in adjunct with docetaxel. Castrate resistant metastatic prostate cancer patients are being recruited (NCT00916123).

## Antigen-Presenting Cell Loaded with Antigen-Based Immunotherapy

### Sipuleucel-T

This is a phase III trial that recruited 127 patients with 2:1 randomization ratio of treatment versus placebo. Eligible patients had metastatic prostate cancer with a prognosis of at least 3 months to live. The treatment arm patients were given APC8015 (Sipuleucel-T) in three doses 2 weeks apart for each dose. There was 48 h between the time of apheresis and infusion of treatment product. The placebo group received non-pulsed APCs. Results showed a significant median survival of 25.9 months for the treatment arm compared to 21.4 months for placebo, a total of 4.5 months improvement in survival. In addition, there was an eightfold increase in T cell stimulation in the treatment arm [65].

An updated study reported the survival results of randomized trial comparing three different doses of Sipuleucel-T to

placebo [66]. The same group recruited 512 castrate resistant metastatic prostate cancer patients in 2:1 treatment placebo ratio. The results confirmed the previous trial result of a survival benefit for the treatment arm of 25.8 months compared to 21.7 of placebo group. The treatment was generally well tolerated.

### Conclusion

The prostate may not be an ideal environment for a naturally effective antitumor immune response, but the new emerging evidence links chronic inflammation and cancer development. HGPIN is a precancerous lesion and chronic prostatitis may play a role in carcinogenesis, and more research into the immune homeostasis in these conditions may hold some keys to understanding of immune tolerance and cancer formation. The challenge for antitumor immune stimulation remains high, and to date the only approved treatment for prostate cancer is expensive and has survival advantage of 4.1 months [66]. It is huge step forward for immunotherapy in prostate cancer but hardly a paradigm shift. Most of the immunotherapy treatment modalities are aimed at end-stage prostate cancer or CRPC, and certainly there is "potential" for targeting early disease perhaps in precancerous conditions.

# Stem Cells in Carcinogenesis of the Prostate

6

Shi-Ming Tu and Sue-Hwa Lin

## Introduction

A key to solving the beginning of cancer is to elucidate its *cell of origin*. Hence, an unspoken appeal of the *stem-cell theory of cancers* is its focus on the cellular aspects of cancer. Many biologic phenomena vital for cancer cells are shared by stem cells. Both stem-cell and cancer cell activities are tightly regulated by their respective microenvironments or niches. Therefore, it is not coincidental that epithelial-to-mesenchymal transition (EMT) and epithelial-stromal interactions, which are critical for organogenesis, also play an important role in carcinogenesis. We propose that the theory of a stem-cell origin of cancers that encompasses all aspects of cancer, including heterogeneity, metastasis, drug resistance, etc., may be our long-sought unified theory of cancer.

This chapter will illustrate the biologic ramifications and clinical implications of stem cells in carcinogenesis of the prostate. We would like to demonstrate that prostate cancer stem cells may be involved in the many facets of prostate cancer and that the theory of a stem-cell origin of cancers represents a major *paradigm shift*, which may completely overhaul our understanding and knowledge of prostate cancer.

## Prostate Stem Cells

Stem cells possess three unique properties, i.e., dormancy, self-renewal, and pluripotency. Stem cells have long been implicated in prostate glandular formation. The prostate undergoes regression after androgen deprivation and regeneration after testosterone replacement. This cycle of regression and regeneration can occur more than 30 times [1]. It is presumed that the cells responsible for this recycling are "immortal" stem cells. Furthermore, the putative prostate stem cells are capable of differentiation into at least three distinct cell types, namely, basal cells, neuroendocrine cells, and luminal cells.

The three prostate cell types can be distinguished by their location, cellular markers, and functions. *Basal cells* and *neuroendocrine (NE) cells* are found in the basal layer of the prostate gland. Basal cells are characterized by expression of high molecular weight cytokeratins (CK) 5 and 14, CD44, integrin $\alpha6\beta1$, and p63. P63 is involved in stem-cell maintenance and differentiation in the normal prostate. Basal cells also express bcl-2 and c-met, which mediate cell survival and invasive growth, respectively. Some NE cells express basal cell CK while others co-express prostate-specific antigen (PSA) and chromogranin A, suggesting that these cells may arise from local stem cells [2]. It is unclear whether NE cells are a subset of the basal cell lineage, belong to a unique epithelial lineage, or represent a lineage derived from a separate stem-cell population [3]. The third are *luminal cells,* terminal differentiated cells located in the luminal layer of the prostate. The luminal phenotype is characterized by expression of low molecular weight CK 8 and 18, androgen receptor (AR), and PSA.

Central to the idea of prostate stem cells is the existence of *intermediate cells*. Intermediate cells that express CK5/14/18 or CK5/18 may be cells in transit between basal and luminal cells [4]. A subset of $K19^+$ intermediate cells could be seen within both the basal and luminal layers, representing basal cells in the process of differentiating into luminal cells [5]. Another rare murine intermediate cell type co-expresses luminal CK8 and AR as well as NE markers [6]. Prostate stem cell antigen is also considered to be a marker of late intermediate prostate epithelial cell [7].

## Stem Cell Markers and Assays

Study of prostate stem cells is still work in progress. A unique prostate-specific stem-cell marker has not yet been found. However, certain stemness markers that are generally present in various normal and cancer stem cells are also found in prostate stem cells. Among these stemness markers are β1 integrins, CD133, Sca-1, CD44, and the ABCG2-associated drug resistance proteins.

Collins et al. [8] showed that integrin α2β1$^+$ cells possessed stemness properties by displaying clonogenic growth and initiating *prostate acinus-like growth in xenografts*. Of interest, β1 integrin was crucial for sustaining a functional stem-cell population and establishing asymmetric division in the mammary system [9]. β1 integrin was also required for stem-cell maintenance and positioning of the stem-cell niche in the Drosophila [10].

*CD133* (prominin-1) is expressed in hematopoietic stem and progenitor cells as well as in non-hematopoietic (epithelial and endothelial) stem cells. *Fluorescence-activated cell sorting (FACS)* based on CD133$^+$ expression is commonly used to isolate and characterize putative stem/progenitor cells. CD133$^+$ prostate cells displayed stemness characteristics by virtue of their ability to form *prostaspheres* and develop prostatic-like acini in immunocompromised male mice [11]. Subclones of CD133$^+$ cells also expressed CK14 or TERT and engendered more numerous and larger branching ducts consisting of basal and luminal cells compared with their CD133$^-$ counterparts.

Stem-cell antigen-1 (*Sca-1*) is expressed by stem/progenitor cells in various tissues including hematopoietic, cardiac, mammary, integumentary, muscular, and testicular. Sca-1$^+$ cells are located in the proximal region of the developing prostate [12]. A majority of Sca-1$^+$ cells also expressed α2 integrin, CD49f, and bcl-2. Isolated Sca-1$^+$ cells were able to regenerate prostatic tubules [13]. Because the regenerated ducts are clonal and contain both basal and luminal cells, these Sca-1$^+$ cells are believed to possess stemness features and the capacity for multilineage differentiation.

*CD44* is a cell-surface receptor involved in cell-cell interactions, cell adhesion, and migration. A specialized sialofucosylated glycoform of CD44 functions as a "bone homing receptor" directing migration of hematopoietic stem cells and mesenchymal stem cells to the bone marrow. Subpopulation of CD44$^+$ prostate cells preferentially formed prostaspheres [14].

Flow cytometry-separated *side population* is another technique used to identify cells with stem-cell properties. The ATP-binding cassette membrane transporter *ABCG2* is associated with multidrug resistance and stem-cell phenotype. It enables efflux of the Hoechst 33342 dye and isolation of enriched stem cells from the prostate [15]. These side population cells developed spheroids and branching structures in 3-D Matrigel culture.

One should point out that the above-mentioned markers are definitely not exclusive, or even specific, for stem cells. Distinct prostate stem/progenitor cells are likely to be present in different species, i.e., CD44$^+$α2β1$^{high}$ in humans and Lin$^-$/Sca-1$^+$/CD49f$^{high}$ in mice (Table 6.1). A recent report refuted CD133 as a potential human or mouse stem-cell marker [16]. Another study indicated that expression of CD44, CD133, or Sca-1 did not correlate with the ability to form spheroids or generate prostate glandular structures [17]. There are bound to be additional, unique stem-cell markers awaiting discovery.

## Location of Prostate Stem Cells

Where do stem cells reside in the prostate? Regenerative studies suggest that prostate stem cells may be found in the proximal duct and in the basal layer of the prostate. Indeed, studies using stem-cell markers in mice have localized prostate stem cells to these sites.

### Proximal Duct

In the mouse prostate, the regenerative capacity occurs in the proximal ducts close to the urethra [18–20]. This is the region characterized by the presence of abundant smooth muscle cells that secrete high levels of TGF-β, which is known to be a prostate stem-cell niche factor [19]. This is also the region within the prostate that contains high proportion of castrate-resistant $CK5^+$, $Bcl\text{-}2^+$, $Sca\text{-}1^+$, and $\alpha6^+$ putative stem cells [12, 13, 20]. Further support for stem cells being located at the proximal ducts of the prostate comes from experiments showing that $Sca\text{-}1^+$ cells isolated from this region reconstitute prostate tissue more effectively than $Sca\text{-}1^-$ cells from the same region or $Sca\text{-}1^+$ cells from other regions [12].

### Basal Layer

Since there is preferential survival of basal cells after androgen ablation, the basal layer of the prostate gland is believed to harbor prostate stem cells [1]. The fact that mice devoid of the basal cell marker p63 are born without a prostate also supports a basal origin of prostate stem cells [21]. Further, luminal secretory cells of the prostate arise from $p63^+$ basal cells [22]. Recently, Goldstein et al. demonstrated that basal cell is a potential cell of origin for prostate cancer [23]. Importantly, they showed that cellular origins of cancer do not necessarily correlate with its histological features.

But not all basal cells are stem cells, because fetal urogenital sinus tissue from p63 null mice can form and regenerate prostate tissue in the absence of basal cells after implantation in immunodeficient mice [24]. Therefore, prostate stem cells are likely to be found in the basal layer of the proximal duct in the prostate. Stromal cells that constitute the stem-cell niche at this site can support and sustain prostate stem cells even in the absence of basal cells.

## Stem-Cell Niche

The stem-cell niche is a specialized microenvironment that houses stem cells. It is known that the stem-cell niche affects stem-cell development. When a stem-cell niche is aberrant, it becomes an onco-niche. Therefore, the niche plays a critical role in the final manifestations of a stem cell—and a cancer cell.

Stevens was the first to demonstrate that a normal stem cell derived from the genital ridge formed a malignant teratoma when implanted in the vicinity of the testes [25]. Conversely, Mintz and Illmensee showed that malignant cells obtained from an embryonal carcinoma behaved like normal cells when inserted into the body of a blastocyst [26]. Also, Rous sarcoma virus did not induce sarcomas in chicken embryos [27], and B16 murine melanoma cells failed to form tumors after exposure to embryonic niche factors [28].

These findings suggest that normal stem cells in an aberrant niche are sufficient for the formation of cancer. Whether an aberrant stem cell becomes a cancer cell or not could also be determined by its niche. Results of these experiments confirm the importance of a cellular origin and the niche effect during carcinogenesis.

## Prostate Onco-Niche

In many respects, the relationship between stem cell and its niche is also observed in prostate cancer. The prostate provides a unique opportunity to study interactions between stem cell and its adjacent stroma, because the urogenital sinus mesenchyme that comprises the embryonic stem-cell niche can be easily separated from the epithelial stem cells. Using this approach, Blum et al. showed that the embryonic prostate stem-cell niche might be representative of the mammalian stem-cell niche in general [29]. Furthermore, disruption of the stromal-epithelial signaling pathways contributed to oncogenesis.

Zhou et al. showed that inactivation of p53 and RB in the stem/ progenitor cells of the proximal prostatic ducts led to the formation of malignant tumors [30]. However, the *same genetic defects* affecting lineage-committed transit-amplifying and/ or differentiated prostate cells in the distal prostatic ducts did not form malignant tumors. Furthermore, prostatic intraepithelial neoplasia (PIN) that developed in the proximal prostate progressed to carcinoma. In contrast, PIN in the distal prostate *never* progressed to carcinoma by the time the mice expired. Interestingly, when Zhou et al. performed the same experiments in a different cellular context (i.e., ectopic transplantation assay), mutant cells derived from either the proximal or distal prostatic ducts developed neoplasms within 3 months [30]. Since p53 and RB genes are absent in both proximal and distal ducts of this mouse model, the biologic manifestation of carcinoma must be a consequence of its locations, which contain different stromal cells.

These observations are consistent with a recent report that demonstrated cancer-associated fibroblasts (CAF) played an important role in the spheroid and glandular formation of prostate cancer stem cells [17]. Another study showed that

human prostate cancer samples expressing high levels of the mesenchymal stem-cell marker CD90 were more likely to contain CAF with tumor-promoting potential compared with those expressing low levels of CD90 [31].

Results from these experiments confirm that stromal cells are an integral component of the onco-niche, which plays a critical role in the development of prostate cancer. In other words, both the right genetic defects and the proper onco-niche contribute to the formation prostate cancer.

## Prostate Cancer

Many characteristics of prostate cancer indicate that it originates from stem cells. For example, *androgen independence* could allude to its stem-cell roots, and the androgen-sensitive cells ($AR^+$) represent the bulk of differentiated prostate cancer cells. In addition, the androgen-regulated gene fusion, *TMPRSS2-ERG*, could be used to clarify the cells of origin as well as the evolution of prostate cancer cells.

### Androgen Independence

A hallmark of prostate cancer is its intrinsic androgen independence. Several studies suggest that androgen independence is an inherited rather than acquired trait of prostate cancer [32, 33]. Furthermore, androgen-independent prostate cancer (AIPCa) expresses stem-cell genes within the basal cell layer [34].

Normal prostate stem cells are $AR^-$. It is possible that prostate stem cells are the source of AIPCa, which is also $AR^-$. Collins et al. showed that primary human prostate cancer cell population with the highest proliferative potential was $AR^-$: It had a stem-cell profile ($CD44^+\alpha2\beta1^{high}$ $CD133^+$) and a basal cell phenotype [35]. The $CD44^+$ tumor-initiating cells from prostate xenograft models were $AR^-$ and expressed stemness genes, such as *OCT3/4*, *BMI1*, *beta-catenin*, and *SMOOTHENED* [36]. Likewise, tumor-initiating cells from a clonally derived hTERT-expressing human prostate cancer cell line were $AR^-$, $p63^-$, and expressed stemness genes, such as *OCT4, Nanog, Sox2, nestin*, CD44, CD133, and *c-Kit* [37]. The regenerated tumor contained basal, luminal, and neuroendocrine-like cells, suggesting that the original clone that engendered the tumor had multilineage differentiation capacity of a stem cell.

AR expression promotes differentiation of prostate epithelial cells. Indeed, overexpression of AR alone does not induce pathological growth but reduces the tubule-forming capacity (i.e., stemness) of normal prostate stem cells [38]. It is important to point out that AR function in mesenchymal cells is sufficient for the development of the nascent prostate [39]. Mesenchymal cells ($AR^+$) produce growth factors and cytokines, which act on epithelial progenitor cells ($AR^-$) and affect the latter cells' AR expression and differentiation. Similarly, bone stromal cells such as osteoblasts are $AR^+$ and may produce growth factors and cytokines that affect metastatic prostate cancer stem cells ($AR^-$) in the bone [40]. These findings indicate that mesenchymal cells influence prostate epithelial cells and that the cellular origin of AIPCa may indeed be inherently $AR^-$.

### TMPRSS2-ERG

Whether TMPRSS2-ERG (fusion of the prostate-specific gene, TMPRSS2, with the transcription factor, ERG) could be a useful biomarker to trace the evolution of prostate cancer-initiating cells during carcinogenesis remains to be determined. Yu et al. found that ERG disrupts AR signaling by binding to and inhibiting AR expression at certain gene-specific loci [41]. Furthermore, ERG directly activates H3K27 methyltransferase EZH2, a polycomb group protein, which prevents the affected cell from differentiation (and from AR signaling) and maintains it in a stem-cell-like epigenetic state. Hence, depending on the affected cell of origin, the TMPRSS2-ERG fusion proteins may cause maturation arrest in an early prostate stem cell or endow stemness properties to a late prostate progenitor/differentiated cell, thereby predisposing and propelling it into a path of carcinogenesis. Although both cell types may express the same TMPRSS2-ERG fusion proteins, we postulate that they will pursue distinct clinical courses, because of their different cells of origin.

## Prostate Cancer Stem Cells

If cancer stem cells are derived from normal stem cells, one may be able to purify cancer stem cells using stem-cell markers because the two cell types share certain stem-cell markers. Bonnet and Dick were the first to isolate so-called cancer stem cells (CSC) from human acute myeloid leukemic cells with the stem-cell marker $CD34^+$ and propagate these cells in immunodeficient mice [42]. Subsequently, subpopulations of CSC with stem-cell phenotypes have also been demonstrated in breast [43], brain [44], and other cancers.

In prostate cancer, Collins et al. identified putative prostate CSC from primary human prostate tumors using the same stem-cell markers ($CD44^+/\alpha2\beta1^{high}/$ $CD133^+$) as those used to designate prostate epithelial stem cells [35]. Interestingly, the $CD44^+/\alpha2\beta1^{high}/$ $CD133^+$ prostate CSC displayed high capacity for self-renewal and for differentiation into $AR^+$ cells. Importantly, Leong et al. showed that a single $Lin^-/Sca\text{-}1^+/CD133^+/CD44^+/$ $CD117^+$ cell was able to produce wild-type prostatic acini in the mouse [45].

Patrawala et al. showed that CD44⁺ prostate cancer cells were intrinsically more tumorigenic and metastatic than their CD44⁻ counterparts [36]. A fraction of CD44⁺ prostate cancer cells undergo asymmetric division, which is a hallmark of slow-cycling stem cells. In addition, Hurt et al. showed that CD44⁺ LNCaP cells exhibited stem-cell features, including formation of prostaspheres in cell culture, colonies in soft agar, and tumors in NOD/SCID mice [46].

Recently, Kong et al. demonstrated that prostate cancer cells exhibiting CSC features also expressed an EMT phenotype [47]. Not only did the PC3 PDGF-D cells showed increased clonogenic and prostasphere-forming capacity, which were used to define CSC characteristics, they also lost epithelial markers and gained mesenchymal markers. Moreover, these cells overexpressed numerous stem-cell genes, such as Nanog, Oct4, Sox2, Lin28B, and activated polycomb repressor complex 2.

## Origin of Prostate Cancer

We know very little about the origin of prostate cancer-initiating cells. For the longest time, we have focused on the nature of oncogenic change. But it is equally important for us to identify the cells of origin within which the oncogenic change occurs. Knowing the cells of origin will help us validate the actual role of oncogenic change during oncogenesis.

### Hierarchy of Stem-Cells Versus Cancers

Results from several lines of experiment support a hierarchical order of stem/progenitor/differentiated cells within which a particular genetic change (or epigenetic aberrations) could elicit different and disparate biologic as well as clinical phenotypes.

Patrawala et al. discovered a hierarchical order in the tumorigenic potential of human prostate xenograft tumors [36]. In particular, a subpopulation of prostate stem cells ($CD44^+/\alpha2\beta1^+$) was enriched in tumor-initiating cells. Hence, the tumorigenic potential of 3 human xenograft tumors (DU145, LAPC4, and LAPC9) was dependent on their cellular origins in a hierarchical order of $CD44^+/\alpha2\beta1^{+/hi} = CD44^+/\alpha2\beta1^{-/lo} > CD44^-/\alpha2\beta1^{+/hi} >> CD44^-/\alpha2\beta1^{-/lo}$.

Mulholland et al. isolated LSC ($Lin^-/Sca\text{-}1^+/CD49f^{high}$) stem/ progenitor cells using FACS in the Pten null prostate cancer model [48]. Using cells derived from in vitro sphere culture or isolated from primary tumors, they performed in vivo regeneration assays and showed that the LSC subpopulation (as opposed to the more differentiated luminal subpopulation) are basal-like cells that recapitulated the pathology of primary Pten prostate tumors and elicited a preponderance of tumor-initiating activity.

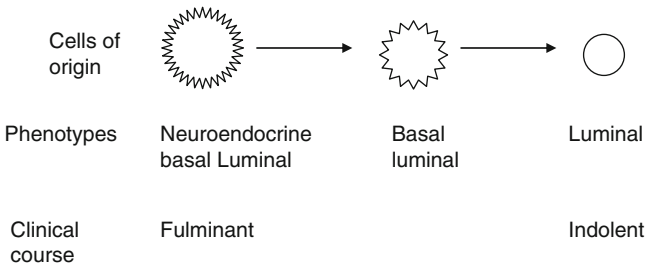

**Fig. 6.1** The stem-cell theory of cancer predicts that tumors arising from earlier stem cells in a stem-cell hierarchy tend to express a more diverse phenotype and pursue a more fulminant clinical course than later progenitor stem cells, which are more inclined to display a more restricted phenotype and follow a more indolent clinical course

Lawson et al. isolated distinct subpopulations of prostate basal/stem cells, luminal cells, and stromal cells using FACS [49]. By introducing various oncogenic stimulations (i.e., FGF activation, ERG1 expression, PI3K signaling) into these cells, they demonstrated that prostate basal/stem cells possessed a greater capacity (i.e., efficiency) for cancer initiation compared with luminal cells and could produce luminal-like disease.

Prostate tumors arising from luminal cells were consistently found to be less aggressive than those originating from basal/stem cells. PSA-driven *Pten* deletion in prostatic luminal cells resulted in hyperplasia [50]. In contrast, Probasin-Cre-induced *Pten* inactivation involving prostatic basal/stem cell led to neoplasia [51]. Similarly, overexpression of AKT1 in Sca-1⁺ cells led to the formation of ductal structures containing PIN while its expression in Sca-1⁻ cells led to predominantly normal ducts [13].

### Cellular Origins of TMPRSS2-ERG

The stem-cell theory of cancers predicts that the same oncogenic stimuli cause differential effects in different cells of origin [52, 53]. Earlier stem cells give rise to tumors that are potentially more heterogeneous and metastatic than the later progenitor cells do (Fig. 6.1).

The TMPRSS2-ERG fusion gene alludes to the relevance of a particular oncogenic gene rearrangement versus the cell types within which it occurs during prostate carcinogenesis. A prospective multicenter study showed that the prevalence of TMPRSS2-ERG was almost 50 % in prostate cancers diagnosed among men who underwent prostate biopsies [54]. But TMPRSS2-ERG transcripts were also discovered in benign prostatic hyperplasia or nonmalignant tissues, not just primary or metastatic prostate cancers [55–57]. These disparate observations could be attributed to the phenomenon of field effect. An alternative explanation is that the cell of origin within which a particular oncogenic gene rearrangement occurs is also important for the expression of a malignant phenotype.

We propose that when the cell of origin has more stemness features, the resultant malignancy is potentially more deadly; when it is more differentiated, the tumor formed tends to be more indolent. This hypothesis could account for the discordant prognostic significance of TMPRSS2-ERG in prostate cancer when the *same* genetic aberration develops in *different* cells of origin. It would explain the discrepancy of TMPRSS2-ERG being associated with a poor clinical outcome in some studies [58, 59], but an improved prognosis in others [60].

## Future Directions

We need stem cells to test the hypothesis that distinct tumor phenotypes arise from unique stem cells in a stem-cell hierarchy. The spontaneously immortalized prostate progenitor (NHPrE1) and intermediate (BHPrE1) cells could be used for this purpose [61]. Of note, NHPrE1 cells expressed higher levels of stem-cell markers (CD133, CD44, OCT4) than BHPrE1 cells. Although it is unavoidable that both of these human cell lines contain mixed populations, they do not produce colony formation in vitro and tumorigenicity in vivo. Furthermore, there is no extrinsic DNA or viral modification being introduced into these cells. These cell lines are as "normal" as they possibly can be for the purpose of such experiments.

A preview of such experiments is already ongoing with the use of homeobox promoter genes in prostate cancer research. Homeobox genes regulate lineage differentiation during development. Different homeobox genes impart different progenitor cells with different stemness packages that confer different stem-cell or malignant phenotypes in a hierarchical manner. Hence, prostate basal stem cells (a relatively early progenitor stem cell) may contain a certain homeobox gene and become a more heterogeneous or form mixed tumor that metastasizes more widely with Pten loss [48]. On the other hand, prostate CARN cells (a relatively late progenitor stem cell containing Nkx3-1) are likely to express a more restricted phenotype and become the more conventional prostate acinar adenocarcinoma with the same Pten loss [62].

### Conclusions

Until recently, the notion of cancers arising from specific mutations that occur and accumulate over time has been the groundwork for cancer research and therapy. The idea that distinct types of cancer are due to abnormalities that occur within unique cells, if proven correct, will be a major *paradigm shift* in prostate and other cancers. The *stem-cell theory of cancers* provides us with a novel frame of reference for better understanding the intricacies of cancer. Importantly, it enables us to discover alternative ways to elucidate the mechanisms of cancer. Ultimately, the stem-cell theory of cancers will affect how we practice clinical oncology: our diagnosis, management, and therapy of prostate and other cancers.

# Murine Models of Prostate Cancer

7

Eric C. Kauffman, Casey K. Ng, and Carrie Rinker-Schaeffer

## Introduction

Preclinical investigation of prostate cancer (CaP) has been greatly assisted by the availability of animal models which enable experimentation in physiologic tissue microenvironments that cannot be recapitulated by current *in vitro* platforms. Such modeling is necessary to study carcinogenesis steps requiring interaction between the cancer cell and microenvironment, such as local invasion, circulatory transit/dissemination, lodging and survival of tumor cells at secondary tissue sites, and tumorigenesis itself. Animal models thus provide invaluable preclinical tools for elucidating molecular mechanisms of CaP carcinogenesis and testing novel CaP therapies.

The development of animal models that accurately recapitulate human disease has been a considerable challenge. The only large animal known to develop spontaneous CaP is the dog; indeed, Charles Huggins first noted the hormone dependence of CaP in aged ferrell dogs. Unfortunately the study of canine CaP has been hindered by infrequency of cases, high cost of maintaining colonies, long gestation and life span, difficult genetic manipulation, and relatively complex regulatory issues.

A variety of rodent models have been developed that recapitulate different biologic states of human CaP, are readily available to biomedical researchers, and have considerable practical utility. Certain rat strains, for example, develop frequent spontaneous prostate tumors, and this tumorigenesis can be accelerated using specific chemical carcinogens or tumor transplant approaches. Unlike rat prostates, mouse prostates do not develop spontaneous tumors and are resistant to carcinogens. However, mouse prostate tumors may be induced by experimental approaches, including recombinant DNA genomic (i.e., transgenic) alteration or *in vivo* reconstitution of genetically transformed urogenital sinus tissue. In addition, immunocompromised mouse strains provide effective hosts for human CaP xenografts.

Murine models are practical for CaP research due to a relatively short life span and gestation period. Furthermore, they are relatively inexpensive to maintain and easy to handle and manipulate. Numerous preclinical discoveries in murine models of CaP have translated well clinically, from the earliest demonstration of androgen-independent subpopulations as a mechanism of androgen-independent clinical progression to the more recent discovery of metastasis suppressor genes. This chapter reviews different approaches to murine modeling of CaP and summarizes various models with respect to their histology, androgen sensitivity, invasiveness, metastatic potential, molecular profiles and important preclinical findings.

## Murine Prostate Anatomy

The murine prostate, similar to the human prostate, is composed of glandular epithelium within a sea of stromal cells and loose collagenous extracellular matrix [1]. The stroma is comprised of smooth muscle, mesenchymal cells including fibroblasts and myofibroblasts, nerve endings, lymphatics, leukocytes, endothelial cells, and their supporting pericytes. The epithelium-stroma ratio is high (5:1) in the murine prostate, a largely parenchymal organ, while in the human gland, the stroma is more equally represented (1:1–2:1). In contrast to the human prostate, which contains zones without clear lobar delineations, the murine prostate has distinct anatomic

lobes: dorsal, lateral, ventral, and anterior/coagulated. Each lobe has a characteristic ductal branching pattern [2]. As with the human gland, murine prostatic ducts are lined by cuboidal-to-columnar epithelium and proximal urothelium, including scattered basal cells lacking a luminal surface [1]. In spontaneous or carcinogen-induced rat CaP, lesions tend to develop in one of two specific regions: (1) the ventral lobe, often microscopic and indolent, or (2) the dorsal and lateral lobes, often macroscopic and invasive, with frequent seminal vesicle involvement. While the dorsal lobe is considered anatomically most similar to the human peripheral zone, which is the site of clinical CaP, it has not been shown that cancers from any one prostate lobe are more representative of human disease.

## Overview of Murine Models of Prostate Cancer

### Murine Model Goals

The foremost goal of CaP murine models is to replicate clinical histopathology and simulate the clinical course of disease, while reliably predicting patient response to various treatments. Secondary goals relate to practicality of study, including accessibility, abundance, ease of handling, and costs. Thus, the ideal murine model would begin with prostatic intraepithelial neoplasia (PIN) and progress to androgen-dependent multifocal adenocarcinoma with stable or increased expression of the androgen receptor (AR) and prostate-specific markers (PSA/PAP/PSMA), followed by preferential metastatic colonization of lymph nodes and bone, with androgen-independent outgrowth following hormonal therapy. On the other hand, common clinical features such as a slow cancer growth rate and a late age of onset may be preferable to avoid in these models to allow more expeditious investigation. Additional desirable features include the availability of large number of rodents, high tumor penetrance/incidence, and technical simplicity for generalized usage. Currently, no murine model recapitulates all aspects of clinical prostate carcinogenesis, and the utility of any one model is often best assessed by its "track record" of predicting clinical CaP biology and outcomes.

### Murine Model Types

Many different murine models are available to the CaP investigator. These models differ in their species of tumor origin (human, rat, or mouse) and species of rodent host (rat or mouse). Murine models are additionally distinguished by whether prostate tumors are **autochthonous**, originating de novo within the host rodent, or whether they are introduced by **tumor transplantation or grafting** (Fig. 7.1). A transplant is referred to as **syngeneic** when the species and strain of tumor is identical to that of the host, in contrast to a **xenograft** (heterotransplant/xenotransplant) in which the species of host and tumor differ. Xenografts require an **immunocompromised** host rodent, while all other types of murine models use an **immunocompetent** host, preserving potential cancer cell-immune cell interactions.

The site of tumor development is another key distinction. Transplanted prostate tumors may be implanted **orthotopically** (intraprostatically) but are most often studied **ectopically** within the subcutaneous tissue (typically in the flank), under the renal capsule or in/over the bone. Autochthonous rodent prostate tumors may similarly be orthotopic or ectopic (Fig. 7.1). Ectopic autochthonous tumors are studied exclusively using the *mouse prostate reconstitution model*, which implants urogenital sinus tissue under the renal capsule to induce prostate organogenesis along with carcinogenesis. Orthotopic autochthonous prostate tumors can develop either *spontaneously* (certain rat strains only), after *induction by carcinogens* (rats only), or using *transgenic DNA recombination* (mice or rats) (Fig. 7.1).

A final key distinction is whether initial transformation steps of prostate carcinogenesis are represented or bypassed in the model. For example, in transplant models, prostate cells are already transformed at the time of inoculation into rodents, thereby *bypassing the initiation and early progression of carcinogenesis*. Accordingly, these models are less useful for studying early tumorigenesis or chemoprevention but enable expeditious investigation of advanced disease. In contrast, autochthonous models recapitulate the entirety of tumorigenesis and are more appropriate for chemoprevention study.

## Spontaneous Prostate Cancer Models

The overall incidence of spontaneous prostate tumors in rodents is very low. Yet for reasons unclear, two rat strains, **Lobund-Wistar** and **August-Copenhagen**, develop frequent spontaneous CaP and are the only animals known to do so besides dogs and humans (Table 7.1). These models are advantageous in that they allow study of "natural" multistep tumorigenesis including precancerous events in an immunocompetent host without added carcinogens or genetic manipulation. Because spontaneous rat CaP models include the earliest steps of neoplastic transformation, they are useful for **chemopreventation studies**. Disadvantages of these models are the long tumor latency (2–3 years) relative to other murine models and lack of bone metastases.

### Lobund-Wistar Model

The identification of spontaneous rat prostate tumors in a Wistar rat strain was reported in 1973 by Pollard, who

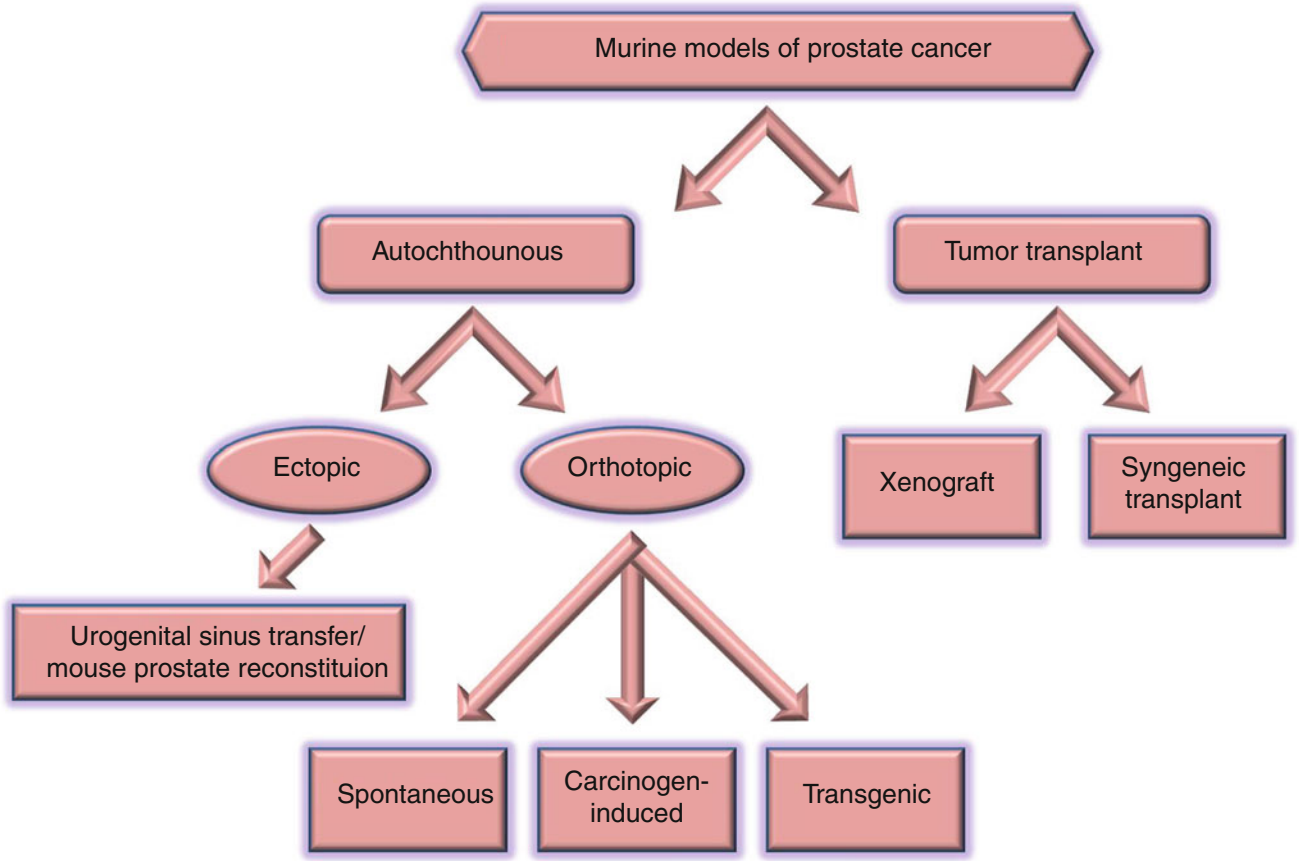

**Fig. 7.1** Murine models of prostate cancer

**Table 7.1** Spontaneous and carcinogen-induced rat models of prostate cancer

| Rat strain | Carcinogen | Incidence | Tumor location | Invasion phenotype | Metastatic |
|---|---|---|---|---|---|
| Lobund-Wistar | (None) | ~30 % by 2–3 years | Dorsolateral and anterior prostate lobes, seminal vesicles | Macroscopic | Yes |
| | MNU + testosterone | ~60–90 % by an average of 11 months | Dorsolateral and anterior prostate lobes, seminal vesicles | Macroscopic | Yes |
| ACI | (None) | ~35–80 % by <3 years | Ventral prostate lobe | Microscopic >>> Macroscopic | No |
| | DMAB (± estrogen) | ~10–50 % by 12–14 months | Ventral prostate lobe | Microscopic | No |
| Wistar, Wistar-Unilever | MNU + testosterone | ~30–75 % by 15–18 months | Dorsolateral and anterior prostate lobes, seminal vesicles | Microscopic > Macroscopic | Yes |
| Fischer 344 | DMAB | <50 % by 14 months | Ventral prostate lobe | Microscopic | No |
| | DMAB + testosterone | ~85 % by 13 months | Dorsolateral and anterior prostate lobes, seminal vesicles | Macroscopic | Yes |
| Noble | Testosterone + estrogen | ~90 % by >18 months | Dorsolateral and anterior prostate lobes, seminal vesicles | Microscopic > Macroscopic | Yes |

Adapted/updated from [3]

observed large pelvic tumors with synchronous lung metastases in two aged rats [4]. The tumors appeared to originate from the prostate and were determined to have adenocarcinoma histology. The rat subline was conventionalized by Pollard to establish the current Lobund-Wistar (L-W) strain, of which **nearly 30 % of rats develop spontaneous tumors by approximately 2 years of age, with slightly higher rates by 3 years** [5]. The etiology of frequent CaP in these rats is unclear, given the parental Wistar line had no known incidence. While Pollard attributed the phenomenon to genetic drift, the cause is generally believed to relate to the naturally high levels of circulating testosterone in L-W rats.

L-W spontaneous prostate tumors grow to palpable size with **aggressive local invasion**, often displacing the entire pelvic cavity, and are **highly metastatic** to the lungs, lymph nodes, and peritoneum. They are believed to originate in the **dorsolateral and anterior lobes** and typically involve the **seminal vesicles**. Whether L-W seminal vesicle tumors develop independently of prostate tumors or as a result of direct extension remains controversial. Necropsies in younger L-W rats reveal occasional (6 %) microscopic involvement in the dorsolateral prostate alone, without seminal vesicle involvement, supporting a prostatic origin [6]. Further support comes from demonstration of PSA expression in cancer cells derived from a L-W spontaneous prostate tumor [7].

The L-W spontaneous CaP model shares several features with clinical CaP. **L-W prostate tumors increase with age**, occurring in 10 % of young adults and 30 % of elderly rats [5, 8]. At the earliest stage of detection, these tumors appear as premalignant intraluminal hyperplasia or carcinoma in situ, similar to clinical PIN [5, 6, 8]. L-W spontaneous prostate tumors **express both AR and PSA**, although with reduced levels relative to benign epithelium [6, 7, 9]. They are initially **androgen dependent** based on suppression with chemical castration [10, 11]. Subsequent outgrowth of androgen-independent disease is suggested based on studies with *carcinogen-induced* L-W CaP tumors (described later in this chapter); however, the genetic etiology of these tumors may be different [8]. Compared to clinical CaP, L-W spontaneous prostate tumors are more locally aggressive, with more common SV involvement, but do not metastasize to bone.

*Preclinical findings*. The L-W model provided the **first demonstration of a role for dietary modifications in CaP prevention**, showing that moderate caloric restriction or fat reduction significantly reduced L-W prostate tumor incidence [5, 12]. More recently, the L-W rat model has supported the chemopreventative use of specific soy protein isolates based on a tenfold (30 % vs. 3 %) reduction in CaP incidence in supplemented rats [8]. The L-W spontaneous rat CaP model has had limited study due to long tumor latency and limited incidence of tumorigenesis, and many investigators have opted instead for more expeditious variants of the L-W model using carcinogen induction or tumor transplant approaches.

## August-Copenhagen (ACI) Model

Spontaneous rat CaP is also observed in the strain, ACI, established in 1926 by Curtis and Bullock by crossing an inbred Copenhagen and August (ACI = A × C with an "Irish" marker; a.k.a. ACI/seg or ACI/segHapBR) [13]. In 1975, Shain and colleagues first described spontaneous prostate tumors in 7/41 (17 %) 3-year-aged ACI rats [14]. Subsequently, a larger investigation by Ward and colleagues demonstrated a 35–40 % incidence of histologic CaP by 33 months, and **rates up to 60–80 % in aged rats** are more recently reported [13, 15, 16]. These cancers are most often **microscopic**, in contrast to L-W spontaneous prostate tumors. ACI rats also develop **PIN-like atypical hyperplasia with virtually 100 % incidence by 2 years of age** [13, 16]. As with L-W rats, spontaneous CaP in ACI rats may be due to high levels of circulating testosterone, and a role for testosterone to estrogen ratio has also been proposed [13].

Histologically, spontaneous CaP in ACI rats is **multifocal** and occurs solely in the **ventral lobe**, in contrast to the dorsolateral/anterior lobe in L-W rats [13, 14]. ACI CaP lesions have a **cribriform** appearance, as observed clinically with high-grade and ductal adenocarcinomas [16, 17]. Varma and colleagues have concluded close ultrastructural similarity with human prostate cancer cells by electron microscopy [17].

In contrast to L-W prostate tumors, ACI tumors are indolent and typically **lack gross invasion or metastasis**, despite high-grade histology. Several heterogeneous and clonal cell lines have been established from spontaneous ACI tumors after serial syngeneic transplantation (C, D, and T families) [18, 19], and much of the known biology of the spontaneous ACI CaP model has been extrapolated from studies in these cell lines or their transplant tumors, including the presence of **both androgen-sensitive and androgen-insensitive cell populations** [18–20]. In serial transplants, **AR and PAP are both expressed** at higher levels than the ventral prostatic epithelium [19]. Levels of AR are variable in isolated cell populations and do not correlate with androgen sensitivity [20].

*Preclinical findings*. The high incidence of microscopic disease in ACI rats, approaching 100 % with advanced age, and the lower incidence of macroscopic invasive disease is considered to mimic the epidemiology of human prostate cancer. Thus, the ACI spontaneous cancer model may be useful for investigation of early CaP tumorigenesis and preventative medicine. As with the L-W model, several groups have employed ACI rats to investigate **dietary modifications**. Kondo and colleagues demonstrated suppression of histologic CaP in ACI rats fed only a low-fat diet [21], and similar outcomes were observed in ACI rats fed a cholesterol-free diet [22]. The ACI spontaneous CaP model also provided among the earliest *in vivo* demonstrations of **chemopreventative activity of a 5-alpha reductase inhibitor in CaP** [15]. More recently, this model has contributed to linkage and microarray analyses for identification of candidate prostate susceptibility genes [23].

### Other Rat Strains

Spontaneous CaP is infrequent to nonexistent in other rat strains. A spontaneous rat prostate tumor discovered in a **Copenhagen** rat was used to establish what is the now the most extensively studied syngeneic transplant tumor model of CaP (see later in chapter, *Dunning model*) [24]. The precise incidence of Copenhagen spontaneous CaP is unclear, but rates of microscopic disease as high as 10 % are suggested [13]. The incidence of CaP in **Noble** rats is <1 % [25]. In **Fischer 344** (**F344**) rats, Reznik and colleagues observed spontaneous prostatic CaP/adenomas in 4 % of animals, which were ventral, cribriform and nonmetastatic, similar to ACI rat CaP [26]. Spontaneous CaP has not been described in other common rat strains, including Wistar, Sprague-Dawley, and Lewis.

## Carcinogen-Induced Models

A classic mechanism used to study tumor initiation and progression is the exposure of animals to chemical carcinogens. The most thoroughly characterized carcinogens in CaP murine models are **DNA-modifying agents**, ***3,2′-dimethyl-4-aminobiphenyl*** (**DMAB**) **or** ***N-methyl-N-nitrosourea*** (**MNU**), **in combination with testosterone supplementation** (Table 7.1). Carcinogen induction enables more expeditious investigation of rat prostate tumorigenesis, with tumor latency periods of months rather than years, and CaP incidence approaching 100 %. Similar to spontaneous models, carcinogen-induced models are useful for investigating chemoprevention because they recapitulate the earliest steps of carcinogenesis, including precancerous changes. The main disadvantage of carcinogen models is the lack of an established role for chemical carcinogens in clinical prostate tumorigenesis, and the resulting rat cancers may not be biologically representative of clinical disease.

### Testosterone/Estrogen

A carcinogenic role for testosterone in CaP is suggested by the high incidence of spontaneous CaP in rat strains with high circulating levels of this hormone; additionally, testosterone supplementation enhances susceptibility to chemical carcinogens, MNU and DMAB, as described below. However, the carcinogenic effect of testosterone alone in fact appears to be minimal in most rat strains. Pollard et al. observed only one case of CaP after chronic testosterone supplementation in 25 Sprague-Dawley rats (4 %) [27]. Among other strains (ACI, Noble, L-W, and Wistar-Unilever) treated with testosterone only, the reported incidence of CaP is similarly just 0–14 % [13, 28–30]. Testosterone supplementation alone thus appears to be insufficient for rat prostate tumorigenesis.

On the other hand, **long-term supplementation with combined testosterone *plus estrogen* leads to frequent CaP** (**microscopic >80 %**, **gross 10–15 %**) **specifically in the Noble rat strain** [31]. Noble testosterone/estrogen-induced tumors originate in the **dorsolateral and anterior prostate lobes**, and intermediate treatment duration (16 weeks) generates dysplasia without adenocarcinoma [32]. The effect of testosterone itself may be due to its aromatization into estrogen [32]. Drago and colleagues, as well as others, have thoroughly described the Noble testosterone/estrogen-induced CaP model, including evaluation of several chemotherapeutic agents [33–36].

### N-Methyl-N-Nitrosourea + Testosterone (MNU + T)

MNU is a **DNA alkylating agent** and the most commonly studied chemical carcinogen in rat CaP models. It is **conveniently administered as a one-time dose** and is most effective in combination with testosterone (MNU + T). Testosterone, in contrast, is more effective in this model when administered continuously and long term. The mechanism behind synergy between MNU and testosterone is unknown. The efficacy of MNU + T is rat strain dependent, with **Wistar-related and Sprague-Dawley** strains having highest susceptibility.

*Wistar-related rat strains*. The carcinogenic effect of MNU + T has been most extensively characterized in L-W rats, which develop **precocious CaP** (**<1 year**) **with up to 90 % incidence** [28, 37]. In comparison, MNU alone generates CaP in just 10 % of these rats by 14 months, similar to testosterone alone [28]. Tumors in other L-W rat tissues are not observed [28]. MNU + T-induced L-W prostate tumors have similar biology as L-W spontaneous prostate tumors. Both originate in the **dorsolateral and anterior prostate lobes with frequent seminal vesicle involvement and express AR**, **with initial androgen dependency** [12, 38]. While it has not been definitively shown in the spontaneous model, androgen-independent outgrowth is described in the carcinogen-induced model [8]. MNU + T treatment also induces dorsolateral CaP with occasional anterior/seminal vesicle involvement and metastasis in the L-W parental strain, Wistar, but the incidence is only 10–30 % (depending on timing of treatment initiation) by 1.5 years [39, 40]. These rats also develop infrequent prostate carcinoma in situ, atypical hyperplasia, and sarcomas, in addition to ear duct/Zymbal

gland tumors. Using another Wistar-related strain referred to as Wistar-Unilever (W-U), McCormick and colleagues recently described CaP (mostly microscopic) in 50–75 % of rats in response to MNU + T treatment compared to 3 % with MNU or testosterone alone [29, 41]. Similar to other Wistar strains, MNU + T cancers in W-U rats form in the dorsolateral/anterior prostate lobes, frequently involve the seminal vesicles and express AR, with lower levels in advanced grade disease [29, 42]. Other neoplasms occur with lower frequency (10–20 %) in this model, including leukemias/lymphomas, kidney tumors, and Zymbal gland tumors [29].

*Sprague-Dawley rat strain*. In contrast to Wistar-related strains, Sprague–Dawley rats treated with MNU + T develop predominantly **precancerous prostatic lesions**. Specifically, 60, 50, and 30 % of rats form prostatic hyperplasia, dysplasia, and PIN, respectively, with only occasional progression to adenocarcinoma [43, 44]. These changes occur in the **ventral prostate lobe** in contrast to the dorsolateral/anterior lesions in Wistar-related strains and may be detectable by as early as 5 months of age. The Sprague-Dawley model may thus provide a useful model for studying early prostate tumorigenesis.

*Preclinical findings*. In MNU + T-induced Wistar rat tumors, Sukumar and colleagues identified a 70 % rate of **mutated Ki-ras gene**, which encodes a GTPase signaling protein mutated in up to 13 % of clinical prostate cancers [47]. Other investigators have shown an important role for **increased Akt activation** in association with decreased AR levels during progression of MNU + T-induced CaP in W-U rats [42]. Preclinical efficacy of numerous **chemopreventative agents** have been demonstrated using MNU + T rat CaP models, including isoflavone [8, 48], vitamin D [8], linomide [8], garlic isolate [49], myoinositol [50], limonene [50], retinoids [29], cocoa powder [51], and COX-2 inhibitors [52].

## 3,2′-Dimethyl-4-Aminobiphenyl + Testosterone and/or Estrogen (DMAB + T/E)

DMAB is an **aromatic amine** similar to benzidine, historically used to manufacture azo dyes which have been linked to clinical bladder cancers. In rats, DMAB forms **DNA adducts** that lead to tumors of the prostate, bladder, colon, mammary glands, preputial glands, and subcutaneous skin. Common DMAB regimens include weekly or biweekly dosing over 20 weeks, in contrast to the one-time dosing of MNU. Low doses over a longer interval are more effective [53].

CaP induced by DMAB alone occurs solely in the **ventral lobe** [54]. These cancers are **microscopic with cribriform histology**, **express AR**, **and lack gross invasion or metastasis** [54, 55]. CaP formation with DMAB occurs at a lower incidence than in MNU + T models. As with MNU + T, there is differential susceptibility to DMAB among different rat strains. **F344 and ACI are most susceptible**, with variable CaP incidence (10–50 %) by approximately 1 year of age and PIN/atypia formation in 70–80 % of rats by 60–74 weeks [54, 56, 57]. Lewis and CD rat strains demonstrate lower susceptibility, while Wistar and Sprague-Dawley rats are resistant [54].

*Testosterone effect*. Long-term testosterone supplementation generates a dramatic shift in DMAB-induced cancer phenotype, **suppressing ventral prostate microscopic lesions while promoting macroscopic CaP in the dorsolateral/anterior lobes and seminal vesicles of >80 % of mice** [58, 59]. These macroscopic lesions demonstrate **noncribriform** glandular differentiation of variable grade, abundant reactive stroma, prominent polynuclear leukocyte infiltration, and frequent perineural invasion. They are **locally invasive and frequently metastatic to the lungs and peritoneum**, with incidence and invasiveness increasing with duration and dose of testosterone supplementation [55, 60]. Histologically and phenotypically, these lesions are similar to those arising spontaneously in Wistar-related rat strains treated with MNU + T. In contrast to these models and tumors induced by DMAB alone, tumors induced by DMAB + T are mostly **AR negative** [55].

*Estrogen enhancement*. While estrogen has no effect on CaP induced by DMAB alone [57, 61], estrogen supplementation does enhance DMAB + T-induced CaP [59, 60]. The effect of estrogen is tissue-specific, however, **increasing CaP in all prostatic lobes but causing reversion of seminal vesicle cancers**. A carcinogenic role of estrogen could explain reports of increased CaP in DMAB-treated rats receiving either AR antagonists or 5-alpha reductase inhibitors, both of which may elevate estrogen levels [62].

*Androgen sensitivity*. In F344 rats treated with DMAB or DMAB + T, androgen sensitivity and AR expression each vary with CaP location. AR-positive microscopic cancers of the ventral lobe are androgen dependent while macroscopic cancers of the dorsolateral/anterior prostate and seminal vesicles lack AR and are androgen independent [55, 63]. Three cell lines have been established from dorsolateral tumors in this model which accordingly lack AR expression, forming metastatic castration resistant tumors when xenografted into nude mice [64]. Castration resistance may occur by a different mechanism than in clinical CaP, given the discrepancy in AR expression.

*Preclinical findings*. TGF-betaRII is a key mediator of TGF-beta signaling and is frequently downregulated in human, rat, and mouse prostate cancers [65]. Yamashita and colleagues recently used microarray analysis of three DMAB cancer lines to demonstrate aberrant methylation of the TGF-betaRII gene, and confirmed this finding in clinical CaP [65]. Masui and colleagues used DMAB-treated rats to identify Ki-ras mutations in CaP lesions [66]. As with other autoch-

thonous rat CaP models, the DMAB model has been used to study the efficacy of chemopreventative agents such as flavonoid antioxidants, and dietary modifications including reduced beef fat intake [67–69]. Conflicting results are reported regarding therapeutic efficacy of AR antagonists and 5-alpha reductase inhibitors in this model [56, 62, 70].

### Other Chemical Carcinogens

Other chemical carcinogens inducing CaP in rats include N-nitrosobis (2-oxopropyl) amine (**BOP**) and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (**PhIP**) [3, 71]. Both agents are DNA alkylating agents that form CaP in the ventral prostate lobe, similar to DMAB, although with increased tumorigenesis from testosterone supplementation. These carcinogen models have undergone only limited characterization and are not routinely studied.

## Syngeneic Transplants

A common approach enabling long-term study of a specific CaP tumor is to serially transplant the tissue in rodents, with or without interval *in vitro* culturing. **Syngeneic models** transplant tumors into the same (i.e., isogenic) strain as which they originated. Most syngeneic transplant models utilize **rat tumors in rat hosts** and originate from either spontaneous or carcinogen-induced rat CaP. The typical site of transplantation is the subcutaneous flank but may also be intraosseous to model bone metastasis.

Advantages of syngeneic transplant models are characteristic of transplant models in general: by **bypassing precancerous steps and initial transformation**, transplant models enable more expeditious investigation compared to other murine models, with relatively **short tumor latency periods**. These models have been embraced by researchers for practical reasons, although there is growing recognition that "faster may not be better" when studying CaP development. Because early carcinogenesis steps are circumvented, transplant models are less useful for chemopreventative study and more appropriately **employed to investigate CaP progression and treatment of advanced disease**. Transplant models are technically simple and allow continuous monitoring of tumor size when grown subcutaneously. Unlike xenograft transplants, syngeneic transplants have the advantage of being performed in an **immunocompetent host**, allowing assessment of immune system effects on carcinogenesis. A disadvantage of syngeneic transplants is the lack of autochthonous tumor development. Also, syngeneic transplants fail to generate spontaneous bone metastases unless using specialized transplantation techniques with a specific rat CaP line described below.

### Dunning (R3327) Model (Table 7.2)

The Dunning rat CaP model was first described by W. F. Dunning in 1963 as a spontaneous tumor developing in the prostate of an aged Copenhagen rat, grossly involving the dorsolateral lobe and a large portion of the lower abdomen, with no identified metastases [24]. The original tumor, designated **R3327**, was transplanted back into the parental Copenhagen strain and passaged serially *in vivo*. The resulting tumors were slow growing, hormonally sensitive, and expressed AR and endogenous 5-alpha reductase activity [73, 74].

During serial *in vivo* passaging of the R3327 tumor, several sublines have been established, including **R3327-A**, **R3327-G**, **R3327-H**, **and R3327-S** [75] (Table 7.2). While these R3327 sublines retain androgen sensitivity, Isaacs and colleagues postulated in 1978 that an androgen-insensitive population comprised 8–29 % of cells in R3327-H tumors based on limited growth in castrate rats [76]. Prolonged hormonal selection in these rats led to the establishment of the hormonally insensitive **HI sublines**, each defined by a specific growth rate, including **HI-S** (**slow**), **HI-M** (**medium**), **and HI-F** (**fast**) [76]. HI tumors differ in histology and molecular biology from H tumors. Histologically, the latter shows abundant large glands with high secretions and appears almost identical by both light and electron microscopy to well-differentiated human CaP [74]. In contrast, HI tumors form small glands with few secretions and a more cuboidal epithelium [76]. HI tumors are AR positive but have lower levels (30–80 %) than hormonally sensitive H tumors, in contrast to stable or upregulated levels often observed with clinical castration resistance [73, 75]. Five-alpha reductase activity is also decreased in HI tumors relative to H tumors, while levels of PAP are unchanged [75].

While hormonally insensitive HI lines retain moderate to high glandular differentiation, clinical castration-resistant CaP is often more dedifferentiated. **R3327-H-G8A1** is a hormonally insensitive Dunning subline originating from a single cell clone of R3327-H which generates undifferentiated CaP *in vivo* [77]. It is unclear whether H-G8A1 derives from a hormonally insensitive clone or mutated from an androgen-sensitive clone. As with HI tumors, H-G8A1 remains AR positive despite androgen insensitivity and also expresses 5-alpha reductase activity. **Together, the H, HI, and H-G8A1 Dunning tumor lines provide a useful system for study of AR-positive CaP progression to hormonal insensitivity** (Table 7.2).

On occasion, genetic instability of serially passaged R3327-H tumors has given rise to anaplastic tumor sublines, designated **AT** [75, 76] (Table 7.2). AT lines are **hormonally insensitive and do not express AR**, in contrast to clinical castration-resistant disease and the HI and H-G8A1 Dunning lines [75]. AT lines also have no estrogen

**Table 7.2** Characteristics of Dunning R3327 rat prostate tumor lines

| Tumor line | Histologic differentiation | Mean tumor doubling time (days) | Androgen sensitive? | Metastatic potential |
|---|---|---|---|---|
| G | Low | 4.0 | Yes | Low |
| A-sublines: | | | | |
| PAP | High | 10.5 | Yes | Low |
| PIF-1 | Moderate | 3.7 | No | Low |
| PAT | Anaplastic | 2.8 | No | Low |
| H-sublines: | | | | |
| H | High | 22 | Yes | Low |
| HI-S | High | 24 | No | Low |
| HI-F | Moderate | 4.8 | No | Low |
| AT1 | Anaplastic | 2.5 | No | Low |
| MAT-Lu | Anaplastic | 2.5 | No | High |
| MAT-LyLu | Anaplastic | 1.5 | No | High |
| AT2 | Anaplastic | 2.5 | No | Low |
| AT3 | Anaplastic | 1.8 | No | High |
| AT6.1 | Anaplastic | 3.0 | No | High |

Adapted/updated from [72]

receptor despite expression in parental H tumors; however, **PAP and 5-alpha reductase expression** is retained [75, 78, 79]. Several AT lines have high metastatic potential and have become among the best characterized lines of the Dunning model, including **AT3**, **AT6.1**, **AT6.3**, **MAT-Lu**, and **MAT-LyLu**, the last two being sublines of AT1 [75]. While **spontaneous lung metastases** are common to each of these lines, MAT-LyLu additionally form frequent **spontaneous lymph node metastases** similar to human CaP. Furthermore, **bone metastases** of mixed osteoblastic/osteoclastic character can be induced with high frequency using MAT-LyLu and alternative implantation techniques, including intracardiac injection, tail vein injection with inferior vena cava (IVC) clamping, and direct intraosseous injection. **The MAT-LyLu Dunning model variant provides a unique investigational tool as a rat CaP model that can generate high-frequency skeletal metastases**. Other Dunning sublines such as those derived from RR3327-A provide a spectrum of CaP differentiation, including high (**PAP**), moderate (**PIF-2**), and low/anaplastic (**PAT-2**), the latter two of which are also androgen insensitive [80].

The Dunning model has been studied by a number of different approaches. Numerous cell lines established from these tumors are described. Isaacs and colleagues characterized seven of these cell lines with comparison to the original primary tumors. In all but one cell line, tumorigenicity in rats was retained with 100 % preservation of various genetic, biochemical, and histologic features [75]. Dunning tumors can also be successfully transplanted into ACI rats because of this strain's genetic similarity to its parental Copenhagen strain. Dunning tumors are also frequently studied as xenografts in immunodeficient mice.

*Preclinical findings*. Collectively, the Dunning tumor lines recapitulate the heterogeneity of growth rates, differentiation, androgen sensitivity, and metastatic potential seen in human prostate carcinogenesis and have generated numerous findings with successful clinical translation. Oltean and colleagues recently demonstrated enrichment of clinical metastatic gene expression patterns in the metastatic Dunning AT3 line relative to its nonmetastatic parental line [81]. Pfundt and colleagues compared the expression of 5,000 genes between hormonally sensitive (H) and insensitive (HI) Dunning tumors, revealing dozens of differentially expressed genes with important roles in carcinogenesis [82]. In addition, **the Dunning model was central for the discovery of metastasis suppressor genes**, genes which inhibit cancer metastasis without affecting primary tumor growth [80, 83]. Carcinogenic roles for survivin, motility factors, anomalous heat-shock protein regulation, nuclear matrix protein alterations, and epithelial-to-mesenchymal transition (EMT) have been demonstrated in this model [80, 84, 85]. Ki-Ras point mutations are also present in the more aggressive Dunning lines, as frequently observed in clinical CaP [86].

The Dunning model also provided **among the first demonstrations of outgrowth of androgen-independent cell populations as a mechanism of androgen-independent relapse** [87], as well as the therapeutic efficacy of LHRH antagonists [88]. More recent hormonal therapy research in this model provides support for (1) combined use with chemotherapy or targeted tyrosine kinase inhibitors [89–91], (2) neoadjuvant administration prior to radiotherapy [92], (3) the additive benefit of 5-alpha reductase inhibition to castrate testosterone levels [93], and (4) the importance of the prostatic stromal microenvironment in hormonal treatment efficacy [94].

With regard to other therapies, the *in vivo* efficacy of suramin, a synthetic multitarget growth factor receptor inhibitor, was demonstrated in the Dunning model leading to phase II and III trials in castration-resistant CaP patients [95–98]. Dietary agents implicated in clinical CaP prevention have been shown to have efficacy in this model, including vitamin D, selenium, vitamin E, lycopene, and certain vegetables [99–102]. The role of the immune system including tumor-specific leukocytes and cytokines has also been extensively characterized in the Dunning model [103–105], and efficacy is described for various immunologic treatments including adoptive immunotherapy, cytokine administration, vaccines, IL2-based gene therapy, and targeting of tumor-associated macrophages [105–110]. A variety of local tumor therapies have been thoroughly investigated in this model, including radiotherapy [92, 111, 112], cryosurgery [113], high-frequency ultrasound [114–117], photodynamic therapy [118, 119], and hyperthermia [120, 121].

## Other Syngeneic Rat Prostate Tumor Models

*Syngeneic grafts from spontaneous L-W rat CaP*. Four syngeneically transplantable cell lines (**PA I–IV**) have been established from spontaneous L-W prostate tumors and are collectively referred to as the **Pollard model** [9, 122–124]. These lines retain the **high metastatic potential** of the original L-W prostate tumors when transplanted subcutaneously in the flank of syngeneic rats, with distant spread to the lymph nodes, lungs, and liver. Additionally, the **PA-III cell line forms osteoblastic/osteolytic bone lesions** when injected over the calvarium and scapula after disruption of the periosteum with the inoculating needle, providing a rare murine mode of CaP bone colonization. The PA-I and PA-IV cell lines, but not PA-II cell line, form less frequent bone tumors with this approach [123]. The PA-III bone colonization model has implicated insulin growth factors (IGF), urokinase plasminogen activator (uPA), and transforming growth factor beta (TGF-beta) in the formation of osteoblastic lesions [9, 125]. There are conflicting reports regarding AR status in PA-III cancers [9, 124].

*Syngeneic grafts from spontaneous ACI rat CaP*. Shain and colleagues have characterized serially transplantable grafts established from spontaneous ACI rat prostate ventral lobe cancers, including morphologic features and C-19 steroid metabolism [126]. Three initial cell lines (C, D, and T) were established, and subsequently eight sublines were derived and characterized [18, 19]. All lines retain tumorigenic potential in ACI rats with prostatic differentiation, cribriform morphology, and AR/PAP/5-alpha-reductase expression. T-family sublines are androgen sensitive, while C- and D-family sublines are androgen insensitive. Extensive investigation of these cell lines has been focused *in vitro*, largely on the role of fibroblast growth factors in prostate carcinogenesis.

*Syngeneic grafts from DMAB-induced F344 rat CaP*. Several studies have employed DMAB carcinogen-induced F344 prostate tumors grafted back into their parental rat strain. Zhao and colleagues characterized the kinetics and timing of spontaneous lung metastasis in this model [127]. Kawai et al. used this model to demonstrate therapeutic efficacy of hyperthermia-activated magnetic cationic liposomes (MCL) [128]. The host rat immune system was shown to play a key role in MCL activity, underscoring the value of an immunocompetent model. DMAB-induced F344 prostate tumors can also be injected directly into the bone of F344 hosts, and the resulting bone lesions are mixed osteoblastic/osteoclastic [129]. Microarray analysis of these lesions by Lynch and colleagues has revealed specific genes upregulated at the tumor-bone interface, such as *MMP-7*, *cathepsin-K*, and *apolipoprotein D* [129].

*Syngeneic grafts from Noble rat testosterone/estrogen-induced CaP*. The Noble rat CaP model induced by combined testosterone and estrogen was described earlier in this chapter. Several tumor lines from this model have been characterized after grafting in syngeneic hosts [33, 35]. These transplants are androgen sensitive with androgen-independent growth potential and are metastatic to both lungs and liver. Numerous chemotherapies agents have been evaluated by Drago and colleagues using this syngeneic transplant model [35, 130, 131].

## Xenograft Transplants

Unlike syngeneic transplants, **xenografts** grow in a different species from which the tumor originates and therefore require an **immunodeficient host**. Immunocompromised strains of mice are most often used (although immunodeficient rats are commercially available) and include ***severe combined immunodeficiency*** (***SCID***) ***mice*** and ***nude mice***. SCID mice have a mutated DNA repair enzyme gene that results in depletion of functional B and T cell lymphocytes and an inability to mount any cell-mediated or humoral immune response. In nude mice, mutations in the *FOXN1* gene prevent thymus development and associated T cell lymphocyte maturation. However, T cell lymphocyte depletion is generally not absolute.

Xenografts can be categorized into two groups: (1) cancers passaged in rodents without *in vitro* culture (**serial *in vivo* heterotransplants**) and (2) cancers cultured *in vitro* prior to

grafting into mice (**cell line xenografts**) (Table 7.3). The site of tumor transplantation is typically the subcutaneous flank, orthotopic, or renal subcapsular [138]. Xenografts share advantages with syngeneic transplant models, including technical simplicity and familiarity. **The primary advantage of xenograft models is the ability to study *human* CaP**. Disadvantages include nonautochthonous tumor formation and an inability to form bone lesions without intricate implantation approaches. As with syngeneic transplants, xenografts are not appropriate for investigating chemoprevention due to circumvention of initial transformation steps. Findings must also be interpreted with caution given the likely importance of the immune system in prostate carcinogenesis, which cannot be assessed in its entirety in these models.

## Serial In Vivo Heterotransplants

Human and rat prostate CaP may be directly transplanted into immunodeficient mice using either minced tumor tissue or cell suspensions after tumor dissociation. When passaged durably in mice, these cancers are referred to as **serial *in vivo* heterotransplants** (**SIVH**). Inefficient murine uptake of engrafted patient CaP tissue has provided a historic challenge for researchers, with early studies in nude mice achieving 0–20 % success rates [139–141]. Several studies suggest compromised xenograft uptake following **cryopreservation**, indicating that tissue quality plays a role [142–144]. Graft uptake may benefit from **androgen supplementation** [139, 144, 145]. Schroeder and colleagues noted 28 and 5 % rates of human prostate tumorigenicity in nude mice with and without androgen supplementation, respectively [139]. However, improved graft uptake with androgen supplementation is not consistently observed [140, 145, 146]. According to Jones and colleagues, **tumor grade** may be more important. These investigators observed no graft uptake for well-differentiated human prostate tumors mice despite hormonal supplementation, compared to occasional (28 %) uptake without growth of moderately differentiated tumors and common (60 %) uptake with growth of poorly differentiated tumors in the absence of androgen supplementation [140].

While features inherent to the primary tumor are important, the most critical factor for successful xenograft uptake appears to be the **host microenvironment**. The role of the **immune system** was demonstrated in 1981 by Reid and colleagues, who showed that treatment with anti-mouse interferon serum or anti-mouse lymphocyte serum increased the efficiency of tumor uptake in nude mice from 0 to 100 % [141]. Subsequently, a 10-fold increase in graft efficiency was described using nude mice with reduced natural killer cells [146]. With the more recent use of immunodepleted SCID mice, high uptake efficiency (60–75 %) has been achieved regardless of testosterone supplementation [138, 144, 147, 148].

**Matrigel** (Becton-Dickinson, Franklin Lakes, NJ, USA) is a mouse sarcoma-derived extracellular matrix gel composed of type IV procollagen, laminin, and heparin sulfate proteoglycan [149]. The microenvironment formed by this matrix is conducive to grafting many types of human cancers into mice, including CaP [150–152]. Co-inoculation of human CaP with Matrigel lowers the critical cell mass for tumorigenesis by 25,000-fold [153]. Matrigel may not be necessary during the second heterotransplant passage for repeat uptake [154]. The **anatomic site of transplant** is also important for uptake; however, studies disagree regarding whether subcutaneous, renal subcapsular or orthotopic sites provide the best "soil." [138, 140]

Many SIVH lines have been generated with human CaP over the past three decades, each representing a unique patient tumor (Table 7.3a). **SIVH tumors typically retain biologic features of the original primary tumors**, such as histologic differentiation, androgen sensitivity, and AR/PSA/PAP expression (Table 7.3a). The first reported SIVH CaP line, PC82, showed durable maintenance of each of these biologic features even after 2.5 years of continuous *in vivo* passaging [155]. In a study characterizing seven different SIVH CaP lines, van Weerden and colleagues noted that the histology and AR/PSA/PAP levels generally reflected the original patient tumors after 5–23 *in vivo* passages [146].

Tumor latency is around 1–3 months in SIVH models, although periods approaching 1 year are reported [146, 147]. The histology of most SIVH model tumors is **moderately or** (**more often**) **poorly differentiated**, consistent with higher-grade tumors grafting more efficiently [140]. These lesions may retain a small stromal constituent [132, 156, 157]. Maintenance of original tumor histology is reported after >30 *in vivo* passages [146, 154, 158–160] and may be retained regardless of cryopreservation, anatomic site of transplantation, or type of host immunodeficiency type [138, 143].

As summarized in Table 7.3a, **the large majority of SIVH models retain expression of AR and PSA and show initial androgen dependence** [146, 154, 156–158, 160–165]. However, only few SIVH lines, including **PC82**, **PC-EW**, **KUCaP**, **and BM-18**, **remain androgen sensitive** even with prolonged androgen deprivation [154, 157, 165]. More commonly, outgrowth of androgen-independent populations occurs during prolonged *in vivo* hormonal selection. These SIVH lines include **LuCap 23.1**, **LuCap 23.12**, **LuCaP-35**, **LuCaP-58**, **LuCaP-73**, **LAPC-4**, **PAC-120**, **and CWR22** and may be useful for **recapitulating progression to androgen independence** [132, 147, 164, 166, 167]. Several of these lines were established from

Adapted/updated from [132, 133]; see also [134–137]

patients who later received androgen deprivation and progressed to castration resistance [132, 147, 161, 165]. Some SIVH lines, including **CWR22 and KUCaP**, have **AR missense mutations** that account for androgen independence. The CWR22 mutation confers AR hypersensitivity to estradiol [168]. Outgrowth of KUCaP tumors occurs with bicalutamide treatment, consistent with the original patient's clinical progression on this therapy [165]. Although the SIVH line, **PC346**, expresses wild-type AR, prolonged *in vitro* androgen deprivation has generated **sublines with AR anomalies**, including tenfold upregulation of AR (*PC346-Flu1*) and the T877A point mutation (*PC346-Flu2*), both frequent findings in clinical disease [166].

Other SIVH lines demonstrate **pure androgen insensitivity**, including **PC324**, **P339**, **PC374**, **and LAPC-3** [146, 147]. The former two are anaplastic with loss of AR expressed in their original patient tumors. In contrast, **PC374 and LAPC-3** retain AR/PSA/PAP expression and may therefore be useful for the study of AR + castration-resistant prostate cancer, as observed clinically.

## Cell Line Xenografts

Xenografts can also be generated by transplantation of cancer cells cultured *in vitro*. Due to the technical and logistic ease, this approach represents **the most common approach to murine modeling of CaP**. Numerous cell line xenografts using human CaP cells have been described, several of which are listed in Table 7.3b. Cell line xenografts tend to be **poorly differentiated** probably due to preferential *in vitro* immortalization of poorly differentiated cancers and artificial selection pressures with *in vitro* culturing over time. Cell line xenografts therefore commonly have **disparate histology and molecular biology relative to their original patient tumors** [139, 169]. In contrast to most SIVH xenografts, cell line xenografts usually lack androgen sensitivity and expression of AR/PSA/PAP. (Table 7.3) Furthermore, stromal cells are removed by *in vitro* selection, precluding study of stromal-epithelial interactions.

**A significant proportion of murine model research has focused on cell line xenografts from three patient tumors** [170–172]. These cell lines, **LNCaP**, **PC3**, **and DU145**, which contribute to over 7,000 peer-reviewed publications based on abstract citations alone, are each **derived from metastatic lesions** (lymph node, bone, and brain, respectively) and display numerous chromosomal alterations. Both PC3 and DU145 are androgen insensitive but lack AR expression, in contrast to clinical castration-resistant prostate cancer. LNCaP tumors are androgen sensitive and express the first identified mutated AR. However, LNCaP is not reliably tumorigenic, limiting its use in xenograft modeling. Numerous findings beyond the scope of summary in this chapter are reported for these three cell lines, with frequent but inconsistent clinical translation.

## Other Xenograft Models

*Small cell prostate cancer xenografts*. Small cell cancer is a rare and highly aggressive clinical variant of prostate cancer characterized by neuroendocrine differentiation. The **UCRU-PR-2** xenograft model developed by Van Haaften-Day and colleagues has histology, ultrastructural features, and a protein expression profile similar to the original patient primary small cell prostate tumor, including expression of the neuron marker, enolase [173]. UCRU-PR-2 tumors lack AR but express low levels of PAP. Despite frequent metastasis of clinical small cell prostate cancer, UCRU-PR-2 tumors are nonmetastatic, and invasive potential varies with site of transplantation [174]. Other small cell prostate cancer xenograft models include **WISH-PC2** and **LuCaP-49**, which lack AR and PSA expression [175, 176]. While spontaneous metastases have not been demonstrated in these models, WISH-PC2 colonizes both bone and liver with direct organ injection. Bone lesions are osteolytic with foci of osteoblastic activity [175].

*Dunning rat CaP xenograft*. Similar to human tumors, rat prostate tumors and cancer cell lines may also be xenografted into immunodeficient mice [177]. The most frequent example of this approach uses the Dunning rat prostate tumor sublines described above. Research in SCID mice using the highly metastatic AT sublines of the Dunning model was central to the initial discovery of metastasis suppressor genes [79, 83].

# Mouse Prostate Reconstitution Model

In the 1970s, the laboratory of Dr. Gerald Cuhna provided a series of investigations describing the ability of urogenital mesenchyme to induce prostate glandular development from urogenital epithelium. It was therein demonstrated that urogenital sinus tissue enzymatically dissociated *in vitro* into its mesenchymal and epithelial components could be reconstituted as a mouse renal subcapsular graft with subsequent *in vivo* prostate organogenesis [1, 178]. In the late 1980s and early 1990s, Thompson and colleagues added retroviral vectors to this model allowing introduction of select genes to generate renal subcapsular prostate tumorigenesis [179, 180]. This *in vivo* reconstitution of genetically modified uro-

genital sinus tissues has been referred to as the **mouse prostate reconstitution** (**MPR**) **model**. This model was among the first to study the effect of selectively modified genes on *in vivo* prostate carcinogenesis and metastasis.

The MPR model offers several advantages as a murine model. Tissues at no point require *in vitro* culturing, thus avoiding associated artificial selection pressures. In addition, unlike transgenic models in which all cells in the mouse prostate contain the transgene, only a small portion (e.g., 0.1 %) of prostate cells are initially affected [180]. This may more accurately reflect tissue patterns of clinical CaP both in terms of multifocality and in terms of limited initial disease with preservation of a largely benign prostate gland [181]. Furthermore, each infected cell will contain a unique retroviral insertion site, allowing tracking of outgrowth and metastasis patterns for different clonal CaP foci. Finally, because urogenital tissue is acquired from the same mouse strain of reconstitution, a fully immunocompetent host can be studied.

The MPR model characterized by Thompson and colleagues employed urogenital sinus tissue with adenoviral vector-mediated overexpression of *ras* and *myc* oncogenes [179–181]. While infection with either gene alone yields only prostatic dysplasia or hyperplasia, respectively, combined ras/myc overexpression in urogenital sinus tissue results in poorly differentiated nonmetastatic CaP with variable incidence based on the mouse strain, including >90 % in C57BL/6 mice [179]. Additional modification of the ras/myc-overexpressing urogenital sinus tissue by mutant p53 introduction increases the penetrance of CaP to 100 % and additionally generates **metastases to bone**, **lymph nodes**, **lungs**, **and liver** [182]. This MPR modification is **among the only murine models of CaP that give rise to frequent spontaneous bone metastases**. Cell lines established from both primary tumors and metastases in this model retain tumorigenic and metastatic potential when grafted orthotopically or subcutaneously in mice [183, 184]. Primary tumor cell lines express AR and appear androgen sensitive initially but progress to AR-positive androgen independence with prolonged passaging *in vitro*.

*Preclinical findings* of significance with this model include among the first demonstrations of high levels of TGFbeta1 and apoptotic bodies in CaP, both of which have been corroborated clinically [181]. MPR studies have also revealed a role for caveolin-1 in progression to metastasis as subsequently implicated in the clinical setting as well [185, 186]. The MPR model has also supported a chemopreventative benefit of retinoids and efficacy of viral-based gene therapy using "suicide genes" or cytokines [181]. However, use of the MPR model is limited by its considerable technical challenge.

## Transgenic Murine Models

Transgenic models are the most recently developed murine models of prostate cancer. Using site-specific recombinant DNA methodology, specific genes of interest (e.g., candidate oncogenes) may be inserted into the mouse genome, and the resulting mouse phenotype examined. Alternatively, specific genes (e.g., tumor suppressor gene candidates) may be "knocked out" of the mouse genome using the **Cre-Lox system** of DNA recombination, which employs a Cre (cyclic recombinase) enzyme derived from bacteriophage P1 to catalyze DNA removal between two 34 base-pair sequences referred to as Lox-P sites. Because gene knockouts are often lethal during embryonic mouse development, investigators frequently choose to knock out only one of two alleles (*heterozygous knockouts*). Alternatively, a nonlethal *conditional* homozygous knockout may be generated employing either prostate-restricted expression or time-restricted expression, inducible following animal development with various pharmacologic or dietary triggers.

*Transgenic models provide the advantage of knowing the precise genetic change*(*s*) *responsible for tumorigenesis*, *and contributions of specific proteins or signaling pathways to carcinogenesis can thus be individually examined*. Tumors form orthotopically and in an immunocompetent host. Transgenic models may recapitulate the entirety of prostate carcinogenesis from precancerous transformation to metastasis, although most of the current models simulate only initial dysplastic changes.

*Promoters*. Expression of transgenes can be limited to the rodent prostate gland by employing a *prostate tissue-specific promoter*. The prototypical example is the promoter for **probasin** (**PB**), a "house-keeping" protein with androgen-driven and prostate-specific expression in rodents and humans. Variants of PB, including **long PB** (**LPB**) and **ARR$_2$PB**, have additional androgen response regions yielding higher levels of transgene expression. Less commonly used prostate-specific gene promoters include the **PSA** promoter and the promoter for the PSA analogue, **PSP94** (prostate secretory protein of 94 amino acids), which is among the most abundant prostate secreted proteins. Other promoters which have been used in transgenic models have lower prostate tissue activity and specificity, leading to tumors of other organs, including the promoter for the mouse mammary tumor virus (**MMTV**) and the androgen responsive gene for the **C3**(**1**) steroid binding protein. Different promoter activities can lead to dramatic changes in prostate phenotype for the same transgene [187, 188].

*Transgenes*. Transgenic model phenotypes using different transgenes are summarized in Fig. 7.2. The first transgenic

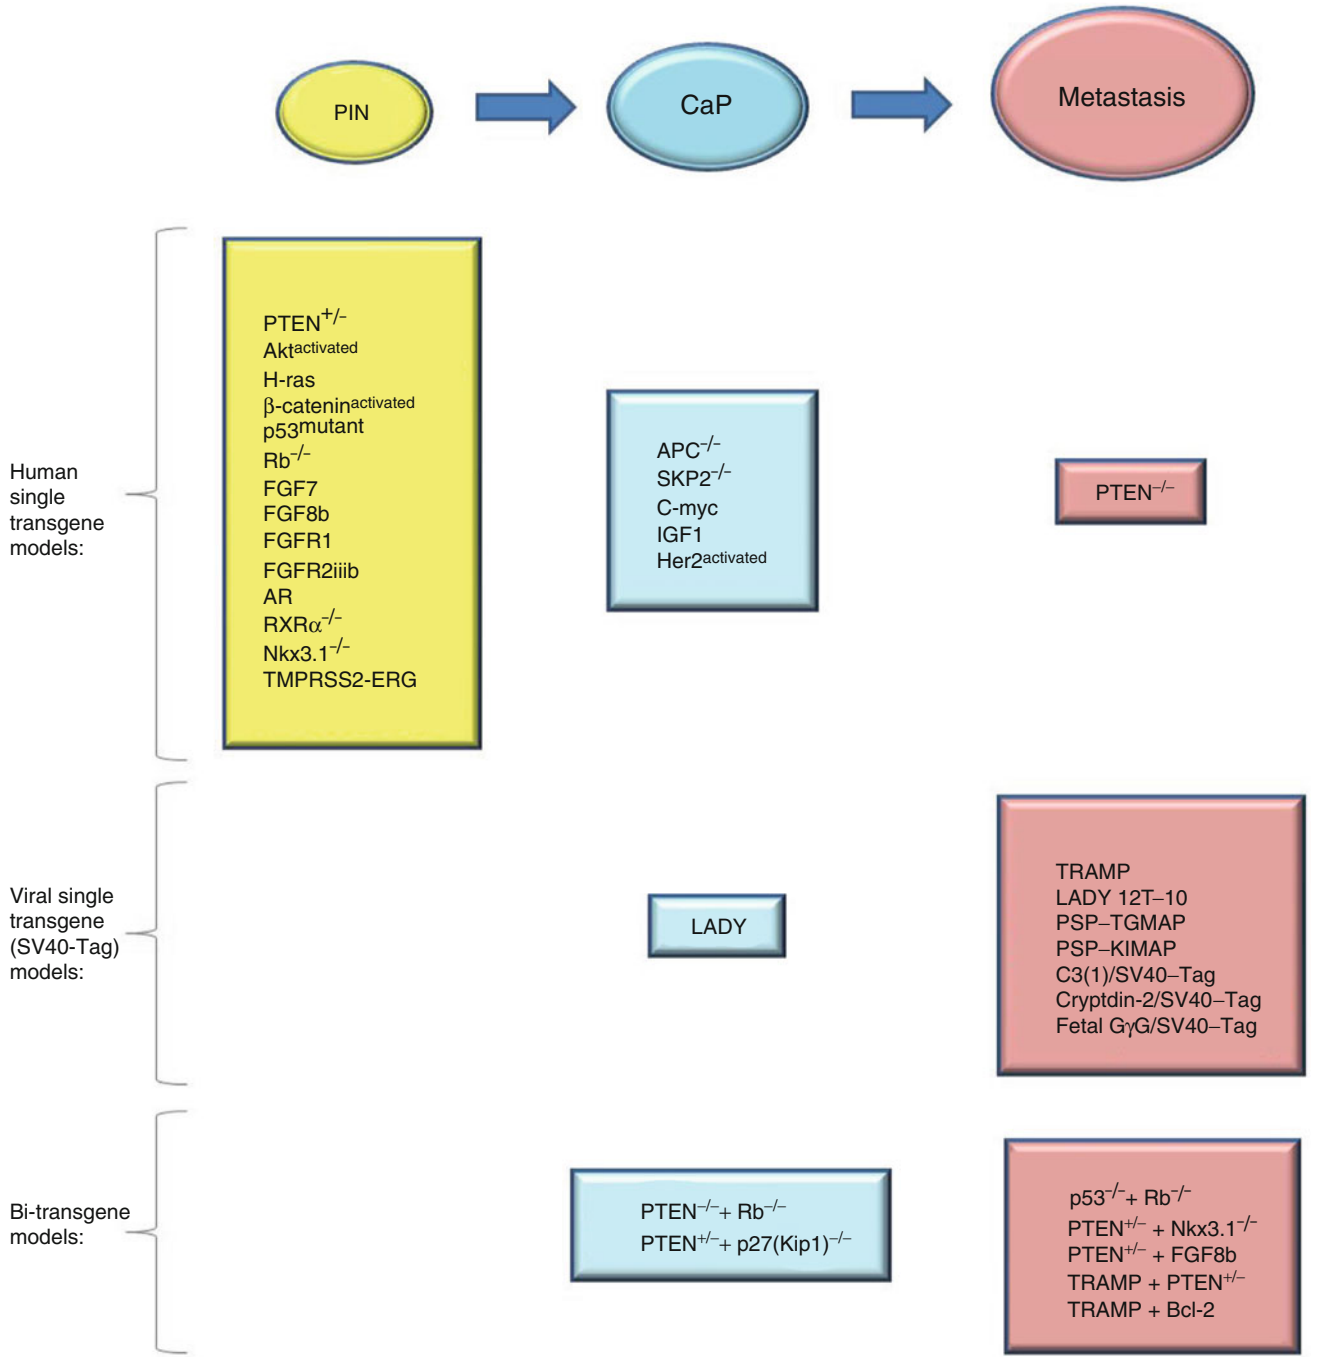

**Fig. 7.2** Transgenic murine models of prostate cancer

murine models of CaP employed ***viral*** **oncogenes** as transgenes, namely, SV40-Tag oncogene derived from simian virus 40 (SV40), which encodes both "large T" and "small t" oncoprotein antigens. SV40-Tag models generate aggressive CaP with high penetrance and short latency (Table 7.4). However, use of these models has been limited due to (1) a lack of a role for the SV40-Tag oncogene in clinical CaP and (2) a predominant neuroendocrine differentiation which is rare in clinical CaP. Other transgenic models employ as trangenes ***human*** **oncogenes/tumor suppressor genes** which are already implicated in clinical CaP. This approach has gained recent popularity with increasing identification of genes and signaling pathways contributing to prostate carcinogenesis. Human transgene models are generally more

**Table 7.4** Metastatic transgenic murine models of prostate cancer using the SV40-Tag oncogene

| Transgenic model name | Promoter | Oncogenes within transgene | Frequency of metastasis (months) | Site of metastasis |
|---|---|---|---|---|
| TRAMP | PB | Large T antigen, small t antigen | 100 % at 6 months | LN, lung, bone, kidney, adrenals |
| LADY 12T-10 | LPB | Large T antigen | 66 % at 6 months<br>88 % at 9 months | LN, liver, lung |
| PSP-TGMAP | PSP94 | Large T antigen, small t antigen | 100 % at 4 months (line A) | LN, kidney |
| PSP-KIMAP | PSP94 | Large T antigen, small t antigen | 85 % at 14 months (LN)<br>25–50 % at16 months (distant) | LN, lung, liver |
| C3(1)/SV40-Tag | C3(1) | Large T antigen | <5 % at 8 months | Lung |
| Cryptidin-2/SV40-Tag | Cryptdin-2 | Large T antigen, small t antigen | 40 % at 6 months | Lung, liver, LN, bone |
| Fetal Gγ-globin/SV40-Tag | Fetal Gγ-globin | Large T antigen, small t antigen | 75 % at 5 months | Kidney, lung, bone, adrenals |

indolent than viral transgene models, with infrequent progression beyond PIN (Fig. 7.2). The following section summarizes specific transgenic murine CaP models using viral or human transgenes.

## Viral (SV40-Tag) Oncogene Transgenic Models

*C3(1)/SV40-Tag*. The first described transgenic prostate cancer model overexpressed the SV40-Tag transgene in prostate tissue by fusing it to a 4.5-kb promoter sequence of the androgen responsive (but not prostate-specific) gene, C3(1) [190–192]. In addition to dysplastic changes in various other organs, male mice develop frequent LGPIN and HGPIN in the ventral and dorsolateral lobes by 3 months, with histologic and genetic changes similar to those seen in humans. Progression to CaP occurs in the ventral lobe after 8 months of age and the dorsolateral lobe after 11 months of age. Ha-Ras, Ki-ras, and p53 mutations are observed in these cancers [191]. However, the C3(1)/SV40-Tag model has received limited study due to relatively low tumor penetrance (40 %) and only rare metastasis (<4 %) limited to the lungs.

*TRAMP model (Pb/SV40-Tag)*. The TRAMP (transgenic adenocarcinoma of the mouse prostate) model is the most extensively characterized transgenic mouse model of CaP. This model was the first to use a prostate-specific promoter to restrict transgene expression to the mouse prostate, fusing SV40-Tag to a rat Pb promoter. Male TRAMP mice develop **highly metastatic tumors in the dorsolateral and ventral prostate lobes with 100 % penetrance**, beginning with PIN by 8 weeks that progresses to poorly differentiated neuroendocrine carcinoma with distant metastasis by 16–32 weeks [193–195]. Tumors are AR positive and initially androgen dependent; however, outgrowth of a metastatic castration-resistant population eventually occurs [196]. While the most common sites of metastasis are the lymph nodes and lungs, **occasional spontaneous metastasis to bone is observed** [197]. The specific mouse strain may alter CaP phenotype with respect to tumor size, distribution, and potential for bone metastasis [198]. Cancer cell lines established from a TRAMP tumor (TRAMP-C1, TRAMP-C2) have been characterized which retain AR expression and tumorigenicity in syngeneic mice [199].

*LADY model* (*LPB/SV40-Tag*). In the LADY model, the SV40-Tag transgene (encoding the large T antigen only) is fused to the long variant of the probasin promoter (LPB/SV40-Tag). LADY tumors begin as PIN-like multifocal lesions in 100 % of mice by 10 weeks, followed by microinvasive carcinomas with neuroendocrine differentiation by 20 weeks [200]. Because the small t antigen is absent, the cancer phenotype is **less aggressive and penetrant than the TRAMP model**, yielding only rare metastases, although initial androgen dependence with progression to androgen independence is similarly observed. Seven LADY model lines have been generated, of which only the *12 T-10* line is metastatic [201]. **LADY 12 T-10 mice develop prostate tumors that spontaneous metastasize to bone**, albeit with lower frequency than observed in TRAMP mice [197, 201].

*Other SV40-Tag models*. Other mouse models similarly use the SV40-Tag transgene (with or without the small t antigen) fused to alternative promoters (Table 7.4). As with TRAMP, these models yield aggressive cancers that progress to metastasis with predominant neuroendocrine differentiation. They are also frequently androgen independent at or near the onset of carcinogenesis. In general, these variant SV40-Tag models have undergone only limited characterization. In rats, a transgenic model using the PB/SV40-Tag transgene referred to as the TRAP (transgenic rat adenocarcinoma of the prostate) model generates strictly androgen-dependent CaP in 100 % of animals by <4 months of age, with complete involution in response to castration at 5 months of age [202].

*Preclinical findings*. Most investigations of SV40-Tag models have been in TRAMP mice. Haram and colleagues performed RNA microarray expressional analysis and

identified 66 genes with concordant alterations in TRAMP and human prostate cancers relative to normal prostate, including the *SOX4* transcription factor gene implicated in many malignancies [203]. Other studies have shown that TRAMP mice have alterations in levels or activation of proteins observed in clinical prostate carcinogenesis, including PI3K/Akt and growth factor receptors for IGF, FGF, and EGF [204–206]. The TRAMP model has also been used to demonstrate efficacy of numerous chemopreventative agents, including genistein, alpha-difluoromethylornithine, COX-2 inhibitors, toremifene, flurbiprofen, green tea polyphenols, catechins, selenium, lycopene, and grape seed extract [207–211]. Chemoprevention studies in the LADY 12 T-10 model support a protective role for reduced dietary fat and various antioxidants, including selenium, vitamin E, and lycopene [212, 213].

## Human Transgene Models

Most human transgene models employ one or more transgenes with functions related to *cell signal transduction*, *regulation of* the *cell cycle/apoptosis*, or *growth factor signaling*. In contrast to viral oncogene models, human transgene models typically generate indolent neoplasms and most often lack progression beyond PIN.

The Wnt/FRZ/beta-catenin signaling pathway regulates cell adhesion and growth, and its dysregulation is implicated in clinical prostate carcinogenesis. **APC** is a negative regulator of Wnt/FRZ/beta-catenin signaling, the loss of which leads to hereditary colon uterine and urothelial cancers, and is frequently observed in spontaneous CaP. Transgenic mice with prostate-specific knockout of APC develop high levels of beta-catenin and PIN-like lesions by 2 months of age that progress to **invasive CaP by 4–7 months of age** [214]. These tumors are androgen dependent based on regression following early castration, with castration-resistant outgrowth observed after an additional 2 months. While upregulation of the oncoprotein, **beta-catenin**,may be responsible for CaP in these mice, only PIN (without CaP) is observed in transgenic mice with prostate-specific beta-catenin constitutive activation [215].

The phosphatidylinositol 3-kinase (PI3K)/Akt pathway mediates a variety of extracellular signals for survival, growth, and migration, and its dysregulation has been increasingly implicated in prostate carcinogenesis. **PTEN** (phosphatase and tensin homolog deleted on chromosome 10) is a key negative regulator of PI3K/Akt signaling and the most commonly mutated gene in clinical CaP. While homozygous PTEN transgenic knockouts cause embryonic lethality, single allele heterozygous knockouts develop LGPIN by 8–10 months, suggesting PTEN haploinsufficiency to be adequate for transformation [216, 217]. In PTEN homozygous knockouts restricted to the prostate (Pb-Cre4/PTEN$^{-/-}$), **100 % of mice develop PIN with rapid progression to CaP by 3 months**, **and 45 % of mice develop metastasis to lungs and lymph nodes by 7 months** without neuroendocrine differentiation [218]. Pb-Cre4/PTEN$^{-/-}$tumors regress in response to castration, although residual cancer cells are observed with a 17-fold higher proliferation rate [218]. PTEN-null prostate tumors have increased Akt kinase activation and demonstrate expression profile signatures similar to clinical metastatic CaP [218]. Bone metastases are not observed in this model. Transgenic mice with a constitutively activated **Akt kinase** transgene develop PIN but not CaP, suggesting carcinogenesis in PTEN-null mice may be in part Akt independent [219]. The GTPase oncoprotein, **H-ras**, activates cell growth through many downstream signaling pathways, including PI3K/Akt and is implicated in several malignancies. Transgenic models with prostate-specific H-ras overexpression form PIN-like lesions but do not progress to invasive CaP, suggesting additional changes are required for carcinogenesis [220].

Loss of cell-cycle and apoptosis regulation is believed to be an important step in the development of many types of malignancies. **p53** and Rb are the most extensively studied cell-cycle/apoptosis regulators, and the former is the most commonly mutated gene in human malignancy. *p53* mutation is common in advanced CaP, and functional loss may occur in up to half of patients with early stage disease as well [221]. While the *Rb* gene is rarely mutated in CaP, loss of a single allele is observed in 17–60 % of early stage tumors. Despite these clinical observations, Evalish et al. observed HGPIN but no CaP in mice with prostate-specific p53 knockout, while Hill et al. observed similar findings in Rb homozygous knockout mice [222, 223]. Similarly, in transgenic models resulting from prostate-restricted overexpression or knockout of the **bcl-2**, **p27$^{Kip1}$** or **c-fos** cell-cycle/apoptosis regulators, no neoplastic phenotype is observed [224–226]. In contrast, invasive CaP is occasionally observed in transgenic mice with prostate-specific overexpression of the **S-phase kinase-associated protein 2** (**SKP2**) proto-oncogene, a ubiquitin ligase which targets p27 and other cell-cycle inhibitors for degradation [227]. However, despite PIN formation in most mice by 4–7 months of age, the incidence of CaP in this model is only 4 %.

*Thus*, *alteration of individual cell cycle/apoptosis regulators is generally insufficient for malignant transformation*. The main exception is highly penetrant invasive CaP observed with ARR$_2$PB-driven prostate-specific overexpression of **c-myc**, a transcriptional activator of cell cycle progression commonly amplified in clinical HGPIN and CaP [187]. Of these mice, **100 % develop HGPIN and invasive CaP** within 3–6 months or 10–12 months depending on whether c-myc levels are high (“Hi-Myc” founder line) or low (“Lo-Myc” founder line), respectively, possibly due to dose dependence. Complete tumor regression occurs with early castration (4

months), but androgen-independent outgrowth occurs with delayed castration (8 months), suggesting a therapeutic benefit for earlier androgen deprivation. RNA microarray comparison between mouse and patient prostate tumors revealed concordant expression patterns for a number of CaP-related genes, including *TMPRSS2, Nkx3.1, and PIM1*. On the other hand, only HGPIN is observed in mice expressing a c-myc transgene driven by the C(3)-1 androgen responsive promoter [188]. This phenotypic discrepancy may reflect lower prostate-specific activity of the C(3)-1 promoter relative to $ARR_2PB$, further supporting dose-dependent transformation.

Increased signaling from cell surface growth factor receptors is a common feature of many malignancies including CaP. **Insulin growth factor 1** (IGF-1) is a potent activator of the PI3K/Akt pathway through its receptor IGF-1R and shows increased levels in CaP patient serum. DiGiovanni and colleagues found that transgenic expression of *IGF-1* in the mouse prostatic basal epithelium using the bovine keratin 5 (BK5) promoter results in **PIN and CaP with rates of 100 and 50 %, respectively**, after >6 months [228]. Li and colleagues observed similar findings in transgenic mice with prostate-specific expression of constitutively activated **HER-2** (Neu/ERBB2/EGFR2), a member of the epidermal growth factor receptor (EGFR) family and PI3K/Akt activator commonly upregulated in advanced clinical CaP [229]. Pb/HER-2 mice develop **LGPIN**, **HGPIN**, **and invasive CaP in a median of 12**, **16**, **and 18 months**, which is notably slower than in PTEN, IGF-1, or c-myc transgenic models. Cancers do not extend beyond the prostatic capsule and are poorly differentiated but negative for neuroendocrine markers. Pb/HER-2 tumors express phosphorylated AR; however, androgen sensitivity has not been evaluated. Other transgenic models overexpress various members of the **fibroblast growth factor** (**FGF**) **family**, whose expression is commonly altered in clinical prostate cancers, including FGF8b, FGFR1, FGF7, and FGFR2iiib. However, these models form only benign changes or PIN-like lesions, and dysregulated FGF signaling alone appears insufficient to induce invasive CaP [230–232].

Steroid hormone receptors are key intracellular regulators of cell growth and apoptosis believed to contribute to many malignancies. Signaling through **AR** has long been implicated in clinical prostate carcinogenesis based on clinical responsiveness of this cancer to androgen deprivation. Stanbrough and colleagues have characterized transgenic mice with high levels of prostatic AR protein using an AR transgene driven by a rat PB promoter (Pb/AR) [233]. These mice have hyperproliferative but otherwise histologically normal prostates up until 1 year of age, after which they develop lesions consistent with HGPIN but without progression to invasive CaP. Other studies have characterized the prostate phenotype in transgenic models of dysregulated **estrogen receptor** (ER) signaling. Knockouts of ER-alpha or ER-beta yield normal prostate morphology or benign prostatic hyperplasia, respectively, without progression to invasive CaP [234, 235]. **Retinoic acid receptors** (RAR/RXR) are steroid hormone receptors of retinoids, regulators of differentiation and apoptosis implicated in the suppression of clinical CaP. Prostate-specific knockout models of different RAR/RXR receptors develop normal prostates, squamous metaplasia, or PIN-like changes [236, 237]. *Overall*, *dysregulated steroid hormone receptor signaling appears to be insufficient for prostate carcinogenesis in transgenic models*.

The **NKX3.1** and **TMPRSS2-ERG** genes are heavily implicated in prostate tumorigenesis and progression. NKX3.1 is an androgen-regulated, prostate-specific homeobox (required for organogenesis) transcription factor with tumor suppressive function that is downregulated in clinical CaP and PIN. This gene maps to a region on human chromosome 8p21 with allelic loss in most CaP tumors and PIN lesions, suggesting haploinsufficiency as a possible early tumorigenic event. Independent studies show that whole-body or prostate-specific NKX3.1 homozygous knockout results in only PIN-like lesions, without progression to CaP [238, 239]. Loss of a single NKX3.1 allele is sufficient to generate low-grade PIN, supporting a role for haploinsufficiency [238]. The TMPRSS2-ERG gene fusion consists of the androgen-driven serine protease TMPRSS2 fused to the ERG member of the ETS transcription factor family and is commonly detected in CaP patients. Transgenic models using a TMPRSS2-ERG transgene yield PIN by 3–4 months but without progression to invasive CaP [240]. *Thus*, *the NKX3.1 and TMPRSS2-ERG genes may contribute to transformation of the prostate but by themselves appear to be insufficient for CaP formation*.

## Multi-Transgenic Models: The Future of CaP Murine Models

With few exceptions (*SV40-Tag*, *PTEN*, *APC*, *c-myc*, *SKP2*, *HER-2*, *and IGF-1*), a single transgene is generally insufficient for progression beyond benign prostatic hyperplasia or PIN-like lesions, suggesting the requirement of multiple genetic mutations for invasive CaP and metastasis (Fig. 7.2). Mouse models with a combination of two or more transgenes have recently been generated and yield invasive CaP with high penetrance and frequent metastasis (Fig. 7.2). For example, while Rb or p53 homozygous knockout mice each fail to develop CaP, combined **$Rb^{-/-}$/$p53^{-/-}$**prostate-specific knockout mice develop **highly metastatic CaP by 6–12 months with 100 % penetrance** [241]. Sites of metastasis include lymph nodes, liver, lungs, and infrequently the adrenal gland. Prostate tumors in this model have neuroendocrine differentiation and AR-positive androgen-independent growth regardless of castration timing. Not surprisingly, this phenotype is similar to transgenic models

of SV40-Tag, which functionally inactivate both p53 and Rb. Several multi-transgenic models have also been generated by crossing PIN-forming **PTEN$^{+/-}$** heterozygous knockouts with various single-transgene mice that alone similarly fail to form invasive CaP, including **p27$^{-/-}$**, **NKX3.1$^{-/-}$**, **or FGF8b$^{+/+}$** [242–244]. The resulting bi-transgene models form **rapidly growing CaP**, **with the latter two metastasizing to lymph nodes**.

In single transgene models that already form CaP, the addition of a second transgene enhances CaP incidence and aggression. For example, **p53$^{-/-}$/PTEN$^{-/-}$**dual homozygous knockout results in **CaP with high local aggression lethal within 7 months** [245]. As technologic advances allow whole genetic profiles of clinical CaP to be readily determined, multi-transgenic mouse modeling will provide a useful tool for investigating mutation-specific directed treatments.

## Murine Modeling of Prostate Cancer Bone Metastasis

Bone metastasis is the underlying cause of significant morbidity and mortality for the vast majority of CaP patients. The development of more effective therapies has been hindered by a scarcity of preclinical models to study this process, as murine models of CaP generally fail to demonstrate the affinity for bone marrow colonization observed clinically. Nevertheless, few murine models have provided useful tools for CaP bone metastasis research. The main examples are described below.

### Transgenic SV40-Tag Models

Several transgenic mouse models using the SV40-Tag oncogene form bone metastases, although generally with only low frequency. In the initial characterization of TRAMP metastases, Gingrich et al. observed only a single skeletal metastasis [194]. The lesion was well differentiated with a cribriform pattern and occurred in the lumbar vertebrae of a young (23 week) mouse. Gupta et al. have since reported a **25 % incidence of TRAMP model bone metastasis by 32 weeks**, as well as complete suppression achieved by chemopreventative green tea phenol [197]. In the **LADY model line 12T-10**, Masumori et al. observed **bone lesions in 9 % of mice >6 months of age**, some without other metastatic sites [201]. Low frequency of bone metastasis is also reported in SV40-Tag models using the cryptdin-2 or fetal gamma globin promoters, although these models are not well characterized [246, 247]. Overall, use of SV40-Tag models for investigation of bone metastasis therapies has been limited by the low incidence of events and predominant neuroendocrine differentiation of metastatic lesions.

The addition of a second transgene to SV40-Tag models may provide an effective approach for increasing bone metastasis, as observed with the **LPB-SV40-Tag/PB-hepsin$^{-/-}$model**. Hepsin is a serine-threonine transmembrane protease involved in maintaining basement membrane organization and is overexpressed by up to 34-fold in clinical CaP. Although PB-hepsin$^{-/-}$mice are nontumorigenic, crosses with the 12T-7 nonmetastatic LADY line have generated offspring that form **bone metastases with a nearly 40 % incidence** [248]. As with other SV40 models, LPB/SV40-Tag// PB-hepsin$^{-/-}$metastases have predominant neuroendocrine differentiation, limiting the model's clinical generalizability. *In transgenic models without SV40-Tag*, *bone metastases are yet to be observed*.

### MPR Models

The **MPR model** recreates prostate tumorigenesis by ectopic implantation of urogenital sinus under the renal capsule of syngeneic immunocompetent mice, as described earlier in this chapter. Using urogenital sinus tissue genetically manipulated to have loss of p53 and overexpression of ras and myc, investigators have achieved bone metastasis in **almost 100 % of mice with high affinity for the sternum and lumbar vertebrae**, common clinical sites of CaP metastasis [182, 249]. **Metastasis formation is rapid**, **requiring less than 2 months**. Shaker and colleagues have used this model to demonstrate a suppressive effect of a synthetic retinoid on bone metastasis [249]. Histopathologic description of bone metastases is needed, and the technical complexity of the MPR model has limited its use.

### Tumor Transplant Models

Two types of assays in tumor transplant models have traditionally been used in mice to study metastasis: *spontaneous* metastasis assays, which generate primary tumors (subcutaneous, renal subcapsular, or orthotopic) that disseminate to form distant metastases, and *experimental* metastasis assays, which bypass primary tumor formation by injection of cancer cells directly into the venous circulation (typically via the tail vein) to induce metastatic colonization. For some cell lines, including CWR22R, LAPC-4, and PC-3 cell lines (and their sublines), micrometastases in bone have been demonstrated using various molecular techniques; however, overt lesions are generally not observed [147, 250–252]. An exception is the **C4-2 clonal tumor line derived from LNCaP xenografts**. Unlike its parental line, the C4-2 xenograft is androgen independent and **metastatic to the lymph nodes**, **long bones**, **and spinal column**, more so in castrated mice. C4-2 bone lesions are mixed osteoblastic/osteolytic and occur

grossly **in approximately 50 and 20 % of castrate mice using subcutaneous and orthotopic transplantation, respectively**, and at higher frequency with specific modifications such as supplementation with parathyroid hormone [253, 254].

Alternative implantation approaches have been described that reliably generate bone metastases when performed with select CaP cell lines, particularly **PC3 and the MAT-LyLu rat CaP cell line**. Specific techniques include (1) intracardiac (left ventricle) injection, (2) tail vein injection with inferior vena cava (IVC) clamping, and (3) direct in intraosseous injection. **Intracardiac injection of the PC3 cell line, or its subline PC3-M, leads to bone metastases involving the femur, thorax, and mandible with variable (20–100 %) incidence** [255–257]. Lesions are osteolytic only, in contrast to clinical bone metastases. While spinal metastases are rare with PC3, **intracardiac injection of MAT-LyLu cells yields lumbar spinal metastases with 100 % incidence** in parental Copenhagen rats which present with hind limb paresis by 2–3 weeks [258, 259]. Mat-LyLu bone lesions are mixed osteoblastic/osteolytic as in clinical disease. MAT-LyLu overexpression of urokinase increases spinal metastasis and involvement of other skeletal sites as well [260].

Similarly, **tail vein injection with transient IVC clamping using Mat-LyLu cells (Geldof model) reliably generates symptomatic lumbar spinal metastases** within a short time frame of two weeks [261]. The incidence of PC3 bone metastases is lower with this approach (20 %), although higher rates are possible with specific PC3 sublines [262].

**Direct intraosseous injection** may also enable study of cancer cell colonization of rodent bone while avoiding metastasis of other organs. Common implantation sites include the calvarium, tibia, and femur. Successful implantation requires prior mechanical disruption of periosteum, often using the inoculation needle [123]. Corey and colleagues used this approach to establish **osteolytic lesions with PC3 and LuCaP35 cell lines, osteoblastic lesions with LuCaP23 cells, and mixed osteolytic/osteoblastic lesions with LNCaP, with success rates of 50–100 %** [263]. Rat prostate cancers studied with intraosseous injection include the **Dunning MAT-LyLu cell line, the Pollard PA-III cell line, and DMAB carcinogen-induced F344 rat CaP** [124, 129, 264, 265]. Each of these cancers generates **mixed osteoblastic/osteoclastic lesions with direct injection in the calvaria, scapula, or femurs of their parental rat strains with near 100 % efficacy**. Preclinical findings using the PA-III line support an important role for insulin growth factor signaling in osteoblastic metastases to bone [125]. Intraosseous injection studies also support a critical role for urokinase plasminogen activator (uPA) and TGF-beta1 activation in osteoblastic reactions, in addition to metallomatrix proteases and RANKL (receptor activation of nuclear kappa-B ligand) signaling in osteoclast reactions [125]. Caveats of this approach include that it disrupts bone architecture and that it may turn out to be more representative of primary tumor bone colonization than metastasis.

## SCID-Human Model of CaP Bone Metastasis

The scarcity of human CaP cell lines which are able to colonize rodent bone may reflect the absence of a growth-promoting microenvironment in mouse bone that is present in human bone. The **SCID-Human (SCID-Hu) model** of CaP bone metastasis described by Nemeth and colleagues uses human bone fragments implanted subcutaneously in SCID mice as targets for metastatic colonization by human CaP cell line xenografts. Supporting the importance of the bone microenvironment in CaP metastasis development, **human CaP cell lines (PC3, LNCAP, DU145, LAPC-4) injected via the tail vein or directly into subcutaneous human bone transplants preferentially colonize the human bone rather than mouse bone or subcutaneous human lung and intestine transplants** [266–268]. Rates of colonization of human adult bone are 35 and 65 % for intravenously injected LNCaP and PC3, respectively [268]. Direct injection using fetal bone approaches 100 % for each cell line [266]. PC3, DU145, and LAPC-4 cell lines generate osteoclastic bone lesions, whereas LNCAP uniquely makes mixed osteoblastic/osteoclastic lesions, and colonization is preferentially in the bone marrow cavity [267]. Bone-tumor interaction sites express high levels of PTHrP, TNF alpha, and IL-6, consistent with osteoclast recruitment and activity [267]. Preclinical findings with the SCID-Hu model support *in vivo* efficacy of an endothelin-1 receptor antagonist in combination with docetaxel and indicate the ability of TIMP to suppress CaP osteolysis [269, 270].

### Conclusion

Murine models are critical to preclinical CaP investigation, as they enable hypothesis-driven experimentation in a diverse tissue/multicellular microenvironment that cannot be recapitulated by available *in vitro* platforms. Numerous of such models for CaP have been characterized and vary widely in both practicality and ability to simulate key aspects of clinical disease. Currently, no murine model mimics all the attributes of clinical prostate carcinogenesis, and the value of any one model may be best assessed by its "track record" for predicting treatment response in the clinical setting. Future challenges of murine modeling of CaP include the development of improved bone metastasis models, avoiding elaborate technical modifications currently required. Ultimately, the generation of multi-transgenic mouse models may provide the most useful tools for evaluating "personalized" treatment of patient tumors with defined mutational profiles.

# Prostate Cancer and the Metabolic Syndrome

8

Stephen E.M. Langley and Jenny P. Nobes

## Introduction

Men with prostate cancer have higher rates of noncancer mortality than men in the general population, with some of this excess attributed to the adverse effects of treatment [1], and there is evidence for an increased prevalence of metabolic syndrome with the therapeutic use of androgen deprivation therapy (ADT) in prostate cancer [2]. The metabolic syndrome is characterized by a cluster of metabolic risk factors for cardiovascular disease (CVD). Because of the generally favorable prognosis for early prostate cancer, decisions about which treatment is likely to offer the most benefit in the long term are particularly important.

ADT may be used to treat men with local and locoregional disease and is the mainstay of treatment for metastatic prostate cancer [3]. ADT may be achieved either through surgical castration (bilateral orchidectomy) or chemical castration with a gonadotropin-releasing hormone (GnRH) agonist, the most common approach in modern clinical practice [4].

Traditionally, the use of ADT was reserved for advanced prostate cancer [5]. There has, however, been a trend toward increasing use of ADT in prostate cancer patients [5–9], both as neoadjuvant and primary therapy, since the advent of PSA testing. A population-based cohort study concluded that widespread detection and aggressive treatment of prostate cancer in the USA has been associated with more, rather than less, use of ADT over time [5].

## The Metabolic Syndrome

The metabolic syndrome (also known as syndrome X, Reaven syndrome [10], insulin resistance syndrome) is defined by a cluster of lipid and non-lipid metabolic risk factors for CVD, with insulin resistance (IR) as the central characteristic.

In IR, there is an exaggerated insulin response to ingested carbohydrates, especially those with a high glycemic index (GI). Insulin acts on fat cells resulting in hydrolysis of stored triglycerides, which elevates plasma levels of free fatty acids. These free fatty acids are absorbed by the liver, resulting in an increased production of triglycerides and very low-density lipoprotein (VLDL) cholesterol and a decreased production of high-density lipoprotein (HDL) cholesterol. Insulin acts on muscle to reduce glucose uptake, whereas in liver it reduces glucose storage, with both effects serving to elevate blood glucose. High levels of insulin cause increased renal sodium absorption, arterial vasospasm, and consequently hypertension. Endothelial effects of elevated insulin levels are also seen, mediated by nitrous oxide. In addition, impairment of cellular repair is apparent, with increased levels of pro-inflammatory cytokines. Concentrations of bound and free serum testosterone, sex hormone-binding globulin (SHBG), and androgen receptor are reduced [11].

The prevalence of metabolic syndrome has increased markedly over the last two decades, coincident with the global epidemics of obesity [12] and type II diabetes [13]. Studies using data from the Third National Health and Nutrition Examination Survey (NHANES III) have indicated that the age-adjusted prevalence of the metabolic syndrome increased from 29.2 % in 1988–1994 to 32.3 % in 1999–2000 [14, 15]. Prevalence varies by race and sex and increases with age [16–18].

## Definitions of the Metabolic Syndrome

Three of the most commonly recognized definitions of the metabolic syndrome are outlined in Table 8.1. Most studies

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_8, © Springer-Verlag London 2013

**Table 8.1** Comparison of three commonly used definitions of the metabolic syndrome (criteria listed may differ for women)

| NCEP adult treatment panel III (ATP III) definition [19] | WHO definition [22] | IDF definition [21] |
|---|---|---|
| Three or more of the following: | Impaired glucose tolerance or diabetes and/or insulin resistance and two or more of the following: | Central obesity (or BMI >30 kg/m$^2$) and two or more of the following: |
| Fasting glucose ≥6.1 mmol/l | Impaired glucose tolerance or diabetes | Fasting glucose ≥5.6 mmol/l or previously diagnosed type 2 diabetes |
| Triglycerides ≥1.7 mmol/l | Triglycerides ≥1.7 mmol/l and/or HDL <0.9 mmol/l | Triglycerides >1.7 mmol/l (or treatment) |
| HDL <1.0 mmol/l | | HDL <1.03 mmol/l (or treatment) |
| Blood pressure ≥130/85 mmHg | Blood pressure ≥140/90 mmHg | Blood pressure ≥130/85 mmHg or treatment |
| Central obesity: waist circumference >102 cm | Central obesity: waist to hip ratio >0.9 and/or BMI >30 kg/m$^2$<br>Insulin resistance (under hyperinsulinemic, euglycemic conditions, glucose uptake below lowest quartile for background population)<br>Microalbuminuria | Central obesity: waist circumference >94 cm (Europid[a] men); >90 cm (South Asian men) |

[a]In the USA, NCEP ATP III definition of central obesity (waist circumference >102 cm) recommended

published to date on the metabolic syndrome, prostate cancer, and ADT have used the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) definition – the presence of three or more of the following: central obesity, elevated triglycerides, low HDL cholesterol, raised blood pressure, or raised fasting plasma glucose [19, 20]. The panel advised that central obesity is more highly correlated with metabolic risk factors than body mass index (BMI) and measurement of the waist circumference is, therefore, recommended to confirm the diagnosis.

Other definitions have been published by The International Diabetes Federation (IDF) [21] and the World Health Organization [22] (Table 8.1). The NCEP ATP III and IDF definitions are very similar, although the IDF definition excludes any person without central obesity and defines central obesity according to geography-specific thresholds.

## The Metabolic Consequences of Androgen Suppression

The importance of treatment-related morbidity and mortality in prostate cancer patients is well-recognized [23]. ADT-induced hypogonadism has been associated with increased BMI and fat mass, reduced lean body mass and muscle strength, osteoporosis (see section "Androgen Deprivation Therapy and Bone Health"), sexual dysfunction, and poor quality of life [2, 24–26], probably as a direct consequence of hypogonadism as prevalence was significantly higher in men prescribed ADT compared with men who had surgery and/or radiotherapy alone or controls [24]. GnRH agonists have also been shown to decrease insulin sensitivity [2, 27] and increase fasting insulin levels [28, 29]. Changes in serum lipoproteins [2, 26, 29] and arterial stiffness [28, 29], as well as possible QT interval prolongation [30, 31], have also been reported.

Male hypogonadism is an independent risk factor for the development of metabolic syndrome. Epidemiological studies have shown that low serum testosterone levels are associated with dyslipidemia, particularly elevated total cholesterol, LDL cholesterol, and triglycerides [32] and that testosterone replacement can improve lipid profiles in hypogonadal men [33]. A cross-sectional survey of 400 men aged between 40 and 80 years revealed that higher testosterone and SHBG levels were independently associated with higher insulin sensitivity and a reduced risk of metabolic syndrome, independent of insulin levels and body composition [11]. Other studies have found that low total testosterone and SHBG levels independently predict the development of metabolic syndrome in middle-aged men [34, 35].

Metabolic syndrome, according to NCEP ATP III criteria, was present in 55 % of men undergoing long-term (12+ months) ADT for prostate cancer, a prevalence significantly higher than in age-matched hormone-naïve patients with prostate cancer (22 %; $p<0.01$) and age-matched controls without prostate cancer (20 %; $p=0.03$) [20]. Men on ADT had significantly higher abdominal obesity and hyperglycemia compared with the other groups and significantly elevated triglycerides compared with controls.

Short-term prospective studies of ADT in men with prostate cancer have shown the development of adverse body compositional changes and increased serum insulin levels after only 3 months' treatment, indicative of reduced insulin sensitivity [28]; and in long-term ADT (12+ months), there are higher levels of fasting insulin and glucose compared with disease and age-matched controls not on ADT, with

evidence of IR in men on ADT, according to the homeostatic model assessment for IR ($HOMA_{IR}$) [36].

Two studies published in 2007 examined the association between ADT and the development of diabetes or worsening glycemic control [37, 38]. Lage et al. [37] concluded that, after controlling for other factors, the relative risk (RR) of incident diabetes was 1.36 ($p=0.01$) in men who received ADT, while Derweesh et al. [38] observed an increase of ≥10 % in serum HbA1c or fasting glucose levels in 19.5 and 28.6 %, respectively, of men with preexisting diabetes. More recently, Keating et al. [39] reported that the use of ADT was associated with a significantly increased risk of incident diabetes (HR 1.28 [95 % CI 1.19,1.38]).

The characteristics of the metabolic syndrome occurring in androgen-suppressed prostate cancer patients may differ from the classic metabolic syndrome [40]. In a prospective study, 26 patients with recurrent or locally advanced prostate cancer were treated with leuprolide for 12 months before analysis. At follow-up, GnRH agonists increased subcutaneous fat mass, HDL cholesterol, and adiponectin but did not alter the waist to hip ratio, blood pressure, or C-reactive protein level.

## Androgen Deprivation Therapy and Bone Health

Another important side effect of ADT with a GnRH agonist is a reduction in bone mineral density (BMD) as a consequence of the decline in sex steroid levels. The loss of BMD affects multiple skeletal locations, is most rapid during the first few months of ADT, and continues with further use [41–44]. Bone loss at the lumbar spine has been estimated at 2–8 % and 1.8–6.5 % at the femoral neck during the first 12 months of continuous ADT [25, 43–46]. Ultimately, osteopenia may lead to osteoporosis, thereby increasing the risk of fracture, as confirmed by epidemiological studies. Shahinian et al. [47] studied the records of 50,613 men with prostate cancer using the Surveillance, Epidemiology and End Results (SEER) database and found that for men surviving at least 5 years after diagnosis, 19.4 % of ADT-treated had a fracture compared with 12.6 % of men who were not treated with ADT ($p<0.001$). Adjusted Cox proportional hazards analysis indicated a statistically significant relationship between the number of doses of GnRH agonist received during the 12 months after diagnosis and the subsequent risk of fracture. While the Shahinian et al. [47] study population included men with metastatic disease, Smith et al. [48] conducted an analysis in a sample of Medicare beneficiaries with non-metastatic prostate cancer and confirmed that GnRH agonists significantly increased the risk of any clinical fracture, hip fracture, and vertebral fracture. The rate of any fracture was 7.88/100 person-years in men receiving a GnRH agonist ($n=3,887$) compared with 6.51/100 person-years in matched controls ($n=7,774$) (relative risk 1.21 (95 % CI 1.14,1.29); $p<0.001$). GnRH agonist treatment independently predicted fracture risk in multivariate analyses, and a longer duration of treatment conferred greater fracture risk.

Randomized-controlled trials have demonstrated that bisphosphonates can help to prevent loss of BMD during ADT [49–54]. Diamond et al. [49] demonstrated the beneficial effects of a single injection of pamidronate (90 mg) while Smith et al. [50] reported the advantages of 4 mg zolendronic acid every 3 months for a year on BMD at multiple sites. Michaelson et al. [51] investigated the effect of a single treatment with zoledronic acid (4 mg) compared with placebo and reported that mean BMD at the posteroanterior lumbar spine decreased by 3.1 % in men assigned to placebo and increased by 4.0 % in men assigned to zoledronic acid ($p<0.001$). BMD of the total hip decreased by 1.9 % in men assigned to placebo and increased by 0.7 % in men assigned to zoledronic acid ($p=0.004$). Satoh [52] also demonstrated that a single infusion of zoledronic acid (4 mg) reduces bone mineral loss and maintains BMD at 12 months during ADT. Among 112 men with non-metastatic prostate cancer receiving ADT, alendronate (70 mg once weekly) was associated with an increased BMD over 1 year of 3.7 % at the spine and 1.6 % at the femoral neck, compared with losses of 1.4 % at the spine and 0.7 % at the femoral neck in men who did not received alendronate [53]. Alendronate has also been shown to reduce fracture risk. Treatment with once-weekly 70 mg alendronate significantly improved the BMD at the lumbar spine and femoral neck in patients with prostate cancer on ADT who had severe osteopenia or osteoporosis and significantly decreased the risk of femoral neck fracture [54].

Smith et al. [55] have reported beneficial effects on BMD and fracture risk with denosumab, a monoclonal antibody, in a double-blind multicenter study in men receiving ADT for non-metastatic prostate cancer. Patients were randomly assigned to receive placebo or denosumab (60 mg) every 6 months. After 24 months, the BMD of the lumbar spine had increased by 5.6 % in the denosumab group compared with a loss of 1.0 % in the placebo group ($p<0.001$). Significant differences between the two groups apparent after only 1 month were sustained at 36 months. Denosumab therapy was also associated with significant and sustained increases in BMD at the hip, femoral neck, and distal third of the radius. Compared with patients who received placebo, patients who received denosumab had a decreased incidence of new vertebral fractures at 36 months (1.5 % vs. 3.9 %; relative risk 0.38 (95 % CI 0.19,0.78); $p=0.006$).

In other studies by Smith et al. [56–58], the effects of selective estrogen receptor modulators on BMD have been observed. In a 12-month open label study of raloxifene (60 mg/day), BMD at the hip was significantly increased and

there was a (nonsignificant) increase in BMD of the spine [56]. In a double-blind, placebo-controlled phase III study, Smith et al. [57, 58] reported fracture incidence in men receiving ADT for prostate cancer during a 2-year period. Six hundred and forty-six men were assigned to toremifene (80 mg daily) and 638 were assigned to placebo. The 2-year incidence of new vertebral fractures was 4.9 % in the placebo group compared with 2.5 % in the toremifene group, a significant relative risk reduction of 50 % (95 % CI −1.5,75.0, $p<0.05$). Compared with placebo, toremifene significantly increased BMD at the lumbar spine, hip, and femoral neck ($p<0.0001$ for all comparisons) and there was a concomitant decrease in markers of bone turnover. Toremifene also significantly improved lipid profiles (see below). It should be noted, however, that venous thromboembolic events (none fatal) occurred more frequently with toremifene than with placebo (7 patients [1.1 %] in the placebo group and 17 [2.6 %] in the toremifene group).

Bicalutamide increases serum concentrations of testosterone and estradiol and may, therefore, have a less deleterious effect on bone health than GnRH agonists [59]. Wadhwa [60] found that among 618 men with prostate cancer who were about to commence ADT, 41 % were osteoporotic, 39 % were osteopenic, and 20 % had normal BMD. Patients with osteoporosis were commenced on bicalutamide while patients with osteopenia or normal BMD were commenced on a GnRH agonist. Both groups received calcium and vitamin D supplements. Men treated with a GnRH agonist had significant decreases in BMD (1.2 % at 1 year, 12.7 % at 6 years) while the osteoporotic group treated with bicalutamide maintained BMD over 6 years.

Results of retrospective studies of ADT-treated patients who did not receive antiresorptive therapy have demonstrated a 21–37 % increase in fracture risk [44], reinforcing the conclusion that an assessment of bone health in men starting ADT is recommended. General measures to prevent bone loss should be encouraged, including regular physical activity and maintaining calcium and vitamin D sufficiency. The use of a pharmacological agent to reduce loss of BMD during ADT may be indicated.

## Androgen Deprivation Therapy and Cardiovascular Disease

From the early 1940s, estrogen was used to treat men with prostate cancer [61]. Reports of a discrepancy between disease-specific survival and overall survival emerged in the late 1960s/early1970s [62–64], however. Although estrogen therapy achieved clinical responses in up to 80 % of patients and delayed disease progression, there was little evidence of improved overall survival; estrogen use was associated with cardiovascular toxicity in up to 35 % of patients [64]. Because of this, GnRH agonists, which were thought to have negligible cardiovascular toxicity, replaced estrogens as standard treatment [65].

It has been reported that men with prostate cancer have higher cardiovascular mortality [66, 67] and death from CVD has become the most common cause of non-prostate cancer-related deaths in these men [68, 69]. Now, several studies have raised awareness of the adverse cardiovascular consequences of androgen suppression in prostate cancer patients.

Keating et al. [70] analyzed outcomes of 73,196 patients treated for locoregional prostate cancer, diagnosed between 1992 and 1999, using the SEER–Medicare database. The mean age of study participants was 74.2 years and follow-up was for a median of 4.5 years. Overall, 36.3 % of men received a GnRH agonist and 6.9 % underwent a bilateral orchidectomy during follow-up. Compared with untreated men, the risk of a cardiovascular event was significantly higher in men treated with ADT (hazard ratios [HRs]: coronary heart disease [CHD] 1.16, $p=0.001$; myocardial infarction [MI] 1.11, $p=0.03$; sudden cardiac death 1.16, $p=0.004$). The risks of cardiovascular events among men who had an orchidectomy were not similarly increased, although this may have been due to small numbers.

Another observational study from Keating et al. [39] used data from the Veterans Healthcare Administration for 37,443 men diagnosed with prostate cancer between 2001 and 2004. After adjusting for age, ethnicity, and other relevant variables, the use of ADT was associated with a significantly increased risk of incident CHD (HR 1.19 [95 % CI 1.10,1.28]), MI (HR 1.28 [1.08,1.52]), sudden cardiac death (HR 1.35 [1.18,1.54]), and stroke (HR 1.21 [1.05,1.40]).

Tsai et al. [67] conducted a retrospective analysis of data from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) registry to assess whether the use of ADT was associated with shorter time to cardiovascular death, after controlling for age and CVD risk factors at baseline. Data were included for 3,262 men with localized prostate cancer who had undergone radical prostatectomy and 1,630 patients who had received EBRT, brachytherapy, or cryotherapy. The median follow-up was 3.8 years. In total, 1,015 patients had received ADT (26.2 % of those were treated by radical prostatectomy), with a median duration of 4.1 months. In the prostatectomy group, 8.2 % of patients had received ADT, compared with 46 % in the group treated by EBRT, brachytherapy, or cryotherapy. Using competing risks regression analysis, the investigators found that ADT use (HR 2.6 [95 % CI 1.4,4.7]; $p=0.002$) and age (HR 1.07 [1.02,1.1]; $p=0.003$) were associated with a significantly increased risk of cardiovascular death in patients treated with radical prostatectomy and that the 5-year cumulative incidence of cardiovascular death among those patients aged 65+ who received ADT was 5.5 % (1.2, 9.8 %) and 2.0 % (1.1, 3.0 %) for those who did not.

Saigal et al. [71] used the SEER-Medicare database to identify patients diagnosed with prostate cancer between 1992 and 1996. Patients were followed for 5 years, and any who experienced a cardiovascular event during the first year of follow-up were not eligible for inclusion. The analysis was based on 22,816 individuals; ADT had been prescribed to 4,810 (21 %). On multivariate analysis, ADT was associated with a significantly increased risk of cardiovascular morbidity (HR 1.2 [95 % CI 1.15,1.26]).

D'Amico's group [72] retrospectively analyzed data for 1,372 men who were pooled from three randomized-controlled trials between1995 and 2001 to investigate whether the use of ADT affected the frequency and timing of MI. The analysis found a shorter time (by 2 years) to fatal MI in men aged over 65 years treated with 6 months of ADT, compared with men of the same age who were hormone naïve ($p=0.017$). Patients aged 65+ who had received ADT for 3 months had an incidence of fatal MI that was similar to that observed in men who had used ADT for 6 months ($p=0.97$), supporting the observation that a 3-month treatment period is enough to cause deleterious cardiovascular effects [28]. In addition, the incidence of fatal MI in ADT-treated patients had an earlier onset than in hormone-naïve patients.

## Metabolic Syndrome as a Risk Factor for Cancer

It is possible that the metabolic syndrome may contribute to tumorigenesis and that the individual components of metabolic syndrome work synergistically to increase cancer risk beyond that of the individual components [73]. At present, however, conflicting evidence exists as to any causal relationship between metabolic syndrome and prostate cancer.

Tande et al. [74] analyzed data for over 1,800 men with metabolic syndrome. After adjusting for other risk factors, men with metabolic syndrome (NCEP ATP III criteria) were significantly *less* likely to develop prostate cancer (RR = 0.77 [95 % CI 0.60,0.98]). Similarly, prevalent diabetes has been associated with a decreased incidence of prostate cancer [75]. Another study by Laukkanen et al. [76], however, assessed the association between IR and the development of prostate cancer in 1,880 men, 19 % of whom had IR. After a mean follow-up of 13 years and after adjusting for age, lifestyle, and diet, the RR of prostate cancer was two (95 % CI 1.07,3.53; $p=0.03$). In patients with IR who were also obese, the RR was three (95 % CI 1.22,7.34; $p=0.02$).

Although the relationship between prevalent diabetes and prostate cancer risk is unclear, diabetes is commonly associated with obesity and obesity has been associated with an increased risk of disease recurrence [77] and greater prostate cancer mortality [78]. Smith et al. [79] analyzed data from the Radiation Therapy Oncology Group (RTOG) 92–02 cohort of men with locally advanced prostate cancer receiving radiation therapy and ADT, where 765 deaths occurred after a median follow-up of 8.1 years. After controlling for age, race, tumor stage, Gleason score, prostate-specific antigen, weight, and treatment, overweight (>89.5 kg) was associated with greater prostate cancer mortality (HR 1.77 [95 % CI 1.22,2.55]; $p=0.002$), whereas overt diabetes was not (HR 0.80 [95 % CI 0.51,1.25] $p=0.34$). The increased insulin and IGF-1 levels apparent in obese patients may be responsible for this association [80], rather than the metabolic consequences of diabetes.

There is some evidence, too, that metabolic factors may accelerate tumor growth. Central obesity and high levels of fasting insulin have been associated with a poorer prognosis in patients with breast cancer [81, 82]. Although the exact mechanism for this association is unclear, increased fat stores are thought to be associated with higher concentrations of bioavailable estrogen, insulin, and insulin-like growth factors (IGFs), which may in turn promote tumor growth [83]. Increased concentrations of IGF-1 and IGF-binding protein-3 have been associated with an increased risk of prostate cancer in epidemiological studies [84].

Mistry et al. [85] suggested that obesity and adipokines could have a role in promoting the progression of established prostate cancer, based on their study of leptin and adiponectin, two adipokines that at high circulating levels are, respectively, stimulatory and inhibitory to prostate cancer development. In addition, there is evidence from in vitro studies suggesting that the unsaturated fats are particularly influential on prostate cancer migrational signaling [86]. Prostate cancer cells take up lipid directly as an energy source in early in vitro bone marrow metastatic development [87], and because prostate cancer cells commonly migrate to adipocytes in bone marrow rather than in subcutaneous fat indicates that adipocytes in different locations may exert different effects [88]. Furthermore, the use of statins has been reported to reduce prostate cancer mortality by 50 % [89].

## Prevention of the Metabolic Syndrome

The metabolic syndrome is characterized by several potentially modifiable lifestyle factors. In the diabetes prevention program, an analysis was undertaken to determine the prevalence of metabolic syndrome, as defined by NCEP ATP III criteria, at baseline, and the effect of intensive lifestyle intervention (diet and exercise) and metformin[1] therapy on the syndrome's incidence and resolution [91]. Study participants ($n=3,234$) were recruited between June 1996 and May 1999;

[1] Metformin is an oral biguanide which acts via a hepatic pathway ultimately to increase muscle uptake of glucose. Although its method of action is not completely understood, metformin remains a mainstream therapy for type 2 diabetes [70, 90].

all had impaired glucose tolerance and no history of CHD or diabetes. Patients were followed-up for a mean of 3.2 years after being randomly assigned to intensive lifestyle intervention, metformin (850 mg bd), or placebo. In a proportional hazards model using data for individuals without the syndrome at baseline ($n=1,523$) compared with the placebo group, the incidence of metabolic syndrome was 41 % lower in the lifestyle group ($p<0.001$) and 17 % lower in the metformin group ($p=0.03$). The cumulative incidence of metabolic syndrome overall (per 100 person-years) was 61 % for the placebo group, 50 % for the metformin group, and 38 % for the lifestyle group.

A pilot study was completed recently at the Royal Surrey County Hospital in the UK in which 40 men with prostate cancer scheduled for ADT received either ADT alone (control group; $n=20$) or metformin, a moderate exercise program and dietary advice (low GI diet) in addition to ADT (intervention group; $n=20$) [92]. After 6 months, there were significantly fewer men with metabolic syndrome (NCEP ATP III criteria) in the intervention arm ($p=0.04$), with significant improvements in abdominal girth, weight, BMI, and systolic blood pressure. The potential benefits of metformin and lifestyle changes in ADT-treated men need to be explored further as it is evident that overall survival may be improved.

Finally, the selective estrogen receptor modifier toremifene has been shown to significantly decrease total cholesterol, LDL cholesterol, and triglycerides and increase HDL cholesterol after 24 months in men being treated with ADT for prostate cancer [5, 8, 93]. The primary end point of this study among men aged 50+ years who had an increased fracture risk (aged 70+ or osteopenia) was new vertebral fracture, and the beneficial effects of toremifene on BMD and fracture risk have been summarized above.

## Conclusion

A complex relationship exists between prostate cancer, ADT, metabolic syndrome, and CVD. Alongside the expanding indications for ADT in prostate cancer, there is emerging (but not conclusive) evidence that ADT increases the risk of cardiovascular morbidity and mortality. The detrimental metabolic effects of ADT have been recognized in a science advisory from the American Heart Association, American Cancer Society, and American Urological Association and endorsed by the American Society for Radiation Oncology, who recommended careful evaluation of patients both before and during therapy [23]. Thus, for men requiring even short-course androgen suppression, efforts to reduce cardiac risk through lifestyle modification and the use of lipid-lowering agents may mitigate some of the risks of ADT, particularly those with early organ-confined disease, who would be expected to have the best long-term prognosis after curative therapy.

# Inflammation and Cancer of the Prostate

9

Sonya Vasto, Emilio Italiano, Vitale Miceli, and Giuseppe Carruba

In response to cell injury elicited by trauma or infection, the inflammatory response creates a complex network of molecular and cellular interactions leading to the facilitation of tissue repair and to return to a physiological homeostatic condition. In case the healthy tissue is not restored, or in response to a stable low-grade irritation, inflammation becomes a chronic condition that incessantly damages the surrounding tissue and whereby immune response, tissue injury, and healing processes occur simultaneously [1].

The inflammatory process is not "per se" a negative phenomenon. Inflammation is a teleonomic response built up by the natural selection to protect human beings until the reproductive age. Humans were set to live about 40 or 50 years, but, nowadays, the immune system has seemingly learned to be active for much longer as compared with the past centuries. This prolonged period of activity may eventually lead to chronic inflammation that inexorably damages most tissues/organs and is phenotypically reflected in both aging and chronic disease(s), including cancer [2].

Chronic inflammation appears in fact to be involved in the pathogenesis of all age-related diseases, including Alzheimer, atherosclerosis, diabetes, sarcopenia, and cancer. The genes involved in the inflammation process are numerous, as well as the genomic variations within most of those genes. Several genes involved in the inflammatory network are important candidates influencing the degree and phenotype of individual response to damage [3]. Furthermore, as recently indicated, the microenvironment surrounding the tumor highly resembles an inflammation site, being featured by interactions between inflammatory cells and neoplastic cells that might facilitate tumor progression [4]. Cytokines, chemokines, lymphocytes, and macrophages might all contribute to neovascularization, increased blood supply, vessel permeabilization, immunosuppression, and metastasis [5]. On the other hand, the inflammatory microenvironment has high levels of growth factors and cytokines, which may in turn stimulate proliferation of initiated cell leading to the promotion and/or progression of a clonal tumor cell population. Specific examples are TNF-α, IL-1β, and IL-6, which have been associated with tumor invasiveness and protease production, inflammatory response, angiogenesis, and metastasis. Cytokines derived from neoplastic cells, activated resident stromal cells, or infiltrating immune cells can regulate tumor growth by affecting angiogenesis and cell survival, death, or differentiation [6].

Production of acute-phase protein, which is evident in systemic inflammation, has also been associated with an increased tumor stage/grade, cachexia, hypercalcemia, anemia, and reduced survival in various malignancies [7]. Interestingly, Toll-like receptor (TLR) is highly expressed in various types of human carcinomas compared with adjacent normal tissue, suggesting a potential role in tumor development [8]. Accordingly, TLR genes may be implicated in cancer development also as a consequence of their role in innate

DOI 10.1007/978-1-4471-2864-9_9, 

immunity and in the regulation of inflammatory reactions and activation of the instructive immune response [9]. In this framework, activation of innate immunity and inflammation may eventually lead to the production of cytokines that can either stimulate or inhibit tumor growth and progression. As previously stated, by and large, most proinflammatory cytokines produced by either host immune cells or tumor cells themselves promote tumor development [1, 10]. On the other hand, anti-inflammatory (IL-10 and TGF-β) cytokines usually interfere with tumor development. Chronic inflammation caused by persistent infection with a parasite, bacterium, or virus, the release of inflammatory mediators, and the resulting inflammatory environment may be a driving force in development of several human tumors, including prostate cancer [11].

## Prostate Cancer

Prostate cancer represents a common cause of morbidity and mortality in men in Western countries, being the most common non-skin tumor and the second leading cause of cancer death in men in the United States, with 217,730 new cases and 32,050 deaths from this disease expected in the year 2010 (*American Cancer Society*, *2010*) [12]. African American men have the highest incidence and mortality rates [12]. In Europe, prostate cancer has exhibited a steady increase in incidence during years, while mortality rates have started to decline since the late 1990s. Incidence rates of prostate cancer vary considerably also across Northern and Southern Europe, respectively being 80.1/100,000 and 44.7/100,000 in 2000 (*IARC databases*). In particular, Sweden has the highest incidence rates (139.3/100,000), while Greece has the lowest (43.4/100,000), with a cumulative risk that ranges from 0.5 up to 2.2 across European countries. Both genetic and environmental factors may contribute to explain this large geographic variation. Previous studies on populations migrating from countries with low incidence/mortality rates (e.g., China or Japan) to countries with higher rates of prostate cancer (United States) have revealed a significant increase in prostate cancer incidence/mortality as compared with their peers in the countries of origin [13–16]. In addition, prostate cancer incidence is rising rapidly in Asian countries, including Japan, as Asians gradually adopt a westernized diet and lifestyle [17, 18]. This evidence suggests that environmental and, especially, lifestyle factors play a dominant role in prostate cancer development. For example, sedentary lifestyle and high-fat diet have been associated with an increase in prostate cancer risk [19] and as an example the involvement of the α-methylacyl-CoA racemase (*AMACR*), the enzyme that plays a key role in the peroxidation of fatty acid. The AMACR gene is overexpressed in prostate cancer but not in the healthy prostate. Upregulation of α-methylacyl-coenzyme A-racemase *AMACR* might explain some of the association between dairy products and prostate cancer [20].

Despite the most recent advances in both basic and translational research, the molecular basis of human prostate cancer remains mostly obscure. Endogenous sex steroids, along with genetic factors, environmental factors (including diet), and host immune and inflammatory responses, are likely to concur in the pathogenesis of this disease.

## Inflammation and Prostate Cancer

It is widely accepted today that inflammation has a role in many human cancers. In particular, clinical and epidemiological studies have suggested a strong association between chronic infection, inflammation, and cancer [21, 22] An inflammatory microenvironment is in fact reputed to promote carcinogenesis through cell and DNA damage, increase of cell proliferation, and angiogenesis [1]. This microenvironment is primarily featured by the presence of infiltrating stromal leukocytes and by hypoxic conditions [23, 24]. Tumor-associated macrophages represent a key player in the inflammatory process, as they produce a multitude of growth factors for epithelial and endothelial cells, along with inflammatory cytokines and chemokines [21] (Table 9.1).

As far as human prostate gland is concerned, there is accumulating evidence that the regenerative epithelium produced in consequence of inflammatory and/or infectious conditions may eventually lead to cellular insults and may precede the development of prostatic intraepithelial neoplasia (PIN) and early carcinoma. Several meta-analyses have indicated a small increase in the relative risk of prostate cancer in men with a history of clinical or symptomatic prostatitis [11].

Pathologists have proposed that a prostatic lesion referred to as proliferative inflammatory atrophy (PIA) is a precursor of PIN and prostate cancer. The PIA lesion is thought to be a consequence of the regenerative proliferation of prostate epithelial cells in response to an inflammatory insult. Epithelial cells in PIA show several genetic alterations, including somatic mutations, gene deletions or amplifications, chromosomal rearrangements, and changes in DNA methylation, along with molecular signs of stress, such as elevated glutathione S-transferase p1 (GSTP1), GSTA1, and cyclooxygenase 2 (COX-2) [34, 35]. The GSTP1 gene, which is expressed in both PIA lesions and over 90 % of prostate cancer cases, does not seem to act as a tumor suppressor gene but as a caretaker gene to prevent genome damage induced by environmental and/or endogenous carcinogens, such as oxidant compounds produced by inflammatory cells [34, 35].

In a recent paper, Harris and colleagues [36] have reported that a 4-week administration of estradiol to Wistar rats, in the presence of dihydrotestosterone propionate, results in the

**Table 9.1** Association between inflammatory genes and prostate cancer

| Genes | Age-associated cancer | References | Association with cancer |
|---|---|---|---|

| | Prostate cancer | Howell and Rose-Zerilli [28] | Yes |
| TLR1-6-10 | Prostate cancer | Sun [29] | Yes |
| TLR1-6-10 | Prostate cancer | Chen et al. [30] and Sun et al. [31] | No |
| TLR4 | Prostate cancer | Zheng et al. [32] | Yes |
| Cox-2 | Prostate cancer | Ghosh et al. [33] | Yes |

production of proinflammatory cytokines, chemokines, and inducible nitric oxide synthase (iNOS) in the prostate. The mechanism(s) by which estrogen induces inflammation is still unknown. It is likely that estrogens act in combination with immunoregulatory factors produced locally within the prostate. Regardless, it is clear that elevated estrogens may eventually lead to a prostate-specific inflammatory response in the presence of testosterone. Since combined treatment of testosterone and estradiol induces prostate inflammation as early as 4 weeks and prostate carcinomas occur only after 50 weeks, it is plausible that estrogen-driven early inflammatory events serve as a prerequisite for the development of prostate cancer.

As there is accumulating evidence that the human prostate is a primary target of estrogen action, it would be important to assess aromatase expression and activity locally and to identify any change that may be associated with prostatic disease, including cancer. In human breast cancer, recent experimental evidence has indicated a direct association of cyclooxygenase (COX)-1 and -2 with aromatase expression [37]. In particular, it has been reported that prostaglandin E2 (PGE2), produced through the COX-2 pathway, induces, along with proinflammatory cytokines, both expression and activity of aromatase [38, 39]. On the other hand, there is consistent evidence that estrogen induces the synthesis of various prostaglandins through the upregulation of either COX-1 or COX-2 or both. This would generate a self-maintaining vicious cycle where estrogen and prostaglandin(s) increase each other's production through the induction of the respective synthesizing enzymes.

Studies that propose a key role of inflammation in triggering prostate cancer development have shown a positive correlation with local accumulation [40, 41] of eicosanoids, including prostaglandins (PGs) and leukotrienes (LTs). These compounds have been implicated in the pathogenesis of a variety of human diseases, including cancer, and are now believed to play a role in tumor promotion, progression, and metastatic disease. The enzymes involved in the conversion of arachidonic acid to PGs and LTs are COXs and lipoxygenases (LOX) [40, 41].

The two isoforms of COX, COX-1 and COX-2, are almost identical in structure but have important differences in substrate and inhibitor selectivity and in their intracellular location. The constitutive COX-1 is present in many tissues, and the PGs synthesized are involved in maintaining tissue homeostasis. The inducible COX-2 is responsible for PGs produced in sites of inflammation and is upregulated by oncogenes, cytokines, growth factors, hypoxia, UV, and tumor necrosis factor alpha [42, 43].

Upregulation of COX-2 has been reported in a variety of human tumors, including prostate cancer, PIN, and the premalignant lesion PIA. This may eventually lead to an increase of PG synthesis that is in turn responsible for inhibition of apoptosis, stimulation of angiogenesis, immunosuppression, and promotion of metastasis [44]. Some studies have indicated that a prolonged treatment with aspirin reduces the incidence of prostate cancer, suggesting that this effect might be, at least in part, a consequence of COX-2 inhibition [45]. Lastly, COX-2 promoter can be modulated through transcriptional and posttranscriptional mechanisms implicating oncogene products, growth factors, cytokines, chemotherapeutics via protein kinase C, *ras* signaling, interleukin (IL)-6, and NF-kB transcription factor [46, 47]. Recently, it has been shown that histone acetyltransferase activity of the CREB-binding protein/p300 coactivator complex is important for AP1-mediated induction of COX-2. Interestingly, a new compound that reduces both expression and activity of CREB may restore the sensitivity of prostate cancer cells to apoptotic stimuli through downregulation of COX-2 [46].

As regards LOX mediators, there is evidence to support an important role for LO-catalyzed products, LTs, and hydroxyeicosatetraenoic acids (HETEs) on development and progression of human cancers. A significant increase of LOX metabolites has been observed in patients with lung, breast, colon, and skin carcinoma, while increased 12-LOX mRNA and 12(S)-HETE levels have been positively correlated with

**Table 9.2** Inflammatory mediators and cancer

| | |
|---|---|
| CCL5 | A chemotactic for T cells, eosinophils, and basophils that plays an active role in recruiting leukocytes into inflammatory sites |
| CCR5 | A *beta*-chemokine receptor involved in the migration of monocytes, NK cells, and some T cells to the inflammation site |
| COXs | Enzymes involved in the conversion of arachidonic acid to inflammatory mediators, prostaglandins. The isoform COX-2 is upregulated in a variety of malignancies, including prostate cancer, throughout the tumorigenic process |
| LO | Enzymes involved in the conversion of arachidonic acid to inflammatory mediators |
| IL-1 | IL-1, IL-1*alfa*, and IL-1*beta* might be considered the prototypic proinflammatory cytokines of the IL-1 family. IL-1Ra competes for receptor binding with IL-1*alfa* and IL-1*beta*, blocking their role in immune activation |
| IL-4 | Member of the Th2 cytokines and is a potent anti-inflammatory cytokine as it reduces the production of proinflammatory cytokines |
| IL-6 | Mediator of experimental cachexia and is a well-documented mediator of inflammation |
| IL-13 | Exerts anti-inflammatory and antitumoral effects through the activation of the IL-13 receptor complex |
| IL-8 | Regulates angiogenesis and tumor growth |
| IL-10 | Anti-inflammatory function, with pleiotropic effects in immunoregulation and inflammation. It downregulates the expression of type 1 cytokines, MHC class II antigens, and costimulatory molecules on macrophages |
| IL-18 | Produced by macrophages and other cells, belongs to the IL-1 superfamily. It is a multifunctional cytokine that induces interferon-gamma secretion and plays an important role in antitumor immunity mediated by type 1 positive regulation loop |
| TGF-*beta*1 | Polypeptide member of the transforming growth factor beta superfamily of cytokines. It is a multifunctional modulator of cellular proliferation, differentiation, and production and degradation of extracellular matrix |
| TLRs | Receptors able to detect microbial conserved components and trigger protective host responses |
| TNF-alpha | Associated with tumor invasiveness and protease production, inflammatory response, angiogenesis, and metastasis |

the metastatic potential of colon and prostate carcinoma [48, 49]. Increased levels of 5-HETE have been reported to stimulate tumor cell growth, while 5-HETE depletion results in massive apoptosis in lung and prostate cancer [50]. Furthermore, it has been observed that LOX-5 is overexpressed in prostate tumors, suggesting that selective LOX-5 inhibitors may be helpful in either prevention or treatment of this malignancy [51].

Accordingly, Caruso and colleagues have reported a significantly increased frequency of COX-2 -765 G/C and of LOX-5 -1708 G/A proinflammatory SNPs in prostate cancer patients, as compared with age-related controls and centenarians (taken as a typical human model of disease-free subjects) in the Sicilian population [52]. This evidence incidentally confirms previous studies suggesting that proinflammatory alleles have an opposite role in longevity and age-related diseases, including cancer [53, 54].

Toll-like receptors (TLRs) represent critical players in both innate and instructive immune response, recognizing ligands for pathogens-associated molecular patterns. In prostate cancer, TLRs seem to represent a potential link between infections, chronic inflammation, and tumor development. In particular, it has been proposed that activation of the innate immune response is brought about through a TLR-mediated recognition of infectious agents or endogenous molecules, such as those produced by cell and/or DNA damage [55, 56]. In addition, most of TLR-activated signaling molecules are also implicated in tumorigenesis and malignant cell proliferation, reinforcing the idea that TLRs may affect tumor development and growth [57, 58].

Importantly, dysregulated or inappropriate TLR activation may result in an excessive production of proinflammatory factors. Upon TLR4 activation, tumor cells produce in fact mediators of inflammation, including nitric oxide, IL-6, and IL-12, mimicking some characteristics of inflammatory cells. In this respect, an interesting TLR4 polymorphism, the ASP299GLY, is known to regulate the inflammatory response, and it has been associated with an increased risk of prostate cancer [58, 59] (Table 9.2).

## Cytokines

Several studies have shown an increased level of proinflammatory cytokines, in both prostatic tissue and fluids in prostatitis [60, 61]. Furthermore, recent reports indicate that the assessment of both pro- and anti-inflammatory cytokine levels in prostatic fluid may be useful not only to diagnose prostatic inflammation but also for early cancer detection and prognosis [60]. Most adult prostate tissues contain an increased proportion of inflammatory cells, also depending on the extent and type of inflammation. This results in a larger pool of cytokines and growth factors, including IL-1, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-18, transforming growth factor-β (TGF-β), and IFN-γ in the prostate tissue. It is of particular interest that cytokines, such as IL-4, IL-10, and IL-13, significantly affect the biological behavior of monocytes/macrophages and result in a microenvironment that may favor tumor growth [61, 62].

Polymorphisms of cytokine genes may have an impact on inflammation and immune response, and some have been reported to be associated with susceptibility to prostate cancer in a large number of case–control studies, twin studies, and segregation analyses [1].

TGF-β1 is a powerful and multifunctional regulator of cellular proliferation, differentiation, and production and turnover of extracellular matrix. TGF-β1 signaling pathways are regulated through several mechanisms by a variety of oncogenic and anti-oncogenic proteins. Since TGF-β1 behaves as a potent inhibitor of growth for most epithelial cells, alterations of TGF-β1 signaling are thought to favor progression of various tumors. Conversely, TGF-β1 has been shown to act as an oncogenic growth factor through the induction of extracellular matrices, angiogenesis, and immune suppression. Therefore, its ultimate effect on tumor progression may essentially depend upon preservation or impairment of TGF-β1 receptor and/or post-receptor mechanisms and, consequently, be divergent in early or advanced tumors [63].

TGF-β1 is synthesized as a larger precursor (pre-pro-TGF-β1) and secreted in a latent complex that needs to be activated to release the mature form of the peptide. The latter, in turn, binds to specific membrane receptor(s) and triggers relevant signal transduction pathways. Hence, the occurrence of modified sequences in the signal peptide could be responsible for the alteration of TGF-β1 signaling, an event that is common to cancer cells in advanced stages of tumor progression. In particular, a leucine-to-proline substitution in codon 10 drastically affects the three-dimensional conformation of the protein leading to the inability of the active form of TGF-β1 to localize into a cell. This would hinder the efficient transduction of the anti-proliferative and pro-apoptotic signals of the TGF-β1, favoring the clonal expansion of refractory tumor cells.

The Leu10Pro genotype confers a 1.8-times greater risk of prostate cancer with respect to general population [64].

Interleukin (IL)-1α and IL-1β might be considered the prototypic proinflammatory cytokines of the IL-1 family. IL-1α is produced by prostate epithelial cells and induces fibroblast growth factor 7 (FGF-7) expression in prostatic stromal cells. The FGF-7, in turn, induces epithelial cell growth and a further increase of IL-1α expression, ultimately leading to an expansion of the prostatic transition zone, which is critical in the pathogenesis of benign prostatic hyperplasia (BPH) [65]. Senescent prostatic epithelial cells are reported as a source of IL-1α. Hence, secreted IL-1α might be one of the major factors responsible for age-related growth of prostatic epithelial cells observed in BPH. Surprisingly, IL-1α receptor is expressed in both BPH and prostate cancer, though its expression is inversely related to tumor grade [66].

Interleukin 4 (IL-4), a member of the Th2 cytokines, is a potent anti-inflammatory cytokine as it reduces the production of proinflammatory cytokines. IL-4 has diverse activities, including the stimulation of fibroblasts' proliferation and the inhibition of smooth muscle cell outgrowth from prostatic stromal clones. Several studies have reported that hyperplastic prostatic tissues and BPH-derived T cells express high levels of IL-4 [67].

Interleukin 6 (IL-6) has many physiologic roles and has been implicated in a number of pathophysiologic processes. A variety of tumor types are stimulated by IL-6, including melanoma, renal cell carcinoma, Kaposi's sarcoma, ovarian carcinoma, lymphoma and leukemia, multiple myeloma, and prostate carcinoma [68].

There is accumulating evidence that IL-6 may contribute to the progression of human prostate cancer. IL-6 has been shown to act as a mediator of experimental cachexia and is a well-documented mediator of inflammation. Elevated levels of this cytokine is associated with signs of morbidity, such as anorexia, anemia, cachexia, asthenia, acute-phase proteins, hypoalbuminemia, edema, anergy (lack of body immunological reaction), and diffuse bone pain, in a number of chronic diseases, including prostate cancer [69]. A cross talk between IL-6 and androgen receptor activation has also been demonstrated [70] Interleukin 10 (IL-10) and 8 are the most studied cytokines in prostate cancer. IL-10 is an anti-inflammatory cytokine that suppresses Th1 response and regulates differentiation of B-lymphocytes, natural killers, and cytotoxic and helper T cells. In prostate cancer, low expression of IL-10 seems to be not associated with PCa susceptibility maybe due to the relatively minor effect that a single SNPs may have on the disease [71]. However, it is more probable that a combination of SNPs in haplotypes or an SNP–SNP interaction may modify the risk for developing a malignancy. In Caruso and collaborators' meta-analysis, it was shown that in the interactions of nine functionally characterized SNPs of three cytokine genes (IL1-$\beta$,-511 CT; IL-1 $\beta$,-31 TC; IL- 1 $\beta$ +3954 CT; IL-10 -1082 AG; IL-10 -819 CT; IL-10 -592 CA; TNF-$\alpha$,-857 CT; TNF-$\alpha$, -308 GA; and TNF-$\alpha$, -238 GA), a single SNP did not modify, unless marginally when adjusted for age, family, smoking, and BPH, the risk of developing PCa, but it was noted that the risk was greatly modified by SNP–SNP interaction [52]. Furthermore, Richardsen and colleagues in their studies did not find differences in IL-10 expression between primary prostatic tumors neither in tumors and corresponding metastases although other studies appear having better association with IL-10 [72]. The apparently conflicting data may reflect the biological function of IL-10 as an anti-inflammatory (potentially cancer promoting) and antiangiogenic (potentially cancer inhibiting) cytokine in relation to the biological patterns of prostate cancer development and progression [72].

IL-8, also known as CXCL8, is a proinflammatory CXC chemokine having documented activity in the regulation of angiogenesis and tumor cell growth. A recent report has indicated that neutralizing antibodies directed against IL-8 inhibit angiogenesis in a human prostate cancer cell line/murine model and reduced tumorigenicity in vivo [73]. Recent studies have measured the production of the

CC-chemokine CCL5 (RANTES), a potent chemotactic factor for inflammatory cells, and its receptor (CCR5) in different human prostate cancer cell lines. It has been demonstrated that chemokine CCL5 may function as an autocrine factor that binds to its CCR5 receptor, expressed on the cell surface, and activates cellular responses favoring tumor progression [74].

Interleukin (IL)-13 exerts anti-inflammatory and antitumoral effects through the activation of the IL-13 receptor complex, a heterodimer consisting of the interleukin-13 receptor α1 (IL13Ralpha1) and the interleukin-4 receptor A (IL4RA) subunits. IL-13 appears to have opposite effects on different cancer cells, being able to inhibit growth of breast cancer and renal carcinoma cells or to promote proliferation in some other cancer cell types. In a recent paper, abnormal expression of IL-13Ralpha 2 has been consistently revealed in prostate cancer tissues [75].

Interleukin 18 (IL-18) is a multifunctional cytokine that induces IFN-gamma secretion and plays an important role in antitumor immunity mediated by type 1 positive regulation loop. A reduced expression of IL-18 in consequence of promoter abnormalities seems to be associated with a reduced stimulation of type 1 response and might be involved in susceptibility to prostate cancer [52].

Apart from the inflammatory molecules mentioned herein, additional studies have suggested that macrophage scavenger receptor 1, a protein with critical functions in host response to infections, and macrophage inhibitory cytokine-1 (MIC-1) may be implicated in the etiology of human prostate cancer [76–78]. The MIC-1 is a secretory protein, and elevated serum levels of MIC-1 are present in a number of diseased conditions. As far as prostate cancer is concerned, elevated levels of circulating MIC-1 are associated with the metastatic progression of the disease. Furthermore, MIC-1 has been associated with inflammatory-related pathways, representing a potential biomarker of p53 pathway activation, a key response to inflammatory stress [79].

**Take Home Message**

- Chronic inflammation and the release of inflammatory mediators and the resulting inflammatory environment may be a driving force in development of several human tumors, including prostate cancer.
- Inflammation can strongly influence prostate growth either in terms of hyperplastic (BPH) or neoplastic changes.
- Cytokines and chemokines play an important role in prostate cancer development.

# HIV and Prostate Cancer

10

Matthew S. Wosnitzer, Jennifer J. Ahn,
and Franklin C. Lowe

## Background

Prostate cancer is the most common noncutaneous malignancy and the second most common cause of cancer-specific death in men from the United States. There were 240,890 estimated new cases and 33,720 deaths in 2011[1]. While prostate screening has identified an increasing number of cases, the increased surveillance has facilitated earlier diagnosis in asymptomatic men and led to subsequent stage migration towards localized disease [2, 3].

Recent data from the World Health Organization and UNAIDS indicate that the worldwide HIV prevalence has plateaued and that new infections have fallen; however, 33.2 million people in 2007 were estimated to be living with HIV, 2.5 million people became infected, and 2.1 million people died from AIDS. Among these patients, 1.2 million individuals, including 870,000 males, carried the diagnosis of HIV/AIDS in the United States [4]. More than 50 % of all newly diagnosed HIV patients are African American, and greater than 25 % are older than 45 years. Prostate cancer incidence increases with age, African American descent, and in some reports with immunocompromised conditions such as HIV/AIDS [5].

Prior to 1995 (the beginning of the highly active antiretroviral therapy (HAART) era), individual case reports described patients with AIDS and prostate cancer exhibiting rapid progression of prostate cancer likely secondary to severely depressed immune system and poor response to androgen deprivation therapy [6–8]. Possible explanations for prostate cancer development in the HIV-positive population include suppressed cell-mediated immunity, dysfunctional immune surveillance, decreased apoptosis, and increased angiogenesis. Since 1995, the utilization of multiple synergistic medications to prevent viral replication has altered the natural spectrum of HIV disease. The progression of HIV to AIDS as well as AIDS-specific mortality has been decreased by HAART. Additionally, there has also been reduced incidence of AIDS-related malignancies including non-Hodgkin's lymphoma, Kaposi sarcoma, and cervical cancer. Although multiple studies identify increased incidence of certain non-AIDS-defining malignancies (melanoma, Hodgkin's lymphoma, anal cancer, and prostate cancer) [9–19], other studies report decreased incidence of other non-AIDS-defining malignancies (breast, uterine, and prostate cancer) [17, 20–29].

During the HAART era, HIV-positive patients with PCa appear to respond to treatment in a similar manner to patients without HIV/AIDS. Despite the increased prevalence of HIV/AIDS and prostate cancer, there is no universally accepted consensus regarding treatment. In this chapter, we summarize the literature regarding this topic and describe the most recent diagnosis and treatment recommendations to guide physicians in the optimal management of HIV/AIDS patients with prostate cancer. A PubMed search was completed utilizing the terms "HIV and prostate cancer," "AIDS and prostate cancer," "prostate cancer and non-AIDS-defining malignancy" "HIV and prostate cancer and diagnosis," "HIV and prostate cancer and treatment." All results were reviewed and cross-referenced for all available English-language articles and review articles between 1975 and 2011.

## Incidence

The precise incidence of prostate cancer (PCa) in HIV-infected patients is unknown. The relative lack of literature on this topic may result from limited association between the conditions, or more likely due to decreased screening of

HIV-infected men [30]. The Silberstein review from August 2008 identified 12 studies describing 60 unique HIV-positive men with prostate cancer [16, 18, 31–40]. We describe an additional 19 patients from our cohort (not previously published), but no additional case reports have been published. Before 2008, population-based studies described 322 patients with HIV and prostate cancer [15, 23, 24, 28]. Since 2008, there have been several additional population-based studies describing 769 HIV-infected patients with prostate cancer [17, 26, 41, 42]. Overall, there is available clinical and demographic data for 87 patients (described in case reports) and 1,091 patients (described in population-based studies). Standardized incidence rates (SIR) of prostate cancer in HIV-positive populations from published literature are described in Table 10.1. Multiple large linkage-based population studies report a lower than expected PCa risk both overall and in the post-AIDS onset period [17, 23–26, 28, 29, 43], but other smaller studies describe contrasting findings of similar or elevated rates of prostate cancer in comparison to the general population [9, 11, 15, 37, 41, 44].

Many recent large population-based studies report decreased prostate cancer incidence in HIV infected men which is similar to the trend in breast cancer incidence in HIV-positive patients and immunosuppressed transplant recipients [20–22, 45, 46]; such findings may reflect a protective role of immunodeficiency [45, 47], the capability of HIV to infect, replicate in, and impair cancer cell proliferation [48, 49], or may be due to HAART-associated changes [50]. Importantly, PSA screening in the detection of prostate cancer may explain the mechanism for decreased incidence found in HIV-infected patients because they receive less rigorous screening than the general population. In an analysis of the US HIV/AIDS Cancer Match study, a linkage of population-based HIV/AIDS and cancer registries in 15 US areas, Shiels et al. examined the epidemiology of prostate cancer among 287,247 HIV-infected men compared with the general population [43]. PSA testing rates were calculated from the Johns Hopkins HIV Clinical Cohort in men ≥40 years of age during 2000–2008. This study identified that prostate cancer rates were higher in the general population than among men with AIDS. Men with AIDS had equivalent prostate cancer risk as the general population in the pre-PSA era before 1992 (before 1992, SIR = 1.00, 17 observed cases), but had a significant reduction during the PSA era (after 1992, SIR = 0.5, 230 observed cases with incidence rate of 28.3/100,000) after accounting for baseline characteristics. The decreased risk was identified in patients with local and regional stage prostate cancer (SIR 0.49 and SIR 0.14), but the difference in risk was not demonstrated in patients with metastatic disease (SIR = 0.85). The authors hypothesize that if a biologic mechanism accounted for decreased risk of prostate cancer in HIV-infected men, then there would have been consistent decreased risk across all stages of prostate cancer. Decreased PSA screening among HIV-infected men may lead to decreased detection of prostate cancer in HIV-infected men in early stage cancers during the PSA era. In men with AIDS, localized/regional prostate cancer was not associated with increased risk of death compared with the general population, similar to trends in the general population. The fivefold increased risk of mortality following distant stage prostate cancer in men with AIDS was similar to the general population. The conclusions regarding differential PSA testing in this study may be confirmed in the future with additional diverse HIV-infected cohorts.

Patel et al., in one of the large analyses of United States cancer incidence trends in HIV-infected patients, compared cancer incidence rates in two multicenter prospective

observational cohorts among 54,780 HIV-infected patients, the Adult and Adolescent Spectrum of HIV Disease (ASD) Project, and the HIV Outpatient Study (HOPS), with noninfected individual data derived from the Surveillance, Epidemiology, and End Results (SEER) program [17]. The authors identified 3,550 cancer cases of which 20 % were non-AIDS-defining cancers. Incidence rates for HIV-infected individuals decreased significantly from 1992 to 2003 for non-Hodgkin's lymphoma and Kaposi's sarcoma and increased significantly for anal, colorectal, and prostate cancer (14.7 in 1992 to 37.5 in 2003 per 100,000 person-years, $p < .01$). The increase in prostate cancer incidence in HIV patients may be secondary to PSA screening which is also reflected by a similar rise in the general population incidence during this time (47.4–60.9 per 100,000 person-years, $p < .001$). Overall, there was decreased incidence of prostate cancer in HIV-infected patients compared to the general population. Antiretroviral therapy was not independently associated with decreased risk for prostate cancer. However, this study may not be generalizable since the SEER database does not record HIV status and thus populations may overlap between the HIV group and the "general population group." Further, the ASD and HOPS databases do not reflect all HIV patients, and the SEER database does not represent the entire United States population.

A study by van Leeuwen et al. from Australia confirmed the results of Patel et al. with identification of 24 HIV-infected patients with diagnosed prostate cancer (cohort of 20,232) between 1982 and 2004 from the Australian National HIV/AIDS Registries [26]. A significant decline in prostate cancer incidence was noted throughout the study period in multivariate analysis ($p = .026$). From 2000–2004, the incidence was decreased compared with the general population. An additional large meta-analysis including 444,172 men with HIV/AIDS identified a decreased risk for prostate cancer in HIV-infected men [51]. Shiels et al. also noted a decreased incidence of prostate cancer in HIV-infected patients compared to the general population [43].

Bedimo et al. completed a retrospective analysis of non-AIDS-defining malignancies in HIV-infected versus matched noninfected patients between 1997 and 2004 using the Veterans Affairs registry which revealed that prostate cancer was diagnosed with equivalent frequency among HIV-infected and HIV-uninfected subjects (441 of 33,420 HIV-infected patients during 5.1 year follow-up vs. 1,041 of 66,840 HIV-negative patients) [41]. Prostate cancer was the only malignancy associated with a higher CD4 count (311 vs. 266; $p < .001$) in HIV-infected individuals when compared with matched non-cancer patients [41]. In a retrospective study (1988–2003) of 4,144 HIV-infected men, the rate of prostate cancer exceeded national rates even after age adjustment [44].

Hessol et al. identified greater than 14,000 adults with AIDS between 1990 and 2001 and noted 482 non-AIDS-defining cancers during the 60 months prior to or following AIDS diagnosis. This included 32 cases of PCa, which resulted in a significantly increased standardized incidence ratio of PCa when compared to general population (Table 10.1) [15]. Another retrospective analysis of 857 consecutive patients with prostate cancer confirmed by prostate biopsy performed in HIV-positive and HIV-negative patients during a 5.5-year period revealed that the likelihood of positive biopsy was significantly higher among 18 HIV-positive patients compared to 839 patients with negative HIV tests (adjusted OR = 3.9; 95 % CI: 1.3–11.5) [42]. In this study conducted at a Veterans Affairs medical center, analyses restricted to prostate cancer patients revealed that HIV-positive patients were not different from the remaining group with respect to their prostate cancer stage, PSA level, PSA velocity, PSA density, or Gleason grade [42].

Epidemiologic analysis of PCa in HIV-infected patients relies on PSA and DRE screening detection. Reports of decreased incidence may be the consequence of decreased screening of these patients [38], although many men with HIV are followed with more intense medical supervision than noninfected men. In addition, men with HIV frequently have decreased androgen levels, which may reduce their likelihood of prostate cancer detection since normal testosterone levels are required for accurate PSA level. It is also feasible that HIV reduces the risk of specific cancers based on viral protein R (Vpr) or gp120-IIIB of HIV-1, for example, which have been shown to enhance host/target cell apoptosis, suggesting possible antineoplastic activity for these proteins [52–54]. Prospective screening studies include analysis of 269 HIV-positive men age 35 years or older during 18 months of follow-up [37]. No patients had abnormal DRE, and 80 % had PSA testing which revealed elevated PSA in seven patients [37]. Of these patients, six had normal PSA on repeat testing, and one patient had prostate biopsy revealing HGPIN. They identified that age, African American ethnicity and duration of HIV infection may be associated with prostate cancer development.

## Case Reports

In the Silberstein review, 60 patients described from case reports between 1996 and 2008 had mean age 57.8 years (40–79), mean PSA 172.7 ng/ml, PSA range 3–5,638, and had average Gleason score of 5–8 with clinical stage T1c (27 %), T2 (19 %), T3 (3 %), and T4 (4 %) [31]. Race data was not available for the majority. Patients had HIV for mean of 8.8 years (0.5–20), with average viral load of 10,006 copies/ml, and average CD4 count of 425.2 cells/mm$^3$ (24–1,070).

In the authors' institutional cohort of 29 patients, the average patient had an age of 56.5 years at diagnosis (range

42–69), had been HIV positive for 9.5 years, had a CD4 count of 517 cells/mm$^3$ (range 75–1,475; 3 patients had CD4 count <200 at diagnosis of prostate cancer), a viral load of 4,713 copies/ml (range 25–106,000; disregarding one outlier, mean viral load was 110 copies/ml), a PSA level of 8.8 ng/ml (range 2.72–33.0) at PCa diagnosis, and a Gleason score of 6.38. Twenty-four (82.7 %) patients had received HAART. Seventeen patients were of African American descent, five were Caucasian, and seven were Hispanic. Family history was identified to be positive for prostate cancer in four patients. Patient treatment and outcomes are described later in this chapter in the treatment section. In addition to the above cohorts, Silberstein et al. describe eight additional HIV-infected patients undergoing robot-assisted laparospic prostatectomy with mean age 54 years (45–66), diagnosis of PCa 14.4 years following HIV diagnosis, with 100 % of patients receiving HAART [55]. Mean PSA of patients was 6.4, mean biopsy Gleason score was 6.6, with 38 % cT1c, 50 % cT2a, 12 % cT2b, mean CD4 count 634 cells/mm$^3$ (506–980), mean viral load <50 with short follow-up of 2.6 months. Outcomes are described in the treatment section.

## Risk Factors in Prostate Cancer

While the specific etiology of prostate cancer remains unclear, it is probable that multiple factors including genetics, infection, inflammation, and environment influence the evolution of the disease [27, 56–60]. Established risk factors include family history, race, and diet (obesity, polyunsaturated fat intake) [5, 58, 61–64]. Increased BMI (body mass index), which can be a consequence of HAART [65], has been consistently associated with increased biochemical progression risk, metastasis, and prostate cancer-related mortality [66, 67]. Relative risk increases according to the number of affected family members, the degree of relation, and the age at time of diagnosis [5, 58, 61]. African American age-adjusted prostate cancer mortality is double when compared to Caucasian men. While studies of similar or reduced incidence of prostate cancer in HIV-positive patients indicate a potential protective role from HIV-induced apoptosis of cancer cells, or a masking effect by HIV or HAART-related hypogonadism, there are suggestions that HIV-positive status may increase the risk of prostate cancer [10, 68, 69]. This may result from delayed diagnosis secondary to hypogonadal state with artificially low PSA levels. Alternatively, immunocompromised patients may be less capable of preventing genetic damage or changes that lead to prostate cancer. The purported mechanism includes impaired cell-mediated immunity, decreased immune surveillance, increased angiogenesis, reduced apoptosis, and chronic inflammation [70].

During the pre-HAART era, there were multiple descriptions of HIV being associated with aggressive prostate cancer, especially in those patients who were hypogonadal at the time of their prostate cancer diagnosis [6–8, 10, 38]. Hypogonadotropic hypogonadism is common in HIV-positive male patients [71–73]. Androgen deficiency in HIV-positive men has been associated with reduced CD4 cell counts, advanced stage of disease, and weight loss or wasting syndrome [74–76]. Hypogonadism is 20 % more common in HIV-positive patients when compared to age-matched healthy cohorts [77]. The etiology may be related to HIV (the testis may provide a sanctuary for the virus to replicate) or to malnutrition. A study of men with weight loss revealed that hypogonadism occurred frequently despite elevated CD4 counts and HAART use [76]. HAART may have a beneficial effect, however, on free testosterone levels (42.6 vs. 69.2 pmol/l in 9 naive compared to 50 HAART treated HIV-positive men, $p = .04$) [78]. The increased frequency of testosterone supplementation and replacement therapy in HIV-positive men may account for an increased risk of prostate cancer detection due to rises in PSA levels.

The effect of HAART on decreasing cancer risk may result from CD4+ T cell counts. Other potential factors include decreased immune activation and cytokine levels, improved immune responses unmeasured by CD4 cell count, and HAART-related suppression of oncogenic viruses. The effects of antiretroviral therapy on the hypothalamic-pituitary-gonadal axis remains unclear [79]. Combination antiretroviral therapy can induce insulin resistance which may cause decreased sensitivity of the hypothalamic-pituitary-gonadal axis and decreased testosterone production by Leydig cells [80] and possibly reduced DHEA levels [81, 82]. With consequently lower PSA levels, these HIV-positive men undergoing HAART are less likely to receive prostate biopsy and therefore have a lower incidence of prostate cancer than the general population.

In the general population, prostate biopsy is frequently completed before testosterone replacement therapy, regardless of DRE or PSA. Since the association between HIV and PCa is currently ambiguous, patients should undergo complete evaluation prior to start of testosterone replacement. In the HIV population, similar to the general population, testosterone therapy is suggested for symptomatic men, with decreased testosterone levels, to improve sexual function, muscle mass, and bone mineral density. Contraindications to starting testosterone therapy include patients with prostate cancer, a palpable prostate nodule or PSA >3 ng/ml without further urological evaluation, erythrocytosis (hematocrit >50 %), untreated obstructive sleep apnea, severe lower urinary tract symptoms (International Prostate Symptom Score (IPSS) greater than 19), or class III or IV heart failure [83].

Some hypothesize that human papillomavirus (HPV) may be related to prostate cancer [84–86]. Since HPV and HIV have been intensely investigated and HIV infection is recognized to elevate the risk of persistent HPV infection, then the role of circumcision and or vaccination against HPV will likely be investigated in additional studies in the future [87]. More recently, xenotropic murine leukemia virus-related virus (XMRV), a gammaretrovirus, has been isolated in human prostate cancers (23 % of 334 specimens had evidence of protein expression), most often in aggressive tumors [88]. Additionally, among ten licensed anti-HIV-1 compounds, zidovudine (AZT) has been shown to block XMRV infection and replication through inhibition of viral reverse transcription [89]. Given this possible viral influence on prostate cancer, the use of HAART therapy, which incorporates AZT, may explain study outcomes of decreased incidence of prostate cancer in HIV-1 patients during the HAART era.

## Diagnosis

Prostate cancer screening includes digital rectal exam and annual serum PSA level measurement. The role of population-wide prostate cancer screening remains controversial following the PLCO and ERSPC studies published in 2009 [90, 91]. Screening of HIV patients for non-AIDS-defining malignancies, such as prostate cancer, remains equally debatable [92]. Screening practices during the PSA era have resulted in stage migration, with enhanced detection of cancer with lower stage and lower volume. The American Urological Association (AUA) current guidelines recommend screening of all men aged 40 years or older with life expectancy of more than 10 years [93]. Baseline PSA is established at this time which determines future screening intervals. Men with increased malignancy risk and life expectancy greater than 10 years (it is common for most HIV patients to now have life expectancy greater than 10 years) should begin screening earlier, although no official recommendations are available from the AUA [94]. According to AUA best-practice guidelines, PSA testing in patients with a serum PSA level greater than 4.0 ng/ml has a sensitivity of approximately 20 % in contemporary series with associated PSA testing specificity of 60–70 % at this cutoff. For men in their 40s and 50s, baseline PSA level above the median value for age is a stronger predictor of future prostate cancer risk than family history or race. Serum testosterone level should also be quantified to ensure that measurement of PSA levels is accurate. Those without prostate cancer may be candidates for chemoprevention, similar to the general population, based on the PCPT and REDUCE trials [95, 96].

Transrectal ultrasound-guided prostate biopsy is indicated in patients with an elevated PSA level or abnormal DRE findings. There are no reports in the literature suggesting increased complications from biopsy in HIV-infected patients when compared to noninfected patients [97]. Patients should refrain from receptive anal intercourse and ejaculation for at least 48 h before a PSA test, as either activity could lead to transient abnormal PSA elevation [98].

## Treatment of Prostate Cancer in HIV/AIDS Patients

The patient's life expectancy and medical comorbidities are of key significance in determining management strategy for prostate cancer and in choosing optimal treatment. Figure 10.1 summarizes management guidelines of prostate cancer in HIV-positive patients. Figures 10.2 and 10.3 summarize special considerations for treating prostate cancer in HIV-positive homosexual men. With the dramatic decline in life expectancy of AIDS patients in the pre-HAART stage, physicians usually offered radiation as treatment for localized disease rather than radical prostatectomy as primary treatment for localized disease since life expectancy for these patients was usually shorter than 10 years. With widespread HAART use and subsequent prolonged life expectancy, the natural history of prostate cancer in the HIV setting is similar to that in the general population in terms of PSA kinetics and cancer stage. Similarly, immunosuppressed renal transplant recipients with prostate cancer (21 patients of 3,150 transplant recipients) can be treated according to standard guidelines for general population with encouraging oncologic results with minimal morbidity [99]. Short-term outcome analyses appear similar, but long-term outcome results are not yet published [97]. Table 10.2 illustrates published reports of patient characteristics by treatment type.

It must be considered whether the HIV-positive patient will exhibit a different response to PCa therapy than HIV-negative patients. Of the 29 patients in our cohort, 6 patients with recent diagnosis of CaP (<6 months) have not had follow-up beyond initial treatment. Of the remaining 23 patients, most recent mean PSA was 3.56 (undetectable in 8: 6 underwent RRP, 1 EBRT, 1 brachytherapy), from baseline PSA 8.8 at diagnosis of prostate cancer. Median follow-up for those followed for <1 year was 6.7 months (1–11) and mean follow-up was 5.5 months. Median follow-up for those patients followed for greater than 1 year was 52.2 months (14–108 months) and mean follow-up was 60.3 months. Mean Gleason biopsy score at diagnosis was 6.38 (5–7). Treatment for this group included prostatectomy ($n=9$), EBRT ($n=4$), brachytherapy ($n=3$), cryotherapy ($n=1$), ADT ($n=5$), and active surveillance ($n=1$). The most recent PSA values indicate that PCa was controlled or stable in all patients regardless of treatment type. No patient has had clinical recurrence at this time (three patients were lost to follow-up with elevated PSA). More specific details of our

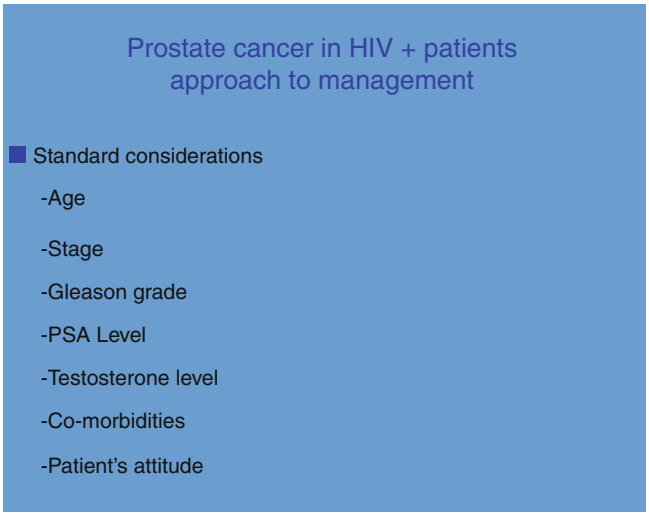

**Fig. 10.1** Prostate cancer in HIV+ patients: approach to management, standard considerations

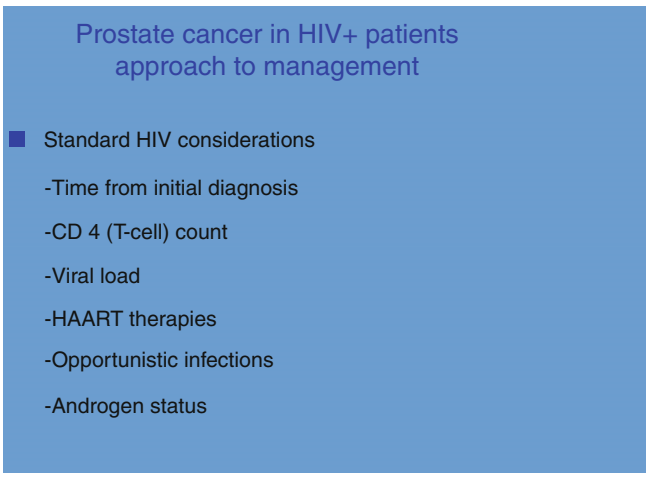

**Fig. 10.2** Prostate cancer in HIV+ patients: approach to management, standard HIV considerations

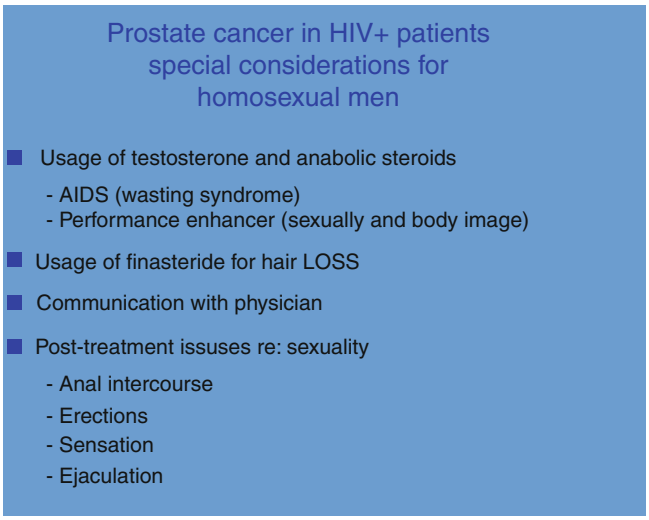

**Fig. 10.3** Prostate cancer in HIV+ patients: special considerations for homosexual men (Santillo and Lowe [98])

cohort according to treatment modality are described throughout this section.

Radiation therapy was shown to be effective with minimal short-term morbidity. One study describes three patients with HIV and clinically-localized PCa that received external-beam radiation therapy with short-term tolerance similar to the general population with 60 % having ≤ grade 1 toxicity and declining PSA measured at 1 month [36]. One patient also underwent concurrent hormone therapy. Patient mean age was 55 years (range 50–58), PSA 5.1 (range 3–9.1), $n=1$ with Gleason score 6, $n=1$ Gleason score 7, and $n=1$ Gleason score 8. Two of three patients were of African American descent, all underwent HAART treatment, and had HIV infection for mean 19.4 months (range 5 months–14 years), and CD4 count of 331 cells/mm$^3$ (range 281–425). The authors hypothesize that RT tolerance may be associated with CD4 count according to a study of HIV-infected patients with anal cancer being treated with chemotherapy and radiation which found CD4 ≥200 cells/mm$^3$ to have reduced morbidity compared to those with lower CD4 count [100]. Overall, there was immediate tolerance, much improved compared with radiation for rectal cancer. Quatan et al. describe two patients with HIV and PCa ages 58 and 64 receiving neoadjuvant hormonal therapy and RT (with subsequent decrease in PSA at last follow-up) and hormonal treatment for metastasis (with good initial response and palliative RT for bone pain), respectively [18]. In our cohort of 29 patients, 4 patients (13.8 %) underwent external-beam radiotherapy with mean age at diagnosis 60 (51–65) years, clinical stage cT1c ($n=3$) and cT2a ($n=1$), and pretreatment PSA 8.15 (4.5–14.5). Mean HIV duration at prostate cancer diagnosis was 18.6 years (14–22), mean CD4 count at diagnosis of prostate cancer was 630 cells/mm$^3$ (76–1,208), and mean viral load was 204 copies/ml (25–501). Mean posttreatment PSA was 0.45 (1.47 <1 year post-XRT, others 0.24, 0.07, and 0.024 respectively) at median follow-up 3.5 years (mean 5.3 years) without major complications.

Brachytherapy has been shown to be safe as a short-term intervention in a retrospective study of 14 HIV-infected patients with PCa, of which 2 received external-beam radiotherapy, 4 received brachytherapy, and 8 completed a combination of brachytherapy and external-beam radiotherapy [33]. All patients were assessed for urinary, bowel, and sexual symptoms after treatment, and the patients fared well when compared with other series. Their conclusion was that radiation therapy and brachytherapy of the prostate were not contraindicated in HIV-positive patients. Brachytherapy has also been reported by Staiman et al. who describe an HIV patient with prostate cancer who underwent brachytherapy

**Table 10.2** Treatment of Prostate Cancer in HIV/AIDS Patients: Published studies including patient characteristics and outcomes

| Treatment | Patients | Study | Mean age | Mean HIV duration | HAART | Mean PSA | Mean biopsy Gleason sum | Clinical stage |

[b]1 patient N/A

and developed a prostatic abscess requiring drainage [40]. In our study cohort, 3 of 29 patients (10 %) underwent brachytherapy with mean age 46.5 (44–48) years, clinical stage cT1c with neoadjuvant leuprolide acetate/bicalutamide, mean pretreatment PSA 6.7 (4.8–8.5), mean HIV duration at time of prostate cancer diagnosis 4.7 years (2 months–13 years), mean CD4 count 505 cells/mm$^3$ (415–620), and mean viral load 37 copies/ml (25–61). Mean biopsy Gleason score 5.7 (5–6). Mean posttreatment PSA <0.1 in one patient at follow-up of 7.6 years; the other two patients were lost to follow-up without known PSA recurrence. A major consideration in the treatment determination for homosexual men is the potential consequences of either XRT or brachytherapy upon the rectum, especially if the patient participates in anal receptive intercourse [101].

Preoperative assessment of HIV-positive patients that are candidates for radical prostatectomy should include the standard variables used in HIV-negative patients (age, stage, and grade of disease, PSA level and comorbid conditions) as well as CD4$^+$ T cell counts, viral load, and serum albumin level (Figs. 10.1 and 10.2). Radical prostatectomy and perioperative complications were described by Huang et al. in a population of five HIV-infected male patients from Memorial-Sloan Kettering Cancer Center [35]. Age range was 45–59 years, PSA 4.1–30.8 ng/ml, and biopsy Gleason sum 6 or 7. CD4 counts prior to surgery ranged from 269 to 870 cells/mm$^3$ and viral load ranged from <50 to 18,700 copies/ml. Three patients were treated with HAART at time of surgery and median follow-up was 26 months. After RP, two of five had wound infections, one requiring hospitalization for IV antibiotics. No patients progressed to AIDS during the study period, and none had biochemical recurrence during follow-up. The authors describe that the patient with the deep wound infection necessitating intravenous antibiotic therapy also had the lowest CD4 count (300 cells/mm$^3$) [102]. An additional recent study of eight HIV-positive men undergoing robot-assisted laparoscopic prostatectomy for prostate cancer demonstrated increased prevalence of perioperative transfusions ($p = .03$) and ileus ($p = .02$) when compared to HIV-negative men with similar preoperative characteristics [55]. There were no significant differences identified between groups in terms of short-term oncologic outcomes or complications.

In our cohort, there was no increased risk of wound infection. Nine (31 %) patients (four open retropubic; five laparoscopic/robotic) who had radical prostatectomy were mean age 54.5 years (50–62) at diagnosis with clinical stage T1c and preoperative mean PSA 6.0 (range 4.1–9.5). Biopsy Gleason score was Gleason 6(3 + 3) ($n = 5$), Gleason 7(3 + 4) ($n = 1$), Gleason 7(4 + 3) ($n = 2$), and 1 unknown. Mean HIV duration at prostate cancer diagnosis was 6.5 years (2–17) and mean CD4 616 (377–837) cells/mm$^3$ and mean viral load 102 (<50–386) copies/ml. Post-prostatectomy Gleason score was Gleason 6(3 + 3) ($n = 1$), Gleason 7(3 + 4) ($n = 4$), Gleason 7(4 + 3) ($n = 1$), Gleason 8(3 + 5) ($n = 1$), Gleason 8 (4 + 4) ($n = 1$). One patient did not have post-prostatectomy pathology available from outside hospital. Prostatectomy specimens revealed biopsy undergrading (by 1 unit of Gleason score) in five patients undergoing surgery with biopsy overgrading (by 1 unit of Gleason score) in one patient. Mean posttreatment follow-up PSA <0.1 ($n = 6$, 2 with follow-up PSA pending as surgery done in 9/2010, 1 patient with recent diagnosis <2 months prior without additional follow-up) without evidence of recurrence at median follow-up of 10 months. Preoperative assessment should include variables used in seronegative patients, along with CD4+ count, viral load, and albumin level. Overall, for patients with CD4 counts above 500 cells/mm$^3$ and asymptomatic HIV infection, prostatectomy is well tolerated and advised [98].

Our study cohort additionally included five patients receiving potency-preserving androgen deprivation (one patient had neoadjuvant ADT and EBRT), one patient receiving cryosurgery, and one patient on active surveillance. For patients receiving ADT, mean age was 56.6 (44–67), median follow-up was 2.1 years (mean 3.6 years), mean duration of HIV diagnosis was 9.25 years (1 month–20 years), mean CD4 count was 387 cells/mm$^3$, (range 75–620), mean viral load <50 copies/ml in all patients, and mean pretreatment PSA level was 17.3 (6.9–33), and mean posttreatment PSA was 11 (0.38–23.9). Mean biopsy Gleason score was 6.5 (5–8). The patient undergoing cryotherapy had pretreatment PSA of 6.4, Gleason biopsy score of 7 (3 + 4) posttreatment PSA 1.05 at 4 years follow-up. The patient on active surveillance protocol had stable PSA level (diagnosis PSA 12.2, most recent PSA 4.74) with initial Gleason biopsy score of 6 (3 + 3) without disease progression at 7.5 years follow-up. This patient did require greenlight laser PVP for LUTS. Active surveillance should be initiated according to the same criteria for the general population following the criteria of Carter et al., which includes Gleason sum ≤6, <3 biopsy cores with cancer, and <50 % involvement of any core with prostate cancer, free/total serum PSA ratio of ≥0.15 [103, 104]. Repeat biopsy within 6 months of diagnosis is the most important predictor of progression for patients on active surveillance [105].

Similar to our cohort receiving various treatments, another cohort study described 17 patients with HIV (mean duration of disease 8.5 years) and PCa [16]. One patient had distant metastasis and one had regional lymph nodes metastasis. Three patients underwent radical prostatectomy, three received brachytherapy, seven received androgen suppression and radiation, and two received androgen suppression alone. The authors noted that all patients with initial localized disease undergoing treatment had a complete response with undetectable PSA level and without

tumor recurrence. No serious treatment-related side effects were noted, and the authors concluded clinical presentation, PSA, and outcomes were not appreciably different in HIV-positive men on HAART. From these relatively small cohorts, response to therapy in HIV-positive patients with prostate cancer seems similar to that of the general population. The reader must recognize, however, that all investigated groups are small, heterogeneous, and not matched to non-HIV positive men so there may be multiple confounding factors limiting definitive conclusions.

## Adverse Effects of Prostate Cancer Treatment in HIV Patients

All therapies for the treatment of prostate cancer can negatively impact quality of life, sexual function, urinary and bowel function as well as psychological state. For patients undergoing surgery, radiation, or androgen deprivation, urologists must evaluate baseline sexual dysfunction. A study of 189 HIV-infected men with mean age 36.8 years described sexual dysfunction in 19.5 % which was postulated to be affected significantly by antiretroviral treatment, particularly protease inhibitors [106]. HIV-induced hypogonadism was not the cause of sexual dysfunction. Patients must be counseled regarding risks of erectile dysfunction following treatment which may be exacerbated by HAART.

For those undergoing surgical procedures, CD4+ counts are important because it has been shown in HIV-positive women having gynecological surgery that those with CD4+ counts <200 have up to four times greater complication risk than HIV-negative age and procedure matched controls [102]. Furthermore, serum albumin, a marker for nutritional status, has been correlated with morbidity and mortality outcomes for those undergoing surgery with end-stage renal disease, cardiovascular disease, numerous types of cancer, and HIV infection [107–110]. Serum albumin is described to have possible prognostic significance for the morbidity and mortality of HIV-infected patients, but our cohort did not include routine examination of preoperative albumin levels [107]. Again, homosexual men who engage in anal receptive intercourse should be advised about radiation effects upon the anus and rectum secondary to both brachytherapy and external beam radiation therapy.

When treating HIV-positive patients with prostate cancer, the physician must consider the tolerability of the treatment regimen. Although studies of patients with prostate cancer are limited, comparison to anal cancer studies is helpful to determine effects of radiation on HIV patients. From published data, the use of combined chemoradiotherapy is reported to be "tolerable" or to result in increased morbidity in immunodeficient patients compared with immunocompetent patients. The oncologic outcome of anal SCC in immunodeficient versus immunocompetent patients is characterized by similar or reduced disease control. Some data indicate increased morbidity and decreased time to cancer-related death in patients with HIV and anal cancer treated with chemoradiation [111]. Direct comparison of prostate cancer and anal cancer treatment is hindered by the use of chemotherapy for anal cancer treatment. A study of 17 HIV-positive patients with anal cancer treated during the pre-HAART era with concurrent chemotherapy (5FU and/or mitomycin C, and/or cisplatin) and radiation (median dose 5,180 cGy) revealed that patients with CD4 ≥ 200 had excellent disease control with acceptable morbidity while patients with CD4 < 200 had markedly increased morbidity (skin, hematologic, gastrointestinal), although disease was controlled in 7 out of 8 of these patients [100]. In the HAART era, Seo et al. studied 19 immunocompetent and 17 immunocompromised patients with anal cancer (14 HIV and 3 post-solid organ transplant patients) who received concurrent chemoradiotherapy [112]. There were no differences in overall or disease-specific survival or toxicity between the two groups.

In the setting of HIV and androgen-independent prostate cancer, there is evidence of possible benefit from protease inhibitors used concomitantly with docetaxel. In addition to protease activity, protease inhibitors have been identified to inhibit growth of DU145 and PC-3 androgen-independent prostate cancer cells using the clonal proliferation assay [113]. Ritonavir blocked docetaxel-induced expression of CYP3A4 at the mRNA level in DU145 cells and enhanced the antitumor effect of docetaxel in vitro and in BNX nude mice bearing DU145 tumors [114]. The group hypothesized that using an active chemotherapeutic drug and a PI (ritonavir) could reverse drug resistance.

### Conclusion

With the prolonged survival of HIV-positive patients receiving highly active antiretroviral therapy, the screening, diagnosis, and treatment of non-AIDS-defining malignancies, such as prostate cancer, now need to be addressed. Although the largest studies of cancer incidence trends among HIV-infected patients have identified significantly higher rates of prostate cancer in the HAART era, the incidence rates appear to be decreased compared with the general population. It is probable that the increasing incidence of prostate cancer amongst HIV-positive patients is related to their longevity and that they are more often now being screened for prostate cancer with PSA testing. Similar to the general population, stage migration secondary to increased PSA screening has identified more prostate cancer at an earlier stage. It is

unclear why the incidence is lower than the general population except for possible differences in racial demographics, less PSA screening in the HIV-infected cohort, HIV-induced apoptosis of cancer cells, or hypogonadism secondary to HIV or HAART. In the HAART era, PSA kinetics and prostate cancer behavior has not been demonstrated to be different between HIV-positive and HIV-negative patients. Prostate cancer screening for HIV-positive patients should be initiated beginning at age 40 following recommendations for the general population along with continued close surveillance of CD4 count, viral load, and serum testosterone level. The extended life expectancy of the typical HIV patient on HAART requires consideration of the full spectrum of treatment modalities including active surveillance, prostatectomy, radiation, cryosurgery, and androgen deprivation in accordance with the AUA guidelines for the general population. Early results indicate that responses to prostate cancer therapies in HIV-positive patients are comparable to those in the general population. The physician must recognize numerous special issues to optimally manage the HIV patient with prostate cancer. With extended follow-up data from population-based and prospective randomized studies, long-term outcomes will further refine treatment algorithms.

## Introduction

Prostate cancer (PCa) is one of the commonest cancers in men and a major cause of cancer-related mortality. Family history is the strongest known risk factor for developing PCa. This is illustrated by the observation that a man with one close relative (such as a father or a brother) with PCa has approximately twice the risk of developing PCa when compared to a man with no family history. A man with two close male relatives affected has a fivefold increase in lifetime risk. This degree of relative risk and the increase in its magnitude indicate a strong genetic component to disease development. However, unlike other cancers such as breast, ovarian, and colonic cancers, the search for mutations in candidate genes is proving to be more elusive. Uncovering the genes that predispose to PCa among families where disease is clustered has been the objective of many research groups over the past 15 years. Epidemiological and twin studies support a role for the genetic predisposition to PCa. Familial cancer loci have been identified, but discovery of the genes that cause familial prostate cancer (FPC) remains largely elusive. Unraveling the genetics of PCa is challenging and is likely to involve the analysis of numerous predisposing factors, which may be manifestations of multiple mutagenic pathways. Increased familial risk of prostate cancer could be due to the inheritance of multiple moderate-risk genetic variants. Although the study of hereditary prostate cancer (HPC) has increased our understanding of its genetic etiology, many issues remain largely unresolved. This difficulty with identification of PCa predisposition genes may be due to a number of reasons. PCa, in terms of total prevalence, is a very common condition, and it may not be far wide of the mark to say that the majority of prostates in the Western world will eventually harbor some cancer cells. The disease varies significantly in the spectrum of aggressiveness. We do not know, with absolute conviction, which patients who have been diagnosed with PCa require treatment. It is against this quandary that genetics could play its influence. PCa is diagnosed in the later years of life; therefore, obtaining DNA samples from living affected men for more than one generation is often not possible, and linkage in large pedigrees may be unfeasible. The presence within high-risk pedigrees of phenocopies (individuals with PCa but without the genetic alteration) weakens the linkage results. The genetic heterogeneity of this complex disease (the fact that different pedigrees may be due to different genetic mutations) and the uncertainty regarding the optimal genetic model could render linkage results inaccurate, making gene identification difficult.

Significant linkage in FPC was first published by a group from Johns Hopkins University, USA [1]. They reported linkage at a locus on chromosome 1q24-25, which they named hereditary prostate cancer 1 (*HPC1*). Since then, several large linkage studies have taken place, and the results of many different groups have uncovered new loci and challenged others [2–5]. To this date, research on PCa linkage has reported genotyping data in over 1,600 families. There are numerous contradictory studies reporting or refuting linkage within a multitude of areas in the genome, and this challenges our understanding of the genetic basis of this disease. This is in contrast from the search for a familial breast cancer predisposition gene in which analysis of linkage in select regions revealed a site where the *BRCA1* gene was situated [6]. This demonstrates that the genetic predisposition to PCa is highly

complex, probably involving numerous predisposition genes and that a high proportion of high-risk families may not be attributable to a single high-risk gene. Conventional linkage may not be the best method of predisposition gene identification in this disease because of genetic heterogeneity whereby various familial clusters are due to different genes. This chapter addresses the current evidence that supports a genetic component to the etiology of PCa and attempts to put into context the diverse findings that have been implicated with the development of HPC. It explores why understanding the genetics of PCa has been so difficult. Lastly, management strategies of men with HPC are discussed.

## Evidence for Genetic Etiology

Current evidence for the genetic etiology of PCa can be grouped into epidemiological evidence, case–control studies, cohort studies, and twin studies.

### Epidemiological Evidence

In the 1950s–1960s, it was noted that the risk of PCa development in relatives of sufferers was higher than the population average [7, 8]. Large families have been observed, in which prostate cancers seemed to cluster. Early observations were made in large families studied in Utah [9, 10]. To further explore the evidence for a familial component to PCa development, case control, cohort, and twin studies have been reported.

### Case–Control Studies

Case–control studies can be divided into two broad strategies. One strategy compares prostate cancer incidence in first-degree relatives of PCa patients (cases) with the incidence in relatives of cancer-free individuals (controls). The second strategy compares the percentage of PCa cases vs. controls with a family history of the disease [7–9, 11–26]. These studies indicated that the relative risks (RR) among first-degree relatives of affected individuals range from 0.64 to 11.00-fold [27–29]. With the exception of the RR of 0.64 [11], in a study, which was carried out on a small sample set of 39 families, 15 of these 16 studies reported an RR of 1.76 or more. This RR increases further when more than one relative is affected. Steinberg et al. [15] demonstrated that the RR with an affected first-degree relative was 2.0, with a second-degree relative was 1.7, but with both first- and second-degree relatives combined, RR rose markedly to 8.8. Additionally, the RR increased as the number of family members increased, with RRs of 2.2, 4.9, and 10.9 observed for 1, 2, and 3 additional affected relatives besides the proband, respectively [15]. This is robust evidence for the involvement of a genetic component in familial disease as these increases in RR are too large to be dismissed solely as an environmental effect. Further evidence of a genetic influence is demonstrated by the observation that the RR to relatives increases as the age of the proband decreases [9, 30]. A brother of a proband with PCa at the age of 50 has a 1.9-fold higher risk of developing prostate cancer compared with a brother of a man diagnosed with the disease at the age of 70 [30].

### Cohort Studies

Cohort studies attempt to avoid potential bias through probing an unselected population. Goldgar et al. [31] showed an FPC RR of 2.21 in first-degree relatives of 6,350 probands from an unselected population from the Utah Population Database. Likewise, Gronberg et al. [32] found an RR of 1.70 from their study involving 5,496 sons of Swedish men from Cancer Registry data.

### Twin Studies

These have demonstrated an increased RR in mono compared with dizygotic twins of just over 3- to 6-fold [33]. Page et al. [34] studied 15,924 male twin pairs and found pairwise concordance (twin pairs where both men were affected) rates among monozygotic twins was 15.7 %, while for dizygotic twins the frequency was 3.7 % ($p = <0.001$). Probandwise concordance (number of concordant affected twins divided by total number of affected twins) was 27.1 % for monozygotic twins and 7.1 % for dizygotic twins, which gives a risk ratio of 3.8. Similar results were noted in a Finnish study [35]. A further study concluded that up to 42 % of PCa risk could be attributable to heritable factors [36]. The absolute risk of prostate cancer for twins diagnosed up to the age of 75 was found to be sixfold higher for mono- vs. dizygotic twins (18 % vs. 3 %). It also demonstrated a statistically significant reduction in time interval between the age at diagnosis for monozygotic twins compared with dizygotic twins (5.7 years vs. 8.8 years; $p = 0.04$).

## Segregation Analyses

"Segregation analyses" is a method that studies the structure of familial clusters and describes the likely mode of inheritance, age-specific cumulative risk (penetrance), and allele frequency of genetic predisposition to a disease. Carter et al. [30], using such analyses, suggested that early-onset PCa (<55 years) may be due to a rare autosomal dominant highly penetrant allele, which could account for up to 43 % of disease in this age group and up to 9 % of PCa in men aged

up to 85 years. Alleles for such a rare autosomal dominant gene were predicted to exist at a frequency of 0.003 and to cause a cumulative risk of disease of 88 % by 85 years of age compared with 5 % for noncarriers. Other researchers have arrived at similar conclusions but have suggested a commoner allele frequency and a lower penetrance of about 67 % (Gronberg et al. [32], allele frequency 0.0167; Schaid et al. [37], allele frequency 0.006). A recessive or X-linked model is suggested by some studies, which noted higher risks to brothers of PCa cases compared with fathers [38, 39]. Ewis et al. [40] report an odds ratio of 2.04 ($p=0.02$) for allele C of dYs19 in Japanese prostate cancer patients, while other alleles of this region were protective against the disease (allele D, OR 0.26 $p=0.002$). The Y chromosome (father-to-son transmission) is therefore also implicated. It is possible that a mixture of several models coexist, giving rise to age-related risks [41]. Dominantly inherited risk allele(s) may predispose to early-onset disease, and a recessive or X-linked model could account for its later onset [42].

## Molecular Analysis Evidence: Linkage Studies (Genome-Wide Scans)

Linkage analysis is a gene-localizing technique that looks for co-segregation of a disease in sizeable, high-risk families, with disease-causing genetic mutations. Linkage analysis has been used to successfully map many familial cancer loci, e.g., colorectal cancer, breast/ovarian cancer, and melanoma [43]. Initially, linkage analysis helps to pinpoint the region within which a disease-causing locus may lie by analyzing co-inheritance of polymorphic stretches of DNA, e.g., microsatellite markers. The sequencing of the human genome will facilitate the use of single nucleotide polymorphisms (SNPs). As these are more common than polymorphic runs of DNA sequence, a denser linkage maps can be determined. Once a region of linkage is identified, then candidate gene mutation analysis within the region can be undertaken to identify the disease-causing mutation.

## Candidate Gene Analysis Evidence

The search for genetic markers of disease susceptibility often utilizes the candidate gene approach. Here, a gene is targeted based on the properties and metabolic pathways of its protein product. PCa cases were noted to be clustered among breast cancer families as far back as the 1990s [44, 45]. The relative risk (RR) of PCa development in male carriers of mutations in the breast cancer predisposition genes *BRCA1* and *BRCA2* is increased. The RR with respect to *BRCA1* was found to be 3.33 [46] and 1.82 in a further analysis by the BCLC [47]. That of *BRCA2* was found to be 4.65. The RR is higher in men with PCa diagnosed before 65 years (RR 7.33), with an estimated cumulative incidence by the age of 70 of 7.5–33.0 %. A founder mutation 999del5 in *BRCA2* has been identified in study carried out in Iceland. This mutation is reported to confer a cumulative PCa risk to carriers of 7.6 % by the age of 70 [48]. Sixty seven percent of men who had the mutation all developed advanced PCa associated with a high mortality rate [49], implying that *BRCA2* predisposes to more aggressive disease. A report in a Swedish family carrying the *BRCA2* mutation 6051delA [50] adds weight to the evidence that such mutations are pathogenic. A mutation screen of *BRCA1* and *BRCA2* genes was conducted by Gayther et al. [51]. Two germline deleterious *BRCA2* mutations were discovered. A study conducted by Edwards et al. [52] on 263 men aged <55 at diagnosis discovered six pathogenic mutations located outside the ovarian cancer cluster region in the gene, implying a genotype/phenotype correlation that accounted for 2 % of PCa at this young age. This equated to an RR of 23 by the age of 60 and conferred an absolute risk of PCa of 1.3 and 10 % by the age 55 and 65, respectively. This supports the notion that *BRCA2* is a high-risk PCa gene. Two recent studies have reported an increased risk of prostate cancer associated with the Ashkenazi founder mutations in the *BRCA* genes, lending further evidence to these data [53, 54]. Subsequently, germline mutations have been found in the *NBS* gene in the Slavic population at a higher frequency in PCa cases than controls [55] and in the *CHEK2* gene [56]. This implies that PCa predisposition may in some instances be due to mutations in genes in the DNA repair pathway, that in the homozygous form give rise to a severe phenotype (in the case of *BRCA2* this would be Fanconi's anemia D2 and in the case of *NBS* would be Nijmegen Breakage Syndrome), but in the heterozygous form, would increase the risk of PCa development.

## Genome Searches

The running of a large number of microsatellites, typically in the region of 400, has many terms: genome-wide search, genome-wide scan, or genome-wide screen – and can conveniently be abbreviated to GWS. Numerous linkage analysis experiments have been conducted across the genome to identify prostate cancer susceptibility loci. The ACTANE (Anglo-Canadian-Texan-Australian-Norwegian-EU Biomed) group has focused on the collection of early-onset clinically detected disease. This is because the disease manifests 10 years later on average than PSA-detected disease, and therefore these men would have had a raised PSA level at even earlier age and may therefore be highly predisposed genetically [28]. Thus far, several GWS have been published for PCa [1, 3, 5, 57–72]. The significant results are as follows.

## 1q23-24: HPC1 and the RNASEL Data

The first GWS identified a locus named *HPC1* (hereditary prostate cancer 1) at 1q24-25. A group from Johns Hopkins University, Baltimore, carried out the study in 91 North American and Swedish families, and their report suggested that up to 34 % of families could be linked to this locus [1]. Several other groups have since either confirmed [73–76] or refuted [57, 58, 60, 64, 77, 78] the original report. Goode et al. [64] and Goddard et al. [79] found evidence of genetic linkage in families with more aggressive PCa. A meta-analysis conducted by Xu et al. [80] representing many groups within the International Consortium for Prostate Cancer Genetics (ICPCG) reported data obtained on 772 families and reported that a lower estimate of 6 % of all families was linked to 1q24-25. A more extensive analysis concluded that *HPC1* might have a role in a subset of families with numerous young-onset cases, particularly among Afro-Caribbean men. Carpten et al. [81] subsequently found mutations in the cell proliferation and apoptosis-regulating gene *RNASEL* which was in this region. Of 8 families that were linked to the 1q region, two had germline mutations; one was a stop Glu265Ter (E265X) termination codon, but the other was a missense mutation. Neither segregated with the disease. Some, but not all, further reports have shown *RNASEL* mutations to be associated with PCa risk but with a much lower relative risk than would have been predicted by the linkage evidence. Rokman et al. [82] showed that the Glu265X in *RNASEL* was present 4.5-fold more often in affected family members compared with controls. Other groups have found that *RNASEL* may confer much smaller PCa risks or have found no mutations at all in PCa cases; therefore, it is likely to be low-penetrance PCa cancer gene that is at odds with the linkage evidence [83, 84]. This suggests that either the linkage results are misleading or that a highly penetrant *HPC1* exists but is still to be discovered.

## Other Loci and Candidates from GWS

Other loci have unfortunately had a similar history to that described above, namely, loci are identified that have significant logarithm of the odds (LOD) scores, and candidate genes have mutations described therein which are subsequently refuted or whose risks fall on further detailed analysis [85, 86].

## Other Significant Loci

*PCaP* (1q42.2-43; Berthon et al. [57]) – this was a locus that was identified in the German/French population but not corroborated by other researchers. *CAPB* (1p36; Gibbs et al. [59]) – a locus which is associated with primary brain tumor and PCa which on further analysis seemed more associated with young-onset PCa than brain tumor [87]. A locus has been described on chromosome 16q in sibling pairs by Suarez et al. [58] and one on 20q (*HPC20*) by Berry et al. [63], but these are yet to be independently confirmed. Another locus has been described on the long arm of chromosome X (*HPCX*; Xq27-28) by Xu et al. [88]). This has been corroborated by some other researchers, but the gene has yet to be identified. There are also loci that are implicated in the development of more aggressive disease, e.g., 7q, 19q [89–91]. Eight GWS have been published recently in one issue of the Prostate (ACTANE Consortium [72]; Lange et al. [65]; Schleutker et al. [66]; Cunningham et al. [67]; Xu et al. [68]; Wiklund et al. [69]; Janer et al. [70]; Witte et al. [71], Dec 2003). A summary of these was published in a review by Easton et al. [5]. The conclusion of these GWS to date is that there are numerous loci suggested by the GWS from various groups which are not consistently replicated by independent groups on study of further PCa families. This implies that there is considerable genetic heterogeneity in PCa. The possibility that PCa is due to a combination of low penetrance means that more common genetic variants may be entertained when large families are rare and it is difficult to locate predisposition genes by linkage. Candidate studies of polymorphisms are presently under way in PCa. There is currently no uniform pattern of polymorphisms that confers markedly increased risk from the data. The most consistent polymorphisms to date that confer a moderately increased risk are in the *SRD5A2*, *GSTP1*, and the *AR* genes [92–102].

## Recent Findings of the UK GWAS and Potential Clinical Role

Eeles et al. previously conducted a genome-wide association study in which 541,129 SNPs were genotyped in 1,854 PCa cases with clinically detected disease and in 1,894 controls. They then extended the study to evaluate potential correlations in a second stage in which they genotyped 43,671 SNPs in 3,650 PCa cases and 3,940 controls and in a further stage involving an additional 16,229 cases and 14,821 controls from 21 studies. They identified seven new PCa susceptibility loci on chromosomes 2, 4, 8, 11, and 22 (with $P = 1.6 \times 10(-8)$ to $P = 2.7 \times 10(-33)$) [103]. It is possible that the seven novel genetic loci found could contain several potential candidate genes, which could contribute to PCa development and progression. A key association was found on chromosome 10, just 2 bp away from the transcription start site of the microseminoprotein B (*MSMB*) gene. *MSMB* encodes PSP94, a member of the immunoglobulin-binding factor family made by

epithelial cells of the prostate and secreted into seminal plasma. Loss of expression of PSP94 is linked with recurrence after radical prostatectomy. This seems to suggest that this SNP may be causally related to disease risk [104]. Therefore, PSP94 could be a future screening target especially as it can be found in blood. There is a region on chromosome 7 that the gene *LMTK2* (also known as *BREK*) which codes for a signaling protein [105] and could act as a novel target for drug therapy. The chromosome 19 hit contains kallikrein genes *KLK2* and *KLK3* which code for the proteins hK2 and PSA, respectively. There is evidence that hK2 may be useful for PCa screening and prognosis [106]. Twenty-four SNPs in the *KLK3* (PSA) gene have subsequently been evaluated in men from five studies, and no association was reported with PCa risk [107]. Eeles et al. looked at the variation in KLK genes, PSA, and risk of PCa. In the first stage of a study, they used controls selected for low PSA levels. Stage 2 controls were not selected for a low PSA. However, they still found an association. Following this a study involving 13 groups worldwide where the controls were not selected for a low PSA level, still showed an association of the chromosome 19 SNP (between *KLK2* and *KLK3*) with PCa risk [108]. The chromosome 6 association is in intron 5 of *SLC22A3*, one of the organic cation transporter (OCT) genes. These have been shown to be critical for elimination of some drugs and toxins [109]. Many genes are near the SNP of interest on the X chromosome. The *NUDT10* and *NUDT11* genes encode enzymes that determine the rate of phosphorylation in DNA repair, stress responses, and apoptosis [110].

### Other PCa GWAS

Two other groups of researchers, CGEMS (USA) [111] and deCODE Group (Iceland) [112], published their PCa GWAS at the same time as the UK GWS. Both confirmed previously reported associations at chromosomes 8q and 17q. CGEMS found similar hits to UK GWS on chromosomes 10 and 11. They additionally found novel tagSNP associations on chromosomes 7 and 10. The deCODE team found a novel region on chromosome 2p15 in their population. Duggan et al. in another GWAS investigated aggressive PCas that were defined by having at least one of the following: stage T3/T4, N+, M+, Grade III, Gleason score ≥8, or preoperative serum PSA of at least 50 ng $mL^{-1}$. This group reported a different association on chromosome 9 located within the *DAB2IP* gene, which encodes a novel Ras GTPase-activating protein [113]. More recently, Sun et al. from the same group identified a second independent risk locus in chromosome 17q12 within the *HNF1B* gene [114].

## Prostate Cancer Predisposition Gene Discovery

There are many uncertainties in the area of genetic predisposition that are currently taxing researchers in this area. These include (a) what is the optimal genetic model for PCa? (b) are there different predisposition genes in different populations? and (c) how much concordance is there between various groups for the putative loci? The results of future large-scale multicenter studies will ultimately answer these questions. It is entirely possible that the studies undertaken thus far are underpowered and pooling of data may improve the chances of finding genuine underlying linkage. This is the aim of the creation of groups such as the International Consortium of Prostate Cancer Genetics (ICPCG). Groups undertaking linkage analyses worldwide collaborate within the umbrella of this consortium. In 2000, via a meta-analysis, the ICPCG found that the 1q24 locus may contribute to about 6 % of PCa families and was more commonly found in larger prostate cancer clusters whose average age of onset was <65 years [80]. Current data indicates that progression to clinical disease is more likely following a raised PSA and occurs a median time of 10 years after the PSA has risen [115]. In theory, patients in families that are diagnosed with clinically detected disease may have different set of predisposing genes to those involved in PSA screen detected patients. At present, whether this is true, this is unknown. On the issue of genetic heterogeneity for linkage, i.e., presence of more than one PCa predisposition genes, it has been shown that two percent of early-onset cases have deleterious mutations in the *BRCA2* gene and that a further small percentage is due to *NBS* and *CHEK2* mutations. Yet models suggest that up to 43 % of such cases may harbor a predisposition gene [30]. This indicates that there are further PCa susceptibility genes that are yet to be discovered. In an age when the majority of monogenic human disease genes have been identified, a particular challenge for human geneticists will be resolving complex polygenic and multifactorial diseases. It is likely that the majority of genetic predisposition to PCa will follow this model where there exist many rather than one PCa predisposition gene per family.

## Clinical Management Concepts for HPC

The question of whether a genetic change influencing PCa causation is associated with factors altering treatment is an important consideration. Recent reports are contradictory. Carefully documented multicentered, prospective family history data collection and outcome analysis are crucial to improving our understanding of this condition. The current management issues surrounding HPC involve several considerations: (i) the degree of biological aggressiveness of HPC, (ii) whether HPC per se is an independent predictor of

treatment outcome, (iii) whether there is a difference in the survival curves between sporadic and HPC, and (iv) the outcome patterns in those patients treated various radical treatments, i.e., prostatectomy vs. radiotherapy by family history.

### Determining the Degree of Biological Aggressiveness

Walsh initially observed that there was no significant difference between phenotypes of sporadic, familial, and HPC undergoing radical prostatectomy with respect to clinical stage, pre-op PSA, PSA density, prostate weight, Gleason score, pathologic stage, or tumor histology [115]. This was challenged by subsequent observation that patients with localized PCa who reported a positive family history tended to have a worse outcome at 3 and 5 years following treatment, be it radiation therapy or surgery, than those with sporadic cancers [116]. This was then again refuted by three subsequent studies that found no difference in the aggressiveness of HPC compared to sporadic disease [117–119]. This area therefore remains unresolved.

### Is HPC an Independent Predictor of Treatment Outcome?

Kupelian et al. [120] first indicated that a positive family history for PCa correlates with treatment outcome, in a sizeable unselected series of patients, suggesting that familial PCa may have a more aggressive course than nonfamilial PCa.

### Is There a Survival Differences Between Sporadic and HPC?

No significant differences in either overall or cause-specific survival were found between sporadic, familial, and HPC patients [121]. Present treatment guidelines do not differ based on presence or absence of FPC.

### Should Men with a Family History of Prostate Cancer Avoid Conservative Treatment?

Based on current evidence, there is a rationale for genetic screening of men at risk once the genes responsible for prostate cancer are identified. The American Urological Association (AUA) recommends that men who are at high risk for developing PCa such as men with a family history of disease or men of African-American descent commence routine PCa screening at the age of 40 [122], whereas The American Cancer Society recommends that men receive PSA or digital rectal examination testing annually at the age of 50 or earlier if they have a family history of the disease or are of African-American descent [123]. In outcomes in HPC men treated with radiotherapy vs. radical prostatectomy, Hanlon et al. [124] found no significant difference in biochemical failure rates between carefully matched men with and without a family history of PCa. This backs other studies that failed to show an elevated risk of failure after definitive therapy for clinically localized PCa in men with either combined hereditary and familial and patients with the sporadic form of the disease.

## Chemoprevention Trials

PCa chemoprevention is the judicious administration of agents that impair one or more steps in prostatic carcinogenesis. The principle aspects of chemoprevention include agents, their molecular targets, strategic endpoint biomarkers, their critical pathways, and cohorts identified by genetic and acquired risk factors [125]. The identification of genetic susceptibility loci would enable a cohort of men at high risk of developing PCa to be identified to serve as subjects for chemoprevention trials. If such trials yield favorable outcomes, they could potentially lead to a recommendation for preventative therapy in genetic mutation carriers. Several putative chemopreventive agents are currently being trailed. Results of a large population-based, randomized phase III trial demonstrated that finasteride might prevent PCa. However, the paper indicated that only low-grade tumors were prevented and in fact the number of high-grade tumors was significantly higher in the finasteride arm. Clarke et al. [126] studied the possible effect of supplemental dietary selenium on the change in the incidence of PCa. They found that although selenium confers no protective benefit on the primary study endpoint of squamous and basal cell carcinomas of the skin, the selenium-treated group in their series had substantially lower incidence of PCa as a secondary endpoint. Further investigations are clearly warranted. Initial data seem to suggest at least some benefit with the use of other agents may potential confer preventative effect. These include vitamin E, vitamin D, other 5-alpha-reductase inhibitors, cyclooxygenase-2 inhibitors, lycopene, and green tea. Some of which are being tested in new large-scale phase III clinical trials [127]. The Selenium and Vitamin E Cancer Prevention Trial (SELECT) is an intergroup phase III clinical trial that aims to test the efficacy of selenium and vitamin E alone and in combination in the prevention of prostate cancer [128]. The emergence of new powerful techniques such as proteomic analysis of tissue-based and secreted proteins [129] and gene chip cDNA microarrays for multiplex gene expression profiling is likely to facilitate the identification of new molecular targets, cohorts at risk, and the design of appropriate combination trials.

## Targeted Screening

Several controversies surround the management of the relatives of PCa patients. Targeted screening involves monitoring serum PSA levels in relatives of young- or early-onset PCa or families with multiple cases. The optimal age at which screening should be initiated is yet to be determined. The sub-30- and sub-40-year-old groups would not be screened by the majority of clinicians, and many would commence screening either at age 5 years younger than youngest age at diagnosis of a relative or 40 years but not normally younger than this. Targeted screening studies have demonstrated a higher proportion of raised PSA levels in relatives of cases in families compared with sporadic cases. In a screening study of PCa, among high-risk families [130], it was shown that previously unsuspected and clinically relevant cancers were found in 24 % of a total of 34 first-degree relatives compared to the approximately 1 (3 %) expected ($p < 0.01$). The study emphasized the paramount importance of thorough screening in first-degree relatives of prostate cancer patients. The first targeted screening study based on *BRCA1/2* genotype started in 2003 (the IMPACT study; Tischkowitz and Eeles, 2003) [131]. In 2011, the team published the findings of one wing of their study involving 300 men (205 mutation carriers; 89 BRCA1, 116 BRCA2, and 95 controls) over 33 months. At the baseline screen (year 1), 7.0 % (21/300) underwent a prostate biopsy. PCa was diagnosed in ten individuals, a prevalence of 3.3 %. The positive predictive value of PSA screening in this cohort was 47·6 % (10/21). One PCa was diagnosed at year 2. Of the 11 PCas diagnosed, 9 were in mutation carriers, 2 in controls, and 8 were found to be clinically significant. Thus, suggesting that the positive predictive value of PSA screening in BRCA mutation carriers is high. Furthermore, it showed that screening seems to detect clinically significant PCa. The findings of this study support the rationale for continued screening in such "high-risk" men [132].

## Future Perspectives

With the recent exponential increase in the development and improvement of techniques involving proteomics, there has been increased optimism in the prospect of finding clinically relevant candidate genes, gene clusters, and signaling pathways. This would potentially lead to better diagnostic and/or more specific targeted therapeutic plans in the management of sufferers of PCa [133].

The current ability to tally and compare genome-wide expression profiles in tissue samples could potentially shed light on the molecular pathology toward PCa detection and monitoring of disease progression and/or recurrence. Early gene expression signature studies were hindered by the inherent limitations of bioinformatic tools. It is anticipated that the validity of molecular signatures of PCa will ultimately be proven by cross-validation on novel datasets and direct coupling of these to prospective and translational studies [134]. Sun et al., in an attempt to predict PCa recurrence based on molecular signatures, conducted a computational analysis of gene expression profile data obtained from 79 cases. Of these, 39 were classified as having disease recurrence. At the 90 % sensitivity level, a novel-derived prognostic genetic signature achieved 85 % specificity. The results were compared to a clinically validated postoperative nomogram. The study was purported to be the first reported genetic signature to outperform a clinically used postoperative nomogram. They demonstrated the feasibility of utilizing gene expression information for potential PCa prognosis [135].

PCa inheritance following a simple Mendelian pattern may be identified in the families of probands with early-onset cases. Currently, the only clinically applicable measure to try to reduce PCa mortality in families with hereditary disease is screening, which aims to diagnose the disease when it is still at a curable stage. The precise mechanism of how gene mutations contribute to an increased susceptibility for PCa remains elusive, but the finding of germline mutations in the *BRCA2*, *CHEK2*, and *NBS1* genes suggest that a proportion may occur due to mutations in the DNA repair pathway. This has ramifications on treatment of such individuals with DNA-damaging agents. It is most likely that the cause of the majority of PCa cases will be multifactorial and will involve environmental and genetic factors. The recent exponential advances in understanding the clinical genetics of PCa offer great optimism toward optimizing the management of PCa. From a clinical genetics point of view, this could usher with it a new paradigm in the way we manage PCa.

# Gene Expression Profiling and Somatic Genome Changes

12

Michael Ittmann

## Introduction

Prostate cancer is the most common visceral malignancy in US men and the second leading cause of cancer deaths. It is estimated that in 2010 more than 215,000 men will be diagnosed with prostate cancer and almost 32,000 will die of this disease. Prostate cancer is extremely heterogeneous in its clinical behavior, ranging from indolent disease to aggressive metastatic cancer with rapid mortality. Over the last 20 years, there have been intensive efforts to elucidate the underlying genetic and epigenetic alterations and associated gene expression changes that lead to prostate cancer. The goal of these studies has been to understand the pathogenesis of prostate cancer, identify therapeutic targets, and to better guide treatment of this disease. Over this timeframe, there have been tremendous advances in our understanding of the molecular basis of prostate cancer, facilitated by continuous improvements in technology and bioinformatics. This chapter will focus on somatic genomic changes and high-throughput gene expression analysis, and, as will be shown below, these topics are intimately related.

## Copy Number Alterations in Prostate Cancer

The study of copy number alterations has played an important role in understanding the pathogenesis of prostate cancer. The initial impetus for such studies was the paradigm that tumor suppressor genes may be inactivated by somatic genomic changes in two ways. In some cases there may be homozygous deletion of both alleles or alternatively, loss of one allele with mutation of the remaining allele. While this has proven to be true in some cases, there is often loss of a single allele without homozygous deletion or mutation of the retained allele, and this has led to the realization that at times loss of even a single allele may be sufficient to promote tumor initiation and/or progression by decreasing expression of the tumor suppressor, which is known as haploinsufficiency [1]. In contrast oncogenes may be overexpressed by amplification. As will be described below, while there are amplifications within the genome of prostate cancers, they are less common than genomic losses, but they are associated with aggressive disease.

Initial studies of copy number alterations were initiated in the early 1990s restriction fragment length polymorphisms and microsatellite polymorphisms. While these techniques have relatively low resolution compared to current technologies, they were quite successful in identifying a number of recurrent copy number alterations in prostate cancer, for example, loss of 8p21 and 13q14 [2]. Comparison of copy number alterations in primary tumors versus metastatic or recurrent tumors in these early studies revealed that copy number alterations are much more frequent in the latter [3].

Compared to these relatively low-resolution techniques, high-density mapping of genetic losses and gains can reveal additional tumor suppressor or oncogene loci. Therefore, high-throughput methods such as comparative genomic hybridization (CGH) arrays and single-nucleotide polymorphism (SNP) arrays have been the method of choice for analysis of copy number alterations in prostate cancer as they have become available due to their high resolution and high throughput. A large number of prostate cancers have been analyzed using CGH, and these studies have identified consistent areas of chromosomal loss and gain [4–10]. SNPs occur at more than two million sites in the genome, allowing high-resolution whole genome allelotyping with accurate copy number measurements. Several studies of allelic gain and loss in prostate cancer using SNP arrays have been reported, which have shown multiple areas of gain and loss, that are broadly similar to many of the common areas detected with array CGH, although unique areas were also identified

**Table 12.1** Regions of high-frequency genomic loss and gain in prostate cancer

| Genomic region | Putative target |
|---|---|
| *Loss* | |
| 2q21–22 | |
| 5q13–15 | |
| 6q14–21 | |
| 8p21–23 | NKX3.1 |
| 10q23–25 | PTEN |
| 12p13 | CDKN1B (p27) |
| 13q14–22 | RB1 and BRCA2 loci |
| 16q13–24 | |
| 17p31.1 | p53 |
| 18q12–23 | |
| 21q21 | TMPRSS2/ERG fusion |
| *Gains* | |
| 3q23–26 | |
| 5p13 | RICTOR |
| 7 | EZH2 |
| 8q13 | TIF2 |
| 8q21–24 | MYC |
| 17q24–25 | |
| Xq11–21 | Androgen receptor |

in these studies as well, perhaps reflecting the higher resolution of later-generation SNP arrays [11–15]. Table 12.1 summarizes regions of high-frequency loss or gain in prostate cancer based on CGH and SNP array studies.

As seen on Table 12.1, putative targets of the losses and gains have been identified in many cases, and many have been validated as being biologically important in prostate cancer. For example, the site of PTEN locus was identified as being lost in prostate cancer prior to the identification of this gene [16]. The PTEN tumor suppressor gene, which encodes a lipid phosphatase that negatively regulates the PI3-kinase/AKT pathway, was subsequently identified in this region, and at least one copy of PTEN is lost in approximately 30 % of prostate cancers [17–22]. Homozygous loss of PTEN has been demonstrated in a subset of prostate cancers [20] as well as mutation and loss of the second allele in PTEN. Knockout mice with homozygous prostate-specific deletion of PTEN develop early onset PCa with metastases [23, 24]. However, in human prostate cancers, in the majority of cases, only a single allele is lost without mutation. Subsequent studies have shown in mouse models with other oncogenic events that loss of PTEN is haploinsufficient to promote cancer initiation and/or progression [1]. PI3- kinase is activated by growth factor receptors causing production of second messenger phospholipids that bind AKT to the plasma membrane and facilitate its phosphorylation by PDK1(Thr308) and mTORC2 (S473), leading to activation of AKT kinase [25]. AKT phosphorylates numerous intracellular proteins that can promote cancer initiation and progression by enhancing cell survival, cell growth and proliferation, angiogenesis, invasion, and metastasis [17]. High levels of phosphorylated AKT (Ser 473) are present in prostate cancer, and this is an independent predictor of biochemical recurrence following radical prostatectomy [26, 27]. It is now widely accepted that activation of the PI3-K/AKT pathway via a number of processes [28] plays a central role in the pathogenesis of prostate cancer [17], and numerous therapies targeting this pathway are currently under preclinical and clinical development for treating prostate cancer. These studies over the last 15 years are strong validation of the concept that studies of copy number alterations can provide critical insights into the pathogenesis of prostate cancer.

It should be noted however that in many cases the target of specific losses has not been clearly identified although candidate genes have been proposed. Even for strong candidate genes, such as c-MYC on 8q24, there is some controversy as to whether this is the only target for this common amplification [29]. It is likely that in some cases multiple genes are affected by loss and amplification, and though one gene may be a dominant driver, other genes may contribute to the phenotype.

One approach to better understanding the genomic alterations in prostate cancer is to carry out cluster analysis to understand whether there are specific patterns of loss and gain that are associated with each other and/or clinical outcome. Lapointe et al. [7] carried out CGH analysis of 55 primary tumors and 9 metastatic lesions and performed cluster analysis on the resulting genomic profiles. This highlighted several distinct groups including a set of cancers with minimal genomic alterations, a group with loss of 6q15, a group with loss of 8p21 and 13q14, as well as a group with 8q24 amplification. Analysis of lymph node metastases revealed much more widespread copy number alterations (consistent with prior results) with more frequent amplifications, particularly on 8q and chromosome 7 as well as other loci and frequent losses including the PTEN and p53 loci. Our group has analyzed primary tumors from 20 African American men using SNP arrays [15]. We carried out hierarchical clustering of our cohort and the entire cohort analyzed by LaPointe et al. (including two African Americans). Interestingly, the majority of African American cancers clustered in two major subgroups. One subgroup consisted aggressive cancers and was characterized by loss of 8p and gain of 8q. The more aggressive Caucasian cancers clustered with this group including a number of the metastatic lesions. The second major subgroup of African American cancers was enriched with less aggressive cancers. Notable features of cancers in this subgroup are loss of 6q and infrequent loss of 13q. These findings indicate that African Americans have specific patterns of copy number alterations that differ from Caucasian patients. Of note, on average, the African American patients had copy number alterations in primary tumors that more closely resembled metastatic lesions in

Caucasian patients when compared to primary tumors of Caucasian patients at an equivalent clinical stage, which may in part account for the higher mortality from prostate cancer in African Americans. Rose et al. [10] compared prostate cancers from African Americans and Caucasians by CGH and also found widespread differences in patterns of loss and gain between these two racial groups. Recent studies of prostate cancers of men in China reveal distinct patterns gain and loss that differ from both African American and Caucasian men [30]. Taylor et al. [8] have recently reported results of the largest current integrated genomic analysis of prostate cancer including 157 primary tumors and 37 metastases analyzed by CGH. They identified a total of six clusters based on cluster analysis of their CGH data. One cluster had minimal copy number alterations as described above and was associated with extremely good outcome. Three other clusters were defined by loss on 6q, 13q, and 8p, respectively. Two clusters were identified which contained the majority of metastatic lesions as well as some primary cancers. These clusters were characterized by either widespread genomic losses and gains or amplification of 8q24 or chromosome 7. Of note, the primary tumors in different clusters had significant differences in the probability of biochemical recurrence following radical prostatectomy. Overall the patterns in these studies are fairly consistent and indicate that patterns of chromosomal alterations have promise in identifying subgroups of cancers with different clinical aggressiveness and differ in prostate cancers from different racial groups. Given the relative stability of DNA even in paraffin-embedded tissues, this finding holds promise for development of new biomarkers of outcome based on DNA copy number analysis.

## Clonal Point Mutations

Most studies to date have shown only infrequent clonal point mutations in clinically localized prostate cancer which usually involve tumor suppressor genes (reviewed in [31] ). The most commonly clonally mutated gene, the transcription factor ATBF1, is mutated in approximately 25 % of localized PCas [32], and other tumor suppressors are mutated at significantly lower rates. For example, work from our group and many others have shown that point mutations in the tumor suppressor PTEN are rare in clinically localized PCa [20] but are present in approximately 30 % patients with of metastatic prostate cancer lesions at autopsy [22]. Similarly, clonal p53 mutations are rare in clinically localized PCa [33] but more common in advanced disease [31]. In most cases mutations have been analyzed using sequencing of isolated tumor RNAs or DNAs. Using such techniques, the mutation must be present in at least 50 % of tumor cells to be reliably detected even in highly enriched tumor samples. Clonal androgen receptor mutations are fairly common in castrate-resistant prostate cancer and appear to be selected for as a mechanism by which PCa cells can survive in low androgen environment [31]. Interestingly, it has been shown that androgen receptor mutations are rare in primary prostate cancer but were present in almost 30 % of pelvic lymph node metastases from men not treated with hormone ablation therapies [34]. This chapter also discusses a number of methodological pitfalls that can lead to overestimation of mutation frequency. Activating clonal mutations in oncogenes, such as RAS, are unusual in prostate cancer in US men but are present in approximately 25 % of Japanese prostate cancers [31]. Taylor et al. [8] have recently reported high-throughput sequencing of the exons of 138 selected genes from 75 primary and 5 metastatic lesions and found that clonal mutations were relatively rare with the androgen receptor in metastatic lesions being the most commonly mutated gene. This is in contrast to the more frequent mutation observed in other common human cancers such as colon and lung cancer. Thus, available data indicate that clonal point mutations are rare in clinically localized prostate cancer, and, while more common in advanced cancer, they are not common in comparison to other epithelial malignancies.

## Expression Array Analysis of Prostate Cancer

A major technical advance in our ability to understand the molecular changes underlying the pathogenesis of cancer is the development of high-throughput technologies such as expression microarray analysis. In expression microarray analysis, thousands of cDNAs or oligonucleotides corresponding to individual genes are spotted on slides. RNAs from two different sources are then labeled with nucleotides-bearing molecules that are fluorescent at different wavelengths, and both labeled RNAs are then hybridized to the array slide. The relative gene expression is then determined by the ratios of the intensity of fluorescence at the two wavelengths in each individual array element. Thus, changes in gene expression associated with two different conditions, that is, normal versus cancer, can be rapidly assessed in thousands of genes simultaneously.

This new technology has been applied to prostate cancer by many groups over the last 10 years. Many of these studies have compared gene expression in prostate cancer tissues to benign prostatic tissues [35–40]. A large number of changes in gene expression in prostate cancer have been identified using this approach, and markers of potential diagnostic utility as well as genes that may be involved in the etiology of prostate cancer have been identified. A recent statistical meta-analysis of these studies has concluded that the results of these studies were significantly similar in the genes identified as up- and down-regulated in prostate cancer despite differences in methodology employed [41], indicating the robustness of this technique.

## Discovery of Genes Involved in the Pathogenesis of Prostate Cancer

Expression array analysis has played an important role in identifying novel genes that play a role in prostate cancer pathogenesis. In 2005, the Chinnaiyan group, using a bioinformatics analysis of expression microarray data, discovered the existence of recurrent gene fusions of ETS transcription factors in prostate cancer [42]. In most cases these fusions involved the androgen-regulated TMPRSS2 gene. The discovery of recurrent fusion of the androgen-regulated TMPRSS2 gene to the ETS transcription factors, most commonly the ERG gene, was a paradigm-shifting discovery since it indicated that a single common pathway is altered in most human prostate cancers. The TMPRSS2/ERG (T/E) fusion gene occurs in approximately 50 % of prostate cancers [43–49]. The T/E gene fusion arises by fusion of the promoter and 5′ exons of the TMPRSS2 gene on chromosome 21q22.3 with the coding sequences of the ERG gene at 21q22.2 [50, 51]. Experiments in prostate cancer cells containing the T/E fusion indicate that the TMPRSS2 promoter can lead to the overexpression of ERG in PCa cells in response to androgens [42]. The almost universal presence of androgen receptor in prostate cancer cells results in the constitutive high-level expression of ERG fusion transcripts in the cancers containing this fusion gene. The extremely high prevalence of the T/E gene fusion implies that ERG plays a critical role in the pathogenesis of many prostate cancers. Other ETS transcription factors are fusion targets at a lower rate but collectively are probably altered in 5–10 % of prostate cancers. On the other hand, analysis of expression microarray data has identified SPINK1 as a gene that is overexpressed in about 10 % of prostate cancers and is an independent predictor of recurrence [52]. Expression of this gene is almost never found in fusion gene expressing cancer and represents a distinct type of prostate cancer.

Several groups, including our own, have examined the biological effects of the T/E fusion gene in vitro in immortalized prostate epithelial cells, VCaP prostate cancer cells, the only prostate cancer cell line that expresses the T/E fusion gene, and in orthotopic and transgenic mouse models. These studies have consistently shown that the T/E fusion gene can promote prostate cancer invasion and to a lesser extent proliferation and decrease differentiation via increased expression of urokinase plasminogen activator (uPA), matrix metalloproteinases (MMP3 and MMP9), and c-MYC [53–55]. More recent studies have also identified activation of the Wnt [56] and NF-κB pathway [57] by the fusion gene. It should be noted that the T/E fusion gene protein has significant biological effects on prostatic epithelial cells but is not able to fully transform them. Importantly, studies by our group have shown that knockdown of expression of the T/E fusion gene decreases primary tumor growth in a VCaP orthotropic mouse model, in which VCaP cells are injected directly into the prostate of immunodeficient mice [53]. Such studies provide the rationale for developing novel therapeutic approach targeting T/E fusion proteins in prostate cancer. Several groups have generated transgenic mice with expression of ERG in the prostate using the androgen-driven ARR2-Pb promoter. Both Tomlins et al. [54] and Klezovitch et al. [58] reported the development of mouse prostatic intraepithelial neoplasia (mPIN) in these mice. Both King et al. [59] and Carver et al. [60] reported that loss of PTEN in conjunction with expression of ERG accelerated development of mPIN, and Carver et al. found fully developed prostate cancer in this context. Activated AKT could also accelerate the development of mPIN in transgenic mice expressing the fusion gene [59]. Using a prostate regeneration system in which genetically engineered prostate stem cells are grown in immunodeficient mice with urogenital sinus mesenchyme under the kidney capsule the Witte group has shown that when ERG was co-expressed with activated AKT or with an shRNA-targeting PTEN, carcinoma develops [61]. These observations support the concept that AKT activation can synergize with fusion gene expression in promoting prostate cancer progression. Expression of ERG rapidly declines in response to removal of androgen in vitro and castration in vivo, and T/E fusion expression was fully restored in castrate-resistant prostate cancer, which indicates that reactivation of T/E fusion expression may contribute to androgen-independent tumor progression [62].

Another major discovery made using expression microarray analysis was the identification of EZH2, a polycomb protein, as an important player in the etiology of aggressive prostate cancer [63]. Recent studies have shown that the T/E fusion gene, the androgen receptor, and EZH2 may form an interacting network that plays an important role in the pathogenesis of prostate cancers with the fusion gene [64].

## Discovery of Diagnostic Biomarkers

In the clinical arena one major success of expression microarray analysis was the identification of alpha-methylacyl-CoA racemase as a gene that is significantly upregulated in prostate cancer [40]. Immunohistochemistry for this marker, usually in conjunction with basal cell specific markers such as high molecular weight cytokeratins and/or p63, is now a part of routine clinical practice. While there are limitations to this marker, including its expression in high-grade prostatic intraepithelial neoplasia and some benign mimics of prostate cancer, it can be extremely useful in the diagnosis of limited PCa in needle biopsies [65].

## Discovery of Novel Prognostic Biomarkers for Analysis by Immunohistochemistry

A number of studies have been performed to identify potential prognostic biomarkers in prostate cancer using expression microarrays. Dhanasekaran et al. [35] compared gene expression in 11 clinically localized and 7 metastatic prostate cancers to normal prostate tissues. These investigators found by cluster analysis that there were significant differences in gene expression between localized and metastatic prostate cancers, as well as many similarities, and both were significantly different than normal prostate. Two genes identified as upregulated in prostate cancer (Hepsin and Pim-1) at the RNA level were correlated with PSA recurrence in localized prostate cancer by using immunohistochemistry of tissue microarrays. As described above, this group also confirmed that tissue expression, as assessed by immunohistochemistry of tissue microarrays, of another gene identified in this analysis (*EZH2*) was correlated with PSA recurrence in localized prostate cancer [63]. Other immunohistochemical prognostic markers discovered by microarray analysis include MUC1 and AZGP1 [66]. In addition, SPINK1 (described above) is associated with aggressive disease [52]. The Rubin group has used a combined expression microarray and proteomic approach to define 12 proteins that as a panel can help predict recurrence following radical prostatectomy [67] and prostate cancer-specific death in a watchful waiting cohort [68]. Thus, expression microarray analysis can identify differentially regulated genes that can be used as prognostic markers on immunohistochemistry.

## Gene Signatures to Predict Prognosis in Prostate Cancer

There have been a number of studies addressing gene expression signatures to predict prostate cancer recurrence, which have employed a wide variety of statistical and laboratory methods. Singh et al. [69] studied expression of 12,600 genes in 21 prostate cancers for which recurrence data was available (8 recurrent, 13 nonrecurrent). Based on this limited set of samples, they were able to define a set of five genes whose expression levels were able to predict recurrence with 90 % accuracy in their samples. These samples included many cases with Gleason scores of 8–10, and such samples were overrepresented in the recurrent group, so it is unclear if their model would work robustly in patients with intermediate Gleason scores. Glinsky et al. [70] reanalyzed this same data set and, by correlation with expression analysis in prostate cancer xenografts, developed three alternative five gene prognosis signatures that could correctly classify the arrays into the appropriate recurrence categories for up to 95 % of cases. However, these studies did not specifically distinguish between early and late recurrence, which is an important distinction clinically since men with early PSA recurrence are significantly more likely to develop metastatic disease. Yu and colleagues [71] developed a 70-gene model by comparing expression profiles between 29 aggressive tumors (defined as cancer invasion into adjacent organs or seminal vesicles, metastases, or recurrence) versus 37 nonaggressive tumors lacking such features. Thus, this study did not look at recurrence specifically. Their 70-gene model was able to classify the original data set into the appropriate category in 86 % of the cases. Lapointe et al. [66] identified a set of 23 genes whose expression levels were either positively or negatively associated with early recurrence in a set of seven prostate cancers with early recurrence and 22 nonrecurrent tumors, although their false discovery rate (FDR) was quite high (16 %), perhaps due to limited clinical follow-up.

A major issue with such gene expression signature approaches is the difficulty in translating them into clinical practice. While RNA extraction from formalin-fixed paraffin-embedded tissues is feasible, it may be difficult in routine clinical practice given limited amounts of cancer in many needle biopsies, variable post-procedure time to fixation in radical prostatectomies as well variable fixation times and other postfixation variables. Despite these difficulties, a 17-gene expression signature predictive of systemic progression and prostate cancer-specific death after PSA recurrence post-prostatectomy has been developed by Jenkins and his colleagues using paraffin-embedded tissues [72]. Kosari et al. [73] examined laser-captured cancer cells from paraffin-embedded tissues to identify genes associated with systemic progression. Whether these signatures and/or gene sets can be applied in other institutions with different clinical practice patterns will need to be determined.

Unfortunately, the gene expression signatures identified in these studies do not show significant overlap. These models are derived from a variety of sample sets, using different platforms (Affymetrix vs. spotted arrays) with a wide variation in the number and identity of genes analyzed, different clinical endpoints (recurrence, early recurrence, systemic progression, etc.), and different statistical approaches. In addition, some studies used laser-captured cells and others enriched tumors. It is clear that prostate cancer stroma contributes to the gene signatures in RNAs extracted from prostate cancer tissues [74, 75] so that different amounts of stroma in tissues and variability within stroma can also contribute to variable in gene signatures, and only a few studies have used laser-captured cancer cells. Thus, it is not surprising that there is little agreement among these gene sets. However, it is highly likely that the genes identified have some importance in determining recurrence following radical prostatectomy.

## Expression Microarrays and Prostate Cancer Classification

One approach that has been successfully applied to breast cancer [76] and non-Hodgkin's lymphoma [77] is to use cluster analysis of large-scale microarray data to classify tumors into categories that are biologically and prognostically relevant. Using this approach, Lapointe et al. [66] were able to identify three subtypes of prostate cancer based on an analysis of 61 primary and 9 metastatic prostate cancers. Subgroup 1 displayed a gene expression profile that was similar to normal prostate, and such tumors were less aggressive, while subgroups II and III were more likely to be higher stage and grade and to recur early. The same group later correlated gene expression patterns with patterns of specific copy number alterations using comparative genomic hybridization as described above. Subgroup 1 was characterized by loss of 5q21 and 6q15. Subgroup 2 was characterized by loss of 8p21 and the presence of the T/E fusion gene. Subgroup 3 showed more diffuse losses and gains at loci similar to Subgroups 1 and 2 but without the distinct features seen in these two groups. To date, there is not a widely accepted molecular classification based on either gene profiling or copy number alterations (see above), but current data indicates that such approaches may be fruitful if combined with other markers such as the presence of the TMPRSS2/ERG fusion gene.

## Alternative Spicing in Prostate Cancer

It is well known that the majority of human genes undergo alternative splicing and that such alternative splicing may have significant impact on cellular biology. Numerous examples of individual genes that are differentially alternatively spliced in prostate cancer have been reported that affect the biology of tumor cells. For example, our group has reported extensive alternative splicing of the T/E fusion gene that is associated with differences in clinical outcome, cellular proliferation and invasion, and signal transduction pathway activation [44, 53, 57]. Little is known about more global changes in alternative splicing in prostate cancer. Recent studies by Thorsen et al. [78] examined relatively small numbers of prostate, bladder, and colon cancers and matched normal tissues using Exon arrays that can detect differences in expression of individual exons, reflecting primarily changes in alternative splicing, although alternative promoter utilization and other posttranscriptional events could also impact results. These authors found more than 2,000 alternative splicing events that were differentially present in cancer and normal tissues. Such preferentially expressed alternatively spliced isoforms are potential diagnostic and prognostic biomarkers. Clearly, more work is needed to define the repertoire of prostate cancer-specific alternative splicing events and whether they will prove to be clinically useful.

## Integrated Analysis of Genomic and Expression Array Data

In order to integrate the large amount of data generated by high-throughput analysis as described above, it has proven useful to focus on alterations in specific signaling pathways in a global manner. This approach was first used analysis of the glioblastoma [79] and has been applied to prostate cancer by Taylor et al. [8]. Using this approach, they examined alterations in gene expression (up and down) and mutations in specific pathway proteins in both primary and metastatic tumors. For example, multiple genes in the PI3-kinase pathway are altered including PTEN (as discussed) above, INPP4 [28], PI3K regulatory subunits, PI3-kinase itself, and the PHLPP phosphatase. By examining all of these components in each tumor, it was determined that at least one component of this pathway was altered in 100 % of metastatic prostate cancers, providing a strong rationale for targeting this pathway in all such cancers. Other key pathways such as the retinoblastoma signaling pathway and the RAS/RAF/MAPK pathway were also altered at high frequency in prostate cancer. This roadmap of cancer signaling alterations will prove extremely useful in designing targeted therapies.

## High-Throughput Sequencing: The Future of Prostate Cancer Genomics

Next-generation sequencing is rapidly evolving with the cost of sequencing dropping precipitously. This technology when linked to appropriate informatics will revolutionize our ability to comprehensively analyze the prostate cancer genome. By sequencing highly enriched cancer DNA and matched normal DNA with high coverage (i.e., with large numbers of sequence reads per DNA region), one can detect both copy number alterations and mutations by comparing the number of reads and their sequence in cancer and normal DNA across the entire genome. Similarly, massive sequencing of RNAs (as cDNAs) can allow quantitative analysis of expression levels (based on numbers of reads) as well as alternative splicing. Expression analysis by sequencing with sufficient reads has an extremely broad dynamic range and is both more sensitive and linear than expression microarrays. In addition, microRNAs can also be sequenced, adding an additional dimension to genomic and expression analysis.

## Limitations to Genomic and Expression Microarray Analysis

As described above, prostate cancer genomics and expression array analysis have been extremely useful in defining many of the key alterations in prostate cancer. We have not discussed epigenomics, that is, modifications of DNA and its associated proteins. Epigenetic changes such as DNA methylation are widespread in prostate cancer and presumably act primarily via changing gene expression, so they should be reflected in expression microarrays. Similarly changes in microRNA expression are widespread in prostate cancer [80], but again such changes seem to primarily impact mRNA levels via alterations in RNA degradation. However, changes in translational efficiency, protein degradation, and posttranslational protein modifications are not reflected in genomic or expression microarray analysis. It is clear that such posttranscriptional and/or posttranslational changes can play an important role in cancer. While there are numerous examples cited above where expression microarrays have identified overexpressed proteins, it is clear that there is far less than 100 % correlation between protein and mRNA levels. Thus, a truly comprehensive understanding of the biology of prostate cancer awaits a high-throughput, accurate, and inexpensive proteomic analysis.

## Summary

Prostate cancer is the most common visceral malignancy in US men and the second leading cause of cancer deaths. Over the last 20 years, there have been intensive efforts to elucidate the underlying genetic and epigenetic alterations and associated gene expression changes that lead to prostate cancer. The goal of these studies has been to understand the pathogenesis of prostate cancer, identify therapeutic targets, and to better guide treatment of this disease. Over this timeframe, there have been tremendous advances in our understanding of the molecular basis of prostate cancer, facilitated by continuous improvements in technology and bioinformatics. Genomic studies of prostate cancer have identified multiple regions of chromosomal loss and gain and have played a key role in identifying and validating specific genes and pathways involved in prostate cancer pathogenesis. Recent high-throughput studies are beginning to identify specific patterns of chromosomal loss and gain that define different types of prostate cancer which differ in pathogenesis and clinical outcome. High-throughput gene expression microarray studies have also been critical in defining key genes in prostate cancer pathogenesis such as the TMPRSS2/ERG fusion gene and EZH2. In addition, these studies have identified a clinically useful diagnostic marker alpha-methylacyl-CoA racemase. Expression microarray studies have also been used to attempt to define specific subtypes of prostate cancer based on patterns of gene expression. Finally, there have been intensive efforts to use expression microarrays to develop better prognostic markers in prostate cancer by identifying single genes or panels of genes whose proteins can be analyzed by immunohistochemistry to aid in assessment of prognosis or by defining specific gene signatures associated with clinical outcome. As next-generation sequencing drops in price, it holds great promise as a means of rapidly and comprehensively defining genomic and gene expression changes in individual patients to help predict clinical outcome and define optimal therapy.

# The Proteomic Approach to Prostate Cancer

13

Sashi S. Kommu and Emanuel Petricoin

## Introduction

Prostate adenocarcinoma (PCa) is currently the second most common cause of cancer death in men and is recognized as one of the most important medical problems facing the male population [1].

Despite major advances in the diagnosis and treatment of PCa, the clinical course of the disease is largely unpredictable. Hence, there is a major thrust, among many groups, toward the early detection of PCa and an optimal and tailored approach to the aggressive forms of the disease. This is complicated by the evolving need to distinguish the aggressive forms from the slower growing indolent tumors. Several studies correlate PCa's etiology to hereditary [2], dietary factors [3], exposure to toxic agents [4], and/or specific medications and inflammatory conditions [5–7]; however, one of the best-established risk factors is increasing age. Previous studies seem to indicate that prostate stem cells that give rise to secretory luminal and neuroendocrine cells could potentially be affected by age-related events such as genetic mutations and alterations in individual stromal-epithelial interactions or in the basement membrane/ECM composition. This in turn could lead to transformation of normal prostate progenitor/stem cells into cancer stem cells [8].

Whereas the incidence of PCa in men of age <50 rises significantly, the clinical course of the disease is poorly understood and hence difficult to predict. PCa can be a localized indolent disease with no impact on quality of life or life span or could significantly affect quality of life and/or lead to death despite treatment. There is hence an imminent and critical need for the early detection and stratification into aggressive and nonaggressive forms. The FDA, in the mid-1980s, approved prostate-specific antigen (PSA) testing for the detection of recurrent PCa and then for early detection. The preliminary diagnostic tests that are still practiced include PSA in conjunction with a digital rectal examination [9]. The combined use of PSA testing with digital rectal examination resulted in an observed decrease in the mortality rates from PCa and a significant increase in the reported incidence of PCa in the United States [10]. However, the continued and widespread use of this approach for screening and diagnosis is controversial [11]. The European Randomized Study of Screening for Prostate Cancer initiated in the early 1990s and ended in 2006 concluded that PSA-based screening reduced overall death rate from PCa by 20 % but is associated with a high risk of overdiagnosis [12]. PSA is a serine protease produced and secreted by prostatic epithelium and from the epithelium of periurethral glands, secreted from benign as well as cancerous cells of the prostate. It has been demonstrated to be largely a marker of prostate volume than of malignant conditions. It is established that serum PSA values correlate closely with both benign prostatic hyperplasia (BPH) and PCa [13, 14]. As observed during the Prostate Cancer Prevention Trial, 80 % of the biopsies taken in patients with PSA levels between 4 and 10 ng/ml were negative for malignancy [15]. Furthermore, Thompson et al. in their study, found that up to 15 % of patients with levels of PSA lower than 4 ng/ml had PCa and of these 14.9 % had a Gleason score of 7 or higher [16]. Candidate biomarkers for PCa under evaluation are itemized in the Early Detection Research Network (EDRN) report. The EDRN is a collaborative initiative of the National Cancer Institute (NCI), geared at coordinating the effort of multiple institutions and laboratories in cancer biomarker research. The prime aim is to accelerate the translation of evolving information about biomarkers into clinical applications.

Current tissue- and blood-based biomarkers under active investigation include the ETS-TMPRSS2 gene fusion product

[17], the noncoding prostate-specific mRNA PCA3 overexpression in tumor cells, and the GSTP1 promoter methylation observed in PCa and high-grade prostatic intraepithelial neoplasia (HGPIN).

The level of expression of CD90 in prostate tissue and urine of PCa patients, loss of expression of CD10 [18], and autoantibodies against the metabolic enzyme N-methylacyl-coenzyme A racemase (AMACR) [19] are also evolving as potential markers. AMACR autoantibodies can be used for the detection of PCa with 72 % specificity and 62 % sensitivity. The early prostate cancer antigen (EPCA) has been recently found to detect patients with PCa with 94 % sensitivity and 92 % specificity [20]. The identification of optimal treatment stratification of patients with PCa remains a daunting challenge. Whereas some groups seem to suggest PSA screening could potentially save lives, PSA screening does not provide a definitive answer to the principal clinical questions as to whether the patient has a cancerous or benign disease. Furthermore, even following biopsy-proven PCa, tumor progression remains ill understood. Established treatment options of PCa currently used include radical prostatectomy, external beam radiotherapy, brachytherapy, and androgen deprivation therapy. Despite published long-term survival rates with each strata of treatment, there is still disease progression in a significant number of men following "definitive" treatment. Following radical prostatectomy, up to 35 % of patients could have biochemical recurrence. The identification of those men at high risk of recurrence could aid the uro-oncologist to design a targeted and signatured treatment plan for adjuvant therapy such as androgen depletion or chemotherapy [21]. Androgen deprivation therapy has been studied since 1940s [22], based on the observation of the dependence of PCa cells for growth and development on androgens, and is currently the therapy of choice for advanced and metastatic disease. Nevertheless, many side effects are associated with androgen deprivation therapy that should be taken into consideration when applied in those clinical settings in which no efficacy on overall survival has been demonstrated [23]. It is thought that clonal selection of androgen-independent PCa cells leads to a more aggressive disease [24]. A personalized diagnosis including the evaluation of risk and benefit for each possible therapy could improve treatment efficiency [25]. In a study of 695 men with T1-T2-b PCa who underwent either watchful waiting or radical prostatectomy, it was observed that while the risk of developing metastasis and death for PCa was lower in men undergoing radical prostatectomy, the overall survival and quality of life does not change significantly [26, 27].

The proteome is the entire set of proteins expressed by a genome, cell, tissue, or organism. More specifically, it is the set of expressed proteins in a given type of cell or an organism at a given time under defined conditions. Proteomics is the study of an organism's complete complement of proteins. Whereas tumors could potentially arise from single or multiple genetic defect(s), proteins are the structural and functional elements of cells. It is postulated that any gene mutation that confers a survival advantage to cells must be conferred to the cell at the level of the proteome. Many investigators are of the impression that the proteome may contain the most highly informative biomarkers for detection of aggressive PCa and patient-tailored therapy once the disease is positively detected. The current status of high-throughput proteomic technologies is that of a promising and evolving platform [28–36]. Proteomic analysis platforms now have the potential to elucidate, in a single experimental step, the abundance, expression, and activation state of hundreds of proteins in tissues and biological fluids. This potentially could offer an insight into the complex events, which underpin tumor development and progression. Herein, we discuss the current proteomic platforms being utilized for the molecular characterization and recently identified candidate biomarkers for detection, prognosis, and tailored therapy of PCa.

## Proteomic Technology in Prostate Cancer Biomarker Discovery

Novel evolving proteomic technologies (Fig. 13.1) now permit a high-throughput approach to the fields of biomarker discovery. To date, the most established proteomic approach is two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), which was described by O'Farrell in 1974 [37]. This allows for the separation of complex mixtures of proteins in two dimensions according to an isoelectric point and molecular weight. During the 1990s, when mass spectrometry (MS) technology was incorporated into the realm of proteomics, 2D-PAGE was successfully coupled to downstream MS analysis for individual protein detection. It then became the tool of choice for the resolution of complex protein mixtures. This permitted the detection of differences in the proteome of clinical samples such that they could be stratified into "normal" and "diseased" tissue. Kuruma et al. analyzed PCa proteomes using two-dimensional gel electrophoresis coupled with mass spectrometry and demonstrated the potential to detect changes in PCa high molecular mass proteomes [38]. While 2D-PAGE methodology brought significant advances in the field of proteomics, it had several technological limitations largely due to the inability to selectively detect the most abundant soluble proteins. Many low and high molecular weight proteins, as well as extremely acidic or basic proteins, cannot be accurately focused. This severely limits the detection of cell surface receptor membrane proteins that are present and differentially expressed within normal, BPH, and PCa tissues [38].

Serum and urine are the preferred sources of biological material to identify stage-specific prostate biomarkers [39–43]. These fluids can be acquired by less invasive means and with little additional cost to accrue thus adding to the

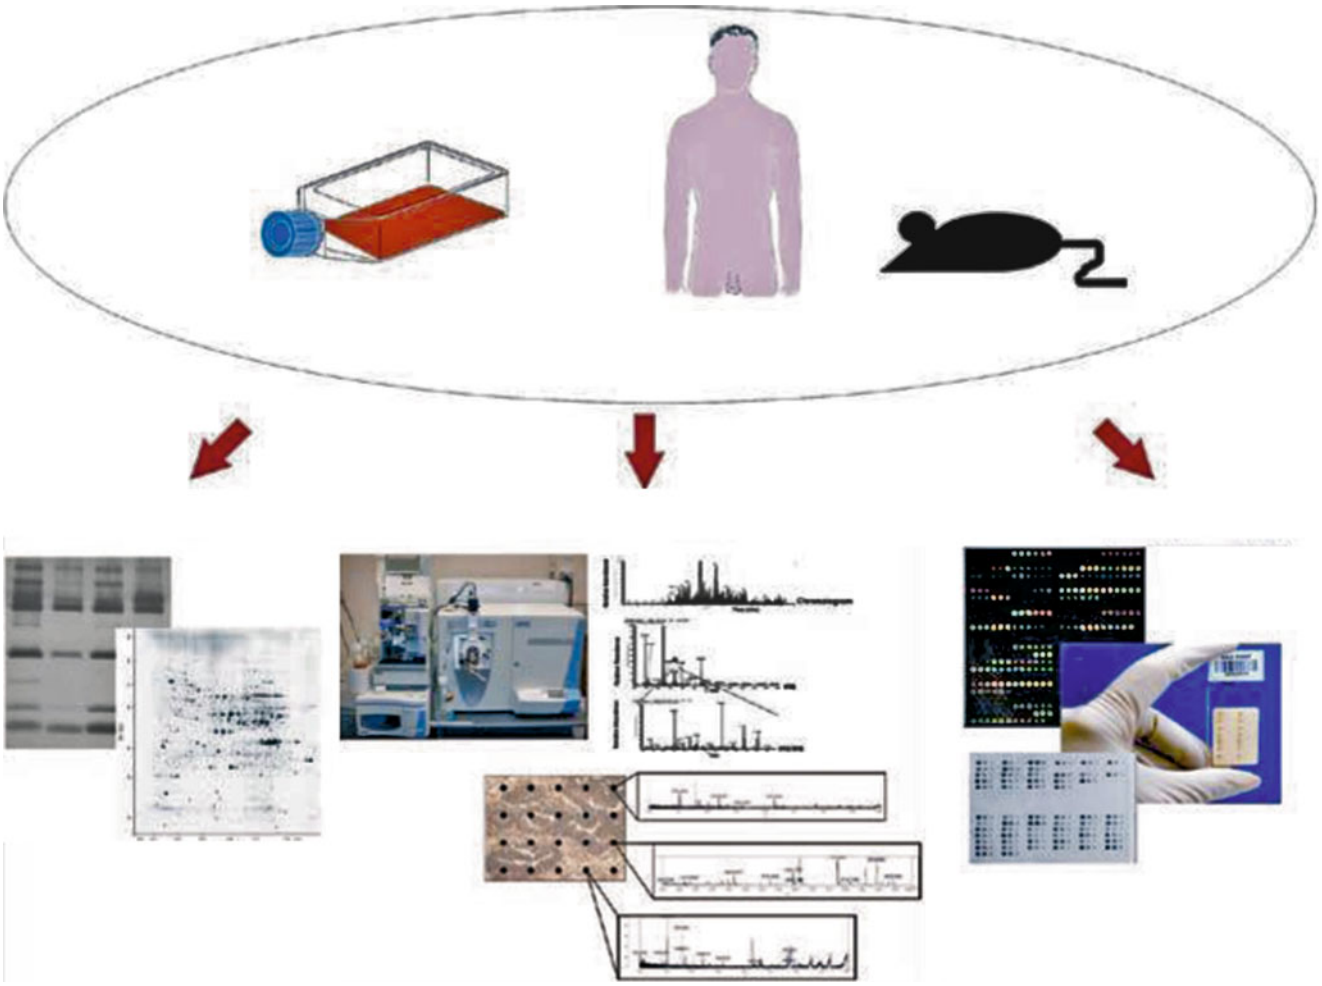

**Fig. 13.1** Proteomic evaluation of prostate cancer. Proteomic analysis can be done to explore the "proteome" of cell lines of prostatic origin, biological fluid, and/or tissue from human or animal models. The tools used include monodimensional gel electrophoresis or two-dimensional gel electrophoresis for protein separation and traditional mass spectrometry. More recently, techniques developed include mass spectrometry imaging (MSI) and reverse and forward protein arrays

potential ease of diagnosing and monitoring diseases such as PCa. Serum, in particular, acts as a large source of biological information. Blood perfuses organs and tissues collecting a "proteomic" record of physiopathological conditions. Intracellular enzymes and pathway components which are shed from various cell types, chemokines, growth factors, and other molecules involved in the cell-cell and cell-stroma interactions diffuse into the circulatory system [44]. The endothelial basement membrane aids proteomics by acting as a filter so that only small proteins, fragments, or parental molecules subjected to proteolytic cascades in the tissue microenvironment enter the bloodstream. Based on this theory, ideal biomarkers could be discovered in the potentially informative low molecular and low-abundant fractions of the blood proteome. A panel of such biomarkers, which could achieve high diagnostic sensitivity and specificity, could potentially be identified.

In 1998, SELDI, a new class of matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) was introduced. Serum SELDI-TOF profiling is based on on-chip retentate chromatography separation of proteins in microliter volumes, using various affinity surfaces to reduce complex protein mixtures to a set of proteins with common properties. Serum is deposited on commercially available array platforms. These are subjected to MALDI-TOF mass spectrometry to produce spectral protein mass profiles. SELDI-TOF technology initially generated a significant amount of optimism due to the seeming ability to simultaneously identify multiple protein changes with a high degree of sensitivity in a rapid high-throughput process. In fact, this technology was used to analyze complex protein mixtures from PCa in 1999 by Wright et al. [45]. PSA, prostate-specific peptide, prostate acid phosphatase, and prostate-specific membrane antigen were identified in cell lysates

and serum and seminal plasma. In 2002, Petricoin investigated the relationship between benign and malignant prostate disease diagnosed histopathologically and by serum proteome profiling [46]. The ability of a SELDI profile to discriminate PCa from benign prostate conditions in men with normal or elevated PSA levels was investigated. Parts of the genetic algorithms described by Holland and elements of cluster analysis methods by Kohonen were used to create initial bioinformatic algorithms. A signature was identified from a pilot sample collected from patients with benign prostatic conditions and PCa. The pattern of ions identified was applied to a blinded sample set of 266 sera. The algorithm was able to correctly predict the presence of PCa in 36 of 38 case subjects. Among men previously diagnosed by histopathologic analysis to have benign disease, 70 of 75 who were asymptomatic and had PSA levels less than 4 ng/ml were correctly classified as having benign disease. Furthermore, 10 of 16 men with high PSA levels (>10 ng/ml) and negative biopsy were found to have been classified correctly as having benign conditions. Although these results seemed promising, a more formal evaluation of SELDI-TOF was performed when Semmes, McLarren, and colleagues undertook a collaborative multicenter study coordinated by the National Cancer Institute/Early Detection Research Network. Their main aim was to validate the utility of serum SELDI profiling for the early detection of PCa [47–49]. They initially attempted to develop and validate a standard platform for processing serum in order to minimize potential error from human and mechanical factors. They then set out to decipher whether, following the process of instrument calibration and output standardization, the separate sites could achieve comparable correct classification rates when challenged with a set of previously characterized PCa and control samples. They concluded, in their study, that "between-laboratory" reproducibility of SELDI-TOF-MS serum profiling approaches that of "within-laboratory" reproducibility as determined by measuring discrete m/z peaks over time and across laboratories [49].

These findings were later followed by two further studies by McLerran regarding attempts to validate the specific SELDI-based biomarker ion fingerprint and development of potential algorithms for the diagnosis of PCa diagnosis. They concluded, based on the findings of the later studies, that the results from their preliminary studies were not generalizable and that SELDI-TOF MS-based protein expression profiling approach did not perform well enough to advance further [47–49]. The failure was attributed to earlier study samples bias that, upon removal, resulted in the technique's inability to discriminate cancer from noncancer samples. Additionally, differences in study design and limitations of proteins detected by SELDI applied to unfractionated serum were attributed to the inability of the validation study to identify men with PCa. It was suggested that the specific failure was not a failure of the "SELDI platform" but of the specific selected pattern. It soon became clear that major challenges existed including identification of a diagnostic ion fingerprint profile that is strictly dependent on a particular MS technology, specific capture chemistry, and precise sample handling and processing techniques. Thus, approaches that exploit patterns of unidentified ions were at inherent risk of being platform-dependent. Therefore, it was critical that the sequencing and identification of the peptides or proteins underpinning the diagnostic ions were identified [50]. It was postulated that the identified proteins could then be validated by any immunoassay platform. If, however, the antibody was not available, MS technology such as multiple reaction monitoring, immuno-MS, and high resolution MS profiling, which may not require a well-performing antibody, could be used.

It is an immense challenge to detect clinically significant biomarkers represented at a concentration less than 1 ng/ml in serum which also contains highly abundant proteins at a concentration of 30–50 mg/ml. Factoring in the fact that for SELDI-TOF analysis the starting volume of serum is 1–10 ul, only few pg of a biomarker of interest at a concentration of 1 ng/ml will be present in the sample. Assuming that the biomarker is fully retained on the chromatographic surface and ionized into the mass spectrometer MS or MS/MS detection, 320 amol of the biomarker would be available for the detection [51]. The detection of this amount of protein may be possible if directly injected into the mass spectrometer in its pure form. However, detection among other protein peak masses in a complex spectrum such as that obtained from a serum sample would be challenging even with the most sensitive mass spectrometers. The adoption of methods that could fractionate and remove high-abundance proteins from the serum prior to the "affinity chromatography step" is expected to increase the likelihood of detecting low-abundance biomarkers in serum by MS methods. Several preprocessing steps have been proposed [52–55] with depletion of high-abundant proteins being the major processing step utilized. The limitation in this case, however, is that low molecular weight proteins exist in solution bound to carrier proteins such as albumin. Thus, albumin depletion will eliminate many of the most important analytes from subsequent analysis [56]. In some studies, investigators have analyzed the serum free media of prostate cell lines as a source for biomarker discovery [57]. Medium from LNCaP (lymph node metastasis) cell was analyzed by SELDI-TOF in order to determine a profile of regulated proteins. Several ion peaks were differentially regulated depending upon the stimulation conditions. A significant androgen-regulated peak of 11.8 kDa that was specifically stimulated by androgen but not by estrogen or IL-6 was identified as beta-2 microglobulin (B2M). The expression of B2M was evaluated in multiple cell lines derived from

patients with PCa and in prostate acinar cells. Human BM2 was found in serum of mice bearing human PCa xenografts and significantly elevated in serum of patients with advanced PCa and in human expressed prostatic secretions [42] suggesting that B2M could be a potential marker of PCa progression. Sardana et al. aimed to investigate the "secretome" of prostate cell lines of different origin. They characterized the conditioned media from three different PCa human cell lines to identified secreted proteins that could serve as novel PCa biomarkers PC3 (bone metastasis), LNCaP, and 22Rv1 (localized to prostate). They worked on the premise that shed and secreted proteins will most likely be produced by the tumor in a measurable amount to be detected via a blood test and focused on this approach. Two-dimensional chromatography and tandem mass spectrometry were applied, and four candidates follistatin, chemokine 16, pentraxin 3, and spondin 2 were validated in serum from patients with or without PCa [58].

A novel approach to proteomic-based biomarker discovery for circulating markers, especially for PCa, is to use the immune systems' "signature" of information. Investigators are currently looking for circulating autoantibodies that are preprogrammed to target tumoral antigens, as a natural "amplification" tool for the detection of low-abundance tumor biomarkers. The concept of creating overexpression or posttranductional modification of specific proteins in tumor cells to induce antibody generation toward tumor related antigens has been explored [59]. Taylor et al. exploited the humoral response of patients with benign prostatic hyperplasia versus clinical localized PCa to identify the profiles of candidate biomarkers. They utilized two-dimensional protein fractionation of localized and metastatic PCa tissue lysates and screened patient autoantibody response by protein microarray [60]. Approximately two thousand fractions were used to generate protein microarrays, probed with 34 sera, 18 from PCa patients and 16 from individuals with BPH. To help with identification of low-abundance proteins, serum samples from patients with PCa and those with BPH were fractionated using anion displacement liquid chromatofocusing chromatography. This separates proteins by a pH gradient and a positively charged column. Results showed improved resolution of proteins within a given preselected pH gradient when compared to the unfractionated samples. Several proteins that were differentially expressed in serum from patients with PCa were identified in the fractionated serum. Of note, from the proteins identified, squamous cell carcinoma antigen 1 (SCCA1), calgranulin B, and haptoglobin-related protein were present in the serum at levels below 1 mg/ml. This study demonstrated that the use of anion displacement liquid chromatofocusing chromatography might reduce the complexity of the serum proteome by separating proteins into distinct pH ranges and aid with the identification of low-abundance proteins [61].

## Hydrogel Nanoparticle Technology: A Novel Platform for Biomarker Discovery

The postulate that there could be information that is still untapped within the low molecular weight proteomic fraction of blood recently led to exploration of nanoparticle technology. The physiological malleability and high surface areas of nanoparticles render them good candidates for developing biomarker-harvesting platforms. It would be useful to tailor nanoparticle surfaces to selectively bind a subset of biomarkers thus collecting them for further evaluation using high-sensitivity proteomic tests. Nanoparticle technology has thus far mostly focused on imaging systems and drug delivery. Biomarker harvesting is an evolving nanoparticle technology [62]. Hydrogel nanoparticles have gained considerable attention in recent years due to their unique potential by combining the characteristics of a hydrogel system (e.g., hydrophilicity and extremely high water content) with a nanoparticle with favorable stability, uniformity, and chemical versatility [63, 64]. In 2008, Luchini et al. demonstrated that NIPAm (N-isopropylacrylamide) hydrogel nanoparticles could be used as a tool to collect low molecular weight candidate biomarkers in serum (Fig. 13.2). Using this technique, low-abundance molecular analytes such as serum proteins, peptides, and metabolites were captured, concentrated, and protected from enzymatic degradations thus preventing erroneous results, which are known to occur when the serum is processed at room temperature [65]. When the nanoparticle is in solution, the three-dimensional NIPAm network acts as a sieve, which traps small proteins and peptides, while the high molecular weight proteins such as carrier proteins and endogenous and exogenous proteases are excluded. The same group demonstrated that by introducing a charged "chemical bait" incorporated into the NIPAm, the affinity of the particles for the target analytes increased significantly. In a study using platelet-derived growth factor (PDGF) as a model of very low-abundant and highly labile clinical biomarker, PDGF was inserted into a solution of diluted serum at an undetectable concentration and mixed with NIPAm/AAc particles. The concentration of the PDGF eluted from the particles was noted to increase to within the levels needed for detection by ELISA and mass spectrometry. A number of rare and low molecular weight proteins were identified within the proteins captured by particles in the diluted serum thus illustrating the role of hydrogel nanoparticle technology [66]. Hydrogel nanoparticles can be produced in large quantity at low cost, are reproducible and uniform in size, and can be coupled with different chemical bait ligands with tailored affinity for a wide range of proteins. Urine is a potential source of diagnostic biomarkers for detection of diseases. However, proteomic evaluation of urine is challenging due to the very low concentration of diagnostic biomarkers (usually below the sensitivity of common immunoassays). Another challenge is the rapid degradation of

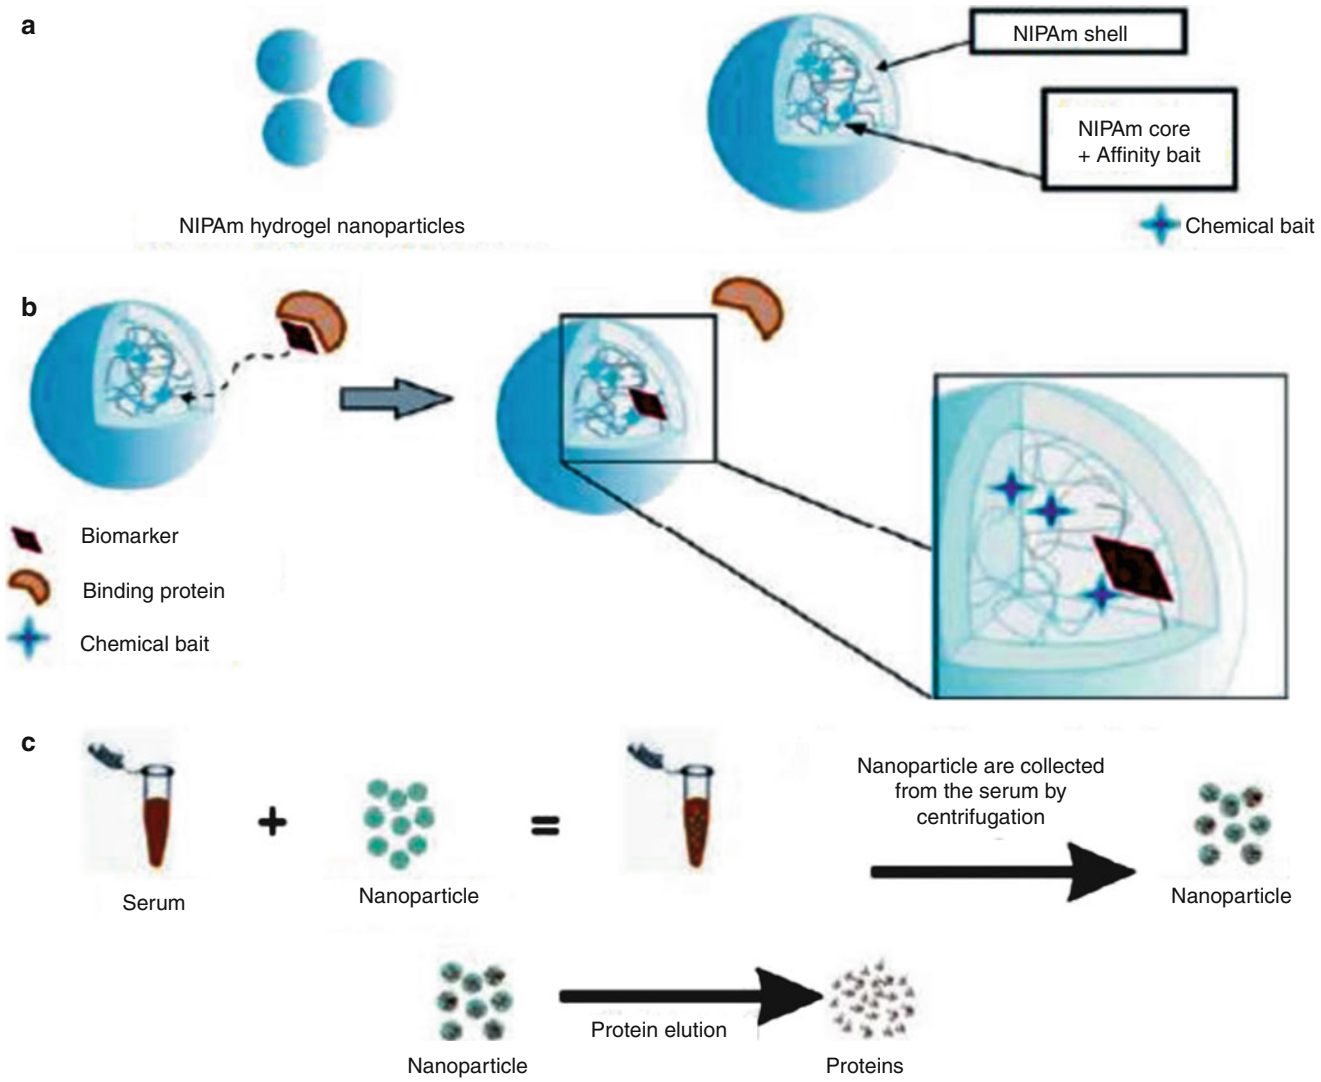

**Fig. 13.2** NIPAm hydrogel nanoparticles—a tool for the collection of low molecular weight potential biomarkers in serum. (**a**) Hydrogel nanoparticles composed of a NIPAm core and coupled to a chemical bait that has affinities for a wide range of proteins together with a shell. (**b**) Low molecular weight proteins in circulation bind to carrier protein attracted from the bait in the particle while the carrier-binding protein is excluded. (**c**) To capture the low-molecular fraction of the serum proteome, serum is incubated with nanoparticles and collected following centrifuge. The proteins are eluted from the particles and can be analyzed

urinary contents. Hydrogel nanoparticles functionalized with Cibacron Blue F3GA (CB) have been applied to address some of the challenges for urine biomarker measurement. Fredolini et al. demonstrated that use of Cibacron Blue F3GA-loaded hydrogel particles allowed detection of human growth hormone (hGH) (one of the most difficult to detect low-abundance hormones) in urine [67]. This was again ratified by studies by Sutkeviciute et al. [68]. Because of the capacity of these nanoparticles to concentrate the target protein to levels not attained by other methods coupled with the ability to exclude high-abundance nonspecific proteins, the sensitivity of the current biomarker measurement and discovery has improved significantly. Several groups are currently working on platforms using hydrogel particles in PCa biomarker discovery.

## Proteomic-Based Molecular Analysis of Prostate Cancer: Tumor Classification

It is known that PCa is primarily an androgen-dependent tumor [22, 69, 70] in which tumor regression occurs in patients in whom serum androgen concentrations are reduced by physical or chemical means. Androgen deprivation therapy and antiandrogens are the commonly utilized adjuncts in the management of advanced PCa. However, following an initial response to these modes of treatment, many cancers develop "androgen-independence" or "resistance." It is thought that this is due to clonal selection of resistant and more aggressive PCa cells. Novel therapeutic and molecularly directed agents are currently under evaluation to target

"androgen-independence" or "resistance." A better understanding of androgen receptor function and proteins that are involved in the pathways that regulate androgen-dependent/independent growth and metastasis is needed in order to help identify novel therapeutic targets. Some mechanisms identified thus far include overexpression of the androgen receptor, mutations in the receptors that permit activation by antiandrogens or other endogenous steroids, ligand-independent activation by growth-factor signaling pathways or loss of phosphatase and tensin homolog, changes in levels of androgen-receptor transcriptional cofactors (e.g., steroid receptor coactivator (SRC) 1, SRC2, CREB-binding protein, and filamin A), and upregulation of the enzymes involved in androgen biosynthesis. These have recently been shown to produce higher concentrations of androgen in tumors relative to blood [71]. Johansson et al. conducted proteomic analysis of the androgen-sensitive PCa cell line LNCaP-FGC and androgen-resistant line LNCaP. Proteins were separated by 2D-PAGE, and differentially expressed proteins were subsequently identified of which HSP60 (60 KDa heat shock protein) was found more abundant in LNCaP-r. This showed a correlation with the resistant phenotype [72]. To date, immunohistochemistry studies on prostate tissues showed a moderate to strong HSP60 staining of prostate epithelial cells without any noticeable correlation between Gleason grade and staining intensity. Furthermore, prostate tissues from androgen-ablated patients showed no obvious predictable staining patterns; i.e., some tumor cells were stained for HSP60 whereas others were largely unstained. The role of this protein in PCa progression and its value as biomarker remains unclear [73, 74]. Alaiya et al. showed alterations in the pattern of polypeptide expression in PCa that are similar to those observed in other carcinomas. Cells were collected from benign prostatic hyperplasia and PCa specimens and subjected to two-dimensional gel electrophoresis (2-DE). The resulting polypeptide patterns were analyzed with computer software (the PDQUEST). Malignant tumors were found to show significant increases in the level of expression of proliferating cell nuclear antigen (PCNA), calreticulin, HSP 90 and pHSP 60, oncoprotein 18(v), elongation factor 2, glutathione-S-transferase pi (GST-pi), superoxide dismutase, and triose phosphate isomerase. Furthermore, decreases in the levels of tropomyosin-1 and 2 and cytokeratin 18 were observed in PCa compared to prostate hyperplasias. The EST-database for prostate tumors [available from NCI (CGAP)] interrogated for the expression of the mRNAs corresponding to proteins identified in the study gels. Large differences in the relative expression of mRNAs and proteins were observed [75]. Rowland et al. worked on the theory that proteins that are responsive to androgen and antiandrogens could be involved in the development and progression of PCa, and the resultant failure of androgen-ablation therapy and that proteins represent potential diagnostic and therapeutic targets for improved management of PCa. They investigated the effect of androgen (R1881) and antiandrogen (bicalutamide) on the androgen-responsive prostate cancer LNCaP cell line using 2D-DIGE and found many proteins within metabolic processes, stress response, oxidative stress, and ER stress to be significantly changed. Moreover, proteins implicated in PI3K /Akt, p38 MAPK, JAK/STAT, and JNK/SAPK pathways were found to be altered. These could act as potential candidates for development as diagnostic/prognostic markers and drug targets [76].

Protein expression is largely influenced by the cellular microenvironment. Hence, the implementation of cellular enrichment and purification techniques is essential for proteomic-based molecular analysis and biomarker discovery. One such technique utilizes laser capture microdissection (LCM), which could potentially aid in collecting pure cell populations under direct microscopic visualization of the tissue [77, 78]. The problem with LCM is that it can be time-consuming process. However, it could be coupled with techniques that require small numbers of cells for molecular analysis such as some MS and protein microarray techniques. A protein microarray platform that is particularly well suited for clinical specimen analysis and multiplexed analyte profiling is the reverse-phase protein microarray (RPMA) [79–81] (Fig. 13.3). RPMA technology has been developed to minimize the analytical challenges of the sandwich and forward phase protein arrays (e.g., mismatch of sandwich antibody affinity, imprecision within and between analytes, and poor sensitivity). The platform has been designed to permit an objective, quantitative, and multiplexed analysis of specific forms of cellular proteins (e.g., phosphorylated, unphosphorylated, and cleaved) from a limited amount of starting sample, such as with a fine needle aspirate or laser capture microdissected (LCM) cellular material to secure populations of the specific target cells. The main advantage of RPMA is the ability to quantitatively measure hundreds of signaling proteins concomitantly from relatively few cells, thus providing a critical means of broad-scale cell signaling analysis directly from tissue samples, cell culture models, and animal tissues from preclinical studies. The RPMA platform (Fig. 13.3) immobilizes or creates a "frozen snapshot" of an individual test sample in each array spot. A given protein array may comprise up to hundreds of patient samples or cellular lysates. Each array is basically incubated with a single primary antibody, and a single analyte end point is tallied. With the RPMA technology, serial dilutions are printed of each sample and control or standard to maintain sample concentration. Each spot contains a "bait" zone measuring only a few hundred microns in diameter. A detection probe can be tagged and signal amplified independently from the immobilized analyte protein. Coupling the detection antibody with highly sensitive amplification systems can yield detection sensitivities to fewer than 1,000–5,000 molecules

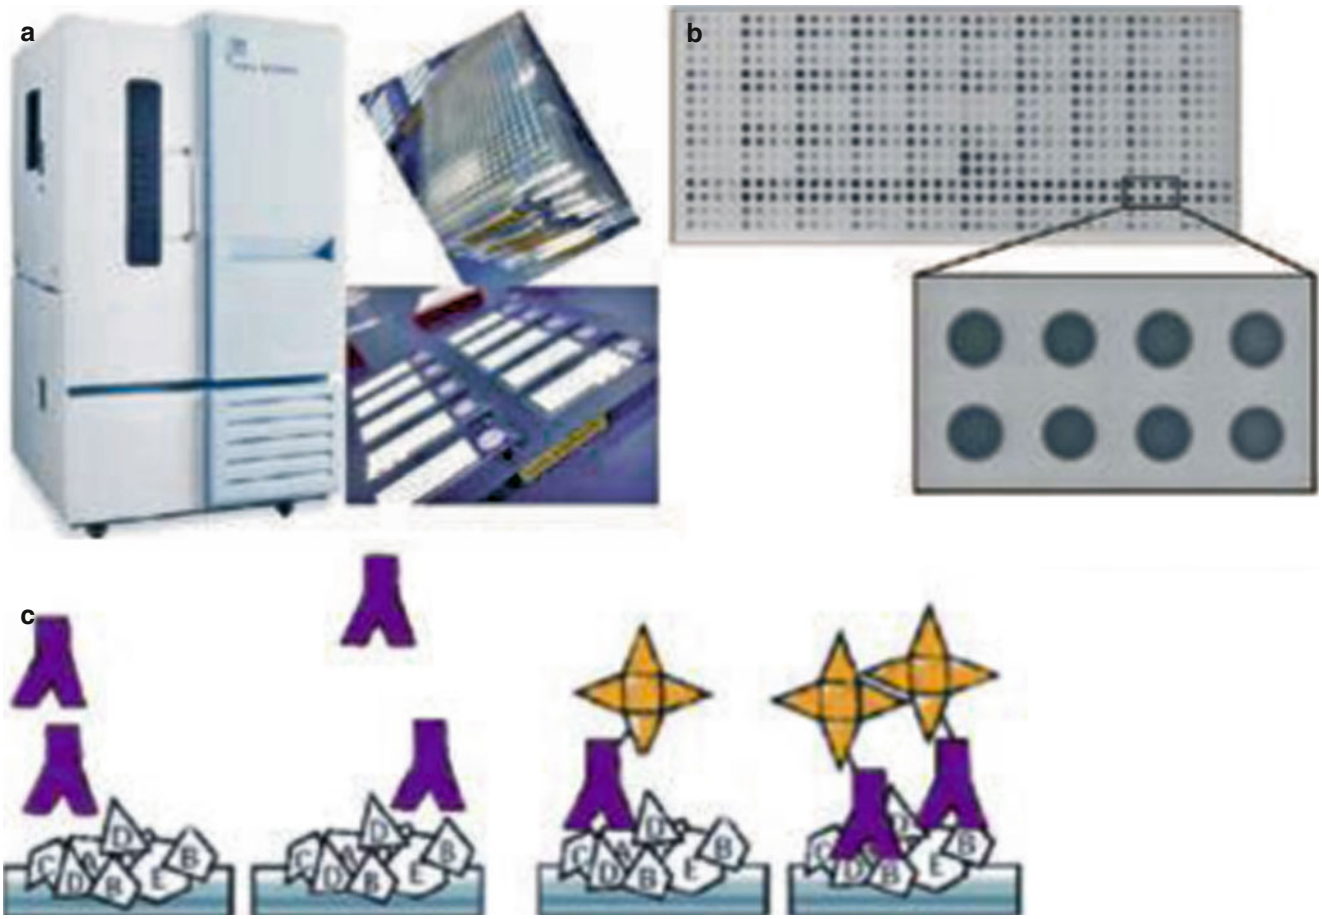

**Fig. 13.3** Reverse-phase protein microarray (RPPM). (**a**) Protein samples obtained from lysates of cells or body fluids are deposited in a nitrocellulose-coated slide by means of an arrayer. (**b**) Multiplicity of samples can be spotted in duplicate or triplicate on the same slide. (**c**) Each slide can be probed with an antibody that specifically binds to a target protein. A signal-amplification system increases the sensitivity. Signal-detection systems include fluorescent, chemiluminescent, or colorimetric methods

per spot [82]. This technology has been applied to evaluate the state of activation of proteins involved in prosurvival, mitogenic, and apoptotic signal pathways within prostate tissue samples. In a recent study, radical prostatectomy specimens were obtained from men with clinically localized PCa with Gleason Score ranging from [2+3=5] to [5+4=9] [80, 81]. For each patient, normal, cancerous, and stromal cells were microdissected, and the cell lysates analyzed by RPMA. An increase on AKT activation was observed in the transition from normal to tumor phenotype, while ERK kinase activation decreased. There was also an activation of GSK3 beta, a known substrate of AKT, indicating pathway network activation was taking place [80]. More recently, Grubb et al. used the same approach to evaluate variations in signaling pathways related to PCa progression [81]. Tissues from androgen-stimulated localized PCa, patients undergoing androgen deprivation therapy for recurrent local disease, and patients with metastatic cancer were profiled by RPMA of LCM procured cells and the activation state, and expression of 38 proteins was evaluated. Unsupervised clustering of the data revealed noticeable differences between stromal and benign epithelial cells compared to the malignant epithelial cells. The proteins Smac/Diablo and Bax, proteins implicated in apoptosis regulation, were more activated in stromal than in malignant cells while proteins involved in EGFR pathway (EGFR, cERBb2, MEK, ERK, and STAT3) were more activated in tumor cells than in stroma. Metastatic prostate epithelial cells from bone, liver, lung, and soft tissues sites were compared to malignant prostatic epithelium from the primary site. Phosphorylation of p38 and SAPK and JNK, all MAPK family members, along with STAT3 was found to be more highly phosphorylated in the malignant epithelial tissues with high Gleason scores. STAT3 is well known for its involvement in malignant transformation [81].

Most recently, there has been an exponential increase in the interest toward mass spectral imaging (MSI) directly from tissue due to the inherent potential for rapid profiling technology to provide clinically important information. Identification and visualization of protein signals directly on thin sections cut from fresh frozen tissue specimens could

combine the advantage of MS to discover protein expression changes to the spatial localization of protein(s) of specific interest in the tissue. Schwamborn et al. in 2007, described the application of MSI on tissue obtained from radical prostatectomy with a bid to identify MS peak patterns that can distinguish cancerous from noncancerous regions. They were able to do this with a sensitivity and specificity of 85 and 91 %, respectively [83]. Other peaks from this study were no different from other proteomic studies in which tissue lysate from normal or cancerous prostate was analyzed by SELDI. IMS analysis has potential clinical importance as it may support and/or enable computer-assisted clinical evaluation of tissue specimens. There are, however, a number of technical challenges. One of the challenges is in obtaining optimal sensitivity (only the top 1 % most abundant proteins are detectable). These limit MALDI-MSI from becoming a routine clinical laboratory technology at present [84, 85].

### Conclusions

The current shortcomings in the ability to distinguish indolent from aggressive forms of PCa and subsequent limitations in tailoring of optimal targeted treatment make clinical management difficult. The paradigm of "personalized or signatured" medicine, which includes proteomic technologies that could facilitate the discovery of new blood- and tissue-based biomarkers, would be particularly helpful in PCa. This is because current-evolving analyses in the proteome could allow the identification of the most aggressive and clinically "significant" cancers thus aiding in individualized and specialized treatment planning. In the past two decades, many types of proteomic technologies have been applied for potential discovery of putative biomarkers for PCa with the added aim of identifying prognostic biomarkers. In particular, MS methods and protein microarrays, which can characterize tissue and blood by high-throughput means, have great potential in translating research findings to clinical practice. It is envisioned, in the near future, that patients with the aggressive forms of PCa could be identified, through proteomic evaluation, at the earliest stages such that and these patients could be effectively treated with targeted chemoprevention techniques to stop the tumorigenic progression before full cellular transformation and invasion starts.

# Epigenetic Changes in Prostate Cancer

# 14

William G. Nelson, Michael C. Haffner,
Angelo M. De Marzo, and Srinivasan Yegnasubramanian

During the pathogenesis of prostate cancer, prostate cells acquire both genetic and epigenetic alterations [1]. Genetic defects have long been considered hallmarks of cancer, but because such changes tend to accumulate during cancer pathogenesis, i.e., they are essentially *irreversible*, only a fraction are likely to act as drivers of the malignant phenotype at any given time [2]. In contrast, epigenetic changes, which affect gene function rather than gene sequence, are potentially *reversible* and thus tend to be maintained only when contributing to cancer growth and progression. During prostatic carcinogenesis, epigenetic alterations can be detected in the earliest of cancer precursor lesions, in localized cancer lesions, and at lethal disease progression [3]. Furthermore, new technologies for genome-wide characterization of chromatin structure and function in normal and neoplastic prostate cells have revealed broad corruption of the regulation of gene function [4, 5]. How the myriad somatic epigenetic alterations collaborate with genetic accidents to create prostate cancer has not yet been fully elucidated. Nonetheless, improved understanding of the nature, extent, and functional consequences of epigenetic defects in prostate cancer appears poised not only to provide new insights into the causes of the disease, but also to yield new diagnostic tests for disease detection and risk stratification and new treatment approaches for disease control.

## DNA, Chromatin, Regulatory RNA, and the Cancer Cell Epigenome

Normal cells with different specialized functions comprising different organs and tissues can be distinguished by patterns of gene expression. These gene function differences are a consequence of differences in chromatin organization, referred to as the *epigenome*. Epigenome states tend to be established during embryonic development and can be propagated through cell replication and division by virtue of distinct DNA and chromatin protein "marks." The key DNA mark is the 5-methyl modification of cytosine bases in self-complementary CpG sequences. More than 70 % of the CpG sequences in the human genome contain 5-methyl-cytosine [6]. The unmethylated CpGs typically cluster at or near the transcriptional regulatory regions of genes, producing chromatin permissive for transcription. When such CpG clusters, termed CpG islands, carry 5-methyl-cytosine, the resultant chromatin structure constitutes a barrier to loading of RNA polymerase, rendering the gene transcriptionally silenced. The 5-methyl-cytosine modification is created and maintained through mitosis by DNA methyltransferases (DNMTs) enzymes, which catalyze the transfer of a methyl group from *S*-adenosyl-methionine (SAM) to cytosine bases [7]. Studies of mice carrying disrupted genes encoding the various DNMTs have both underscored the vital function of the enzymes in the creation of somatic epigenome states during embryonic development and hinted that dysregulation of enzyme activity, resulting in either under- or overmethylation of the genome, might lead to cancer development [8, 9].

Histone proteins, which are present at near stoichiometric equivalence with DNA in the cell nucleus, bear most of the chromatin protein epigenome marks, present as posttranslational modifications which constitute a histone "code" [10]. Histones assemble genomic DNA into nucleosomes, the first order of DNA organization in eukaryotic cells. One of the most studied of the histone marks, the methylation of lysine-27 in histone H3 by polycomb complex enzymes, provides an instructive example [11]. Polycomb complexes act

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_14, 

during development to ensure selective gene expression in differentiated cells, placing H3-K27 methylation marks at sites targeted for gene repression. In metastatic prostate cancers, a polycomb complex component, enhancer of zeste homolog 2 (EZH2), which possesses H3-K27 methyltransferase activity is overexpressed [12]. An analysis of the distribution of acquired abnormal H3K27 methylation marks in prostate cancer cells provides evidence for an epigenome state, which undermines androgen-regulated terminal differentiation in favor of activating embryonic stem cell pathways of gene expression [13]. Elucidating the interplay between enzymes which place and maintain DNA marks and histone marks may ultimately divulge the mystery of how the epigenome is corrupted during cancer development. Regions of the genome, which carry polycomb-associated chromatin marks seem to be disproportionately targeted for de novo DNA methylation, especially in the setting of chronic inflammatory states prone to spawn most solid organ cancers [14, 15]. Often, genes repressed by polycomb complexes can be maintained in a transcriptionally silenced state by DNA methylation changes at the gene promoter, even when the H3-K27 histone mark is lost [16].

The DNA methylation marks attract complexes of proteins containing 5-methyl-CpG-binding domain (MBD) proteins [17]. MBD proteins contain both amino acid motifs that mediate binding to DNA carrying 5-methyl-cytosine and transcriptional repression domains (TRDs) that allow recruitment of enzymes capable of remodeling chromatin structure and placing histone marks, leading to heterochromatin formation [18]. One of the MBD family proteins, MBD2, plays a significant role in somatic epigenome silencing in cancer cells, as siRNA knockdown of *MBD2* mRNA expression unleashes transcription from hypermethylated gene promoters in cancer cells in vitro, and disruption of *Mbd2* genes prevents intestinal tumorigenesis in $Apc^{Min/+}$ mice in vivo [19, 20]. The heterochromatin formed during somatic epigenetic gene silencing segregates apart from more active chromatin regions in the cancer cell nucleus. New insights into the organization and function of DNA in mammalian cell nuclei have been afforded by chromatic conformational capture technologies, capable of revealing high-order chromatin architecture at a DNA sequence level of resolution [21]. Two higher order structures merit consideration: *chromatin globules*, reflecting looping interactions between genes and regulatory elements along the length of chromosomes and *transcription hubs* (also called *transcription factories*), created by movement of activated genes to fixed sites for high-intensity transcription [22]. Steroid hormone receptor-induction of selective gene transcription is one pathway known to trigger both new looping interactions and migration of target genes to transcription hubs [23, 24]. The corruption of this higher order structure in cancer cells may underlie the oft-noted chromatin defects seen by cancer pathologists using routine cytopathology and histopathology stains.

In addition to chromatin regulation of gene transcription, microRNAs (miRs) provide additional epigenetic control of gene product expression. miRs are 20–24 nucleotide stem-loop RNAs that can bind to 7 nucleotide regions of mRNAs to promote degradation and/or prevent translation [25–27]. Synthesized from as many as 300–1,000 miR genes in the human genome by RNA polymerase II, primary miR transcripts are processed in the cell nucleus into 70 nucleotide stem-loop pre-miR precursors by a complex containing the RNase III endonuclease Drosha and its partner Pasha, exported into the cell cytoplasm by exportin 5 and Ran-GTP, and then further processed into miRs by a complex containing the RNase III endonuclease Dicer and its partner Loqacious. The processed miRs are then loaded into the RNA-induced silencing complex (RISC), composed of Dicer, a double-stranded RNA-binding protein (TRBP), and another nuclease named Argonaute2 (Ago2) [28]. By base pairing with a 7 nucleotide sequence in miRs, the miRs direct the RISC effector functions to specific mRNA targets. Computational analyses and transcriptome profiling studies have hinted that each miR may have as many as 200 target mRNAs and that the efficiency of mRNA degradation/repression may depend on the number of 7-nucleotide miR-binding sequences in the target mRNA, the level of miR expression, and/or the level of target mRNA expression. Altered expression of miR has been found to contribute to the pathogenesis of several different cancers, with both increased and decreased expression of specific miRs regulating the neoplastic phenotype. In one example, the *let-7* miR, which targets the mRNA products of the *RAS* oncogenes, exhibits decreased expression in lung cancers, leading to increased RAS protein levels [29]. In another example, *R-15a* and *R-16-1* miRs, which target the mRNA product of the anti-apoptotic *BCL2* gene, have been reported to be downregulated in chronic lymphocytic leukemia (CLL) cells which express high levels of BCL2 protein [30]. The mechanism(s) by which miRs are expressed at higher or lower levels in cancer cells have not been fully elucidated, though somatic genome and epigenome alterations, including deletions, mutations, DNA methylation changes, etc., have been suspected and/or reported [31–33].

MiRs are not the only RNA species that may play a regulatory role in gene function. Poliseno et al. have reported that pseudogenes, and other noncoding transcripts, might compete for miRs by acting as "sponges," thwarting the fine tuning of translation needed for the ordered behavior of somatic cells [34]. An example of this phenomenon is the noncoding pseudogene *PTENP1*, which when expressed physiologically upregulates *PTEN* mRNA and its translation by functioning as a decoy for miRs binding 3′-untranslated sequences in *PTEN*. Loss of *PTENP1* sequences commonly occurs in human cancers, leading to downregulation of *PTEN*; i.e., *PTENP1* can be considered a tumor suppressor which acts

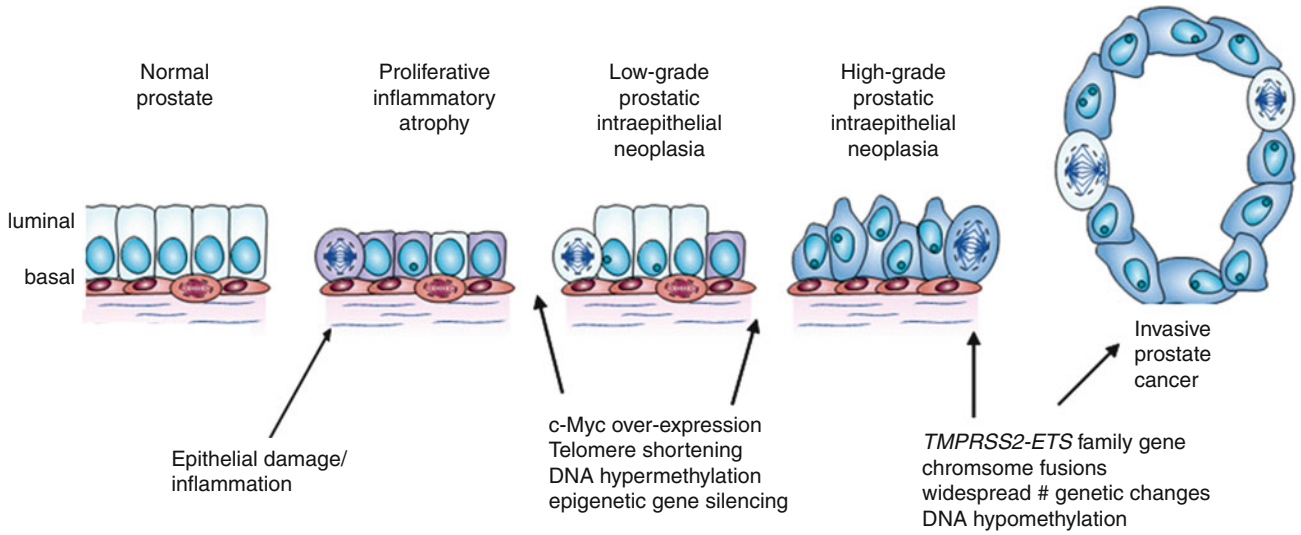

**Fig. 14.1** Epigenetic and genetic defects accumulate during prostatic carcinogenesis (Adapted from De Marzo et al. [42]. With permission)

via an epigenetic mechanism [34]. Long noncoding RNAs, which often contain antisense sequences to coding RNAs, can affect gene function, providing another epigenetic layer to gene and chromatin regulation [35–38]. These antisense RNA species attenuate gene transcription by interacting with RNA sequences polymerized from the sense strand of the gene promoter [39]. Other noncoding RNAs, such as *PCA3*, differentially expressed in prostate cancer cells versus normal cells, do not yet have a known function [40]. In a cancer cell containing a collection of genome and epigenome alterations, somatic corruption of the expression and function of the various regulatory RNAs will further undermine normal patterns of gene expression, permitting the disordered growth and defective differentiation that leads to malignant cancer progression.

## The Molecular Pathogenesis of Prostate Cancer

Like most solid organ cancers, prostate cancers arise in a milieu characterized by chronic or recurrent inflammation, likely in response to some sort of damage to the prostate epithelium [1, 41]. The source of the epithelial injury has not been established, though dietary carcinogens, infections, estrogens, ischemia, and urinary reflux have all been plausibly implicated as candidate carcinogens [42]. What is more clear is that epithelial damage and regeneration in the context of inflammation tends to give rise to distinct lesions termed proliferative inflammatory atrophy (PIA), which constitute the earliest precursors to prostate cancers [42, 43] (see Fig. 14.1). PIA lesions, on rare occasions, can progress to prostatic intraepithelial neoplasia (PIN) lesions and to invasive adenocarcinomas. The first consistent molecular events evident in PIA lesions giving rise to PIN tend to be overexpression of C-MYC, shortening of telomere sequences and epigenetic gene silencing [44–46]. The induction of *C-MYC*, which occurs by a mechanism not yet elucidated, directly modulates the chromatin structure in nuclei of the epithelial cells such that an increased number of enlarged nucleoli become readily apparent by routine histopathology evaluation [47]. C-MYC accomplishes this transformation of nuclear structure by activating the transcription of *FBL*, a gene encoding the nucleolar component fibrillarin and other target genes [47]. Telomere shortening, a common phenomenon seen in chronic tissue injury and/or accompanying cancer development in many organ sites, either reflects a history of cell proliferation in the absence of adequate telomere maintenance or some sort of direct damage to telomere sequences. Whether short telomeres directly affect cell phenotype, or merely present a risk for critical shortening, triggering genome damage responses and genetic instability has not been fully resolved. Like telomere shortening, the appearance of epigenetically silenced genes has been consistent finding in cancer precursor lesions and in inflamed tissues at many different organ sites at risk for cancer development [48]. Unlike telomere shortening, epigenetic gene silencing directly alters cell phenotype. Nonetheless, mechanism by inflammatory stress to epigenetic gene silencing has remained elusive, though in inflamed bowel tissues, at least 70 % of genes carrying new DNA methylation marks appeared to be targets of polycomb complex enzymes [49].

In normal prostate epithelial cells, the androgenic hormones testosterone and dihydrotestosterone, acting via the androgen receptor, promote terminal differentiation to a columnar cell that contributes secretions to the ejaculate. Prostate cancer cells co-opt this androgen signaling pathway to drive cell proliferation and survival. The cells appear to do so by virtue of chromosome deletions and translocations that

produce fusion transcripts between androgen-regulated genes, such as *TMPRSS2*, *KLK2*, *CANT1*, *SLC45A3*, *AX747630*, and putative oncogenes, including *ERG1* and other members of the ETS family of transcription factors [50]. As a consequence, antagonism of androgen signaling, through therapeutic reduction in androgen levels and/or the administration of antiandrogens, can attenuate prostate cancer progression [51]. The acquisition of the targeted gene deletions and translocations may itself be a consequence of dynamic chromatin organization and function. The androgen receptor is a ligand-dependent transcription factor capable of coordinating prostate cell differentiation by activating transcription of hundreds of genes or more. To do so, the receptor binds to regulatory regions of genes distributed throughout the prostate cell nucleus, dramatically changing its chromatin structure. For access to high intensity transcription, many such genes are moved by actin-myosin motors to transcription hubs [24]. In PIN lesions, the movement of these genes appears error-prone in that the recruitment of the DNA untangling enzyme topoisomerase IIβ (TOP2B) leads to DNA double strand breaks and illegitimate recombination via nonhomologous end-joining, producing *TMPRSS2-ERG1* and other translocations [23]. These genetic alterations, driven by changes in chromatin structure, may be what demarcate prostate cancers from PIN lesions. Nonetheless, why the initiation of transcription should generate more TOP2B-mediated double strand breaks in PIN cells than in normal prostate cells has not been determined. Perhaps, since c-MYC activation, telomere shortening, and epigenetic gene silencing precede the development of androgen-target gene translocations and fusions, one or more of these events may increase the vulnerability of the chromatin in PIN cells to dysfunction upon activating the androgen receptor-associated transcription program.

## Epigenome Changes in Prostate Cancer

Changes in DNA comprise the earliest somatic epigenome defects in human prostate cancer, resulting in gene silencing. Hypermethylation at the transcriptional regulatory region of *GSTP1*, encoding the π-class glutathione S-tranferase (GST), an enzyme responsible for detoxifying carcinogens and reactive oxygen species, has been the most intensively studied [3, 52]. As described above, the pathogenesis of prostate cancer may begin with the appearance of the precursor lesion PIA. *GSTP1* methylation changes, present in >90 % of prostate cancers, may define this initiation step, with *GSTP1* methylation evident in 5–10 % of PIA lesions [46, 53]. Progression of rare PIA lesions to PIN and prostate cancer may involve the acquisition of somatic genetic defects, such as *TMPRSS2*-ETS family translocations, which are thought to arise in PIN lesions or prostate cancers [23]. At the earliest stages of prostatic carcinogenesis, activation of *C-MYC* appears coincident with *GSTP1* silencing in rare PIA cells. This may reflect a tumor suppressor function of *GSTP1* in c-MYC-expressing cells: loss of π-class GST function renders prostate cells vulnerable to accelerated tumorigenesis in mice with forced *c-Myc* expression in the prostate. Also, loss of GSTP1 enzyme activity may render PIA, PIN, and prostate cancer cells sensitive to heterocyclic amine carcinogens, such as those found in overcooked meats, providing an explanation for the contribution of diet to prostate cancer development in epidemiology studies [54].

The mechanism by which *GSTP1* acquires de novo methylation changes at the gene promoter has not been established, though detection of *GSTP1* hypermethylation in PIA lesions implicates chronic or recurrent inflammation in a causative role for epigenetic gene silencing. Curiously, epithelial cells in all but a few PIA lesions tend to express very high levels of GSTP1 and other GSTs, likely exhibiting stress induction of GST gene transcription [43, 55, 56]. Whether an open chromatin state accompanying *GSTP1* activation might constitute a configuration that is particularly vulnerable to overmethylation of DNA at the gene promoter is not known. Nonetheless, inflammation has been associated with epigenetic gene silencing in gastritis, hepatitis, and inflammatory bowel disease [48]. The mechanism for this association has been proposed to involve: (1) dysfunction of DNMTs, (2) recruitment of DNMTs to selected regions of the genome carrying defined chromatin protein marks, or (3) modulation of chromatin protein marks at specific genes by stress or inflammatory signal transduction pathways (Nelson review). In support of these possibilities, nitric oxide formed at sites of inflammation might augment DNMT activity, interleukin 1β, and other inflammatory cytokines have been found to cause epigenetic silencing of key genes, and the intestinal epithelial cells of mice genetically prone to intestinal inflammation and carcinogenesis show new DNA methylation marks in some 250 genes, with 70 % of the genes representing targets of polycomb complex-mediated repression [39, 57].

Of course, the epigenetic catastrophe that leads to *GSTP1* hypermethylation at the initiation of prostatic carcinogenesis in PIA cells affects hundreds of sites in the genome, both near genes and in regions without known genes [5, 58]. Also, because the epigenetic changes are potentially reversible, corruption of the epigenome may well be ongoing throughout the pathogenesis of prostate cancer through progression to lethal metastatic disease. The propensity for epigenome defects to be maintained only if providing a selective growth or survival advantage renders the detection of epigenetically silenced genes potentially useful for discriminating indolent from aggressive disease states. Yegnasubramanian et al. reported that while hypermethylation at *GSTP1* was present in early localized cancers and maintained throughout

metastatic dissemination, hypermethylation at *ERα*, *hMLH1*, and *p14/INK4a* were only found in metastatic prostate cancers at autopsy [59]. The appearance of these changes appeared to represent clonal evolution of a lethal prostate cancer cell phenotype [59].

A reduction in total 5-methyl-cytosine content evolves progressively during prostate cancer progression, with physiologic or higher total 5-methyl-cytosine levels characteristic of prostate cancer precursor lesions, and variably low levels found in metastatic prostate cancer deposits [6, 60]. This undermethylation of the genome is likely attributable to poor fidelity of 5-methyl-cytosine maintenance during genome replication and cell division. Repeat sequences distributed throughout the genome, which usually carry methylated CpG dinucleotides, illustrate this phenomenon. In one case series, diminished *LINE-1* repeat methylation was detected in up to 53 % of prostate cancer cases, with decreased methylation of LINE-1 repeats in 67 % of cases with, and 8 % of cases without, lymph node metastases [61]. Reduced repeat sequence methylation may provide a mechanistic connection between epigenetic and genetic alterations in cancer cells. Mice carrying disrupted *Dnmt* genes exhibiting low 5-methyl-cytosine levels are prone to genetic instability via a tendency toward illegitimate recombination, and when crossed to mice with *p53* gene defects, show increased tumorigenesis [8, 62]. Life-threatening prostate cancers show large numbers of gene copy number gains and losses, of gene deletions, and of gene amplifications [63]. Whether the epigenetic defect of inadequate DNA repeat sequence methylation contributes to these genetic defects has not been rigorously established but the available evidence supports this hypothesis: there is a clear correlation between reduced DNA methylation and copy number alterations involving chromosome 8 in prostate cancer cases, and lethal prostate cancers at autopsy show both low 5-methyl-cytosine levels and high numbers of copy number changes throughout the genome [38, 64].

Reductions in DNA methylation, when affecting the transcriptional regulatory regions of genes physiologically maintained in a silent state in normal prostate cells, can result in gene activation (Yegnasubramanian). Such genes, which include *CTAG1B*, *CTAG2*, *GAGE2*, *GAGE3*, *GAGE4*, *GAGE6*, *GAGE7*, *GAGE7B*, *MAGEA1*, *MAGEA3*, *MAGEA6*, *MAGEA12*, *PAGE1*, and *TSPY1*, tend to be expressed at some critical stage of development but become epigenetically repressed in adult tissues [38]. For this reason, many of the protein products encoded by these genes have attracted interest and "neo-antigens" for prostate cancer vaccine immunotherapy [65]. Of interest, while the somatic hypermethylation changes at *GSTP1* and other genes seen in prostate cancers tend to be maintained throughout the natural history of the disease, the hypomethylation changes, which occur *within the same cells* as the disease progresses appear quite variable case-to-case, lesion-to-lesion within a case, and cell-to-cell within a lesion [38]. By causing both genetic and epigenetic instability in such a variable manner during prostate cancer progression, DNA hypomethylation may be the major driver of tumor cell heterogeneity during prostate cancer progression.

The expression and function of miRs is also extensively corrupted in prostate cancers [66]. In a systematic review of dysregulated miRs (from more than 100 published papers) in prostate cancer, 10 upregulated and 16 downregulated miRs were identified, with predicted functions in critical neoplastic phenotypes, including androgen signaling, apoptosis avoidance, cell proliferation, cell migration, and cell metabolism [66]. The mechanisms by which the various miRs are over- or underproduced in cancers can include genetic alterations, including deletions and amplifications, and epigenetic changes, with as many as 40 % of miR-coding sequences located in proximity with CpG islands [66]. Somatic loss of *mIR-101*, which targets *EZH2* mRNA encoding a component of the epigenetic regulator polycomb complex, is evident in as many as 38 % of localized prostate cancers and 67 % of metastatic prostate cases [67]. As a consequence, an acquired genetic defect affects the epigenome, with resultant increases in EZH2 disrupting polycomb complex action. In addition to the somatic cis-regulatory defects leading to alterations in miR expression, the trans-regulatory consequences of other genetic and epigenetic alterations can also contribute to miR dysfunction in prostate cancers. C-MYC, a master trans-regulator of genome function that is consistently overexpressed in prostate cancers, triggers significant perturbations in miR levels and actions which can dramatically alter cell phenotype. As an example, C-MYC-mediated transcriptional repression of *miR-23/b* in PC-3 prostate cancer cells results in increased production of mitochondrial glutaminase, which converts glutamine to glutamate, promoting a metabolic shift to glutamine consumption as a source of energy production [68]. Finally, marked changes in mIR expression have been reported to accompany prostate cancer progression from androgen-dependence to castration-resistance. In a comprehensive assessment, 41 miRs were found to be upregulated and 42 downregulated in castration-resistant LNCaP prostate cancer cells, most targeting genes encoding signal transduction pathway participants [69]. *MiR-221* and *miR-222*, which target mRNA for p27/Kip1 and other key proteins, have been implicated in maintenance of a castration-resistance phenotype in prostate cancer cell lines [70].

The accumulating body of knowledge of the epigenome of prostate cancer has revealed that epigenetic changes precede genetic alterations and continue to accrue during disease progression from PIA to PIN to invasive cancer to metastatic dissemination to castration resistance. As a result, there is no prostate cancer phenotype unaffected by epigenome defects. Furthermore, many interactions between processes corrupting the genetic and epigenetic regulation of

genome function have been recognized, leading to a complex and dynamically evolving prostate cancer cell genome, endowing many progressive prostate cancers with the propensity to ultimately resist all attempts at therapeutic intervention.

## Epigenome Biomarkers for Prostate Cancer Screening, Detection, and Diagnosis

The screening and early detection of prostate cancer, though responsible for improvements in prostate cancer mortality, leave much to be desired [71]. Neither serum prostate-specific antigen (PSA) values nor the texture of prostate tissue felt by digital rectal examination direction reliably discriminates prostate cancer from other prostate disorders. In an early study, a serum PSA between 4.0 and 9.9 ng/mL was associated with a 22 % chance of finding prostate cancer by prostate biopsy; in a later study (the placebo arm of the Prostate Cancer Prevention Trial), 24.4 % of men with a serum PSA less than 3.0 ng/mL were found to have prostate cancer [72–74]. The diagnostic approach to localized prostate cancer is also inadequate. Because no imaging strategy can distinguish prostate cancer lesions from other anatomic disruptions of the glandular architecture in the prostate peripheral zone, such as inflammation and atrophy, the preferred approach to prostate biopsy is transrectal ultrasound (TRUS)-guided sampling of ~0.3 % or so of prostate tissue. Of course, TRUS-guided prostate biopsies can miss significant cancer lesions, under- or overestimate the extent of cancer, and sample low grade but not high-grade cancer lesions when both are present. Despite all of these difficulties, at least 48 million serum PSA tests are done each year, prompting more than a million prostate biopsy procedures to diagnose 250,000 prostate cancers. If an epigenome biomarker can improve prostate cancer screening, detection, and diagnosis, a significant unmet medical need could be addressed.

Ideal attributes of any new biomarker for prostate cancer screening include a high enough test sensitivity and specificity that when applied to a population of men at risk for disease, the biomarker would exhibit better positive and negative predictive values than serum PSA tests and digital rectal examination. In this way, men most likely to have prostate cancer could be navigated toward prostate biopsy, while men not likely to have the disease could be steered away from biopsy procedures. Several epigenetic biomarkers might have such attributes. Two such markers, hypermethylation of the *GSTP1* CpG island and overexpression of the noncoding RNA *PCA3*, are under development for this purpose, though establishing the clinical utility of the markers has been difficult. One challenge has been the need for better assays. For example, *GSTP1* hypermethylation, though present in nearly all prostate cancers, could be detected only in 90 % or so of prostate cancer cases using first generation DNA methylation assays, performed using bisulfite modification and polymerase chain reaction (PCR) amplification [58]. This challenge may have been overcome as second generation assays for *GSTP1* hypermethylation, featuring capture of 5-methyl-cytosine-containing DNA using MBD protein fragments followed by PCR, and have shown 99.2 % sensitivity and 100 % specificity for prostate cancer versus normal prostate tissue [75]. A second difficulty has been determining which biospecimen to target for epigenetic prostate cancer tests: would such biomarkers best be tested in blood, expressed prostate secretions, or urine? Prostate cancer DNA showing *GSTP1* hypermethylation has been detected in each of these types of specimens, while prostate cancer RNA with *PCA3* has mostly been found in the urine [76–82]. The third and most daunting challenge has been that for each biomarker, a positive test (the presence of the biomarker) has been well correlated with the presence of cancer in the prostate, while a negative test (the absence of the biomarker) has not had a high enough of a predictive value to preclude the need for a biopsy. The problem may be that prostate cancer DNA and RNA may only be intermittently present, or present at too low an amount, in blood, prostate secretions, or urine to be reliably sampled. In this way, many biospecimens giving "negative" tests might be more accurately labeled "uninformative." To minimize the mischaracterization of "uniformative" as "negative" for *PCA3* tests, a ratio of *PCA3* RNA to *PSA* mRNA is typically provided, ensuring that prostate epithelial cells, which could be normal or neoplastic, were in the biospecimen assessed [81]. To further increase the negative predictive value of epigenetic prostate cancer tests for prostate cancer screening, the frequency of "uninformative" tests need to be minimized, perhaps by combining *GSTP1* hypermethylation and *PCA3* RNA tests, introducing assays for additional DNA methylation changes and/or RNA targets, or repeatedly sampling the biospecimens [83]. Of interest in this regard, the negative predictive value of fecal occult blood testing for colorectal neoplasia screening reaches an adequate level only after three successive tests.

Because of the limitations of TRUS-guided prostate biopsies for prostate cancer, many men with negative biopsies are subjected to additional biopsy procedures before a prostate cancer diagnosis is established. The clinical quandary confronted by urologists is whether and when to perform additional biopsies for men suspected to harbor prostate cancer despite a negative biopsy. To address this unmet medical need, both *GSTP1* hypermethylation and *PCA3* RNA tests of biopsy tissues, of plasma, and especially of urine, which tend to outperform serum PSA testing in predicting prostate biopsy results, have been introduced into this clinical setting [81, 84]. In a recent study of the placebo arm of the REDUCE trial, which tested the propensity for dutasteride to lower the risk of

prostate cancer in men with negative prostate biopsies, *PCA3* urine tests were performed before planned prostate biopsy procedures at years 2 and 4 [85]. The findings were that an elevated *PCA3* was predictive of prostate cancer before each biopsy; furthermore, an elevated *PCA3* at year 2 predicted a positive biopsy at year 4 even if the biopsy at year 2 was negative. The sensitivity and specificity of the current prostate cancer epigenome assays may be good enough now to permit informed decision-making regarding the timing of repeat prostate biopsies for men suspected to have prostate cancer. Of course, as the assay strategies continue to improve, the clinical utility of epigenome urine tests for prostate cancer will improve as well, hopefully complementing advances in prostate imaging that might allow better targeting of prostate biopsies.

## Epigenome Biomarkers for Prostate Cancer Risk Stratification and Treatment Monitoring

The propensity for prostate cancers to arise in more than half of men in the USA and the developed world aging beyond 50 years but to threaten life far less often has triggered a backlash against prostate cancer screening and early detection [71, 86]. The worry is that as prostate cancer screening tests become progressively more sensitive, the overdiagnosis of nonthreatening prostate cancer will tend to increase. A current estimate suggests that for prostate cancers detected by screening, nearly 50 men need to be subjected to aggressive local therapy to save one life [71, 87]. In response to this evolving challenge, many men with prostate cancer found by screening pursue conservative treatment approaches, termed watchful waiting or active surveillance, in which aggressive local therapy is used only for disease progression to a more risky state. The key tool used for treatment decisions in such approaches tends to be Gleason grading of cancer deposits seen in prostate biopsy specimens; as an example, an increase in Gleason score from 3 + 3 = 6 seen on initial biopsy to 4 + 4 = 8 on a subsequent biopsy would likely steer a man with prostate cancer on active surveillance toward prostate surgery or radiation therapy. When applied by an expert prostate pathologist, Gleason grading provides a fairly accurate prognostic tool: a study of more than 2,500 men with Gleason 6 or less prostate cancer treated with radical prostatectomy revealed that none had died of the disease [88]. The unmet needs that could be addressed by epigenome biomarkers arise out of three major limitations with Gleason scoring. The first is that many of the pathologists reading prostate biopsies, especially those who are not expert prostate pathologists, have difficulty assigning Gleason grades. A biomarker tool that might aid in the accuracy of Gleason grading could improve Gleason scoring throughout the USA and elsewhere. Another difficulty is the reduced utility of Gleason scoring for prostate cancer seen in biopsies versus in radical prostatectomy specimens, as the biopsy sampling can miss higher Gleason grade cancers, leading to apparent "upgrading" at surgery. This problem, which bedevils active surveillance approaches, could be solved using epigenome biomarkers that can be assayed in biospecimens that sample the entire prostate gland, such as blood or urine. Finally, the possible presence of rare aggressive prostate cancer cells in some Gleason pattern 3 lesions may be a harbinger of poor prostate cancer outcome despite favorable histopathological appearance. If an epigenome biomarker can be detected with high sensitivity, such as through amplification of nucleic acid sequences, this possibility could be addressed, leading to an improvement in prognostic accuracy beyond that which can be achieved by Gleason scoring.

Epigenome biomarkers that define the prostate cancer phenotypes captured by Gleason grading, or add additional prognostic information, will likely be applied to biopsy tissues, blood, and urine, in hopes of refining prostate cancer prognosis. Already, 5-methyl-cytosine marks at *EDNRB*, *RAR*β, *RASSF1a*, *ER*β, and *TIG1* in prostate cancer DNA have been reported to correlate with tumor stage and/or Gleason grade [59, 89–92]. Another epigenome biomarker, methylation at *PTGS2*, better predicted recurrence of localized prostate cancer after radical prostatectomy than did tumor stage or Gleason grade [59]. Increased serum miR-141 levels may also portend a poor prognosis [93], while serum miR-21 levels appear to be associated with docetaxel resistance [94]. With new genome-wide platforms available for discovery of DNA methylation biomarkers, miR biomarkers, and other species, a plethora of candidate epigenome biomarkers of prostate cancer prognosis are forthcoming. The challenge will be to pursue critical approaches to sifting through such candidate to identify biomarkers that accurately direct clinical decision-making to improve prostate cancer outcomes.

## Epigenome Defects as Rational Therapeutic Targets for Prostate Cancer

Epigenome defects in cancer cells are attractive therapeutic targets because the DNA-coding sequences remain intact. Epigenetic treatments that have advanced to human use thus far act to reverse epigenetic gene silencing enforced by DNA methylation and by the removal of histone acetylation modifications. Four drugs are currently on the market: azacitidine (Vidaza®) and decitabine (Dacogen®) are DNMT inhibitors approved for the treatment of myelodysplasia, while vorinostat (Zolinza®) and romidepsin (Istodax®) are inhibitors of histone deacetylases (HDACs) approved for the treatment of cutaneous T cell lymphomas [95–102]. In addition, several epigenetic drug targets, particularly enzymes that catalyze histone modifications, are being evaluated and credentialed for new drug discovery and development

throughout the biotechnology and pharmaceutical industry. Nonetheless, clinical trials of epigenetic drugs for prostate cancer have been limited. In one small phase 2 clinical trial ($n = 14$ men), decitabine was administered intravenously every 8 h at a dose of 75 mg/m$^2$ for x doses every 5–8 weeks to men with androgen-independent metastatic prostate cancer [103]. Only 2 of the 12 men who could be evaluated for response to treatment showed any hint of benefit, with disease stabilization for as long as 10 weeks or so [103]. This experience is reminiscent of the activity of the nucleoside DNMT inhibitors for other solid organ cancers, where use as a single agent has been disappointing. Newer preclinical data, which have emphasized the epigenetic properties of the drugs over the cytotoxic properties per se, have suggested that different dose and/or dosing schedules of DNMT inhibitors, or DNMT inhibitors given in combinations with other drugs, might be more effective for prostate cancer and other solid organ tumors [59, 104–114]. One attractive therapeutic avenue may be the use of epigenetic drugs to activate expression of key drug targets, rendering cancer cells sensitive to growth inhibition or cytotoxicity mediated by existing drugs that hit the targets. The paradigm for such a target is the silenced *ER* gene in estrogen-independent breast cancer cells, where induction of receptor expression in tamoxifen-resistant breast cancer cells by DMNT and HDAC inhibitors promotes sensitivity to growth suppression by tamoxifen [115]. A candidate therapeutic target for epigenetic reactivation in prostate cancer cells, as well as in other cancer cells, is retinoic acid signaling: each of the available epigenetic drugs seems to be able to restore the signaling pathway in cancer cells, sensitizing the cells to growth suppression by isotretinoin [106, 108–110].

## Conclusions

Somatic alterations of the epigenome constitute the earliest, most extensive, and most reversible drivers of prostatic carcinogenesis, collaborating with genetic defects to promote malignant prostate cancer progression. New genome-wide discovery platforms promise to provide new epigenetic biomarkers that can serve to improve prostate cancer screening, detection, diagnosis, and disease stratification. Already, several such markers are under development as clinical tests, including assays for *GSTP1* hypermethylation and for *PCA3* RNA species; more candidates will be introduced in the future. Epigenetic treatments have had only limited use in clinical trials for advanced prostate cancers, and the results have been underwhelming. New epigenetic drugs and drug combinations will be needed to realize more significant benefits.

## Introduction

Prostate cancer is the most frequently diagnosed malignancy and the second leading cause of cancer-specific deaths in men in Western-industrialized countries; that is, prostate cancer currently constitutes up to 25 % of all male cancer diagnoses and accounts for 10 % of cancer deaths among men in these countries [1]. In recent years, the majority of patients with prostate cancer have been diagnosed at an early stage without any symptoms [2]; therefore, the conventional approaches for prognostic prediction, such as the Partin tables and the Kattan nomograms [3, 4], are no longer variable as in the past. Accordingly, the focus has now moved from early detection to characterizing the clinical features of this disease diagnosed at an early stage.

To date, intensive efforts have been made in the field of prostate cancer research, and thus the molecular mechanism mediating the progression of prostate cancer has been gradually clarified [5, 6]. However, there have not been any biomarkers introduced into the clinical practice, except for prostate-specific antigen (PSA). Although PSA is demonstrated to be useful for the detection as well as the monitoring of prostate cancer, several limitations of PSA as a cancer-specific biomarker have been pointed out [7, 8]. In fact, no concentration of PSA exists below which the risk of prostate cancer does not exist, and high PSA values sometimes reflect a large prostate volume rather than a high risk of the presence of prostate cancer. Considering these findings, it would be necessary to identify novel and useful biomarkers that can assist in clinical decision-making during the prostate cancer diagnosis and treatment.

With progress in the research targeting molecular biology of prostate cancer, upcoming biomarker candidates mainly involved in the acquisition of aggressive phenotype have been identified [9, 10]. In the following, therefore, we have attempted to summarize recent progress in the development of biomarkers that show promise for the management of patients with prostate cancer.

## Limitations of PSA as a Prognostic Indicator

PSA, a serine protease secreted by the epithelial cells of the prostate, is considered to be the most useful tumor marker currently in use [11]. The common use of PSA testing has resulted in an increased detection of prostate cancer at an earlier stage. PSA is also shown to be useful as a marker related to the extent of prostate cancer and the prognosis in some categories of men with this disease.

However, there are serious limitations of the PSA test mainly due to the absence of cancer specificity [12]. For example, elevations of PSA are observed in men with benign enlargement of the prostate gland, such as benign prostatic hyperplasia (BPH) and those with inflammatory disease in the prostate [13]. Similarly, PSA levels do not have a direct association with increase in grade and stage of prostate cancer, particularly in patients with comparatively low PSA values [14]. This lack of specificity to the PSA test led to both overdiagnosis and overtreatment of clinically insignificant disease [15]. Furthermore, it is usually difficult to precisely predict the prognosis of patients with prostate cancer based on the PSA test even after combined assessment with other clinical parameters, since the prognosis of patients after prostate cancer diagnosis is extremely variable [16]. Collectively, these findings suggest that there is pressing need for new prognostic biomarkers that can distinguish between indolent and aggressive prostate cancers.

## Novel Prognostic Biomarkers

### PSA-Derived Biomarkers

One attractive approach for overcoming limitations of the PSA test is to measure PSA derivatives, including PSA velocity, PSA density, and age-specific PSA intervals, but the significant utilities of these derivatives over the PSA test have not been clearly demonstrated [17].

PSA is present in serum in various molecular forms that can be divided into the two major categories of free and complex forms [18]. Of these, the significance of percent free PSA (%fPSA) as a prognostic indicator is intensively investigated; however, these findings remain controversial [19, 20]. For example, Southwick et al. found %fPSA to be a better predictor of postoperative pathological outcome than Gleason score [19], whereas Graefen et al. reported that %fPSA has no significant impact on the prediction of disease progression following radical prostatectomy [20].

### Biomarkers Specifically Produced by the Prostate

The usefulness of several genes, that are specifically expressed in the prostate gland like PSA, as possible biomarkers for prostate cancer have been investigated, and promising findings have been demonstrated in studies assessing the significance of some of these candidate genes, such as human kallikrein-related peptidase-2 (KLK2), prostate cancer antigen-3 (PCA3), prostate-specific membrane antigen (PSMA), and prostate stem cell antigen (PSCA) [21].

For example, KLK2, a member of the kallikrein gene family of secreted serine proteases same as PSA, shows greatest abundance in the prostate gland. It has been well documented that measurement of serum KLK2 levels could contribute to enhance the diagnostic accuracy of prostate cancer [22]. KLK2 has also shown to provide precise prognostic information in men undergoing radical prostatectomy compared with PSA [23]. Furthermore, PCA3, also known as differential display code 3, is a noncoding RNA produced exclusively in the prostate gland, particularly in the prostate cancer cells. Several previous studies have demonstrated the utility of the PCA3 test by the measurement of PCA3 mRNA in urine sediment for improving the diagnostic specificity of PSA [24]. In recent studies, PCA3 urinary assay has been shown to be useful for predicting pathological features in prostate cancer patients [25]; however, it remains unknown whether this test could be used as a prognostic prediction.

### Apoptosis-Related Biomarkers

A number of studies have demonstrated the involvement of apoptosis-related molecules in the progression of prostate cancer [26]. Of these, the Bcl-2 protein family, including anti-apoptotic (such as Bcl-2 and Bcl-xL) and proapoptotic (such as Bax and Bak) genes that have opposite role in the process of apoptotic cell death, is one of the most intensively investigated molecules as biomarkers of prostate cancer [27]. In consistent with preclinical studies demonstrating powerful activity of Bcl-2 resistant to a wide variety of therapeutic stimuli [28], several studies have reported the significant impact of Bcl-2 expression on the prognosis of patients with prostate cancer. Overexpression of Bcl-2 was shown to be closely correlated to the subsequent development of biochemical recurrence in patients with prostate cancer following radical prostatectomy [29, 30]. In addition, Pollack et al. reported the increased biochemical failure in patients with Bcl-2 overexpression in biopsy specimens who underwent radiotherapy [30]. In the study by Pollak et al. altered Bax expression, defined as under- or overexpression compared with staining intensity of nonneoplastic cells, also appeared to be an independent predictor of biochemical recurrence [30].

Recently, changes in expression profiles of numerous genes at various time-points after castration have precisely characterized using animal model systems mimicking the diverse behavior of human prostate cancer and highlighted genes showing dramatic changes during progression to castration resistance. Based on these outcomes, special attention has been paid to several genes that become upregulated after castration, most of which are associated with antiapototic activities and functions like a molecular chaperone [31, 32]. To date, these genes, such as clusterin and heat shock protein 27 (HSP27), have been mainly investigated as molecular targets for the treatment of prostate cancer [33], while it is currently under active assessment whether these genes could be used as biomarkers for predicting the prognosis of prostate cancer [34–40].

Clusterin, also known as testosterone-repressed prostate message-2, apolipoprotein J, or sulfated glycoprotein-2, is associated with a wide variety of pathophysiological processes, including tissue remodeling, lipid transport, reproduction, complement regulation, and apoptosis [41]. In prostate cancer, experimental and clinical studies have demonstrated that clusterin expression is associated with the development of castration-resistant progression and plays a protective role against a wide variety of apoptotic signals; therefore, clusterin is regarded as a cytoprotective gene upregulated by apoptotic triggers and conferring resistance to conventional therapeutic modalities used in a clinical setting [42]. Recently, several studies have addressed the significance of clusterin as a biomarker for prostate cancer [34, 35]. Miyake et al. also previously showed that the expression of clusterin is significantly increased in radical prostatectomy specimens after neoadjuvant hormonal therapy compared with that in biopsy specimens and that the expression level of clusterin in prostate cancer tissue after neoadjuvant hormonal therapy could be a useful parameter predicting biochemical

recurrence [36], whereas the expression level of clusterin protein failed to show a significant correlation with biochemical recurrence in patients undergoing radical prostatectomy without neoadjuvant hormonal therapy [37]. In consistent with these studies, we measured serum levels of clusterin in prostate cancer patients and showed that serum clusterin level and its density in men with prostate cancer are shown to be closely correlated to disease extension and that postoperative biochemical recurrence-free survival in patients with elevated clusterin density was significantly lower than that in those with normal density [38].

HSP27, an ATP-independent molecular chaperone, is one of the most potent cytoprotective proteins, is highly induced as a stress response, and forms oligomers to increase affinity for client proteins, preventing their precipitation and aggregation [43]. Like clusterin, HSP27 expression is highly upregulated by proapoptotic stimuli and inhibits therapy-induced apoptosis in prostate cancer models [44]. In clinical specimens, overexpression of HSP27 is observed in various kinds of malignant tumors, including prostate cancer [39]. In addition, we previously reported that despite the lack of independent significance, the expression level of HSP27 in prostate cancer tissue after neoadjuvant hormonal therapy, which may inversely reflect the therapeutic effect of neoadjuvant hormonal therapy, could be a useful parameter predicting biochemical recurrence in patients undergoing radical prostatectomy [40].

## Cell-Cycle-Related Biomarkers

Abnormalities in the regulation of cell cycle are present in the majority of malignant tumors [45]. In prostate cancer as well, a number of studies have shown the association between the outcomes of prostate cancer treatment and the expression of cell-cycle-related markers, including p16, p21, p27, Aurora-A, and Ki-67 [46–51]. Of these markers, p27, an endogenous inhibitor of cyclin-dependent kinase, is one of the most widely characterized proteins as a biomarker of prostate cancer [47, 48]. For example, Freedland et al. showed that low expression of p27 in biopsy specimen could be used as an independent predictor of biochemical recurrence in patients with prostate cancer following radical prostatectomy [48].

We also previously analyzed the prognostic significance of a potential cell-cycle regulator, Aurora-A, a serine/threonine protein kinase belonging to the Drosophila aurora and Saccharomyces cerevisiae Ip11 kinase family, that has been shown to play a crucial role in chromosome segregation and centrosome functions [52], in patients with prostate cancer [50]. In this study, we demonstrated that the expression of Aurora-A was significantly decreased in radical prostatectomy specimens compared with that in biopsy specimens prior to neoadjuvant hormonal therapy; however, persistent overexpression of Aurora-A was detected in approximately 40 % of radical prostatectomy specimens after neoadjuvant hormonal therapy and that the expression level of Aurora-A in prostate cancer tissue after neoadjuvant hormonal therapy could be a useful parameter predicting biochemical recurrence in patients undergoing radical prostatectomy [50]. We subsequently assessed the predictive value of twelve kinds of molecular markers as well as conventional prognostic parameters for biochemical recurrence in patients undergoing radical prostatectomy alone. Of these markers, Ki-67, p53, androgen receptor (AR), matrix metalloproteinase-2 (MMP-2), MMP-9, and HSP27 expression were shown to be significantly associated with biochemical recurrence; however, only Ki-67, reflecting a tumor proliferation index, in addition to seminal vesicle invasion and surgical margin status appeared to be independently related to biochemical recurrence on multivariate analysis [51].

## Signal Transduction-Related Biomarkers

Aberrations in signal transduction pathways are demonstrated to play crucial roles in the progression of a wide variety of malignant tumors [53]. In prostate cancer, the molecules that are able to drive signal transduction through the phosphoinositol 3′-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) and the RAS/mitogen-activated protein kinase pathways are shown to stimulate cell-cycle progression and proliferation of prostate cancer cells, resulting in the conferment of aggressive phenotypes [54]; thus, these molecules and downstream pathways could be promising biomarkers for predicting therapeutic outcomes in patients with prostate cancer.

McCall et al. reported the interesting findings using clinical specimens that upregulation of the PI3K/Akt pathway is associated with phosphorylation of the AR during development of castration-resistant prostate cancer [55]. Similarly, Dai et al. also showed the activation of at least one component of the mTOR signaling pathway in most patients with prostate cancer, which was significantly proportional to clinicopathological variables, including serum PSA level, Gleason score, and pathological T stage [56]. Furthermore, caveolins, which act as regulators of signal transduction, have also been assessed for their prognostic values in prostate cancer, and overexpression of caveolin-1 was demonstrated to be related to an increase in biochemical recurrence in patients undergoing radical prostatectomy [57].

## Other Biomarkers

In addition to possible biomarkers described above, there have been a number of molecules showing close association with prognosis in prostate cancer patients, such as cellular

adhesion-related markers, angiogenesis-related markers, epithelial-mesenchymal transition (EMT)-related markers, cytokines, and epigenetic markers [58–62]. For example, Gravdal et al. reported that cadherin switching characterized by low E-cadherin and high N-cadherin expression indicated a strong relation to biochemical recurrence in patients after radical prostatectomy [58], while microvessel density (MVD) in prostate cancer specimens has been shown to be an prognostic predictor in patients undergoing radical prostatectomy; that is, biochemical recurrence was likely to develop in patients with high MVD disease [59]. Inflammatory cytokines are currently regarded as promising biomarkers in several types of malignant tumors [63]. Of these, interleukin-6 (IL-6), a pleiotropic cytokine involved in various pathophysiological processes, has also been shown to be a potential factor having strong protumorigenic activity through the modulation of growth, angiogenesis, invasion, metastasis, and apoptosis in various types of malignant tumors, including prostate cancer [64]. In addition, circulating levels of the IL-6 and its receptor have been found to be elevated proportional to features of aggressive prostate cancer, such as that with higher Gleason score, advanced stage, and decreased survival [60].

## Novel Approaches for Identifying Useful Biomarkers

### Discovery of Biomarkers Using Microarray

In recent years, microarray technology has been widely used for evaluating the complex molecular aberrations involved in cancer development at a genome-wide scale [65]. In the field of prostate cancer research, microarray expression profiling studies have been performed and identified a number of genes with differential expression, including α-methylacyl-CoA racemase (AMACR), enhancer of zeste homolog 2 (EZH2), TMPRSS2-ERG, miR-221, and miR-141, in several settings, such as nonmalignant versus malignant prostate tissues, localized versus metastatic prostate cancer tissues, and hormone-naive versus castration-resistant prostate cancer tissues [66–70]. Although variation among outcomes from different studies should be overcome, data on such genes could be a valuable source for identification of novel useful biomarkers.

AMACR, an enzyme involved in oxidative metabolism and synthesis of branched chain fatty acids, is one of the first genes that were identified as consistently overexpressed in prostate cancer tissue compared with benign prostate tissue by microarray expression profiling [68]. In addition, Rubin et al. reported that low AMACR expression in localized prostate cancer correlated with biochemical recurrence and cancer-specific death [69]. Another major discovery achieved by microarray technology is the detection of gene fusions between the androgen-regulated transmembrane serine protease, TMPRSS2, and the Ets family transcription factor genes, ERG and ETV1. It has been shown that approximately 60 % of prostate cancers harbor Ets gene fusions, and of these fusion genes, TMPRSS2: ERG has been found to have a close association with high Gleason score, metastasis, and poor survival [70].

### Development of Urine Biomarkers

In recent years, intensive efforts have been made to discover biomarkers using urine samples from patients with prostate cancer, since noninvasive urine-based tests might be particularly attractive for carrying out large-scale screening. To date, there have been some promising urine biomarkers in prostate cancer, such as glutathione-S-transferase P (GSTP1), PCA3, AMACR, annexin-3, metalloproteinase, sarcosine, and telomerase activity [71–73]. As described above section, of these urine candidates, the PCA3 urine test is one of the best tests to supplement serum PSA, and it has proven clinical relevance, providing diagnostic accuracy superior to traditional serum biomarkers [24]; however, the prognostic significance of the PCA3 urine test remains unknown.

The loss of GSTP1 expression due to promoter hypermethylation is one of the most common molecular abnormalities in prostate cancer [74]. To assess the prognostic value of this gene as a urine biomarker, Woodson et al. analyzed aberrant methylation of GSTP1 in urine sediment DNA and observed a high frequency of GSTP1 methylation in the urine specimens from men with advanced-stage cancer [75]. It would be an interesting approach to identify urine biomarkers using proteomic or metabolomic profiling, which enables analyses of alterations in their posttranslational modifications and total protein expression levels [71]. Of several markers identified this strategy, sarcosine, an N-methyl derivative of the amino acid glycine, is one of the most promising biomarkers predicting the prognosis of patients with prostate cancer [76].

### Introduction of Biomarkers into Conventional Nomograms

Nomograms are multivariable tools that combine clinical as well as pathological data to provide physicians with various risks for individual patients. Although several nomograms have been introduced into the field of prostate cancer [3, 4], considering unique biological features of prostate cancer characterized by the heterogenous genetic backgrounds, it would be difficult to exactly predict clinical outcomes in patients with prostate cancer using limited conventional

**Table 15.1** Lists of major biomarkers as candidates for predicting therapeutic outcomes in patients with prostate cancer

| Biomarker | Classification | References | Biomarker | Classification | References |
|---|---|---|---|---|---|
| PSA | PSA-derived | [11–16] | AR | Signal transduction-related | [51, 55] |
| PSA density | PSA-derived | [17] | mTOR | Signal transduction-related | [56] |
| PSA velocity | PSA-derived | [17] | Caveolin-1 | Signal transduction-related | [57] |
| Percent free PSA | PSA-derived | [18–20] | HER-2 | Signal transduction-related | [26] |
| PSMA | Prostate-specific | [21] | EZH2 | Signal transduction-related | [54] |
| PSCA | Prostate-specific | [21] | E-cadherin | Angiogenesis-related | [58] |
| KLK2 | Prostate-specific | [21–23] | N-cadherin | Angiogenesis-related | [58] |
| PCA3 | Prostate-specific | [24, 25] | MVD | Angiogenesis-related | [59] |
| Bcl-2 | Apoptosis-related | [29, 30] | GSTP1 | Epigenetic | [74, 75] |
| Bax | Apoptosis-related | [30] | TMRPSS2:ERG | Epigenetic | [70] |
| Bcl-xL | Apoptosis-related | [30] | TMRPSS2:ETV1 | Epigenetic | [70] |
| p53 | Apoptosis-related | [26, 51] | IL-6 | Cytokine | [60, 64, 77] |
| MDM2 | Apoptosis-related | [26] | TGF-β1 | Cytokine | [77] |
| Clusterin | Apoptosis-related | [34–38] | miR-221 | MicroRNA | [66] |
| HSP27 | Apoptosis-related | [39, 40, 51] | miR-141 | MicroRNA | [66] |
| p16 | Cell-cycle-related | [46] | MMP2 | Cell invasion | [51, 61] |
| p21 | Cell-cycle-related | [49] | MMP9 | Cell invasion | [51] |
| p27 | Cell-cycle-related | [47, 48] | AMACR | Oxidative stress | [68, 69] |
| Aurora-A | Cell-cycle-related | [50] | Annexin-3 | Immune response | [71] |
| Ki-67 | Cell-cycle-related | [51] | Telomerase activity | Cell immortality | [71] |

parameters alone. Therefore, it has recently been investigated whether a significant improvement in predictive accuracy could be achieved by adding biomarkers to established parameters in the nomogram [77–79].

In this context, Kattan et al. added preoperative plasma IL-6 soluble receptor and transforming growth factor-β1 (TGF-β1) levels to the standard nomogram for predicting risk of biochemical recurrence following radical prostatectomy using pretreatment PSA values, clinical stage, and biopsy Gleason score [77]. They reported an improved prognostic ability of the nomogram with these additional biomarkers; that is, the novel nomogram resulted in the increase in predictive accuracy of biochemical recurrence from 75 to 83 %. Similarly, Stephenson et al. analyzed gene expression profiling using microarray technology in prostate cancer specimens from patients undergoing radical prostatectomy [79]. In this study, models combining conventional parameters and gene expression profile could accurately classify 89 % of patients in terms of the development of postoperative biochemical recurrence with a predictive accuracy superior to the standard nomogram.

## Conclusions

Prostate cancer is shown to have a biologically heterogeneous nature, and the prognosis of patients after a diagnosis of this disease is extremely variable. Accordingly, despite the widespread use of the PSA test, it would be absolutely necessary to identify molecular biomarkers for exactly predicting the clinical course of this disease in an individual patient. As summarized in Table 15.1, based on recent intensive studies for the identification of novel biomarkers for prostate cancer using newly developed attractive approaches, a number of candidate biological markers have been discovered. Then, the relevance of these candidate markers has been validated in clinical setting, and some of them showed promising outcomes. Furthermore, the integration of selected biomarkers with conventional clinicopathological variables has been reported to produce predictive models showing outcomes superior to standard predictive system, like a nomogram. Collectively, these findings suggest that despite several limitations to be overcome prior to the introduction of these biomarkers into clinical practice of prostate cancer, once strictly evaluated, such biomarkers may help provide variable information on clinical decision-making during treatment of patients with prostate cancer.

# Prostate Tissue Banking

16

Harveer Dev, Prasanna Sooriakumaran,
and Ashutosh K. Tewari

As the most common non-dermatologic malignancy affecting males in the Western world, and the second leading cause of male cancer-related deaths, the importance of prostate cancer research needs little justification [1]. Epidemiologic reports have described the significant heritability of such malignancies, with one twin-study attributing 42 % (CI 29–50 %) of prostate cancer cases to heritable factors [2]. Genome-wide linkage analyses of germline single nucleotide polymorphisms (SNPs) continue to uncover many low-risk genetic associations with prostate cancer [3]. These findings are being supplemented with expression arrays in an effort to identify individual somatic mutations such as TMPRSS2-ERG gene fusions [4] as well as more global gene expression profiles.

Despite these advances, the low predictive function of such screening tests (with ROCs of 0.61–0.63 for current SNP-based models) [3, 5] suggests that the real clinical value may be found in identifying markers which distinguish aggressive from latent disease in men already found to have prostate cancer. Indeed, gene mutations are beginning to emerge which correlate with disease aggressiveness [6] and, in combination with unique molecular signatures, may yield invaluable prognosticators to help guide clinical decisions.

This sophisticated genetic research places a great reliance upon the accumulation of large amounts of high-quality prostatic tissue and has led to the development and refinement of *biobanking* protocols which seek to provide pathologic samples without compromising the patient's histopathologic evaluation. At the heart of a well-developed prostate biobank is the proficiency and regularity with which the protocol can be implemented, and this is in no small part a function of the expertise of the urology and pathology services which underlie it. We have benefited from a high throughput of patients undergoing radical prostatectomy at our institution and are able to describe a validated biobanking protocol, which has been used to collect over 2,000 prostate specimens.

## Patient Consent and Ethical Approval

Before a biobank can be established, the appropriate ethics approval must be sought, in keeping with local and national governance. In the USA, Institutional Review Board (IRB) approval is obtained in order to support specific research endeavors; in the case of the *Weill Cornell Medical College* (*WCMC*) *radical prostatectomy biobanking protocol*, this was obtained in order "to collect prostate samples after robotic prostatectomy for the treatment of clinically localized prostate cancer."

Each patient must receive adequate explanation of tissue biobanking and the details of the consent form, allowing ample time for an appropriately qualified member of the biobanking team to answer any questions which the patient may have.

## Specimen Procurement

A fundamental requirement of a successful tissue biobank rests with the method of tissue collection, its reliability, consistency, and impact on specimen quality. The WCMC protocol relies upon prostate specimens derived entirely from a single institution and

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_16, © Springer-Verlag London 2013

led by a single surgeon (AKT). An Advanced Robotic Technique™ is employed to complete the radical prostatectomy, centered on delicate handling of prostatic and periprostatic tissues in order to preserve the trizonal neural architecture while ensuring maximal cancer clearance [7]. Once the prostate is devascularized, the vesicourethral anastomosis is completed before extirpating the prostate within an EndoCatch bag (Covidien, North Haven, CT). Suspicious nodules and nerve-sparing details are recorded before rapidly transporting the sample to the pathology department to be received by a technician for immediate preparation.

## Specimen Preparation

Once received, the prostate is weighed and correctly orientated using permanent black and green ink to highlight the left and right sides, respectively. The apex and base are shaved and sectioned perpendicularly to the distal and proximal inked margins. The prostate is then cut in 5 mm serial sections perpendicular to the urethra and sequentially labeled A to D–H (depending on prostate size), starting from apex to base. Further preparatory steps require the additional division of each section into four (or six) equal parts (depending on the size of the sections) in order to place the samples into individual cassettes. Alternate sections (i.e., A, C, E, and G) and samples from the surgical margins are formalin-fixed for histopathologic evaluation, allowing the remaining alternate prostate samples (i.e., B, D, F, and H) to be coated in optimal cutting temperature (OCT) media (Sakura Finetek, Torrance, CA) prior to snap freezing in liquid nitrogen. Typically, two to three sections of the biobanked specimens are retained, equating to approximately 40 % of the total prostate body per specimen. This ensures enough tissue remains for diagnostic evaluation without compromising gross tissue architecture [8] and the ability to select specific cell populations for microarray studies.

The biobanked cassettes are labeled with unique identifiers in order to sufficiently de-identify samples and are then stored in a plastic bag at −80 °C in a specifically designated secure tissue laboratory. The storage of adjacent biobanked sections permits the retrieval of stored samples from the tissue laboratory in the unlikely event that an area of suspicion is only identified at the border of a sample section.

This process of specimen collection is summarized in Fig. 16.1.

## Pathological Characterization

The utility of biobanked specimens can be further enhanced by preparing hematoxylin- and eosin-stained microscopic slides for each biobanked tissue sample. Each slide is evaluated for cancer grade, stage, and margin status. Furthermore, the demarcation of malignant and benign as well as epithelial and stromal compartments permits accurate notation of tissue histology of the biobanked samples. This is vital for utilization of those samples for future molecular biologic research.

## Robotic Prostatectomy Biobank Database

In addition to the pathologic data on the series of samples for each prostate specimen, detailed pre-, intra-, and postoperative data are also collected and stored in an encrypted biobank database (Microsoft Access, Redmond, WA). Variables stored include patient age, body mass index, preoperative prostate-specific antigen, console time, total operative time, estimated blood loss, grade of nerve sparing, prostate volume, the presence of any positive surgical margin, Gleason score, pathologic stage, and storage time.

## Quality Assessment

The ability of any biobank to provide useful tissue for prostate cancer genetic studies is determined by the quality of the nucleic acid material within each sample. In order to validate our tissue biobanking process, we have performed a quality assessment of samples procured by the above protocol, using advanced electrophoretic techniques. We obtained the RNA integrity numbers (RIN) for 142 biobanked specimens and obtained a mean RIN of 7.25 (standard deviation 1.64), with 73 % of sample demonstrating a RIN ≥7, and hence of sufficient quality for genetic studies [9].

A general belief of RNA quality diminishing with ischemic time hypothetically raised doubts as to the appropriateness of robotic platforms for the collection of high-quality prostate specimens, given the extended periods of ischemia in which samples are subjected to between devascularization and extirpation. However, our validation study not only confirmed the attainment of high-quality specimens using such a technique but, using multivariate regression analysis, established the lack of a relationship between warm ischemia time (averaging 120 min, standard deviation 30 min) and RIN (unstandardized coefficient −0.010, $p=0.147$) [8]. Quality assurances are fundamental to assessing the suitability of collected tissue for studies which require different standards of cellular and genetic material.

### Conclusions

A successful biobank requires the concerted efforts of both urologic and pathologic services in order to produce a consistent and reliable process of tissue procurement, processing, and storage. The specimens collected by the

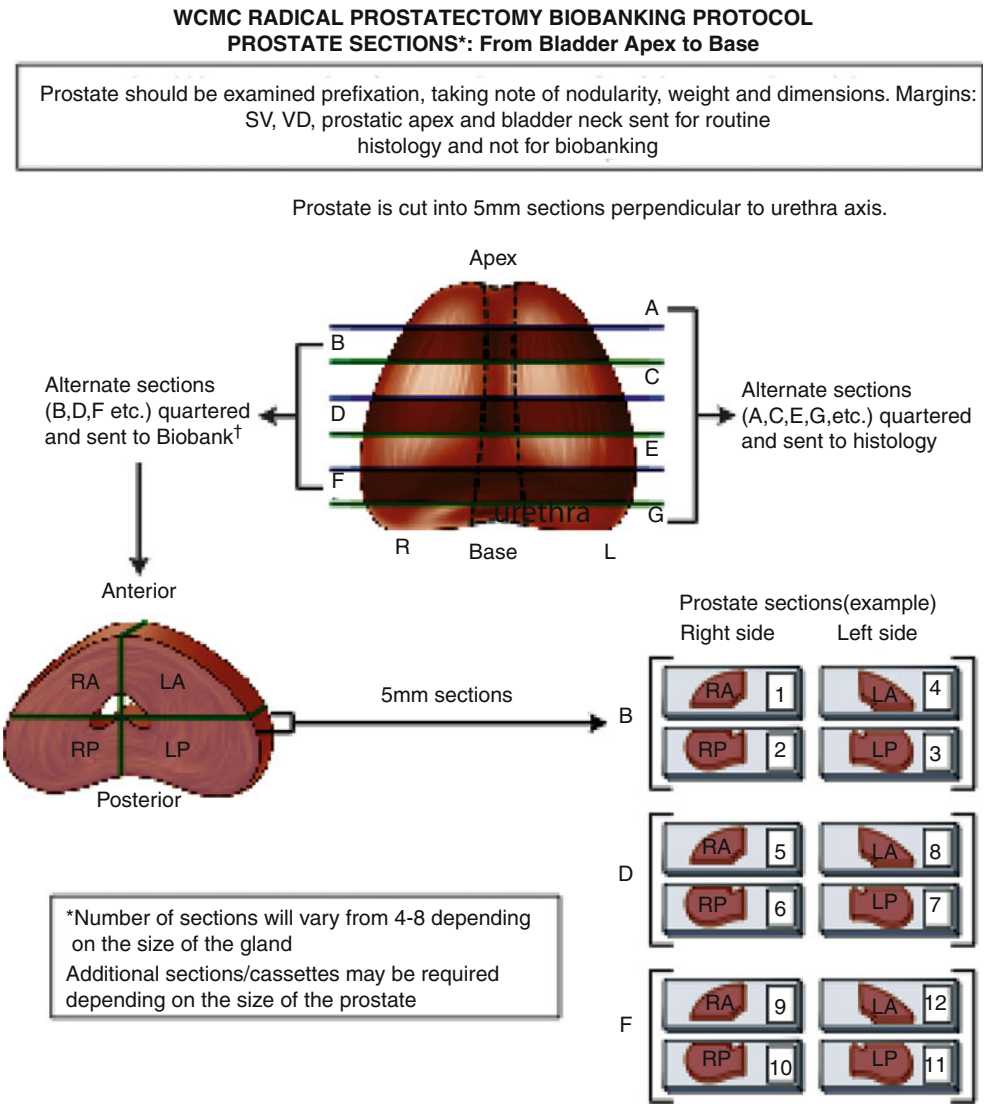

**Fig. 16.1** WCMC radical prostatectomy biobanking protocol. Prostate sections: from bladder apex to base

protocol should be validated in order to verify the quality of the tissue and its appropriateness for the studies which it is being used for. We are able to demonstrate the suitability of the robotic radical prostatectomy procedure for procuring specimens which are suitable for high-quality genetic research.

## Introduction

Prostate cancer is the most common malignancy and the second most common cause of cancer-related mortality in men. Despite the downstaging we have observed over the last 20 years with the widespread use of PSA screening, we continue to observe conflicting data regarding its effect on prostate cancer survival [1, 2]. While treatment for localized prostate cancer is highly successful, about 30–50 % of men will experience a biochemical failure within 10 years from the primary treatment, suggesting that prostate cancer can metastasize relatively early in the course of disease [3–6]. This is supported by the discovery of circulating prostate cancer cell in bone marrow biopsy of patients with apparently localized disease [7]. A portion of men with biochemical failure will develop locally recurrent disease, and as many as two-thirds will have evidence of osseous metastatic involvement [8–11]. In the study by Pound et al. after primary surgical treatment, 15 % of patients developed biochemical recurrence. The median actuarial time to metastases was 8 years from the time of PSA relapse. Once men developed metastatic disease, the median survival time to death was 5 years [12]. If men develop castrate resistant metastatic disease, the 1-year survival is about 24 % with a median survival of only 8-18 months [13]. The hormone-refractory state is believed to occur via bypassing or sensitizing the androgen receptor (AR) signaling pathway. Patients with biochemical recurrence and metastatic disease are left with imaging modalities that neither provide enough information to change management nor are able to predict patient's prognosis or evaluate patient's treatment progress. The reason is that traditional imaging techniques are focused on evaluating the anatomy rather than the function of prostate cancer. Unlike traditional structural imaging, molecular imaging takes advantage of the functionality of tumor. These imaging techniques can theoretically provide functional information regarding prostate cancer. In this chapter, we review the current literature on the potential and emerging role of molecular imaging in prostate cancer.

## Molecular Mechanism of Various Markers

### FDG

Several hallmarks of cancer include self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis, limitless replicative potential, sustained angiogenesis, tissue invasion and launch of metastasis envoys, evasion of tumors from the immune system, and increased glucose metabolism [14]. The ability of FDG–PET to detect cancer is based on the latter hallmark (Warburg effect). The relationship between tumor growth and the inefficient energy production from glucose metabolism is not well understood but may be explained in terms of adaptation to hypoxia through upregulation of glucose transporters and increased enzymatic activity of hexokinase [15].

Glucose transporter (GLUTx, currently approved gene symbol is SLC2Ax) is the first rate-limiting step for glucose metabolism that allows energy-independent glucose transport across the cell membrane down the concentration gradient, while hexokinase-II phosphorylates glucose to glucose-6-phosphate. Similarly, FDG is phosphorylated to

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_17, © Springer-Verlag London 2013

FDG-6-phosphate but, contrary to glucose-6-phosphate, it cannot be metabolized further in the glycolytic pathway and becomes trapped in the cell because of its negative charge and the very low activity of the reverse enzyme, glucose-6-phophatase, in most cancers.

GLUT1 mRNA expression has been assessed in the androgen-independent cell lines DU145 and PC-3 and the androgen-sensitive cell line LNCaP [16]. The poorly differentiated androgen-independent cell lines showed higher mRNA expression than the well-differentiated androgen-sensitive cell line, suggesting that GLUT1 expression may be directly related to the malignancy grade [17]. Another study evaluated the expression of several hypoxia-associated genes within benign prostatic hyperplasia (BPH) and human prostate cancer tissue (Gleason score, 5–10). GLUT1 gene expression was not only significantly higher in the tumor than in BPH but also correlated directly with Gleason score ($R=0.274$; $P=0.026$), corroborating the direct relationship between GLUT1 expression and tumor grade [18]. Castration has been shown to decrease glucose metabolism in prostate tumors [19–21]. This results in accumulation of higher levels of FDG in castrate resistant tumors than in castrate sensitive tumors as demonstrated by Jadvar et al. [19]. Because of this unique quality, it is believed that FDG–PET imaging can be used to monitor androgen deprivation therapy and to potentially predict an impending hormone-refractory state in patients with castrate responsive disease.

## Choline ([18F] or [11C])

Increased choline uptake in prostate cancer cells may be explained by increased cell proliferation in tumors and by upregulation of choline kinase in cancer cells. Hallmark of cancer growth is uncontrolled cell proliferation. Choline is believed to participate in cancer growth through two mechanisms, the malignancy-induced upregulation of choline kinase that leads to the incorporation and trapping of choline in the form of phosphorycholine and the collection of large amounts of phospholipids, in the form of phophatidylcholine, which may induce signaling processes within cells for cell proliferation and differentiation [22, 23]. Choline uptake in prostate tumor appears to be uncorrelated to cellular proliferation but may be affected by hypoxia [24]. It has been demonstrated that under aerobic conditions, both androgen-sensitive and androgen-independent prostate tumors show higher choline uptake than that with radiolabeled acetate or with FDG. However, during hypoxia, the tumor uptake with FDG and acetate is higher than that with choline [25]. 11C-choline has a shorter half-life (20 min) that requires an onsite cyclotron facility and generally displays no or little bladder urine activity [26].

## Acetate ([18F] or [11C])

The biological basis for radiolabeled acetate uptake in tumors is likely related to increased fatty acid synthesis. 11C-acetate is actively transported across cell membranes through monocarboxylate transporters. After conversion to acetyl-CoA in mitochondria, acetyl-CoA enters the TCA cycle in tissues with high rates of oxidative metabolism, resulting in carbon dioxide production. Acetate participates in cytoplasmic lipid synthesis, which is believed to be overexpressed in prostate cancer [27]. The cellular retention of radiolabeled acetate in prostate cancer cell lines is primarily due to incorporation of the radiocarbon into phosphatidylcholine and neutral lipids of the cells [28]. It has been suggested that fatty acid metabolism rather than glycolysis may be dominant in prostate cancer in view of alteration in several enzymes involved in the metabolism of fatty acids and enhanced beta-oxidation pathway [29] Recent in vitro and animal model in vivo studies by the group at Washington University in St. Louis confirmed the extensive involvement of the fatty acid synthesis pathway in 11C-acetate uptake in prostate tumors as an imaging marker for fatty acid synthase expression [30]. Fatty acid synthase is the major enzyme required for converting carbohydrates to fatty acids, and its upregulation plays a role in prostate tumor progression in the transgenic mouse prostate model [31]. A suitable 3-compartment, 3-parameter model for 11C-acetate uptake kinetics in prostate cancer and the radiation dosimetry in humans has been reported [32, 33].

## In-111-Capromab Pendetide (Prostascint)

Originally known as murine monoclonal antibody CYT-356, capromab recognizes prostate-specific membrane antigen (PSMA). PSMA is a non-secreted protein anchored to the plasma membrane of prostate cancer cells. Even though it is expressed in certain non-prostate cells, such as small intestine, proximal renal tubules, and salivary glands [34], it is expressed at 100–1,000× lower level than in prostate tissue [35]. Not only is it expressed at significant elevated concentration by prostate cancer cells, its expression is correlated with tumor grade [36, 37]. Despite various advantages offered by capromab, it suffers from a major weakness; the antibody is targeted against the intracellular portion of the PSMA motif. As a result, capromab has no binding site on the extracellular and is only able to bind to cells that have disrupted cell membrane, such as necrotic cells. For this reason, capromab could not be used to help identify patients with early bony metastasis. Unlike soft tissue lesions where cells more commonly outgrow their blood supply resulting in cell death, micrometastases in marrow are well perfused with intact cells that do not allow for capromab binding to

the intracellular portion of the PSMA moiety. Currently, capromab scan is FDA approved to detect small volume soft tissue disease, such as in the lymph nodes.

## Localized Disease

### FDG-PET

Currently, the role of FDG-PET in patients with localized disease is limited. The major barrier to its use is the strong activity in the urine found in the adjacent urinary bladder [38]. The authors found only 4 % sensitivity for detecting primary prostate cancer with FDG-PET. Attempts have been made to ameliorate FDG activity from urine by performing continuous bladder irrigation during the scan, but the results were not encouraging [39]. Even if we are able to overcome urinary activity, a comparative study showed that there is no difference in FDG uptake between primary prostate cancer, benign prostatic hyperplasia, recurrent prostate cancer, local scar tissue, or post-radiation inflammation [40]. These findings were confirmed by other authors [41–43].

### Choline

There is conflicting data on choline's ability to differentiate between normal prostate tissue, BPH, and prostate cancer. Sutinen et al. observed that there is no difference in 11C-choline uptake in prostate cancer and benign prostate tissue [26]. The authors also did not find any association between uptake of 11C-choline and prostate cancer aggressiveness based on histological grade, Gleason score, volume of the prostate, or PSA. On the other hand, Li et al. analyzed choline PET data from 49 patients with prostate lesions visually and semiquantitatively by measuring maximum standardized uptake value (SUV) of the prostate lesions and the muscles and calculating their P/M ratios. The authors found that 11C-choline PET-CT is able to differentiate between BPH and prostate cancer. It had a sensitivity of 90.5 % and a specificity of 85.7 % and a negative predictive value of 92.3 % for differentiating BPH tissue from prostate cancer [44]. When comparing 11C-choline PET to MRI, Testa et al. found that the sensitivity and specificity for detecting prostate cancer were 55 and 86 % for PET-CT, 54 and 75 % for MRI, and 81 and 67 % for spectroscopic MR, respectively [45]. The authors concluded that 11C-choline PET-CT demonstrated a lower sensitivity relative to spectroscopic MR alone or combined with MRI. The conflicting results may be due to differing methodology in data collection or analysis and in patient population. Currently, there is ongoing study to provide enhanced image fusion software to accurately register anatomic MRI, diffusion MRI, 11C-choline PET, and histologic section of prostate gland [46].

In terms of staging, a group of 57 intermediate or high-risk prostate cancer patients underwent 11C-choline PET/CT prior to radical prostatectomy with extended pelvic lymphadenectomy [47]. The authors found on patient analysis, the sensitivity, specificity, PPV, and, NPV were 60.0, 97.6, 90.0, and 87.2 %, respectively; while on node analysis, these values were 41.4, 99.8, 94.4, and 97.2 %, respectively. There was a significant difference in the mean diameter of metastatic deposit of true-positive and false-negative lymph nodes (9.2 cm vs. 4.2 cm, $p=0.0001$). Compared to the Briganti et al. [48] and the Kattan [49] nomogram, PET/CT showed higher specificity and accuracy than the nomograms; however, the areas under the curve were not statistically different. These promising results suggest that an improved 11C-choline PET/CT may one day be incorporated into the preoperative workup for high-risks patients.

18F-fluorocholine offers no significant improvements over 11C-choline for primary diagnosis of prostate cancer. Schmid et al. reported no significant difference in 18F-fluorocholine uptake between malignant and benign lesions [50]. Disease was missed in up to 75 % of patients with elevated PSA [51]. Semiquantitative analysis performed with maximum SUV was not helpful in the discrimination of malignancy with significant overlap with benign prostate tissue and normal prostate tissue. In the same study, the use of dual-phase protocol offered no clear improvements in discriminating between benign and malignant tissue. This finding contradicts an earlier study by Kwee et al. on 26 patients (15 with newly diagnosed prostate cancer, 2 with recurrent prostate cancer, 6 with no evidence of prostate cancer recurrence after treatment, and 3 with no history of prostate cancer). It suggested that dual-phase protocol used in conjunction with 18F-fluorocholine may be helpful in distinguishing malignancy from benign tissue in view of the observation that malignant tissue displays stable or increasing tracer accumulation, whereas benign tissue shows decreasing uptake [52].

In terms of staging, Beheshti et al. prospectively evaluated 132 patients with intermediate-risk prostate cancer and found that 18F-fluorocholine PET/CT demonstrated sensitivity, specificity, and positive and negative predictive values of 45, 96, 82, and 83 %, respectively, for detecting malignant lymph nodes [53]. Husarik et al. evaluated 115 lymph node samples from 25 patients [54]. Only one of these lymph nodes showed pathologic 18F-fluorocholine uptake and was proven to be a metastasis of greater than 1 cm. Four lymph nodes that did not show accumulation turned out to contain metastatic cell with the overall tumor load measuring less than 0.5 cm. Because of the inability to detect micrometastasis to the lymph nodes, the authors concluded that the results were discouraging for 18F-fluorocholine PET/CT to evaluate nodal status in the preoperative setting. However, it must be noted that detection of micrometastases is challenging for any imaging modality, and its impact on long-term outcome remains unsettled.

## Acetate

The literature on acetate PET for the purpose of primary prostate cancer detection is very limited. Because of the lack of accumulation of 11C-acetate in urine, it offers significant advantages over FDG. Various studies have been performed comparing 11C-acetate and FDG-PET. In a study by Oyama [55], 18 patients with prostate cancer underwent both 11C-acetate and 18F-FDG PET scans. Adenocarcinoma of the prostate showed variable uptake of 11C-acetate, with SUVs ranging from 3.27 to 9.87. In contrast, SUVs for 18F-FDG ranged from 1.97 to 6.34. By visual inspection, 11C-acetate uptake in primary prostate tumors was positive in all patients, whereas 18F-FDG accumulation was positive in 15 of 18 patients. The authors concluded that 11C-acetate PET was more sensitive in detection of prostate cancer than 18F-FDG PET. However, 11C-acetate was not able to differentiate benign prostate tissue from prostate carcinoma. In 36 patients (6 with prostate cancer, 21 with no prostate pathology, and 9 with benign prostate hyperplasia), Kato et al. showed that the prostate was clearly visualized and distinguished from adjacent organs in PET images in most of the cases [56]. The SUV of the prostate ($2.6 \pm 0.8$) was significantly higher than that of the rectum ($1.7 \pm 0.4$) or bone marrow ($1.3 \pm 0.3$) ($P < 0.0001$ in each case); the difference in the SUV between subjects aged ≥50 with normal prostate or with BPH and the patients with prostate cancer ($1.9 \pm 0.6$) was not statistically significant. The authors concluded that 11C-acetate uptake is not specific for prostate cancer and not well suited as a screening tool. From a clinical planning standpoint, early results from Seppala et al. revealed that 11C-acetate PET can be used to define the intraprostatic lesions in prostate cancer and in combination with a simultaneous integrated IMRT; the defined areas can theoretically be treated to ultra-high doses without increasing the treatment toxicity [57].

## Capromab

There is currently no indication to use capromab scan to diagnose prostate cancer. One study from Duke showed that it did not localize prostate cancer to a particular quadrant based on comparison with radical prostatectomy specimens [58]. Mouraviev et al. performed a prospective comparison between 111In-capromab pendetide scans and final pathology in 25 hormone-naïve men with clinical localized prostate cancer. The authors found that the capromab scan provided a sensitivity of 37–87 % for four quadrants with 0–50 % specificity. But in the preoperative staging setting, several studies have evaluated capromab's ability to detect disease in lymph nodes. In a small series, 22 preoperative patients with heterogenous risk categories of prostate cancer (PSA range 3.9–33 ng/mL and Gleason range 6-9) underwent capromab scan to evaluate obturator and iliac lymph node involvement. The scan yielded a sensitivity of 17 %, specificity of 90 %, negative predictive value of 94 %, and a positive predictive value of 11 % [59]. In a larger series looking specifically at intermediate and high-risk patients, Manyak et al. performed capromab scans on 152 patients prior to pelvic lymph node dissection. The authors found that the sensitivity and specificity for lymph node detection was 62 and 72 %, respectively. In comparison, the sensitivity of CT and MRI was 4 and 15 %, respectively. Unfortunately, given the positive predictive value of 62 % and a negative predictive value of 72 %, nearly a third of lesions were missed by capromab scans. For the purpose of predicting biochemical failure in the pre-radiation treatment setting, Ellis et al. evaluated the use of capromab pendetide scan with computerized tomography to detect occult metastatic disease in patients about to undergo radiotherapy [60]. The authors found that extra-periprostatic metastatic disease on SPECT/CT significantly predicted a 4.2-fold great risk and a 4.5-fold great risk of failure than organ confined disease adjusting for treatment and risk group. The intermediate risk group appears to benefit most from the scans. While the study provides some intriguing data, it must be confirmed with a larger cohort of patients with longer follow-ups.

## Biochemical Failure

About 30–50 % of patients can experience biochemical failure after definitive treatment for prostate cancer. Radical retropubic prostatectomy is associated with overall 5- and 10-year actuarial biochemical progression-free survival rates ranging from 59 to 84 % and from 47 to 75 %, respectively [3–6]. Clinical and pathologic stage, pretreatment PSA, and pathologic Gleason score are all predictors of progression after surgery [61]. Accurate delineation of local versus metastatic disease is critical for selection of appropriate therapy, to irradiate the prostatic fossa in those patients with presumed local recurrence or to provide systemic therapy for those with disease outside the fossa.

## FDG

Multiple studies have suggested that FDG-PET may have a role in the evaluation of patients with biochemical failure (Fig. 17.1). In one of the very first studies, Sanz et al. evaluated ten patients with biochemical recurrence after radical prostatectomy, radiotherapy, or orchiectomy [62]. The authors reported that FDG-PET was able to show recurrence of prostate cancer more clearly than did CT in two patients; both patients had recurrence in soft tissue. These findings were further reinforced by Chang et al. who performed FDG-PET on 24 patients with biochemical failure after either radical prostatectomy or radiation therapy for localized prostate

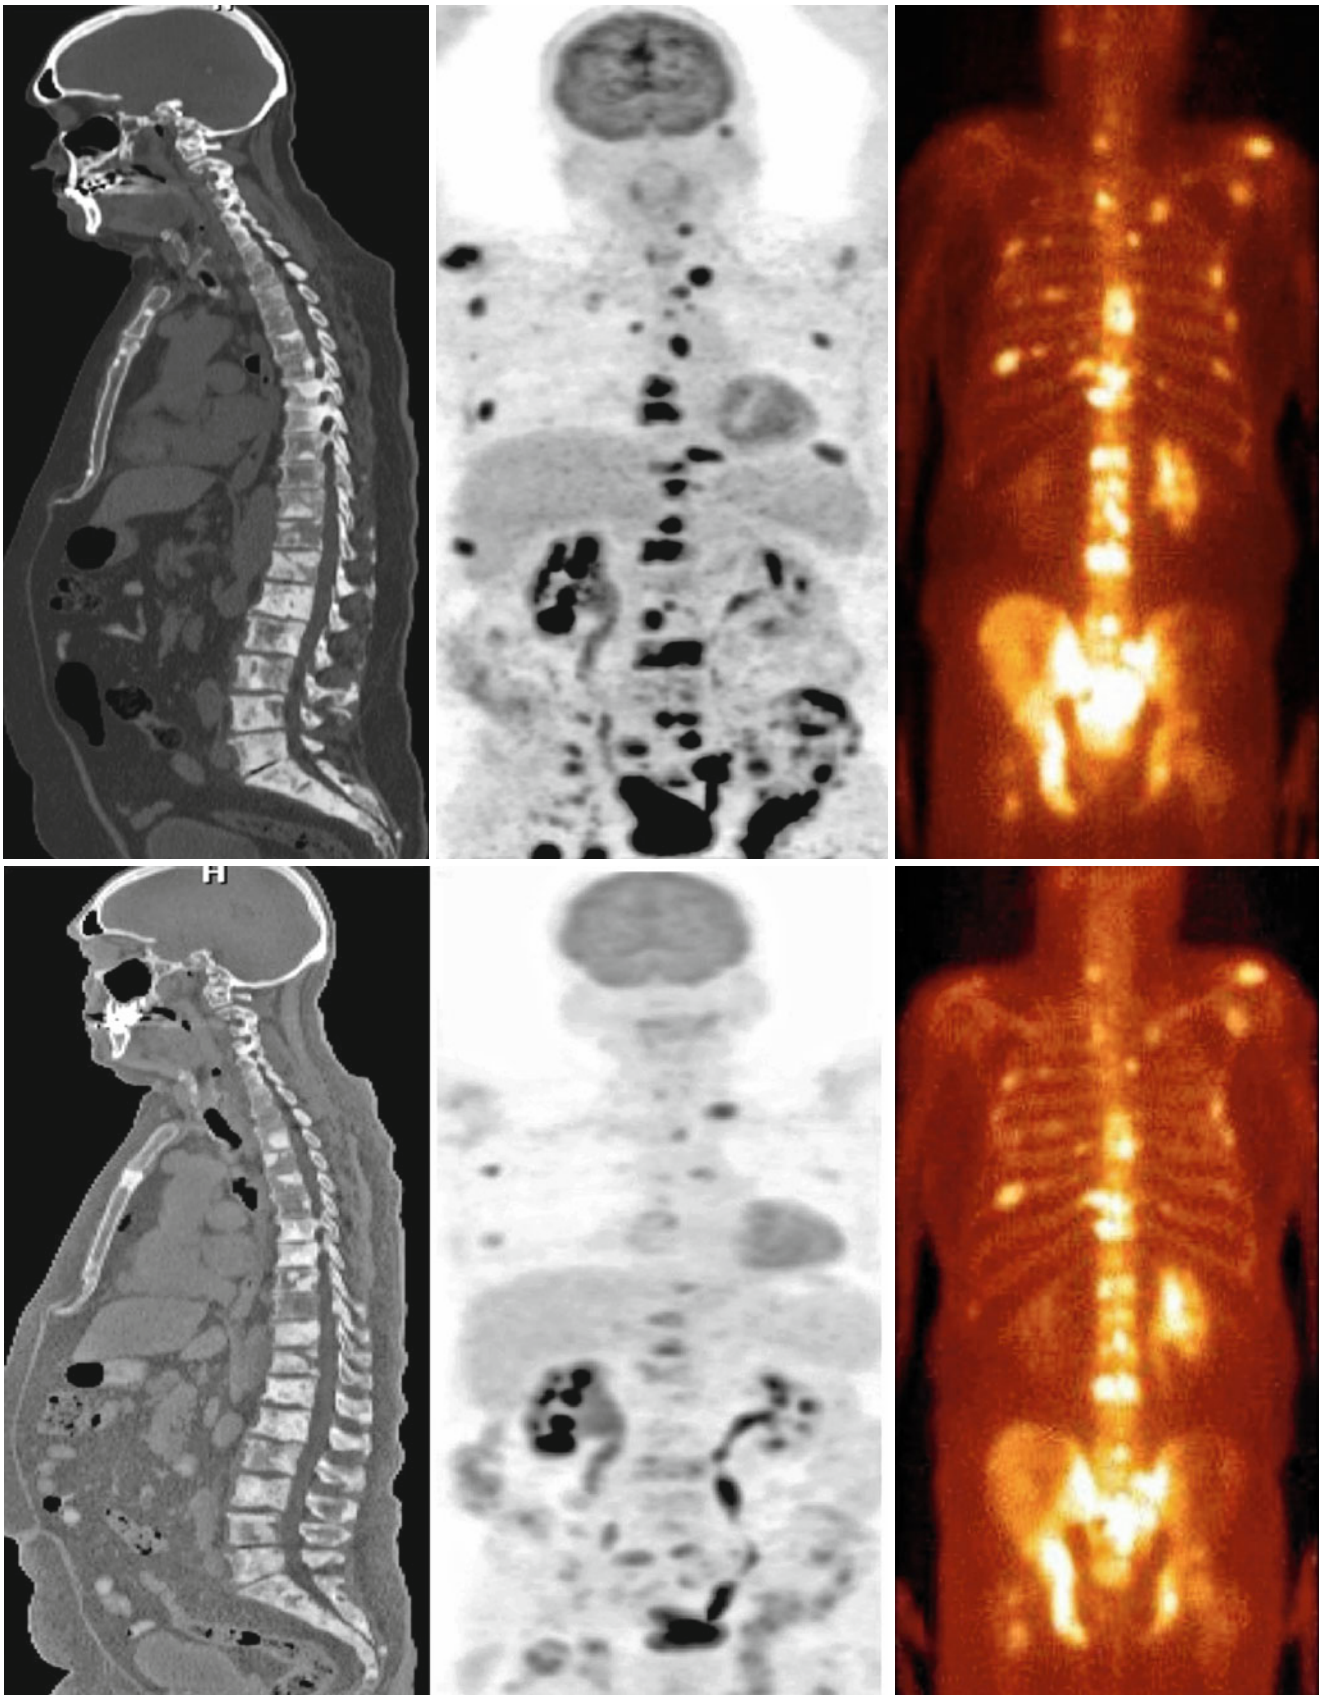

**Fig. 17.1** Midsagittal CT scan at bone window level (*left*), 18F-FDG PET scan (*middle*), and 99mTc-methylene diphosphonate bone scan (*right*) images of a 63-year-old man with castrate-resistant metastatic prostate cancer before (*top row*) and after chemotherapy (*bottom row*). Note that 18F-FDG PET best demonstrates the favorable response to treatment concordant with decline in serum PSA level (from 223 to 52 ng/mL). Also note that the sclerosis of osseous lesions on CT increase as the corresponding metabolic activities on 18F-FDG PET decline with treatment

cancer prior to pelvic lymph node dissection [63]. All patients had normal CT and whole-body bone scans. Histology revealed that 16 of the 24 patients had lymph node metastases, and increased FDG uptake was found in 12/16 patients. The sensitivity, specificity, accuracy, and positive and negative predictive values of FDG-PET in detecting metastatic pelvic lymph nodes were 75, 100, 83.3, 100, and 67.7 %, respectively. Among patients with bony metastases, Oyama et al. found that there was a tendency for higher FDG uptake accumulation in prostate cancer [39].

In a series looking more specifically at biochemical failure after radical prostatectomy, researchers from Memorial Sloan-Kettering Cancer Center retrospectively evaluated 91 patients who underwent FDG-PET [64]. Local or systemic disease was found in 31 % of patients. Imaging revealed lesions in the prostate bed ($n=5$, all true positives), bones ($n=22$, 20 true positives), lymph node ($n=7$, 6 true positives), and one liver metastasis. Receiver operating characteristic analysis showed that a PSA of 2.4 ng/mL and PSA velocity of 1.3 ng/mL/year resulted in the optimal sensitivity (80 % for FDG-PET positive and 71 % for FDG-PET-negative patients) and specificity (73 % for FDG-PET-positive and 77 % for FDG-PET-negative patients). When compared to capromab scans, one study seems to suggest that FDG-PET may be superior. Seltzer et al. evaluated 45 patients with PSA relapse after treatment for localized prostate cancer and found that FDG-PET had a detection rate of 50 % in all patients with elevated PSA or elevated PSA velocity, greater than 4 ng/mL or greater than 0.2 ng/mL/month, respectively [65]. In the subset of patients who also underwent fine needle aspiration, monoclonal antibody scan was true positive in only 1 of 6 patients, while FDG-PET was true positive in 6 in 9 patients.

## Choline

Similar to FDG-PET, the use of choline PET for evaluation of patients with biochemical failure has been well studied. In one of the first studies, de Jong et al. evaluated 36 patients with localized prostate cancer treated by either radical prostatectomy or by external beam radiation [66]. Choline PET was able to detect the site of recurrence accurately in 78 % of patients after external beam radiation compared to 38 % of patients after radical prostatectomy. It is important to note that no positive PET scans were observed in patients with a serum PSA of less than 5 ng/mL. When comparing choline PET to FDG-PET for patients with biochemical failure, Picchio et al. found that out of 100 patients (77 post-prostatectomy and 23 post-radiation), all except one of 14 choline-PET-positive findings were concordant with conventional imaging and all except 1 choline-PET-negative cases had negative conventional imaging after 1 year [67].

More recent studies sought to determine if choline PET could be utilized for patients with PSA less than 4-5 mg/dL. Krause et al. found that out of 63 patients with biochemical recurrence after primary therapy for prostate cancer, 56 % of them showed a pathological 11C-choline uptake [68]. More importantly, the authors demonstrated a relationship between the detection rate of choline PET/CT and the serum PSA level. The detection rate was 36 % for a PSA-value <1 ng/mL, 43 % for a PSA-value 1 to <2 ng/mL, 62 % for a PSA-value 2 to <3 ng/mL, and 73 % for a PSA-value ≥3 ng/mL. The use of antiandrogen therapy did not affect the detection rate. These findings were confirmed in a study by Giovacchini et al. [69]. After evaluating 358 patients who experienced biochemical failure after prostatectomy for prostate cancer, the authors found that choline PET was positive for recurrence in 161 (45 %) patients. The most common sites of recurrence were in the pelvic lymph nodes (66 %), prostatectomy bed (34 %), and skeleton (29 %). These findings were validated by either histological criteria or follow-up clinical and imaging criteria. The overall sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy were 85, 93, 91, 87, and 89 %, respectively. The authors also correlated positive PET scan results with PSA levels. The percentage of positive scans was 19 % in those with a PSA level between 0.2 and 1 ng/mL, 46 % in those with a PSA level between 1 and 3 ng/mL, and 82 % in those with a PSA level higher than 3 ng/mL. ROC analysis showed that PET/CT-positive and PET/CT-negative patients could be best distinguished using a PSA cut-off value of 1.4 ng/mL. To evaluate the diagnostic value of choline PET/CT in patients with suspected lymph node involvement before salvage lymphadenectomy, Rinnab et al. evaluated 15 patients with rising PSA following primary treatment for prostate cancer [70]. Eight of the 15 patients were found to have positive histology. Despite being a small study, the authors believed that choline PET/CT may be a useful technique in detection of lymph node metastases in patients with biochemical failure. Reske et al. further evaluated the accuracy of choline PET/CT for localizing occult relapse of prostate cancer by comparing 36 patients with and 13 patients without biochemical failure after prostatectomy [71]. In the test group, PET/CT showed true-positive focal lesions with increased choline uptake in 70 % of the patients with histological verification of local recurrence. The sensitivity and specificity of choline PET/CT were 0.73 and 0.88, respectively.

## Acetate

In one of the earliest trials, Kotzerke et al. evaluated 31 patients with biochemical failure after prostatectomy [72]. Transrectal ultrasound biopsies were also obtained. TRUS biopsy revealed recurrence in 18 patients and acetate PET demonstrated local recurrence in 15 out of the 18 patients. No focal acetate uptake was seen in the prostate bed in patients with negative biopsy. In the subgroup of patients with PSA <2.0 ng/dL, five had positive PET findings with four of them verified by biopsy.

Similar to choline PET, it appeared that there is a correlation between PSA level and detection of prostate cancer recurrence with acetate PET. Fricke et al. demonstrated that acetate PET and FDG-PET were able to detect lesions in 83 and 75 % of patients, respectively [73]. A positive correlation was observed between serum PSA level and both acetate and FDG uptake. This data conflicted with the findings from Oyama et al. [74]. After evaluating 46 patients with biochemical recurrence (30 post prostatectomy, 16 post radiation), the authors found that while 59 % of patients with serum PSA >3 ng/dL had positive finding on acetate PET, only 4 % of patients with serum PSA levels <3 ng/dL had positive findings. Furthermore, acetate PET had higher sensitivity for detecting metastatic lesions with positive finding in 59 % of patients compared to only 17 % using FDG-PET.

In an attempt to increase the accuracy of detection, Wachter et al. performed fused acetate-PET images with either CT or MRI in patients with biochemical failure [75]. Fusion images were able to precisely define the anatomic location of abnormal uptake in 73 % of sites. It also changed characterization of equivocal images as normal in 10 % of 51 suspicious sites and abnormal in 18 % of the 51 sites. More importantly, findings from acetate PET/CT influenced patient management in 28 % of patients. Using acetate PET/CT, Sandblom et al. analyzed 20 patients with biochemical failure after undergoing radical prostatectomy [76]. Pathologic uptake was seen in 75 % of the patients; eight patients had solitary lesion and seven had multiple lesions. The false-positive rate was 15 %, but additional investigations in these men revealed pathologic findings other than prostate cancer (primary lung cancer, esophagitis, and lymphadenitis). Because acetate is not cancer-specific, any disease mechanisms that increase lipid metabolism can result in false positivity. Looking specifically at the use of PET-CT in patients with low PSA levels, Vees et al. evaluated patients with PSA <1 ng/mL by comparing the use of choline and acetate PET/CT with endorectal MRI [77] (Fig. 17.2). The authors found that while both choline and acetate PET/CT were able to detect local residual or recurrent disease in half the patients, endorectal MRI was a more sensitive study, detecting local disease in 15 of 18 patients. Acetate PET is able to detect recurrent disease in patients with biochemical recurrence. The use of fusion images with either CT or MRI can enhance the quality of these studies. However, tumor detection was limited by patients with low PSA. In that cohort of patients, endorectal MRI appeared to be the optimal imaging modality.

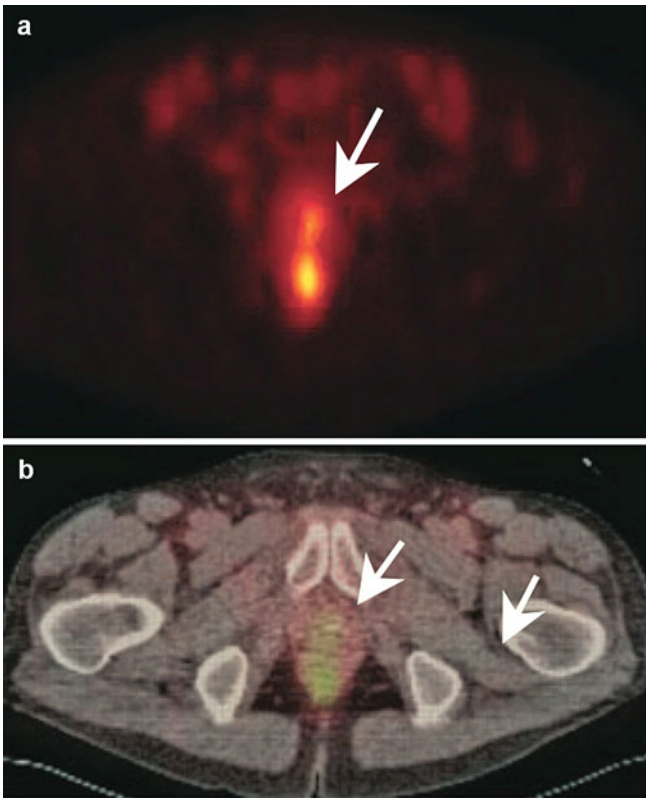

**Fig. 17.2** Example of the use of 11C-acetate PET to detect recurrence. Focal hyperactivity is seen in the prostate bed (**a**) and the fused imaging with the corresponding CT (**b**). The small, focal hyperactivity (*arrow*) reached a SUV of 2.5 (Used with permission from publisher. Vees et al. [77])

## Capromab

Capromab pendetide imaging can localize early PSA recurrence. In one of the largest series, Raj et al. for the Prostascint study group, looked at 255 hormone-naïve men with biochemical failure after radical prostatectomy [78]. Capromab pendetide uptake was seen in 72 % of 255 men with PSA ranging from 0.1 to 4.0 ng/mL, with 31 % of them having local recurrences only. Among those who underwent additional imaging studies, only 12 and 16 % showed evidence of recurrent disease by bone scintigraphy and computed tomography, respectively. Given such promising results, various researchers sought to evaluate if the use of capromab pendetide scan could improve outcomes in patients with localized recurrent disease. One of the first studies to evaluate capromab pendetide's role in evaluating patients with biochemical failure after prostatectomy came from Khan et al. [79]. The author evaluated 32 patients who had biochemical failure after radical prostatectomy. The predicted probability that a durable complete response would be obtained with a normal scan was 0.88; for men with a positive scan limited to the prostatic fossa, it was 0.62; and for men with a positive scan outside the pelvis, it was 0.27. While the median pre-radiation PSA in the nonresponders was higher, multivariable analysis showed that a negative capromab scan was the only significant predictor for durable complete response. These findings were confirmed by Levesque et al. [80]. In 48 patients with biochemical failure following prostatectomy, 13 of the 48 patients underwent adjuvant radiation. Among the six patients who had activity beyond the field of radiation, four patients did not attain durable disease control; on the other

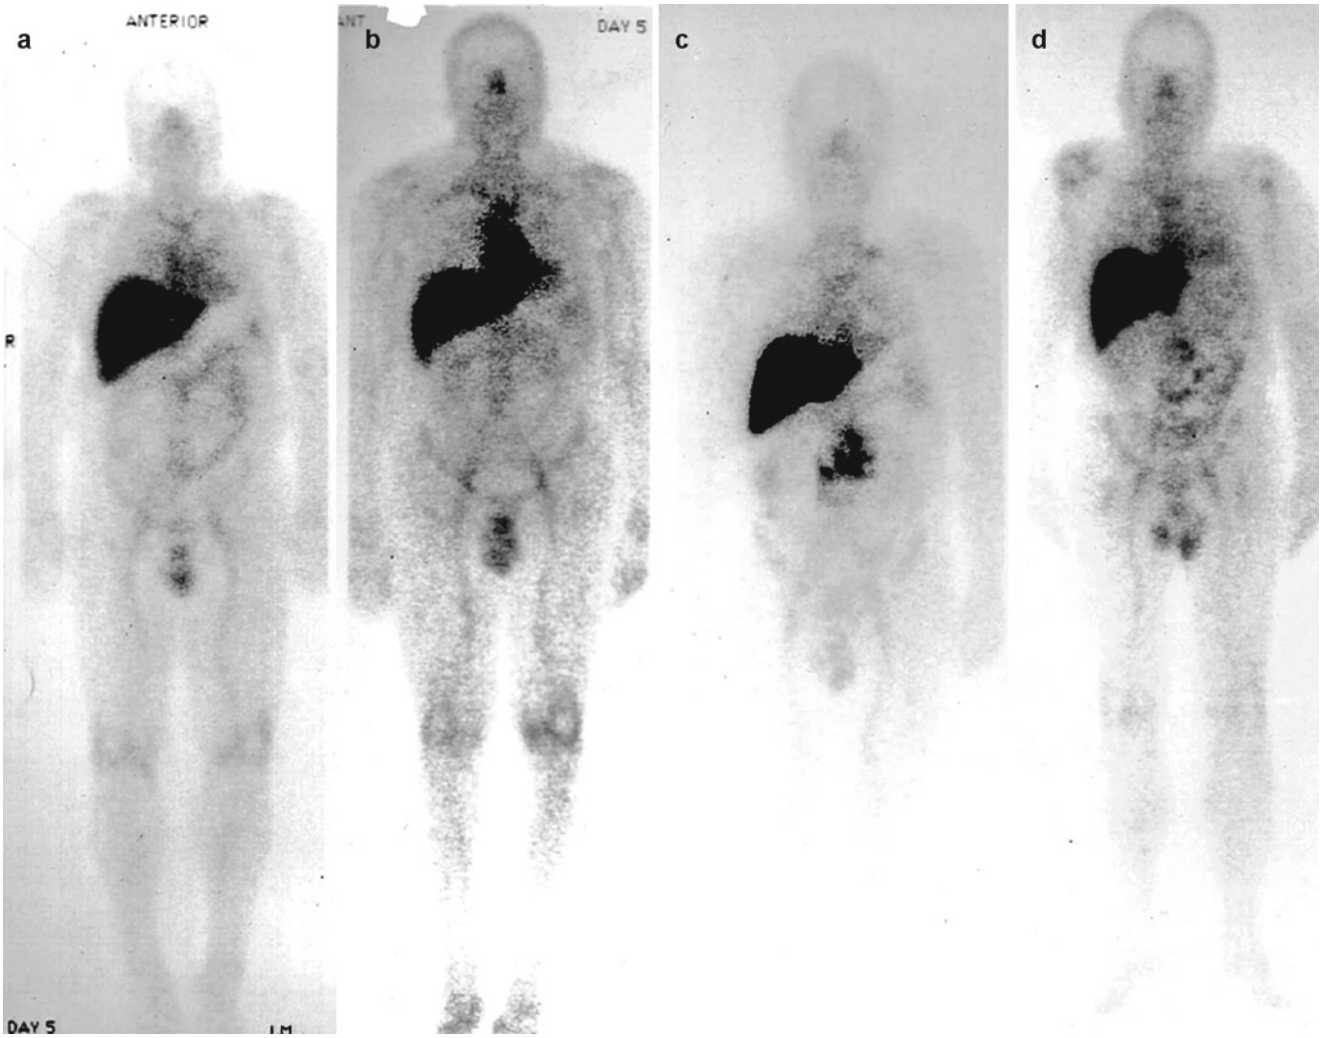

**Fig. 17.3** Coronal images of indium-111-labeled capromab pendetide scans in four patients. (**a**) Negative scan outside the pelvis; prostate-specific antigen (PSA) was uncontrolled by salvage radiation (RT). (**b**) Negative scan outside the pelvis; PSA controlled following RT. (**c**) Positive mesenteric and para-aortic lymph nodes; PSA uncontrolled following RT. (**d**) Positive mesenteric and para-aortic lymph nodes; PSA controlled following RT (Used with permission from publisher. Thomas et al. [81])

hand, of the seven patients who had no activity beyond the field of radiation therapy, only two patients failed treatment.

However, these findings were refuted by data from Thomas [81] and Wilkinson and Chodak [82]. Thomas et al. retrospectively reviewed 30 men with biochemical failure after prostatectomy who underwent salvage radiation therapy. The cumulative 2-year PSA control after salvage radiation therapy was 0.38 compared to 0.31 for men with a positive scan and a normal antibody scan in and outside the prostate fossa, respectively (Fig. 17.3). The hazard ratio for 2-year probability of PSA control after salvage radiotherapy for men with positive scan results outside the prostate bed was 0.81, with the 95 % confidence interval of 0.17–3.78. Meanwhile, Wilkinson and Chodak similarly evaluated 16 patients who underwent salvage radiation therapy for biochemical failure. Of the 15 patients who had isolated uptake in the prostatic fossa based on capromab scans, only 7 (46.7 %) showed a durable response to salvage radiation therapy. Both studies found that capromab scan findings outside the prostate fossa were not predictive of biochemical control.

## Metastatic Disease

### FDG

In terms of metastatic staging, FDG-PET was found to be less sensitive than bone scintigraphy at identifying bony metastases. Shreve et al. evaluated 34 patients with biopsy-proven prostate cancer with known or suspected metastatic disease [83]. Blinded interpretation of the PET images was compared with bone scan, CT, and clinical follow-up findings. The authors found that FDG-PET can help identify metabolically active osseous and soft tissue metastases. Furthermore, in patients undergoing treatment for metastatic prostatic cancer, utility of FDG-PET is fairly limited. Sung

et al. sought to determine the value of FDG PET-CT in evaluating patients with advanced prostate cancer [84]. The authors compared FDG PET-CT scans with bone scintigraphy in 30 patients with advanced prostate cancer (13 with locally extensive prostate cancer and 17 with metastatic disease). They found that staging of advanced prostate cancer may be enhanced by FDG-PET imaging in patients who are untreated, who have had an incomplete response to therapy, or who have a rising PSA despite treatment. Twenty of the 30 patients were positive for radioisotope uptake in the prostate or extraprostatically. The patients with PET-detected prostate cancer were untreated ($n=7$), treated hormonally while they had rising PSA levels ($n=8$), or treated hormonally with a detectable but stable PSA ($n=5$). The remaining ten patients with negative scans were receiving hormone therapy and had undetectable PSA levels.

FDG-PET has been investigated for its use in the assessment of response to treatment of prostate cancer. In one report, FDG accumulation in the primary prostate cancer and metastatic sites decreased over a period of 1–5 months after initiation of androgen-deprivation therapy, which was consistent with results from animal xenograft studies [19, 85, 86]. However, an earlier study of prostate cancer in rats showed that the global FDG SUV was unchanged after treatment with gemcitabine [87]. Preliminary results show that tumor FDG uptake decreases with successful treatment (using androgen-deprivation or various chemotherapy regimens), in concordance with other measures of response, such as decline in serum PSA level [88] (Fig. 17.1).

## Choline

Even though bone scintigraphy is the current gold standard for evaluation of osseous metastatic disease, one of its weaknesses is the lack of differentiation between metastatic and benign inflammatory bone disease. Beheshti et al. evaluated 72 men with prostate cancer with fluorocholine (FCH)-PET/CT for metastatic disease [89]. A total of 262 lesions demonstrated FCH-PET uptake, of which 210 of them were osseous metastases. Fifty-six sclerotic lesions that were considered highly suspicious for metastatic disease on CT or bone scintigraphy demonstrated no FCH uptake. The overall sensitivity, specificity, and accuracy of FCH-PET/CT in detecting bone metastases from prostate cancer were 79, 97, and 84 %, respectively. In a larger cohort of patients, FCH-PET was performed on 111 patients prior to radical prostatectomy with extended pelvic lymph node dissection [53]. The authors found that on a per-patient analysis, the sensitivity, specificity, and positive and negative predictive values of FCH-PET/CT in the detection of malignant lymph nodes were 45, 96, 82, and 83 %, respectively. If the analysis were limited to lymph nodes greater than or equal to 5 mm in diameter, the sensitivity, specificity, and positive and negative predictive values were 66, 96, 82, and 92 %, respectively. FCH-PET/CT led to a change in therapy in 15 % of all patients and 20 % of high-risk patients. Results from these two studies appear to suggest that FCH-PET/CT could be useful to preoperatively exclude high-risk patients with possible metastatic disease (Fig. 17.4). When compared to MR, a small study performed

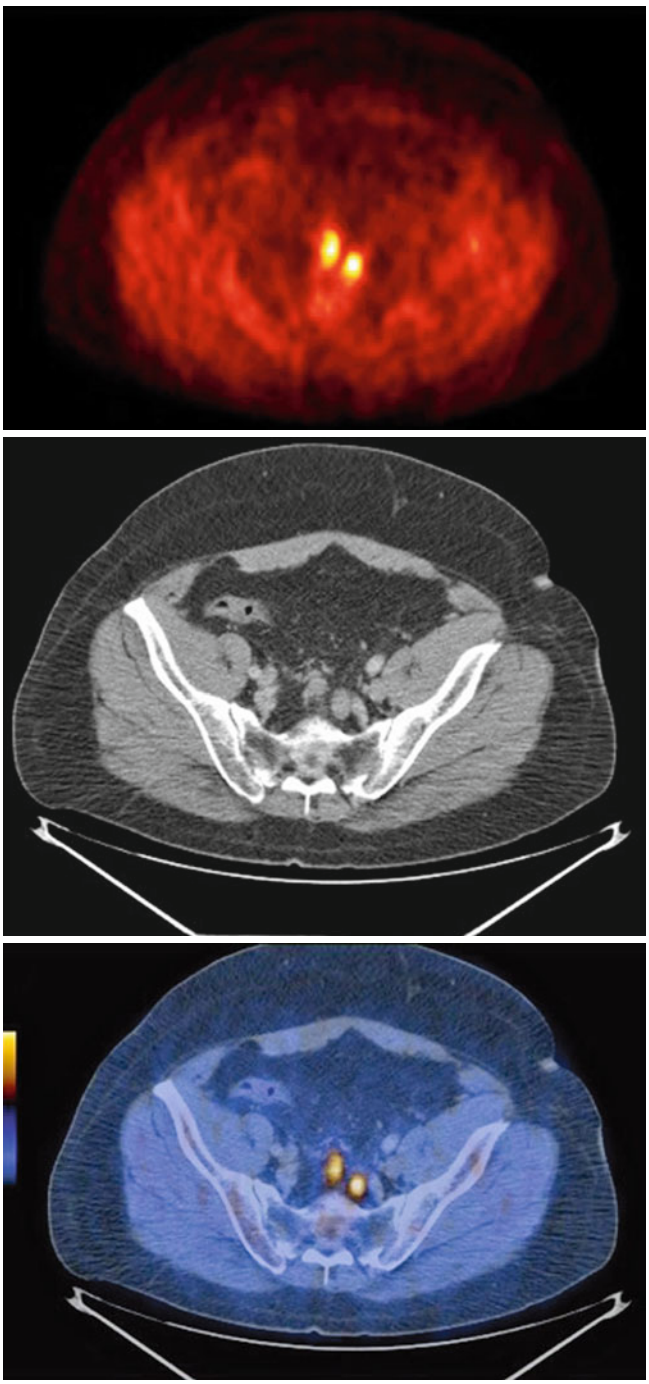

**Fig. 17.4** 18F-fluorocholine PET-CT in metastatic prostate cancer. From *top* to *bottom*: 18F-fluorocholine PET, pelvis CT, and fused PET/CT images demonstrating abnormal accumulation of radiotracer in pelvic lymph node (Courtesy of Mohsen Beheshti, St. Vincent's Hospital, Linz, Austria)

by Luboldt, et al. found that 11C-choline PET/CT was equally effective in detection of bone metastases as diffusion-weighted MRI [90]. But not all choline-based tracers are created equal. Steuber et al. evaluated the use of 18F fluroethylcholine in 20 patients with localized prostate cancer and greater than 20 % risk of lymph node metastases based on published nomogram [91]. Forty-five percent (45 %) of the patients had positive lymph nodes, but fluroethylcholine PET/CT did not detect one single positive lymph node. In terms of evaluation of hormonal therapy status, there is a case report of the use of choline PET/CT that demonstrated decline in tracer localization in lymph nodes of a patient with metastatic prostate cancer [92]. This finding would be of great interest, but a formal series in a much larger cohort of patients would be required.

### Fluoride

Currently, bone scintigraphy scan is the standard method for detecting bone metastases in prostate cancer. More recently, SPECT/CT has been evaluated due to higher sensitivity [93]. 18F-fluoride PET/CT has been shown to be superior to Tc-99m-based bone scintigraphy. In a recent study [94],18F-Fluoride PET/ CT was statistically more sensitive and more specific than planar or SPECT bone scintigraphy ($p=0.05$). The sensitivity, specificity, positive predictive value, and negative predictive value of planar bone scintigraphy were 70, 57, 64, and 55 %, respectively; of multi-FOV SPECT were 92, 82, 86, and 90 %; and of 18F-Fluoride PET/CT were 100 % for all parameters. Furthermore, study by Beheshti et al. prospectively compared 18F-fluorocholine and 18F-fluoride PET-CT for the detection of bone metastases for 38 prostate cancer patients [95]. The sensitivity, specificity, and accuracy of PET–CT in the detection of bone metastases in prostate cancer was 81, 93, and 86 for 18F fluoride, and 74, 99, and 85 % for 18F fluorocholine, respectively. Fluoride PET/CT appears to be an extremely promising tool to detect bone metastases in men with prostate cancer.

## Other Promising PET Radiotracers in Prostate Cancer

Although beyond the scope of this chapter, it is of note that several other promising radiotracers have been investigated in the imaging evaluation of prostate cancer including 16b-18F-fluoro-5a-dihydrotestosterone (FDHT), targeted to the androgen receptor; anti-1-amino-3-18F-fluorocyclobutane-1-carboxylic acid (anti-FACBC), which is a synthetic L-leucine analog, 1-(2′-deoxy-2′-fluoro-beta-D-arabinofuranosyl)thymine (FMAU), which is a cellular proliferation biomarker; and prostate-specific membrane antigen (PSMA)-based PET radiotracers (96-101) [96–100]. However, the exact diagnostic roles of these radiotracers remain undefined and will require additional studies. It is, however, quite plausible that different PET radiotracers, singly or in combination, may be best suited for accurate imaging evaluation of the various clinical phases of such heterogenous disease as prostate cancer [101, 102].

# Molecular Risk Profiling

18

Neil E. Martin

## Introduction

Despite a stage migration toward lower-risk disease at diagnosis in the setting of prostate-specific antigen (PSA) screening [1], prostate cancer remains a heterogeneous disease with the prognosis, treatment approach, and outcomes largely dependent on the biology of the tumor. Prostate cancer is the second most common cause of cancer death in males in the United States, but the rate of prostate cancer mortality is relatively low with 8-year cause-specific survival of more than 95 % [2]. Currently, in populations with PSA screening, over 90 % of prostate cancers are clinically localized at time of diagnosis [1], and in this setting, traditional methods of stratifying patients into groups with similar outcomes following local therapy based on clinical and pathologic features [3] lose much of their discriminatory power. Additionally, evidence from randomized trials of PSA screening [4–6] demonstrate that a significant fraction of newly diagnosed men are being treated for insignificant disease. With an expanding set of tools capable of broadly profiling the biology underlying prostate cancer, novel therapeutic agents coming to the market, and a need to better categorize those men with low-risk disease who should be treated, there has been an increasing interest in the molecular prognostic factors in prostate cancer.

## Risk Profiling

The most consistent clinical and pathologic predictors of outcome in prostate cancer are the Gleason score [7, 8], T-category [9], and PSA value at diagnosis [10, 11] which, when combined, form the basis for a widely used risk stratification system [3]. Alone though, these markers lose their power to capture the heterogeneous clinical course for men with low- and intermediate-risk disease. To improve upon these factors, researchers have investigated both genomic and molecular markers of prognosis in prostate cancer. In this chapter, we will focus on molecular prognostic factors believed to be driving many of the features of cancer.

## Tumor Factors

Selective markers from each general characteristic of malignant cells are outlined in Table 18.1. Broadly, most markers have been tested predominantly in radical prostatectomy (RP) samples given the tissue availability and so inform disease recurrence following surgery and not necessarily at the time of diagnosis. There is very limited data about markers of prognosis in active surveillance or watchful waiting cohorts despite the clear clinical need. For structure, markers are categorized according to the six broad hallmarks of cancer [45].

### Self-Sufficiency in Growth Signals

In contrast to normal cells, tumor cells develop the ability to promote growth in the absence of normally regulated signaling systems. There are numerous pro-growth signaling pathways implicated in prostate cancer progression including androgen signaling, phosphoinositol 3-kinase (PI3K), epidermal growth factor receptor (EGFR), RAS, and metabolic dysregulation. Selected studies for each of several pathways of interest are presented in Table 18.1 as they relate to prognosis.

**Table 18.1** Selected tumor-specific molecular markers associated with prognosis in prostate cancer

| Marker | Action | Notes |
|---|---|---|
| *Self-sufficiency in growth signals* | | |
| Androgen receptor | Acts as a transcription factor mediating cell growth | Heterogeneous data based on IHC but large RP series appear to support its prognostic value [12] Mutations are common in the castration-resistant setting and are associated with response [13] |
| Ki67 | Nuclear antigen used as a marker of cellular proliferation | Ki67 has been found to be prognostic in radiation-treated patients [14] as well as those undergoing RP [15] |
| TMPRSS2:ERG | Gene fusion between androgen-responsive element and a family of transcription factors | Present in approximately 50 % of localized prostate cancers, this gene fusion has been associated with lethal disease in watchful waiting cohorts [16, 17] but in contrast was not associated with outcomes in other RP series [18] |
| AKT/PTEN | Components of the phosphoinositol 3-kinase oncogenic pathway | Loss of the tumor suppressor gene *PTEN* is related to clinical outcomes in RP specimens [19, 20]. Similarly, the presence of the activated form of AKT [21] and the unaltered protein itself [22] have prognostic value following RP |
| Epidermal growth factor receptor (EGFR) | Transmembrane receptor mediating extracellular pro-growth signals to numerous downstream pathways | Increased EGFR staining and copy number is associated with an increased risk of recurrence following RP [23]. Only 18 % of tumors overexpressed EGFR, and there was heterogeneous amplification in most tumors |
| RAS | Oncogene related to numerous pro-growth pathways | Despite extensive research, mutations in *RAS* are infrequent and apparently unrelated to clinical course [24] |
| Fatty acid synthase | Metabolic enzyme critical in long chain fatty acids | The *FASN* gene is implicated as an oncogene in prostate cancer [25] and has independent prognostic value following RP [26] |
| EZH2 | Gene silencing protein | High expression of *EZH2* is associated with a poor prognosis in localized disease and is present in metastatic disease [27] |
| *Insensitivity to antigrowth signals* | | |
| p16/INK4A | Tumor suppressor gene related to cell cycle control | Overexpression of p16/INK4A is independently related to recurrence of disease [28] |
| p21/WAF1/CIP1 | Regulates $G_1$ of the cell cycle | Increased p21/WAF1/CIP1 staining is independently prognostic for recurrent disease following RP [29] |
| p27/KIP1 | Cell cycle inhibitor | Decreased expression of the protein is independently associated with poor outcomes [30]. The protein SKP2 targets p27/KIP1 for degradation, and higher levels also correlate with worsened outcome [31] |
| C-MYC | Oncogenic transcription factor | Fluorescence in situ hybridization (FISH) copy number for the gene significantly predicts progression and survival [32] though with IHC, expression of C-MYC is not independently related to clinical outcome [33]. Single-nucleotide polymorphisms in the region of 8q24, the region of the *MYC* gene are associated with an increased risk of prostate cancer [34] |
| *Limitless replicative potential* | | |
| Telomeres | Nucleoprotein complexes capping chromosome ends | Though there is limited looking at telomeres in prostate cancer, decreased telomere length is associated with a poor prognosis [35] |
| *Evasion of apoptosis* | | |
| p53 | Tumor suppressor gene associated with DNA repair | In the post-RP setting, nuclear p53 expression is independently associated with disease progression [36] |
| BCL2 | Apoptosis regulator | Increased nuclear expression of BCL2 is independent prognostic for recurrence following RP [37, 38]. Similar results were found on biopsy specimens from patients receiving radiation [39] |
| BAX | Proapoptotic member of the BCL2 family | The ratio of BCL2:BAX was predictive of worsened outcome following radiation [40] |
| *Sustained angiogenesis* | | |
| Vascular endothelial growth factor | Driver of neovascularization | Among patients receiving radiation [41] and surgery [42], VEGF staining predicted shored time to biochemical recurrence |
| *Tissue invasion and metastasis* | | |

**Table 18.1** (continued)

| Marker | Action | Notes |
|---|---|---|
| E-cadherin | Cell adhesion molecule | Low expression of E-cadherin is independently associated with death in men treated with TURP [43] |
| Transforming growth factor-β (beta) | Pro-growth cytokine | TGF-β (beta) is implicated as a key factor in the tumor microenvironment of prostate cancers, and increased tumor expression is associated with metastases and poor prognosis [44] |

### Insensitivity to Antigrowth Signals

Progression through the cell cycle in normal cells is a well-regulated process involving the interplay of numerous signaling factors. Loss of these control mechanisms provides tumor cells the opportunity to grow unchecked. In prostate cancer, disruption of several of these molecular features provides prognostic information following RP including p16/INK4A, p21/WAF1/CIP1, and p27/KIP1 (Table 18.1). An additional marker thought to be central to antigrowth regulation is the oncogenic transcription factor C-MYC. High gene copy number for *MYC* is prognostic for worsened outcome in prostate cancer.

### Limitless Replicative Potential

Normal cells have a finite capacity to replicate as determined by telomeres. These base-pair repeats at the ends of chromosomes shorten with each cell division ultimately leading to cell death when they are no longer capable of protecting the chromosome ends. Shortened telomere length in tumor cells has been associated with a poor prognosis though there are relatively few studies investigating this marker in prostate cancer.

### Evasion of Apoptosis

Tumor development is characterized not only by increased pro-growth and decreased control signaling but also decreased cell attrition through apoptosis. This well-regulated process of cell death is mediated by a variety of factors; some of which have been explored as prognostic factors in prostate cancer. A central signaling molecule for DNA damage and regulator of apoptosis is p53. The *TP53* gene is commonly mutated in other solid tumors but less frequently in prostate cancer [46]. Localization to the nucleus of the p53 molecule in prostate tumors has been independently associated with poor prognosis though as have other markers of disrupted apoptosis signaling (Table 18.1).

### Sustained Angiogenesis

In light of the limited diffusion capacity of oxygen and essential nutrients, tumors require the development of new blood vessels as they increase in size. This typically highly regulated process becomes disorganized in tumors and in prostate cancer, and both vessel density [37] and morphology [47] have been shown to have prognostic implications. Additionally, vascular endothelial growth factor (VEGF) expression has been associated with poor prognosis in those receiving both surgery and radiation as primary treatment (Table 18.1).

### Tissue Invasion and Metastasis

Lethal prostate cancer inevitably metastasizes to distant sites in the body. The processes controlling this capacity to invade and ultimately metastasize are not fully understood, but the tumor microenvironment is thought to play a crucial role. As seen in Table 18.1, markers of cell adhesion such as E-cadherin and cytokines such as transforming growth factor beta (TGF-β) have prognostic significance following surgery in prostate cancer.

## Circulating Biomarkers

While tumor markers are appealing because they are thought to reflect true biologic changes within the cells of interest, investigators have also looked to other sources for prognostic markers in prostate cancer. Blood or urine markers are appealing not only for their ease of access but also because they may ameliorate concerns of the sampling errors and heterogeneity from the tumor itself.

### Circulating and Disseminated Tumor Cells

The development of overt metastases has been typically considered a late event in the malignant progression, but there is evolving evidence suggesting that dissemination of primary cancer cells to distant sites might occur earlier in tumorigenesis [48].

Several assays for the detection of disseminated tumor cells (DTCs) in bone marrow and circulating tumor cells (CTCs) in the peripheral blood have been developed to better understand this process and its clinical implications. Broadly, the two techniques employed are based on an immunological

identification of cell-surface markers and a PCR-based approach of identifying prostate-specific RNA in cells [49]. Although antibody-dependent, the immunological method has the advantage of being easy to perform and enables the evaluation of cell size and morphology. The PCR-based assays have the advantage of being extremely sensitive and able to detect aberrations at a single-cell level, though may not be more sensitive for detecting circulating tumor cells. Transcripts specific to prostate such as PSA, prostate stem cell antigen (PSCA), and prostate-specific membrane antigen (PSMA) are typically utilized as single or multiplexed surrogate markers in blood CTCs using PCR. The major limitation of the molecular approach is poor specificity due to illegitimate transcripts and heterogeneous expression of target markers. A cell-enrichment step during the CTC isolation process and identification of reliable cutoff values for analysis may overcome these problems [50].

The bone represents the most common location of metastatic disease in prostate cancer, and therefore most clinical reports on DTC focus on the bone marrow. There are significant correlations between the presence of DTC and clinical-pathological parameters such as high Gleason score or metastatic disease [51, 52]. The presence of DTC in the bone marrow at the time of diagnosis is also an independent negative prognostic parameter in patients with localized prostate cancer [53].

Because bone marrow aspiration is invasive and potentially uncomfortable for the patients, more recent efforts have focused on the detection of CTCs in the peripheral blood. Using PCR, CTCs can now be detected in the blood at the time of diagnosis as well as over the course of therapy. Their increased number has been positively associated with higher Gleason score and stage [54]. Using PCR, the detection of PSA mRNA is significantly correlated to time to progression and overall survival [55].

Immunologic approaches to detecting CTCs were developed in the face of technical limitations of the PCR technique and the need for more standardized methods in the peripheral blood. The Food and Drug Administration has now approved a technology (Cell Search, Veridex) that can be used for the monitoring of metastatic breast, colon, and prostate cancer. With recently collected peripheral blood, this device is able to isolate single CTCs by immunomagnetic enrichment followed by fluorimetric count.

Data generated using this system shows that CTCs are detectible in 55–62 % of patients with castration-resistant prostate cancer [56, 57]. A baseline CTC count ≥5 cells/7.5 mL of blood before therapy was found to represent a powerful predictor of poor overall survival [58]. The change in detectable number of CTCs following therapy is also predictive of clinical outcomes [55]. In one study, patients with a CTC count that dropped from ≥5 cells at baseline to <5 cells after treatment had a better overall survival compared with those showing an increase during therapy [59]. Though potentially valuable in the metastatic setting, in patients with organ-confined prostate cancer, few CTCs are detectible using currently available technologies and do not appear to correlate with known prognostic factors, though further studies are needed [60].

In addition to their potential prognostic value, there is clearly potential utility in characterizing CTC or DTC in cancer patients to provide additional information on cancer biology and treatment selection. Both high- and low-resolution techniques such as FISH or CGH can be performed on isolated cancer cells to obtain a genomic profile of CTCs/DTCs that could be related to prognosis and response to therapy [61–63]. In non-small cell lung cancer, a proof of concept study showed that CTCs could identify tumors with specific *EGFR* mutations sensitive to anti-EGFR small molecules demonstrating the value of these "liquid biopsies." [64].

## Urine Markers

Given the proximity of the urethra and bladder to the prostate, urine is also considered a potential source of clinically useful biomarkers in men with prostate cancer. The prostate cancer antigen 3 (PCA3) gene is differentially expressed in prostate cancer samples compared to normal prostate tissue [65]. The protein product can be identified in urine, particularly in the first void after a digital rectal exam when tumor cells are known to be present [66, 67]. To date, much of the work with PCA3 has been limited to the diagnosis of men with prostate cancer. In this setting, it has been shown that PCA3 can improve upon the specificity of PSA [68]. One study also showed that PCA3 was independently correlated with extracapsular extension identified on radical prostatectomy [69]. The *TMPRSS2:ERG* fusion has also been investigated in the urine [70, 71]. Using FISH or PCR, it can be detected in post-DRE urine, and its presence may eventually be used in combination with other biomarkers to improve the specificity of screening for prostate cancer [72, 73]. The kinetics of these markers with treatment and disease progression has not been fully investigated, and they may eventually be used to help follow response to treatment.

## Serum Markers

Multiple serum markers have been investigated for their potential role in providing prognostic information in prostate cancer. Members of the human kallikrein gene family which include PSA and bone turnover markers have been investigated for their utility in prognostication in prostate cancer with mixed results [74, 75]. Given its proven role in the tumor microenvironment, TGF-β (beta) has also been

explored in the serum as a prognostic factor [76]. Another marker believed to come from the tumor microenvironment is interleukin-6, and levels of its soluble receptor in the blood have been shown to be prognostic following RP [77].

**Conclusions**

As outlined in this chapter, molecular markers of prognosis in prostate cancer are plentiful in the literature. Despite this, they remain, to a large extent, unused clinically. This is likely the result of numerous factors including relatively modest effect size for any given marker and poor standardization of the tools of detection and analysis: from antibody selection to interpretation to selecting cut points for "positive" and "negative," there is significant room for variability. This variability leads frequently to poor reproducibility between studies and difficulty interpreting negative results. To improve the interpretability of these molecular markers, there are now standardized reporting criteria which are used by some journals for biomarker studies [78]. The widespread adoption of these recommendations will help overcome some of these methodological issues. Technologic advances in biomarker assessment such as multispectral imaging [79] may also prove useful as multiple markers may be needed simultaneously to best predict the clinical course. Despite continued advances in our understanding of the molecular underpinnings of prostate cancer, and some markers which show promise, there remains a strong clinical need for reliable molecular prognostic factors in prostate cancer.

## Updates

Advances in our understanding of the underlying genetics and genomics of prostate cancer have recently led to new molecular signatures of poor outcome in prostate cancer. As with any prognostic marker, a molecular signature should be predictive of outcome independent of Gleason score and other clinical markers. Four potentially useful signatures are outlined below:

*Copy number alterations.* Taylor performed an integrative genomic analysis of 218 prostate cancer tumors from patients followed for a median of 5 years for biochemical recurrence [80]. Whole genome mRNA, miRNA, and copy number aberrations were assessed. No mRNA signatures could be identified relating to poor outcome following surgery. They were able to identify a signature within the copy number data that predicted differences in time to biochemical relapse, independent of Gleason grade.

*Cell-cycle progression signature.* Cuzick used a pathway-based approach to identify a prognostic signature, focusing on genes involved in cell cycle progression [81]. They measured mRNA levels of a set of 31 genes to robustly capture cellular proliferation. Among 366 prostate cancer patients who underwent prostatectomy, mRNA expression of genes in the cell-cycle progression signature significantly predicted biochemical recurrence, independent of Gleason and other clinical factors. Additionally, in a cohort of 337 men with prostate cancer diagnosed on transurethral resection of prostate, the same signature predicted prostate cancer mortality, independent of Gleason grade and Ki67 expression.

*4-marker signature of lethal prostate cancer.* Ding and colleagues performed comparative oncogenomics to derive a signature of prostate cancer prognosis [82]. After identifying *SMAD4, PTEN, SPP1, and CCND1* as drivers of invasive and metastatic prostate cancer in a mouse model, they explored the protein expression of these same markers in a human cohort. At the mRNA level, the signature was significantly associated with biochemical recurrence and lethal prostate cancer in two small cohorts. Among 367 prostate cancers from men in the Physicians' Health Study who had undergone radical prostatectomy, the 4-marker signature was a significantly better predictor of lethal prostate cancer than Gleason score alone.

*Signature of Gleason score*. In light of the importance of the Gleason score in prediction clinical course, Penney and colleagues developed a 157-gene mRNA expression signature of Gleason grade [83]. To develop the signature, tumors comprised of Gleason 3 + 3, and Gleason ≥8 was compared. When applied to Gleason 7 tumors, an increased probability of high-grade disease was associated with a significant increased risk of lethal prostate cancer. For every 33 % increase in the prediction of the higher-grade tumor, there was an odds ratio of 1.47 (95 % CI 1.11–1.94) for lethal outcome in a multivariate model.

These four signatures illustrate the promise of molecular and genetic signatures in the prognostication of outcome for men diagnosed with prostate cancer. As with all biomarkers, clinical validation in additional cohorts with lethal prostate cancer as the endpoint will be crucial before they can be used widely in the clinic.

# Premalignant Lesions of the Prostate

19

Daniel M. Berney and Anne Y. Warren

## Introduction

A premalignant condition is a disease, syndrome, or constellation of features that, if left untreated, may lead to invasive cancer. When discovered, it demonstrates a significantly increased risk of cancer for that individual when compared to the general population. In pathological terms, premalignancy equates to morphologically altered tissue in which cancer is more likely to occur than its apparently normal counterpart.

In many organs, premalignancy has been described and defined for centuries. In 1851, Sir James Paget was the first to specifically suggest an association between a benign oral mucosal lesion and the subsequent development of oral malignancy [1]. A century later, Slaughter found premalignant lesions adjacent to tumor in squamous cell carcinomas of the head and neck leading to hypotheses of "field change" secondary to carcinogens in tobacco and alcohol [2]. Since this time, nearly every epithelial tissue has been shown to be associated with a premalignant morphological stage. In the vast majority of these, the threshold between premalignancy and malignancy has been invasion of the basement membrane, though this is not universal.

The premalignant lesions associated with prostate cancer have proved a more recent development and harder to elucidate and define. This is for a number of reasons. Firstly, the extremely high rate of malignancy in developed countries on full inspection of the prostate means that associated premalignancies cannot be identified in comparison with control populations.

Secondly, difficulty in examination of the whole gland in control cases makes contemporary comparisons difficult. Thirdly, as we have limited knowledge of the etiological causes of prostate cancer, the reasons for its unusual geographical distribution, and have minimal knowledge of its molecular biology, linking premalignancies with known epidemiological factors is virtually impossible. This chapter will consider the development, morphology, and significance of each of the putative premalignant conditions associated with prostate carcinoma, as well as morphological changes, which are not premalignant in themselves, but their identification is significantly associated with the later diagnosis of prostate cancer.

## Prostatic Intraepithelial Neoplasia (PIN)

Prostatic intraepithelial neoplasia (PIN) is defined as a neoplastic proliferation of the prostatic acinar cells, which is confined by the basement membrane and is therefore intraepithelial and unlike prostatic adenocarcinoma does not display invasion of the stroma. It demonstrates specific morphological features, which separate it from other potential premalignant conditions, which will be discussed later. A morphological constellation of features termed high-grade prostatic intraepithelial neoplasia (HGPIN) is the most likely precursor of prostatic adenocarcinoma according to virtually all available evidence; however, the development of this entity is tortuous and a historical resume of its evolution is necessary.

### The History of PIN

Morphologically identified atypical lesions, which do not display stromal invasion, have been identified for many

years. In 1949, with remarkably astute observational work, Andrews from Bristol, UK, identified a "latent carcinoma of the prostate" in which he discussed lesions which could be identified in cases of prostatic carcinoma where the basal cell appeared absent, but the relationship with the stroma was that of a benign gland [3]. Illustrations from this article could serve as exemplary articles of PIN today (Fig. 19.1).

A large number of diagnostic labels have been applied to PIN. Atypical hyperplasia was a term used by Gleason among others [4]. Two different potential preneoplastic entities were described by McNeal which he termed intraductal dysplasia (what we now term PIN) and adenomatous hyperplasia (which we now call adenosis or atypical adenomatous hyperplasia) [5]. Morphological characteristics of the grades of dysplasia were provided by McNeal and Bostwick in 1986 [6] and shortly after this, it was advocated that the preneoplastic lesion should be termed PIN, which was accepted at a consensus conference in 1989 [7], as well as adoption of a high-grade and low-grade stratification rather than a three level stratification. This is the system in use today.

PIN is characterized by cellular proliferations within preexisting ducts and acini, with nuclear and nucleolar enlargement similar to that seen in prostate cancer, although unlike cancer, HGPIN retains a basal cell layer. The recognition of HGPIN is clinically important because of the strong association between this disease and prostatic carcinoma. The predictive value for cancer of an initial diagnosis of HGPIN on needle biopsy has substantially declined, with values falling from 36 to 21 %. A major factor contributing to this decline is related to increased use of needle biopsy core sampling, which has provided the means for many cancers associated with HGPIN to be detected on initial biopsy; repeat biopsy, even with good sampling, does not detect many additional cancers. Other possible findings in the prostate might indicate premalignant disease (low-grade prostatic intraepithelial neoplasia, atrophy, malignancy-associated changes, and atypical adenomatous hyperplasia or adenosis), but the data for these premalignant diseases are much less convincing than those for HGPIN.

## The Morphology of Low-Grade PIN

Low-grade PIN is a challenging descriptor that is placed on non-invasive epithelial lesions, where the amount of atypia falls short of a diagnosis of HGPIN. In low-grade PIN, there is nuclear enlargement compared with normal secretory cells and increased nuclear pleomorphism and hyperchromatism (more intense staining with hematoxylin secondary to increased DNA content of the nucleus). Crucially, there are small or inconspicuous nucleoli [6]. Mitotic figures are difficult to identify and lower than HGPIN but higher than in normal prostate tissue [8]. The poor interobserver reproducibility of low-grade PIN even between expert

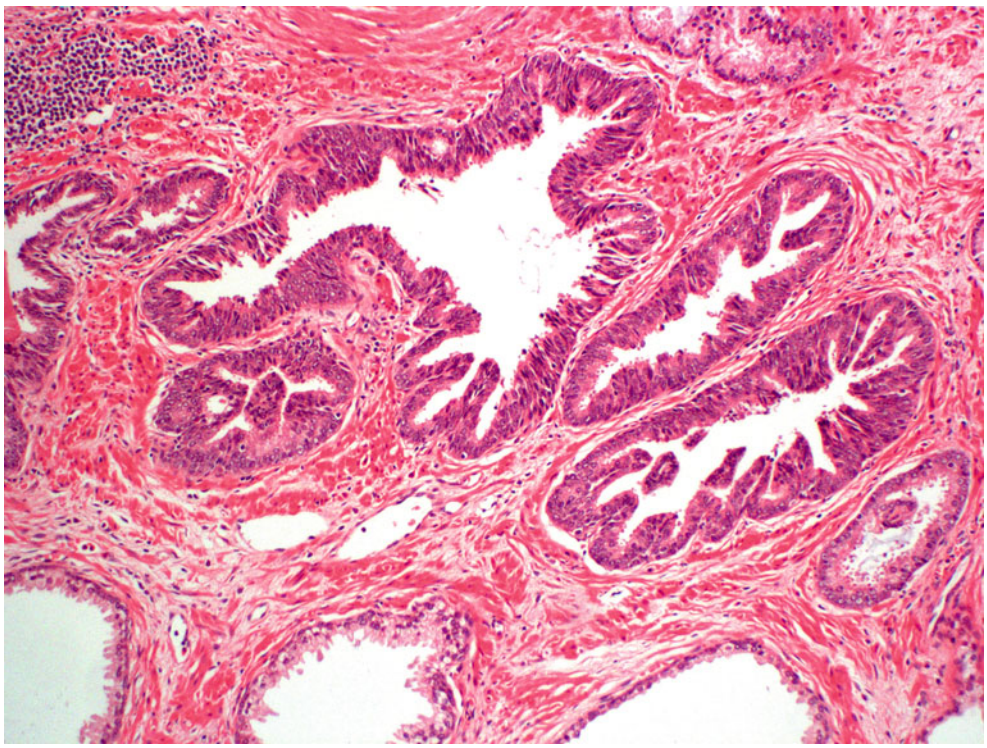

**Fig. 19.2** High-grade PIN. Low-magnification image showing glands with high-grade PIN (*center*) more deeply staining than surrounding benign glands

pathologists [9], and its unproven relationship to invasive carcinoma, means that it is not a useful entity to report in routine diagnostic work.

Low-grade PIN alone, therefore, is regarded as part of the spectrum of changes seen in benign prostatic tissue in histology reports and does not represent a well-defined pathological entity. For these reasons, we have chosen not to illustrate low-grade PIN as it remains unhelpful in the diagnosis and treatment in prostate cancer. Should it become better defined and interobserver error-improved, it may prove of interest in the future both for epidemiological and pathogenetic reasons, and it has been reported in studies linking morphology with genetic changes [10]; however, at present, it remains unproven as a robust diagnosis.

## The Morphology of HGPIN

In all cases of HGPIN, it is a requirement, by definition, that the lesion is not invasive. Together with this requirement are nuclear features, which resemble those of invasive prostatic adenocarcinoma. These include many of the features seen in low-grade PIN but usually to a greater extent: nuclear enlargement, hyperchromatism, and increased clumped chromatin. High-grade PIN is usually recognizable at low-power magnification in normal-sized or enlarged ducts due to its complex architectural features (discussed below) and darker appearance imparted by its deeply stained "amphophilic" cytoplasm and atypical nuclear features, when compared with adjacent normal ducts (Fig. 19.2). Characteristic partial duct involvement by the atypical epithelium may also aid recognition. The principle morphological features are summarized in Table 19.1 (Fig. 19.3). Most authors would not diagnose HGPIN without the presence of macronucleoli (greater than 3 μm). However, unsurprisingly, there is a spectrum of morphological features between HGPIN and low-grade PIN, and number, clarity, and size of nucleoli can all affect diagnosis. There appears to be no minimum requirement of the number of macronucleoli seen in HGPIN. Additional features, such as perinuclear haloes, a sharp luminal border, and a variety of luminal contents similar to those in invasive carcinoma, may also be helpful in diagnosis. Distinction from benign mimics of HGPIN that may also have prominent nucleoli, such as basal cell hyperplasia [11], inflammatory atypia, or atypia in glands adjacent to an infarct, can be difficult and results in over diagnosis of PIN or malignancy [12]. Other well-known benign pitfalls are radiation atypia, normal central zone glands [13], cribriform hyperplasia, seminal vesicle or ejaculatory

**Table 19.1** Morphological features of high-grade PIN

duct epithelium, and transitional and squamous metaplasia [14]. The correct diagnosis requires careful assessment of the architectural and cytological appearances and an appreciation of other associated features that aid distinction.

High-grade PIN can be defined according to its architectural variations and also occasionally by variations in the differentiation patterns of the cells.

There are four main architectural patterns: tufting, micropapillary, cribriform, and flat [15]. Tufting and micropapillary are the commonest, although multiple patterns are often present, with the tufting pattern present in 97 % of cases. In the tufting pattern, the luminal cells have an undulating arrangement of the thickened epithelium due to the cellular crowding and stratification. The micropapillary pattern has fine papillary structures, usually lacking in fibrovascular cores that protrude into the duct lumen. The cribriform pattern is characterized by a more florid and solid cellular proliferation, with intercellular spaces that impart a sieve-like appearance. The uncommon flat pattern may be overlooked due to the lack of an obvious architectural abnormality at low power, as the atypical epithelium often consists of only a single layer of cells (Fig. 19.4a–d).

## Differentiation Patterns in HGPIN

Several variants of HGPIN have been described in terms of the cytoplasmic differentiation of the cells rather than overall architectural patterns: signet ring cell [16], small-cell neuroendocrine, mucinous [16], foamy [17], and inverted [18], solid and squamous differentiation. They are inevitably associated with corresponding differentiation patterns in the invasive component, but are rare, and probably have no clinical significance. However, the presence in HGPIN of these various histological features provides additional support for a close relationship between HGPIN and the variants of invasive prostate carcinoma.

## Immunochemistry of HGPIN

The majority of cases of HGPIN show immunochemical positively for α-methylacyl-CoA racemase (AMACR), which, similar to carcinoma cells, decorate the cytoplasm with a coarse apical pattern though there is a lower frequency of expression than is seen in invasive adenocarcinomas [19–21] (Fig. 19.5a–d). By definition, the basal cell layer is intact in PIN, but while circumferential basal cells are usual in low-grade PIN, there may be a high degree of loss of basal cells in HGPIN where they are interrupted, less frequent, and occasionally lost altogether [22]. Immunohistochemistry for basal cell markers such as nuclear p63 [23, 24] or a cytoplasmic high-molecular-weight cytokeratin such as 34βE12 [25] therefore reveals patchy staining but no widespread complete loss. Correlation of basal cell patterns of loss with the hematoxylin and eosin slide is necessary to fully interpret the nature of difficult foci. Rare cases of carcinoma that express 34βE12 may also prove diagnostically problematic [26].

## Incidence of HGPIN

The incidence of HGPIN is extremely variable in reported series. This is due partly to differences in specimen type but also due to differences in population (age or ethnicity), biopsy procedure, and also on the thresholds for diagnosis of the reporting pathologist.

Prostate glands may be removed in total for invasive carcinoma and also may be removed when no carcinoma is suspected, such as for a radical cystectomy and also at postmortem. When carcinoma is present, the incidence of HGPIN that has been reported varies from 31 to 99 % [27, 28], though the vast majority report rates of 60 % or higher [6, 29, 30]. When carcinoma is not present, the rate is lower,

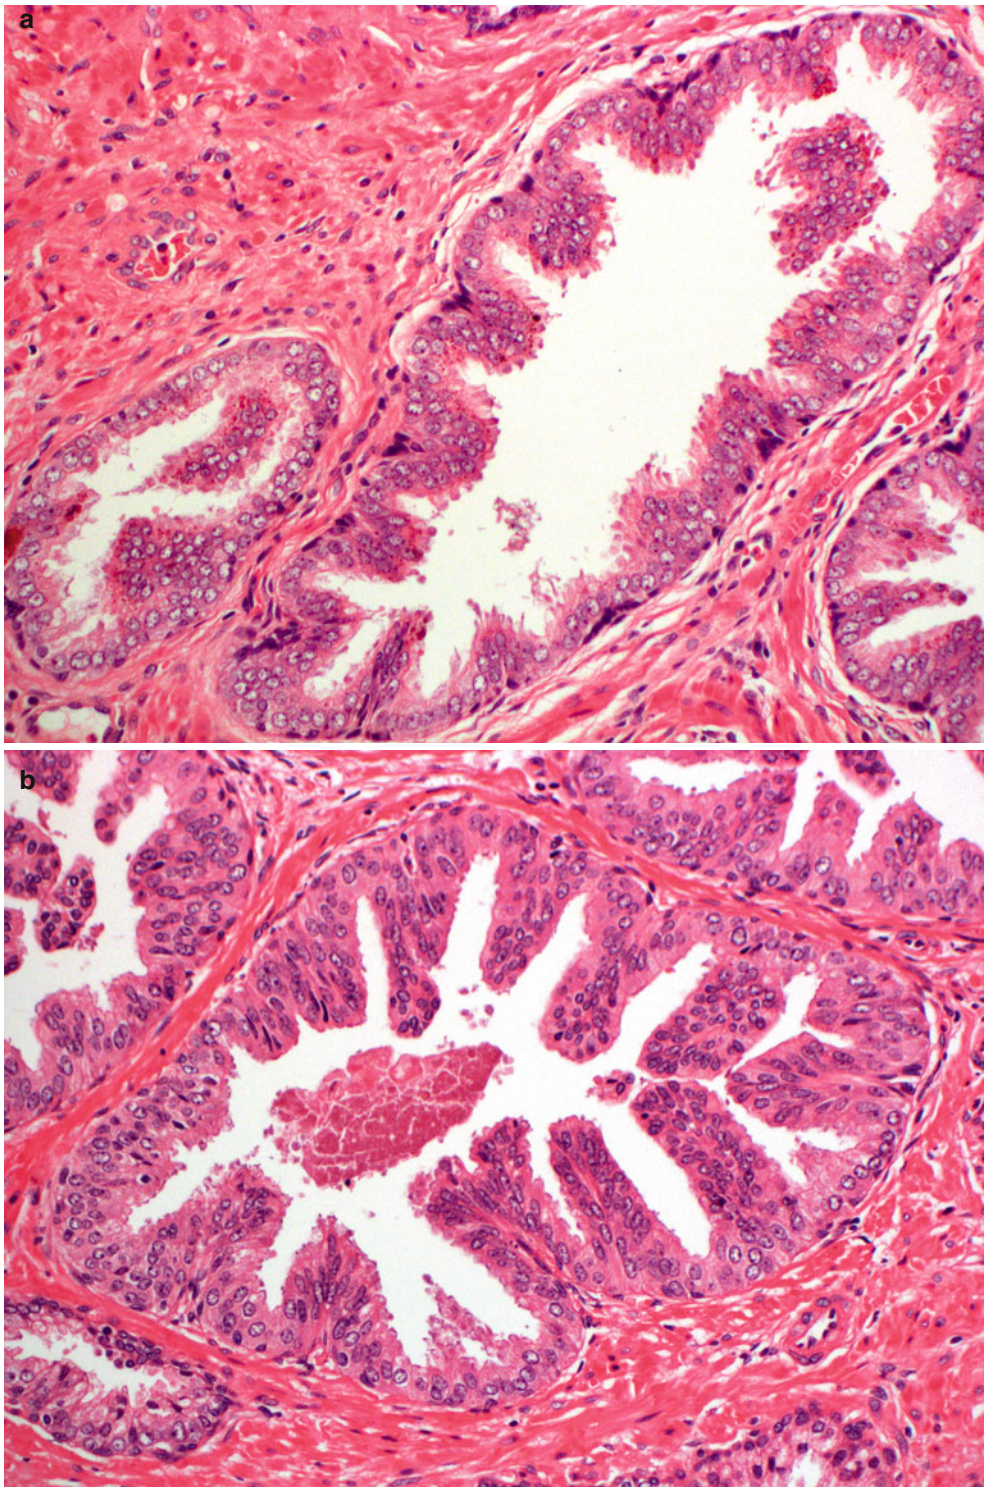

**Fig. 19.4** Patterns of high-grade PIN. Tufting (**a**), micropapillary (**b**), cribriform (**c**), and flat (**d**). The small atypical acini in (**c**) are invasive cancer adjacent to the high-grade PIN (*center*)

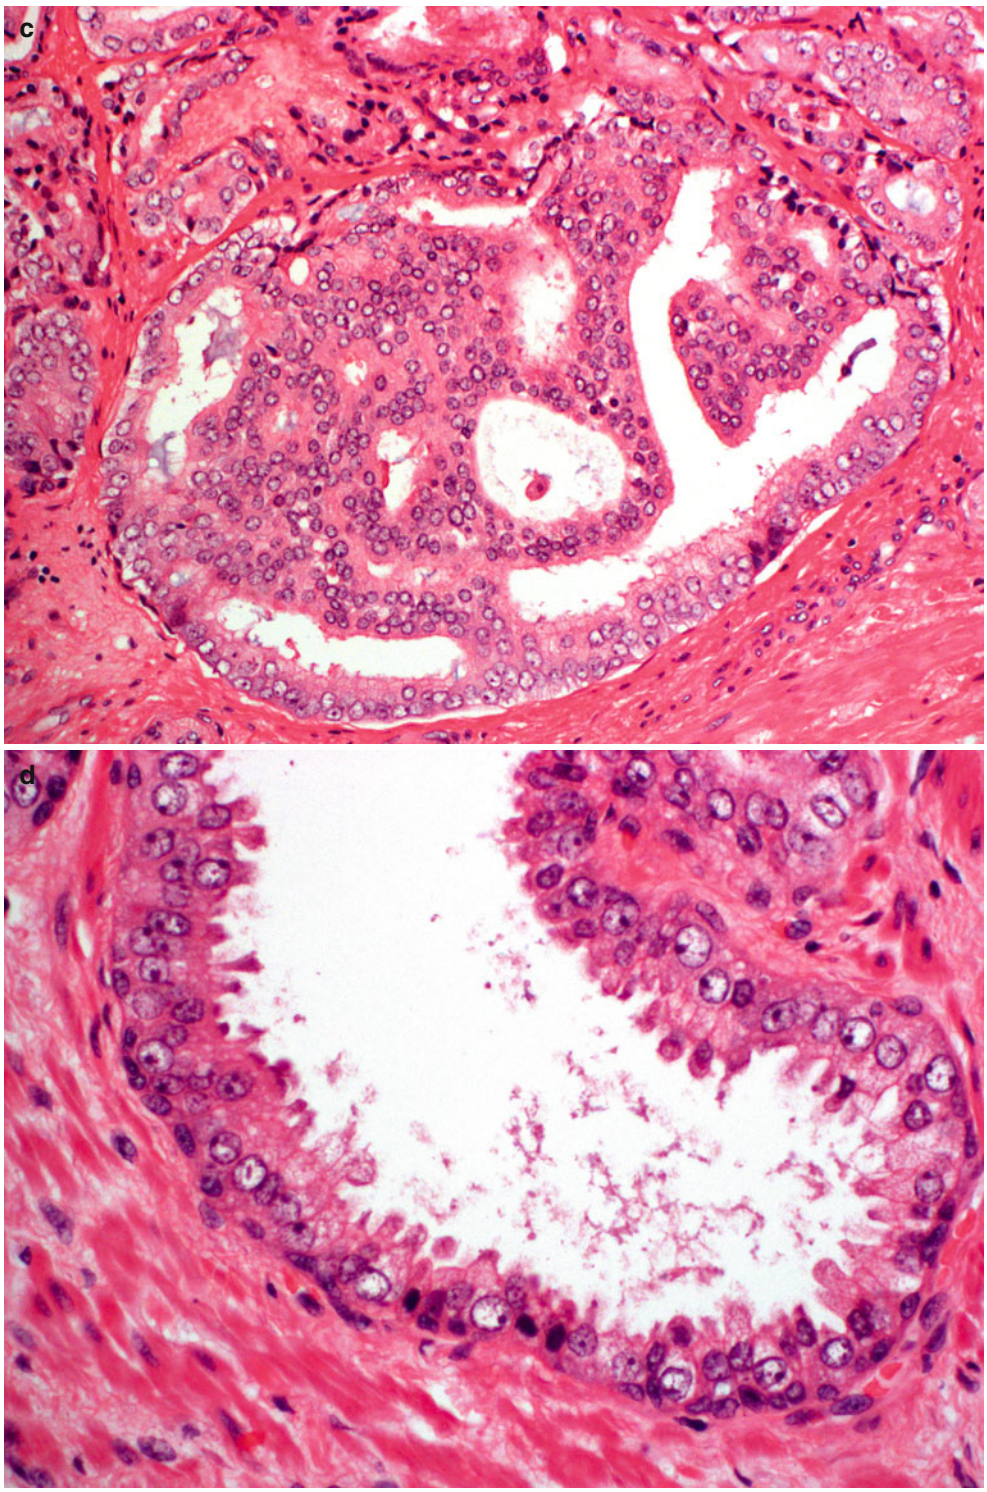
**Fig. 19.4** (continued)



ranging from 3 to 60 % [6, 27] and is related greatly to age. The incidence appears to reach 5–10 % in the age range 30–40 but is greater than 40 % after age 50.

In transurethral resection specimens (TURP), the incidence of HGPIN is far lower, ranging from 2 to 15 % in specimens without cancer and 3–58 % in specimens with cancer [31–34]. This is probably because the vast majority of prostate cancers arise in the peripheral zone: usually poorly sampled on TURP and therefore HGPIN, a largely peripheral zone lesion, is rarely seen.

Although all the above studies are of great academic interest, the incidence of PIN and its association with cancer in needle core biopsy specimens is of far more interest. The incidence of HGPIN in studies, which are largely

retrospective, varies from 0.7 to 25 % [35, 36] though most are intermediate falling into the 5–10 % range [37–42]. However, in some of these studies, the distinction between high- and low-grade PIN is not made. Unsurprisingly, HGPIN is also seen in biopsies which also contain invasive carcinoma, ranging from 10 to 40 % in incidence [33, 43–45].

The multifactorial reasons for such widely discrepant results are worthy of consideration. Different patient populations may account partly for this variability, including ethnicity and also method of detection: screening, symptomatic, or serendipitous. While prostate biopsy strategies involved taking two to four cores in the 1980s and early 1990s, the increase in the number of biopsies taken, to sextant, decant,

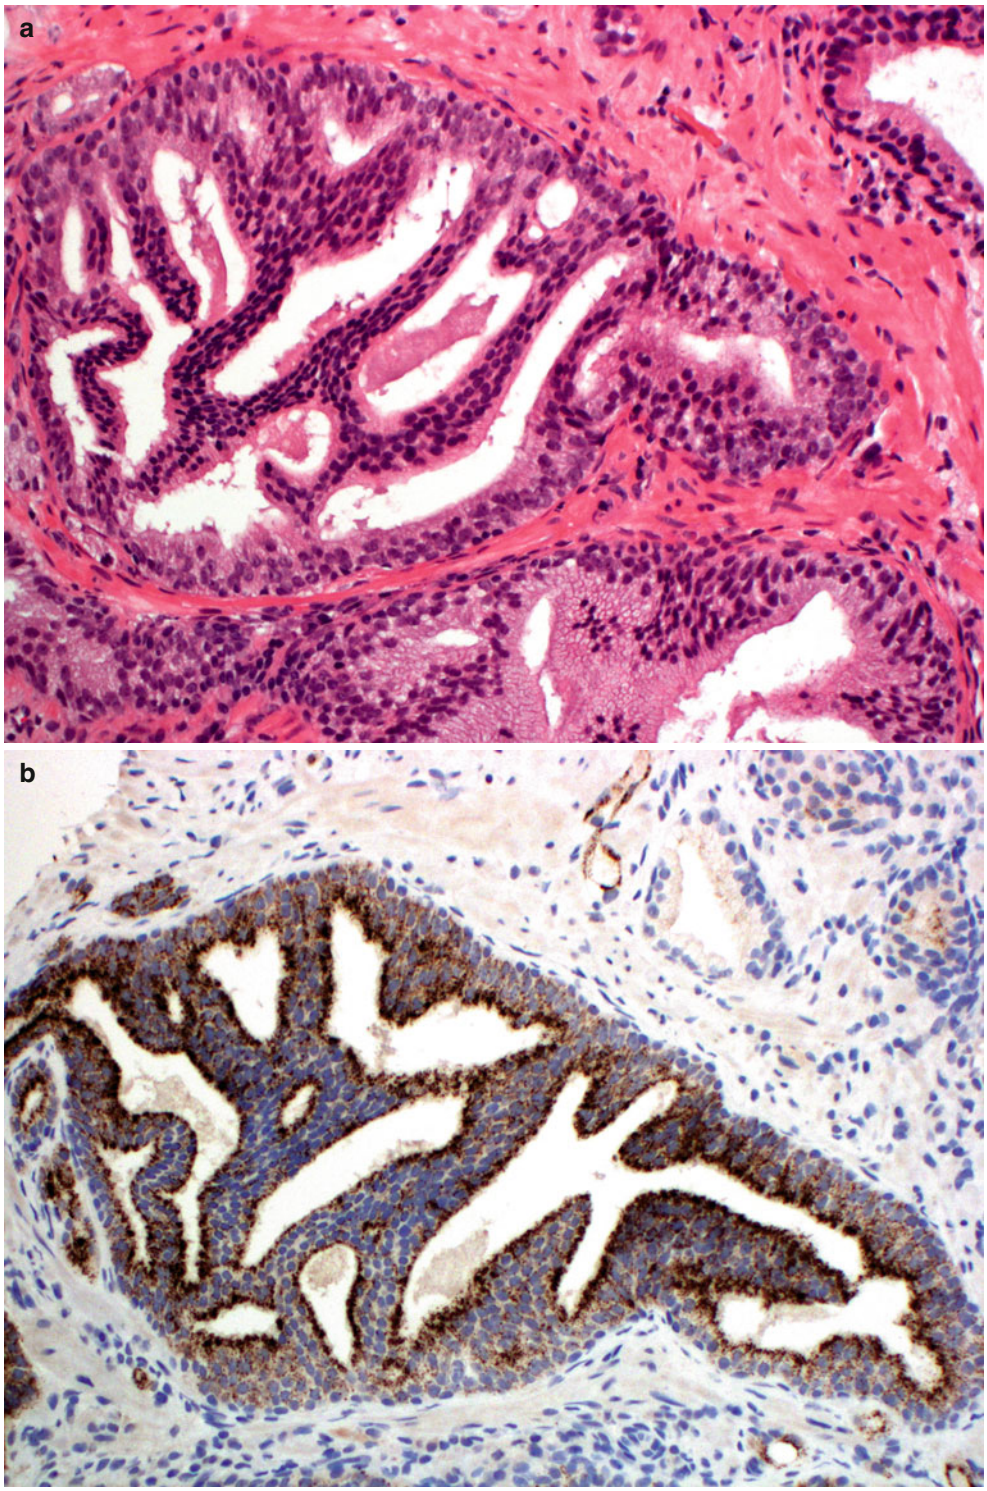


**Fig. 19.5** (**a**–**d**) High-grade PIN immunohistochemistry. Hematoxylin and eosin (**a**) of a gland showing high-grade PIN (*center*), with positive staining for AMACR (**b**) and basal cells demonstrated with p63 (**c**) and 34βE12 (**d**)

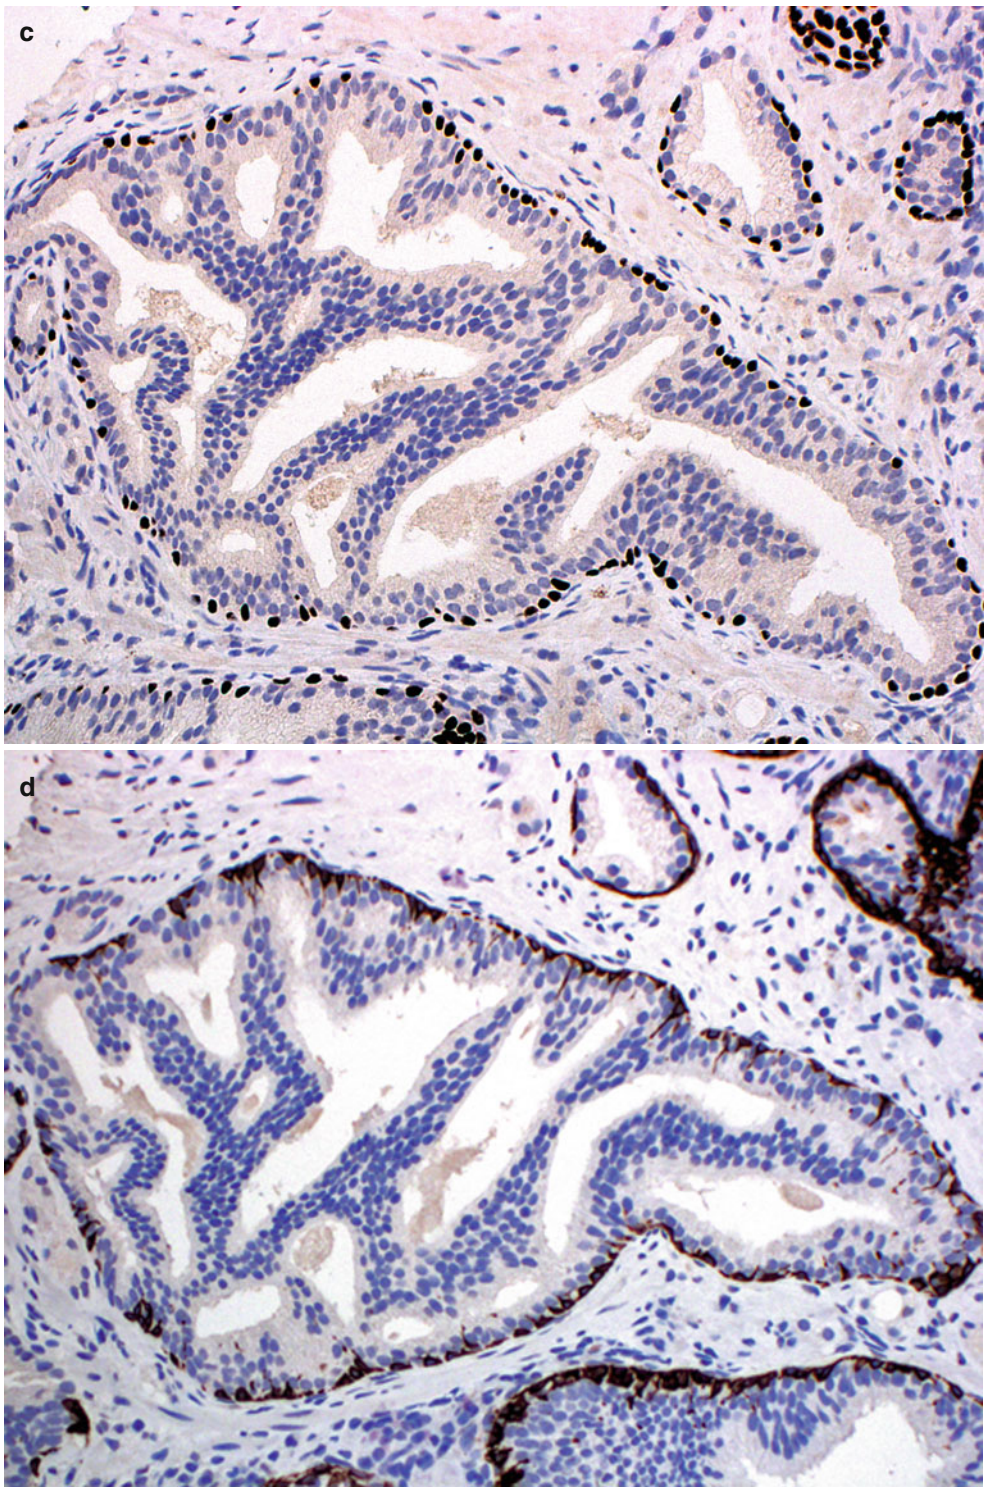
**Fig. 19.5** (continued)



and later saturation biopsies, will affect incidence, as small foci of HGPIN will be more likely to be detected. There will also be an effect on the balance of HGPIN detected in isolation and that detected with cancer, as more intensive biopsy strategies will also detect smaller prostate cancers with increased frequency [46].

Unfortunately, methods of pathological processing may also affect the incidence of HGPIN diagnosis. Bouin's fixative gives better nuclear detail than formalin fixation, and therefore nucleoli are easier to see and HGPIN more readily diagnosed [47]. Section thickness and quality of hematoxylin and eosin staining may also affect the diagnosis.

Interobserver variation is also, inevitably, an important factor [48].

## Review of Evidence Linking HGPIN and Malignancy

The evidence that HGPIN is the precursor lesion for at least some adenocarcinomas of the prostate comes from a variety of sources including epidemiology, histopathological morphology, immunochemistry, and increasingly shared genetic changes. As suggested by the incidence of HGPIN above, it may be identified in prostates at a younger age than carcinoma, preceding it by about 10 years. With increasing age, there is an increase also in the amount of HGPIN seen, and multifocal cancers are associated with increasing HGPIN [27, 49, 50].

HGPIN has been shown by a number of studies to be more common in the peripheral zone, mirroring the location of invasive adenocarcinoma [51, 52]. The cytological features of HGPIN mirror those of invasive carcinoma (by definition), but there is also, as suggested earlier, an association between the differentiation patterns seen in HGPIN and the associated malignancy [16]. HGPIN is sometimes associated with small "outpouchings" of invasive cancer (covered in more detail later) [53].

While benign glands with no HGPIN almost always have a complete basal cell layer and invasive malignancy shows a lack of basal cells, HGPIN often shows a disrupted and incomplete basal cell layer [22].

Immunohistochemical positivity for AMACR in HGPIN is frequently seen, though probably lower than that in invasive carcinoma [19–21], and this mirrors the literature in most of the identified immunochemically investigated oncogenes and tumor suppressor genes such as BCL-2 [54], RER [55], hK2 [56], and EGFR [57].

HGPIN tends to be aneuploid but less so than invasive carcinomas [58]. The TMPRSS2-ERG fusion gene which has been described as a common change in prostate cancer [59] has also been described in a significant but lower percentage of HGPIN lesions [60, 61] and also in whole-mount prostatectomy specimens where there is a definite, though complex, relationship between the fusion gene in HGPIN and adjacent cancers[10]. Among other chromosomal changes, loss of chromosome 8p and gain of 8q have been both described in prostate cancer and HGPIN. Gain of chromosomes 7,8,10, and 12 has also been described [62]. Telomere shortening is seen in both HGPIN and invasive carcinomas [63].

Unlike many other organs, such as the cervix, where the preneoplastic lesions can be monitored and rebiopsied, it is not possible at present to identify HGPIN with the certain knowledge that there is no invasive malignancy present or to prove that the invasive focus arises from a known premalignant focus. For these reasons, the evidence linking HGPIN to prostate cancer remains circumstantial but extremely convincing.

However, there is circumstantial evidence that some cancers may not arise from HGPIN. Many prostate cancers identified in the transition zone by TURP are low grade and show no HGPIN. Even in radical prostatectomy specimens, which have been completely embedded, many early cancers lack associated HGPIN, and there is frequently a lack of spatial relationship between the HGPIN and the invasive focus [27, 64]. Possible preneoplastic lesions other than HGPIN will be described later.

## HGPIN and Diagnosis of Adenocarcinoma on Repeat Biopsy

The only clinical import of a diagnosis of HGPIN, at present, is when it is diagnosed without associated malignancy in biopsy specimens. Probably uniquely among all cancers, prostatic adenocarcinoma is now largely diagnosed by a nonspecific test (PSA) and using an essentially "blind" biopsy method where lesions are not targeted. Therefore, a negative biopsy does not completely exclude malignancy, though recent increases in the number of biopsies taken and use of saturation techniques have reduced this false negative rate. If patients with HGPIN in isolation on prostatic biopsies are to be followed up in a different manner than a negative biopsy, then it must be clearly proven that they are at increased risk of harboring or developing a significant invasive malignancy.

Unfortunately, the evidence for this is clouded by a number of different factors. As mentioned above, when discussing the incidence of HGPIN, multiple pathological factors lead to variation in the diagnosis of HGPIN as well as clinical factors such as the number of cores taken and patient population. In addition to this, follow-up strategies have varied over the past 20 years and from center to center, which means that results are not easily comparable. Table 19.2 summarizes some selected series over the past 20 years. It can be seen that the incidence of cancer detection on rebiopsy varies wildly from 2 to 100 % [65, 66] with virtually every percentage in between [67–93]. However, this crude analysis fails to appreciate fully the differences in techniques used and changes in biopsy practice, which may allow a refinement of clinical practice in the future.

Due to the insensitivity of prostate biopsies to detect invasive cancer, there remains a false negative rate of cancer diagnosis with first biopsy even after a biopsy with normal histological appearances, varying in the literature between 2 and 32 % [83, 94] with a reported aggregate mean in one analysis of all studies as 19 %[95]. As can be seen from

**Table 19.2** Publications on HGPIN rates

| Author | Year | Carcinoma on rebiopsy/total no of HGPIN cases | Percentage (%) | No. of cores taken |

| *Aggregate* | | *830/3,183* | *26.1* | |

Table 19.2, between 1991 and 2010, there has been an increase in the number of biopsies taken at initial consultation, which will have reduced this false negative rate (as smaller cancers are detected). Saturation biopsies, which are now more common, and also transperineal biopsies, which sample the anterior portions of the prostate, will further distort the figures in the literature.

Unfortunately, very few studies have shown this in a systematic fashion, with only two studies showing a significant difference between cancer rates after HGPIN compared to a benign diagnosis [69, 83] while many others show no difference [76, 86, 89, 96, 97].

More recent studies have attempted to refine the risk factors for invasive cancer by examining the amount of HGPIN seen on biopsy. While some studies have shown there is no association between the amount of cancer seen on rebiopsy by looking at the number or percentage of cores involved [79, 80, 83], other studies have suggested that two or more cores involved with HGPIN are significant risk factors, whereas those cases where only a single focus of HGPIN can be seen are less significant and can probably be followed up in a similar manner as a negative core [85, 87]. Two very recent studies from the same group [92, 98] involving 12,304 prostate biopsies and studying only extended set biopsies in one paper [98] confirmed the association between cancer risk and the number of involved cores with HGPIN.

## Intraductal Carcinoma

Intraductal carcinoma (IDC) is a controversial entity, which has come under increasing attention in the past 20 years. It was first characterized in 1985, when prostatic ducts "invaded" by tumor cells were associated with Gleason grade and tumor extent [99].

McNeal et al. showed that cribriform carcinomas were often intraductal and concluded that these intraductal cancers actually arose within the affected ducts and were of more aggressive appearance and stage than noncribriform cancers [100]. In 1996, McNeal and Yemoto suggested the term "intraductal carcinoma" to describe intraductal proliferations that were associated with poor prognostic factors [101].

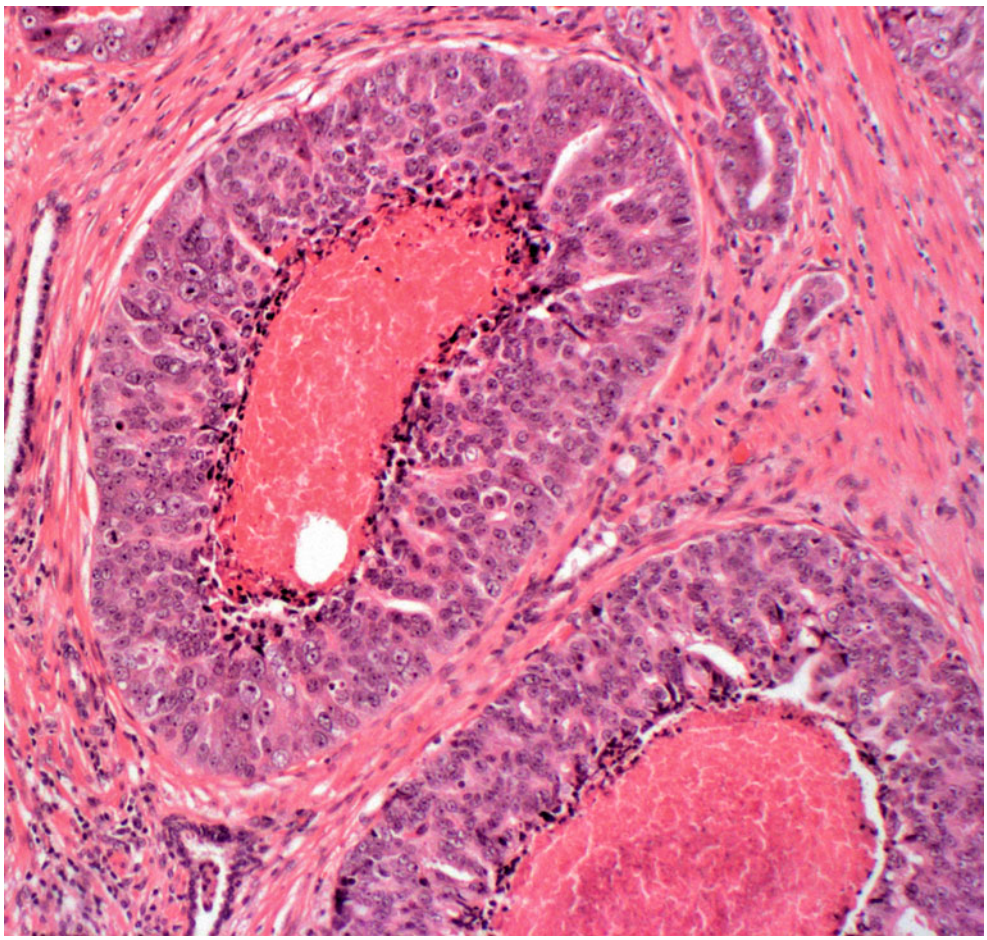

**Fig. 19.6** Intraductal carcinoma in two large ducts. The central "comedo" type of necrosis precludes this from being high-grade PIN. There are intervening small atrophic benign glands (*left*) and invasive malignant glands (*right*)

**Table 19.3** Comparison of morphology of intraductal carcinoma with HGPIN

| | HGPIN | IDC |
|---|---|---|
| Duct/gland size | Normal | Increased (2×) |
| Lumen spanning cells | Absent | Present |
| Patterns | Flat | Micropapillary/trabecular |
| | Tufted | Cribriform |
| | Micropapillary | Solid/comedo |
| | Cribriform | |
| Nuclear size | Slightly increased (×2–3) | Markedly increased (6×) |
| Nuclear atypia | Mild atypia only | Marked pleomorphism |
| Mitoses | Absent | Present |
| Comedo necrosis | Absent | May be present |
| Immunohistochemistry | AMACR+ve | AMACR+ |
| | PSA+ve | Central compartment: PSA+ |
| | | Peripheral compartment: AR+ |

This aimed at distinguishing these lesions from HGPIN, low-grade PIN, and invasive cribriform tumors. They postulated that this lesion represents intraductal spread of adenocarcinoma [101] (Fig. 19.6). An alternative would be an "end-stage" of PIN before invasion. There are overlapping morphological features between HGPIN and IDC, hence the controversy with the diagnosis, although comedo necrosis and more extreme atypia are indicative of the latter (Table 19.3). In support of the association with malignancy, a number of groups have shown that IDC has a very high risk of carcinoma elsewhere in the prostate [102, 103] showing that these cancers tended to be of high stage and grade. More recently, it has been advocated that if IDC is diagnosed on needle biopsy, the outcome for the patients is so adverse

that radical therapy can be contemplated without the need for identification of invasive tumor [103].

A recent study examined 83 men with IDC in isolation without associated cancer [104]. Twenty-one of these cases went on to radical prostatectomy, and although 19 of the cases had invasive tumors which tended to be high stage and grade, 2 patients (10 %) had IDC only with no invasive malignancy. Although the authors recommend that all cases of IDC should be treated radically, their results suggest there may be dangers in this approach.

## Glandular Atypia as a Premalignant Lesion: "ASAPs"

Occasionally, a pathologist will encounter an area of glands that fulfill some, but not all, of the cytological and architectural features of a carcinoma. There is, however, little consistency between pathologists in the diagnosis of essentially subjective criteria [105]. The question of the number of atypical glands that are required for a diagnosis of malignancy is unanswerable. These glandular foci therefore include a chimeric assembly of different entities including undersampled carcinomas, reactive changes in benign glands, PIN, or inflammatory atypia (Fig. 19.7a, b).

Assigning a name to this constellation of uncertain entities has proven difficult: mostly because any name assigned immediately invites an acronym and therefore by default, it becomes an entity in its own right. Therefore, the synonyms focal glandular atypia (FGA) and atypical small acinar proliferation (ASAP) have been used, as well as terms such as "borderline for malignancy" and "suspicious for carcinoma"[106–108]. For practical reasons, we will refer to ASAPs, without in any way agreeing that this term implies an entity, merely an uncertain diagnosis for carcinoma.

However, the diagnosis of ASAP in a clinical setting is important because, as will be discussed, of its association with a higher risk of prostatic malignancy than HGPIN.

### Incidence of ASAPs

The challenge of diagnosis of ASAP is largely confined to needle biopsies where it has clinical significance. Larger prostate specimens such as TURPs or radical prostatectomies are occasionally "dignified" with the diagnosis of ASAP; however, where there is the possibility of more complete assessment of the lesion, with multiple immunohistochemistry assessments, logic dictates that this assignation should be avoided where possible. There is variability in the diagnosis of ASAP in TURP specimens [109], and the clinical significance of such a finding is doubly dubious. We suggest that the diagnosis of ASAP should be rendered for prostate biopsies alone where it has clinical significance.

The incidence in needle biopsies varies from 1 to 9 % [39, 110] in contemporary series, with most studies falling between 2 and 5 % [78, 80, 107].

### The Diagnosis of ASAP

ASAP is, by definition, limited in extent, though there may be multiple foci of ASAP in one case [107]. Reasons for making the diagnosis include a focally infiltrating pattern, nuclear features in limited glands, or features which are often contributory to the diagnosis of malignancy, but which in isolation are of limited value. These include the presence of blue mucin or crystalloids.

The uncertain nature of the lesion means that some lesions that are benign are "interpreted" as ASAPS and includes lesions such as adenosis, atrophy, basal cell hyperplasia, or changes induced by hormones or radiation.

Additional further studies may be performed to differentiate ASAPs into definitive benign and malignant categories. These include further levels as well as immunochemistry for basal cell markers [111] or AMACR [112]. Importantly, the presence of basal cells in these atypical foci may help definitively render a benign diagnosis. However, absence of basal cells in a few glands may not be enough to diagnose malignancy as foci of adenosis may show occasional glands lacking basal cells. AMACR can also be used in this setting but should be used cautiously as occasionally benign glands can show positivity. In our experience, pathologists use AMACR cautiously in foci that they are "almost certain" are cancer in order to provide the final proof before sign out, and in those cases this seems a reasonable activity. There are, of course, degrees of pathological uncertainty, between benign and malignancy, and the term ASAP may cover a broad spectrum of lesions. Stratification of risk in atypical lesions has been attempted in the past [106, 113] but has not proven helpful in determining later risk for cancer. Unsurprisingly, interobserver error has recently shown to be high for the diagnosis of ASAPs, especially when the gland number falls below 6 [105]. Expert uropathologists are more likely to render a definitive diagnosis than general pathologists [48].

### ASAP and Diagnosis of Adenocarcinoma on Repeat Biopsy

Many studies have shown that the diagnosis of ASAP places the patient in a higher risk group for the later diagnosis of malignancy. However, the level of risk varies between different studies due to variations, not only in pathological diagnosis but also in number of biopsies taken (a higher number of biopsies will detect a higher percentage of low-volume cancers and lower the rate of ASAP diagnosis), operator, and whether spares are kept for immunochemistry later, which

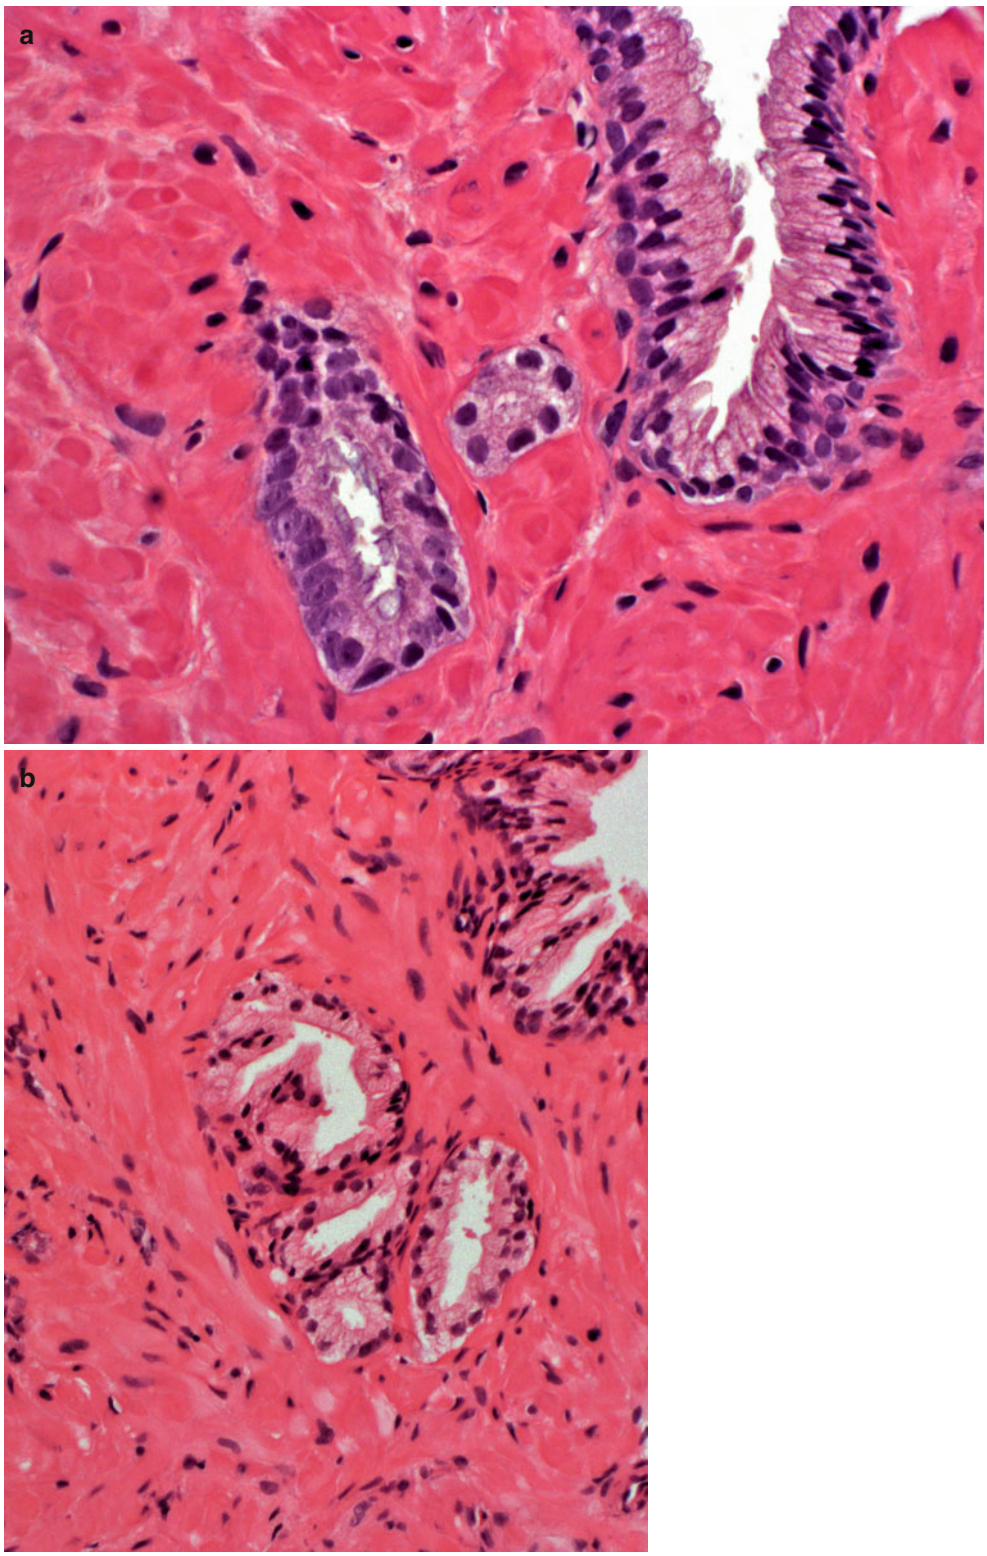

**Fig. 19.7** ASAP. Atypical small acini that lacked basal cells. Those in (**a**) are more suspicious of malignancy than those in (**b**). A benign large gland is on the right in (**a**) and (**b**)

may lower the rate of ASAP diagnosis as more definitive diagnoses can be made at first biopsy.

Virtually all studies suggest, however, that the risk of prostate cancer on repeat biopsy is substantially higher following a single ASAP focus than for PIN with the risk varying between 29 and 60 % [71, 107] with an average of 45 % [35, 76, 78, 80, 86, 106, 108, 110, 113–117] (Table 19.4). There is no significant trend in positivity rate over the past 20 years. This high rate of later diagnosis of cancer means that, in contrast to PIN, diagnosis of ASAP always warrants early repeat biopsy.

**Table 19.4** Publications on ASAP rates

| Author | Year | Carcinoma on rebiopsy/total no. of ASAPs | Percentage |
|---|---|---|---|

## High-Grade PIN associated with ASAP

Occasionally, prostate biopsies show both HGPIN and ASAPs. These can be of two types. The ASAP focus and the HGPIN may be unrelated spatially: either because they are in different biopsies or because they are in different parts of the same biopsy.

A second and more studied entity is when the ASAP is in association with the HGPIN. This has been given a variety of names including PIN with "outpouchings," PINATYP, or PIN/ASAP (Fig. 19.8).

The challenge of these foci is that the association of the atypical glands with the HGPIN creates a problem. HGPIN may show an interrupted basal cell layer and may be slightly irregular in appearance due to tangential cutting of the sectioning or "budding." There are few studies on the significance of PINATYP, but they confirm the high risk of later diagnosis of malignant disease, which is equivalent or possibly even higher than that of either HGPIN or ASAPs alone with studies by Alsifaki and Kronz showing rates of 46 and 75 %, respectively [77, 118]. Therefore, similar to ASAPs, these cases warrant early rebiopsy.

## Other Potential Preneoplastic Entities

Despite a wealth of epidemiological data, the causes of prostate cancer are still unclear. While inherited genetic risk factors have been identified [119, 120], there is a widespread belief that the differences in prostate cancer incidence in different ethnic groups may be due to environmental influences, which are yet to be fully identified. It has been suggested that chronic inflammation may be a key etiological factor in the development of prostate cancer [121].

In support of this, an entity has been described where glandular atrophy is associated with glandular proliferation and chronic inflammatory cells. This has been termed proliferative inflammatory atrophy (PIA) [122].

The finding that atrophic changes in the prostate could show a high proliferation rate was shown serendipitously initially [123] and the potential significance not recognized. However, more recent studies provided indirect evidence that these lesions may be an intermediate stage between PIN and normal prostate, which has a low proliferation rate [124–126].

Other evidence linking PIA to cancer include studies which show shared genetic and immunohistochemical changes with PIN and invasive malignancy [124, 127–129]. Morphological papers show contradictory findings with some studies showing transitions between PIN and PIA [130–132], while others show no morphological association [133–135].

An animal model has shown that in rats fed a carcinogen present in charred meat it leads to significant prostatic inflammation and atrophy followed by HGPIN [136]. However attractive this hypothesis, it remains unproven. PIA is common throughout the prostate and is present in young adults [137], whereas HGPIN and cancer develop predominantly in the peripheral zones in older age groups. PIA is likely to remain as an addendum to any discussion of premalignant lesions until considerable further evidence is forthcoming.

### Conclusions

The Red Queen Hypothesis [138] is a term used primarily for evolutionary theory taken from the Red Queen's race in Lewis Carroll's *Through the Looking-Glass*. The Red Queen says to Alice, "It takes all the running you can do, to keep in the same place." Such problems also occur in

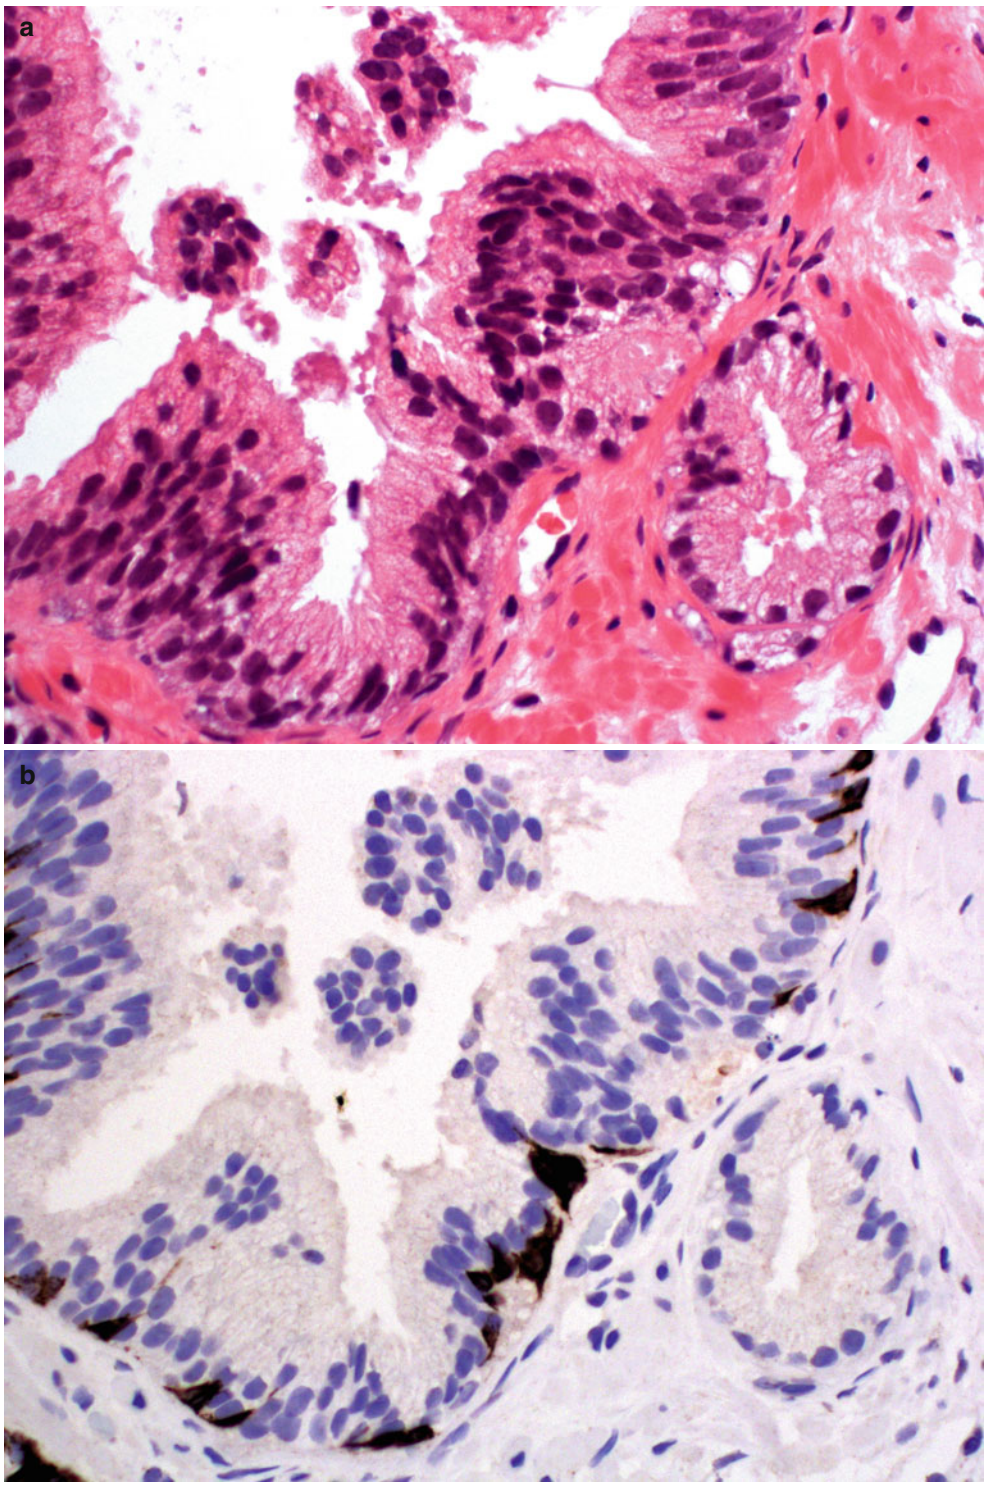

**Fig. 19.8** High-grade PIN with a closely adjacent atypical acinus that could represent an "outpouching" from the PIN or invasive carcinoma (**a**). This acinus lacks basal cells on the 34BetaE12 immunohistochemistry (**b**)

rapidly evolving medical problems where every study is immediately outdated by the time it is published as practice has changed.

The revolutions that have occurred in the treatment and diagnosis of prostate cancer over the past 20 years have enhanced our understanding of the disease in many respects but left other problems unsolved and confusing for clinicians, pathologists, and basic researchers. On the positive side, we now understand the pathogenesis of probably the majority of prostate cancers, with a clear association with HGPIN. However, other entities such as "ASAP" and low-grade PIN are often used with little understanding of their role or otherwise in the pathogenesis of prostate cancer or their risk for the development of malignancy.

Also, most importantly, changes in practice have led to immense variability in the predictive value for cancer when these lesions are diagnosed, and many papers where sextant biopsy data has been utilized are no longer relevant, rightly or wrongly, to modern practice. Progress in these areas is undoubtedly necessary if we are to optimize the treatment of patients with a diagnosis of HGPIN or ASAP. Only close collaboration between urologists, pathologists, other members of the multidisciplinary team, and basic researchers in multiple institutions will help to solve the many conundrums of premalignancy in the prostate.

# The Pathology of Prostatic Carcinoma

20

Maria M. Shevchuk and Brian D. Robinson

## Adenocarcinoma

### Diagnosis

*Adenocarcinoma* of the prostate comprises 95 % of the malignant neoplasms of the prostate, and most of these are of the "conventional" acinar type. The histopathologic diagnosis of adenocarcinoma (also referred to as prostatic carcinoma) is made on the basis of a combination of several histologic features. No one feature is sufficient on its merits, except for perineural invasion and possibly mucinous fibroplasia and glomeruloid bodies (glomerulations). The diagnostic features are grouped into primary and secondary criteria. Tertiary criteria are helpful and supportive of the diagnosis.

*Primary criteria* refer to the *architecture* or *pattern* of the glands. Benign prostatic glands are medium-sized and arranged in lobules. Carcinomatous glands are (1) frequently small (microacini), (2) crowded, (3) haphazardly arranged, not in lobules, (4) fused, (5) have an infiltrative pattern, and (6) invade between benign glands or cut-across muscle fibers, splitting them (Table 20.1) (Fig. 20.1). *Perineural invasion*—the presence of malignant glands in a perineural space—is an architectural feature that most pathologists consider to be diagnostic of prostatic carcinoma on its own merits (Fig. 20.2). There are two other relatively uncommon architectural features some consider to be diagnostic on their own merits. *Mucinous fibroplasia* consists of scar-like fibrous replacement of extravasated glandular mucin. *Glomerulations*, which are intraglandular cribriform and papillary proliferations attached to the malignant gland at one pole that resemble fetal glomeruli, are the third rare diagnostic feature (Fig. 20.3).

*Secondary criteria* are *cytologic* (Table 20.1). They include (1) *the absence of the basal cell layer* and (2) the presence of *large*, *hyperchromatic nuclei* with *prominent nucleoli*.

Since prostatic adenocarcinoma derives from the inner secretory cell layer, malignant acini *lack a basal cell layer* and are lined by a single layer of cells (Fig. 20.4). Immunohistochemistry can be used to confirm the absence of a basal cell layer, and pathologists typically employ both the cytoplasmic stain for high molecular weight cytokeratin (*HMWCK*, also known as CK903 and 34BE12) as well as the nuclear stain for *p63*. These two stains are frequently combined with an immunohistochemical stain for *AMACR* (alpha-methylacyl-CoA-*racemase*), which is positive in the cytoplasm of approximately 85 % of prostatic adenocarcinomas, and generally negative or only faintly positive in benign glands (Fig. 20.5). The triple immunohistochemical stains are used only for confirmation of diagnostically challenging or minute tumor foci and should never be used as the sole or main criterion for the diagnosis of prostatic carcinoma.

The other main cytologic criterion is the presence of *large*, *occasionally red*, *nucleoli* in large hyperchromatic nuclei (Fig. 20.4). These nuclear features are important for the diagnosis of carcinoma, but they may occasionally be obscured by suboptimal fixation and by other artifactual changes.

*Tertiary criteria* are supportive of the diagnosis of malignancy and often help to distinguish malignant glands from the adjacent benign counterparts. These tertiary criteria include (1) *luminal blue mucin*, (2) *luminal pink amorphous secretions*, (3) *crystalloids*, (4) *sharp luminal borders*, *and* (5) *amphophilic or foamy cytoplasm* (Fig. 20.6) [1].

**Table 20.1** Criteria for the diagnosis of prostatic carcinoma

| |
|---|
| Primary criteria |
| *Architectural—diagnostic* |
| 1. Small glands (microacini) |
| 2. Crowded glands |
| 3. Haphazardly arranged glands, not in lobules |
| 4. Fused glands |
| 5. Infiltrative pattern |
| 6. Small glands around/between benign glands |
| 7. Perineural invasion |
| 8. Mucinous fibroplasia |
| 9. Glomerulations |
| Secondary criteria |
| *Cytologic—diagnostic* |
| 1. Absence of basal cells |
| 2. Large nucleoli |
| 3. Large hyperchromatic nuclei, with an increased nucleus-cytoplasm ratio |
| Tertiary criteria |
| *Cytoplasmic/luminal—supportive* |
| 1. Luminal blue mucin |
| 2. Luminal pink amorphous secretions |
| 3. Crystalloids |
| 4. Sharp/rigid luminal borders |
| 5. Amphophilic or foamy cytoplasm |

## Clinicopathologic Summary

*Diagnosis of prostatic adenocarcinoma*:

1. The *diagnosis* of prostatic *adenocarcinoma* is made on the basis of a combination of *primary* (*architectural*) and *secondary* (*cytological*) criteria.
2. Features, which are diagnostic on their own merit (although uncommon), are
   (a) *Perineural invasion*
   (b) *Mucinous fibroplasia*
   (c) *Glomerulations*
3. *Tertiary—cytoplasmic/luminal* criteria are supportive of the diagnosis of carcinoma.
4. The diagnosis of adenocarcinoma might require confirmation from immunohistochemistry to show the *absence of HMWCK and p63* staining for basal cells and the *presence of AMACR*.

## Gleason Grading

Grading of tumors gives important information about the malignant potential of the neoplasms and is usually based on their degree of deviation from normal histology. For prostatic carcinoma, the Gleason grading system is the internationally accepted standard, with extensive clinical validation. It was developed in the 1960s by Donald Gleason and his colleagues [2, 3] and has recently been updated to accommodate current diagnostic practices [4]. The Gleason grading system is based on the premise that the prognosis of prostatic carcinoma is related to the degree of differentiation of the two most common patterns/grades and is not solely determined by the least differentiated foci, as is commonly done for most other tumors. The *Gleason grading system* is based entirely on the primary criteria of *architecture*, evaluated at low to intermediate magnification (using the 4× and 10× objective lenses). The grade of the most common (*primary*) pattern *is added* to the grade of the second most common (*secondary*) pattern. Patterns range from 1 to 5, with pattern 1 being the most differentiated (Fig. 20.7). The sum of the primary and secondary patterns is called the *Gleason score* and ranges from 2 to 10. An example is a Gleason score 7 (4+3) (primary pattern 4+ secondary pattern 3). Should only one pattern be present in the prostatic carcinoma that pattern is doubled to give the Gleason score. An example is Gleason score 6 (3+3). Reporting of the Gleason score, along with the primary and secondary patterns, is recommended because this gives valuable information to the treating physician.

The *2005 ISUP consensus* update also stipulates that should there be a *tertiary pattern 5* on needle biopsy, it should replace the secondary pattern in computing the Gleason score. For example, a positive core with Gleason patterns 4+3 and tertiary pattern 5 should be diagnosed as Gleason score 9 (4+5) to reflect the significant impact that a Gleason pattern 5 carcinoma has on prognosis and the uncertainty about possible sampling error of a tumor that contains a Gleason pattern 5. However, in prostatectomy specimens, the consensus is to grade such a tumor as Gleason score 7 (4+3; primary pattern+secondary pattern) with tertiary pattern 5 because the entire carcinoma is available for evaluation.

*Gleason pattern 1* consists of a completely circumscribed nodule of tightly packed microacini. The international consensus is that in almost all cases, this pattern represents *atypical adenomatous hyperplasia* (*AAH*) (Fig. 20.8), and therefore Gleason pattern 1 should not be used in grading prostatic carcinoma.

*Gleason pattern 2* consists of a circumscribed nodule of small acini, with some variation in size, which are less tightly packed than in pattern 1 and may show minimal peripheral invasion into stroma but never into benign lobules (Fig. 20.9). This pattern is rarely diagnosed in needle biopsies because the entire nodule cannot be visualized on the thin needle biopsy core, and, therefore, the nodule's circumscription cannot be ascertained. Furthermore, this pattern is most common in the transition zone, which is usually not biopsied.

*Gleason pattern 3* consists of glands infiltrating benign lobules and stroma. These glands are discreet microacinar and occasionally macroacinar structures, frequently with irregular contours. Infiltrating glands in needle biopsies belong to this pattern (Fig. 20.10).

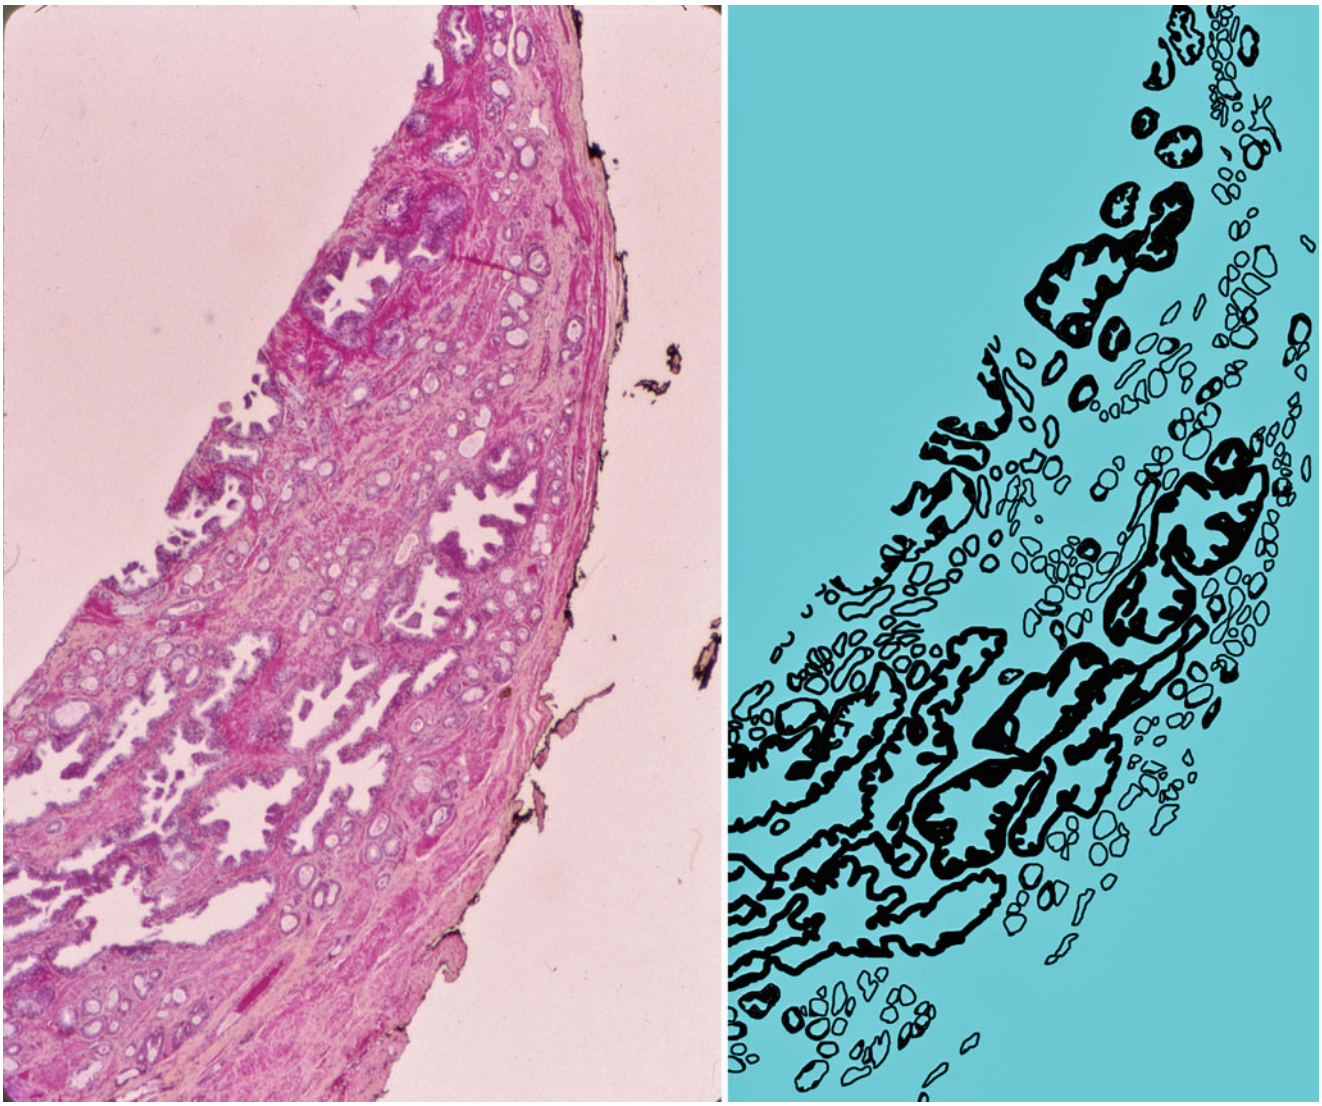

**Fig. 20.1** Malignant microacini infiltrating between two benign lobules. The *right panel* emphasizes the lobular pattern of the benign larger glands, in contrast to the haphazardly infiltrating abnormal small glands of the carcinoma

*Gleason pattern 4* is considered a high-grade pattern, with important clinical implications. It consists of fused glands either forming "chains" or cribriform sheets. The 2005 ISUP consensus also added "ill-formed" glands to this category. Several studies found a worse prognosis for tumors in which pattern 4 was primary, as compared with those in which pattern 4 was secondary: Gleason score 7 (4+3) versus Gleason score 7 (3+4) [5]. Therefore, the primary and secondary Gleason patterns should always be indicated in these cases in addition to the Gleason score sum (Fig. 20.11).

*Gleason pattern 5* is the highest grade, constituting an essentially undifferentiated adenocarcinoma. Glandular architecture is completely lost, and the tumor cells grow in single file, nests, and sheets. The comedo pattern—glandular tumor with central necrosis—also belongs to pattern 5. As mentioned in the discussion about tertiary patterns, the presence of pattern 5 is so clinically significant that it should be part of the biopsy Gleason score, irrespective of its quantity (Fig. 20.12).

In cases with *multiple positive cores with different Gleason scores/primary and secondary patterns*, the most common practice is to assign the highest Gleason score to the case and use it in nomograms and tables [6]. The highest Gleason score on biopsies correlates reasonably well with the subsequent prostatectomy Gleason score. The global Gleason score, which is the sum of the primary and secondary patterns of the tumor foci on all the positive cores taken together, predicts the prostatectomy Gleason score slightly better than the highest Gleason score (though not statistically significant) and gives additional information to the clinician. It also presents an opportunity to indicate whether a Gleason pattern 5 is likely to be the secondary or the tertiary pattern in the prostatectomy [7].

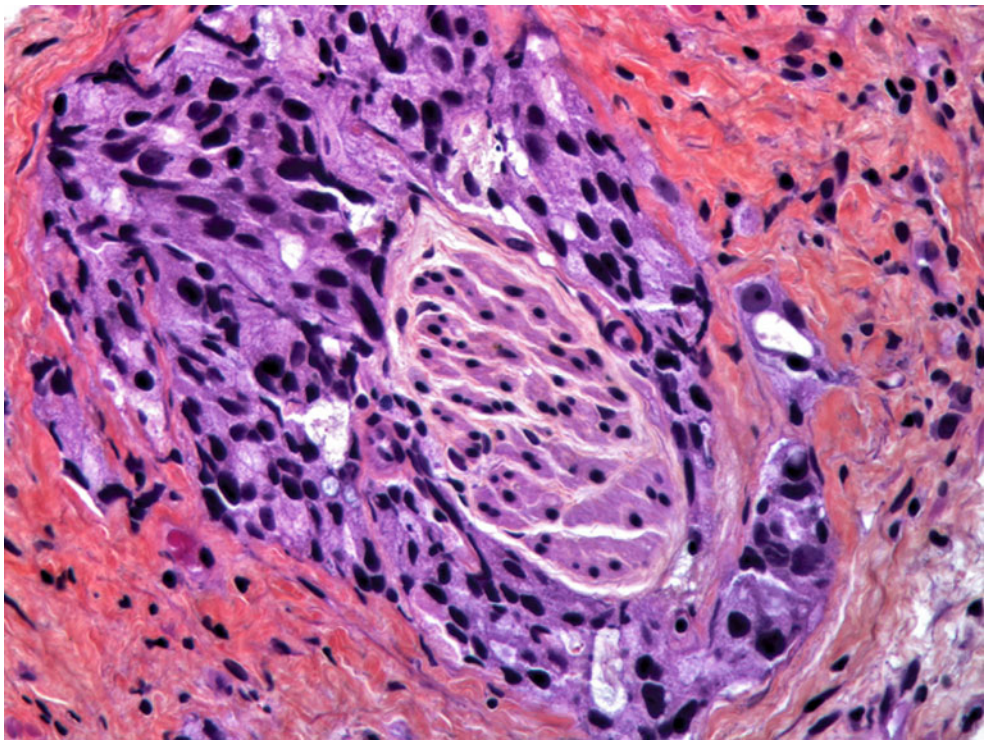

**Fig. 20.2** Perineural invasion. Cribriform malignant glands occupy the perineural space and completely surround the nerve

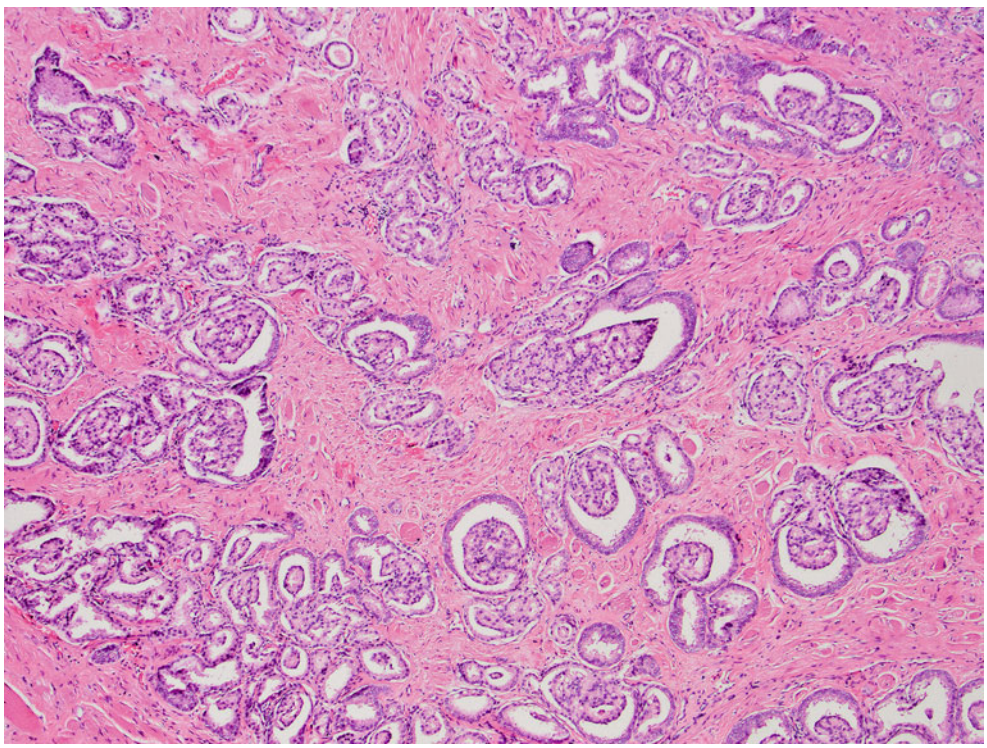

**Fig. 20.3** Glomerulations. Intraglandular cribriform and papillary growth with a unipolar attachment within the malignant glands. These bear some resemblance to fetal glomeruli, accounting for their name. These structures are considered to be part of Gleason pattern 4

## Reproducibility of Gleason Grading

Since the Gleason grade plays such an important role in treatment choice and prognosis of prostatic carcinoma, urologists and other treating clinicians need to factor in issues of reproducibility and reliability of the Gleason grading rendered on biopsy. Gleason himself addressed this question in a study in which he graded the same series of prostatic carcinomas twice, 1 year apart. He assigned the same score on both reviews in 50 % of cases and a score of ±1 in 85 % of

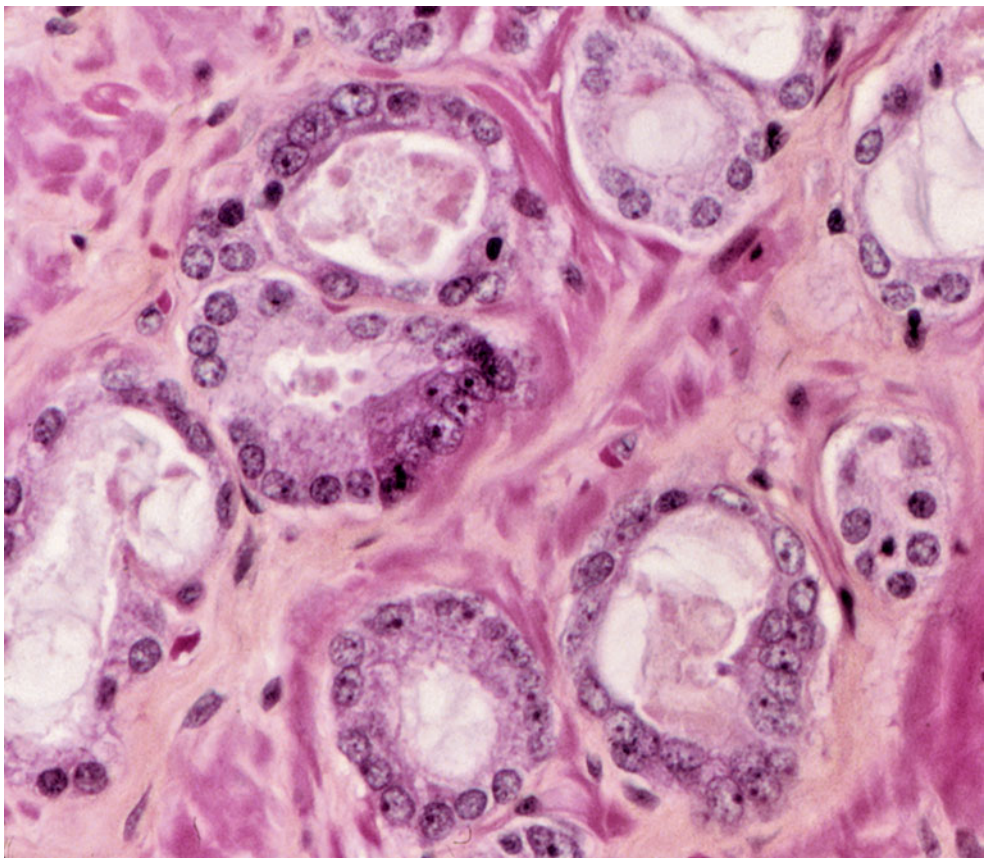

**Fig. 20.4** Cytologic features of malignancy. The malignant glands have a single cell layer, and the nuclei are enlarged and hyperchromatic with prominent nucleoli. The cytoplasm is amphophilic

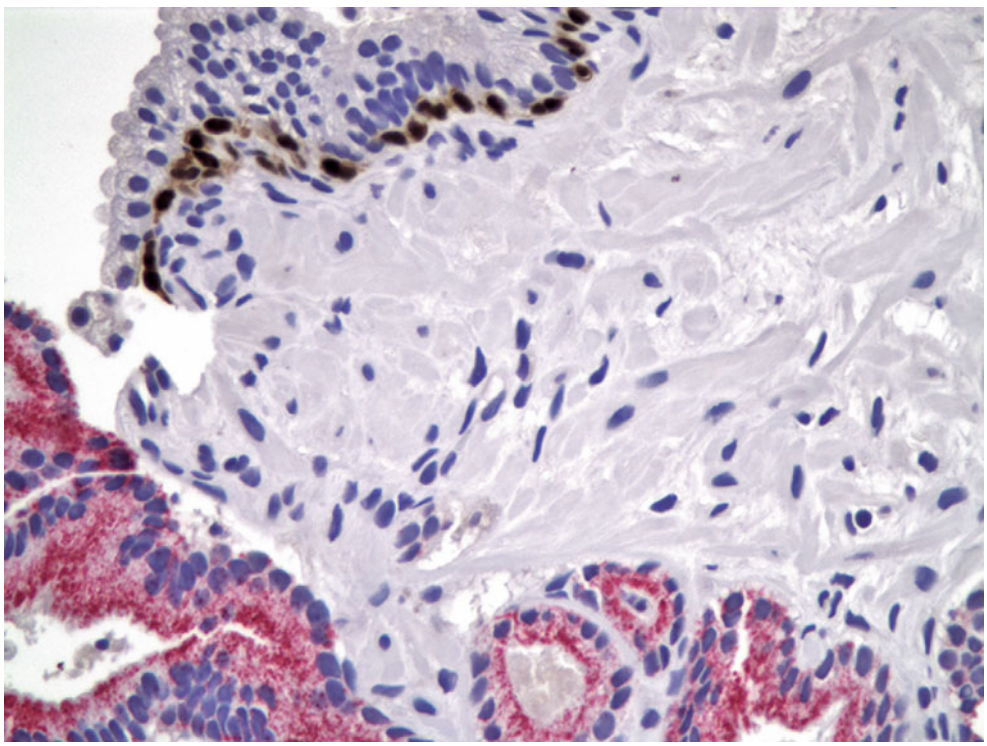

**Fig. 20.5** Triple immunohistochemical stains. The benign gland in the left upper corner is outlined by basal cells, whose cytoplasm is positive (*brown stain*) for HMWCK and whose nuclei are positive (*brown stain*) for p63. The malignant glands at the bottom of the image lack the brown basal cell stains but are strongly positive for the red-staining AMACR

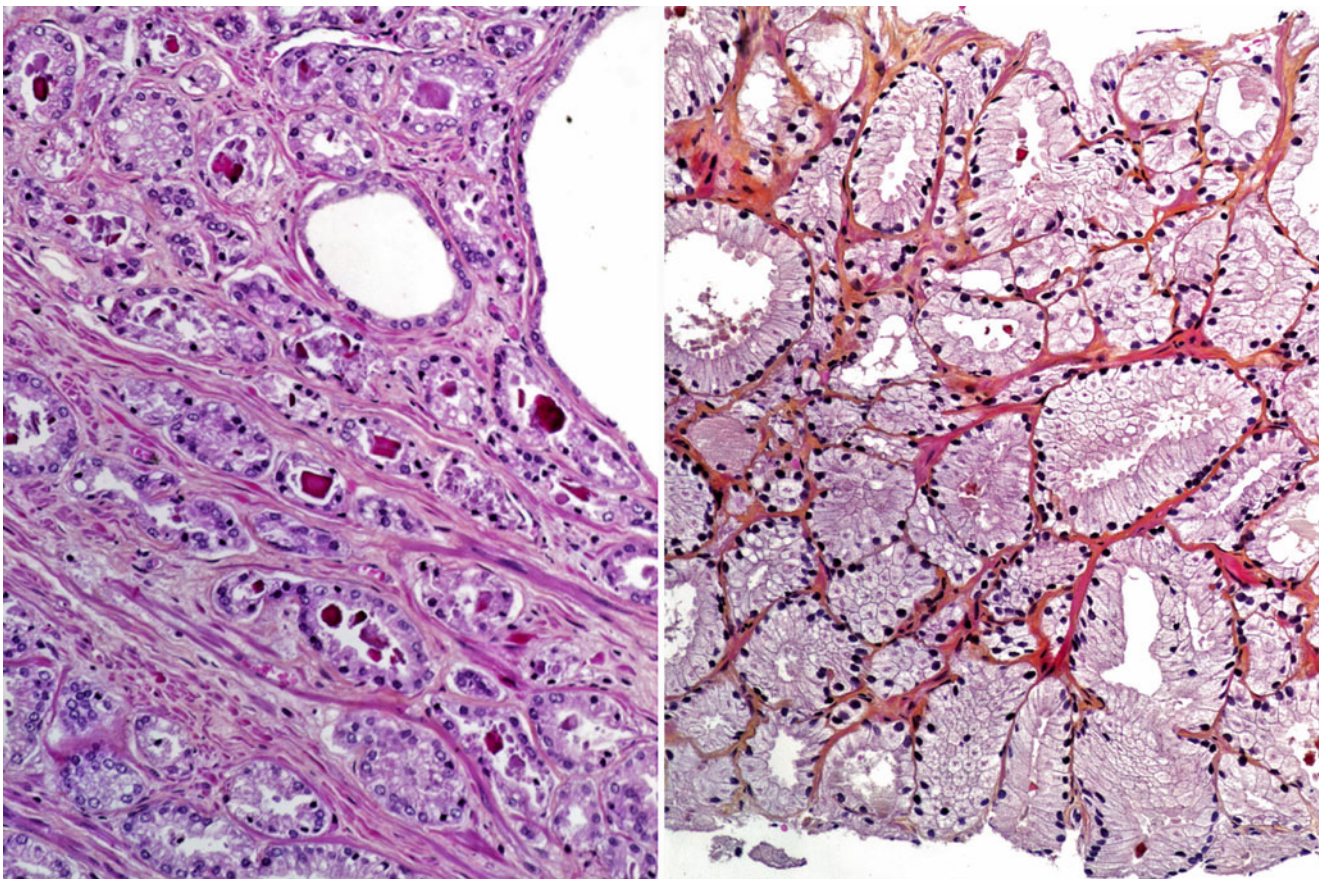

**Fig. 20.6** Examples of tertiary criteria. The malignant glands in the *left panel* show an amphophilic cytoplasm, and the lumina contain prominent crystalloids. The malignant glands in the *right panel* show a foamy cytoplasm

cases [8]. Subsequently, good reproducibility of Gleason grade has been documented among expert uropathologists [9], but not among general pathologists [10].

## Biopsy Versus Prostatectomy Gleason Score

The predictive value of the biopsy Gleason score versus the subsequent prostatectomy score has been addressed by many studies. In one study, the exact Gleason score was recorded in 40 % of prostatectomies and a ±1 Gleason score in 87 % of the cases when compared to the needle biopsies if diagnosed by an uropathologist [11]. However, a review of the Gleason score that had been rendered on these same cases by multiple general pathologists "in real-life practice" revealed the exact Gleason score in only 20 % of cases. Other studies by expert uropathologists reported the exact Gleason score on biopsy versus prostatectomy in the range of 60–81 % of cases [1]. This is a fair-good correlation, and Gleason grading of biopsies does provide valuable information.

In discrepant cases, there is usually an *upgrade* of the Gleason score in the prostatectomies. This is particularly true of cases diagnosed as Gleason score 4 (2+2) and Gleason score 5 (2+3; 3+2), in which an upgrade should be expected in virtually all cases.

However, Gleason score *downgrading* is also seen. Donahue et al. [12] reported significant downgrading in cases with biopsy Gleason scores of 8–10.

## Reason for Discrepancy Between Biopsy and Prostatectomy Gleason Scores

In the experience of uropathologists, there are two main reasons for Gleason score discrepancy between biopsy and prostatectomy:

1. There is a continuum of changes between the Gleason patterns (Fig. 20.7), such that tumor foci may have borderline features, and there can be *interobserver* (and even intraobserver) *variability* in assigning Gleason patterns (Fig. 20.13).
2. The second reason for a discrepant Gleason score is a *sampling* problem. Needle biopsies represent a minute fraction of the prostate and may not have sampled the entire histologic spectrum of the tumor present in the prostate (Fig. 20.13).

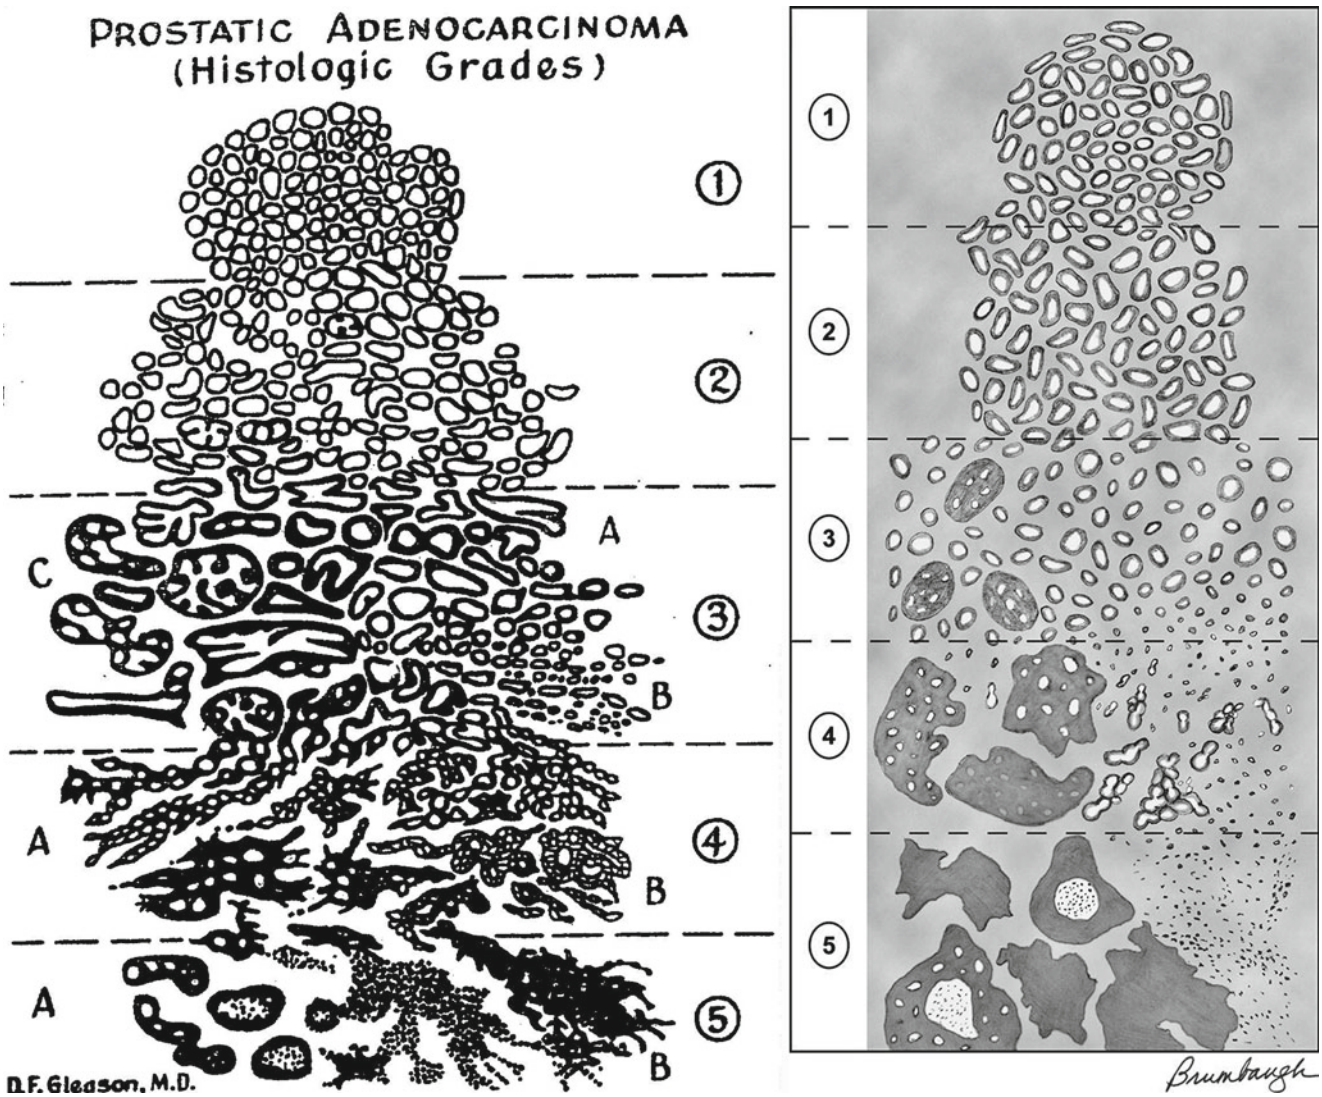

**Fig. 20.7** Gleason's patterns for his grading system. In the *left panel* is Gleason's original drawing of the various patterns. In the *right panel* are the patterns as modified by the 2005 ISUP Consensus Conference

## Changes in Gleason Grading after the 2005 ISUP Consensus Conference and "Gleason Score Inflation"

The 2005 ISUP Gleason Grading Consensus Conference resulted in the following main clarifications and modifications of the Gleason grading system:

1. Gleason pattern 1 is almost always atypical adenomatous hyperplasia (AAH), which has now been confirmed in most cases by basal cell stains. The stains were unavailable to Gleason when he developed his grading system. Therefore, Gleason pattern 1 and Gleason scores 2 and 3 are incorrect and should not be used.
2. Gleason pattern 2 requires circumscription of the tumor focus, which cannot be ascertained on needle biopsy. Therefore, Gleason pattern 2 and the corresponding Gleason score 4 should generally not be diagnosed on needle biopsies.
3. Infiltrating microacini, seen on needle biopsies, are Gleason pattern 3.
4. Most cribriform tumor foci and "ill-formed glands" are Gleason pattern 4.

As a consequence of the 2005 ISUP Consensus Conference, urologists have noted "Gleason grade inflation." Most of the "inflation" is due to the correction of the erroneous assignment of Gleason patterns 1 and 2 and scores 2–4. An additional reason for the "inflation" is the assigning of cribriform foci and "ill-formed" glands into pattern 4, rather than pattern 3. A recent study found an overall increase in Gleason scores following the 2005 Consensus Conference but also noted that the new Gleason scores corresponded to the patients' prostatectomy results and outcomes even better

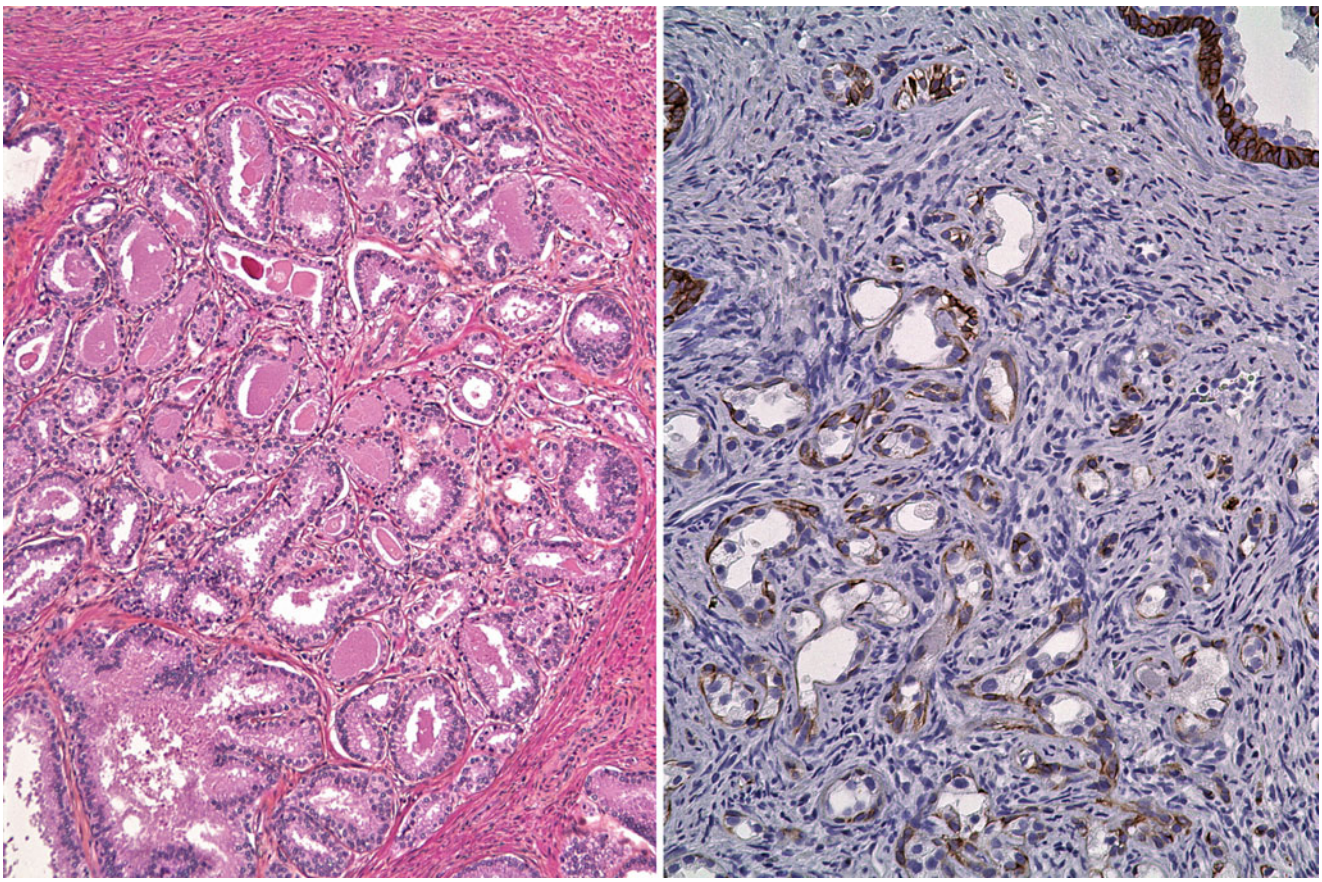

**Fig. 20.8** Gleason pattern 1, consisting of a nodule of tightly packed microacini. This pattern is now considered to represent AAH, as demonstrated by the presence of the brown-staining discontinuous basal cell layer in the *right panel* (Stain is for HMWCK)

than the Gleason scores assigned prior to the 2005 Consensus Conference [13].

## Clinicopathologic Summary

*Gleason grading of prostatic carcinoma*:

1. Each biopsy core or separately submitted specimen (set of cores) should be Gleason graded, including the Gleason score and the component primary and secondary patterns.
2. *Gleason scores 2–5*. The diagnosis of adenocarcinoma Gleason score 2–3 should never be rendered, and the diagnosis of adenocarcinoma Gleason score 4 is almost always incorrect, except in rare prostatectomy cases. A Gleason score 5 adenocarcinoma on needle biopsy is almost always upgraded in the prostatectomy. An expert second opinion might be indicated in some of these cases [4].
3. *Gleason scores 8–10*. A Gleason score of 8–10 on biopsy indicates that there is a clinically significant high-grade component, although a number of these cases will be downgraded on prostatectomy. Catalona's group has shown that if the Gleason score 8–10 carcinoma is present in only 1 core or in less than 15 % of the biopsy material, 2/3 of these patients will have organ-confined disease and can benefit from radical prostatectomy [14].
4. *Tertiary pattern 5*. Because of its clinical prognostic significance, tertiary pattern 5 should replace the secondary pattern in needle biopsy diagnoses but remain as tertiary pattern 5 if it is a minor component of prostatectomy specimens.
5. *Gleason score on biopsy as predictor of prostatectomy Gleason score*. The prostatectomy Gleason score is expected to be ±1 of the biopsy Gleason score in 85–90 % of cases, especially when diagnosed by uropathologists. Extended sampling of the prostate has been reported to increase the likelihood of better tumor sampling and therefore to improve the reliability of Gleason grading in biopsy specimens [15, 16].
6. *Multiple positive cores with different Gleason scores*. The global Gleason score is the best predictor of prostatectomy Gleason score, but the highest Gleason score is a good predictor and most widely used.

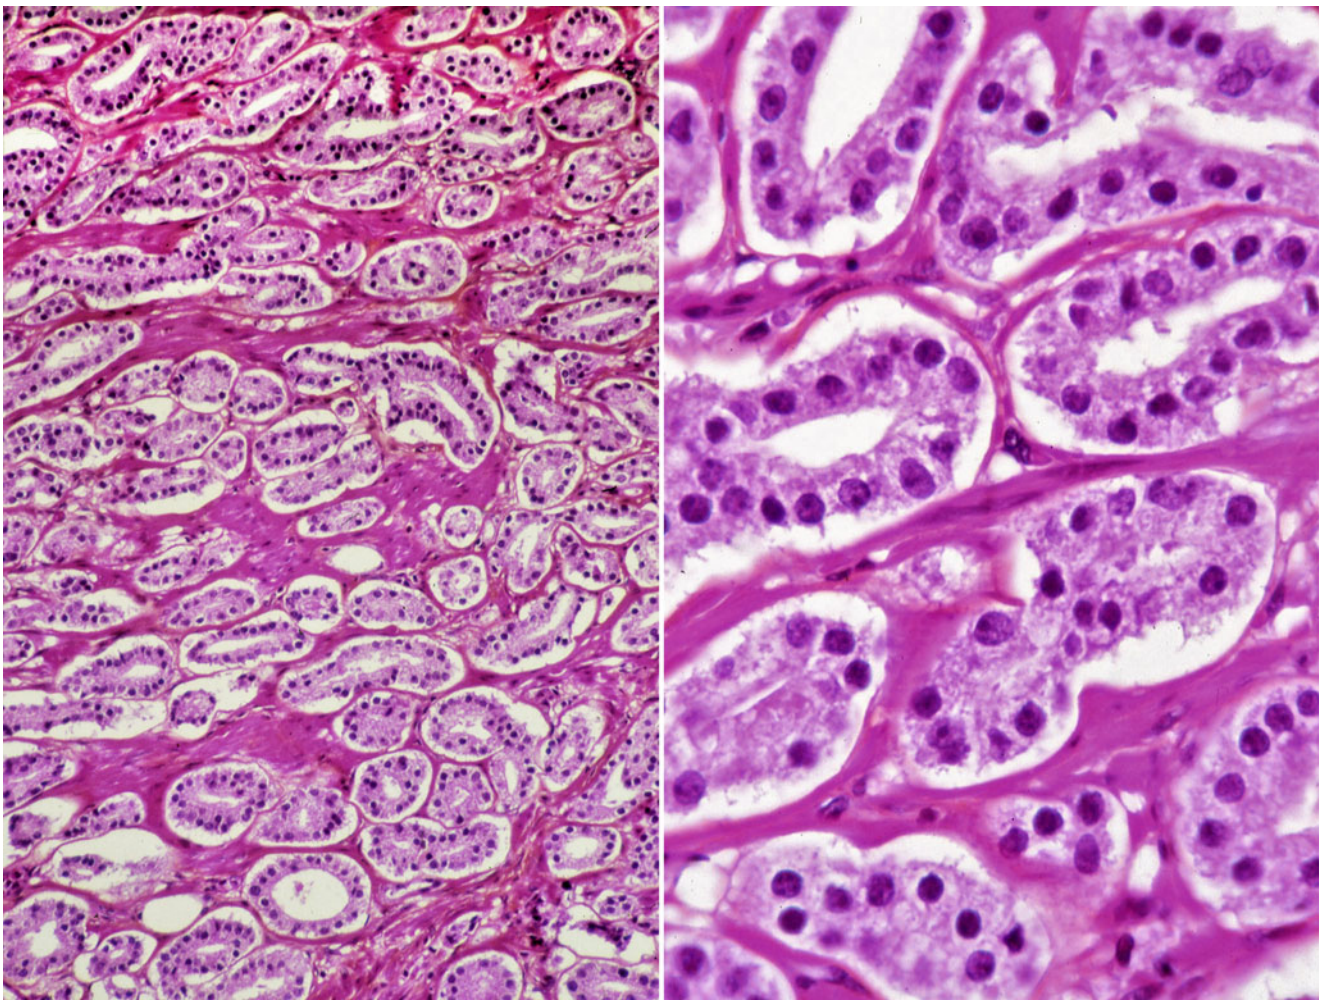

**Fig. 20.9** Gleason pattern 2. This is the center of a well-circumscribed nodule of well-formed, crowded microacini, characteristic of Gleason pattern 2. In the *right panel* is a higher magnification of this tumor

## Mimickers of Prostatic Carcinoma

The main mimickers of prostatic carcinoma are considered here since these entities can cause diagnostic difficulties and are frequently mentioned as differential diagnoses for prostatic carcinoma (Table 20.2).

*Clear cell cribriform hyperplasia* is a mimicker of prostatic carcinoma because of its intraglandular cribriform proliferation. However, this growth occurs in preexistent normal ducts, with small nuclei without nucleoli, and is surrounded by a basal cell layer. This lesion is completely benign (Fig. 20.14).

*Atrophy* can mimic adenocarcinoma because it consists of small glands (microacini), which can be tightly packed and have dark nuclei. However, atrophic glands are usually arranged in a lobular pattern around a central duct and have scant cytoplasm. The benign diagnosis occasionally requires confirmation with basal cell stains, which usually show a discontinuous basal cell layer. AMACR can be faintly positive.

An even more problematic mimicker of prostatic carcinoma is *partial atrophy*. Although part of the lobule may show the changes described above for atrophy, other microacinar units contain moderate cytoplasm, enlarged nuclei, and a few nucleoli. The presence of basal cells, although sometimes very sparse, helps to confirm the benign nature of these lesions (Fig. 20.15).

*Basal cell hyperplasia* is frequently associated with atrophy and consists of the proliferation of basal cells with hyperchromatic nuclei and occasional nucleoli. HMWCK and p63 stains are intensely positive in basal cell hyperplasia, and therefore the benign nature of these proliferations can be easily confirmed (Fig. 20.16).

*Atypical adenomatous hyperplasia* (*AAH*) *and adenosis*, which most expert uropathologists now consider the same entity, are reported by Epstein with a prevalence rate of 1.6 % in TURP specimens and in 0.8 % of needle biopsies [17]. The consensus is that AAH is not a premalignant lesion,

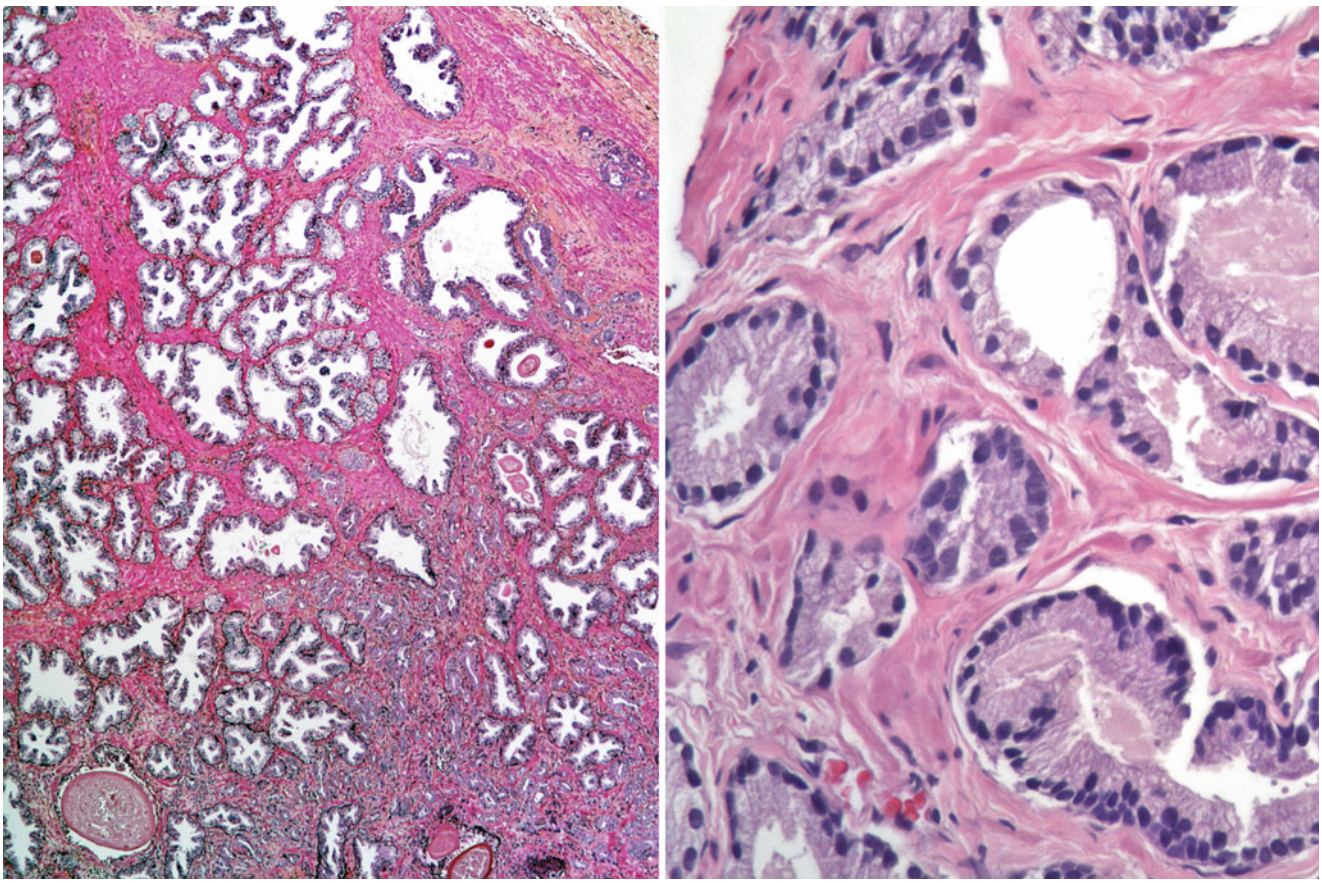

**Fig. 20.10** Gleason pattern 3. The *left panel* shows the characteristic infiltrative pattern of a Gleason pattern 3 carcinoma. The carcinoma invades the stroma of a benign lobule and surrounds the benign glands. The *right panel* is a higher magnification, highlighting the greater irregularity of these infiltrating malignant microacini

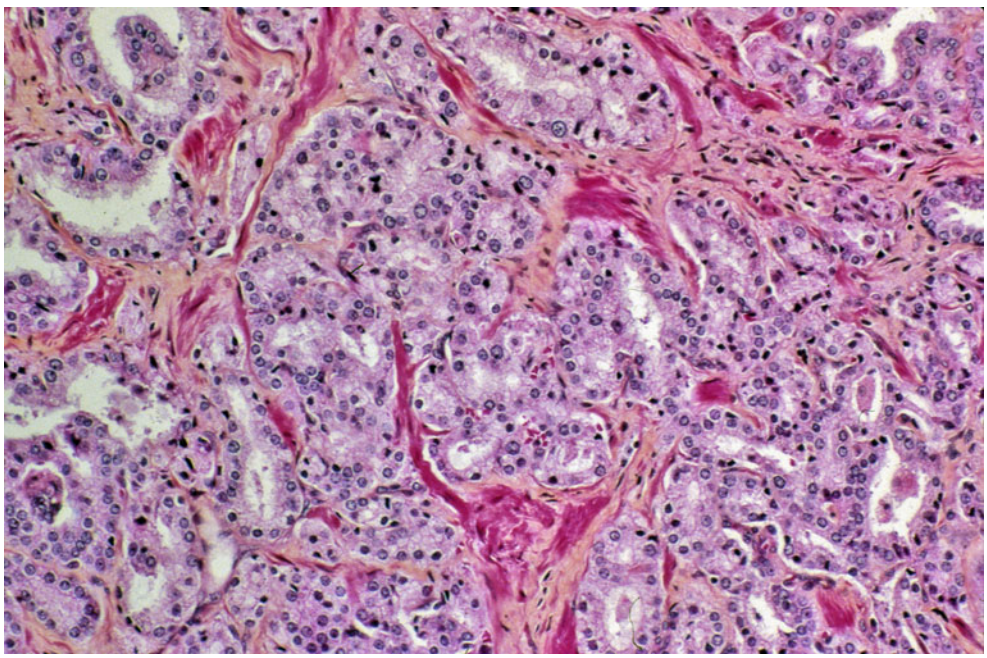

**Fig. 20.11** Gleason pattern 4. The malignant glands are no longer discrete and separate. They are fused into chains and cribriform sheets

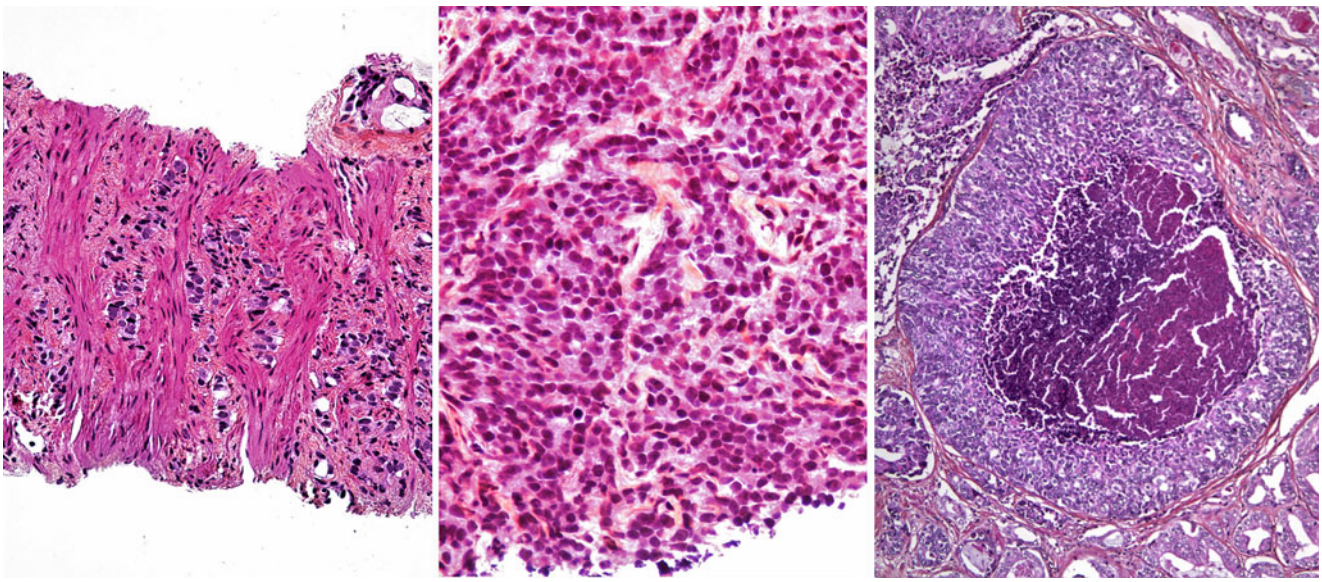

**Fig. 20.12** Gleason pattern 5. No glandular architecture remains. This is an undifferentiated carcinoma, growing in single file and sheets. The *middle panel* is a higher magnification of the Gleason pattern 5 carcinoma, which highlights the total lack of glandular structures. The *right panel* shows comedonecrosis in carcinoma, which is part of pattern 5

although several investigators suggest that it might be a precursor lesion for some of the low-grade tumors seen in the transition zone [18].

Adenosis consists of a circumscribed nodule of tightly packed microacini. Atypical adenomatous hyperplasia (AAH) has the same architecture but also includes enlarged nuclei with nucleoli. These lesions, therefore, demonstrate some primary (architectural) and secondary (cytologic) criteria of malignancy. As mentioned above, most uropathologists consider Gleason pattern 1 to be AAH. A definitive diagnosis of these foci requires immunohistochemical staining to identify the rare basal cells. Faint AMACR staining is also usually present (Fig. 20.17).

*Seminal vesicles and ejaculatory ducts* can be mistaken for prostatic carcinoma in small thin needle biopsy specimens. They consist of tightly packed small glands around the central lumen and contain pleomorphic, hyperchromatic nuclei with large nucleoli. However, recognition of the relationship of these clustered atypical glands to a central duct and the characteristic of cytoplasmic golden-brown lipofuscin pigment is usually sufficient for proper diagnosis [19]. Rarely basal cell stains, positive in seminal vesicles and ejaculatory ducts, need to be performed for confirmation.

## Clinicopathologic Summary

*Mimickers of prostatic carcinoma*:

The main benign mimickers of prostatic carcinoma, *clear cell cribriform hyperplasia*, *atrophy*, *partial atrophy*, *basal cell hyperplasia*, *adenosis*, *atypical adenomatous hyperplasia*, *seminal vesicles*, *and ejaculatory ducts* (Table 20.2), are recognized by their characteristic architecture and cytology. Occasionally immunohistochemical stains are required for confirmation.

## Special Issues Relating to Needle Core Biopsies of the Prostate

In the current PSA screening and extended core biopsy era, a diagnosis of carcinoma is rendered in approximately 25–30 % of biopsied patients. In the study by Berger et al., the mean was 27.7 % and the range was 25.1–30.1 % for positive cancer diagnoses in their series of cases [20].

The small size and thinness of the biopsy core specimens has implications for the pathologists' ability to diagnose and grade prostatic carcinoma. The inability to definitely diagnose Gleason pattern 2 has already been mentioned. In addition, foci suspicious for carcinoma may be very small, at a tissue edge, or crushed. Immunohistochemical stains, particularly the triple stains, are frequently utilized and can help to resolve diagnostic difficulties. In other cases, the diagnosis of atypia or ASAP (atypical small acinar proliferation) is used to indicate that the focus may represent carcinoma, but it cannot be definitively diagnosed.

The presence of *perineural invasion* should always be reported if identified in needle biopsies because it indicates an increased *risk of extraprostatic extension* of carcinoma [17, 25]. The number and percent of positive cores, as well as the length of tumor in involved cores, are all reported to be predictors of extraprostatic extension as well [21]. Occasionally

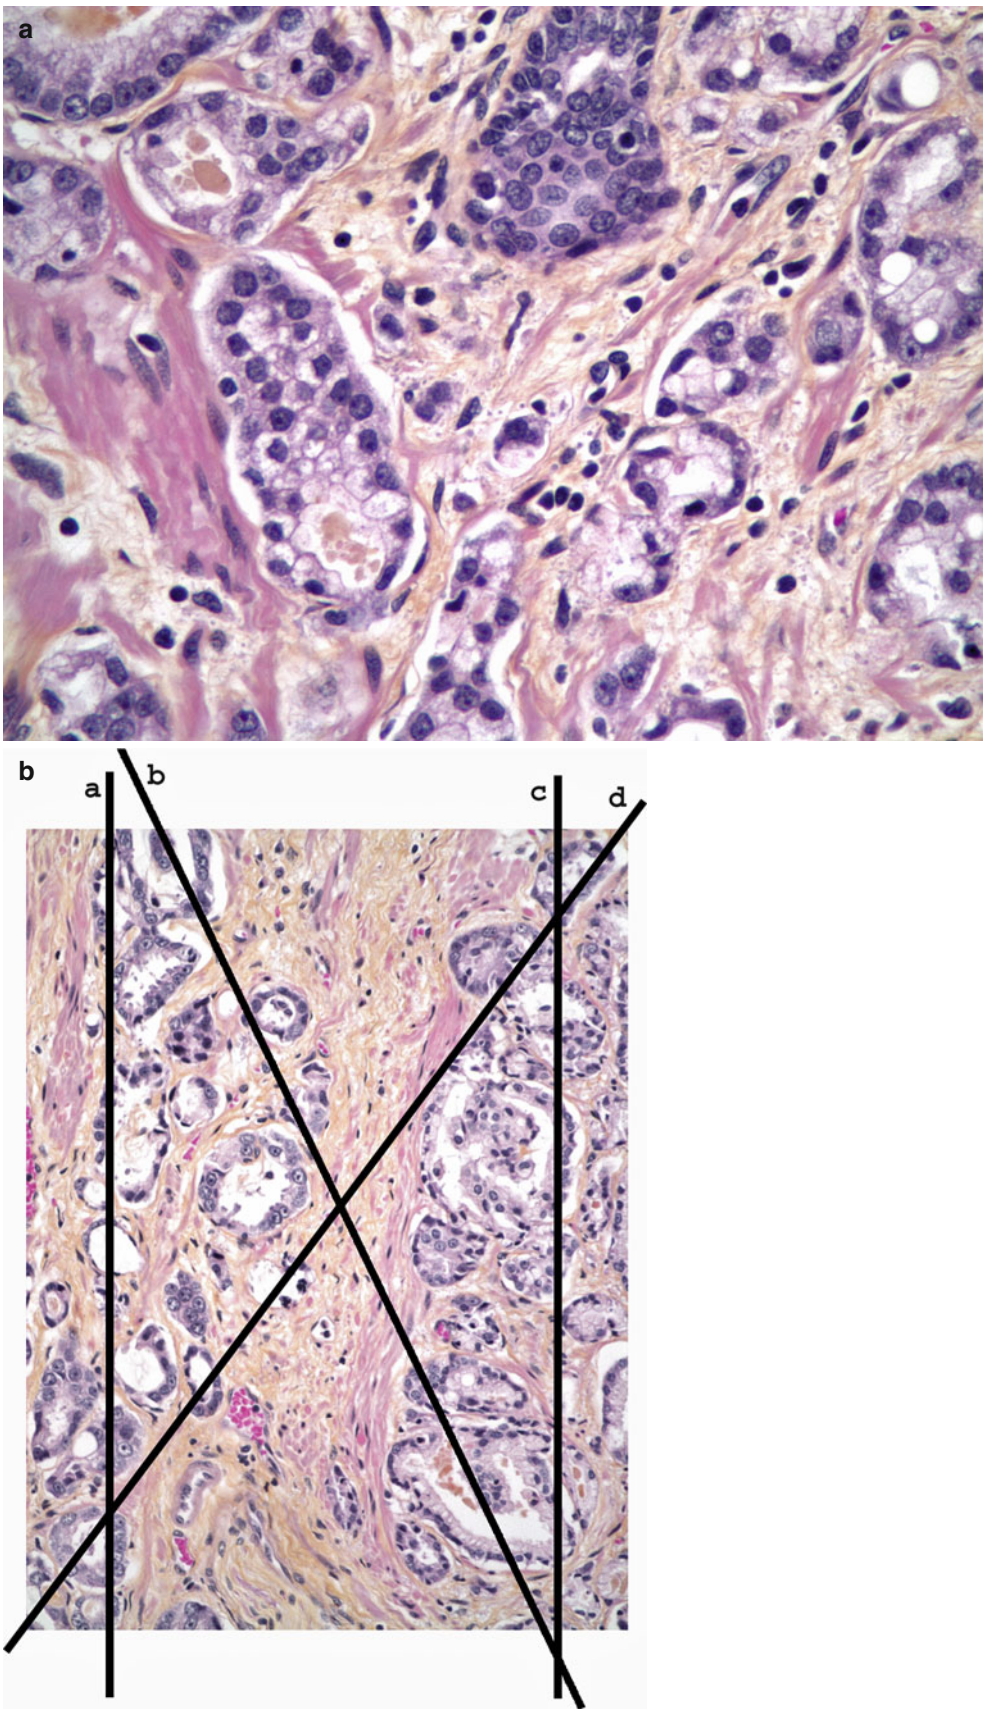

**Fig. 20.13** (**a**) This is an example of histology, which is borderline between patterns 3 and 4. Some observers would consider the entire focus to fit into pattern 3 (Gleason score 6 (3+3)); whereas others would consider the glands on the right to be "ill-formed" and beginning to fuse and would assign a Gleason pattern 4 to this focus (Gleason score 7 (3+4)). (**b**) This section from a prostatectomy specimen is used to demonstrate sampling issues related to needle biopsies of the prostate. In this section, if the needle tract were represented by *line a*, the diagnosis would be carcinoma, Gleason score 6 (3+3). If the needle were to follow *line b*, the diagnosis would be carcinoma, Gleason score 7 (3+4). If the needle were to follow *line c*, the diagnosis would be carcinoma, Gleason score 8 (4+4). If the needle were to follow *line d*, the diagnosis would be carcinoma, Gleason score 7 (4+3)

adipose tissue or seminal vesicle tissue, present in the biopsy core, contains invasive adenocarcinoma. In such cases the prostatic carcinoma can be *pathologically staged as pT3* disease.

Favorable parameters on needle biopsy, such as a *small tumor focus/small tumor volume and a low Gleason score*, do not necessarily predict a favorable outcome or an insignificant tumor on prostatectomy [17, 22–24].

## Special Issues Relating to TURP Specimens

Incidental adenocarcinoma is less frequent in TURP (transurethral resections of prostate) currently than it was prior to PSA screening. However, all TURP specimens are examined carefully. Epstein advocates submitting eight cassettes initially (or nine cassettes, if an additional cassette would sample the entire specimen) [1]. The standard in other institutions is to initially submit 12 cassettes.

**Table 20.2** Benign mimickers of prostatic carcinoma

| |
|---|
| 1. Clear cell cribriform hyperplasia |
| 2. Atrophy |
| 3. Partial atrophy |
| 4. Basal cell hyperplasia |
| 5. Adenosis |
| 6. Atypical adenomatous hyperplasia (AAH) |
| 7. Seminal vesicle and ejaculatory duct |

Should a carcinoma be found in the initial set of sections, many uropathologists would then submit the entire TURP specimen in order to properly Gleason grade the tumor and to stage it: *stage pT1a if there is <5 % tumor or pT1b if there is >5 % tumor*. Other authors suggest taking more sections only if there is <5 % tumor on the initial set of sections [1].

## Special Issues Relating to Radical Prostatectomy

### Characteristics of Prostatic Carcinoma at Prostatectomy in the Current PSA Screening Era

Prostatic adenocarcinomas are generally smaller and at a lower stage currently than those reported before PSA screening was instituted [20, 25]. Eighty-five percent of stage pT1c and pT2 tumors are in the *peripheral* zone [17]. Single, grossly visible dominant tumor masses are less common. Eighty-five percent of prostatic adenocarcinomas are now *multifocal*, and 70 % are *bilateral*. Taking this information into account is essential if one is contemplating focal or localized treatment of prostatic adenocarcinoma.

### Grossing Prostatectomy Specimens

Upon receipt in the pathology laboratory, the prostatectomy specimen is weighed and measured with notation of any specific

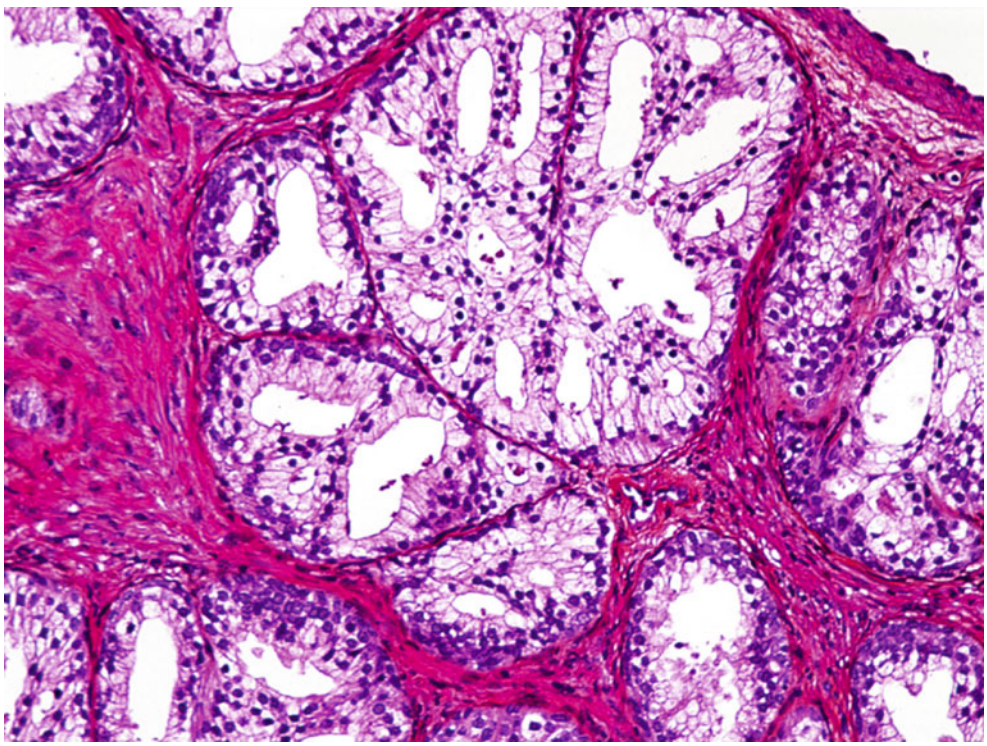

**Fig. 20.14** Clear cell cribriform hyperplasia, a mimicker of carcinoma. Note the intraglandular cribriform proliferation with clear cytoplasmic change. The nuclei are small, and there are no nucleoli. This is a benign lesion

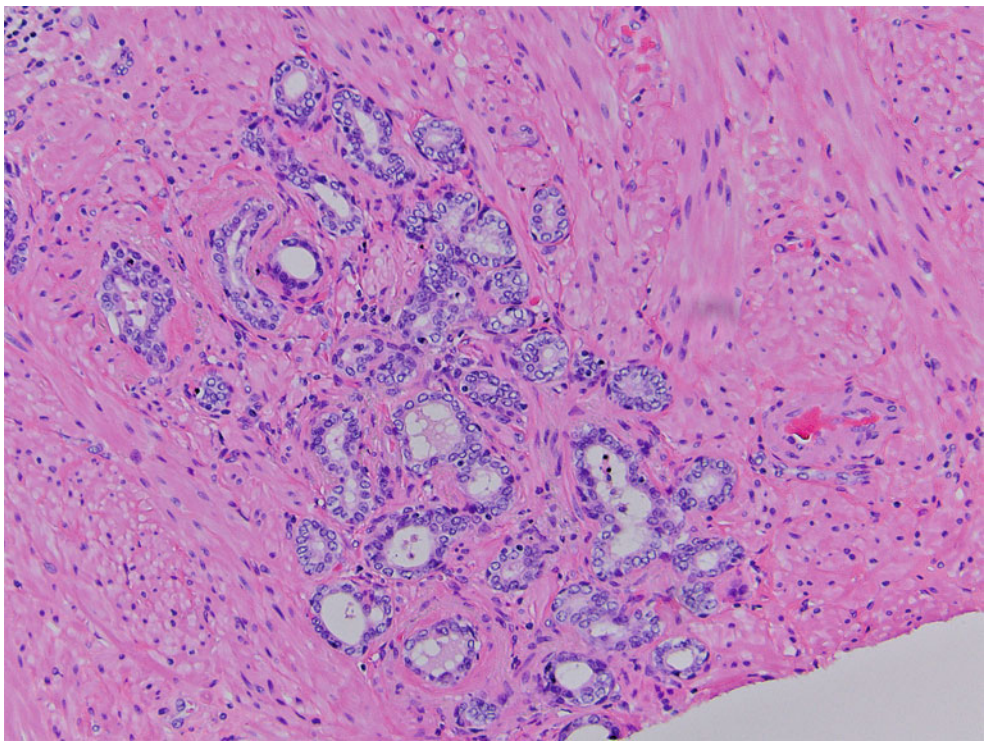

**Fig. 20.15** Partial atrophy. This lesion consists of microacini in a subtle lobular pattern. There are enlarged nuclei and occasional nucleoli

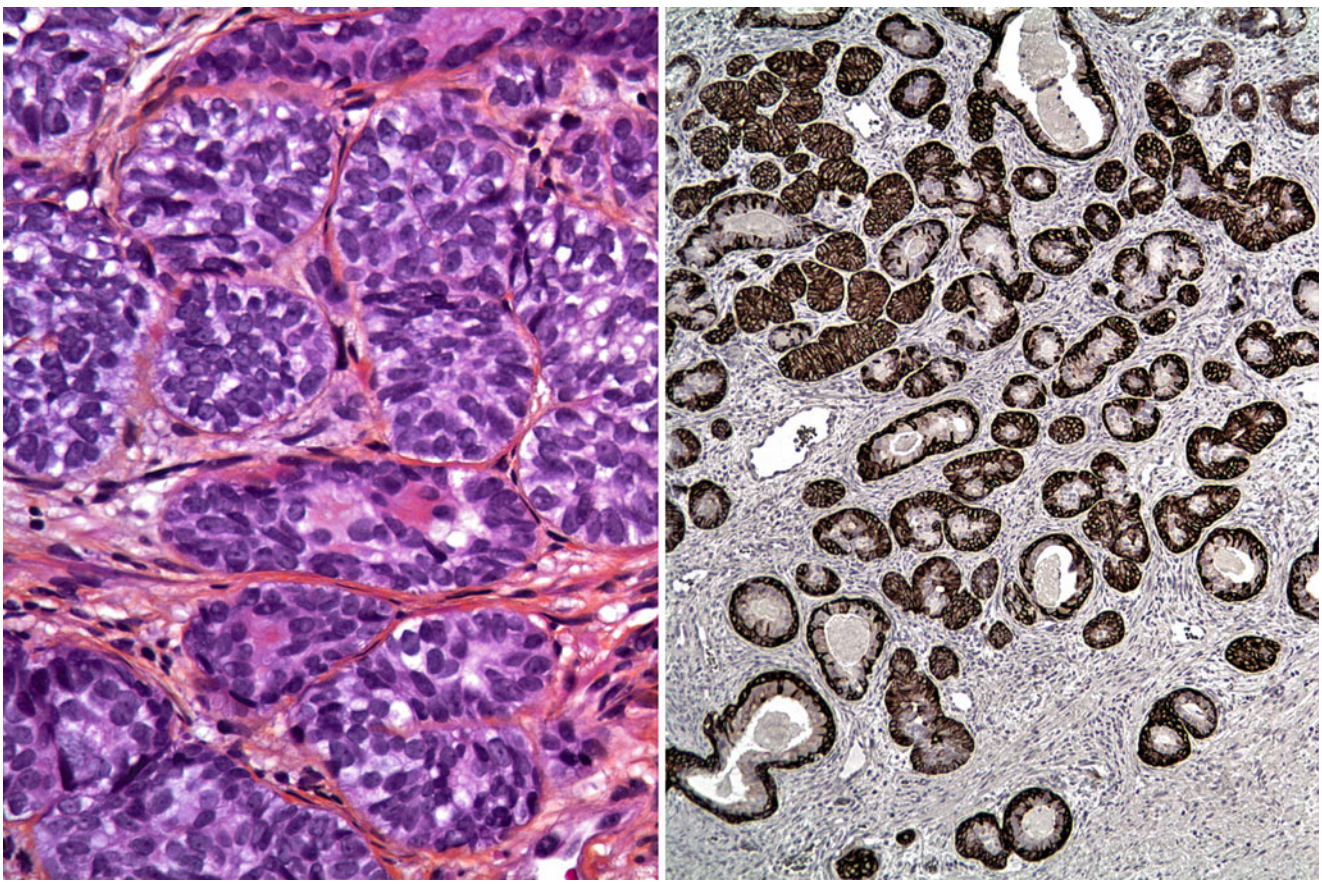

**Fig. 20.16** Marked basal cell hyperplasia in atrophic glands. These microacini are lined by a multilayered epithelium, with very hyperchromatic large nuclei, which contain nucleoli. The cytoplasm is sparse. HMWCK stain in the *right panel* shows intense staining of these proliferating basal cells

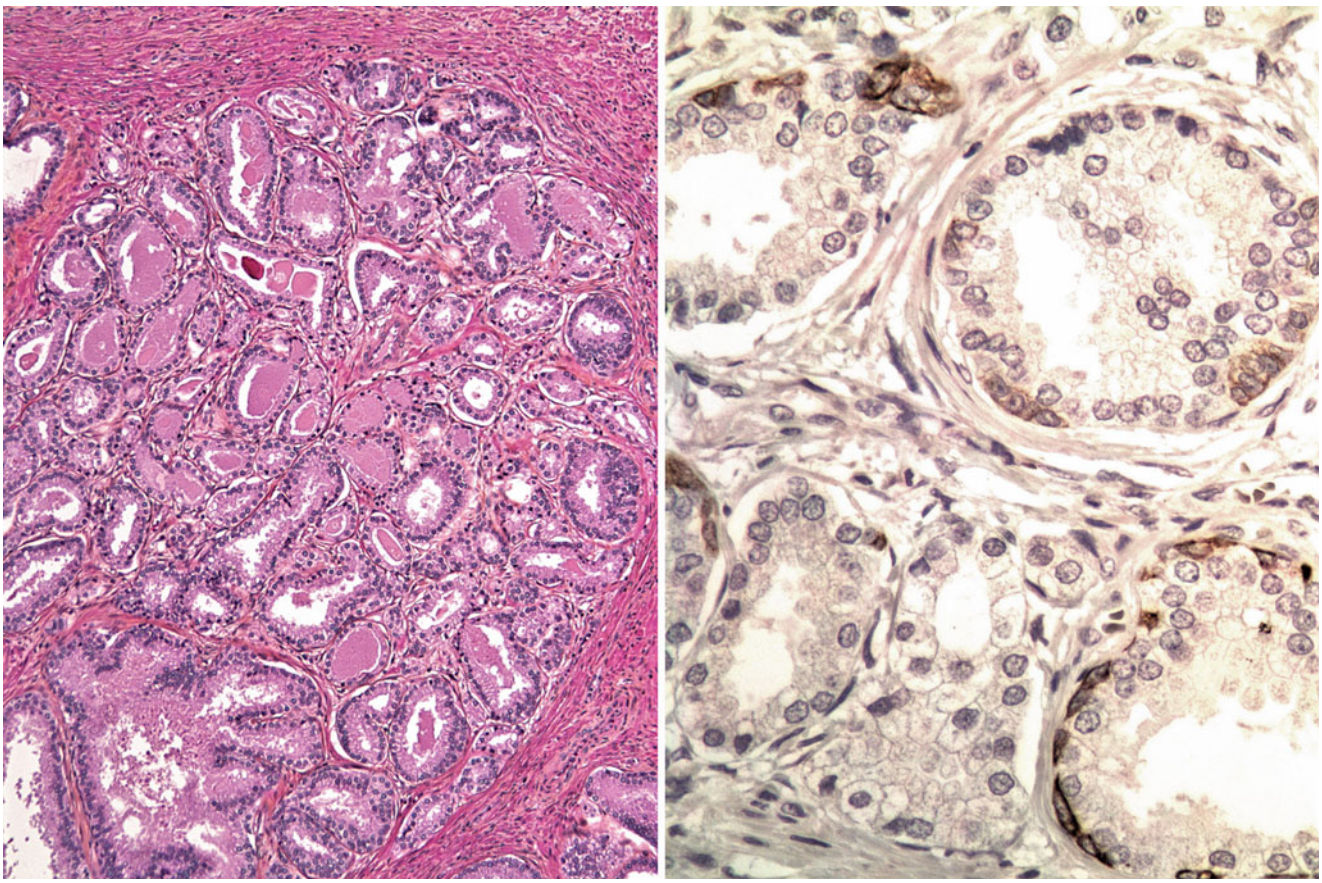

**Fig. 20.17** Atypical adenomatous hyperplasia (AAH). This lesion is architecturally abnormal because it consists of tightly packed microacini. It is also cytologically abnormal, as seen in the *right panel*, because there are large nuclei and a few large nucleoli. However, the HMWCK stain shows a few basal cells in these microacini. Please note that there is one unit, bottom middle, which is devoid of basal cells. However, it is part of this proliferation, and therefore the entire lesion, including this acinus, is benign. This type of lesion would pose diagnostic difficulty in a needle biopsy

surface changes. The entire specimen is then inked for histologic identification of margins. It is customary to use different colored inks, at least two to denote the left and right sides. The apex, para-apex, base, and para-base are sectioned and entirely blocked. The bases of the seminal vesicles are sectioned in continuity with their prostatic attachments. The remainder of the prostate is either blocked completely, or every other section is taken for initial review. If the prostate is incompletely sectioned initially, the remainder is kept for possible further examination. The gross description in the pathology report should indicate how the sections were taken, from where each section was taken, and if the entire prostate was sectioned.

## Pathologic Staging of Prostate Cancer

*Perineural invasion*, when identified in prostatectomy specimens, does not increase the risk of progression [26]. *Blood and lymphatic vessel invasion* is a significant negative risk factor for progression but is infrequently seen [27].

*Positive surgical margins* are most often identified at the apex and laterally. Frequently these positive margins are intraprostatic, in which case they do not raise the pathologic stage of the tumor; however, some expert uropathologists advocate staging these tumors as *pT2+* to indicate that extraprostatic extension cannot be entirely excluded. Regardless of whether they are intraprostatic or in an area of extraprostatic extension, positive margins are associated with a significantly increased risk of progression (Fig. 20.18).

The prostate does not have a true capsule. The area referred to as "capsule" consists of the compressed fibromuscular stroma of the prostate. *Extraprostatic extension* (*stage pT3a*) is diagnosed when malignant glands are identified in loose periprostatic fibroadipose tissue. In addition to diagnosing extraprostatic extension, many pathologists also indicate whether this extension is focal/localized or multifocal/established and its location/laterality (Fig. 20.18). Difficulties in determining the presence of extraprostatic extension may occur anteriorly toward the apex because in this location there is a fibromuscular ligament, which extends

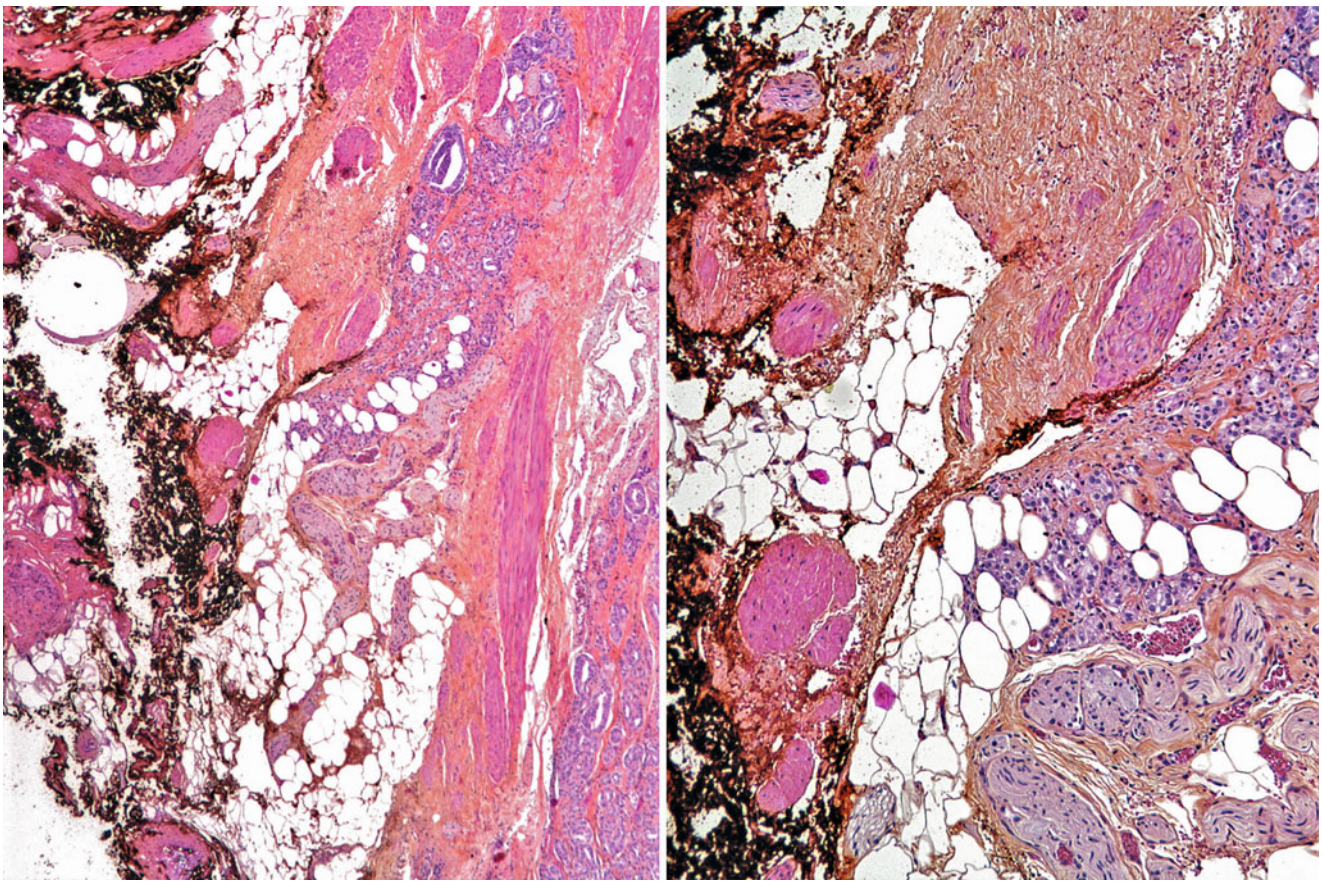

**Fig. 20.18** Extraprostatic extension of prostatic adenocarcinoma and negative surgical margins. Both the lower magnification *left panel* and the higher magnification *right panel* show malignant microacini infiltrating periprostatic adipose tissue, constituting a pT3a tumor. The inked margins are negative for tumor

from the fibromuscular "capsule" of the prostate, with little or no adipose tissue and no clear demarcation of the edge of the prostate (Fig. 20.19). Another potentially difficult area is posterior lateral, where there might be a fibrotic reaction in an area of periprostatic tumor extension, which might obliterate adipose tissue, making this area appear like part of the prostate. Pathologists use the contour of the organ with the adjacent benign glands as a guide. In cases in which a definite determination cannot be made, the pathologic diagnosis will be "suspicious for extraprostatic extension," or "extraprostatic extension cannot be excluded" [27].

*Seminal vesicle invasion* (*stage pT3b*) is diagnosed when prostatic carcinoma is identified in the muscularis propria or among the glands of the seminal vesicle (Fig. 20.20). Invasion of the small intraprostatic portion of the seminal vesicle does not constitute stage pT3b disease.

*Intraoperative lymph node evaluations* (*frozen sections*) are currently infrequent following several significant clinical observations. First, only two-thirds of micrometastases are identified in frozen sections due to sampling issues and because pelvic lymph nodes are fatty, which makes them technically difficult to section as fat does not freeze. Secondly, if the carcinoma is less than Gleason score 8, a prostatectomy provides a prolonged tumor-free survival even in cases with lymph node micrometastases. Therefore, the intraoperative lymph node evaluation would not alter the operative procedure [17].

The only cases in which lymph node frozen sections might be warranted are during surgeries for prostatic carcinomas with Gleason scores 8–10. Some of these patients can be cured by prostatectomy, if the lymph nodes are negative, and therefore lymph node status might be evaluated intraoperatively before prostatectomy is attempted [17].

## Low-Volume Prostatic Carcinoma

Low-volume carcinoma in prostatectomy specimens should not be considered a clinically insignificant tumor. El-Gabry et al. report that in their series of prostatic carcinomas of less than 0.5 $cm^3$, 35 % were Gleason score 7 or greater, 8 % had positive margins, and 2.5 % had biochemical failure in 1–66 months post-prostatectomy [28]. Similar findings were reported by other groups, including Cheng et al. [22].

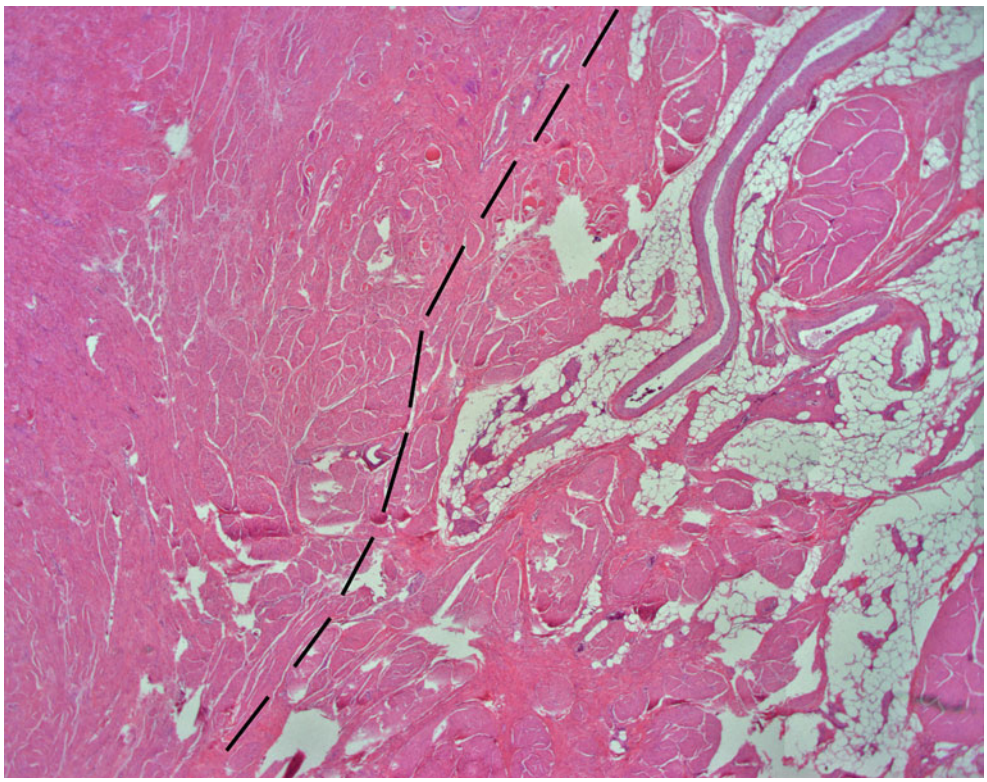

**Fig. 20.19** The fibromuscular tissue of the anterior ligament (*right side* of *dotted line*) is continuous with the fibromuscular stroma of the prostate (*left side* of *dotted line*), making demarcation of the beginning of extraprostatic tissue difficult. The placement of the *dotted line* in this image, which indicates the boundary of the prostate and extraprostatic tissue, is somewhat arbitrary

## Clinicopathologic Correlation in Prostatectomy Specimens

1. Gleason score is confirmed.
2. Pathologic stage is determined, including evaluation for extraprostatic extension, seminal vesicle invasion, and lymph node metastases.
3. Surgical margins are evaluated. Positive margins are most commonly found at the apex and laterally.
4. Frozen section evaluation of lymph nodes is not indicated in most cases.

## Problem Areas in the Pathologic Diagnosis of Prostatic Adenocarcinoma

### Treatment Effect

Hormone and radiation therapies have a profound effect on the histology of both benign and malignant prostatic tissues. In order to avoid misinterpretation of these changes, the pathologist should always be informed of the patient's treatment history.

*Hormone treatment* usually results in atrophy of the *benign* prostatic glands, often with basal cell hyperplasia and squamous metaplasia. *Malignant* glands showing hormone effect usually lose their glandular structure and frequently have pyknotic small nuclei without nucleoli. They can either be mistaken for infiltrating lymphocytes or histiocytes, or, if recognized as tumor, they may be diagnosed as a Gleason score 10 carcinoma. Both of these would be significant misdiagnoses. The consensus among uropathologists is that hormonally treated tumors should not be Gleason graded. Occasionally, there are tumor foci that do not show evidence of hormonal effect. These should be mentioned in the report, Gleason graded, and are considered an adverse prognostic sign.

*Radiation-treated benign* glands acquire cytologic atypia and nuclear pleomorphism, suspicious for carcinoma. A pathologic clue that there is radiation effect is that these changes are seen throughout the entire prostate in glands that are architecturally benign. *Malignant* glands are also affected, showing cytologic atypia or atrophy-like changes (Fig. 20.21). The consensus is that radiation-treated prostatic carcinoma should not be Gleason graded. If prostatic carcinoma is identified in the prostate 12–18 months post radiotherapy and particularly if it does not show significant radiation effect, the prognosis is poor [17].

### "Vanishing Carcinoma"

"*Vanishing carcinoma*" refers to the absence of carcinoma in the prostatectomy specimen after a definitive diagnosis on biopsy. This phenomenon has been recorded in the literature to occur in less than 1 % (close to 0.5 %) of cases. Most of these cases had a biopsy diagnosis of a Gleason score 6 adenocarcinoma on only one or two cores [29, 30].

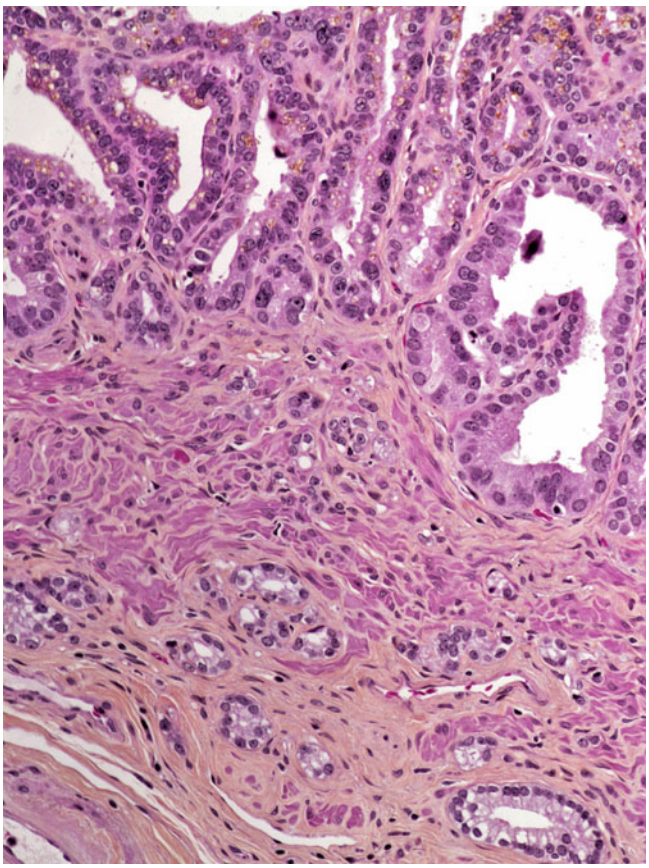

**Fig. 20.20** Seminal vesicle invasion by prostatic adenocarcinoma. The *upper portion* of the image consists of benign seminal vesicle glands. Note the small clustered glands with large hyperchromatic nuclei and the characteristic cytoplasmic golden-brown pigment. These glands are generally oriented perpendicular to a large lumen. In the *lower portion* of the image are infiltrating microacini of prostatic carcinoma, constituting seminal vesicle invasion, a pT3b tumor

## Clinicopathologic Summary

*Hormone and radiation-treated carcinoma*, "*vanishing*" *carcinoma*:

1. *Hormone and radiation* therapies have a profound *effect* on both *benign and malignant* prostatic glands.
2. *Radiation-treated benign glands* acquire nuclear atypia and *could be mistaken for carcinoma*.
3. *Hormone-treated* prostatic carcinoma may have small pyknotic nuclei and be *mistaken for histiocytes or Gleason pattern 5 carcinoma*.
4. *Radiation-treated* prostatic carcinoma may lose its glandular architecture, acquire pleomorphic nuclei, and *resemble Gleason pattern 5 carcinoma*.
5. Proper diagnosis by pathologists requires *adequate history of prior radiation/hormone therapy* from clinicians.
6. Carcinoma showing *treatment effect should not be Gleason graded*.
7. Carcinoma *without treatment effect* is reported, *Gleason graded*, and a *negative prognostic indicator*.
8. *Prostatectomies without carcinoma* following a positive needle biopsy occur at a *rate of 0.5 %*.

# Histologic Variants of Prostatic Carcinoma

## Morphologic Variants of Acinar (Conventional) Adenocarcinoma

The vast majority of acinar adenocarcinomas, which are derived from secretory epithelial cells, display the typical features described in the previous sections of this chapter (i.e., glandular structures comprised of cuboidal cells with amphophilic cytoplasm and round to ovoid nuclei having prominent nucleoli). Occasionally, acinar adenocarcinomas may show distinct histologic features that diverge from the usual morphology, and these variant morphologies may comprise anywhere from a small portion of a usual acinar adenocarcinoma to the tumor in its entirety. Some of these variants have been associated with a more favorable or unfavorable clinical prognosis; however, other variants have not been shown to portend a prognosis different from usual acinar adenocarcinomas of comparable grade, and the recognition of these variants is mainly of academic interest and to aid pathologists in the diagnosis of such carcinomas.

Acinar adenocarcinomas that contain abundant extracellular mucin (at least 25 % of the tumor being composed of pools of extracellular mucin) have been termed *mucinous* (*colloid*) *adenocarcinoma* (Fig. 20.22). If this strict diagnostic criterion is applied, these tumors are quite rare (0.2 % of prostate cancers). Mucinous carcinomas have a prognosis similar to comparable usual acinar adenocarcinomas. That being said, the majority of mucinous adenocarcinomas are moderately to poorly differentiated, with Gleason pattern 4 often predominating [31–33].

*Foamy gland carcinoma* denotes those tumors with abundant, pale, foamy cytoplasm (Fig. 20.23). These tumors often have small, round, pyknotic-appearing nuclei without prominent nucleoli, which can make diagnosis difficult on limited needle core biopsies. Immunohistochemistry to demonstrate the absence of basal cells (negative p63 and high molecular weight cytokeratin stains) is often necessary to make the diagnosis in many cases. Most of these tumors are Gleason score 6 (3+3) cancers, although they can be large volume, bilateral tumors, and sometimes of higher Gleason grade with an aggressive clinical course [34, 35].

Virtually all acinar adenocarcinomas will show some degree of neuroendocrine differentiation by immunohistochemical staining, even in the absence of light microscopic features of such differentiation [36]. However, these neuroendocrine cells are often single or in small clusters and scattered throughout the tumor. Occasionally, though, tumors will contain abundant cells with bright eosinophilic neurose-

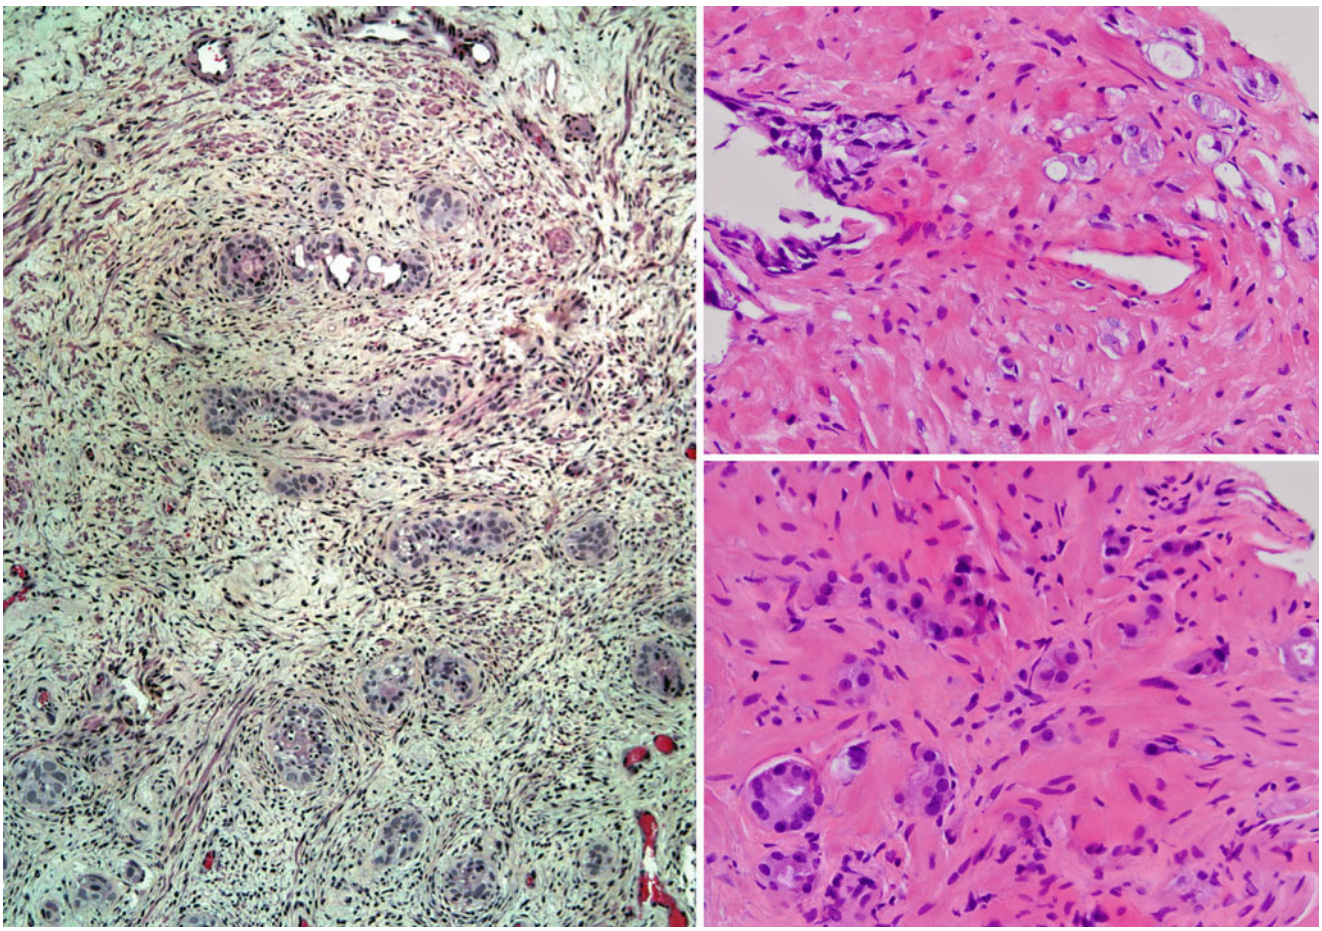

**Fig. 20.21** Radiation change of benign and malignant prostatic glands. In the *left panel*, note the glandular atypia, with nuclear pleomorphism of benign radiation-treated prostatic glands. These may be difficult to distinguish from carcinoma. On the *right* are two images of radiation-treated prostatic carcinoma. Note in the *top panel* that the carcinoma is pale, does not form glands, and may be missed or mistaken for histiocytes. The *lower right panel* shows the "single file" pattern, which would be diagnosed as a Gleason pattern 5 tumor, if the radiation history were not known

cretory granules within the cytoplasm (Fig. 20.24). These prostate cancers have been termed *prostatic adenocarcinoma with Paneth cell-like neuroendocrine differentiation*, given the resemblance to Paneth cells of the gastrointestinal tract. Although these tumors may appear high grade histologically in that they often grow as sheets, nests, or cords of cells, Tamas and Epstein reported a favorable prognosis for these cancers, and, therefore, Gleason grading is not recommended for areas of Paneth cell-like differentiation, as the assigned Gleason score will often not reflect the underlying biologic behavior [37, 38].

*Pseudohyperplastic carcinoma* denotes acinar adenocarcinomas characterized by large, dilated glands with branching or papillary luminal infolding. The cells often contain abundant, pale cytoplasm with the nuclei basally oriented. In contrast to foamy gland carcinoma, pseudohyperplastic carcinoma typically has prominent nucleoli, which also helps distinguish this variant of cancer from benign hyperplastic glands (Fig. 20.25). Nevertheless, immunohistochemistry is often necessary to definitively diagnose this variant of prostatic adenocarcinoma, especially on needle core biopsies. Most of these tumors are Gleason score 6 (3+3) and frequently are associated with conventional acinar adenocarcinomas of the same Gleason score [39, 40].

The *atrophic variant* of prostatic adenocarcinoma is composed of small malignant glands with scant cytoplasm, mimicking benign atrophy (Fig. 20.26). On needle core biopsy, the diagnosis of atrophic prostate cancer may be extremely difficult, with the diagnosis resting primarily on the infiltrative nature of the glands and occasional nuclear atypia beyond that seen in benign atrophy. The presence of non-atrophic prostate cancer, as is commonly present in cancers with atrophic features, is also useful in making the diagnosis. Clinically, most of these tumors are Gleason score 6 (3+3), but the biologic behavior of these tumors is likely dictated by

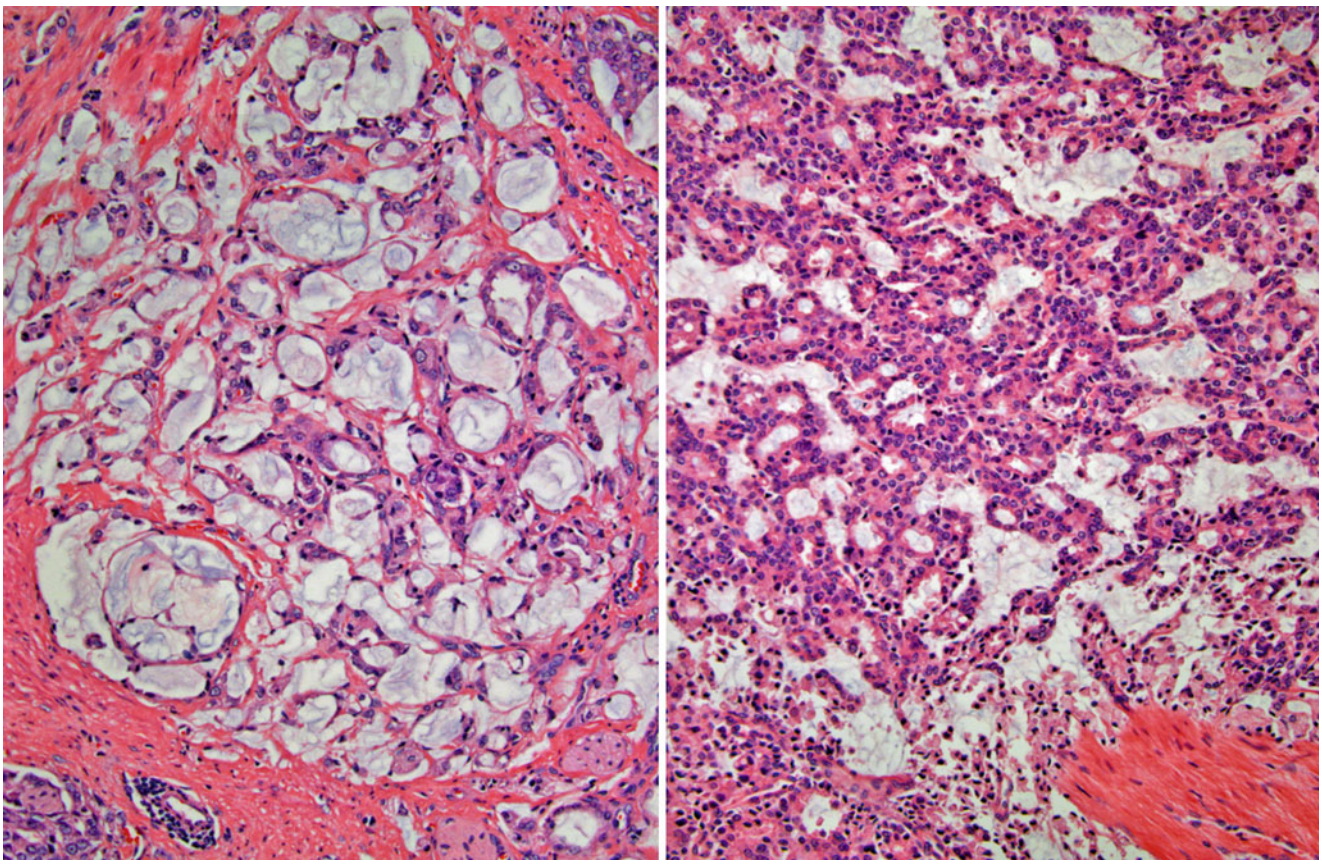

**Fig. 20.22** Mucinous (colloid) carcinoma. The *left panel* shows individual glands with abundant extravasated mucin surrounding each gland. On the *right*, extravasated mucin has coalesced to form a lake containing numerous cribriform glands

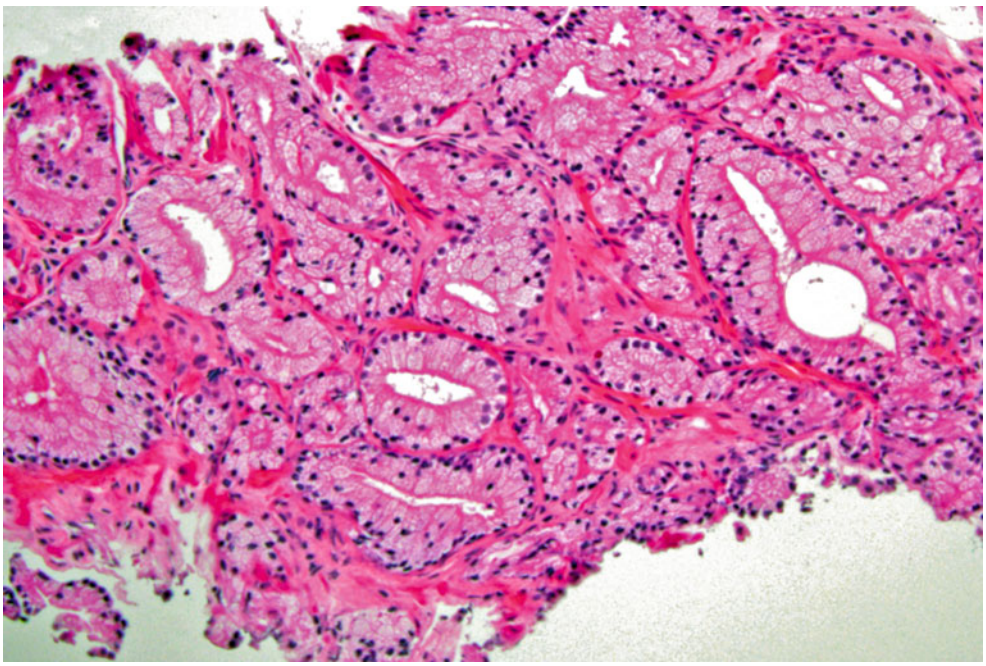

**Fig. 20.23** Foamy gland carcinoma. The glands have abundant pale cytoplasm with small, hyperchromatic nuclei that are basally oriented. Nuculeoli are usually absent at higher power examination

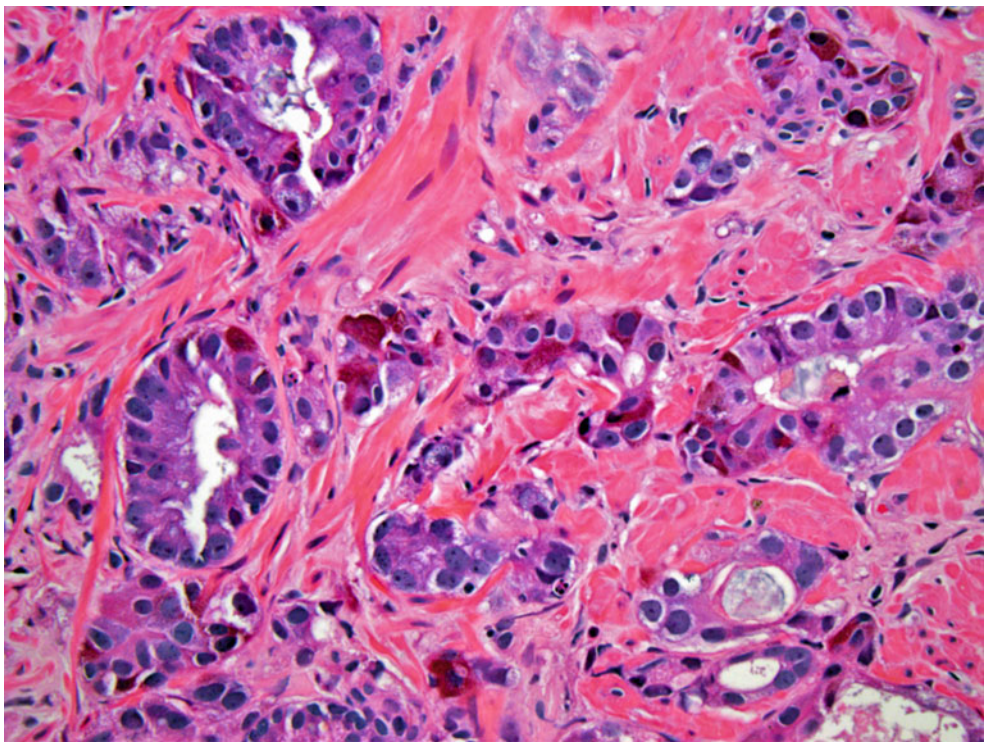

**Fig. 20.24** Paneth cell-like neuroendocrine differentiation in prostatic adenocarcinoma. The neuroendocrine cells contain bright, eosinophilic neurosecretory granules and appear similar to Paneth cells of the gastrointestinal tract. Even though many of the glands are poorly formed with even some single cells seen infiltrating through the stroma, these tumors are suggested to behave in a fashion similar to Gleason score 6 (3+3) conventional adenocarcinomas

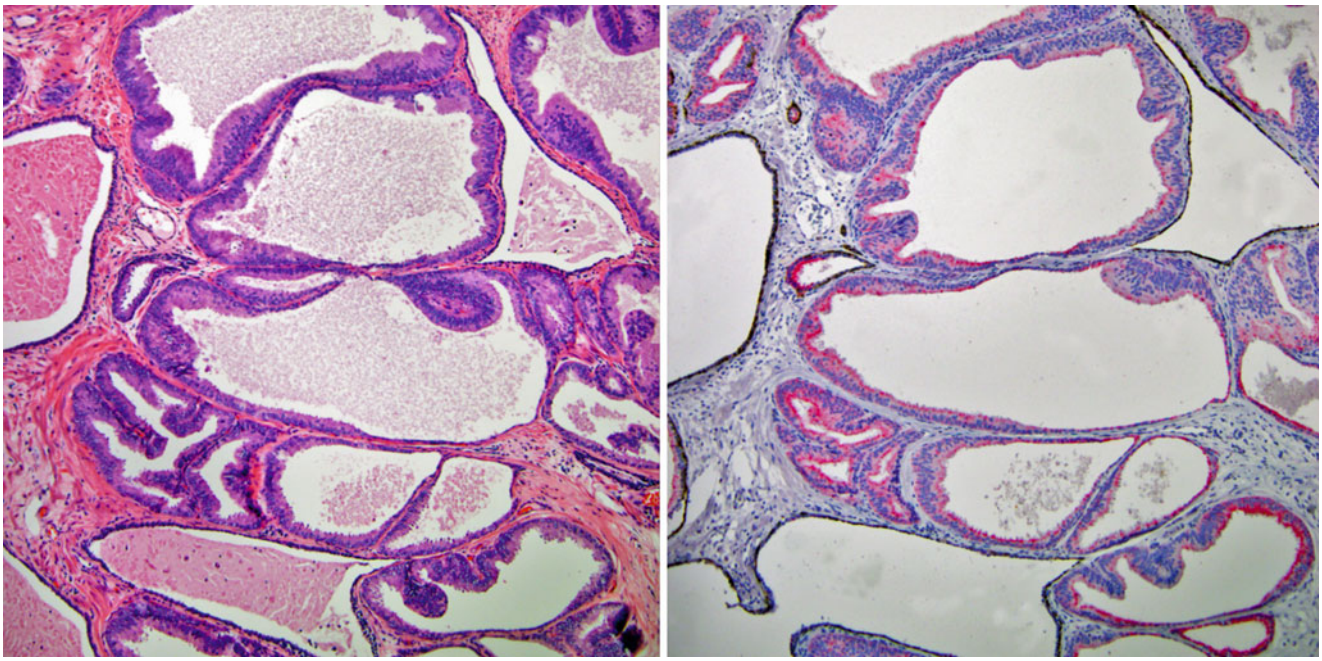

**Fig. 20.25** Pseudohyperplastic carcinoma. While large, dilated glands containing papillary infoldings (*left panel*, H&E) are typically a feature of benign prostate glands, in pseudohyperplastic carcinoma, the nuclear atypia (enlarged nuclei with prominent nucleoli) is beyond that seen in benign prostate. Cancer glands also demonstrate an infiltrative pattern characteristic of carcinoma, seen here as entrapped and dilated benign atrophic glands. Immunohistochemistry (*right panel*) is often necessary to confirm the diagnosis of pseudohyperplastic carcinoma, which demonstrates the absence of basal cells (*no brown staining* in the malignant glands) and the overexpression of AMACR (*red staining* in malignant glands)

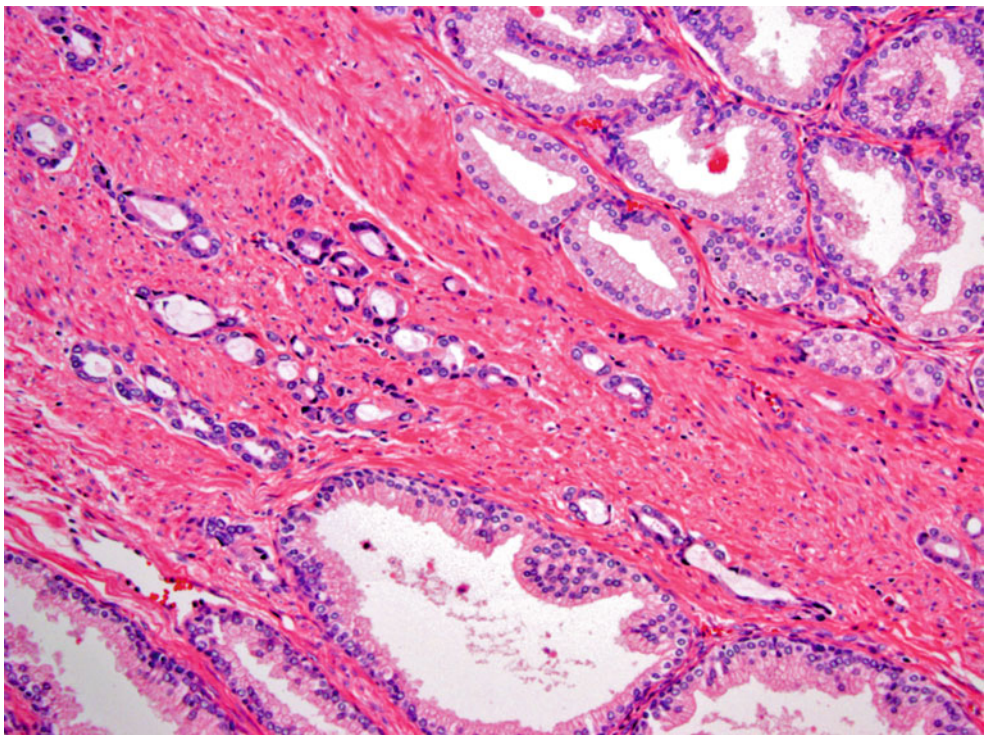

**Fig. 20.26** Atrophic variant of prostatic carcinoma. Malignant glands with scant cytoplasm and only mildly enlarged and hyperchromatic nuclei (*middle of image*) are seen infiltrating between benign glands (*top right* and *bottom left*). Only the infiltrative pattern and occasional nucleoli suggest malignancy as opposed to benign atrophy on H&E sections. Immunohistochemistry can be employed to confirm the diagnosis

the Gleason score of any higher grade non-atrophic cancer admixed with the atrophic variant [41, 42].

Although the term *PIN-like ductal adenocarcinoma* is used to describe prostate cancers that mimic high-grade PIN, these tumors are frequently cytologically and architecturally more similar to usual acinar adenocarcinomas than prostatic duct adenocarcinomas (described below). In addition, while prostatic duct adenocarcinomas are typically considered aggressive tumors, PIN-like adenocarcinomas have a more favorable prognosis and behave similarly to Gleason 6 (3 + 3) conventional acinar adenocarcinomas. Histologically, these tumors are composed of large glands with pseudostratified epithelium having amphophilic cytoplasm and enlarged nuclei with prominent nucleoli. In limited biopsy material, the diagnosis may be difficult to make, as the only distinction from PIN may be the crowded and/or infiltrative nature of the glands combined with the absence of basal cells on immunohistochemistry (Fig. 20.27) [43, 44].

## Clinicopathologic Summary

1. *Mucinous* (*colloid*) *carcinoma* often has significant component of *Gleason pattern 4*.
2. *Foamy gland carcinoma*, *atrophic carcinoma*, and *pseudohyperplastic carcinoma* typically have predominantly *Gleason pattern 3*.
3. *PIN-like ductal adenocarcinoma* and *prostatic adenocarcinoma with Paneth cell-like neuroendocrine differentiation* are usually considered Gleason pattern 3 and have a *favorable prognosis*.

## Intraductal Carcinoma of the Prostate (IDC-P)

Occasionally, conventional acinar adenocarcinoma cells may exist within preexisting ducts that immunohistochemically demonstrate retention of their basal cell layer (Fig. 20.28). This phenomenon has been termed *intraductal carcinoma of the prostate*, or IDC-P, and should not be confused with prostatic duct adenocarcinoma (see below), as the cells of IDC-P are acinar in morphology and not ductal. IDC-P is almost always seen in association with an invasive, high-grade (Gleason score ≥7) acinar adenocarcinoma. The presence of IDC-P on needle core biopsy, even in the absence of documented invasive adenocarcinoma, indicates a high likelihood of extraprostatic extension and/or seminal vesicle invasion at the time of radical prostatectomy [45, 46].

## Clinicopathologic Summary

*Intraductal carcinoma of the prostate*:
1. Associated with *high-grade acinar adenocarcinoma*
2. More frequently seen in *high-stage* (*pT3*) *tumors*

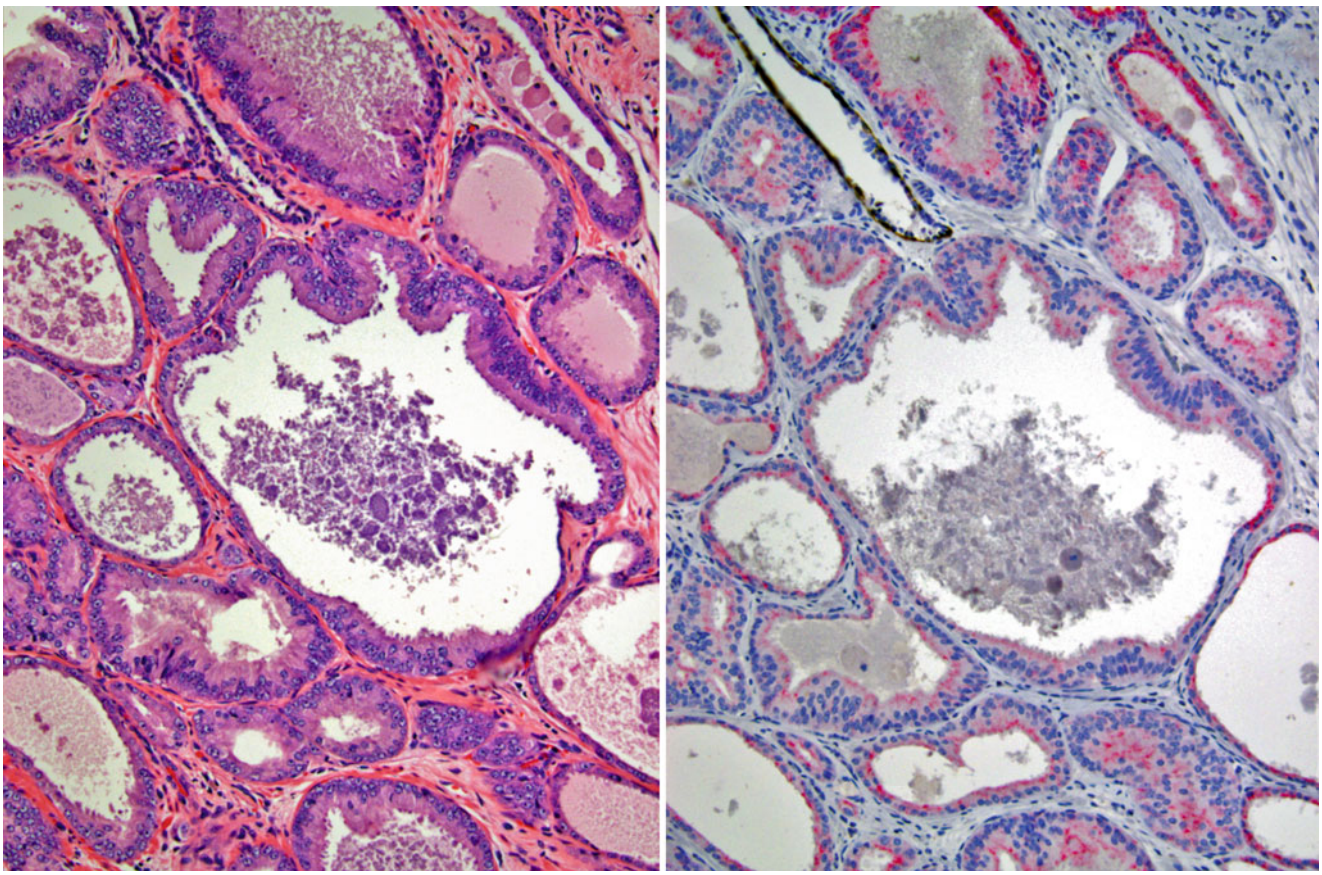

**Fig. 20.27** PIN-like ductal adenocarcinoma. On H&E (*left panel*), the glands of PIN-like ductal carcinoma resemble high-grade PIN in that they are large glands with tall columnar cells and pseudostratified nuclei. Immunohistochemistry (*right panel*) shows the absence of basal cells (*no brown staining*) in these large glands and an infiltrative pattern, whereby the cancer glands surround benign atrophic gland (*upper left corner*). AMACR (*red stain*) is also overexpressed in the cancer glands

## Prostatic Duct Adenocarcinoma

Pure *prostatic duct adenocarcinoma* (ductal adenocarcinoma) is a relatively uncommon form of prostate cancer, accounting for 0.2–0.8 % of all cancers. More commonly, ductal adenocarcinoma is seen admixed with conventional acinar adenocarcinoma, such that around 5 % of all prostate cancers are mixed ductal-acinar tumors. Histologically, these tumors display a cribriform, papillary, or solid growth pattern, and the tumor cells are tall and columnar with amphophilic cytoplasm. The nuclei are usually more elongate than acinar adenocarcinoma, and nucleoli are typically quite prominent (Fig. 20.29). Historically, these tumors were defined by their central location around and within the prostatic urethra; however, more recent studies have shown these tumors to involve only the peripheral zone in many cases and both the *peripheral and central zones* in an even greater proportion of cases, suggesting that central location is not necessary for diagnosis. Nevertheless, prostatic duct adenocarcinoma should be included in the differential diagnosis of any prostatic urethral mass [47–50].

Prostatic duct adenocarcinomas are considered poorly differentiated tumors. Although assignation of a Gleason score is not recommended by some authors, they are considered similar to Gleason score 8 (4 + 4) acinar adenocarcinomas. In cases of mixed ductal-acinar carcinoma, the ductal component is frequently considered *Gleason pattern 4 or 5*, depending upon the absence or presence of comedonecrosis, respectively. These tumors tend to present at a later, higher stage than comparable acinar adenocarcinomas, with some series reporting metastasis in up to 1/3 of patients at the time of diagnosis. At radical prostatectomy, nearly 2/3 of ductal adenocarcinomas have extraprostatic extension, and around 10 % show seminal vesicle invasion. The pattern of metastasis is similar to acinar adenocarcinomas, and treatment options are also the same. A recent study indicated that men with ductal adenocarcinoma of the prostate frequently present with lower serum PSA levels than comparable acinar adenocarcinomas, potentially complicating clinical diagnosis and contributing, at least partially, to the higher stage at presentation [4, 51–53].

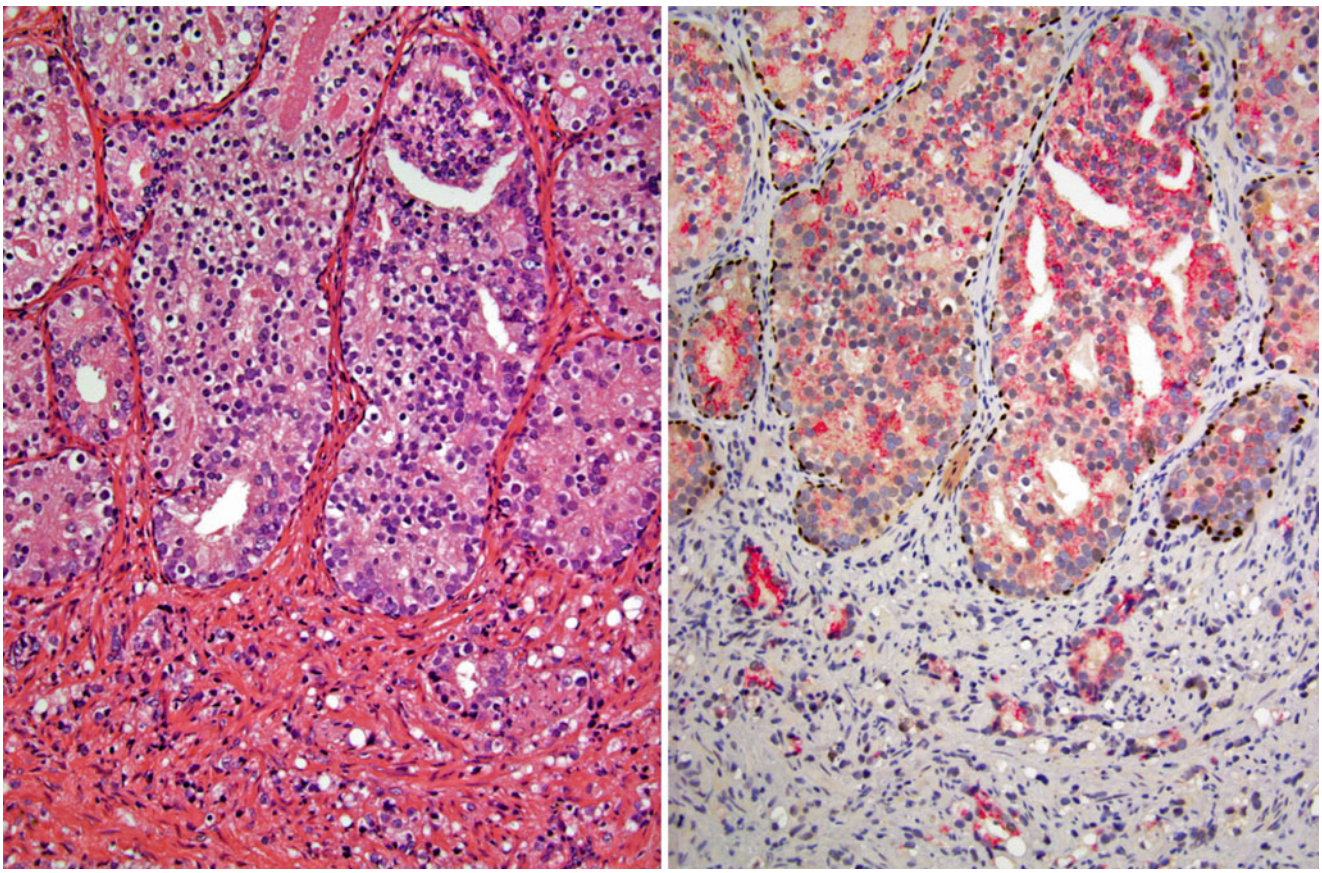

**Fig. 20.28** Intraductal carcinoma of the prostate (IDC-P). By routine H&E examination (*left panel*), IDC-P often resembles invasive cribriform carcinoma (Gleason pattern 4; *top half of image*). However, immunohistochemistry (*right panel*) reveals the presence of a basal cell layer surrounding these glands (*brown staining*). IDC-P is almost always seen in the context of invasive high-grade acinar adenocarcinoma, which can be seen at the bottom half of these images as single, infiltrating cancer cells (Gleason pattern 5). Both IDC-P and invasive cancer overexpress AMACR (*red staining*)

## Clinicopathologic Summary

*Prostatic duct adenocarcinoma*:

1. *High-grade*, *aggressive* variant of prostate cancer with frequent *extraprostatic extension*
2. May be *central* and/or *peripheral* in location
3. Frequently has a *conventional acinar adenocarcinoma component*

## Basal Cell/Adenoid Cystic Carcinoma

Prostatic carcinomas proposed to originate from the basal cells lining prostatic ducts and acini are termed *basal cell carcinomas* (also known as *adenoid cystic carcinomas*). These tumors are extremely rare, with fewer than 75 cases reported in the literature. Two major histologic growth patterns characterize this cancer, both of which may be present in the same tumor: (1) variably sized nests, cords, or trabeculae of cells with scant cytoplasm, vesicular nuclei, and peripheral palisading, similar to basaloid carcinomas of other organs (*basaloid pattern*; Fig. 20.30, left panel) or (2) nests of cells with a prominent cribriform architecture, wherein these microcysts contain eosinophilic basement membrane-like material or basophilic mucinous secretions, similar to the salivary gland tumors of the same name (*adenoid cystic pattern*; Fig. 20.30, right panel). As with all non-acinar adenocarcinomas of the prostate, a Gleason score is not assigned to basal cell carcinomas. These tumors may be locally aggressive with extensive bladder neck invasion, but they uncommonly metastasize to distant sites. Ali et al. found that the presence of necrosis, high proliferation index, and the

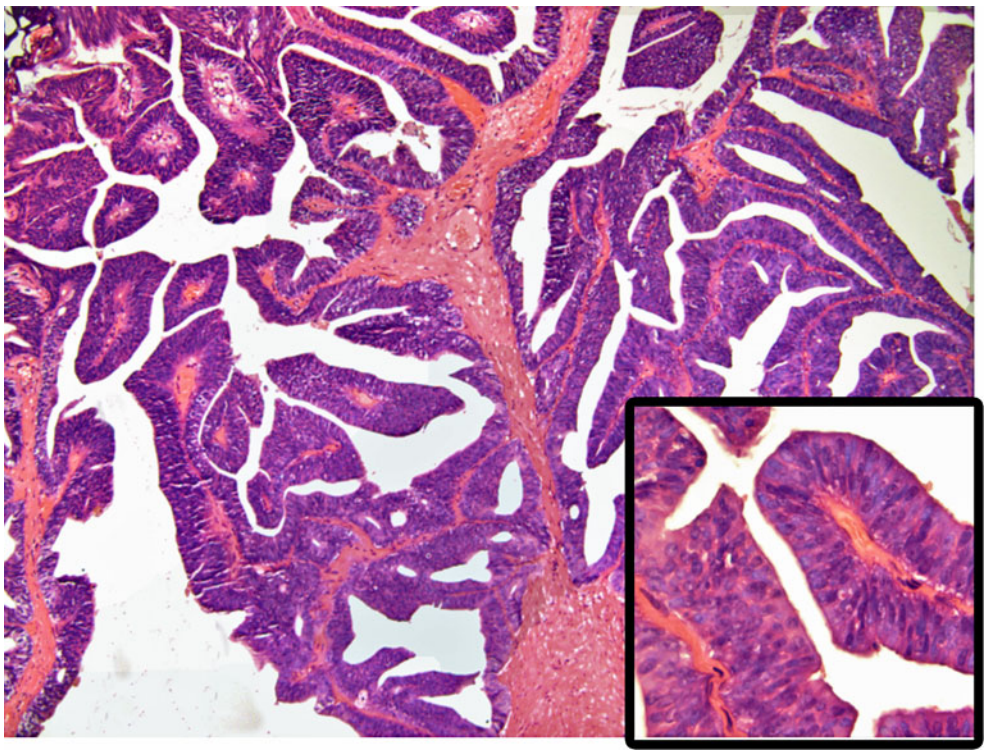

**Fig. 20.29** Prostatic duct adenocarcinoma. Ductal adenocarcinoma of the prostate typically grows in a solid, cribriform, or papillary architectural pattern, the latter of which is demonstrated in this image. Cytologically, the cells of prostatic duct carcinoma differ from acinar adenocarcinoma cells in that they are tall, columnar cells with ovoid or cigar-shaped nuclei that are pseudostratified (inset). Nucleoli are often prominent and may be multiple

solid pattern of basaloid growth were the most significant predictors of increased metastatic potential [54, 55].

## Clinicopathologic Summary

*Basal cell/adenoid cystic carcinoma*:
1. Rare tumor, often *locally aggressive*
2. *Necrosis* and the *basaloid pattern* are indicators of *metastatic potential*

## Sarcomatoid Carcinoma (Carcinosarcoma)

Similar to kidney, bladder, and other organs, malignant spindle cell proliferations that demonstrate epithelial origin by either light microscopy (e.g., concomitant adenocarcinoma) or immunohistochemistry (e.g., cytokeratin or p63 staining) have been termed *sarcomatoid carcinomas*. Some authors reserve the term *carcinosarcoma* for those rare subsets of sarcomatoid carcinomas containing foci diagnostic of a particular type of sarcoma, such as chondrosarcoma, osteosarcoma, or rhabdomyosarcoma (Fig. 20.31). Regardless of terminology, the spindle cell and/or heterologous elements share immunohistochemical, ultrastructural, and molecular characteristics with the associated epithelial component, indicating that the terms sarcomatoid carcinoma and carcinosarcoma likely reflect variations of the same entity, which should be *considered epithelial in origin*. The majority of sarcomatoid carcinomas occur in the setting of either *existing high-grade acinar adenocarcinomas* or in patients with a *history of prostate cancer*, most of whom have received hormonal and/or radiation therapy. Uncommonly, patients may present with pure sarcomatoid carcinoma in the absence of any previously documented adenocarcinoma. Clinically, these tumors behave aggressively, with frequent metastases and a mortality rate of 20 % within the first year [56–60].

## Clinicopathologic Summary

*Sarcomatoid carcinoma* (*carcinosarcoma*):
1. Epithelial-derived malignancies showing *spindle cell* or *heterologous elements*
2. *Aggressive* clinical course with *poor prognosis*
3. Most *associated with high-grade acinar adenocarcinoma* and/or *prior hormone or radiation therapy*

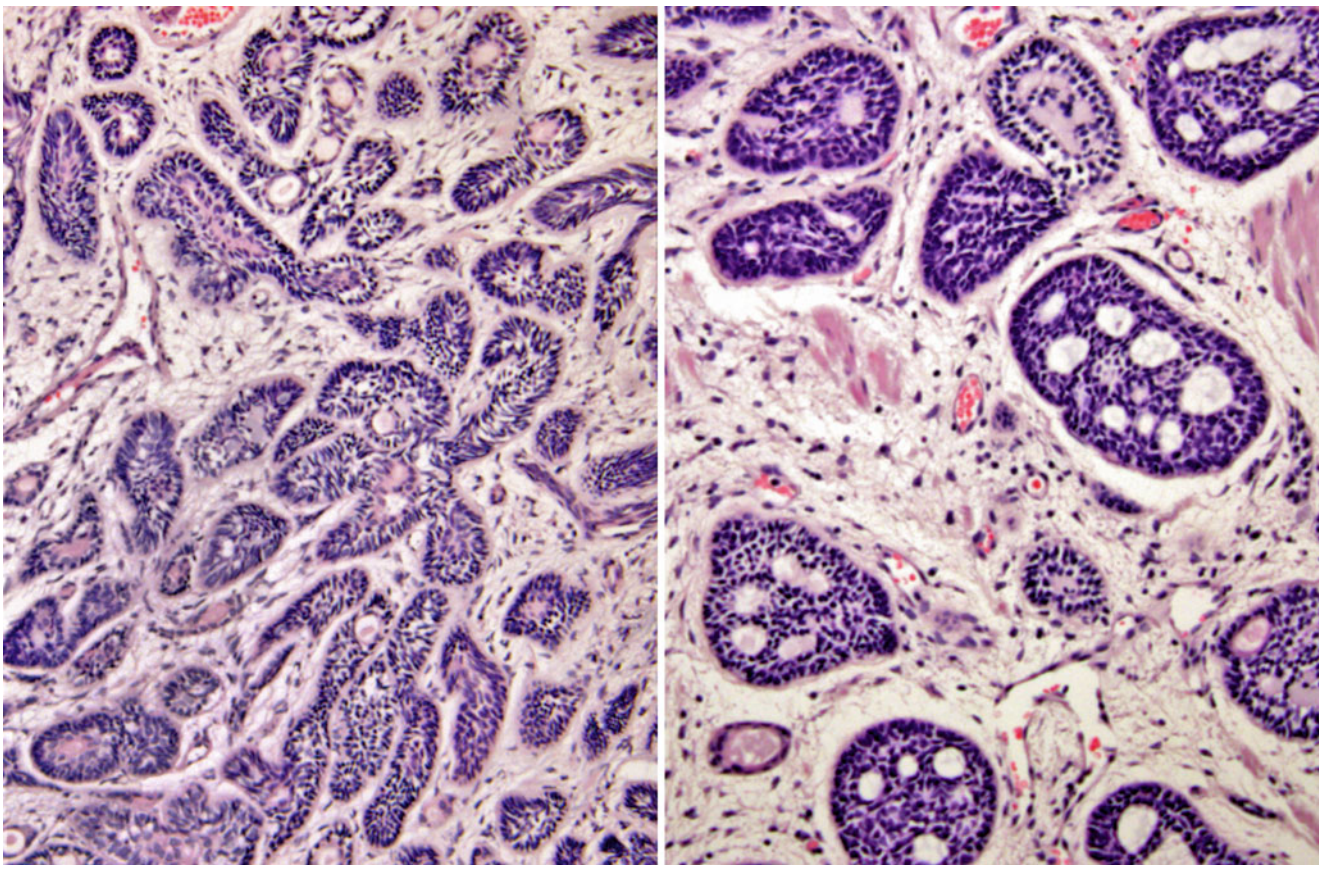

**Fig. 20.30** Basal cell/adenoid cystic carcinoma. The basaloid pattern (*left panel*) of this variant of prostate cancer grows as trabeculae and nests of tumor cells with peripherally palisading nuclei. The adenoid cystic pattern (*right panel*) exhibits cribriform growth pattern with blue mucin or pink basement membrane-like material within the cystic spaces. Both patterns may be present in a single tumor

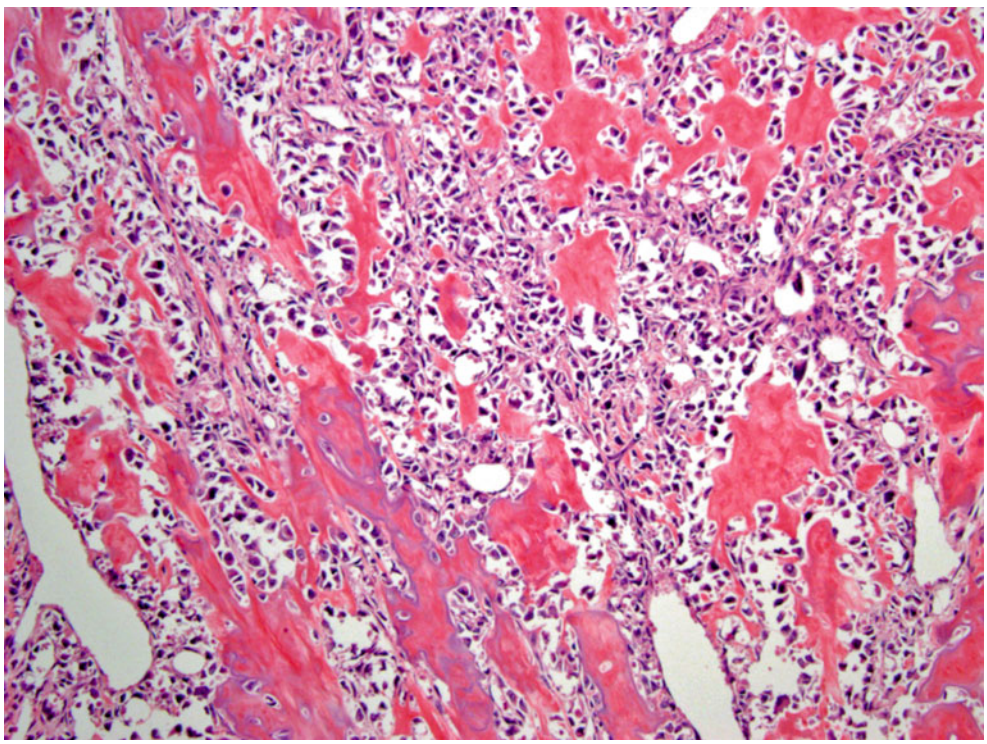

**Fig. 20.31** Sarcomatoid carcinoma (carcinosarcoma). Epithelial-derived malignancies, including prostate cancer, may show mesenchymal differentiation, usually manifest as nondescript spindled cells. In some cases, areas resembling true mesenchymal neoplasms, such as osteosarcoma (*shown here*), may be evident. Such carcinomas are termed sarcomatoid carcinomas, or carcinosarcomas

# The Pathology of Non-epithelial Tumors of the Prostate

21

Maria M. Shevchuk and Brian D. Robinson

## Mesenchymal Tumors

### Prostatic Stromal Tumors

Tumors of specialized prostatic stroma are rare neoplasms with varied histopathologic patterns and clinical behavior. These tumors are classified according to the WHO as either *stromal tumors of uncertain malignant potential* (*STUMP*s) or prostatic *stromal sarcomas*, based upon histologic features [1]. Only a few large studies on these lesions have been published to date [2–4]. Both STUMP and stromal sarcoma stain immunohistochemically for CD34 and progesterone receptor, similar to nonneoplastic prostatic stromal cells, supporting the specialized stromal nature of these tumors.

#### Stromal Tumor of Uncertain Malignant Potential (STUMP)

*STUMP*s are the more frequent of the two lesions and generally have a good prognosis, with most following a benign clinical course. Occasionally, STUMPs may recur rapidly after resection or, rarely, progress to malignant stromal sarcomas with metastatic potential [2]. For these reasons, definitive treatment is often performed for STUMPs in younger men. However, due to their rarity and therefore the lack of reliable clinical data, the preferred treatment modality for these lesions is unclear.

Patients with STUMPs often present with symptoms of urinary obstruction, hematuria, hematospermia, or rectal fullness, while some cases are detected by digital rectal examination or elevated serum PSA levels. Patients tend to be in their sixth and seventh decades, with a mean age of 58 at presentation. STUMPs may involve either the transition zone or peripheral zone of the prostate and can be greater than 10 cm in size. They are tan-white on cut surface and can be entirely solid or have both solid and cystic areas, with the cysts containing blood, mucin, or clear fluid. Microscopically, four patterns of STUMP have been described. The most common pattern features hypercellular stroma with atypical, degenerative-appearing stromal cells and intermixed benign glands (Fig. 21.1). Other patterns include cellular stromal pattern, stromal predominant/myxoid pattern, and phyllodes pattern. In these latter three patterns, the stromal cells are typically cytologically bland. Mitoses are infrequent. A mixture of these four patterns is seen in many cases of STUMP, and various patterns of epithelial proliferation have also been described within these tumors [5].

#### Stromal Sarcoma

*Stromal sarcomas* may present similarly to STUMP, but stromal sarcoma patients tend to be younger, with approximately half of all cases occurring in men under the age of 50. They are typically solid lesions with a fleshy cut surface, typically greater than 2 cm in size. The diagnosis of stromal sarcoma is made when there is a solid or infiltrative proliferation of stromal cells with hypercellularity, cytological atypia (not degenerative type), mitotic figures (especially atypical mitotic figures), and/or necrosis (Fig. 21.2). Occasionally, stromal sarcomas may have a phyllodes growth pattern with leaflike glands and hypercellular atypical stroma. Stromal sarcomas may be locally invasive with extraprostatic extension, and metastasis from stromal sarcoma, such as to bone and lung, has been reported.

#### Clinicopathologic Summary

*STUMP* and *stromal sarcoma* are rare prostatic neoplasms derived from specialized prostatic stroma. Stromal sarcomas are malignant tumors with an aggressive clinical course, while many STUMPs behave in a benign fashion.

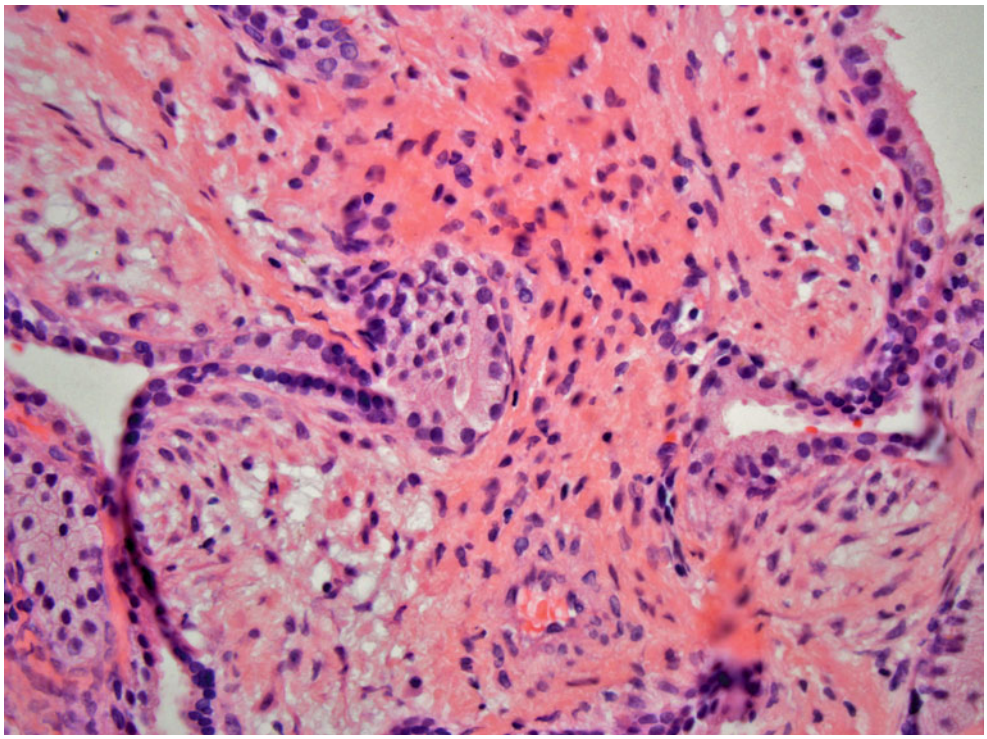

**Fig. 21.1** STUMP. Increased stromal cellularity and mild cytologic atypia of the stromal cells are features of the cellular stromal pattern of STUMP

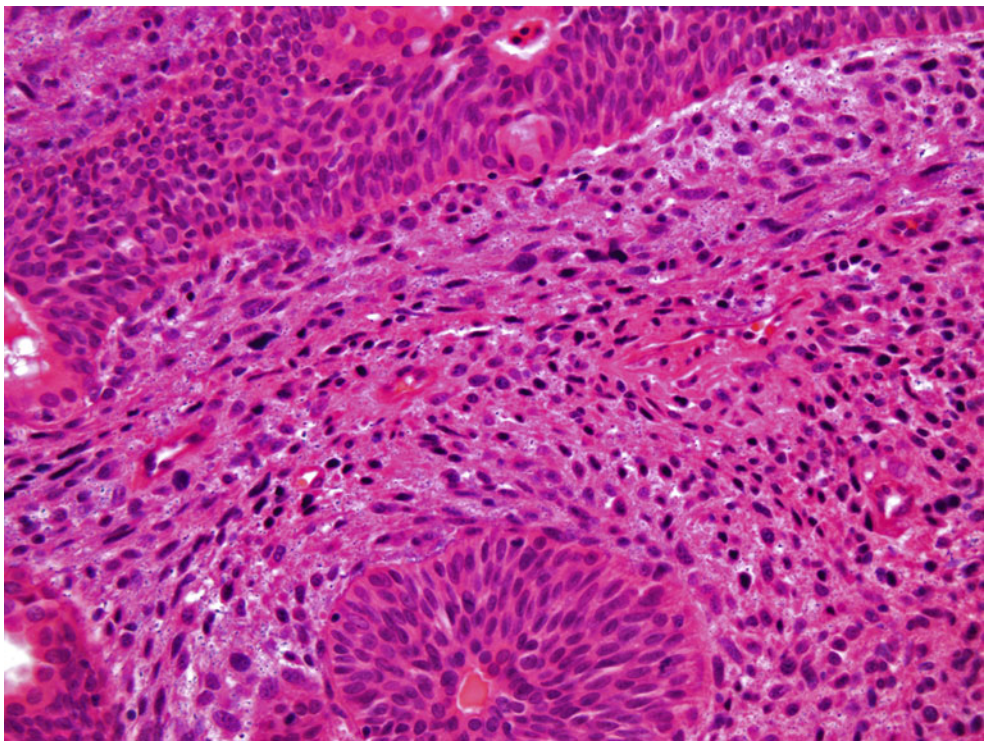

**Fig. 21.2** Stromal sarcoma. Stromal sarcomas typically have a highly cellular stromal component with cells that display severe cytologic atypia, including nuclear pleomorphism and hyperchromasia

## Smooth Muscle Tumors

### Leiomyoma

*Leiomyoma* of the prostate is rare, and the distinction between a leiomyoma and stromal nodule of BPH is difficult, making definitive diagnosis of leiomyoma nearly impossible. Indeed, some consider a prostatic "leiomyoma" to be an expression of stromal hyperplasia of BPH [6]. Others have recommended the diagnosis of prostatic leiomyoma only be made when there is a well-circumscribed proliferation of smooth muscle at least 1 cm in diameter [7]. Additional features that favor the diagnosis of leiomyoma include organized fascicular growth, hyalinization, and calcification [8].

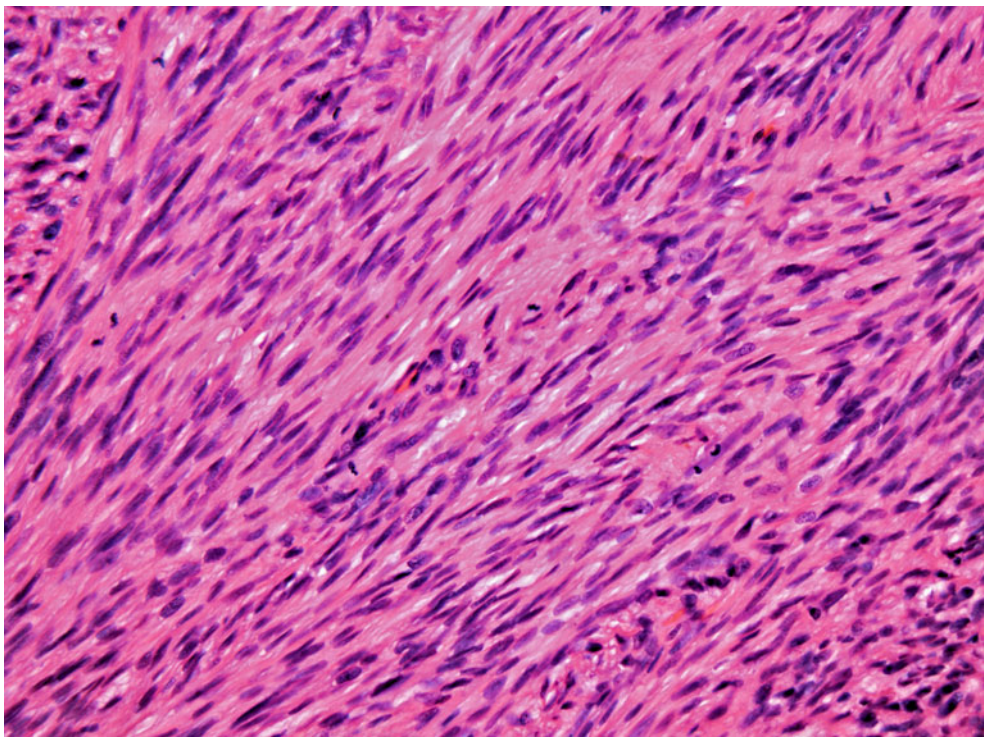

**Fig. 21.3** Leiomyosarcoma. Leiomyosarcomas are composed of intersecting fascicles of malignant smooth muscle cells. Mitotic figures are typically frequent, as seen in this case

## Leiomyosarcoma

Although still exceedingly rare, *leiomyosarcoma* is the most common sarcoma to occur in the prostate [9, 10]. It affects men typically in the fifth to eighth decades and is almost always high grade. Microscopically, the lesions are hypercellular, composed of spindled smooth muscle cells arranged in intersecting fascicles with moderate to marked atypia (Fig. 21.3) [1]. Frequent mitotic figures and necrosis are common features. Survival is relatively short, with patients often suffering from multiple local recurrences as well as metastatic spread, commonly to lung. More than half of men with prostatic leiomyosarcoma die within 5 years of diagnosis.

## Clinicopathologic Summary

1. *Leiomyosarcoma* is the most common sarcoma of the prostate, although still exceedingly rare. These malignant smooth muscle tumors are typically high grade and carry a poor prognosis.
2. *Leiomyoma* of the prostate is a controversial benign entity, with many considering these lesions to be part of the BPH spectrum.

## Inflammatory Myofibroblastic Tumor

*Inflammatory myofibroblastic tumors* (*IMT*s), also known as postoperative spindle cell nodules, pseudosarcomatous fibromyxoid tumors, inflammatory pseudotumors, myofibroblastomas, and pseudosarcomatous myofibroblastic proliferations, are benign tumors that may occur in the prostate. Previously, lesions that occurred following a surgical procedure, such as transurethral resection, were separated from similar lesions that occurred de novo. However, their overlapping morphological, immunohistochemical, and molecular features and identical clinical behavior have led to the unified classification and designation of all such lesions as IMTs [11–17].

Most IMTs of the prostate occur in men in the fifth to seventh decade and may be relatively small (<1 cm). Microscopically, they are identical to IMTs of the bladder and other organs. The tumors are composed of spindle cells with abundant dense eosinophilic to amphophilic cytoplasm. The cells are fibroblastic/myofibroblastic in appearance with long tapering processes in a loose myxoid stroma, which often contains chronic inflammatory cells. They are classically described as having a "tissue culture" appearance. They may be arranged haphazardly or in intersecting fascicles. Nuclei are not hyperchromatic, in contrast to sarcomatous lesions with which this benign entity should not be confused, and the chromatin pattern is delicate with only one or two micronucleoli (Fig. 21.4). Mitotic figures may be abundant, but this should not raise concern for malignant behavior, as virtually all IMTs behave in a benign fashion. They may recur, however, if incompletely resected. Positive ALK immunohistochemical staining, or detection of ALK gene fusion by fluorescence in situ hybridization (present in approximately three-fourths of all cases of IMT), can confirm the diagnosis [14, 17].

## Clinicopathologic Summary

*Inflammatory myofibroblastic tumors* are benign lesions that may occur de novo or following a surgical procedure. Their appearance may mimic a high-grade sarcoma, yet

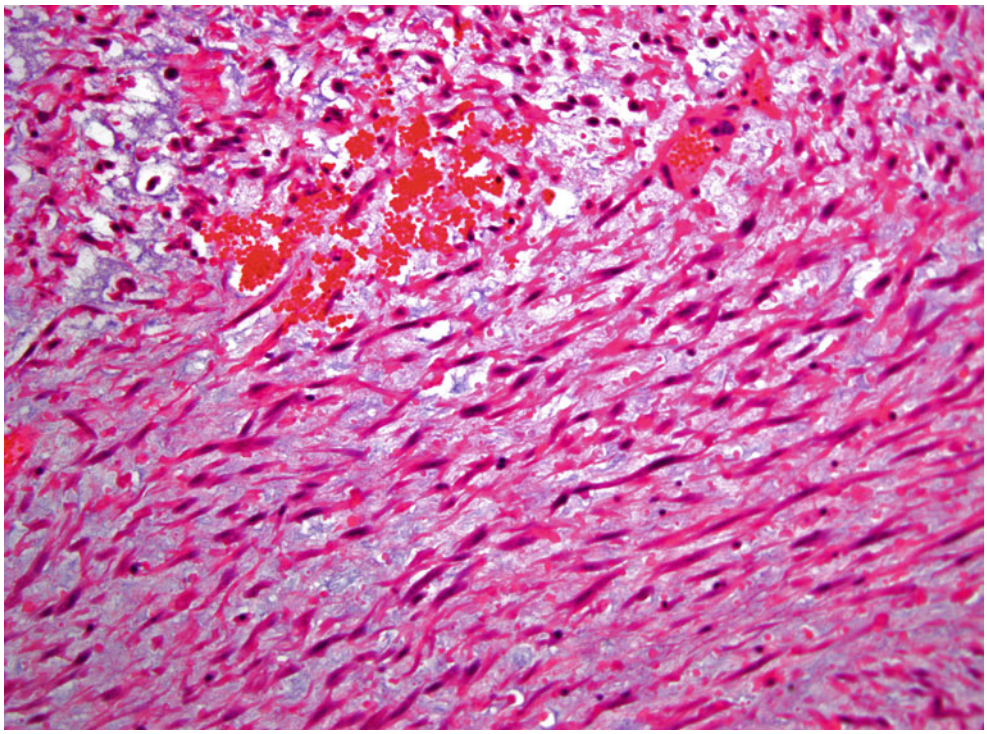

**Fig. 21.4** Inflammatory myofibroblastic tumor. IMTs are composed of cells with a spindled shape and long tapering cytoplasmic processes. The cells are embedded in a loose, myxoid stroma that frequently contains inflammatory cells and extravasated red blood cells

careful examination and ALK gene rearrangement status can help in difficult cases. Conservative complete resection is generally curative.

## Rhabdomyosarcoma

*Rhabdomyosarcomas* of the prostate occur almost exclusively in pediatric patients, and the mean age at diagnosis is 5 years [1, 18, 19]. Fewer than 20 adult cases of prostatic rhabdomyosarcoma have been reported [20, 21]. Tumors typically present at advanced stage, with gross disease remaining following incomplete resection or biopsy (stage 3) or metastasis (stage 4). Many patients with stage 1 or stage 2 disease may be cured with the use of effective chemotherapy, and even stage 3 patients often experience long periods of disease-free survival with only 15–20 % mortality. Stage 4 patients, on the other hand, have an extremely poor prognosis with most dying from this malignant tumor. Occasionally, it may be difficult to distinguish primary bladder rhabdomyosarcomas from prostatic rhabdomyosarcomas due to their often large size and advanced stage at presentation. In cases where chemotherapy and radiotherapy are unsuccessful, radical surgery is performed. While the majority of these tumors are of the embryonal subtype (rarely as *sarcoma botryoides*), it is clinically important to distinguish those rhabdomyosarcomas of the alveolar subtype, which have an unfavorable histology, so that more aggressive chemotherapy regimens may be administered [1].

### Clinicopathologic Summary

*Rhabdomyosarcoma* is the most common mesenchymal tumor of the prostate in pediatric patients. Although many patients present with advanced stage disease, current chemotherapy and radiotherapy regimens can offer long-term disease-free survival and even cure.

## Solitary Fibrous Tumor

Fewer than 20 cases of *solitary fibrous tumor* (SFT) of the prostate have been reported, and the largest case series included 13 patients [22–25]. While none of these has behaved in a malignant fashion, long-term clinical follow-up is recommended based upon the malignant potential of SFTs at other sites. They have been reported to occur in a wide age range of adult men, and a broad size range is also reported, with many larger than 5 cm. Microscopically, SFT of the prostate is similar to SFT of other sites, being composed of spindle cells with bland nuclei embedded within a ropy collagenous stroma. The tumor is classically described as having a "patternless" pattern to the cells. Hemangiopericytoma-like vessels are also a common feature (Fig. 21.5). Immunohistochemically, these tumors are diffusely positive for CD34, bcl-2, and vimentin, while typically negative for S100, CD117, and cytokeratins.

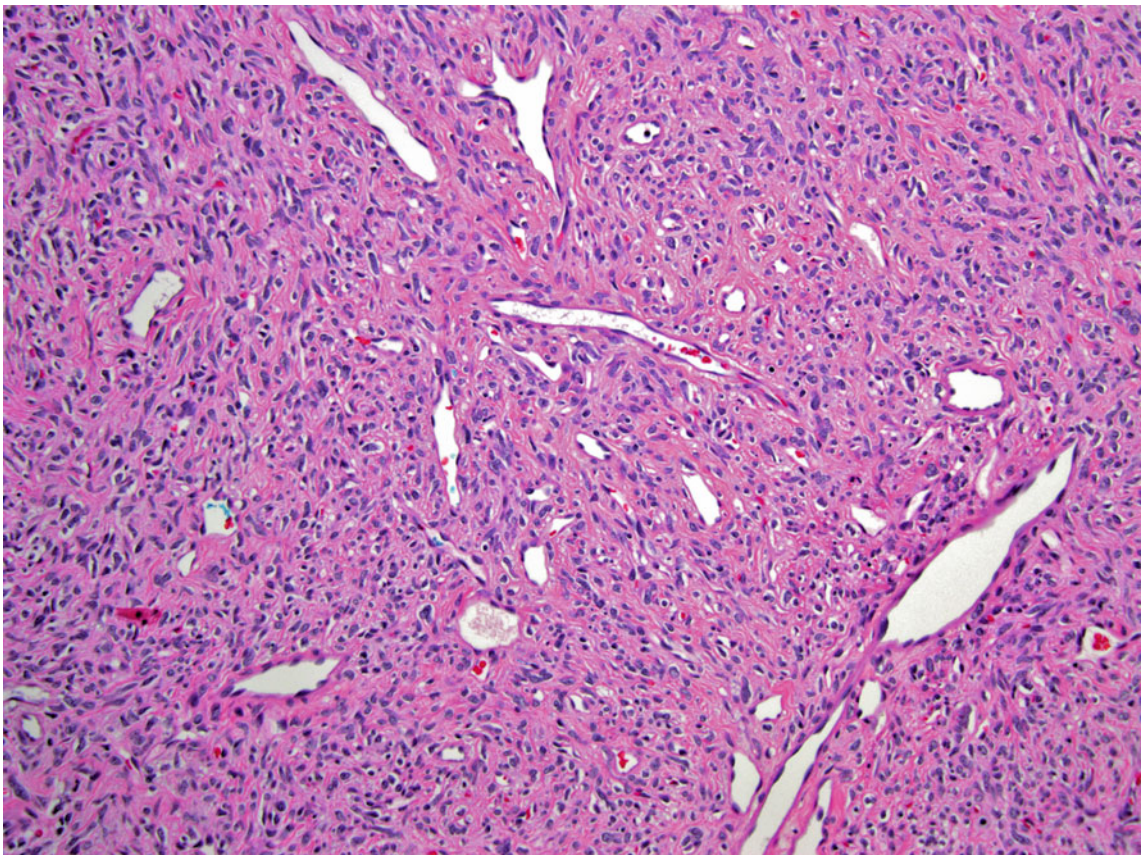

**Fig. 21.5** Solitary fibrous tumor. Features of SFTs include fibroblastic-appearing cells with dense pink cytoplasm embedded within a ropy collagenous stroma. The vessels typically have a staghorn appearance resembling those seen in hemangiopericytomas

### Clinicopathologic Summary

*Solitary fibrous tumors* of the prostate are uncommon neoplasms, and their appearance in the prostate is similar to those in other sites. While none has behaved in a malignant fashion, close observation is warranted based upon malignant behavior in other organs.

## Miscellaneous Non-epithelial Tumors

Several additional tumors have been reported to occur in the prostate, including melanocytic lesions. Primary *malignant melanoma* of the prostate has been reported only rarely [26, 27], and melanoma involving the prostate is more likely to be secondary and represents metastasis from a distant site. In our experience, these melanomas frequently demonstrate a spindle cell morphology.

*Blue nevus*, on the other hand, is a benign melanotic lesion that has been reported to occur in 4 % of prostates [8, 28–31]. Blue nevi appear microscopically as pigmented spindle cells filled with melanin within the fibromuscular stroma (Fig. 21.6a, b). Melanin deposition within glandular epithelium (glandular melanosis) is also seen in approximately 4 % of all prostates [8, 32, 33]. Neither blue nevi nor glandular melanoses have been reported to show malignant transformation.

Rectal *gastrointestinal stromal tumors* (GISTs) may be detected on transrectal prostatic needle core biopsy specimens, and occasionally rectal GISTs may radiographically appear to arise from the prostate gland [34–36]. However, to date, no GIST has been confirmed to arise from the prostate.

*Paraganglioma* (*extra-adrenal pheochromocytoma*) arising in the prostate has been reported in the literature in less than 30 cases [37–44]. The patients' ages were from 8 to 37, and most presented with the characteristic symptoms of hypertension and headache, along with hematuria. Sometimes these symptoms were exacerbated by micturition. The tumors measured 3–5 cm, and the treatment was usually a radical prostatectomy. Most of these tumors had a benign course, but lymph node metastases have been reported [45, 46].

*Germ cell tumors* have been described in the prostate. They probably arise from germ cells sequestered during migration, similarly to the cells that give rise to other extragonadal midline germ cell tumors. The diagnosis of a prostatic germ cell tumor is made only after the exclusion of a testicular primary. Most types of germ cell tumors have been

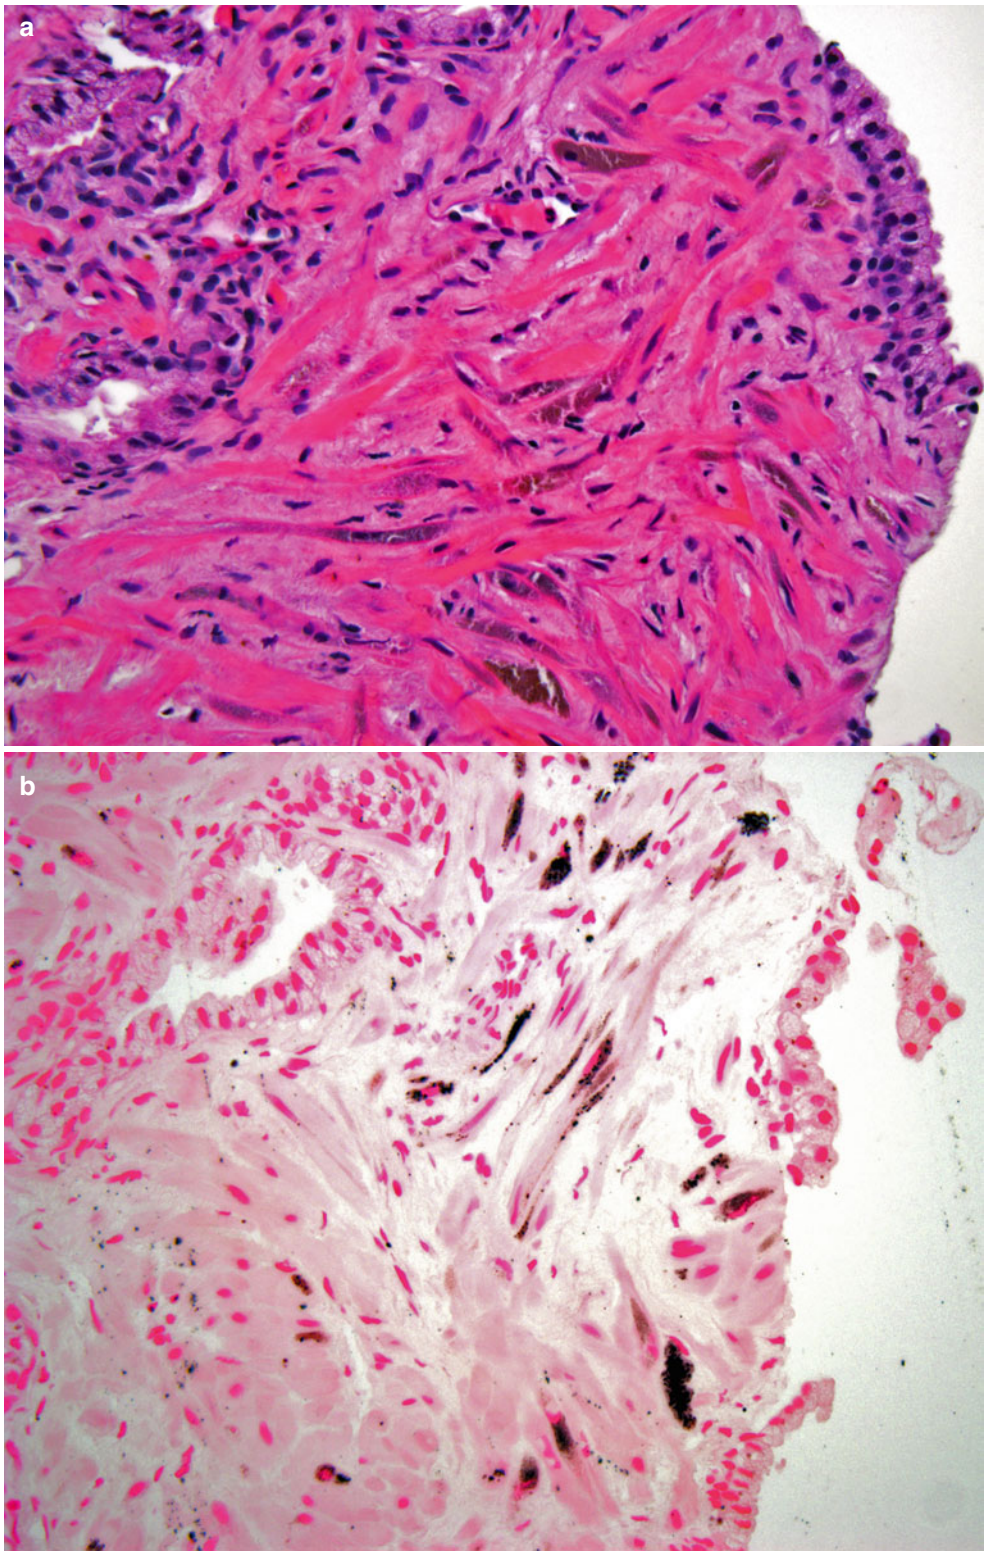

**Fig. 21.6** (**a**) Blue nevus. Melanin-containing spindled stromal cells are seen in *blue* nevi of the prostate. (**b**) A Fontana-Masson stain highlights the melanin pigment (*black*)

described, including *embryonal carcinoma*, *yolk sac carcinoma*, and *choriocarcinoma*, as well as *seminoma* [47–61].

*Angiosarcoma* [62], *peripheral neuroectodermal tumor* (*PNET*) [63, 64], *neuroblastoma* [65], *malignant peripheral nerve sheath tumor* (*MPNST*) [66], *synovial sarcoma* [67–69], *malignant perivascular epithelioid tumor* (*PECOMA*) [70], and *Wilms' tumor* [71] have all been reported to occur in the prostate.

### Clinicopathologic Summary

1. Melanotic lesions occur not uncommonly in the prostate; however, most of these represent benign *nevi* or *melanosis* without malignant potential. Rare primary *melanomas* of the prostate have been reported, but most melanomas involve the prostate only secondarily.
2. *Gastrointestinal stromal tumor* (GIST) has not been documented to occur in the prostate. Rectal GIST may be detected incidentally on needle core biopsy of the prostate.
3. *Paraganglioma* may occur in the prostate, most of which have a benign clinical course, though lymph node metastases have been reported.
4. *Germ cell tumors*, both seminomatous and non-seminomatous types, may rarely occur in the prostate, but diagnosis requires the exclusion of a testicular or mediastinal primary tumor.
5. Multiple additional benign and malignant lesions have been reported in the prostate as case reports or small series.

## Hematologic Neoplasms of the Prostate

### Chronic Inflammation

*Chronic inflammation* is frequently seen in prostates, particularly in specimens from benign prostatic hyperplasia with obstruction. The histologic spectrum ranges from individual scattered lymphocytes to large aggregates of chronic inflammatory cells, frequently centered on or surrounding prostatic glands. Characteristically, there is an admixture of small lymphocytes with plasma cells and histiocytes (Fig. 21.7a, b). Since chronic inflammation can be associated with a modest elevation of PSA, its presence is often noted in needle core biopsies. More importantly, cases of leukemic and lymphomatous infiltration of the prostate need to be distinguished from the common chronic inflammation and not overlooked (see below).

### Leukemia

#### Chronic Lymphocytic Leukemia (CLL)

*Chronic lymphocytic leukemia* (*CLL*)/*small lymphocytic lymphoma* (*SLL*) involves the prostate in 20 % of cases of disseminated systemic disease [72]. Occasionally, CLL presents in the prostate, often with symptoms of urinary tract obstruction, and a subsequent hematologic workup confirms the diagnosis of CLL [8]. Histologically, CLL involvement of the prostate consists of extensive infiltration of the prostatic stroma by sheets of monomorphic small lymphocytes, which spare the prostatic acini and glands (Fig. 21.7c). Marked chronic inflammation can be distinguished from CLL, because the former has an admixture of plasma cells and histiocytes, which the latter lacks. The diagnosis of CLL must always be corroborated by the proper hematologic workup.

#### Myeloid Sarcoma (Chloroma)

Rare cases of *myeloid sarcoma* (*chloroma*) have been reported in the prostate, usually in the context of known *acute myeloid leukemia* (*AML*) [73, 74].

#### Multiple Myeloma

*Plasmacytoma*, causing bladder outlet obstruction, has been reported in a few patients with *multiple myeloma*. There is a mass-like infiltration of prostatic stroma by atypical plasma cells. The diagnosis is confirmed by specific immunohistochemical and genetic studies, in the context of the appropriate hematologic evaluation [75–77].

### Lymphoma

#### Secondary Lymphoma

Most *lymphomas* of the prostate are *secondary* and part of disseminated disease. They are uncommon and usually present in older men, with an enlarged smooth prostate causing obstructive symptoms. Most of the different types of lymphoma have been described in the prostate, but by far the most common is the *diffuse large B-cell lymphoma* (Fig. 21.8a) [78, 79].

#### Primary Lymphoma

*Primary lymphoma* of the prostate is rare and its prevalence among extranodal lymphomas has been reported to be 0.2 % [80, 81]. The diagnosis of primary lymphoma of the prostate can only be made after excluding all other sites of involvement, with the possible exception of pelvic lymph nodes (whose involvement is accepted by some authors in cases of primary prostatic lymphoma) [81–83] (Fig. 21.8b–d). Most primary lymphomas of the prostate are *diffuse large B-cell lymphomas*; however, rare cases of other types of lymphoma have also been reported. Of particular interest are the reported cases of *mucosa-associated lymphoid tissue lymphoma—MALT lymphoma* (Fig. 21.9a–b) [84].

Histologically, both primary and secondary lymphomas consist of malignant lymphoid proliferations (specific to lymphoma type) infiltrating and expanding prostatic stroma, while preserving the prostatic glands.

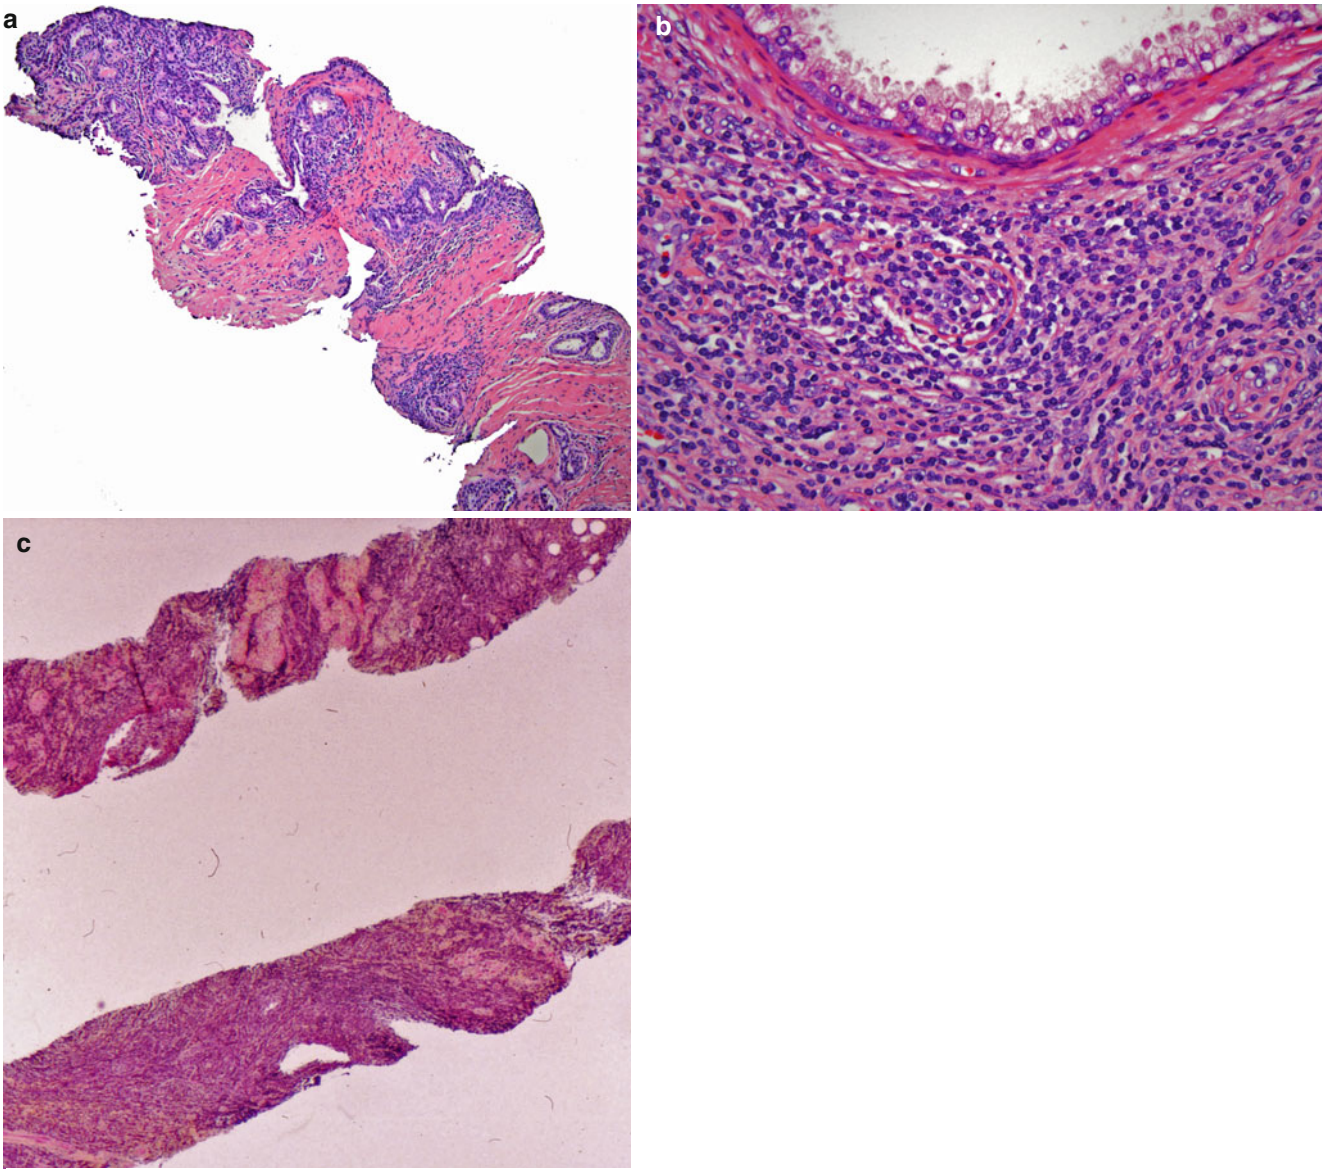

**Fig. 21.7** (**a**) Chronic inflammation of the prostate. Inflammatory cell aggregates are present primarily around prostatic glands. (**b**) Chronic inflammation of the prostate. Note that the inflammatory foci consist of lymphocytes, plasma cells, and histiocytes. (**c**) Chronic lymphocytic leukemia involving the prostate. Note the extensive diffuse stromal infiltration by neoplastic small lymphocytes

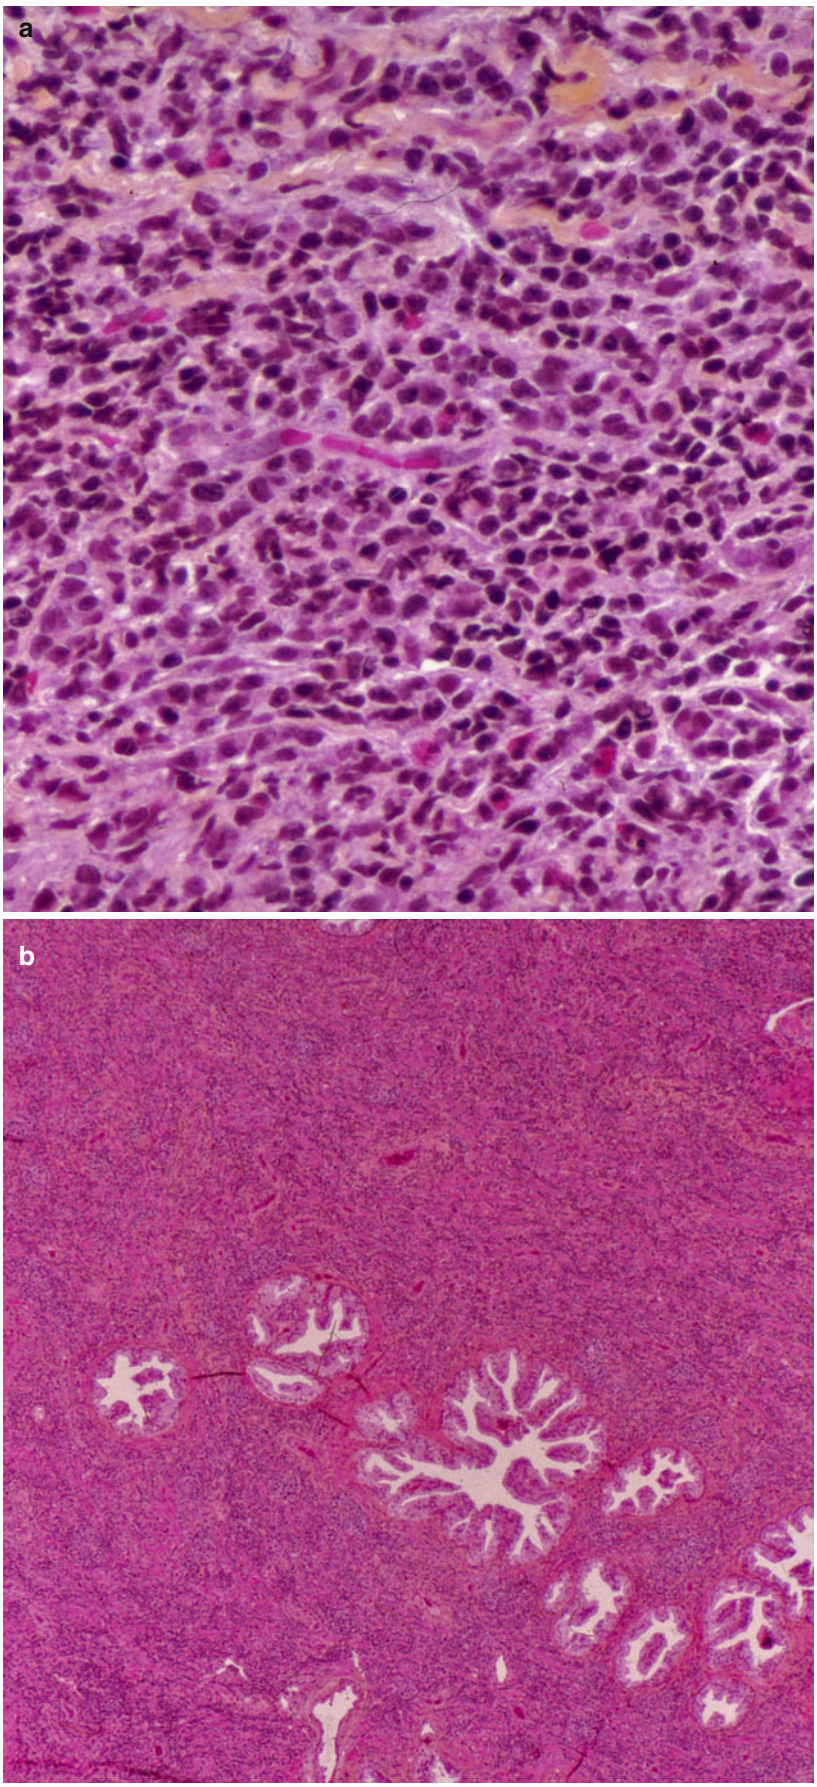

**Fig. 21.8** (**a**) Retroperitoneal diffuse large B-cell lymphoma, secondarily involving the prostate. Note the classic appearance of diffuse large B-cell lymphoma. (**b**) Primary diffuse large B-cell lymphoma of the prostate. Note the diffuse infiltration of prostatic stroma by the lymphoma, with sparing of prostatic glands (40×). (**c**) Primary diffuse large B-cell lymphoma of the prostate (200×). (**d**) Primary diffuse large B-cell lymphoma of the prostate (400×)

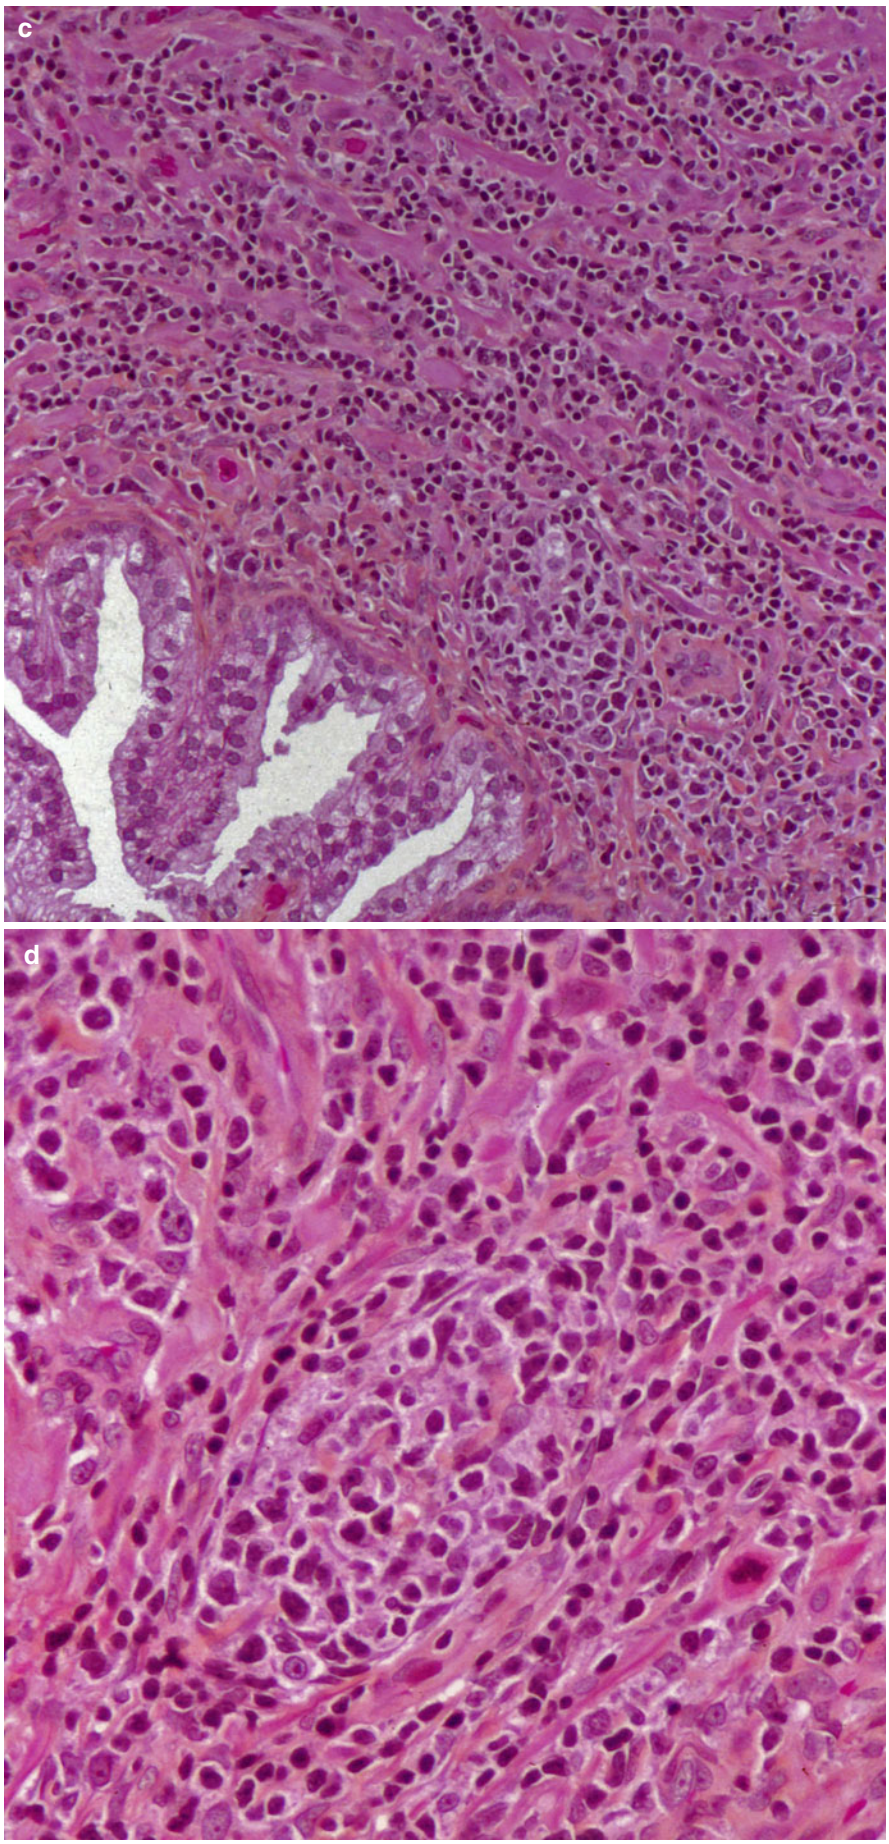
**Fig. 21.8** (continued)



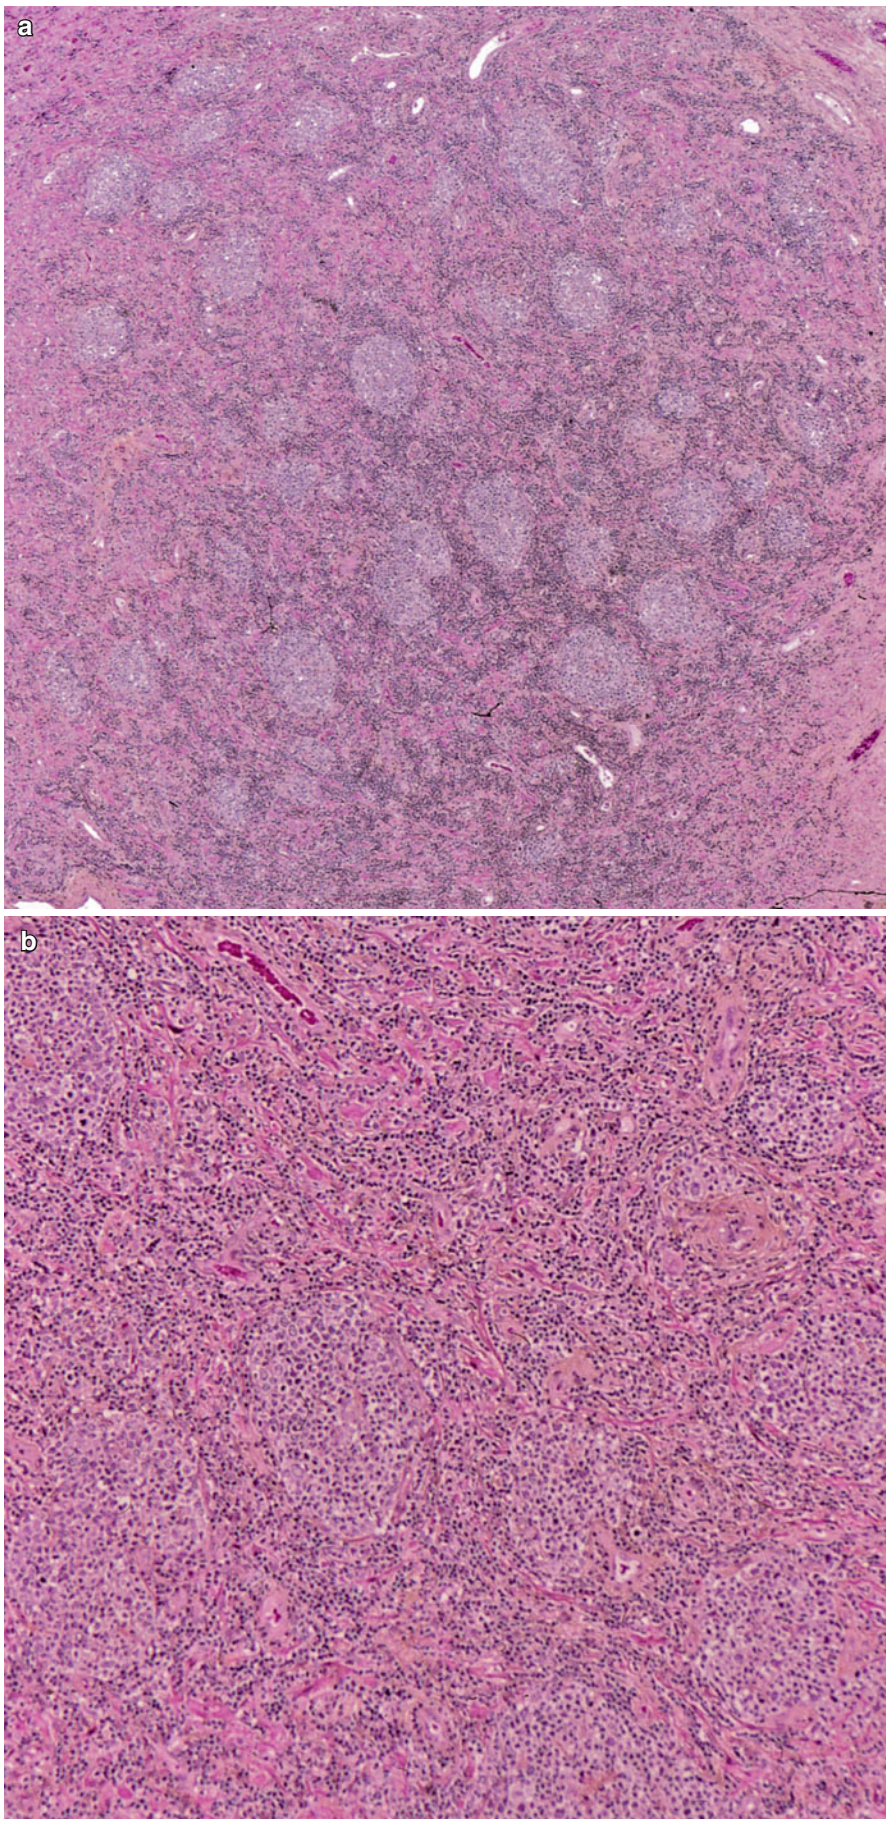


**Fig. 21.9** (**a**) Primary MALT lymphoma of the prostate. Note the numerous follicular structures characteristic of this lymphoma. (**b**) Primary MALT lymphoma of the prostate. Higher magnification of the neoplastic components of the tumor

## Clinicopathologic Summary

1. *Chronic inflammation* of the prostate is very common and consists of a mixture of chronic inflammatory cells. The pathologic diagnosis of "chronic inflammation" is preferable to "chronic prostatitis," which is a clinical term with treatment implications. Leukemic and lymphomatous involvement, especially CLL, has to be distinguished from chronic inflammation.
2. The presence of *leukemia/lymphoma* should be suspected in cases with extensive infiltration of the prostatic stroma by lymphoid or hematopoietic cells, particularly with the preservation of prostatic glands. A hematologic workup is required, and in most cases this is secondary involvement.

# Neuroendocrine Prostate Cancer

# 22

Himisha Beltran, Juan Miguel Mosquera,
and Mark A. Rubin

Neuroendocrine prostate cancer (NEPC) is a highly aggressive subtype of prostate cancer that may either arise *de novo* or much more commonly after hormonal therapy for prostate adenocarcinoma. It is estimated that up to 30 % of late stage prostate cancers harbor a predominance of neuroendocrine differentiation [1]. However, due to a general lack of biopsy diagnoses for advanced disease, this may underrepresent the frequency of neuroendocrine PCa (NEPC). Since androgen deprivation therapy promotes the development of NEPC, its incidence is anticipated to escalate with the introduction of new potent hormonal agents into the clinical arena.

NEPC is more aggressive than prostate adenocarcinoma, does not secrete prostate specific antigen (PSA) or express androgen receptor [2], and can be suspected in patients with progressive disease despite a normal or modestly elevated PSA and/or elevated serum markers of neuroendocrine differentiation (i.e., chromogranin A or neuron-specific enolase (NSE)). These tumors are highly aggressive, with nearly all patients dying within 1 year of diagnosis [25].

## Neuroendocrine Cells in the Normal Prostate

The epithelial compartment of the normal prostate gland is composed of basal cells, secretory (luminal) epithelial cells, and neuroendocrine (NE) cells. Prostate adenocarcinoma shows features of secretory cells. Basal cells are androgen insensitive and have recently been shown to display stem cell features [27].

Neuroendocrine cells are distributed throughout the normal prostate (<1 %), with a higher frequency in ducts compared to acinar tissue [3]. There are two types of NE cells: "open" cells with apical extensions that connect with the lumen and "closed" cells with dendritic-like processes that extend between adjacent cells and rest on the basal lamina in close relation to adjacent nerves. NE cells have features of epithelial, neural, and endocrine cells and act in a paracrine fashion to communicate with luminal and stromal cells via these extensions (or neurites) [4].

The physiological role of NE cells in the normal prostate is not well established, but they are thought to be involved in regulation of epithelial cell growth and differentiation. NE cells contain dense-core cytoplasmic granules that store peptide hormones and prohormones, including chromogranin A, NSE, chromogranin B, somatostatin, bombesin, and calcitonin gene family of peptides (calcitonin, katacalcin, and calcitonin gene-related peptide) [5, 6]. Normal prostatic NE cells lack the proliferation-associated Ki-67 antigen, are considered differentiated postmitotic cells, and do not express p63 or PSA. They lack androgen receptor (AR) expression and are thus androgen insensitive.

## Neuroendocrine Differentiation of Prostate Cancer

Focal neuroendocrine differentiation can be seen in 5–10 % of localized prostate cancers, and this proportion rises with disease progression [7]. The amount of neuroendocrine differentiation in prostate tumors correlates with the rate of

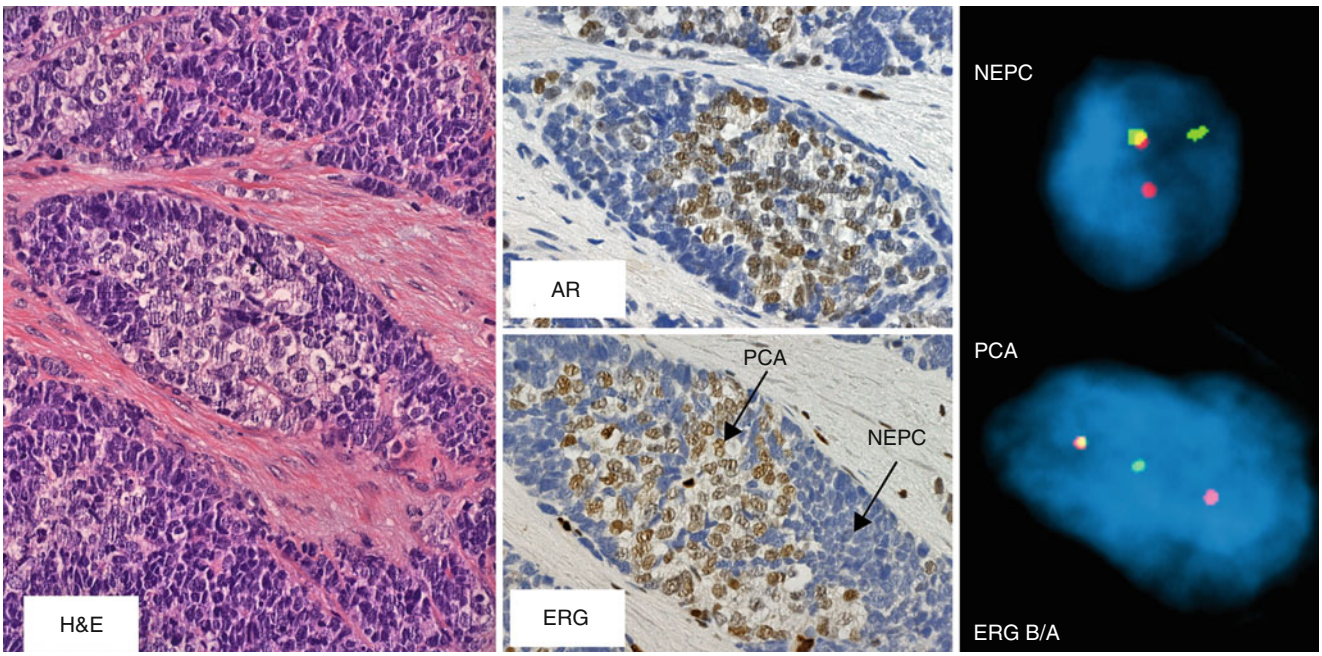

**Fig. 22.1** Hematoxylin and eosin (*H&E*) staining showing a tumor focus with mixed features of NEPC and PCA. Immunohistochemical analysis for androgen receptor (*AR*) and ERG, and FISH for ERG break-apart (indicating gene fusion) reveals that ERG gene fusion is present in both NEPC and PCA, but AR and ERG protein expression is positive in PCA and completely negative in NEPC

tumor progression, adverse outcome, and with surrogate markers of adverse outcome (such as tumor grade and stage) [8, 9]. NE cells may also contribute to a significant percentage of prostate cancers developing resistance to hormonal therapy. Elevated serum chromogranin A levels are associated with worse survival in men with metastatic PCa, adding prognostic information to clinical stage and Gleason grade [10]. Chromogranin A and PSA serum levels show a weak but positive correlation in many patients, supporting the presence and growth of both chromogranin A and PSA-expressing cells simultaneously. Neuroendocrine differentiation is becoming increasingly recognized as an independent prognostic factor, especially for patients with castrate-resistant prostate cancer (CRPC), though sequential measurement and calculation of chromogranin A kinetics in men with prostate cancer does not add prognostic value [11].

Prostate adenocarcinomas may eventually completely escape androgen blockade and become truly hormone refractory, associated with the development of a predominantly neuroendocrine phenotype. How this occurs is poorly understood. There is evidence that when prostate adenocarcinoma cells are exposed to various cytokines (IL6, IL8, heparin-binding EGF) or an androgen-depleted environment in cell culture, they are able to differentiate into neuroendocrine cells transiently and then revert back to their original phenotype when the inducer is removed [12]. Prostate adenocarcinoma cell lines (LNCaP) have also been shown to become "neuroendocrine-like" when stably transfected with the gene that encodes the transcription factor (and oncogene) N-myc (MYCN), with upregulation of neuroendocrine markers and downregulation of androgen receptor and androgen-regulated genes occurring via direct binding of N-myc to promoters of synaptophysin (SYP), NSE, and AR [28]. This suggests a transdifferentiation model of progression, with direct evolution of NEPC from adenocarcinoma cells. As opposed to normal prostate neuroendocrine cells, neuroendocrine cells in cancer express cytokeratin 18, bcl-2, and alpha-methylacyl-CoA racemase (AMACR) [13].

As further support of a transdifferentiation model of NEPC and clonal origin from prostate adenocarcinoma, the frequency of the prostate cancer-specific ERG gene rearrangement is similar to that of prostate adenocarcinoma [14]. Histologic evaluation of mixed tumors reveals that NEPC and prostate adenocarcinoma can coexist and intermingle within the same tumor focus, and tumors that are ERG fusion positive demonstrate rearrangement in both the NEPC and adenocarcinoma foci (Fig. 22.1). Since the upstream genes commonly involved in ERG gene rearrangements are androgen regulated (e.g., TMPRSS2), the downstream ERG protein expression is limited only to the adenocarcinoma component of mixed tumors. Thus, ERG fusion positive NEPC is AR negative and ERG protein negative.

It has also been suggested that the neuropeptides released by neuroendocrine cells in the prostate may facilitate the development of androgen independence, acting as autocrine and paracrine growth factors for malignant cells. In prostate cancer cells, neuropeptides have been shown to promote cell growth, migration, and protease expression [15]. For instance, the neuropeptides bombesin and gastrin-releasing peptide (GRP) transmit their signals through G protein-coupled receptors,

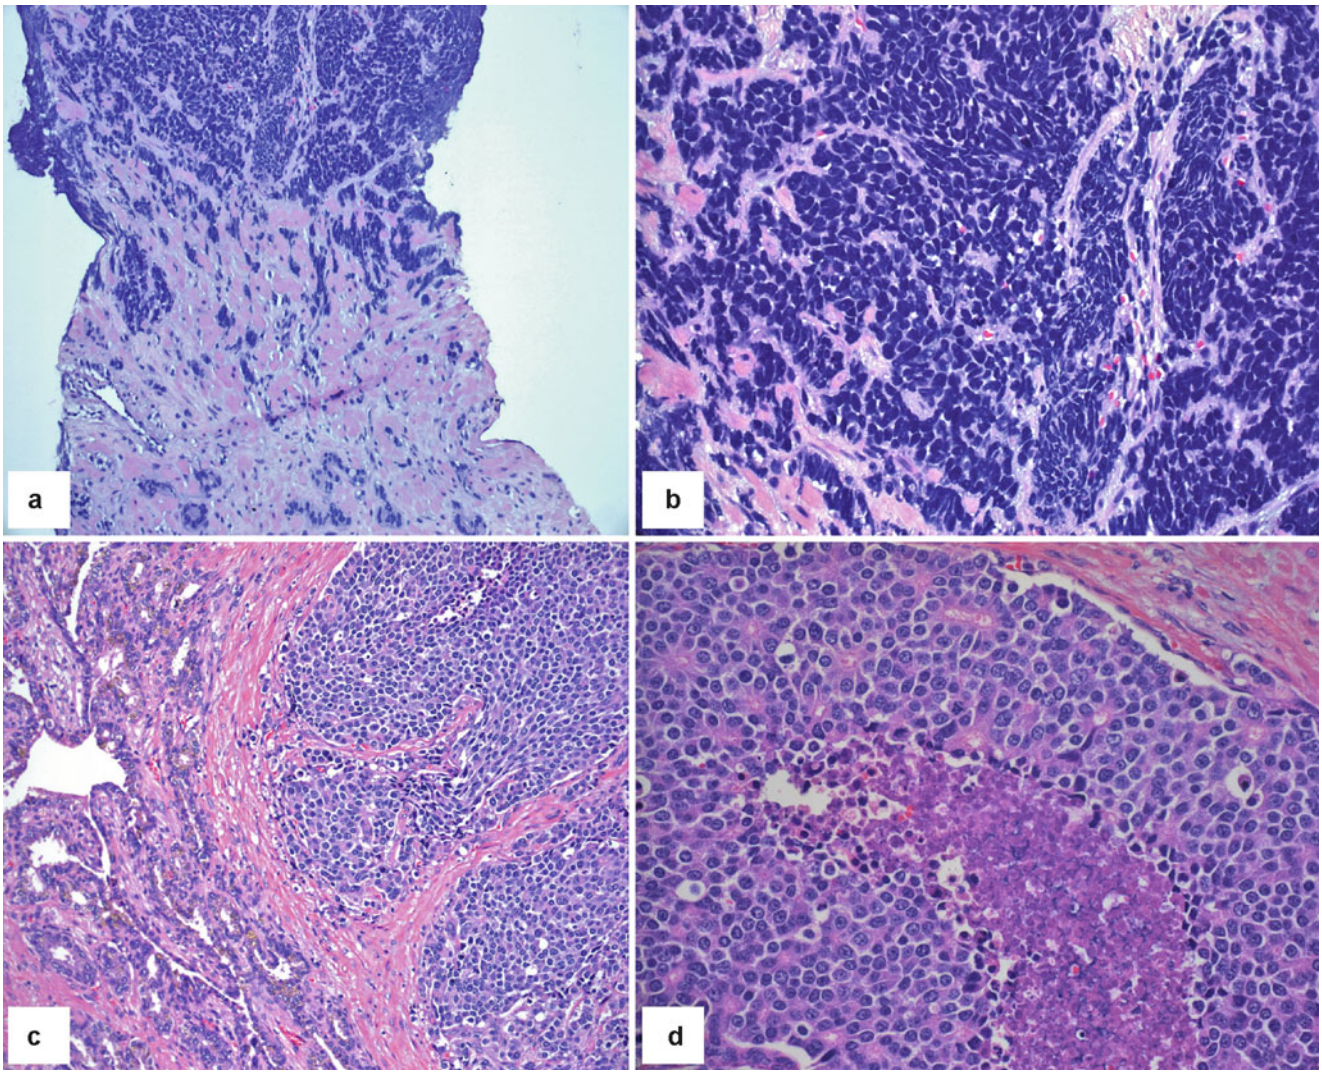

**Fig. 22.2** (**a**, **b**) Small cell carcinoma of prostate. Core biopsy (**a**) with poorly differentiated neuroendocrine carcinoma (*upper half*). Note the "crush" artifact at the edge of the tissue. Conventional acinar prostatic adenocarcinoma is also present (*bottom*). At higher magnification (**b**), tumor cells have hyperchromatic nuclei and nuclear molding, characteristic features of small cell carcinoma (Original magnification 20× and 40×). (**c**, **d**) Large cell neuroendocrine carcinoma of prostate. Section of prostatectomy specimen (**c**) with a neuroendocrine carcinoma (*right*) invading into the seminal vesicle (*left*). At higher magnification (**d**), the tumor is composed of larger cells with abundant eosinophilic cytoplasm, rosette-like structures, and necrosis (*center*) (Original magnification 20× and 40×)

which are often overexpressed in prostate cancer, and can aberrantly activate AR in the absence of androgen [16].

Thus, neuroendocrine differentiation and hormone-refractory disease seem to be an associated phenomenon: extensive neuroendocrine differentiation of a tumor renders prostate cancer androgen-independent, and androgen blockade induces neuroendocrine differentiation.

## Histology

Pure neuroendocrine prostate cancers resemble small cell carcinomas, large cell neuroendocrine carcinomas, or carcinoid tumors of other primary sites. Small cell carcinoma is composed of sheets and nests of uniform cells with scant cytoplasm, rounded hyperchromatic nuclei, coarse chromatin, and unapparent nucleoli (Fig. 22.2a,b). Mitotic figures are numerous, at a rate of 5–10 per high power field. Cells tend to be arranged without structure or cell-to-cell orientation. Microscopic or larger foci of tumor necrosis are evident, and there tends to be wide and diffuse infiltration with poorly circumscribed margins at the advancing edge. Lymphatic and blood vessel invasion is common. Electron microscopy of NE cells reveals small neurosecretory dense-core granules. Large cell neuroendocrine carcinoma is an unusual variant arising in the prostate. It consists of solid sheets and ribbons of cells with abundant cytoplasm, large nuclei with coarse chromatin,

brisk mitotic activity, rosette-like structures, and foci of necrosis (Fig. 22.2c,d). Both small cell and large cell neuroendocrine carcinomas are high-grade aggressive tumors and behave in a similar fashion clinically. On the other side of the spectrum, low-grade neuroendocrine carcinoma (carcinoid) can rarely arise in the prostate. This is a well-differentiated tumor composed of uniform cells arranged in an organoid pattern of nests, ribbons, or acini (not shown).

In secondary NEPC, adenocarcinoma tumor cells are adjacent or intermingling with NEPC cells (Fig. 22.1). The adenocarcinoma tends to be moderately to poorly differentiated, displaying microacinar or cribriform morphology. The amount of NEPC in the tumor focus can vary considerably and increases with clinical disease progression and in response to androgen deprivation therapy. Distinguishing NEPC from high-grade adenocarcinoma, especially Gleason pattern 5, may sometimes be challenging. The presence of rosettes, nuclear molding, "crush" artifact, and fine chromatin supports NEPC.

The diagnosis of NEPC is primarily based on morphology, though immunohistochemistry can support or confirm the diagnosis. Typically one or more of neuroendocrine markers, chromogranin A, synaptophysin, neuron-specific enolase, and CD56, are positive by immunohistochemistry. In a minority of cases (10 %), neuroendocrine markers are all negative, but the morphology still supports the diagnosis. Again, immunohistochemistry is negative for AR, PSA, and prostatic acid phosphatase (PAP), distinguishing NEPC from conventional prostate adenocarcinoma. The presence of the prostate-specific ERG gene fusion by FISH break-apart occurs in approximately 50% of NEPC, which rules out small cell carcinoma from other primary sites [17, 18].

## Neuroendocrine Differentiation of Clinically Localized Prostate Cancer

A number of studies have implicated the presence of neuroendocrine differentiation in localized prostate cancer as a prognostic biomarker. Evaluation of 104 prostatectomy specimens of patients with clinically localized prostate adenocarcinoma revealed that either histological grade or the presence of neuroendocrine differentiation predicted the development of biochemical recurrence [8]. Furthermore, the presence of neuroendocrine differentiation also distinguished tumors of Gleason sum ≥6 into groups with high and low risks for progression, independent of Gleason sum. Theodorescu D et al. also evaluated 71 prostatectomy cases and found the level of chromogranin A immunoreactivity to strongly predict disease-specific survival and was superior to standard pathologic prognostic factors (such as Gleason score, capsular penetration, seminal vesicle invasion, and percentage of tumor in the specimen) [19]. A multivariate analysis of neuroendocrine differentiation and cell proliferation (Ki-67 labeling index) on radical prostatectomy specimens found neuroendocrine differentiation to be the second most significant predictor of biochemical progression, after Gleason score [20].

## Clinical Presentation

Pure NEPCs, most commonly small cell prostate cancers, that arise de novo (primary NEPC) are rare (<1 %), tend to occur in younger patients and most patients present with overt metastases. There are no established risk factors. Patients that do present with localized disease usually have few symptoms. Distant spread is often to visceral organs (such as liver and brain) or lytic bone lesions, unlike prostate adenocarcinoma that tends to metastasize to bone and produce blastic lesions. Presenting symptoms may include constitutional symptoms, hydronephrosis, bone pain, abdominal pain, hematochezia, or hematuria. Paraneoplastic syndromes occasionally are present, due to ectopic production of hormones (such as adrenocorticotropic hormone, antidiuretic hormone, etc.) [21].

Distinguishing pure NEPC from small cell carcinomas of other primary sites can be challenging, especially if a patient presents with widely metastatic disease. Histologically, they appear similar and may have a similar immunohistochemical profile (negative for androgen-regulated genes and positive staining for neuroendocrine markers). Assessment of the presence of ERG gene rearrangement by FISH can be performed to help distinguish prostate adenocarcinoma from other sites, as it is positive in approximately 50 % of NEPC and is universally negative in small cell carcinomas of lung and bladder [17, 18].

Much more commonly, NEPC arises after therapy of prostate adenocarcinoma (secondary NEPC, also called treatment related NEPC or t-NEPC). It is believed that hormonal therapy accelerates the development of NEPC, as evidenced by increased chromogranin A expression in prostate or serum, while patients are on continuous androgen deprivation therapy [22], as well as preclinical studies showing transdifferentiation of prostate adenocarcinoma cells to NEPC in response to androgen depletion. Clinically, t-NEPC may be suspected in a patient with advanced prostate cancer showing evidence of progression (especially visceral metastases) without an appropriate rise in serum PSA. Serum markers of neuroendocrine differentiation, such as chromogranin A and NSE, are frequently elevated in advanced prostate cancer [23] but if extremely high may support the diagnosis of NEPC.

Similar to small cell lung cancer, pure NEPC is a chemosensitive and radiosensitive tumor. However, despite high initial response rates, all patients progress,

and average survival is less than 1 year [24, 25]. There appears to be no significant difference in survival between primary de novo NEPC and those that arise after treatment of prostate adenocarcinoma.

## Treatment

Since hormonal therapy promotes neuroendocrine differentiation, intermittent androgen deprivation therapies for hormone responsive prostate cancer theoretically may prevent or delay the development of NEPC though this has not yet been proven.

Localized NEPC that remains only in the prostate is rare at diagnosis, and data are limited on how to manage these patients. Positron emission tomography (PET) may be useful in confirming localized stage disease. If identified early, chemotherapy with concurrent or consolidative radiotherapy similar to limited stage small cell lung carcinoma may be considered. Surgical resection may also be considered, but data in this setting is scarce.

Patients with metastatic disease with mixed features of NEPC and PCA that have not yet had hormonal therapy are often started on androgen deprivation initially but usually progress rapidly since NEPC is hormone refractory and only the adenocarcinoma component would be expected to respond.

Patients with NEPC and castration resistance are treated with chemotherapy and often with platinum-based regimens similar to small cell lung cancer. Radiotherapy is sometimes added for local control or palliation of symptoms. Cisplatin and etoposide is commonly used, and other agents such as ifosfamide and doxorubicin have shown activity. Few prospective clinical trials have been conducted for patients with NEPC. In one phase II trial of 38 patients, the addition of doxorubicin to cisplatin and etoposide produced a 61 % response rate with 22 partial responses but was associated with greater toxicity than cisplatin and etoposide [25]. Median time to progression was 5.8 months, and overall survival was 10.8 months. Carboplatin and etoposide has also been evaluated, with similar survival rates [24]. An ongoing phase II trial is prospectively evaluating the combination of carboplatin and docetaxel for patients with known or suspected NEPC (clinicaltrials.gov/ct2/show/NCT00514540).

Pharmaceutical agents aimed at blocking neuroendocrine cancer cells, such as serotonin and bombesin antagonists, are under investigation. In addition, a Phase II trial evaluating the aurora kinase A inhibitor MLN8237 is planned.

Although elevation of serum chromogranin A and NSE levels is prognostic and can support the diagnosis of NEPC, following levels on therapy has not been shown to correlate with response to therapy [26]. Circulating tumor cells have not been evaluated in this specific population but are also under investigation.

## Molecular Alterations

Recent advances in understanding tumor biology, development of new diagnostic, prognostic, and predictive biomarkers, and identification of new therapeutic targets have come through sequencing efforts for a variety of tumor types. Similarly in prostate cancer, transcriptome sequencing and assessment of DNA copy number changes of both PCA and NEPC has brought new insight into NEPC pathogenesis. Despite clonal origin of NEPC from adenocarcinoma cells, there exist dramatic gene expression differences with nearly 1,000 genes showing differential expression [28]. In addition, the genome of NEPC is widely aberrant with frequent amplifications and deletions. There are subpopulations of PCA patients that demonstrate mixed molecular features and may be at high risk for progression to NEPC. For instance, co-amplification of the genes encoding the oncogenes Aurora kinase A (AURKA) and N-myc (MYCN) genes are frequently found in primary tumors of patients that later develop t-NEPC, and are infrequent in other primary prostate adenocarcinomas (Mosquera, Beltran et al, In Revision) and may predict patients at high risk for the development of t-NEPC. Prospective clinical validation of such of novel biomarkers will help identify high-risk populations for early intervention. Also from these types of analyses, targetable pathways implicated in NEPC pathogenesis have been identified and functionally validated. For instance, Aurora kinase A also cooperates with N-myc to directly promote the neuroendocrine phenotype in preclinical models, and Aurora kinase inhibitor therapy has shown dramatic and preferential effect against NEPC cell lines and xenografts. Further studies are underway, including clinical studies investigating Aurora kinase A and N-myc alterations as predictive and prognostic biomarkers, as well as a Phase 2 clinical trial evaluating the role of the aurora kinase A inhibitor MLN8327 for patients with NEPC.

## Summary

NEPC is a highly lethal form of prostate cancer that is believed to often progress from treated adenocarcinoma of the prostate but can also arise de novo. Chemotherapy used for other small cell neuroendocrine cancers is the mainstay of treatment; however, more targeted approaches are being developed based on an emerging understanding of this aggressive form of prostate cancer.

## Incidence

### United States

In the USA and worldwide, prostate cancer is the most commonly diagnosed non-dermatologic cancer in men and remains the second most common cause of cancer death in men in the developed world. In a lifetime, prostate cancer will affect approximately 1 in 5 American men [1].

Over the past several decades, changes in prostate cancer incidence in the USA can be contextualized by background trends in the diffusion of different technologies applied to the management of prostate disease. With the increased popularity of transurethral resection of prostate (TURP) to manage BPH in the 1970s followed by the advent of widespread population-based prostate-specific antigen (PSA) screening in the late 1980s, incidence rates started to increase dramatically after 1986. The incidence rate increased 108 % from then on and peaked in 1991 [2]. Interestingly, the incidence of distant disease decreased starting in 1991, with the most likely explanation being earlier detection and screening with PSA [3].

Recent reports have estimated that prostate cancer accounted for 28 % (217,730) of incident cases in men in the United States in 2010 [4] (Fig. 23.1). The peak incidence for both Caucasian and African American men in the USA was around 1986–1992. It is entirely unclear why the incidence started to decline after 1992; however, a likely explanation is the introduction and widespread use of the prostate-specific antigen (PSA) early detection test in 1989, with a "cull effect," in the context of the diffusion of a technology that increased the rates of diagnostic activity to detect latent disease in the population. This decline continued at a rate of 2.4 % per year from 2000 to 2006 and likely reflects several factors including a widespread use of PSA, an actual decrease in detection, or a reduced number of undiagnosed cases of prostate cancer [4, 5]. Although the benefit of the PSA screening on disease mortality remains the subject of controversy, it stands to reason that the advent and widespread adoption of PSA screening explains a substantial degree of the observed changes in prostate cancer incidence in recent decades. For prostate cancer, variation by state is like that of various countries in which incidence reflects differences in the use of screening tests as well as to differences in disease occurrence. For example, Arizona has the least incidence at 116.6 cases, and Michigan has the greatest at 186.4 cases per 100,000. Recent studies have suggested that the incidence rates be leveling off in the USA.

#### Racial Differences in US Prostate Cancer Incidence

African American men have the highest incidence of prostate cancer, not only in the USA, but also in the world. The relative incidence in these men was 1.6 times that of their Caucasian counterparts in the USA [6]. From 1986 to 1993, the overall incidence in African American men increased from 124 to 250 per 100,000, a 102 % increase [7]. Though incidence in Caucasian men rose over this same interval to a roughly proportional degree, the absolute rates were lower (from 86 to 179 per 100,000) [7]. In 1995, the Caucasian incidence decreased to 110 cases per 100,000, while the African American incidence decreased to 170 cases

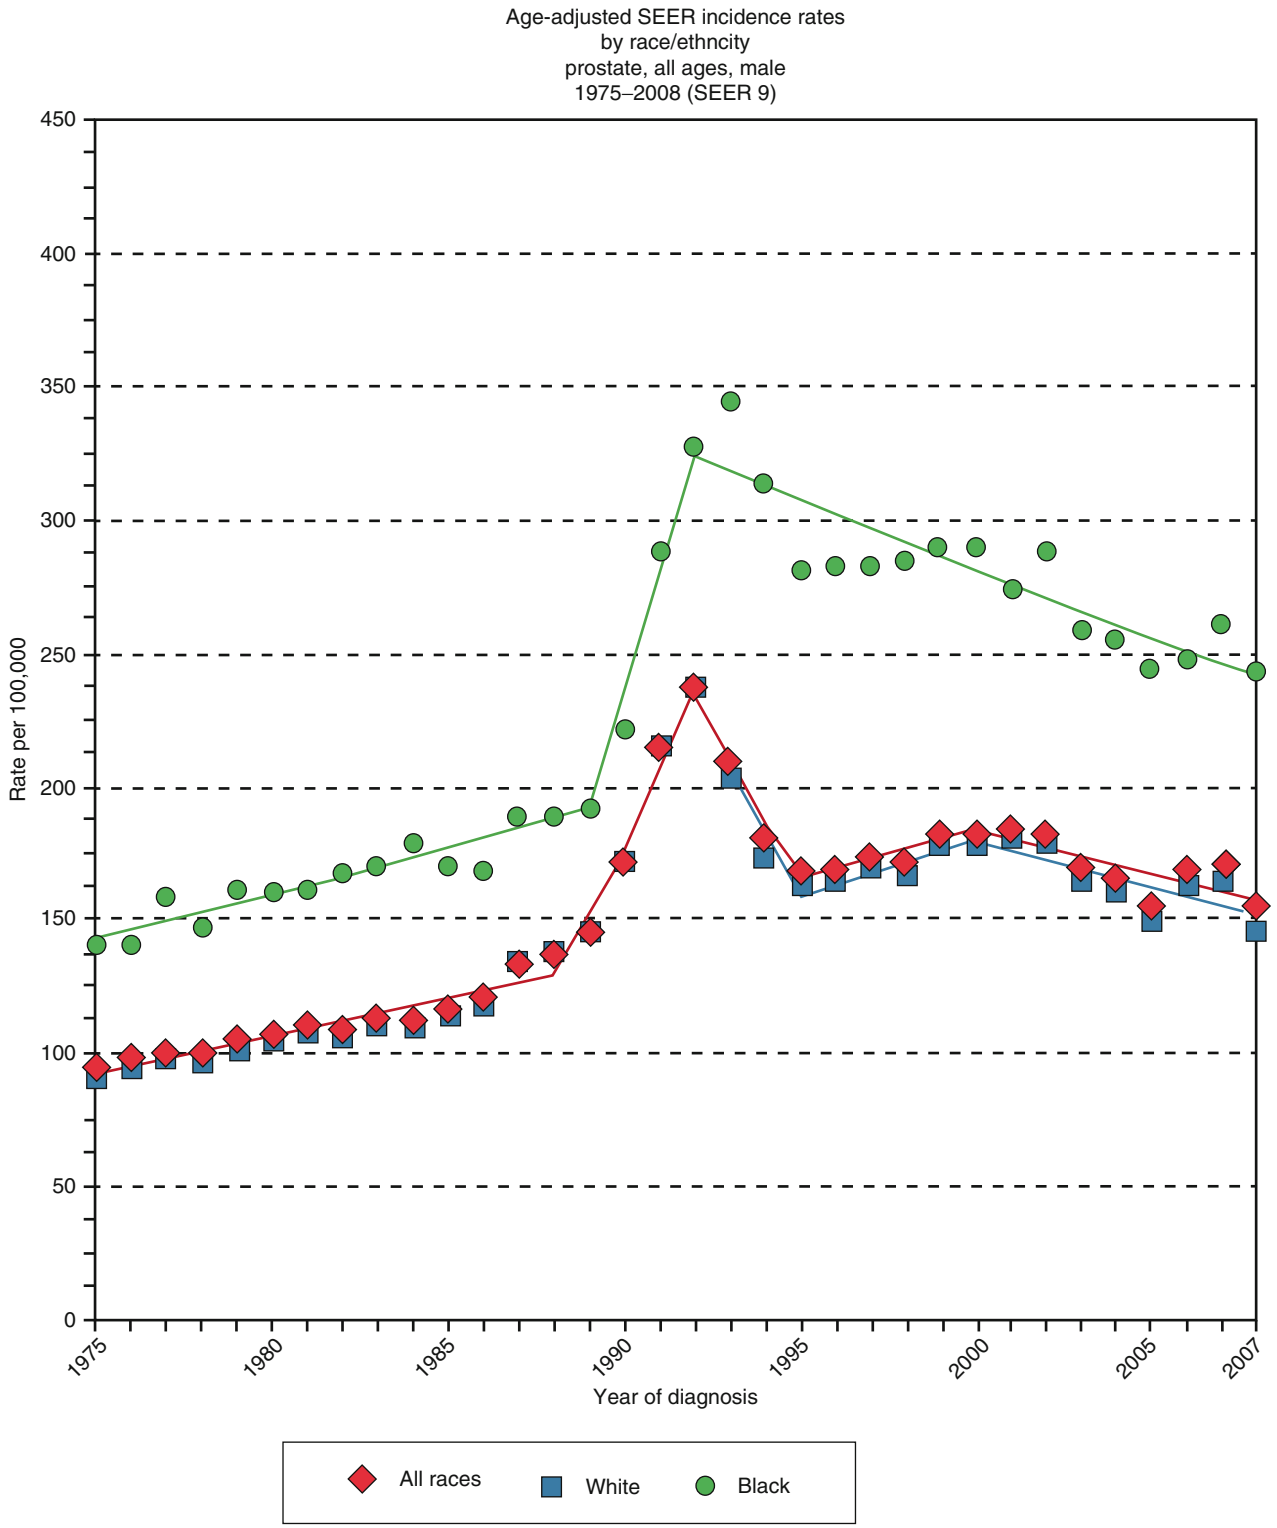
**Table 23.1** The burden of prostate cancer in the United States

| | Caucasian | African American | Total |
|---|---|---|---|
| Incidence | 164.3 | 272.1 | 170.1 |
| Mortality | 30.2 | 73.0 | 32.9 |
| New cases in 2005 | 201,320 | 30,770 | 232,090 |
| Mortality in 2005 | 25,300 | 5,050 | 30,350 |

per 100,000 [8]. The estimated lifetime risk of disease is 17.6 % for Caucasian men and 20.6 % for African American men, with a lifetime risk of death of 2.8 and 4.7 %, respectively [8] (Table 23.1, Fig. 23.2).

## Worldwide

In 2002, there were over 679,000 new reported cases of prostate cancer, making it the fifth most common cancer in the world and the fourth most common cancer in males worldwide [9]. Worldwide prostate cancer incidence rates vary almost 65-fold among countries reflecting, at least in part, variability in the adoption of screening and early detection programs in each country [7]. Interestingly, industrialized nations tend to have higher incidence and mortality rates than in developing nations. Prostate cancer comprised 11.7 % of all new worldwide cancer cases in 2002: 19 % in developed countries and 5.3 % in developing countries. There are several explanations for variations in prostate cancer incidence worldwide and among various ethnic groups, and such reasons would include differential genetic susceptibilities and environmental exposures and access to healthcare, as well as variably reliable ascertainment and reporting of cases in cancer. As incidence is clearly sensitive to the intensity of diagnostic activity, countries with widespread screening and early detection are likely to have a "higher" incidence level, though the true burden of latent cases in unscreened populations is largely unknown. For example, the USA, Scandinavian countries and Western European countries are high-incidence countries, but also have common screening protocols [9] (Fig. 23.3). East Asian countries like China and Japan have some of the lowest incidence rates in the world, around 4 cases per 100,000, and do not have widespread use of PSA test or other screening tools [8]. However, as Japan and China begin to become more Westernized, recent observed increases in incidence may be due to greater awareness of the disease or possibly an actual increase in the risk of occurrence [10]. According to the 2002 Global Cancer Statistics report, the average increase in the estimated age-adjusted incidence of prostate cancer worldwide between 1985 and 2002 was around 1.1 % annually. Though these estimates were largely driven by a surge in the USA after the advent of PSA screening, at this rate, the report predicted almost 900,000 cases worldwide per year by 2010 [9].



Cancer sites include invasive cases only unless otherwise noted.

## Age at Diagnosis

Prostate cancer is primarily a disease of men above the age of 65 with a median age of diagnosis at 67 years old [7]. It is comparatively rare for a man younger than 50 to be diagnosed with prostate cancer, and such cases account for less than 0.1 % of all cases. However, this number is recently increasing with an incidence rate of 1.9 % per year, likely attributable to PSA screening [8]. Based on the SEER report, a study comparing age at diagnosis in the pre-PSA era from 1980 to 1985 with PSA era (defined as 1990–1995) showed a lower mean age at diagnosis in the PSA era (1.7 year younger in Caucasian men and 1.3 year younger in African American men). Furthermore, African American men had a

younger median age at diagnosis than their Caucasian counterparts by 2 years. Incidence peaks in men between the ages of 70 and 74, with over 35 % of all cases between 65 and 74 years old [7] and 85 % of cases diagnosed after the age of 65 [11].

### Stage at Diagnosis

The stage distribution for prostate cancer in the USA from SEER data in 1999–2006 revealed that over 80 % of patients with prostate cancer were diagnosed as having confined, localized disease; 12 %, spread to regional lymph nodes; 4 %, metastasized to other sites; and 3 %, unstaged/unknown [7]. The large percentage of localized and regional stages may be attributable to the early onset of prostate cancer screening with PSA testing.

Since the introduction of the PSA test in 1986, there has been a huge shift in the stage of prostate cancer at diagnosis. The proportion of men diagnosed with stage IV prostate cancer decreased from 28.1 cases per 100,000 in 1988 to 12.3 cases per 100,000 in 2003, a 6.4 % annual decrease [12]. The decrease in late-stage distant metastatic prostate cancer at diagnosis was even greater and fell from 18.4 in 1988 to 6.7 cases per 100,000 in 2003, a drop of over 8.0 % annually [12]. The decrease continued around 12.5 % annually through 1995 [13]. The incidence of local and regional disease has increased, while there has been a decrease in late stage or metastatic stage of prostate cancer [7, 14]. On the basis of prostate cancer cases diagnosed between 1996 and 2004, an estimated 91 % of these new cases are expected to be diagnosed at local or regional stages. From 1988 to 1992, there was an increase of 18.7 % of locoregional disease and then almost a 10 % decrease through 1995 [13]. Interestingly, these trends are paralleled with an increase in the number of radical prostatectomies for local- and regional-staged patients [7, 13].

These trends in the stage of prostate cancer diagnosis can imply several important points, including the fact that a substantial stage migration has occurred, toward earlier diagnosis and away from late-stage diagnosis; that there is a shift in age of diagnosis; and that there is an increase percentage of men treated for clinically localized disease with a radical prostatectomy. It stands to reason that a major explanation for these observed trends is the widespread availability of PSA screening since the early 1990s.

### Lifetime Risk

Based on data from 2005 to 2007, almost 1 in 6 men (16.2 %) will be diagnosed with prostate cancer in his lifetime. As would be anticipated from the above-referenced figures, the lifetime risk for an individual varies significantly by race, with African American men having the highest lifetime risk. It should also be understood that this lifetime risk also varies by age group and that the older a man is, the higher risk he has of being diagnosed with prostate cancer. Recent data showed that 1 in 8 men above the age of 70 will develop cancer whereas 1 in 16 men between the age of 60 and 69 will develop prostate cancer [4]. Using lifetime risk, or the probability of developing cancer in a lifespan, enables a better understanding of risk disease from a public health standpoint and can influence screening programs within certain races or age groups.

### Migration Studies

Epidemiological studies of migrant populations have shown that men who move from low-incidence countries to high-incidence countries experience a shift in risk toward the rates observed in men in the high-incidence country. For example, individuals from Asian countries like Japan and China who immigrate to the USA have a higher risk for prostate cancer than men living in Japan and China [15]. The role of environmental factors, in particular dietary norms discussed in more detail below, of high-incidence countries is further supported by studies showing increasing incidence in Japan as the country has become more Westernized over the last decade [16]. Nevertheless, it is important to point out that the Japanese and Chinese men who immigrated to the USA still have lower incidence rates than Caucasian and African American men, underscoring the complex interactions of genetic and environmental factors in prostate cancer predisposition.

## Mortality

As important it is to assess prostate cancer incidence, it is equally, if not more important, to measure disease mortality. Mortality is expressed in terms of the number of deaths from prostate cancer per year over the number of men at risk in the same year. Calculating mortality for prostate cancer allows a clear gauge of the severity of disease from both a clinical and public health standpoint. While mortality is sometimes used as a quick index of the risk of disease in a given year, the long natural history of prostate cancer requires a longer time horizon to ascertain the ultimate effects of shorter-term changes in epidemiological trends [17].

### US Mortality

Since 1976, SEER has tracked trends of US prostate cancer mortality, and Table 23.2 shows that there was a statistically significant increase in the mortality rate at 3.0 % annually

**Table 23.2** US prostate cancer mortality trend for all races between 1975 and 2007

| Male | |
|---|---|
| Trend | Period |
| 0.9 | 1975–1987 |
| 3.0 | 1987–1991 |
| –0.5 | 1991–1994 |
| –4.1 | 1994–2005 |
| –2.6 | 2005–2007 |

from 1987 to 1991. The likely increase in mortality during these years can be attributed to several factors including an actual increase in the number of lethal prostate cancer cases, a decrease in the effectiveness of therapy, or a change in the management of patients that was not effective [18]. From 1991 the observed mortality rate started to decrease: first at a slow rate of 0.5 % per year through 1994 and then at a more rapid decline of 4.1 % annually per year from 1994 to 2005. The US prostate cancer mortality rate has since steadily decreased at 2.6 % from 2005 to 2007 [7]. Since mortality decreased after 1991, the decrease in effectiveness of therapy is an unlikely cause of the original increase in mortality [18]. In 2005, the US mortality was 32.9 cases per 100,000 for men of all races, and there were a reported 32,050 deaths from prostate cancer that same year [4, 11]. From 2003 to 2007, the median age of death from prostate cancer in the USA was 80 years old, with over 30 % of these deaths in men over the age of 85 [7]. The age-adjusted death rate from prostate cancer during the same period was 24.7 cases per 100,000 and varies significantly by race (discussed below).

Since 1995 for Caucasian men and 1997 for African American men, prostate cancer mortality rates have dropped below the 1986 levels, the first year the PSA test was introduced. Epidemiological evidence suggests that recent declines in mortality are strongly associated with the stage migration and, specifically, decreasing rates of stage IV disease in this time period [19]. These results are consistent with the suggestion that decreasing prostate cancer mortality is a result of earlier detection, with concomitant improved prognosis as a consequence of widespread PSA screening in the USA [19–21].

Hankey et al. further suggested that at least a portion of the observed decline in prostate cancer mortality in the USA may also a reflect misclassification in death certificates. They concluded that if men with another fatal disease in addition to prostate cancer were assigned as prostate cancer deaths, then the mortality rates would tend to rise and fall with the incidence rates [13]. Hence, it is difficult to attribute declining mortality rates solely to PSA testing or death certificates, but one should understand that it is a combination of factors that influence the declining rates.

In addition to the PSA test, advancements in prostate cancer treatment modalities for men with local and regional disease may also have contributed to the lower mortality rates in the USA in the recent past. This is validated in the SEER data since incidence-based mortality rates do not decline until 1997 [7]. Further, the SEER data classifies local tumors as regional disease, so improved treatments for patients with locally advance prostate cancer do not account for the decrease in mortality for men with distant disease [23]. However, since localized prostate cancer, the predominant stage detected by the PSA test, has a long natural history, the true mortality rates associated with widespread treatment of localized disease will not be appreciated for another decade [18]. Compared to patients diagnosed during the pre-PSA era, whose mortality levels are reflected in statistics from the 1990s, the long-term outcomes of patients diagnosed in the PSA era continue to accumulate. Additional follow-up is required to ascertain the longer term impact of widespread treatment of screen-detected disease with curative intent [18].

## Worldwide Mortality

As with the incidence trends, there is significant worldwide variation in prostate cancer-specific mortality trends. For instance, worldwide mortality has shown increases, especially in developed nations where there are already high-risk incidence levels. However, since the use of PSA testing, mortality has slightly decreased in developed nations, though not at rates comparable to the USA, which may be a result of screening and earlier detection testing [24]. Interestingly, however, prostate cancer mortality in the UK has declined, although there is neither a formal prostate cancer screening program in the country nor are there large increases in incidence [25]. On the opposite end of the spectrum, despite the existence of a formal screening program in Australia, there is no sign of decreasing mortality in the country [26]. Thus, we can infer that there are multiple causes for worldwide variations in prostate cancer, and not only screening programs but also the access and quality of healthcare affect mortality rates.

## Risk Factors

While the etiology and pathogenesis of prostate cancer are clearly complex and multifactorial, the variable risk in individuals and populations has revealed a number of important risk factors. In general, the risk of prostate cancer is increased by African American ethnicity, increasing age, strong family history, and behavioral risk factors such as diet and, to a lesser extent, smoking and alcohol consumption. Variations among high- and low-incidence countries are also attributed to genetic predisposition among different ethnic populations as well as with differences in diet and variety in the availability of healthcare, in addition to variable quality of available

**Table 23.3** Percent of US men who develop prostate cancer over 10-, 20-, and 30-year intervals according to their current age, 2005–2007 (SEER)

| Current age | 10 years | 20 years | 30 years |
|---|---|---|---|
| 30 | 0.01 | 0.32 | 2.49 |
| 40 | 0.31 | 2.52 | 8.30 |
| 50 | 2.30 | 8.30 | 14.40 |
| 60 | 6.62 | 13.36 | 16.11 |
| 70 | 8.50 | 11.97 | N/A |

cancer surveillance data. In this section, we review a selection of these risk factors in the context of relevant literature.

## Age

Typical of epithelial malignancies, it is well established that the risk of prostate cancer increases with age (Table 23.3). A diagnosis under the age of 40 years old is rare, and there is a probability of only 0.01 of men in this age group who are diagnosed with prostate cancer [4]. The probability slightly increases to 2.44 (1 in 41) between men 40 and 59 years old [4]. This is a significant difference when compared to men over 65 years old in which prostate cancer accounts for 70 % of cases in the USA [30]. The probability of prostate cancer increases to 12.48 (1 in 8) for men over 70 years old [4]. The table produced by SEER (below) shows the percent risk of developing prostate cancer for each age group over a time interval (table). Interestingly, prostate cancer is known to have a high prevalence as a subclinical disease as the risk of having histological evidence of prostate cancer in men >50 years old is 42 %, whereas the clinical manifestations of men in the same age group is only 9.5 % with a 2.9 % risk of mortality [31]. To further substantiate a subclinical prevalence, autopsy studies have shown that 10 % of men at the age of 20 have histological evidence of cancer in the prostate [32]. This number increases to nearly 80 % by 80 years old. These data underscore both the long natural history of disease and the substantial reservoir of disease in the population which may be detected with widespread screening programs.

## Familial/Hereditary Predisposition

The incidence of prostate cancer in men with a strong family history is two to four times higher when compared to control populations [33]. Specifically, men with a first-degree relative who has prostate cancer have a two- to threefold risk compared to individuals without affected family members. Furthermore, the risk increases with the number of affected men in the individual's family as well as with younger age at which a relative was diagnosed [34]. Furthermore, men are more likely to get prostate cancer if they have a brother with the disease than if their father has the disease, which suggests a recessive characteristic or X-linked association to prostate cancer [35]. Twin studies show a high concordance rate between monozygotic twins, bolstering the evidence for a familial predisposition to prostate cancer [36].

While it might be argued that the observation of an association of elevated prostate cancer risk among family members may be attributable to similar environmental exposures, there are strong data from multiple genetic studies implying a similar environment, alone, does not explain the prostate cancer risk observed among men with a family history. Linkage studies have identified chromosome loci that involve prostate cancer genes with high penetrance [37]. It is estimated that between 5 and 10 % of all prostate cancer cases have at least one relative who is also affected [38], with estimates of genetic factors in up to 40 % of those cases diagnosed before the age of 55 years old [39]. Additional indirect evidence supporting the significance of hereditary prostate cancer is the observation of diagnosis at an average of 7 years earlier than the sporadic form of prostate cancer, diagnosed in men without a family history [39]. Whereas only 5–9 % of prostate cancer cases meet the criteria for hereditary prostate cancer (three successive generations or at least three members of a nuclear family), approximately 20 % of all cases represent familial forms of the disease [39]. The prevalence of these familial and hereditary forms of this common malignancy supports the current guidelines' recommendations for earlier screening in individuals with a family history.

## HPC-1

Among candidate genes identified in linkage studies, the HPC1 locus on the long arm of chromosome 1 appears to be implicated in at least some kindreds with familial prostate cancer [40]. In families with prostate cancer linked to HPC1, the main features were that the disease was diagnosed at a younger age (usually <65 years old), more than one member was affected, and spanned two generations. In a separate study, higher grade tumors and greater rates of advanced stage disease in HPC1 families were two more distinguishing characteristics of hereditary cases [41].

## BRCA1 and BRCA2

BRCA1 and BRCA2 are also felt to be prostate cancer susceptibility genes. The risk in men with a BRCA2 mutation is approximately five- to sevenfold higher when compared to men with the general population [42]. The link between the BRCA1 mutation and prostate cancer is not well established, yet researchers have shown that there is approximately double the risk for prostate cancer for men <65 years

old compared to the general population [43]. The IMPACT (Identification of Men with a genetic predisposition to Prostate Cancer: Targeted screening in BRCA1/2 mutation carriers and controls) is a multicenter study that targets the utility of PSA testing for prostate cancer in men who are known to have a genetic predisposition to prostate cancer. Analysis from this study showed that men with BRCA1 and BRCA2 mutations have a relative that has a risk of prostate cancer of 1.82 and 4.65, respectively [44]. Not only does BRCA2 mutation have a higher relative risk, but also it is reported to lead to a more aggressive disease with a higher mortality rate than men in the general population [45, 46].

## Race

Race is a complex construct, including genetically discrete populations of individuals, as well as cultural and environmental characteristics of racial groups. Incidence and mortality rates, as previously discussed, vary significantly with race [27, 28]. Noteworthy, however, though incidence and mortality for African American men are consistently highest, there is no consistently reported difference in the grade distribution of prostate cancer among the races [47]. Migration studies, discussed below, suggest that behavioral and environmental moderate baseline population-based risk levels and that observed differences between ethnic populations are in fact multifactorial and, to a certain degree, potentially modifiable [29].

## Inflammation/Infection

The consequences of inflammation, infection, and oxidative stress in a spectrum of disease processes, and a number of investigators have elucidated potential mechanisms by which inflammation and infection may play a role in the pathogenesis and biology of prostate cancer. Chronic inflammation causes cellular hyperproliferation to replace and repair damaged tissues, and several well-established associations exist between infectious disease and cancer in other organ sites [48]. A number of candidate inflammatory and infectious mechanisms have been associated with prostate cancer risk and are briefly presented in the following section. A more detailed discussion of this topic area is addressed elsewhere in the textbook.

## Glutathione S-Transferase

Glutathione S-transferase (GST) is an enzyme involved in biosynthesis and metabolism of potential carcinogens and reactive metabolites associated with cigarette, diesel fuel, and grilled meat exposure [49]. Isoforms of GST, M1, T1, and P1, are expressed in the prostate, and genetic polymorphisms that activate these GST isoforms have been associated with activation of carcinogenic metabolites in the prostate, thus increasing the risk of prostate cancer [50, 51]. Results from a GST polymorphism study revealed that isoform T1 increased the risk of biochemical recurrence of prostate cancer in African Americans but not in Caucasians with both high-grade and high-stage tumors, whereas the inverse association was observed with the M1 isoform [52].

## Cyclooxygenase

Cyclooxygenase (COX) is a prostaglandin with two isoforms, constitutively active COX-1 expressed in several cell and tissues types and inducible COX-2 that is induced by cytokines and growth factors, some of which have been implicated as tumor promoters [53]. COX-2 is an enzyme involved in the conversion of arachidonic acid to prostaglandins and has been associated with several cancers and cancer cell lines, including prostate cancer [54].

## Anthropometric Risk Factors

### Obesity

Though obesity has clear associations with increased risk in the settings of breast and colon cancer, the association with prostate cancer is somewhat more complex. Some investigators have suggested an inverse relationship between obesity and prostate cancer risk, whereas others have suggested that morbid obesity is associated with higher grade tumors and biochemical recurrence rates after surgery [55–57]. A body of literature supporting the biological plausibility of obesity and the associated metabolic syndrome as a risk factor for prostate cancer is briefly reviewed here and discussed in greater detail elsewhere in the textbook.

On the one hand, obese men have in general a hormonal profile that might be presumed to be protective against prostate cancer, by having lower levels of testosterone and higher levels of estrogen due to peripheral conversion in fat cells [58]. At the same time, obesity can theoretically promote prostate cancer by leading to the metabolic syndrome, resulting in increased levels of both leptin and insulin-like growth factor one (IGF-1) [59].

### Height

The results of an anthropometric study on height, weight, and hip circumference showed only a slight direct association between height and prostate cancer risk, after adjusting for BMI [60]. However, these results were not statistically significant. There was a stronger correlation for men who were taller than >74 in., with almost a 6–70 % higher risk of advanced disease in these men compared to men shorter than

<68 in. [60]. Another study found no association between height and prostate cancer [55].

## Leptin

Leptin is an adipocyte-derived hormone that regulates satiety and energy expenditure while contributing to the control of body weight, representing a potential mechanism through which prostate cancer is associated with obesity. Leptin deficiency is associated with morbid obesity since there is no sense of satiety or communication with the brain when there is enough energy, or food intake [61]. Leptin receptors are highly expressed on the prostate [62], and increased levels of leptin are associated with angiogenesis and proliferation of prostate cancer cell lines in vitro [63]. Leptin is also known to have a hand in secondary organ growth during puberty, and thus it could play a role in prostate cancer development directly through cellular effects [64].

## Insulin-Like Growth Factor 1 (IGF-1)

IGF-1 is a peptide hormone produced in response to growth acting in both an autocrine and paracrine manner to promote normal cell growth and malignant cellular proliferation, differentiation, and apoptosis [65]. IGF-1 has been demonstrated to promote cell proliferation by acting locally through receptors on the prostate, suggesting a potential role in prostate cancer biology [66]. The major circulating binding protein for IGF-1 is insulin-like growth factor-binding protein-3 (IGFBP-3), which regulates the availability of plasma IGF-1 while also exerting its own pro-apoptotic properties on prostatic cells [67]. Interestingly, while IGF-1 increases proliferation of prostate cancer cell lines, IGFBP-3 decreases the growth-stimulating effects of IGF-1 and thus decreases prostate cancer development.

One study reported a 1.7–4.3-fold higher risk of prostate cancer in men with higher levels of IGF-1 [68]. Measuring IGF-1 could be one explanation for the higher incidence of prostate cancer in the USA, since a Westernized sedentary lifestyle and larger consumption of fats result in increased production of insulin and, in turn, IGF-1.

## Behavioral Risk Factors

### Smoking

There is no question that environment is an influential factor in prostate cancer rates worldwide; however, there are limited studies beyond diet that determine the link between these factors and prostate cancer. Cigarette smoking is suggested to be a risk factor for prostate cancer since it is a source of carcinogens which are associated with increasing levels of androgens and decreased estrogen in the body, causing oxidative stress and leading to prostate cancer progression [69]. Specifically, men who reported smoking more than 1 pack per day had a relative risk of 1.5 higher than men who did not smoke or smoked less than 1 pack per day [70].

### Diet

Ecological studies have suggested, and migration studies have affirmed, that prostate cancer is highly associated with a Westernized lifestyle including a diet consisting of high intake of fat, meat, and dairy. Particular components of the typical Western diet have been consistently associated with prostate cancer including α-linolenic acid (polyunsaturated fats found in vegetables and dairy products) and calcium [71]. One mechanism whereby high dietary fat may affect prostate cancer risk is α-methyl-CoA remarcase (AMACR), an enzyme involved in the oxidization of branched chain fatty acids, common in dairy products, and is upregulated in prostate cancer tumors. The oxidation of fatty acids produces reactive oxygen species which may exert carcinogenic effects in the prostate [72].

Diet has provided several explanatory hypotheses for the observed comparatively lower incidence of prostate cancer in Asian countries. Traditional Asian diets have less meat than traditional Western diets and instead have a higher consumption of soybeans and other dietary phytoestrogens [34]. Phytoestrogens have been observed to have an effect on prostate cancer by decreasing tumor size, increasing apoptosis, and decreasing secretion of PSA [73]. Isoflavonoids, a type of phytoestrogen, when metabolized in gut, undergo conversion into hormone-like compounds with weak estrogen. Soybeans and isoflavones work by inhibiting tyrosine kinase enzymes, which promote cellular proliferation and angiogenesis [74].

In the Physicians' Health Study, it was reported that men who had a higher than 600 mg intake of calcium per day were 1.32 times more likely to develop prostate cancer than men who consumed 150 mg or less of calcium per day [75]. Further, this association was found to be the strongest among patients with advanced and metastatic disease. Calcium may influence prostate cancer by downregulation of 1,25-dihydroxyvitamin $D_3$, a form of vitamin D that is protective against prostate cancer [76].

To the extent that oxidative stress is implicated in prostate cancer risk, foods with antioxidant properties may provide a means of mitigating these risks. Foods containing lycopene, including tomato-based foods, and other antioxidants have been associated with a reduced risk of prostate cancer. One study showed a 16 % lower risk of prostate cancer in men who consumed large amounts of lycopene when compared to men who consumed little to no lycopene [77]. Another study showed that increased consumption of tomato juice weeks prior to a radical prostatectomy resulted in a decreased

follow-up PSA, an increased lycopene in the prostate, and a decreased oxidative damage in the prostate [78].

Selenium and vitamin E are two nutrients also being studied in their influence on prostate cancer, and weak evidence shows that both reduce the risk of prostate cancer [79]. Selenium is a nonmetallic element with preclinical data suggesting antitumor properties mediated by antioxidant and pro-apoptotic effects in prostate cancer [80]. In one follow-up study, prostate cancer risk was 66 % lower in a group given selenium than a placebo group who did not receive selenium [81]. The potential of selenium as a primary preventive agent for prostate cancer was suggested by indirect evidence from the Nutritional Prevention of Cancer trial, which randomized patients with a history of skin cancer to oral selenized yeast versus placebo. The report showed a reduction in prostate cancer incidence in the group who had selenium supplementation and that reduction was strongest for men who had a PSA 4.0 ng/mL and lower [82].

Likewise, a Scandinavian study of vitamin E, a fat-soluble vitamin with antioxidant properties, showed a 40 % decrease in incidence and mortality of prostate cancer in men taking vitamin E compared to a placebo group [83]. New data emerging from the SELECT study, specifically designed to address these hypotheses, have cast some doubt on the potential benefit of this approach and will be discussed in greater detail in the chemoprevention section elsewhere in the book [84].

## Alcohol

The interest in alcohol consumption and the influence on prostate cancer is a popular topic because the risk of other cancers like oral, larynx, and pharynx is associated with excessive drinking. In this vein, one study evaluating total alcohol consumption reported a significantly increased risk of prostate cancer among heavy drinkers (>8 drinks/day), in whom the relative risk was 1.9 compared to nondrinkers or men with moderate levels of consumption [85]. These risks were similar among blacks and whites, and no differences were observed by alcohol type (beer or wine vs. liquor). In a slightly different vein, moderate red wine consumption has been the subject of epidemiological studies, given the antioxidant effects of polyphenols which have been associated with growth inhibition in prostate cancer cell lines in vitro [86]. The results of one study suggested that red wine consumption may be associated with a reduced risk in prostate cancer; however, further research is needed to evaluate the type of wine, red or white, to confirm these results [87].

## Vitamin D Link to Worldwide Incidence

Vitamin D deficiency is a worldwide health problem that affects both developed and developing nations alike. It has been estimated that there may be approximately 30–50 % risk reduction for developing prostate cancer by increasing vitamin D intake to more than 1,000 IU/day or increasing sun exposure to increase blood levels of $1,25(OH)_2D_3$. Recent theories have hypothesized that low levels of vitamin D may increase the risk for clinical prostate cancer [88]. The sun is the primary source for vitamin D, and a deficiency can lead to autoimmune, infectious, and cardiovascular diseases as well as cancers like prostate and colon cancer [89]. In the USA, India, Asia, Australia, and New Zealand, vitamin D deficiency is known to be common among young, middle-aged, and adult men [89, 90]. There is significant evidence suggesting the link between sun exposure, vitamin D level maintenance, and prostate cancer [22, 89]. Woo et al. [91] showed that men with stage IV prostate cancer who received 2,000 IU/day of vitamin D had a 50 % reduction in PSA levels after 21 months. Another study examined the geographic distribution of UV radiation and prostate cancer mortality and concluded that there is a significant north-south trend, with lower rates of prostate cancer in the more sun-exposed southern geographical areas [88]. This result has several implications and may be one explanatory hypothesis for the observation of higher incidence rates in more northern latitude countries like Norway and Sweden, whereas countries closer to the equator are low-incidence countries for prostate cancer.

## Vasectomy

Historically, there was some concern regarding a potential link between vasectomy and elevated prostate cancer risk. Though the exact mechanism is unknown, one study reported that a vasectomy influences prostate cancer by decreasing the amount of prostatic fluid secreted after the procedure or that there is a post-vasectomy immune response to sperm antigens, creating anti-sperm antibodies [92]. History of vasectomy was reported to have a relative risk of 1.56 compared to in men who did not undergo the procedure. Further, this risk increased with time, so that men who had a vasectomy at an earlier age had a higher risk of developing prostate cancer than men who underwent the procedure at an older age, with a relative risk of 1.89 among men who had a vasectomy >20 years prior to diagnosis [93]. Subsequent studies have suggested that the observed association may have in fact reflected healthcare usage patterns among men with an established relationship with a urologist [94].

## Sexual Activity

To the extent that prostate carcinogenesis has been associated with inflammation, there has been some interest in evaluating the possibility of a relationship between sexual activity and sexually transmitted infections as mediators of prostate cancer risk. Prostate cancer risk has been associated with earlier age at first intercourse, large number of sexual partners, and

history of STDs [95]. The odds ratio for prostate cancer diagnosis among men with a history of greater than eight sexual partners was 2.24 compared to men who had fewer than eight sexual partners. Another study on sexual behaviors reported that there was no relation between sexual orientation and prostate cancer, and the risk estimate increased directly with the number of female sexual partners but only slightly increased with the number of male partners [96].

In addition to sexual behaviors, infectious agents have been reported to increase risk for prostate cancer. Hayes et al. showed a significant 60 % increased risk among men who had a history of an STD [92]. Further, men who had three or more STDs had a threefold increased risk for prostate cancer compared to men who did not have a history for STDs, with the observation of a significantly increased risk in men with a history of gonorrhea but no association observed with a history of syphilis [95].

Observational data have suggested that higher ejaculation frequency may be associated with subsequent decreased prostate cancer risk [97]. This is substantiated by a study of Roman Catholic priests, assumed to be celibate, who had an above-average risk of dying from prostate cancer [98].

### Summary

Prostate cancer is a common condition with a complex and multifactorial etiological basis. Genetic studies have substantiated the existence of familial and hereditary forms of the disease, and geographic and racial disparities likely reflect, to a degree, variable baseline levels of risk in different populations. At the same time, a large body of literature describes the importance of environmental, nutritional, and dietary exposures as additional moderators of prostate cancer risk. These factors help inform not only our understanding of the potential mechanisms of the disease but also provide a basis for targeted screening, risk factor modification where possible, and potentially primary and secondary prevention strategies, outlined in greater detail elsewhere in the textbook.

## Molecular Epidemiology

Sex hormones are known to play an intermediary role between exogenous effectors, such as environment and diet, and molecular targets in the development of prostate cancer.

### Androgens

It is well established that male sex hormones, or androgens, and prostate cancer are strongly interrelated. Testosterone, the principal male androgen, is necessary for growth of secondary sex organs as well as for prostate epithelium formation, proliferation, and differentiation throughout adulthood. The prostate converts testosterone to dihydrotestosterone (DHT), the primary nuclear androgen and a substrate for hormone metabolism. Testosterone is also responsible for the production of prostate-specific antigen (PSA), and it has long been implicated as a promoter of prostatic cancer growth since castrated men or men with lower levels of testosterone have reduced incidence rates of prostate cancer [99].

Within the prostate, DHT binds to the androgen receptor to form an intracellular complex that binds to androgen-response elements in the DNA of prostate cells inducing proliferation. The potent action of DHT in the prostate is mediated by the androgen receptor. The receptor is encoded by the X chromosome and contains CAG repeats. CAG repeats decrease the transactivation of testosterone while it is bound to the androgen receptor [100], decreasing intracellular stimulation and cellular proliferation and providing a potential protective mechanism to prostate cancer. There is an inverse relationship between the number of CAG repeats and transcriptional activity of the receptor [101]. There is also a racial difference in CAG repeats in that African American men have a shorter mean of 20 repeats compared to 22 repeats for Caucasians [102]. It has been demonstrated that men who had fewer than 20 repeats were at a threefold increased risk compared to men who had more than 22 repeats [103]. Given these observations, this represents another possible mechanism for increased prostate cancer risk in African American men. Further, shorter CAG repeats have also been associated with a higher risk for advanced prostate cancer [104], and the data is still inconclusive for the influence of fewer CAG repeats on lower stage disease.

DHT binds to the receptor, forming an intracellular complex that binds to DNA in prostate cells and induces proliferation of prostatic cells. Non-androgenic hormones like estradiol, vitamin D, and IGF-1 can also trigger this pathway [105]. Similarly, coactivator proteins ARA, p160, and BRCA1 also enhance androgen receptor activity several-fold and cause cellular proliferation [106].

Differences in polymorphism frequencies for genes mediating testosterone metabolism, including CYP17 and SRD4A2, have also been studied as putative mechanisms for differential prostate cancer risk. One example CYP17 (encoding cytochrome P450c17, necessary for steroid biosynthesis) has a polymorphic T to C substitution in the 5′-untranslated region, giving rise to two alleles, A1 and A2. The base pair change at the promoter site may enhance transcriptional activity and influence the risk of prostate cancer [107]. Allele A2 is known to have a higher frequency in Caucasian men (70 %) who have prostate cancer compared to control patients (57 %) [108], whereas A1 is reported to have a higher risk of prostate cancer among Japanese men [109]. If the A2 polymorphism is considered to correlate with the racial differences in prostate cancer

incidence, then Japanese men with A2 should be hypothesized to have a higher incidence than African Americans and Caucasians, but that is the reverse of actual incidence rates. This underscores the complex interaction of genetic and environmental influences in racial differences in prostate cancer incidence.

In the prostate, testosterone converts to the more bioactive DHT by the enzyme catalyst 5α-reductase type II, which is encoded by the SRD5A2 gene. This gene is involved in androgen biosynthesis and metabolism, and polymorphisms of the gene have the potential to alter long-term androgen exposure and prostate cancer susceptibility. One polymorphism, V89L, replaces valine with leucine, causing a reduction in 5α-reductase activity, thus creating a decreased conversion to DHT and reduced risk for prostate cancer [110]. V89L is also associated with lower circulating AAG, a marker for SRD5A2 activity, in both Asian and Caucasian men [111], explaining the possible racial variation in prostate cancer incidence, particularly a lower risk in the Asian male population. V89L frequency was low in African Americans (22.1 %) but much higher (46.1 %) in Asians [111].

Despite convincing data that supports the role of androgens in prostate cancer growth, epidemiologic studies on serum levels of androgens remain inconclusive. One study with over 9,000 men reported no association between serum levels of testosterone and prostate cancer risk [112]. Differences in the study population, testing accuracy, and confounding factors could account for this discrepancy. More specifically, there was a slight association between low-grade disease and serum testosterone levels [113]. Even the largest study, the Prostate, Lung, Colorectal and Ovarian (PLCO), found no association with prostate cancer, but did report a higher testosterone to sex hormone-binding globulin (SHBG) ratio had an increased risk of prostate cancer in men >65 years old [114]. Of all serum testosterone studies, only one to date has found a significant inverse relationship between androstenedione concentration and the risk for advanced stage prostate cancer, in addition to a weak positive association between testosterone concentration and the risk of prostate cancer in younger men [115].

Testosterone deficiency is common among aging American males, and men suffering from testosterone deficiency may actually have a protective affect against prostate cancer. Evidence supports this hypothesis since African American men have 15 % high circulating testosterone than Caucasian men: a possible explanation for the higher level of prostate cancer incidence in African American men [116]. Though this link is established, the extent of testosterone deficiency and cancer risk is yet to be determined.

## Estrogens

To the extent, testosterone is linked to prostate cancer; it follows that estrogen may also have potential implications in prostate cancer biology. In vitro, estrogen has both stimulatory and inhibitory effects on prostate cancer cells [117], and estrogen-dependent transcriptional factors are found in both normal and cancerous prostatic tissue as well as in prostate cancer cell lines [118]. Estrogen receptor-α, ERα, promotes prostatic epithelial cell growth when estradiol binds to it, whereas estrogen receptor-β, ERβ, inhibits cell growth and loss of ERβ causes tumor progression [119]. Since both receptors are located on normal and malignant prostate epithelium, the imbalance of their expression may be a crucial factor that determines estrogens' effect on prostate cancer.

As discussed previously, individuals from countries with typical diets rich in phytoestrogens, including soybeans, have a comparatively low incidence of prostate cancer. In one study of American men, there was an inverse relationship found between soy milk consumption and prostate cancer risk. The association was strong with nearly 70 % reduction in disease risk in men who drank soy milk several times a day versus those who did not drink soy milk at all [120]. See risk factors for more information.

# Racial Disparities and the Global Picture

# 24

James E. Ferguson III, Matthew E. Nielsen, Eric M. Wallen, and Raj S. Pruthi

## Objectives

1. To understand current trends in racial/ethnic disparities in prostate cancer outcomes
2. To understand the potential causes of these disparities; sociologic, and/or biologic
3. To understand the potential contribution of detection bias due to high prostate cancer prevalence and differences in screening penetrance as possible confounding variables to explain prostate cancer disparities between populations

## Introduction

Epidemiologic studies in prostate cancer have evaluated the impact of race and geographic location on prostate cancer risk and outcomes, with the goal of further understanding risk factors, molecular mechanisms, and the impact of potential differences in practice patterns between populations. Important epidemiologic differences in prostate cancer incidence and mortality have been discovered between different ethnicities and geographic regions with African American men (AAM) having one of the highest reported incidence rates in the world as well as much higher mortality than European American men (EAM) (Fig. 24.1). These data raise the following questions which are currently under investigation: (1) Are these differences representative of inherent environmental or biologic differences between ethnic groups? (2) Are they representative of different screening and treatment patterns between populations? and (3) Are they simply artifacts of data collection and cancer registry accuracy (i.e., increased attribution of mortality to prostate cancer due to increased detection)? If the answer to any of these questions is "yes," how can we use this information to improve our knowledge and better prevent and treat prostate cancer in all men? Each of these questions is addressed in this chapter, with particular attention to the first two questions.

A few caveats must be kept in mind when reviewing studies involving race/ethnicity, geography, and prostate cancer. First, prostate cancer is, among epithelial malignancies, a relatively slow-growing disease. Five-year survival rates in the USA are above 95 % in the PSA era. Thus, any changes in screening or treatment that affect the progression of the disease are unlikely to manifest in mortality differences until 10–15 years later. In addition, because prostate cancer incidence increases exponentially with age, any changes in life expectancy will drastically affect this measure. It is therefore critical to use age-adjusted incidence rates for accurate analysis and to ensure that the same age-adjustment standards are used when comparing different populations. Second, prostate cancer is extremely prevalent on autopsy, with close to 80 % of 80-year olds harboring the disease. Thus, reported prostate cancer incidence rates are highly sensitive to screening as well as other health care phenomena that result in histologic evaluation of prostate tissue (i.e., transurethral resection of the prostate for benign prostatic hyperplasia). PSA screening is not universally supported or implemented across the globe (or even the USA), with developing countries showing drastically lower penetrance of

PSA screening as well as other health care technologies including transrectal ultrasound and biopsy, pathologic evaluation, and surgical treatment of BPH. As these practices are adopted in developing countries, the incidence of prostate cancer (and likely, mortality attributed to prostate cancer) will undoubtedly rise. Finally, race/ethnicity is often a patient-reported attribute and is based more on cultural than biologic characteristics. While self-reported race/ethnicity may be appropriate for studies investigating the effects of cultural differences and barriers to care, it may not provide the resolution necessary to compare genetic variables in cancer outcomes [1]. These caveats must be kept in mind when attempting to glean meaningful and accurate inferences from the relevant literature [2].

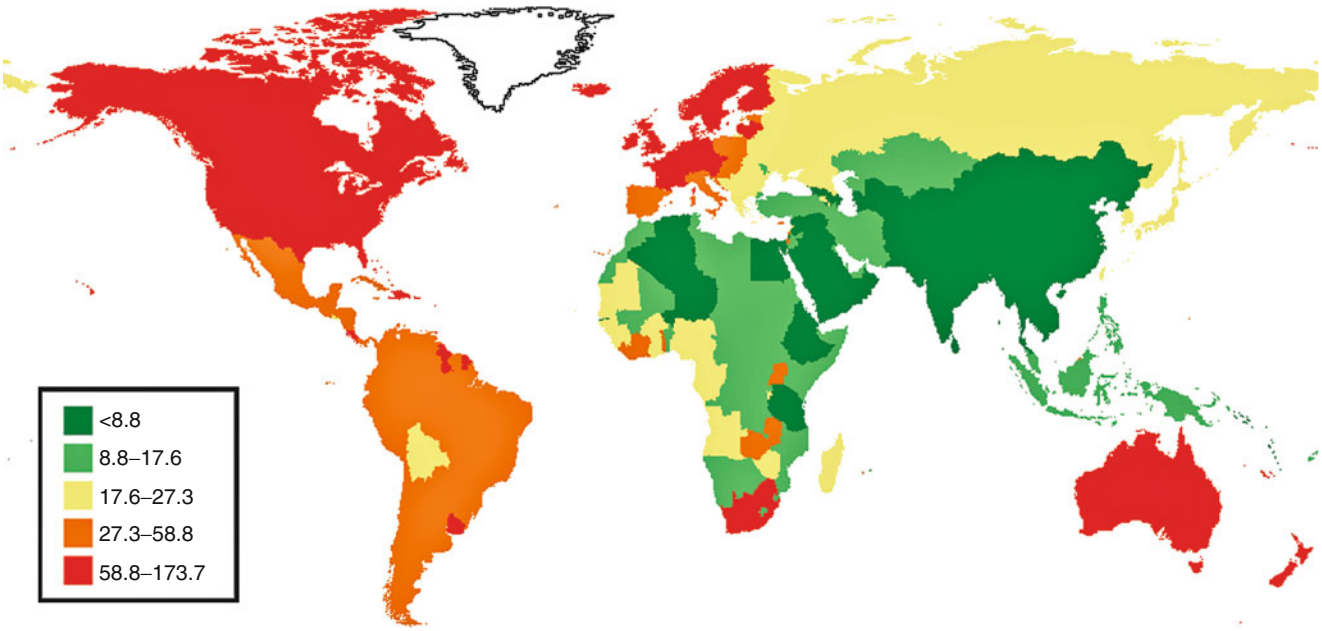

**Fig. 24.2** Worldwide incidence

## Epidemiology

### Overall Incidence

According to data from the United States National Cancer Institute's Surveillance Epidemiology and End Results (SEER) database, it is estimated that 217,730 men will be diagnosed with and 32,050 men will die of prostate cancer in 2010 [3]. (For more details on overall prostate cancer epidemiology, see Chap. 20). Between 2003 and 2007, the total age-adjusted incidence rate was 157 per 100,000 men/year. However, there were significant differences between races with AAM showing the highest yearly incidence (235 per 100,000 men), EAM and Hispanics showing intermediate incidence (150.4 and 126 per 100,000 men, respectively), and Asians and American Indians showing the lowest incidence (90 and 78 per 100,000 men, respectively) (see Fig. 24.1).

The incidence of prostate cancer on the global scale varies widely and is highly affected by implementation of health care resources and epidemiologic resources as mentioned above [4]. While it is widely accepted that Asian countries have comparatively low rates (>10 per 100,000 men/year) and western/developed countries have higher rates (over 100 per 100,000 men/year), the actual incidence in developing countries in general, and Sub-Saharan African countries in particular has been difficult to accurately ascertain (Fig. 24.2) [5]. PSA screening, prostate biopsy, and TURP for BPH in these populations is comparatively low, as is general knowledge about prostate cancer [6, 7]. Incidence and mortality have been increasing in many African countries including Uganda and Nigeria, with rates now approaching those of AAM in some cases [8, 9]. While authors have postulated that this is due to a "Westernization" of lifestyle and associated dietary/environmental exposures, others have posited that it represents a combination of increased access to care, "Westernization" of health care (i.e., more TURP for BPH), and increased sensitivity of cancer registries, all in a population at high baseline risk [10]. While reliable data from Africa are relatively few, recent studies have found high incidence and mortality rates in populations of West-African decent on multiple continents and suggested a residual genetic link from the Transatlantic Slave Trade to explain the apparent racial disparity [10, 11].

### Mortality

In the United States, AAM die of prostate cancer more frequently than other races/ethnicities. According to the SEER database [3], the overall age-adjusted prostate cancer-specific death rate was 25 per 100,000 men/year, with rates for AAM higher than average (54 per 100,000 men/year), rates for EAM, American Indians, and Hispanics close to

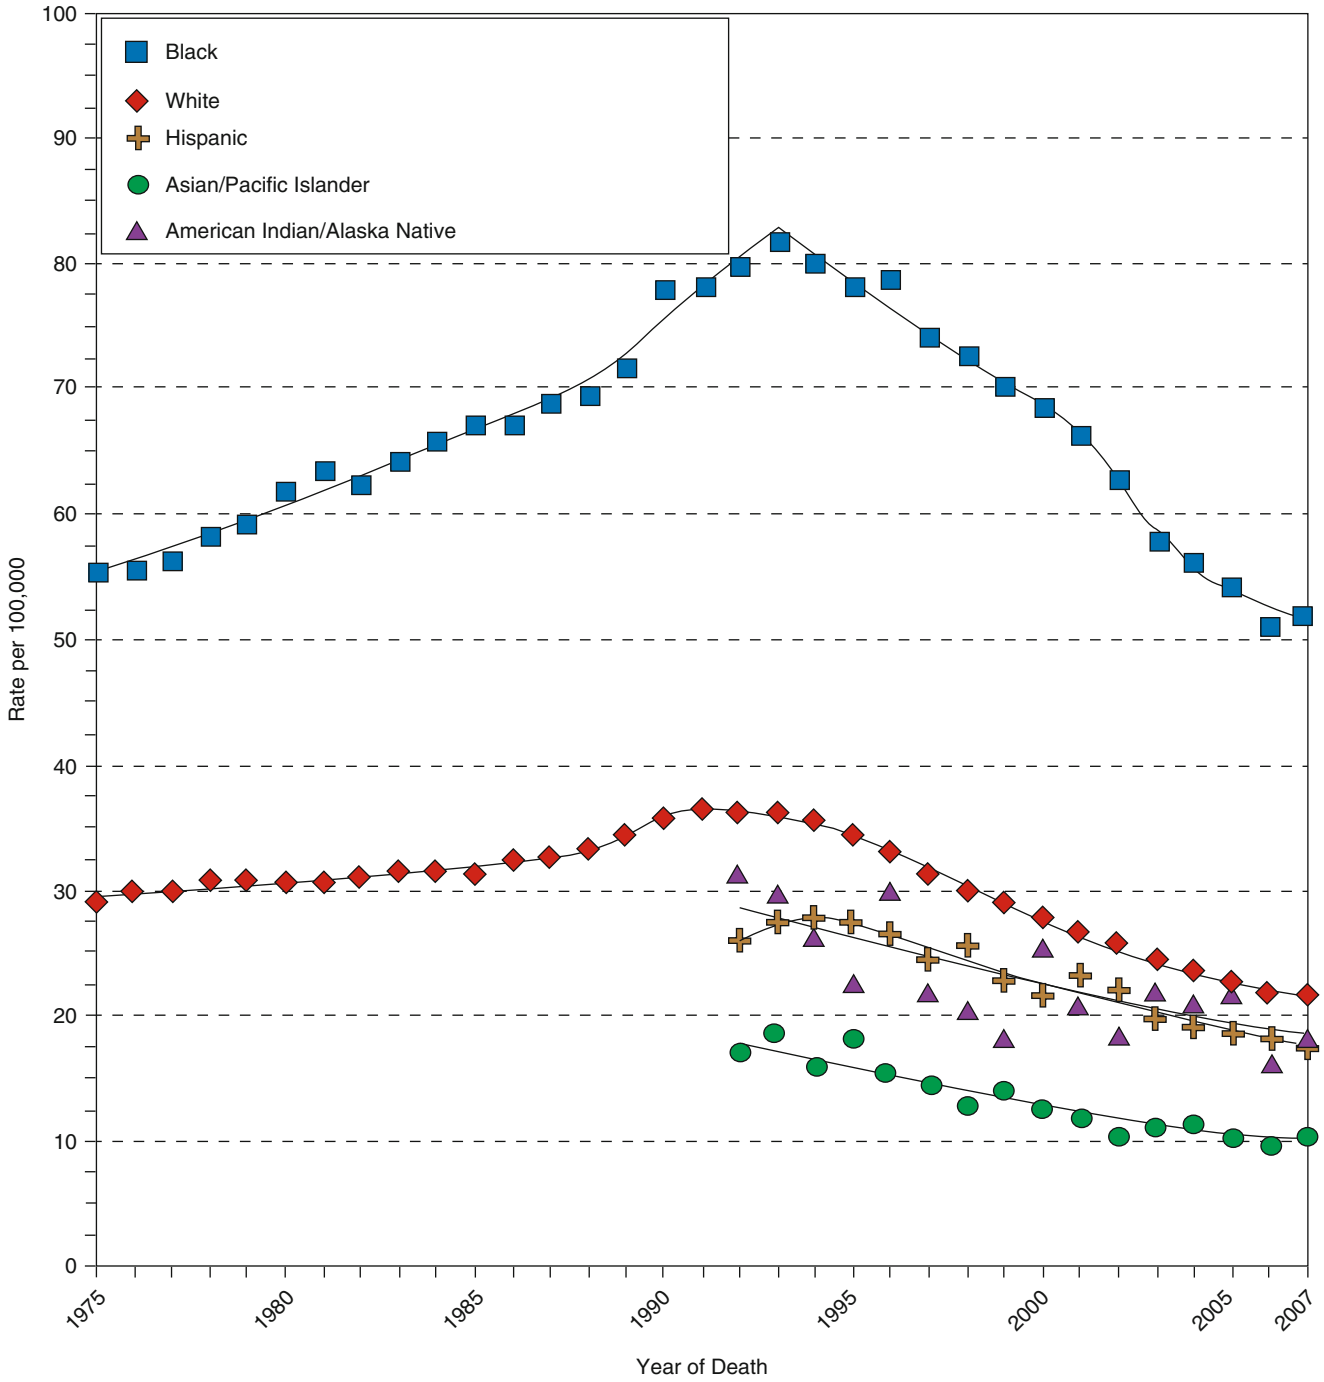

**Fig. 24.3** SEER mortality by race

average (23, 20, 19 per 100,000 men/year, respectively), and rates for Asian Americans lower than average (11 per 100,000 men/year) (Fig. 24.3).

These US racial and ethnic mortality trends are also reflected on the global scale with Asian countries showing relatively low prostate cancer-specific mortality rates (>5 per 100,000 men/year), and Sub-Saharan African countries showing higher mortality rates (~30 per 100,000 men/year), although the data from developing countries should be interpreted with caution (Fig. 24.4) [5]. Mortality remains highest in Scandinavian countries. It should be noted, however, that US and global data use different age-standards; thus, the point estimates between the two databases are not directly comparable.

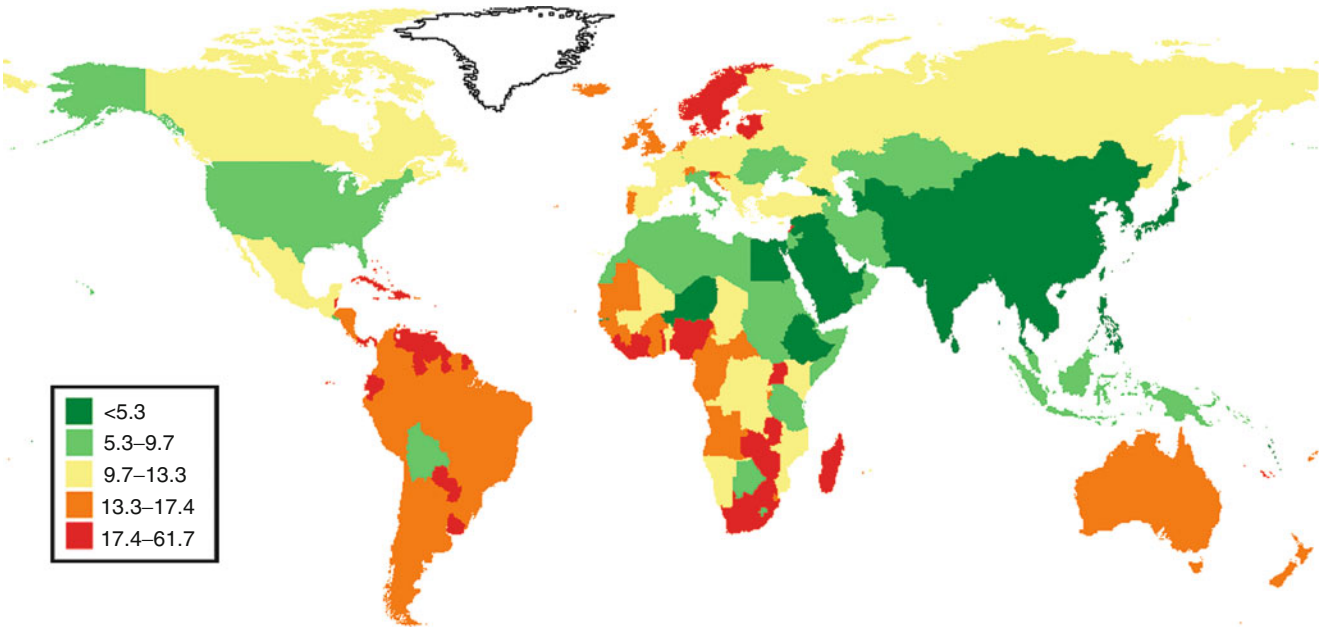

**Fig. 24.4** Worldwide mortality

## Trends in Incidence and Mortality

Importantly, these disparities are changing over time, and the gaps of both incidence and mortality between AAM and EAM appear to be narrowing since 1992, when the gaps were at their widest. When compared to 1975, however, the disparities have not changed. The exact causes of these observed trends are not entirely clear, but are likely due to a combination of factors including increased utilization of PSA screening, more effective treatment modalities, and perhaps changes in other-cause mortality in these populations. Whether the gap will continue to narrow, or will return to pre-PSA levels is debatable and requires further research.

Incidence rates in Sub-Saharan Africa are increasing with rates in Uganda rising 4.5 % annually between 1992 and 2005. This is likely due to changing access to care and increasing sophistication of medical care and cancer surveillance [12]. In fact, a similar pattern is seen across the globe where rates in developing countries are increasing and mortality rates in most developed countries are slowly decreasing [13].

## Prevalence, Disease Presentation, and Intermediate Outcomes

Autopsy studies have shown that the baseline prevalence of prostate cancer is quite high (31 % in fourth decade of life, increasing to over 80 % in the eighth decade) but is not different between AAM and EAM [14, 15]. In fact, even worldwide autopsy series have found similar prevalence rates between populations with very different incidence and mortality rates [16]. Despite this baseline similarity in prevalence, AAM have historically presented with higher tumor stage [17–19], higher grade [20–22], and a higher PSA level at diagnosis, although these differences at presentation appear to be diminishing in the last 10 years [23, 24]. Interestingly, in the UK, when compared to white men, black men only have higher PSA levels and show no difference in disease stage or grade [25]. Finally, when receiving treatment with curative intent for locoregional disease, AAM have higher recurrence rates and earlier failure after radical prostatectomy even after controlling for stage, grade, and PSA at diagnosis [26–29]. However, a separate study evaluating the influence of stage, age, and year of diagnosis suggested that these results are highly dependent upon the stage migration due to PSA screening, and that differences between black and white men over age 70 had disappeared by the late 1990s [24, 30].

## Potential Explanatory Variables for Observed Disparities

What differences between AAM and EAM can explain these differences in prostate cancer incidence and mortality? Are they sociologic, biologic, or both? If sociologic, are they due to behaviors/circumstances of the patients, behaviors/circumstances of the physicians and workup, or some combination? If biologic, are they environmental, genetic, or both? The remainder of this chapter will address these questions.

## Socioeconomic Factors and Patterns of Care

Access to care may play a central role in explaining part of these disparities, and many studies have attempted to control for socioeconomic status to evaluate the impact of this confounding variable, with varying results [19, 26, 31–38]. In fact, a recent systematic review and meta-analysis evaluating all of the studies that controlled for clinical predictors and socioeconomic variables found that while there was no longer a difference in overall survival, AAM still had increased risk of prostate-specific mortality and biochemical recurrence [39]. Other studies have been performed in "equal access" settings, with older studies showing differences between races, and more recent studies showing fewer differences [20, 40–43].

The processes of screening, diagnosis, and therapy for prostate cancer provide many opportunities for variations in care that may mediate observed differences in outcome between different population subgroups. The patterns of care between men of different races have been extensively investigated, with particular attention to PSA screening rates and choice of definitive therapy. In the early 1990s, various studies showed that EAM were significantly more likely to receive PSA screening than AAM, but this difference had essentially disappeared by the early 2000s [44–46]. In fact, in response to practice guidelines recommending AAM screening starting in the fifth decade of life, vastly more young AAM are screened by PSA [46]. However, the extent of mortality benefit due to PSA screening remains a contentious issue, and the effect of this closing screening gap, if significant, is unlikely to manifest itself until 10–15 years later. Furthermore, AAM showed higher prostate cancer incidence rates before and after PSA screening [3], suggesting that much of the mortality disparities historically cannot be attributed solely to screening differences. However, to the extent that black men truly have more aggressive disease, one might speculate that this group may experience a comparatively greater benefit from early detection through screening. Unfortunately, two large randomized controlled trials did not have the statistical power to address this question specifically for the subgroup of AAM [47, 48].

One group of investigators described that once elevated PSA levels are found, AAM are also less likely to undergo an ultrasound-guided biopsy than are EAM at all time points [49]. Data on treatment selection following diagnosis have been somewhat mixed. Multiple studies have documented treatment differences between EAM and AAM, with AAM less likely to undergo curative treatment for clinically locoregional disease [22, 43, 50–59]. In a few reports, these differences disappeared when controlling for age and poverty [31], or stage and grade [22]. Interestingly, in an "equal access" setting, the age-adjusted rate of radical prostatectomy for AAM in the VA system between 1998 and 2003 was nearly double that of EAM at all time points [49].

While the possibility of provider discrimination to explain these discrepancies has not been formally evaluated, patient behaviors have shown some differences. Some studies have pointed to access to care and educational differences between races/ethnicities [32]. Others have found that AAM are "well aware of their risk," and that the main barriers to diagnosis arose from "constrained opportunities for health care access and utilization, lack of long-term primary care, and reduced trust in physicians" [60]. This is likely reflected in an increased PSA screening interval which may result in later diagnosis of more advanced disease in AAM older than 65 [61, 62].

In summary, while the debate over the exact contribution of socioeconomic factors and patterns of care to disparities in prostate cancer outcomes remains contentious, there is good evidence to support that they play *some* role. Access to care and patient education is a major issue and should be attempted to be improved across all races/ethnicities, and the possibility that PSA screening and follow-up could preferentially aid AAM is a provocative but unproven concept. More research is needed to more accurately understand these effects, particularly with regard to choice of curative treatment between AAM patients and their physicians.

## Biologic Factors

Due to the inability of many retrospective trials to assign all of the increased prostate cancer risk of AAM to socioeconomic/behavioral factors, much work has been done to investigate the role of biology in determining this apparent elevated risk, with many studies illuminating potentially relevant biologic differences between men of different races and ethnicities that may explain some of the observed disparities.

### Androgen Axis

Since the pioneering work of Huggins and Hodges, prostate cancer has been understood to be exquisitely androgen-sensitive. In this context, many studies have evaluated various aspects of the androgen axis between AAM and EAM. Among college-age men, AAM have testosterone levels that are 15 % higher than EAM; however, this difference has not been found in older populations [63–67]. AAM have also been found to have differences in the gene encoding 5-alpha reductase, which could result in increased prostatic levels of dihydrotestosterone in AAM [68, 69]. Perhaps most convincing, androgen receptor (AR) expression is 21 % higher in benign prostates and 81 % higher in cancerous prostates of AAM versus EAM. ARs with shorter polyglutamine repeats are more highly expressed and bind testosterone and its metabolites with greater affinity. Interestingly, the length of polyglutamine repeats vary consistently among races/ethnicities and are inversely proportional to their overall prostate cancer risk [13, 70, 71]. If AAM truly have increased

activity in the androgen axis, they should theoretically be more sensitive to androgen blockade. However, there was no increased magnitude of 5 alpha reductase inhibitor prevention observed among black men in the PCPT or REDUCE randomized controlled trials, although these trials were not adequately powered to detect small differences in this subgroup (only 2 % of participants were AAM) [72, 73].

While the significance of the results of each of these studies individually may be debatable, the preponderance of the data clearly points toward an increase in androgen activity in AAM and may explain at least part of the higher incidence, PSA at diagnosis, HGPIN on autopsy, and mortality in these men. The recent elucidation of the role of androgen-sensitive topoisomerase-mediated DNA double strand breaks, and the resulting androgen-responsive TMPRSS2:ETS fusion genes in prostate cancer raises the interesting possibility of racial/ethnic differences in susceptibility to the molecular ramifications of this genetic rearrangement [74]. Early studies are finding some differences with Japanese men showing lower rates of rearrangements, but larger studies and longer follow-up will be needed to fully understand the contribution of these differences to prostate cancer incidence and mortality disparities [75–77].

## Diet and Environmental Factors

Migration studies have provided some insight that some of the geographic risk of prostate cancer may be environmental. In a study comparing Japanese-American immigrants to native Japanese men, Shimizu et al. found that immigrants had increased prostate cancer risk, but that their risk did not become equivalent to that of AAM or EAM [78–81]. The authors postulated that this increased risk is due to exposure to carcinogenic substances in the USA, either through diet or the environment, but could not exclude the contribution of differential health care practices between the populations (PSA screening, prostate biopsy, and TURP for BPH, etc.) [82].

Ecologic data reveal that the Asian and American diets are very different, with Asians consuming, on average, more fiber and soy protein and less saturated fats [83]. (The epidemiologic evidence of dietary risk factors for prostate cancer is reviewed in Chap. 20.) A number of epidemiologic studies have implicated diet in prostate cancer risk, especially a high intake of saturated fat, red meat, and dairy products [84–86]. In fact, differences in dietary fat are thought to account for approximately 10 % of the difference of prostate cancer incidence between AAM and EAM [87]. Specifically, omega-6 fatty acids are thought to act as promoters of prostate cancer while omega-3 fatty acids are thought to be protective, and the typical diet of AAM has been shown to contain the highest overall saturated fat and omega-6 fatty acid content in the world [88, 89].

Alternatively, increased dietary fat in AAM may simply be a surrogate for the conferred risk of obesity in prostate cancer. Obese prostate cancer patients present at younger ages, with higher Gleason grades and more advanced stages. AAM are more obese than EAM, which may explain some degree of their elevated risk [90, 91]. While the biologic processes underlying this observed association are not yet firmly established, obesity has been associated with hormonal alterations that may promote prostate carcinogenesis [90]. In particular, abdominal obesity is associated with lower levels of insulin-like growth factor-binding protein (IGFBP), resulting in higher levels of free IGF-1, a growth factor strongly implicated in prostate cancer growth. AAM have been shown to have lower IGFBP and higher concentrations of IGF-1 than EAM [92–94].

Finally, because AAM have darker skin pigmentation and because men at higher latitudes have the highest prostate cancer risk, it was postulated that vitamin D levels may be protective for prostate cancer. While the slim majority of studies have found lower vitamin D levels in AAM, especially at higher latitudes, other large cohort studies have failed to find racial differences in plasma vitamin D levels or associations with prostate cancer risk [95, 96]. Some authors have suggested vitamin D supplementation as a strategy to prevent prostate cancer, especially in high-risk populations such as AAM at high latitudes, though this strategy remains to be tested in large prospective trials [97].

### Conclusions

Prostate cancer incidence and mortality differences between ethnicities in the USA and across the globe are heavily influenced by health care utilization patterns, and are likely the result of a combination of environmental and genetic factors. However, the narrowing gap in mortality between AAM and EAM suggests that some of this disparity may be abrogated by continuing to increase access to care. It has been postulated that because of their higher risk, AAMs may receive the greatest benefit from PSA screening, and that efforts to aggressively screen this population will yield benefit regardless of biologic cause. Unfortunately, large randomized trials evaluating the efficacy of PSA screening have not shown racial-group-specific differences, perhaps because of insufficient statistical power [47, 48].

While it is hoped that the historical gaps of prostate cancer incidence and mortality between AAM and EAM will continue to narrow and perhaps close completely, most believe that the underlying bases for these disparities are complex and multifactorial, still exist, and remain incompletely addressed. Improving access to care remains an important and potentially actionable goal, and efforts should continue to understand and improve prostate cancer knowledge and quality of care in AAM. At the same time, further study investigating the molecular

susceptibilities of prostate cancer in AAM may ultimately result in a refined understanding of the biologic basis of prostate cancer which could lead to more accurate risk-stratification, and in turn, less over-testing and overtreatment in all men.

# Natural History of Prostate Cancer

25

Nicholas J. Hegarty and Paul K. Hegarty

*For a patient with prostate cancer, if treatment for cure is necessary, is it possible?*

*Dr. Willet Whitmore Jr.*

## Introduction

The natural history of prostate cancer raises many questions as to the appropriate approach to diagnosis and treatment. While it remains one of the leading causes of cancer death, clinicians and patients are keen to limit the morbidity of treatment to those likely to benefit from it.

Prostate cancer is the most frequently diagnosed cancer and the most frequent cause of cancer-related death in men. In the USA, it accounts for nearly 30 % of all newly diagnosed male cancers with an estimated 240,000 men being diagnosed with prostate cancer in 2011. The lifetime incidence of prostate cancer is 30 % [1], with 10 and 15 years survival of 91 and 76 %, respectively [2]. Much of the increase in incidence and improved survival of prostate cancer over the past decades have often been attributed to prostate cancer screening and early detection. Definitive evidence supporting this relationship is, however, still awaited with alternative explanations such as improved treatment at advanced stages that could lower prostate cancer mortality.

## Establishing a Baseline: How Common Is Prostate Cancer?

The incidence of prostate cancer increases dramatically with age, rising from 1 in 10,000 in men <40 to 1 in 8 in those >80 (Fig. 25.1) [3]. Thus, in comparing incidences between countries, it is important to account for differences in life expectancy. The age-standardized worldwide incidence and mortality of prostate cancer are shown in Fig. 25.2. A very clear difference in incidence is seen between more and less developed regions of the world [4]. Certainly, differences in healthcare systems, public and physician awareness, and availability of screening contribute to this, while environmental and dietary factors have also been implicated. Prostate cancer incidence increases in populations who move from areas of low incidence to high-incidence areas, demonstrating an increase in incidence approaching that of their new location: increasing incidence is seen when Japanese migrate from their native country (low incidence) to Hawaii, with a further increase with migration to US mainland [5]. The amount of time spent in the new host country is also a factor with immigrant Chinese having a threefold greater incidence of prostate cancer if they have spent more than 25 years in the USA, compared to those who have spent less than 25 years [6].

Another limitation in determining the incidence of prostate cancer is that diagnosis is typically restricted to those in whom the diagnosis is suspected. In the Prostate Cancer Prevention Trial (PCPT), 15 % of men with "normal" PSA (<4 ng/mL) had prostate cancer [7]. These were diagnosed on the basis of sextant biopsy, which for many years was considered the standard. The introduction of additional lateral biopsies to TRUS biopsy protocols increased the detection rates of prostate cancer further. Saturation biopsies, by both the transrectal and transperineal routes, lead to higher yields [8], with 3D mapping strategies suggesting that better characterization may be made between significant and low-volume cancers [9].

A more in-depth analysis of the incidence of "histologic" prostate cancer is estimated by post-mortem findings. In looking at a predominantly African American population, Sakr et al. [10] showed foci prostate cancer in 27 % of men aged 30–39 and 34 % of men in their 40s. Similar findings are seen in international studies – in comparing the prevalence of microscopic disease with clinically detected prostate cancer in West Africa and in African Americans, Jackson

DOI 10.1007/978-1-4471-2864-9_25, 

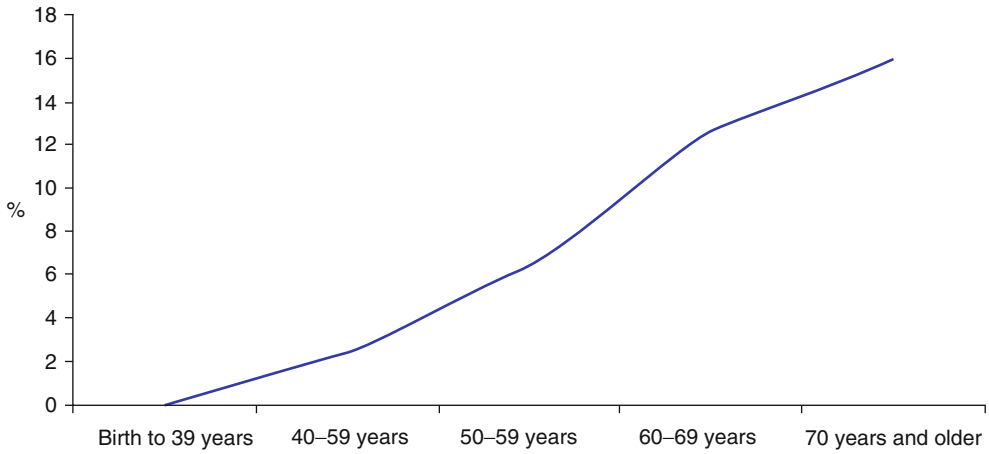

**Fig. 25.1** Probability of developing prostate cancer in different age groups (Jemal et al. [3])

et al. showed comparable incidence of microscopic disease, though a tenfold greater detection of clinical cancer in the American cohort [11].

What these studies have confirmed is that screening has led to the problems of overdiagnosis and overtreatment. It has been estimated that 1.3 million extra patients have received "unnecessary" treatments for prostate cancer since the introduction of PSA 3 decades ago [12]. In an attempt to clarify those needing treatment, a number of definitions of clinically significant or insignificant prostate cancer have been proposed. These generally include details as to clinical stage, tumor grade, and tumor volume.

Perhaps the most widely used is that proposed by Epstein et al. [13] who define clinically insignificant disease as:

Tumor volume < 0.5 mL

No Gleason grade 4 or 5 disease

PSA density > 0.15

The presence of less than 3 mm of tissue in a single needle core (Epstein et al. [13])

Using this definition of insignificant disease, Lucia et al. [14] explored the relationship between PSA and significant cancer in the Prostate Cancer Prevention Trial (PCPT). Among cancers detected, a little over half the subjects with PSA 1.0 ng/mL or less had an insignificant cancer, approximately one-third of those with a PSA between 1.1 and 2.5 ng/mL, falling to 17.8 % in those with PSA between 2.6 and 4.0 ng/mL, and 11.7 % in subjects with PSA between 4.1 and 10 ng/mL. In this setting, PSA can be seen to perform well in predicting significant disease at higher levels, though the majority of subjects with cancer and a "normal" PSA still harbor significant disease.

## Disease Progression

Much of what we know of the natural history of prostate cancer comes from longitudinal population studies prior to the introduction of PSA. Rates of progression of disease have consistently been shown to be dependent on prostate cancer grade. Chodak et al. [15] reported 10-year progression in 17 % of patients with low-grade disease increasing to 74 % in poorly differentiated cancer (Fig. 25.3) [15, 17]. Mortality is also related to cancer grade. Overall 15-year prostate-cancer-specific mortality is of the order of 20 % [16]. Studies from Albertson and Johansson [17, 18] report 6 % cancer-specific mortality at 15 years in low-grade disease rising to between 56 and 86 % in patients initially diagnosed with Gleason 8–10 disease (Fig. 25.4).

More recent data from the Prostate Intervention Versus Observation Trial (PIVOT) reported the mortality from prostate cancer at median of 9 years of 8.4 % in the observation group compared to 5.8 % in those undergoing following radical retropubic prostatectomy. The biggest difference was seen in those with high-grade disease where the operated group had an 8.4 % absolute reduction in prostate cancer mortality compared to the observation group [19].

## Natural History in the PSA Era

The emergence of PSA as a screening tool in the 1980s has impacted dramatically on the field of prostate cancer. An almost fourfold greater rate of decline in age-adjusted prostate cancer mortality was observed in the USA (where screening has been far more prevalent) compared to the UK where the uptake of PSA has been less widespread in the last two decades [20]. Improvements in survival in recent years must be interpreted with caution as PSA is thought to increase the lead time for prostate cancer between 5 and 11 years [21]. It was hoped for many years that the true value of PSA screening might come from large prospective randomized screening studies. The Prostate Lung Colorectal and Ovary (PLCO) Screening Trial looked at 76,693 men randomized to either annual screening (38,343 subjects) or nonscreening arms (38,350 subjects) between 1993 and 2001. After 7–10 years

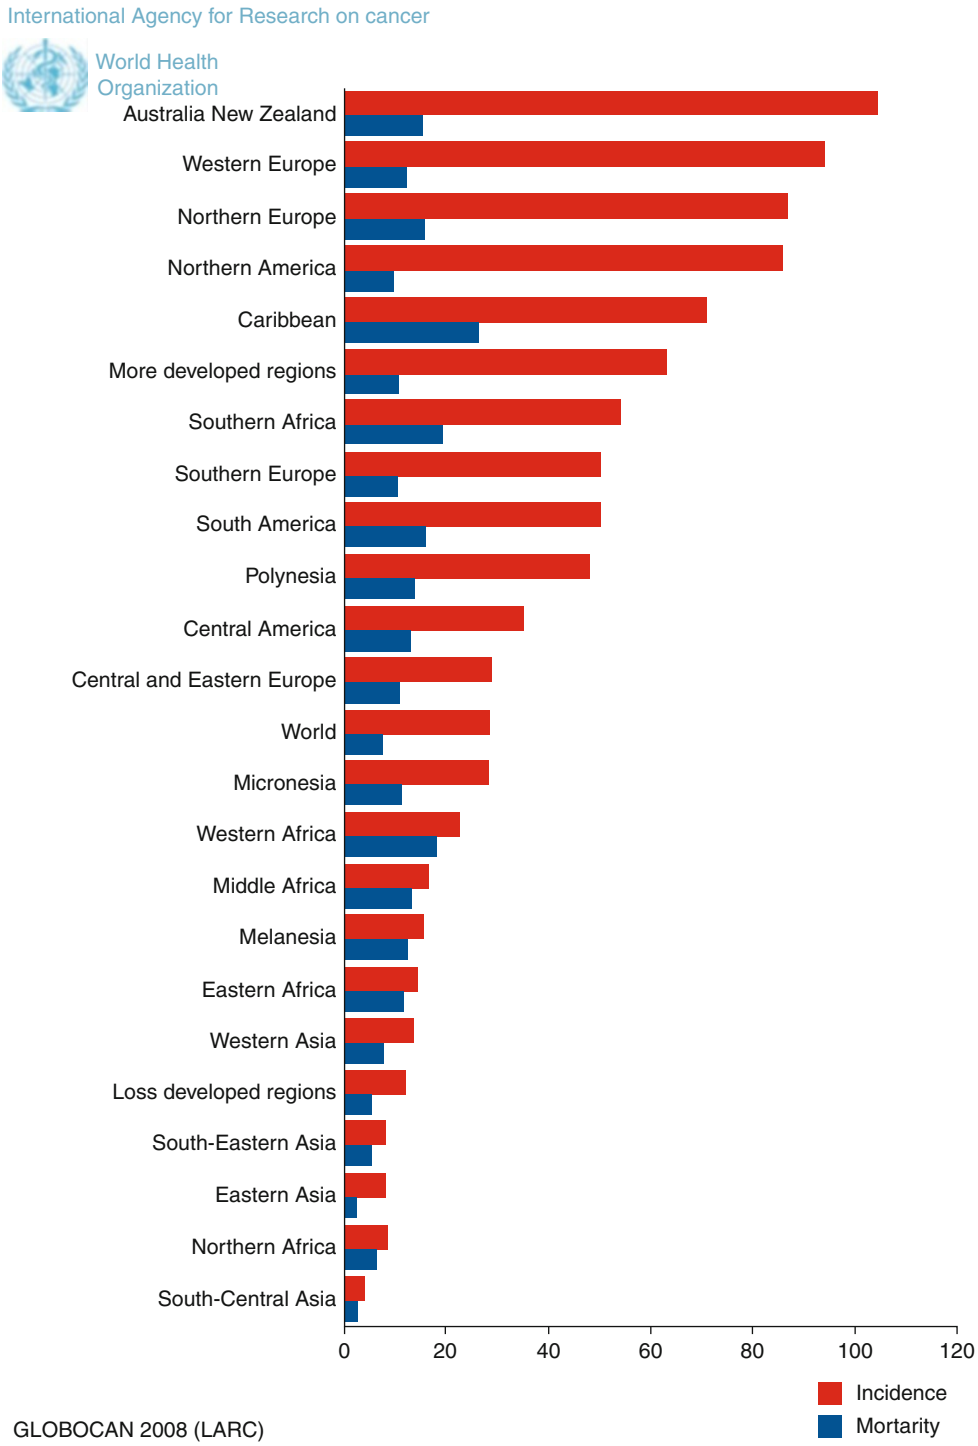

**Fig. 25.2** Estimated age-standardized rates (World) per 100,000 (WHO) [27]

follow-up, no conclusive benefit was seen to prostate cancer screening in terms of prostate cancer mortality. Mortality rates were low in both screened and nonscreened groups, and many in the nonscreening arm had PSA measurements performed leading to difficulty in interpreting the results [22]. The European Randomized Study of Screening for Prostate Cancer (ERSPC) looked at 182,000 men between ages of 54 and 74 years, with a core group of 162,243 between the ages of 55 and 69 years receiving more detailed study. Subjects were randomized to receive PSA screening on average once every 4 years or no PSA screening, with a median follow-up of 9 years. Contamination of the nonscreened group by PSA testing outside of the study was less of an issue than was seen in the PLCO, with the screened population showing a 20 % reduction in prostate-cancer-specific mortality. The number

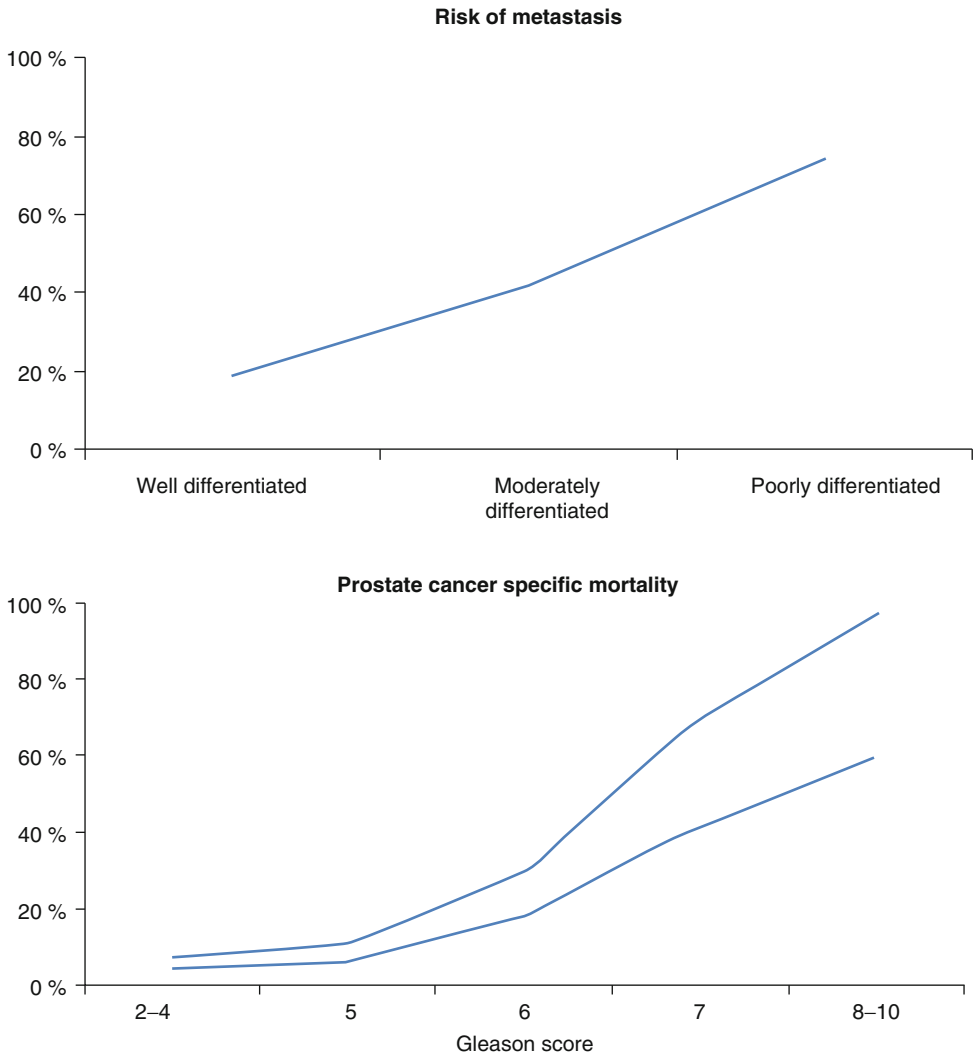

**Fig. 25.3** (**a**) Ten-year risk of developing metastases in men diagnosed with prostate cancer (Chodak et al. [15]). (**b**) Albertsen 15-year data [17]

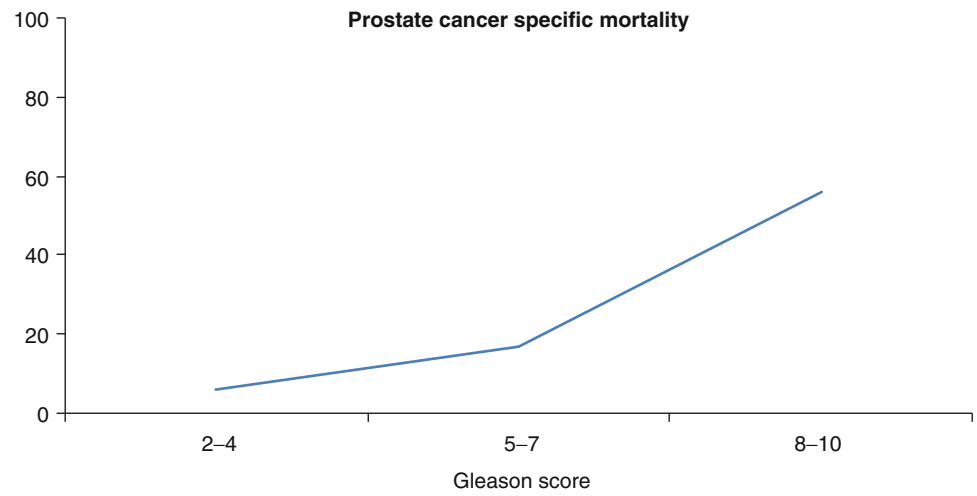

**Fig. 25.4** The 15-year cancer-specific mortality for men diagnosed with prostate cancer (Johansson et al. [18])

needed to screen on initial review was 1,410 and with an extra 48 cases requiring treatment to prevent one death from prostate cancer at 9-year median follow-up. The number needed to treat to prevent metastasis was lower at 24, suggesting smaller screening numbers will be required to achieve benefit with more prolonged follow-up [23].

## Natural History Following Treatment

An advantage of radical prostatectomy over radiation and other ablative treatments is that accurate pathological staging can be achieved. Combining this information with patient follow-up, several predictive algorithms have been constructed. Eggener developed a model derived from four institutions where 11,521 were treated by radical prostatectomy between 1987 and 2005 [24]. This was then validated using data from 12,389 patients from a separate institution treated over the same interval. Following radical prostatectomy, the 15-year cancer-specific mortality was 7 %. High-grade cancer (primary or secondary Gleason grade of 4 or 5), seminal vesicle involvement, and the year in which RRP was performed were all predictive for mortality. For those men with organ-confined disease with a Gleason score of 6 or less, only 3 of 9,557 (0.031 %) died of prostate cancer. Similar studies have been performed with radiotherapy cohorts, though histology is based on pretreatment biopsy rather than the final surgical specimen.

## Natural History of Biochemical Relapse (BCR)

PSA recurrence following radical prostatectomy is cause for worry for patient and physician alike. However, PSA recurrence is not necessarily a harbinger of inevitable disease progression. Pound et al. looked at a cohort of men who underwent RRP for localized disease at the Johns Hopkins Hospital between 1982 and 1997 by a single surgeon. Of the 1997 men operated, 315 (15 %) had BCR during a median follow-up of 5.3 years. Thirty-four percent of these men with BCR developed metastasis. In this group, the actuarial interval between PSA rise and development of metastasis was 8 years, and the time between metastasis and death was 5 years. Thus, for the 34 % of men who will progress, the time between BCR and death is an estimated 13 years [25].

A more recent retrospective review of 14,632 men who underwent radical prostatectomy between 1990 and 2006 at the Mayo Clinic identified 2,462 men (16.8 %) with BCR [26]. This series had very few node-positive cases, as they tended to receive early adjuvant treatment and were thus excluded from the cohort. Overall, 5.8 % of those with BCR died of prostate cancer during follow-up period (median 11.5 years). In this study period, the median progression-free survival and cancer-specific survival had not been reached. The 15-year cancer-specific survival following BCR was estimated to be 83.6 %. Factors that were predictive of death from prostate cancer were greater age, higher Gleason grade, higher stage, and rapid PSA doubling time. Of note, patients who received salvage therapy did not seem to have improved survival, in the retrospective study.

## Summary

Understanding the natural history of prostate cancer is fundamental to decisions on treatment in individual patients and recommendations with regard to screening and diagnosis of potentially curative cancers. The histological incidence greatly exceeds the proportion of individuals who will manifest overt disease, and while there has always been a desire not to misdiagnose those harboring cancer within the prostate, there has also been increasing focus on identifying patients who might be considered for surveillance. The introduction of PSA has impacted greatly on detection rates and our overall understanding of prostate cancer. Since its introduction, a stage migration has been observed with an increase in the proportion of patients presenting with early stage disease. Whether this has translated into an overall improvement in prostate survival remains controversial. Following a dramatic rise in the detection of prostate cancer and a brief increase in prostate cancer mortality rates in the 1990s, a reduction in prostate-cancer-specific mortality was then observed. This has been sustained with prolonged follow-up. The ERSPC appears to confirm that screening can reduce prostate cancer mortality. In confirmed cases, cancer-specific survival decreases from low- to intermediate- to high-grade cancer. The relatively low cancer-specific death rates seen in low-grade cancer mean that survival benefits from curative treatment strategies with medium-term follow-up have been modest at best. More definite benefit is seen in patients with high-grade disease who undergo surgery. Postoperative PSA testing remains important in determining the oncological outcome following treatment. Biochemical recurrence following surgery was thought to be synonymous with treatment failure. Almost two-thirds of patients with BCR however will show no evidence of disease progression. Median survival in those that progress is reported as 13 years.

Our knowledge of prostate cancer continues to evolve as we observe a continued increase in incidence with reducing mortality. PSA level and tumor grade remain two of the most important indicators of significant prostate cancer, the likelihood of progression, and the need for curative treatment. Improved imaging and better markers of disease progression have long been awaited, and it is hoped that these will facilitate the dilemma of avoiding or deferring cure in those that do not need it while not denying treatment to those who possess potentially lethal disease.

# Population-based Health Systems as a Foundation for Prostate Cancer Control Research: The Cancer Research Network

26

Mark C. Hornbrook and Joan Holup

## Health Systems as Research Laboratories

This chapter describes the rationale and opportunities for collaborating with the Cancer Research Network (CRN) on prostate cancer research—prevention, screening, treatment, survivorship care, and end-of-life care. The CRN represents a consortium of population-based integrated health care delivery systems operating largely under capitation payment from a wide range of public and private payers. As such, their motivation for collaborating on prostate cancer research stems from a desire to improve the evidence base for prostate cancer prevention and treatment while providing affordable health care to prostate cancer patients and survivors. Prostate cancer is the leading cancer among men. Its incidence, at 156.9 per 100,000 males, is nearly twice as high as the second leading cancer for men, lung/bronchus, at 80.5 cases per 100,000 (see Fig. 26.1). These health plans view public-domain research as desirable because it stimulates critical thinking about the evidence foundations for clinical and managerial decisions among their clinicians and managers, contributes to advancing health care technology, and helps fulfill their social missions (a requirement for tax-exempt status). Defined representative populations, accountable care organizations, extensive informatics systems, and public-domain research programs represent the CRN's strategic assets. This chapter provides an overview of how these assets are pertinent to building research collaborations with the CRN. This chapter will also highlight the comparative advantages of integrated delivery systems as research laboratories serving multiple stakeholders—patients and families, physicians and other clinical professions, public and private purchasers, pharmaceutical firms, radiotherapy device manufacturers, health administrators and policymakers, and researchers. This chapter aims to strengthen the CRN's prostate cancer research program and facilitate translating research findings into clinical practice and improving patient well-being.

## Founding the Cancer Research Network

In 1997, the National Cancer Institute (NCI) announced a competition for funding [2] "to encourage the expansion of collaborative cancer research among health care provider organizations." NCI recognized that the only readily available automated data on cancer care came from the linkage of Surveillance, Epidemiology, and End Results (SEER) tumor registry data with Medicare claims data. The SEER-Medicare data link, however, excludes people under age 65 years unless they are disabled, has limited data for individuals enrolled in Medicare Advantage plans, does not permit direct contact with patients or providers, and lacks detailed data on cancer treatments. This realization foreshadowed later efforts to involve community-based health care organizations in research, primarily to support the translation and dissemination of findings into the delivery system [3]. The original CRN Request for Applications defined the desired health care provider organizations as being "oriented to community care, hav[ing] access to large, stable and diverse patient populations and able to take advantage of existing integrated data-bases that can provide patient-level information" [2]. Systems involved in the CRN meet these criteria in large part because they are integrated health care delivery systems. Specifically, CRN systems incorporate clinicians, care facilities, and insurance components into a system that facilitates coordinated delivery of a full range of health care services with explicit quality and cost management controls. These systems also emphasize preventive care and chronic disease management to improve long-term health outcomes and overall patient well-being. Member institutions of the HMO Research Network [4] collaboratively submitted a successful

application, resulting in the 1999 formation of the CRN. The CRN was granted a Certificate of Confidentiality from NIH to protect CRN research data from Freedom of Information Act disclosure requests. This step was essential for obtaining cooperation from participating medical groups in research on the effectiveness of cancer screening programs, especially determination of rates of missed diagnoses when cancer screening test results were reanalyzed [5].

The CRN has reapplied successfully for funding. The most recent funding announcement, [6] *Funding Opportunity Announcement, RFA-CA-11-502, would continue the network's funding until 2017*. The CRN has been funded through an NCI cooperative agreement that ensures substantial NCI involvement in attaining research goals and catalyzing new collaborations. AHRQ became a cosponsor of the CRN in 2003, which invokes the Agency's statutory protections on data collected for the purposes of research from being used for nonresearch purposes (such as malpractice case finding). The CRN is planning for continued operations into the future.

## CRN Setting and Structure

### Participating Health Systems

The CRN has included these integrated health care delivery systems and their associated research centers: Fallon Community Health Plan/Meyers Primary Care Institute (MPCI), Geisinger Health System/Geisinger Center for Health Research (GHS), Group Health/Group Health Research Institute (GH), Harvard Pilgrim Health Care/Harvard Medical School Department of Population Medicine (HPHC), HealthPartners/HealthPartners Research Foundation (HPRF), Henry Ford Hospital and Health System/Health Alliance Plan/Department of Biostatistics and Research Epidemiology and Center for Health Services Research (HFHS), Kaiser Permanente Colorado/Institute for Health Research (KPCO), Kaiser Permanente Georgia/The Center for Health Research-Southeast (KPG), Kaiser Permanente Hawaii/The Center for Health Research-Hawaii (KPH), Kaiser Permanente Northern California/Division of Research (KPNC), Kaiser Permanente Northwest/The Center for Health Research-Northwest (KPNW), Kaiser Permanente Southern California/Department of Research and Evaluation (KPSC), Lovelace Clinic Foundation Research (LCFR), and Marshfield Clinic Security Health Plan/Marshfield Clinic Research Foundation (MCRF). Figure 26.2 illustrates the CRN's geographic range. The CRN has been described more extensively elsewhere [7]. Collectively, these organizations provide care to diverse population of nearly 11 million individuals, possess extensive automated data, and employ scientists conducting research in the public domain [2, 8].

The CRN member systems include a variety of types of health systems, including group and network HMOs, independent practice associations, consumer-directed self-insured health plans, high-deductible health plans, and point-of-service option plans. This variety of arrangements reflects historical precedents as well as health plans' response to marketing opportunities. Kaiser Permanente represents a national-group-model HMO, as contrasted with the Henry

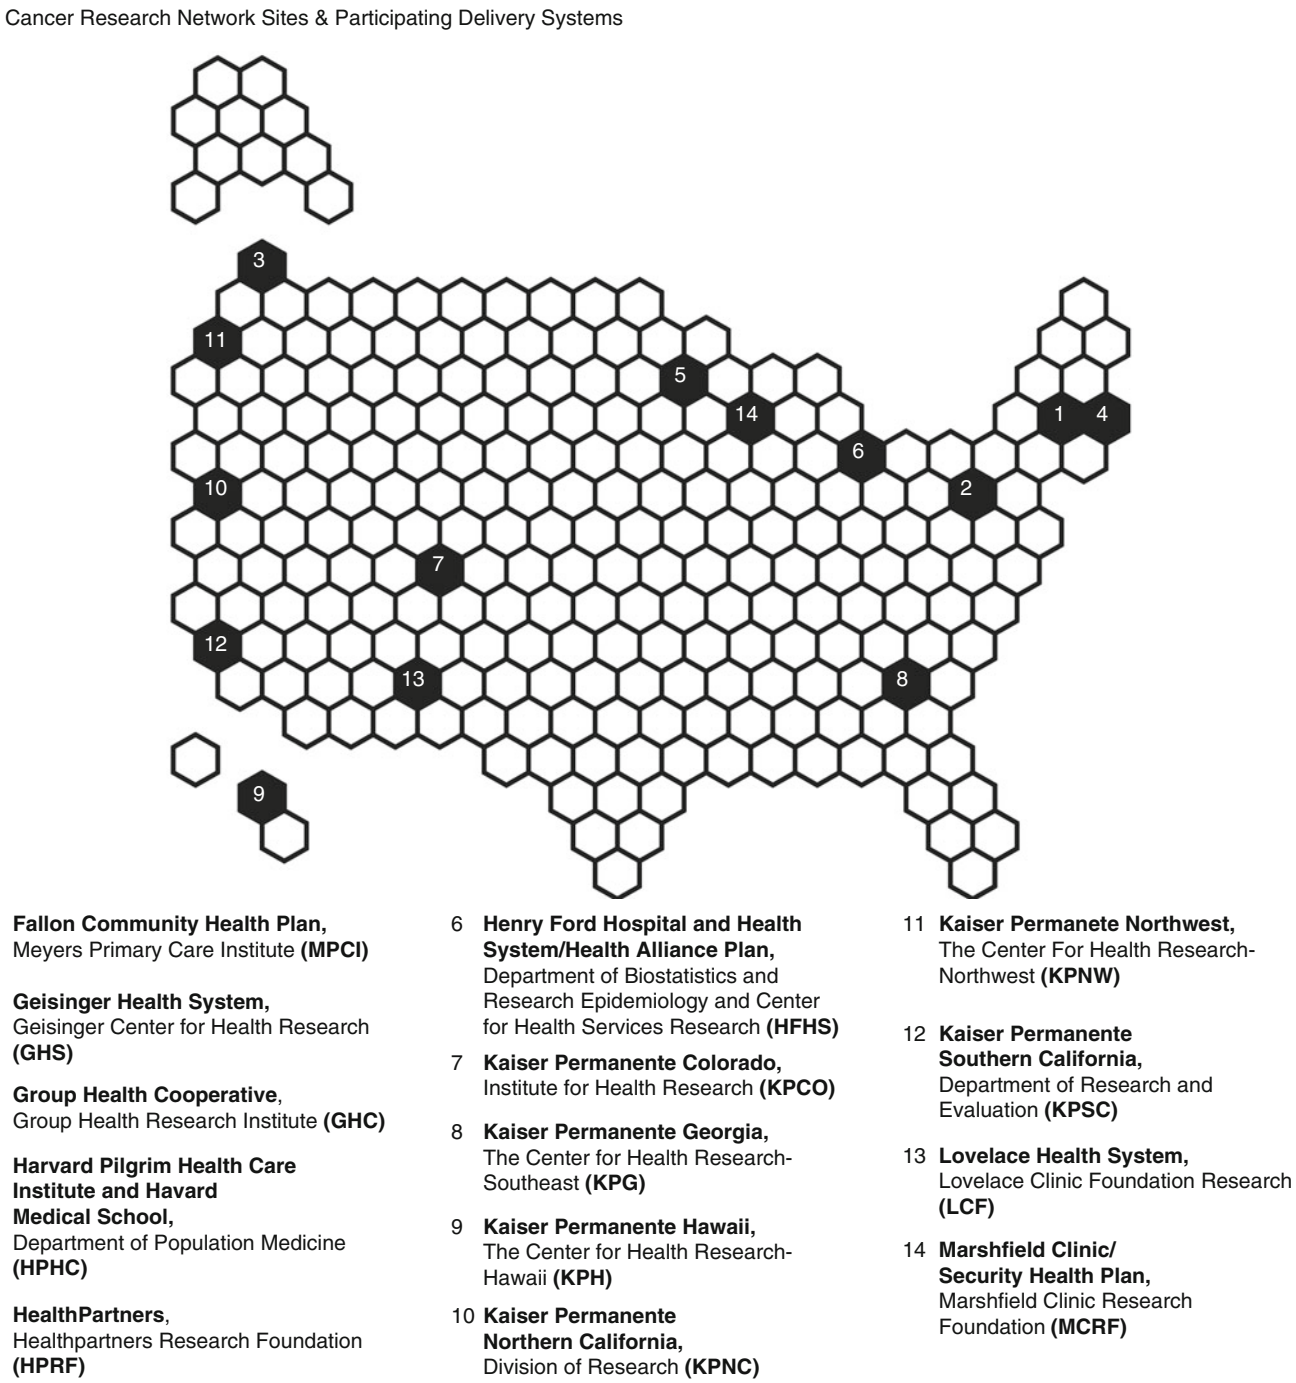

**Fig. 26.2** Sites and participating health care delivery systems that have been part of the CRN

Ford Health System Health Alliance Plan, an HMO insurance product that is offered by the Henry Ford Medical Group alongside its dominant fee-for-service system. CRN health plans offer a variety of benefit options that change with each open enrollment season in response to competitive pressures in the CRN members' markets. This means that consumers in CRN plans face varying out-of-pocket costs for health care services over time, which provides natural experiments on the effects of out-of-pocket costs on access to and use of medical care, including prostate cancer screening services. Clinicians in CRN plans also face varying financial incentives in making treatment decisions for their patients depending on their remuneration/reimbursement systems and the financial status of their health plans and medical groups. Key characteristics of the CRN members are highlighted in Table 26.1.

All systems participating in the CRN have research centers akin to academic departments in that they conduct research in the public domain, rely on external funding to support their studies, and disseminate their results through peer-reviewed publications. Professionally autonomous scientists within the centers have substantial expertise about their health care delivery system's patients, providers, scope of services, facilities, and informatics systems. These scientists lead their own studies and also actively collaborate with scientists from other institutions.

To support collaborative cancer research and help meet the CRN's goals, several systems have formal affiliations with NCI-designated Cancer Centers [8]. Many of the CRN systems also participate in clinical trials through national cooperative groups and the Community Clinical Oncology Program.

## Population Diversity

As of this writing, the systems fully involved in the CRN provide care for approximately 11 million people in the United States [8]. The cumulative population within the CRN has substantial age, gender, socioeconomic, racial, and ethnic diversity. Health plans with Medicaid risk contracts and contracts with state-subsidized health insurance risk pools have greater representation of lower socioeconomic status groups, which tend to have greater racial and ethnic diversity. The CRN cumulative population is similar with regard to gender and age distribution and has a higher portion of racial/ethnic minorities than the USA as a whole [9]. As an example, Table 26.2 shows the high degree of similarity in the distributions of KPNW members and the Portland, Oregon, metropolitan area for 2010. One notable discrepancy is that Hispanics are somewhat underrepresented among KPNW members.

The CRN includes population centers with relatively higher percentages of African Americans (Henry Ford Hospital and Health System, Harvard Pilgrim Health Care, and Kaiser Permanente Georgia), Asian Americans (Kaiser Permanente Hawaii, Kaiser Permanente Northern California, and Kaiser Permanente Southern California), Hispanics (Lovelace Health System, Kaiser Permanente Southern California, Kaiser Permanente Northern California, and Kaiser Permanente Colorado), and rural and underserved rural populations (Geisinger Health System and Marshfield Clinic). Racial, ethnic, and socioeconomic diversity is an important strength of the CRN, which permits studies emphasizing effectiveness research focused on these subpopulations [8]. The CRN has analyzed disparities among these populations in health behaviors, treatments, and outcomes [11–21]. Many HMORN health plans also cover large populations of Medicare/Medicaid and uninsured persons, further enhancing representativeness. While it is true that integrated delivery systems are not present in every community, approximately one in four US residents is enrolled in a health maintenance organization [22]. The CRN also includes settings that share features with integrated delivery settings, such as the Veterans Health Administration and primary care networks organized around academic medical centers. Thus, the CRN provides an opportunity to study the impact of clinical questions for nearly all demographic groups and insurance relationships within a unified health services delivery and health information system framework.

**Table 26.2** Distribution of KPNW membership and Portland, Oregon metropolitan area by race and ethnicity, 2010

| Race/ethnicity | KPNW | Portland |
|---|---|---|
| White alone | 86.17 % | 87.49 % |
| Black alone | 2.94 % | 3.10 % |

## CRN Research

Originally conceived as a "population laboratory" centered in community-based health care systems, the CRN is able to harness these organizations' data and health informatics systems, as well as their clinical staff and enrolled populations to conduct research. This allows for large, multicenter, multidisciplinary observational and intervention [11, 17, 23] research that starts from the foundation of integrated health care delivery systems with defined populations and comprehensive health informatics systems. This unique position allows the CRN to measure complete episodes of the spectrum of cancer control and care in support of studies of prevention [11, 13, 17, 23–30], early detection [5, 16, 21, 30–45], treatment [19–21, 46–55], survivorship [56–60], surveillance [15, 21, 61, 62], secondary preventive care [13, 53–55, 58, 60, 63], and end-of-life care [14]. One study conducted at five CRN sites found the retention rate among survivors for all cancers combined at 1 and 5 years after cancer diagnosis was 96 and 84 %, respectively. This ample proportion of enrollees diagnosed with cancer who remained enrolled and available for evaluation suggests that the CRN is well suited for studies of the quality of care for cancer patients, survivorship, and long-term outcomes [23, 57].

The CRN is also uniquely positioned to conduct multisite studies in geographically diverse community-based settings [5, 19, 20, 28, 29, 31, 37, 38, 40, 48, 52, 54, 55, 58–60, 62–64].

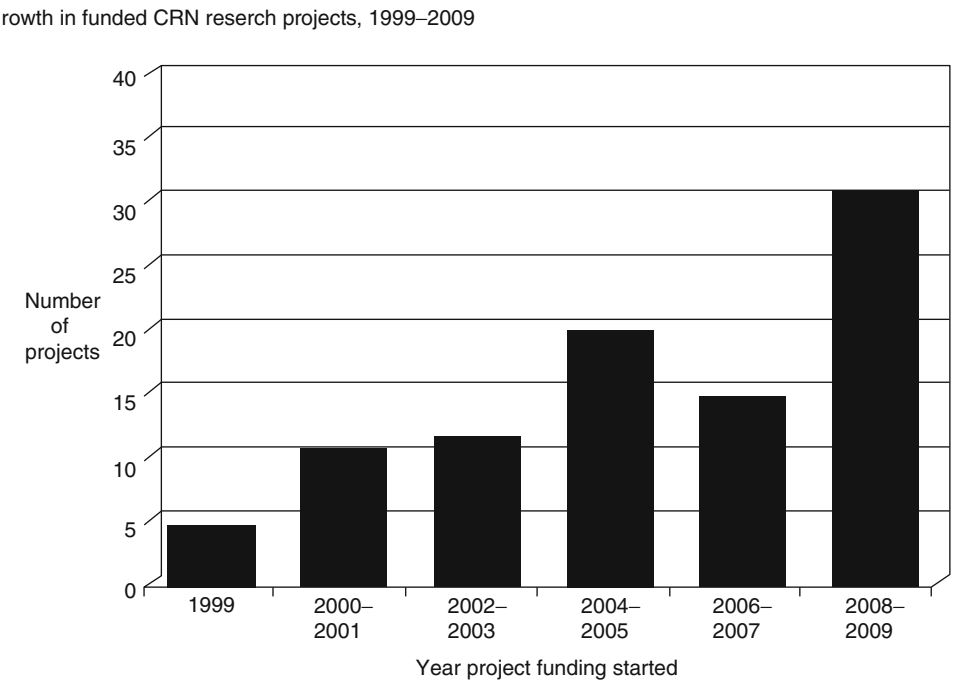

**Fig. 26.3** Growth in funded Cancer Research Network projects, 1999–2009

CRN research focuses on examining the characteristics of patients [14, 46, 59], clinicians [12, 13, 41, 45], and health care systems [37, 64, 65]. The CRN also develops and uses standardized approaches to data collection, data management, and analyses across health systems [66]. Since 1999, the CRN has conducted dozens of joint research projects and published over 200 peer-reviewed papers [8]. The number of funded CRN research projects has increased over time and reflects many successful efforts to address important cancer control questions in the CRN population laboratory (see Fig. 26.3). We hope this chapter stimulates growth in research collaborations focused on prostate cancer.

## CRN Data Systems

### Understanding CRN Data

All health systems have automated databases containing information on membership and utilization claims for outpatient visits, hospitalizations, surgical procedures, imaging, laboratory tests, pharmacy, home health, hospice, and durable medical equipment. These databases feed the Virtual Data Warehouse [66]. All but one health system have implemented an electronic medical record, most using the EpicCare™ system. All CRN research centers have developed procedures for collecting death certificate data for all individuals who have ever been members. Cancer registries and many other types of automated data can be analyzed independently of other information [20, 47, 57, 67, 68] or used in conjunction with other types of data [19, 46, 52, 53, 55, 59, 60, 62, 69–72]. The CRN has experience with many data collection modalities, including data extraction from medical records [5, 18, 19, 21, 24, 27, 29, 31–36, 38, 40, 42, 43, 47–55, 57, 62, 63, 66, 73], natural language processing of chart text [27, 74], online patient surveys [17], surveys of patients by mail [12, 26, 28, 58–60] and phone [37, 46], and physician surveys [12, 13, 41, 45].

The CRN's Virtual Data Warehouse (VDW) comprises a set of data-extraction programs at each CRN system that translate health care delivery system data from unique local data into a common format across the CRN, along with data-quality checks and documentation. The VDW increases study efficiency by facilitating access to data elements commonly used in research studies. VDW data-quality checks include comparisons of relationships among variables across health systems (e.g., inpatient days per 1,000 members by age and gender) to detect aberrant patterns, which in turn define a focus for investigation of potential data entry and processing errors.

Developing the VDW makes it appear that CRN data are relatively easy to use and interpret. It is not possible, however, to capture and summarize all of the information required to fully understand CRN data in the data dictionary. The essential reason for this disparity is that health plans are continually modifying their organizational structures, processes of care, contracting practices, and informatics systems.

An electronic medical record (EMR) system, for example, is updated multiple times annually, and each update incorporates new variables, tables, and functions and may eliminate some variables. The data systems reflect the dynamic nature of health care—from new technologies (new drugs, new surgical techniques, new imaging techniques, new genetic tests, new imaging modalities) to cost containment efforts (changes in health insurance eligibility, premium increases, changes in benefits, changes in facility staffing).

A major asset of the CRN is the sophisticated medical informatics systems supported by the health plans. These systems convey a comparative advantage for conducting clinical trials and biospecimen research, enable epidemiologic and health services research, and support translational research. With approval of health systems and their IRBs, research can be conducted using limited data sets without individual patient consent when projects are judged by the IRB to carry minimal risk to human subjects. The key components of the data systems are described below.

### Tumor Registries

Cancer registries are in place at most of the CRN's participating systems. CRN health systems have established procedures to capture new cancer diagnoses and assemble the data required by state tumor registries. Nearly all CRN health systems either operate or have access to a SEER (http://seer.cancer.gov/), State, or accredited internal tumor registry that covers all their enrolled members. Accredited tumor registries represent the preferred procedure for identifying cancer cases due to standardized definitions and medical record abstraction procedures. The National Association of Accredited Cancer Registries conducts regular accreditation reviews to enforce high data-quality standards (http://www.naaccr.org/). Tumor registries provide rigorous outcome measures for prostate cancer prevention and screening research (e.g., was an elevated PSA screening test followed by a new tumor registry record), as well as rigorous case definitions for clinical trials and epidemiologic, genomic, and health services research. Prostate cancer diagnoses extracted from claims and encounter information systems do not represent research-quality data because they are influenced by payment rules, use billing clerks rather than tumor registrars to extract data from patient charts, and are not verified by tissue examinations. Ensuring comprehensive cancer reporting for CRN populations is complicated by outside and patient self-referrals related to cancers diagnosed by non-HMO providers and cancers diagnosed while not an active HMO enrollee. Most tumor registries will not release identified data on tumors not reported by the HMO. However, comparison of tumor data for KP Hawaii with the Hawaii SEER Tumor Registry for the period 2000–2008 revealed that only 1.22 % of KPH members had tumors that were not identified in the KPH tumor registry. This reveals the high membership stability among cancer patients in HMOs.

### Tumor Specimen Repositories

CRN oncology departments maintain tumor specimen repositories (paraffin blocks and tissue slides) for legal and research purposes. These repositories are indexed by tissue accession numbers, which are linked to patient-identifying information. The KPNW tissue repository has been operating for more than 30 years. These samples deteriorate over time and some samples are used up by various research studies. For the future, the CRN needs to determine the feasibility of converting hard-copy tumor repository accession lists into searchable relational databases.

### Enrollment and Demographics Information Systems

CRN health systems tie health insurance and health care delivery. As such, they have enrollment and eligibility information systems that provide comprehensive enumeration of every individual who is eligible (e.g., at risk) for covered services. This enables population-based epidemiologic studies (incidence of prostate cancer) as well as studies of barriers to access and financial incentives related to copayments and travel time to care facilities for prostate cancer screening, treatment, and survivorship care. Residential address data enables geocoding to link census data and health care system attributes to describe the neighborhood context of prostate cancer patients. One potential research question is whether neighborhood housing and individual housing status is associated with prostate cancer risk, age at diagnosis, and tumor aggressiveness, operating through mediating factors such as diet, physical activity, and genetic polymorphisms and whether these relationships differ by race (prostate cancer is much more prevalent among African-American men than White men).

### Encounter and Claims Data Systems

Encounter data systems describe the activities of hospitals, emergency departments, and medical offices. Claims data systems describe the professionals' and facilities' billing processes and insurer payments for medical care services. These data systems support measurement of prostate-related diagnoses, procedures, utilization events, and medical care expenses. The rules for assigning diagnoses to insurance claims are not the same as for tumor registries. For example, diagnoses on claims for imaging services can represent the reason for ordering the imaging service not the disease detected by the image; hence, diagnoses on imaging and laboratory procedure claims represent unknown mixes of rule-out diagnoses.

### Electronic Medical Records Systems

All CRN health systems have installed some form of an electronic medical record system (EMRs), with the most common vendor being EPIC, Inc. (Madison, WI). All sites are working to obtain meaningful use certification for their EMR systems from the DHHS Office of the National Coordinator for Health Information Technology as of this writing [75]. CRN research centers are working to develop data-extraction programs to collect expanded information on medical care processes from EMRs. For cancer research, perhaps the most important advance is development of medical oncology EMR interfaces that provide detailed information on chemotherapy protocols and actual dosages delivered to patients (as compared to supplies delivered from the oncology pharmacy). CRN sites have started work on extracting and standardizing chemotherapy treatment data. One potential research opportunity is evaluating whether oncology EMR systems lead to more standardization of chemotherapy regimens for prostate cancers.

### Laboratory Information Systems

Data on PSA test results are required for research on prostate cancer screening programs. The CRN has developed a standardized Laboratory Results data file that includes PSA testing results. These data are also required for research on prostate cancer recurrence. Laboratory tests include genetic testing procedures. Unfortunately, for research purposes, the technology of genetic/genomic testing is advancing so rapidly that the Health Care Procedure Coding Systems (HCPCS) listing used by CMS cannot keep up. The newest tests carry "miscellaneous" procedure codes until CMS updates the HCPCS to include these tests, which is unfortunately a multiyear lag. This is relevant for future research on introduction of tests to identify genetic markers of prostate cancer risks.

### Vital Signs

EMR systems encode vital signs data routinely collected in ambulatory care settings—weight, height, systolic and diastolic blood pressure, respiration, and body temperature. These data are useful for identifying patients with uncontrolled hypertension, obesity (body mass index), infections, and sudden unexplained weight loss. As hospitals are converted to EMR systems, vital signs will be available for inpatients as well.

### Medication Dispensing Information Systems

Most CRN health systems operate internal pharmacies as a means of managing quality of pharmaceutical services and care and of controlling total expenses for prescription drug benefits. Internal pharmacy departments, staffed with clinical pharmacologists, drug information specialists (PharmDs), and clinical pharmacists, manage the health system's formulary, negotiate medication purchases with drug manufacturers and wholesalers, develop evidence-based prescribing guidelines in collaboration with physicians, and interact with patients at the point of dispensing. Drug dispensing information systems provide data on all outpatient medications dispensed to prostate cancer patients. Such medication records are needed to assess care processes for these patients, including oral chemotherapy agents, oral medications to treat the side effects of chemotherapies and radiotherapies, and opiates for management of cancer pain. In the context of prostate cancer research, medication systems provide measures of androgen deprivation therapy (ADT) so that relationships of ADT to bone fractures, cardiovascular disease, and diabetes can be studied. Medication systems also support pharmacoepidemiologic studies of the relationships between long-term exposures to selected drugs and prostate cancer risk.

### Infusion Information Systems

A new informatics development in the CRN is infusion information systems that track outpatient chemotherapy protocols and sessions. This EMR module allows oncologists to preload chemotherapy protocols into an online directory, select a protocol for a patient, tailor it to the patient's clinical needs, and track actual timing and quantities of mediations administered. The infusion module supports the entire infusion team and their work flow—oncologist (writing medication orders), pharmacist (setting up infusion bags), and nurse (administering infusions). Kaiser Permanente has preloaded over 600 chemotherapy infusion protocols for oncology, rheumatology, and gastroenterology. CRN researchers have developed a standardized extract of the infusion data tables for research purposes. One goal is to improve use of evidence-based protocols but also to enable research on individual differences among patients in their toxic and allergic reactions to a prescribed protocol and the modification strategies implemented by medical oncologists.

### Imaging Information Systems

Data on imaging procedures—x-rays, ultrasound, computed tomography, magnetic resonance imaging, positron emission tomography, and other nuclear imaging—are needed for research on prostate cancer diagnostic work-ups and surveillance for progression and metastases. Patients who show chemical recurrence through elevated PSA values after initial cancer treatment are usually scanned to identify the specific locations of metastatic tumors, which is information required to formulate a treatment plan. The CRN has developed standardized data files to identify the performance of all imaging procedures. Future research can access digital imaging libraries to reinterpret these images and examine clinical decision criteria for interpreting patterns as cancer, metastatic lesions, or other abnormal tissue structures.

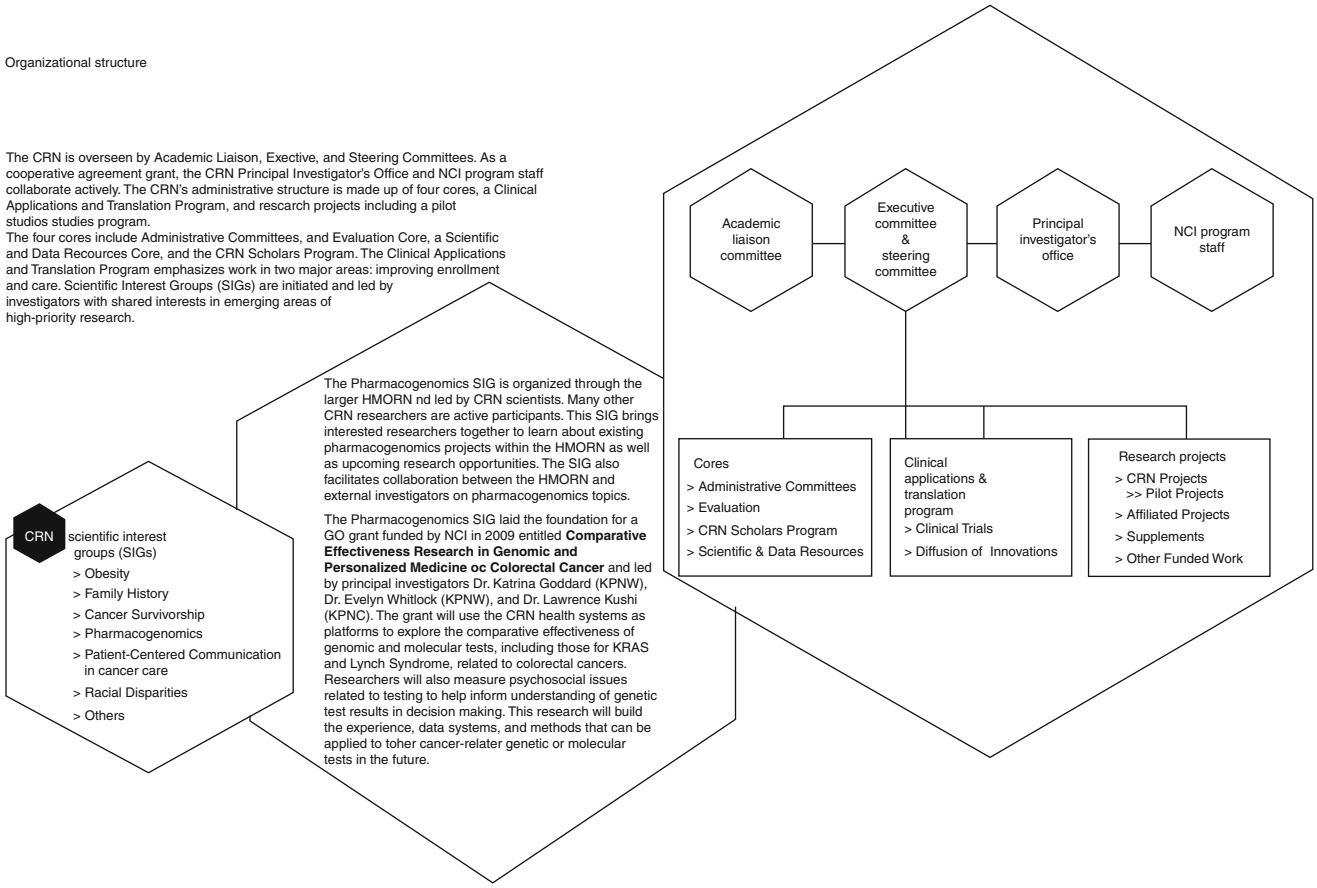

**Fig. 26.4** Organizational structure of the Cancer Research Network

### Home Health, Hospice, Palliative Care, and DME Information Systems

Prostate cancers are diagnosed throughout the last years of life. Hence, some patients will be institutionalized in long-term care facilities, terminally ill from another disease, or very frail with multiple chronic diseases. The CRN data systems enable tracking prostate cancer patients who require long-term and end-of-life care. A study of hospice use in CRN sites among men who were dying of prostate cancer revealed that the rate of hospice use exceeded 80 %, but the average length of stay in hospice was only 5 weeks [76].

## CRN Governance Structure

We provide a brief description of the CRN governance structure to illustrate the overall infrastructure that has been established to facilitate cancer research. This infrastructure supports collaborative research across multiple disciplines and CRN systems and other institutions and provides a foundation for future studies. A Steering Committee with representation from the NCI and each health system provides scientific and administrative leadership across the CRN. Four cores provide infrastructure. The Evaluation Core conducts an annual evaluation of CRN-wide and study-specific processes and productivity [77]. The Administrative Core includes three committees: a Communications and Collaboration Committee facilitates information exchange across systems and studies, and with researchers, advocates, and others outside the CRN; a New Proposals Committee ensures new proposals avoid overlap, are scientifically sound, and involve appropriate collaborators; and a Publications Committee encourages publications and presentations, advises studies on writing strategies and authorship issues, and verifies that submitted publications appropriately describe the CRN. The Scientific and Data Resources Core includes expertise in measurement, economics, and data and maintains the CRN's Virtual Data Warehouse [66]. The Research Training Core, known as the CRN Scholars Program, is designed to nurture and develop new talent through a 20-month training activity that helps junior investigators develop research independence [8]. Figure 26.4 provides a visual depiction of the CRN's organizational structure. This structure will likely change in response to the most recent NCI RFA issued to continue CRN funding.

## Developing Collaborations with the CRN

Scientists from all institutional affiliations are welcome to approach the CRN with ideas and are encouraged to allow ample time to establish collaborative relationships and design rigorous studies. Initial steps in this process include assessing whether an idea is well suited to the CRN, forming a partnership with at least one CRN-based scientist and submitting a concept proposal to the CRN New Proposals Committee. The process for external researchers who are interested in collaborating with the CRN is outlined in Fig. 26.5.

Developing collaborations with the CRN should begin early in the stages of formulating the research questions and specific aims. Inviting CRN scientists and sites to participate after funding has been obtained for a study is more likely to result in mutual disappointment because the project budget will not be adequate to cover the research costs. External investigators are not well-informed about the procedures and costs of conducting research in CRN environments. Early discussions of research questions enable full discovery of the needs for all parties to the collaboration as well as mutual understanding of the respective research priorities. The research questions that have the highest priority for health systems often diverge from the priorities developed by NIH. Thus, collaborations between academic and CRN scientists enable identification of translational research opportunities—why do observed patterns of practice diverge from current evidence standards; which evidence gaps carry the highest priority for practicing clinicians; which evidence gaps have the greatest impact on patient well-being.

## Nonconsented Versus Consented Data

Potential collaborators should be aware of a crucial distinction regarding properties of CRN data. Data that has been collected under express written consent from the patients included in the dataset are governed by the IRB-approved consent forms. As an example, it is possible to create public use microdata files on members of CRN health plans if each person contained in the files (or their power of attorney) has signed a consent form permitting use of their health information. However, one of the key strategic advantages of the CRN is the ability to use patient-level clinical data for legitimate minimal-risk research purposes when appropriate permissions have been obtained from IRBs and health plan officials. From a health plan perspective, patient-level data are proprietary because their commercial success depends on protecting their reputations. Therefore, access to CRN microdata requires a written research proposal (preferably peer reviewed), IRB approval, compliance with HIPAA regulations regarding PHI and data security, and approval from the participating health plans. All CRN members have well-established policies and procedures for obtaining these permissions. This is one reason we strongly recommend that CRN scientists be included on the investigator team of any collaborative research project.

## Human Subjects' Protections

The IRB system is a critical, but currently burdensome, part of the infrastructure to perform multicenter studies. Local IRBs feel simultaneous demands to review more clinical and translational research, but the requirements of federal regulations were not designed for multicenter studies. Several studies have looked at the problems arising from the review of multicenter projects by multiple IRBs. Greene and Geiger's review of challenges and strategies for IRB review of multicenter studies identified 46 key bibliographic sources for the review, including 40 peer-reviewed articles and 6 reports from commissions or advisory groups on this topic [78]. Recurring themes in the literature include delays and inconsistencies associated with multicenter reviews that result in questionable benefits but extract high-opportunity costs in terms of knowledge, time, and money [79]. To enable more efficient multisite research, the sites in the CRN recently adopted a model of facilitated IRB review, in which it is possible for a single site's IRB to serve as the IRB of record, and other participating study sites' IRBs can elect to cede to this "lead" IRB. The CRN is working to educate IRB chairs and members, as well as CRN scientists on the availability and desirability of the delegated IRB model.

## Clinical Trials

Nearly all CRN sites support cancer clinical trials research, and most are affiliated with national cancer clinical trials groups such as the Southwest Oncology Group, the Community Clinical Oncology Program, the Gynecologic Oncology Group, and the National Surgical Adjuvant Breast and Bowel Project. This means the presence of the following elements: (1) a formal administrative process for reviewing proposed clinical trial protocols for acceptability and implementability in the local setting; (2) a formal administrative process for obtaining IRB and HIPAA approvals for approved protocols; (3) electronic data systems covering the health plan membership to identify persons who are presumptively eligible for a specified protocol, which supports feasibility and desirability evaluations and enables direct recruitment of these persons, thereby reducing the costs of screening patients for trial eligibility; (4) trained research support staff to implement trial protocols, improve recruitment yields and

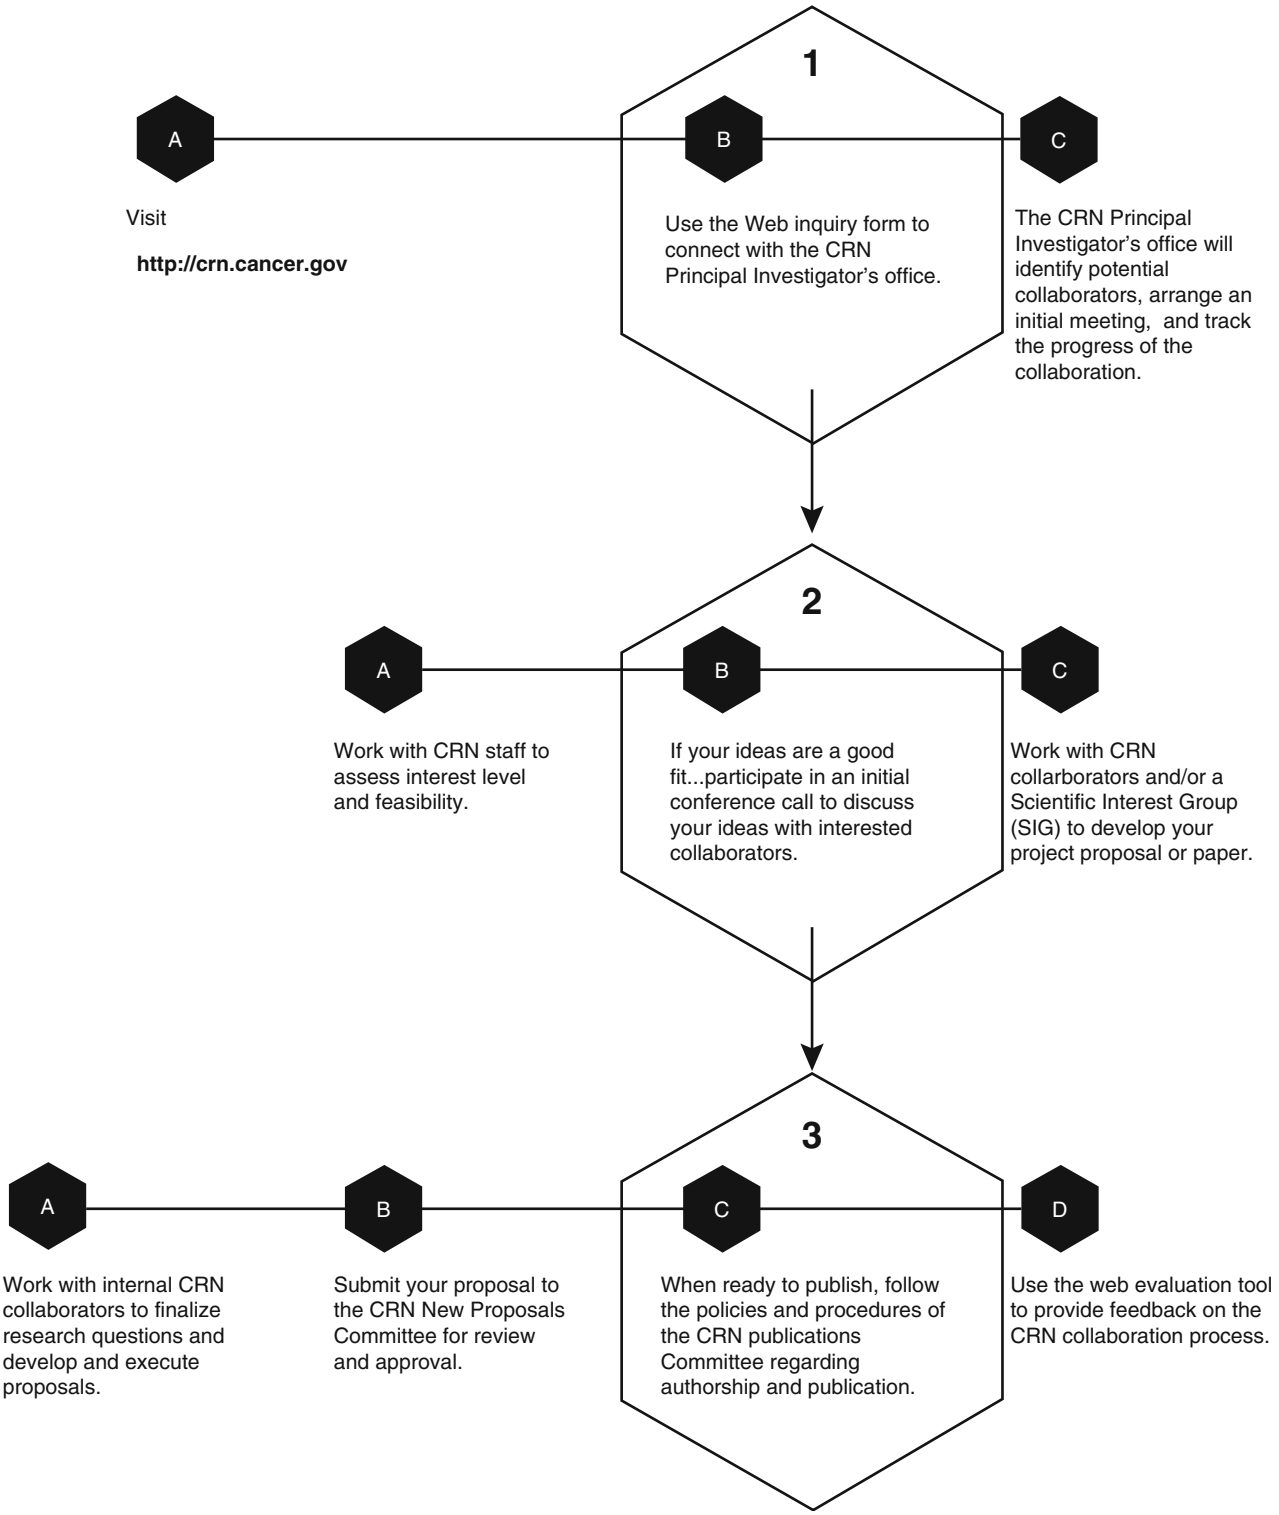

**Fig. 26.5** Avenues for developing collaborations with the Cancer Research Network

protocol fidelity, and reduce IRB violations; (5) clinical and utilization data systems to support identification of key clinical events post randomization; (6) expert data analysts to extract electronic clinical and utilization data on trial subjects from the EMR and other data sources; (7) oncology specialty pharmacies to manage blinding and prepare experimental medications; (8) mechanisms for communicating with all clinic staff across the health plan about the opening

of a new clinical trial and its target recruitment population; and (9) biostatisticians to consult on data safety and monitoring questions. Compared to advertising in the mass media, CRN members are able to conduct direct personal recruitment strategies—letters, e-mail, and telephone calls to health plan members from health plan research staff. Participation rates are substantially improved when potential subjects are contacted by their own health plan. Moreover, administrative approval of a trial protocol means that the health plan's clinical staff and managers are supportive of the trial.

## Practical Clinical Trials

Per regulations of the Food and Drug Administration, testing safety and efficacy of new pharmaceutical agents requires placebo-controlled clinical trials in order to obtain nonconfounded measures of rates of adverse events and poor outcomes. Usual-care controlled clinical trials are needed to answer the question of whether a new pharmaceutical agent performs better and/or has a lower risk profile than existing approved medications. One of the key features of controlled clinical trials is adherence to the trial protocol, for both administering the therapies and measuring the outcomes and adverse effects. Clinical trials impose strong controls on care processes that are not present in routing clinical care. Hence, outcomes for a usual-care control group are often better than regular nonresearch care.

The concept of practical clinical trials has been formulated to describe trial designs that are more flexible than the traditional rigidly controlled approach but still incorporate randomization [80–82]. One type of practical trial design is to recruit patients who are willing to be randomized to alternative initial treatment protocols, but let them cross over to another treatment if the one they are randomized to is not working to their satisfaction. For prostate cancer, men with early stage disease could agree to be randomized to alternative first-round treatments—prostatectomy, brachytherapy, external beam radiation, or cryotherapy. Randomization is a critical element here because it removes the problem of selection bias in treatment choice—unmeasured factors influence patient's choice of treatment and confound the attribution of outcome to the treatment.

## Comparative Effectiveness Research

In clinical scenarios where inadequate evidence is available on the relative effectiveness or cost-effectiveness of competing treatments and insufficient numbers of patients are willing to be randomized to competing treatments that are safe and effective, a tool for filling in this evidence gap is retrospective comparative effectiveness research (CER) using large samples of patients on whom complete clinical and utilization data are readily available. The key to CER is identifying large samples of patients who could have had equipoise between alternative treatments for their disease and for whom we have good data on pertinent attributes on which they vary. Equal preference among alternative treatments can arise when there is positive evidence of equivalence, when practice guidelines give equal weight to more than one treatment option, when there is no evidence to differentiate among treatments, or when variations in preferences for one treatment over others do not appear to result in different health outcomes. Statistical models can be estimated in an attempt to approximate randomization by controlling for measurable differences between the treatment groups. High-dimensional propensity scoring models are one statistical technique to reduce the effects of unmeasured factors that create selection bias with purposive choice of therapy [83]. The CRN, with its relatively large numbers of prostate cancer patients and strong informatics resources, is well suited to conduct retrospective comparative effectiveness studies of alternative screening and treatment strategies for prostate cancer.

### Conclusions

Nonprofit integrated health care delivery systems committed to public-domain research represent a highly strategic foundation for multisite collaborative research on prostate cancer. Their defined populations, sophisticated health informatics systems, and organized research centers are sources of efficiencies in prostate cancer clinical trials—targeting patients most likely to be eligible for a trial, reducing demands for primary data collection, and enabling strong fidelity to trial protocols. Defined populations with medical homes provide advantages to studies of prostate cancer screening—who is never screened, who is screened too frequently, and what happens to patients receiving false-positive and false-negative screening results? EMRs with embedded clinical decision support systems represent a means for rapid translation of new evidence into clinical practice as well as a means for identifying providers who are most resistant to drop practices demonstrated to be unsafe, ineffective, or too costly. Moreover, patients with higher continuity of primary care with a specific provider represent potential early adopters of improved cancer screening practices. In an insured population with a high degree of primary care access, continuity with a specific primary care physician was associated with greater likelihood of PSA testing [36]. CRN oncologists are interested in offering access to experimental treatments for prostate cancer patients who are eligible for such studies. EMRs and VDWs enable closer oversight of virtually every clinical activity, which eliminates medicine as a cottage industry (aka independent professional practice) and brings the health care

system under scientific controls. Health informatics also generates a synergy between research and clinical practice (the learning health care organization) and makes large-scale genomics research and comparative effectiveness research and cost-effectiveness analysis possible. A major challenge to clinical research is that only about 7 % of adult cancer patients in the CRN participate in clinical trials [84]. This represents an opportunity for developing and testing interventions to inform prostate cancer patients and their families about the role of clinical research and about how to become better prepared to deal with opportunities to participate in clinical trials should they arise.

# Screening for Prostate Cancer

27

David R. Yates and John B. Anderson

## Introduction

In 2010, 217,730 men will have been diagnosed with prostate cancer (PCa) in the United States of America (USA), and around 32,730 will have died from the disease [1]. Depending on the extent of prostate-specific antigen (PSA) testing, similar ratios of incidence and mortality will be seen throughout Europe; PCa is the second commonest cause of death from cancer in men in the UK, and in the USA, it is estimated that a man aged 40 years has a 16 % chance of being diagnosed and a 3 % lifetime chance of dying from PCa [2]. Once diagnosed, the chance of a man dying from his cancer rather than other causes depends not only on the biological aggressiveness of the tumor and the age and comorbidity of the individual in question but crucially on the stage of the disease at diagnosis and, by definition, how early it has been detected. Screening for disease to allow early detection is now an integral part of modern medicine, and screening for breast, cervical, and colorectal cancer is now standard practice in some countries. Although PCa is an equally important health problem, PSA testing to screen for the disease, allowing earlier detection and thereby reducing the chance of a man dying from PCa, remains controversial with the medical community divided on whether this approach causes more harm than good.

## The Principles of Screening

### Definitions

Cancer screening aims to identify preclinical and asymptomatic cases of a disease in a population at risk rather than waiting to make a diagnosis once a patient presents at a later stage with signs and symptoms. The rationale behind screening is simple: to detect cancer at an early stage when it is still curable. Population-based screening programs aim to reduce cancer mortality and morbidity by detecting cancer at an early stage, on the assumption that earlier diagnosis and treatment will potentially improve prognosis and survival. The criteria against which any screening program is designed or critically assessed originate from the 1968 World Health Organization (WHO) document written by Wilson and Jungner [3], while the United Kingdom National Screening Committee has recently produced comprehensive standards to assess the efficacy and effectiveness of any screening program (www.screening.nhs.uk). Screening for cancer may take place in a variety of ways ranging from mass screening of a general population, through more selective screening by targeting "high-risk" populations, opportunistic screening which is incorporated as part of a medical consultation for other reasons, and simple case finding.

## Screening for Prostate Cancer

### General

As with any cancer screening program, the primary goal of screening for PCa is to reduce PCa mortality. Other potential benefits may be prolongation of life, prevention of advanced disease with less morbidity, and patient reassurance if the test is truly negative. Against these advantages, the often-cited negative criticisms of PSA-based screening which include too many unnecessary biopsies, an increased detection rate of "insignificant" cancer, dilemmas over active treatment versus surveillance, uncertain effects on morbidity and mortality, unclear cost-effectiveness, and psychological harm have to be balanced.

Screening for PCa has been debated for years and has divided opinion within the international urological community and the regulatory bodies of the USA, UK, and Europe. This is most obviously seen in the advocacy for PSA-based screening in the USA [4, 5], but not in the UK or Europe [6]. In the USA, 87 % of male physicians over the age of 50,

21 % below 50, and 98 % of male urologists report having had their PSA measured [7]. It is estimated that >55 % of American men over 50 years of age undergo annual PSA testing, while up to 75 % have been tested at some point [8]. This compares to an overall annual rate of only 6 % in asymptomatic men aged 45–84 in the UK [9].

The assumption that underpins the potential introduction of PCa screening is that PCa can be diagnosed at an early stage by PSA testing and prostate biopsy, and patients with organ-confined PCa can be cured of their cancer by radical surgery or radiotherapy. Although serum PSA estimation has established itself as the primary screening test for PCa [10], the test is prostate specific, not disease specific, and therefore its operating characteristics as a PCa marker are not robust [11]. Nevertheless, the widespread use of PSA to diagnose PCa has resulted in a significant stage migration of the disease. Before the widespread introduction of PSA testing, only 27 % of newly diagnosed PCa cases were clinically localized. Now, with investigation of men who have a marginally elevated PSA (2–10 ng/ml) and normal DRE, the majority of cases diagnosed today (70–80 %) are confined to the prostate [12].

A big challenge to the assumption that PSA screening might reduce the PCa mortality rate is the heterogeneous behavior of this cancer. Although a man has been estimated to have a 10–20 % (1 in 6) risk of developing clinical PCa during his lifetime [2], the chance that he may harbor the disease may be as high as 60–70 % [13]. Furthermore, a man's lifetime risk of dying from PCa is only around 3–4 % (1 in 30) [2]. This observation gives substance to the often-quoted saying "men die with PCa, not of it." Autopsy studies of men who have died of non-cancer causes have been found to have a very high prevalence of cancer within the prostate with pathologists diagnosing disease in 3–43 % of men in their 40s, 14–70 % of men in their 60s, and 31–83 % of men in their 70s [14]. Since only 1 in 30 of these men will die from PCa, one can understand the complexity of early detection and screening for PCa. A credible screening program will need to provide evidence that the benefits of screening outweigh the main disadvantages of overdiagnosis and overtreatment (and its potential complications). Further unresolved controversies in PCa screening include the age range within which screening should take place, how often to screen (screening interval), the PSA threshold to prompt prostate biopsy, the development of risk-based strategies for early detection, and ideally the ability to differentiate "insignificant" PCa from more aggressive life-threatening disease.

## National Guidelines on PCa Screening

Evidence-based medicine together with guidelines and protocols is a key driver in the contemporary management of many health conditions including PCa. It is therefore interesting to see that the division of opinion among the urological community is reflected in the most recent viewpoints and guidance offered by the key regulatory bodies in the USA, UK, and Europe.

### American Urological Association (AUA)

The AUA published a "PSA best practice statement" in 2009 which remains in favor of PSA screening [4]. This was an update to the previous statement in 2000 but with two notable differences. Firstly, the 2009 statement abandoned the AUA's former position that "a single threshold value of PSA should prompt a prostate biopsy." The decision to proceed with a biopsy should now be a matter of individual choice based primarily on PSA and DRE results but also taking into account other factors that potentially increase an individual's risk of PCa, e.g., free/total PSA ratio, age, PSA velocity, PSA density, family history, race, comorbidities, and prior biopsy history. Secondly, the age at which a baseline PSA estimation is recommended has been reduced from 50 years to 40.

### National Comprehensive Cancer Network (NCCN), USA

The NCCN annually review online guidelines (www.NCCN.org) which have been developed for men who are considering PCa screening. Their guideline recommends offering a baseline PSA and DRE at the age of 50 along with information on the risks and benefits of screening. These are one of the few guidelines that have incorporated PSA kinetics (PSAV and % free PSA) into the various algorithms to aid in the decision-making process for men with a PSA 2.5–4 ng/ml or for men with a PSA >4 ng/ml but with significant comorbidity.

### American Cancer Society (ACS)

The 2010 ACS guidelines do not support routine population PCa screening for all men because "the benefits are unclear or unproven." Instead, it recommends that asymptomatic men over the age of 50 who have at least a 10-year life expectancy should have an opportunity to make an informed decision about PSA testing, together with their health care provider, after they have received information about the uncertainties, risks, and potential benefits of the test. They do recommend that men in higher-risk groups should be given this information before the age of 50 years [5].

### US Preventative Service Task Force (USPSTF), USA

In 2008, the USPSTF concluded that "current evidence is insufficient to assess the balance of benefits and harms of screening for prostate cancer in men younger than age

75 years." They are explicit that one should "not screen for prostate cancer in men age 75 years or older," which differs from the AUA and ACS guidance [15].

### European Association of Urology (EAU)

Following the publication of the European Randomized Study of Screening for Prostate Cancer (ERSPC) [16], the EAU produced a "position statement" where they concluded that "current data is insufficient to recommend adoption of population screening because of the significant overtreatment that would occur" [6]. This view is echoed in the latest EAU guidelines on prostate cancer which recommend that, in the absence of population screening, early detection (opportunistic screening) should be offered to the well-informed man aware of the risks and benefits of screening and individual risk assessment [17].

### United Kingdom National Screening Committee (UKNSC)

The UKNSC have defined 22 criteria for PCa screening largely based on the original WHO criteria (www.screening.nhs.uk) and recently published a document which concluded "the harms from screening using PSA are currently likely to outweigh the benefits and in this circumstance screening for PCa cannot be justified on current evidence" [18].

## PCa Screening Tools and Methods

### Digital Rectal Examination (DRE)

The sensitivity of DRE for diagnosing prostate cancer depends both on the stage of the tumor and the experience of the examiner. While DRE is of limited value in detecting tumors confined to the prostate gland, it remains a useful adjunct to PSA testing in identifying higher-risk cancer when the PSA is low. Twenty percent (20 %) of tumors detected by DRE when the PSA is less than 2 ng/ml are not organ confined [19]. Since the positive predictive value (PPV) of an abnormal DRE can be as high as 50 % and DRE screening tends to detect non-organ-confined disease not identified by PSA screening, the opportunity for cure with DRE screening alone however is limited.

### PSA and PSA Thresholds

PSA expression is prostate specific rather than PCa specific, and this makes it a less than ideal screening marker for PCa [20]. Although PSA lacks sensitivity and specificity for PCa, these parameters will vary depending on the threshold level employed to recommend a prostate biopsy. Furthermore, we are aware of the influence of increasing age on the development of benign prostatic hyperplasia which will raise the baseline PSA level, and this has led to age-specific reference ranges for PSA [21].

Traditionally, a PSA >4 ng/ml has been used as a common threshold above which a prostate biopsy should be considered since approximately 70 % of cancers will be detected using this cutoff. Up to 30 % of men with a PSA in the range 4–10 ng/ml will have PCa on biopsy [22]. However, Thompson et al. [11] have reported a high prevalence of PCa among men with a PSA ≤4 ng/ml and showed that at these levels many men can harbor clinically significant disease (in men with PSA 3.1–4.0 ng/ml, 26.9 % had PCa, and of these, 25 % were high-grade cancers). It is probably more useful, therefore, to consider a continuum of risk attributed to PSA values and not a "safe" value below which a man can be reassured he does not have PCa.

Altering the PSA thresholds to recommend prostate biopsies will obviously affect the sensitivity and specificity of PSA to detect PCa. Lowering the PSA threshold will lead to an increased number of prostate biopsies, a consequent increase in sensitivity (more cancers detected), but a decrease in specificity and PPV (more negative biopsies) [23]. Holmstrom et al. [24] have evaluated the validity of PSA as a screening test in order to see whether it could attain the standard necessary for large-scale population screening. They reviewed the PSA levels, some 7 years before diagnosis, from 540 men with PCa identified from their regional cancer registry and compared them with 1,034 age-matched noncancer controls. The area under the curve (AUC) for PSA was 0.84 (95 % CI 0.82–0.86), and the sensitivity of PSA to diagnose cancer at thresholds of 3, 4, and 5 ng/ml was 59, 44, and 33 %, respectively. The specificity at these thresholds was 87, 92, and 95 %. The positive likelihood ratios (+LR) for the same thresholds were 4.5, 5.5, and 6.4, respectively (a + LR >10 is needed to "rule in" disease), while the negative LRs (–LR) were 0.47, 0.61, and 0.7. (a – LR <0.1 is needed to "rule out" disease). PSA levels <1 ng/ml virtually ruled out a PCa diagnosis during follow-up, with a – LR of 0.09. The authors concluded that no single cutoff value for PSA reached a likelihood ratio formally required for a screening test.

### Age Range for Screening

A key criterion for any screening program is to define the population who are likely to benefit from screening, and therefore, we need to clarify the age at which to commence screening and the age at which to stop. While it is difficult to be prescriptive about the upper age limit of screening, the ACS have recommended men need a life expectancy of at

least 10 years if they are to benefit from screening and the upper age limit in most screening trials is 80 years.

With regard to the lower age limit for PCa screening, the current AUA guidelines have recently lowered the age threshold from 50 to 40 for men at average risk of PCa. Among men in their 40s and 50s, a baseline PSA above the median value for their age is a stronger predictor of future risk of PCa than family history or ethnicity. Studies have shown there is a significant association between baseline PSA at a younger age (40s or 50s) and the subsequent risk of PCa diagnosis, ranging from a threefold to a 7.6-fold increase, with the median PSA levels (ng/ml) for men in their 40s, 50s, 60s, and 70s being 0.7, 0.9, 1.2, and 1.5, respectively [25]. Vickers et al. [26] have examined the association of a single baseline PSA taken at age 60 in 1,162 men with PCa. The PSA level at 60 was associated with the risk of a clinical PCa diagnosis (AUC 0.76, 95 % CI 0.71–0.81, $p<0.001$), metastatic disease (AUC 0.86, 95 % CI 0.79–0.92, $p<0.001$), and death from PCa (AUC 0.90, 95 % CI 0.84–0.96, $p<0.001$) by the age of 85 years. Using a PSA cutoff of 2 ng/ml, the odds ratio (OR) for a clinical diagnosis of PCa was 13 (95 % CI 5.7–29), for metastatic disease 17 (5.2–57), and for death from PCa 26 (6.2–113). If the PSA is <1 ng/ml at 60, there is only a 0.5 and 0.2 % probability of developing metastatic disease and dying of PCa, respectively, by the age of 85. The authors concluded that if at the age of 60 years, a man's PSA is <1 ng/ml, then there is little need to screen any further. However, if the PSA level is >2 ng/ml, further regular PSA testing may be appropriate, while for men with a PSA between 1 and 2 ng/ml, an informed discussion about the relative merits of screening with PSA will allow an individual to make an informed decision according to his needs and wishes. Taking this approach, up to 50 % of men at age 60 can be reassured and excluded from long-term follow-up.

## Screening Interval

The ideal interval between separate rounds of screening for PCa has yet to be defined. The common intervals studied are every 1, 2, or 4 years although it has also been suggested that a single baseline PSA taken at a specific age and compared with the population median PSA levels would allow for a future screening interval to be determined according to risk [25, 26].

The downside of a shorter interval between rounds of testing is an increase in the number of negative biopsies, increased workload, cost, anxiety for the patient, and risk of overdiagnosis. However, if the interval is too long, one runs the risk of a cancer developing during the interval period, which can be important if the cancer is high risk and the opportunity for cure has been compromised.

Evidence from the Rotterdam section of ERSPC suggests that when using a 4-year interval, the average tumor stage and grade at diagnosis is lower among men whose cancer is not detected in the first round of screening. The interval cancer rate in this study was low (13 %), and since the screening protocol had a high sensitivity (85.5 %), the authors concluded that a 4-year screening interval is reasonable [27]. Roobol et al. [28] compared the interval cancer rate using a 2-year (Göteborg) and 4-year (Rotterdam) screening interval in the ERSPC trial. Reassurance was provided that of the 4,202 men screened every 2 years in Göteborg, the 10-year cumulative incidence of interval cancer was 31 (0.74 %) compared to 31 of 13,301 (0.43 %) men screened every 4 years in Rotterdam ($p=0.51$).

## The Evidence Base for Screening in Prostate Cancer

Along with the recent publication of two large international randomized controlled trials (RCTs) of screening [16, 29], there have been a number of other trials and studies that have helped to inform the debate about screening for PCa.

## The European Randomized Study of Screening for Prostate Cancer (ERSPC)

The ERSPC trial [16] was designed in the early 1990s to determine whether a reduction of 25 % in PCa mortality could be achieved by PSA-based screening alone. Seven European countries (Holland, Belgium, Switzerland, Italy, Finland, Sweden, and Spain) recruited patients from June 1991 to December 2003. Portugal had originally planned to include patients but withdrew in 2000 because of a lack of necessary data, and although France joined in 2001, their data was too immature to include in the 2009 publication. The screening protocol (eligibility, recruitment, randomization, and follow-up) differed slightly between countries leading to speculation that the ERSPC is actually a combination of different studies from seven centers. The ERSPC trial coordinators refute this, claiming that the ERSPC study group originally agreed on a common data set, centralized data collection, and other key matters at the inception of the trial in 1994. The target age group was 50–74, but the investigators also defined a "core group" within this of 55–69. The study had an 86 % power to show a 25 % reduction in death from PCa. Lateral sextant biopsies of the prostate were performed by the study groups, the pathology was not centrally reviewed, and after a diagnosis of PCa, the treatment decision and execution of that treatment were left to the regional health care providers.

182,160 men aged 50–74 (core 162,243) were randomized to screening with PSA every 4 years (82,816) or to a control

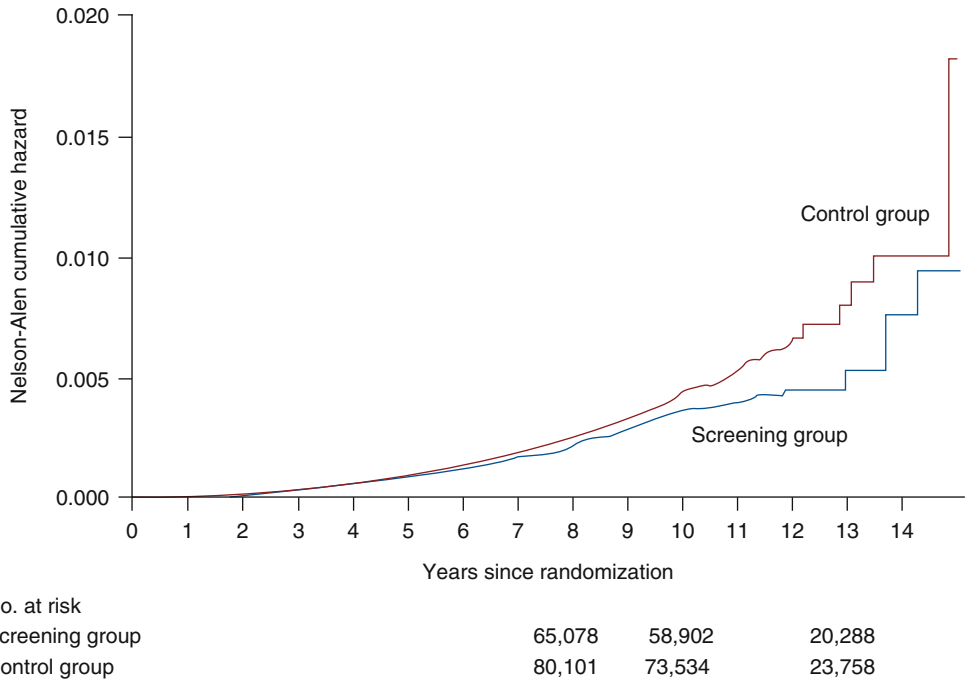

**Fig. 27.1** Cumulative risk of death from prostate cancer in ERSPC. The adjusted rate ratio for death from prostate cancer in the screening group was 0.80 (95 % CI 0.65–0.98, $p=0.04$) (Reprinted from [16] with permission from *The New England Journal of Medicine*)

group (99,184). Originally, a PSA >4 ng/ml led to a recommendation of a prostate biopsy, but this threshold was subsequently lowered to >3 ng/ml in 1997. As well as differences in the age groups included in the trial, there was some variation in the interval between the screening events, the age when screening was discontinued, the PSA cutoff value used to determine a positive test, the use of ancillary screening for borderline positive tests (e.g., DRE, ratio of free to total PSA, transrectal ultrasonography), and the biopsy techniques. Local policies also guided treatment of newly diagnosed cancers.

The mean age at randomization was 60.8 years, and 82 % of men in the screened group accepted at least one offer of screening with compliance for biopsy of 85.8 %. 16.2 % of men in the screened group had a PSA >3 ng/ml, and of the men biopsied, 13,308 (75.9 %) had no evidence of cancer, i.e., a 75 % false-positive rate and a PPV of biopsy of 24.1 %.

In October 2008, the data-monitoring committee of ERSPC reported "a significant difference in PCa mortality in favor of screening." This was based on complete data follow-up to the end of 2006 (the time of the third interim analysis), and the study group followed self-imposed rules and published their findings. Among the 82,816 men screened, 6,830 cancers were diagnosed (5,990 in core group) compared to 4,781 (4,307) in the control group. This gave a cumulative incidence of PCa of 8.2 % and 4.8 %, respectively. After an average follow-up of 8.8 years, 214 PCa deaths had occurred in the screening arm versus 326 in the control arm. The rate ratio (RR) for PCa mortality in the screened group, compared to the control group, was 0.80 (95 % CI 0.65–0.98, $p=0.04$), i.e., a 20 % reduction in rate of death from (Fig. 27.1). The absolute difference in the number of PCa deaths was small at 0.71 deaths per 1,000 men. This means that 1,410 men (1,142–1,721) needed to be screened and 48 men would need to be treated in order to prevent one death from PCa. It is also worth noting that 41 % more men were diagnosed with metastatic disease in the control arm at 9 years compared to those who were screened, suggesting the possibility of further longer-term reduction in PCa mortality in the screened arm. The authors concluded that "PSA-based screening reduced the rate of death from prostate cancer by 20 % but was associated with a high risk of over-diagnosis." Based on previously published ERSPC trial data, Welch and Black have estimated this risk of over-diagnosis to be approximately 67 % [30].

Roobol et al. [31] have further analyzed the ERSPC results, adjusting for both nonattendance in the screened population and contamination in the control group, both of which have an effect on the intention-to-screen (ITS) analysis. Adjusting for nonattendance resulted in a RR of 0.73 (95 % CI 0.58–0.93), and then adjusting for contamination gave a RR of 0.69 (95 % CI 0.51–0.92), suggesting that PSA screening reduces risk of dying by up to 31 % in men who were actually screened. Although no overall survival advantage has been demonstrated for screening in this study, a mean follow-up of 9 years may be insufficient time to identify such a difference. It is planned to reanalyze the data once

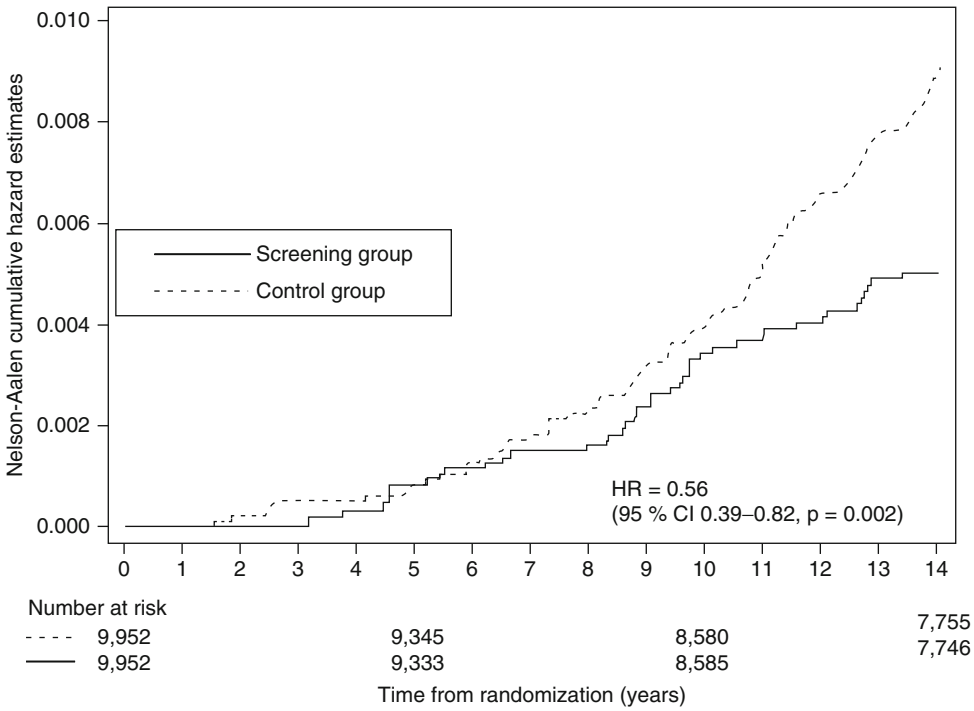

**Fig. 27.2** Cumulative risk of death from PCa in the Göteborg population-based screening trial. The RR for death from PCa was 0.56 (95 % CI 0.39–0.82, $p=0.002$) in the screening group compared to the control group (Reprinted from [33] with permission from Elsevier)

a mean follow-up of 11 years has been reached, and given the trend seen in the PCa mortality curves (Fig. 27.1), one might expect that the benefits of screening will become more apparent with longer follow-up.

## Göteborg Trial, Sweden, 2010

Biennial PSA testing in the Göteborg section of the ERSPC trial was originally reported to significantly reduce the risk of being diagnosed with metastatic prostate cancer after 10 years of follow-up [32], and in 2010, Hugosson et al. [33] reported the mortality results from this randomized population-based PCa screening trial. Started in 1995, 20,000 men (aged 50–64), randomly sampled from the population register, were randomized to either a screening group (invited for PSA testing every 2 years) or to a control group (not invited). Of the 9,952 invited to be screened, 7,578 (76 %) men attended at least one screening round. Only men with a raised PSA were offered DRE and prostate biopsy.

With a median follow-up of 14 years and seven screening rounds completed by 2008, 1,138 (11.4 %) men in the screened group and 718 (7.2 %) men in the control group had been diagnosed with PCa. The cumulative PCa incidence in the screened group and control group was 12.7 % and 8.2 %, respectively (HR 1.64, 95 % CI 1.50–1.80, $p<0.0001$). In the screened group, 44 men died of PCa compared to 78 deaths in the control arm. The cumulative risk of death from PCa fell from 0.90 % in the control group to 0.50 % in the screened group, giving an absolute risk reduction of death from PCa at 14 years of 0.40 % (95 % CI 0.17–0.64). The rate ratio for death from PCa was 0.56 (95 % CI 0.39–0.82, $p=0.002$) in the screened group (Fig. 27.2). The number needed to screen (NNS) to prevent one PCa death was 293 (177–799), while the number needed to treat (NNT) was 12, results which compare favorably with other established cancer screening programs, e.g., breast and colorectal.

This study is, in part, a subgroup analysis of the ERSPC trial, as it became associated with the ERSPC in 1996 without any changes in the protocol. 11,852 men had already been in ERSPC at the time of enrolment to this study, so one might reasonably ask why the RR for death from PCa should be so different in the Göteborg study (0.56 vs. 0.80 in the ERSPC). Certainly the median age of men in this study (56 years) was lower than ERSPC (>60 years), and this is important as advanced disease is less likely to be present at the time of screening in younger men thus leading to a higher cure rate if PCa is diagnosed. In addition, the overall median follow-up is longer for this study (14 years) compared to ERSPC (9 years), and it would appear that most of the benefit from screening occurs after 10 years (Fig. 27.2) which is what one would expect from a disease with a long lead time and a long natural history.

## Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, USA, 2009

The prostate component of the Prostate, Lung, Colorectal, and Ovarian (PLCO) [29] Cancer Screening Trial was designed to determine the effect of annual PSA testing *and* DRE on

mortality from PCa and randomized 76,693 men aged 55–74 to either screening or to "usual care" at 10 centers in the USA between 1993 and 2001. The age range was originally 60–74, but the protocol was changed in 1996 while also limiting pre-randomization PSA testing to one such event in the preceding 3 years. The study sample size and power calculations were based on 13 years follow-up after randomization from 2001. 38,343 men were randomized to screening which involved annual PSA testing for 6 years and annual DRE for 4 years. The control group consisted of 38,350 men who were managed as per "usual care" which interestingly "sometimes included screening"! A PSA >4 ng/ml or abnormal DRE triggered recommendation for a prostate biopsy, and regional health care providers made the final decisions on when to biopsy, the technique, and treatment choice after a positive diagnosis. The primary end point was causing specific mortality, and the investigators used an ITS method of data analysis. Assuming 100 % compliance, the study had a 91 % power to show a 20 % mortality reduction in men aged 60–74.

In contrast to ERSPC, the independent data-monitoring committee for the PLCO study terminated the trial early and recommended publication of results because of "a continuing lack of a significant difference in the death rate between the two study groups at 10 years (with complete follow-up at 7 years) and information suggesting harm from screening."

At 7 years, with 98 % full follow-up data, PCa was diagnosed in 2,820 of screened men vs. 2,322 in the control group (RR 1.22, 95 % CI 1.16–1.29), giving a crude incidence of PCa of 7.4 % vs. 6.1 %, respectively (RR 1.11, 95 % CI 0.83–1.5). This is an incidence of 116/10,000 person-years vs. 95/10,000, respectively, and is a relative 22 % increase in rate of PCa diagnosis in the screened arm. At 10 years (67 % complete data for mortality), 3,452 screened vs. 2,974 controls were diagnosed with PCa (RR 1.17, 95 % CI 1.11–1.22).

With regard to PCa mortality at 7 years, 50 deaths had occurred in the screened arm vs. 44 in control arm (RR 1.13, 95 % CI 0.75–1.7). This gives an incidence of 2/10,000 person-years vs. 1.7/10,000. By 10 years, 92 deaths had occurred in the screened arm vs. 82 in the control arm (RR 1.11, 95 % CI 0.83–1.5). The study concluded that the death rate from PCa was very low, and screening men aged 55–74 with annual PSA and DRE did not reduce the mortality rate from PCa when compared to a control group (Fig. 27.3).

Compliance for screening was high at 85 % for PSA and 86 % for DRE, but of those men with a positive PSA test or abnormal DRE, compliance with prostate biopsy was low in both the first and subsequent screening rounds (40.2 and 30.1 %, respectively). The PPV of the first biopsy, and subsequent biopsy was 44 and 33 %.

Although at 7 years, there was no statistical difference in PCa mortality between the 2 groups (RR 1.13), the 95 % confidence intervals (ranging from 0.75 to 1.70) are wide, and this means that the PCa mortality potentially ranged from a 25 % *reduction* in mortality (0.75) to as high as a 70 % *increase* in mortality (1.70). The lowest margin of the

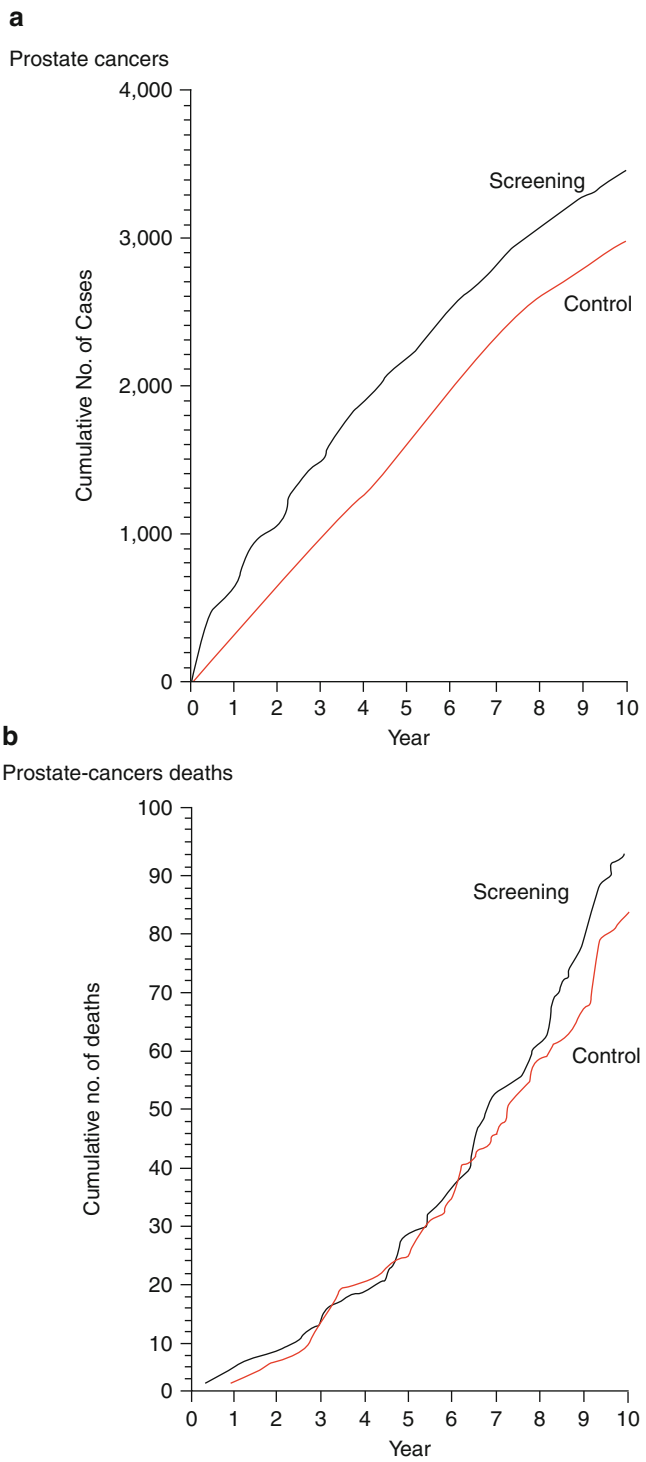

**Fig. 27.3** The number of diagnoses of all PCa (*panel* **a**) and number of PCa deaths (*panel* **b**) in PLCO. The incidence of PCa was higher in the screening group (RR 1.22, 95 % CI 1.16–1.29), but the rate of death from PCa did not differ significantly between the two groups (RR 1.13, 95 % CI 0.75–1.70) (Reprinted from [29] with permission from the *New England Journal of Medicine)*

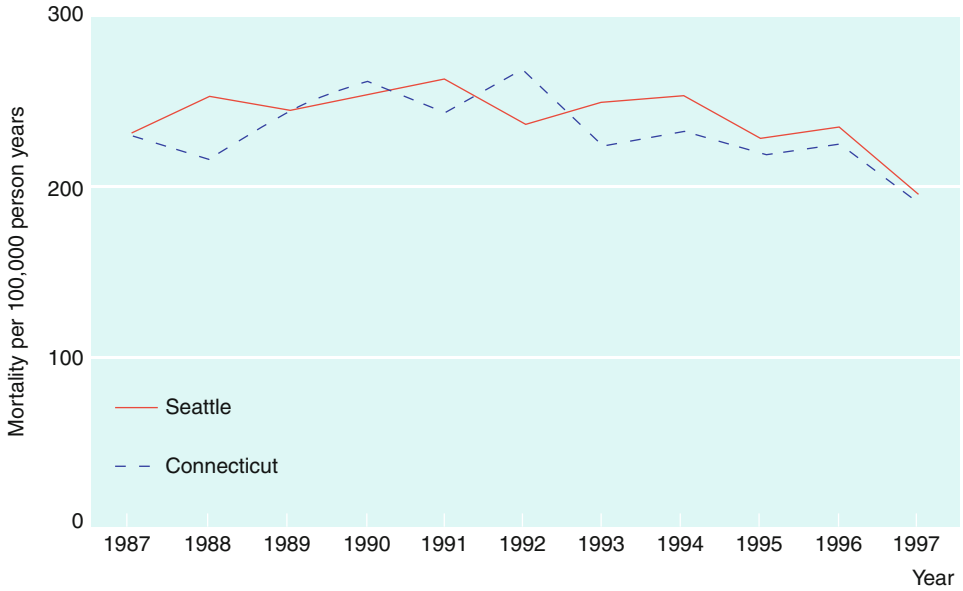

**Fig. 27.4** Age-adjusted prostate cancer mortality per 100,000 person-years for men in Seattle-Puget Sound and Connecticut, 1987–1997. Despite the increase rate of PSA testing and prostate biopsy leading to more men undergoing radical treatment for PCa in Seattle compared to Connecticut, no significant difference in PCa mortality existed during the 11-year follow-up period (RR 1.03, 95 % CI 0.95–1.11) (Reprinted from [35] with permission from BMJ Publishing Group)

95 % CI is 0.75 which is the same as the point estimate of the positive effect of screening with PSA in the ERSPC trial (0.73 for those actually screened).

There are a number of explanations for the discrepancy between the results from the PLCO, ESRPC, and Göteborg studies:

1. A PSA threshold of >4 ng/ml for recommending a prostate biopsy in the PLCO trial is higher than the ESRPC trial, and one could speculate that if the threshold had been lower, then more cancers would have been diagnosed in screened group.
2. There was substantial contamination (PSA testing outside of study) in the control arm of the PLCO study, increasing from 40 % in year 1–52 % by year 6 which may well have diluted the difference in cancer detection rates. The PCa incidence in the control arm of the ESRPC (4.8 % at 8.8 years) was lower than in the "usual care" arm of PLCO (6.1 % at 7 years), suggesting that contamination was much less common in the ERSPC study.
3. The PLCO reported their results after a median of only 5–6 years. Since the mortality curves did not diverge in the ERSPC trial for at least 7–8 years, this potentially premature reporting of the results may well explain why no difference was seen in the PCa mortality rates and represents a major limitation of the PLCO trial.
4. The power of the PLCO study was limited with only 174 PCa deaths overall compared to 540 deaths in the ERSPC trial.

When one considers the ERSPC and PLCO studies together and examines the trial differences in terms of goals, design, and results, one can see that the results may well be complementary rather than conflicting in nature [34]. Overall, one cannot state that population screening with PSA is either effective or ineffective. The most rational conclusion is that the PLCO trial did not demonstrate benefit at 10 years for more intense compared with less intense PSA screening combined with community standards of care during the study period. The ERSPC trial showed that PSA screening with a cutoff of 3 ng/ml in certain age groups led to a small improvement in cancer-specific mortality albeit with unknown effects on morbidity, costs, and quality of life and significant risks of overdiagnosis and overtreatment. Longer follow-up may well change this conclusion.

## Other Studies

### Seattle, USA, 2002

Lu-Yao et al. [35] examined the impact of aggressive screening and treatment on PCa mortality in two fixed cohorts of Medicare beneficiaries from the Seattle-Puget Sound area (94,900 men) and Connecticut (120,621) in an 11-year longitudinal study during the "early PSA era," defined as 1987–1990. During this time, the observed increased frequency of PSA testing, prostate biopsy, and radical prostatectomy (RP) among men in Seattle should arguably have led to an earlier and larger decline in PCa mortality when compared to Connecticut where aggressive screening did not take place. Prior to PSA testing, the age-adjusted PCa death rates were almost identical (115.5 vs. 155.6 per 100,000 person-years for white men aged 65–79 and 317.2 vs. 323.3/100,000 for black men aged 65–79, from 1977 to 1986). Between 1987 and 1990, the authors reported that the PSA testing rate and prostate biopsy rate in Seattle were 5.39 (95 % CI 4.76, 6.11) and 2.20 (1.81, 2.68) times greater than in Connecticut, respectively. The adjusted cumulative incidence of PCa was 93 % (81–107) higher in Seattle, and men in Seattle had a 5.9-fold (5.0, 6.9) higher rate of RP and 2.3-fold (2.2, 2.5) higher rate of radical radiotherapy. However, no significant difference in PCa mortality existed between the two cohorts (Fig. 27.4) with up to 15 years of follow-up (RR 1.03: 0.95, 1.11) [36].

This was termed a "natural experiment" in which the majority of men were over 70 years at diagnosis, and it should be noted that the outcomes of men in this age group do not represent the expected outcomes for men in the usual core age who are screened. Their older age at diagnosis along with competing morbidity may dilute any benefit from screening in this age group.

### Norrkoping Trial, Sweden, 2004

In 1987, 9,026 men aged 50–69 residing in the city of Norrkoping (Sweden) were identified from the national population register, and every sixth man ($n=1,494$) was randomly selected to be screened for PCa every third year over a 12-year period, leaving 7,532 men to act as controls. At the first two screening sessions (1987 and 1990), DRE was the sole screening method used, but from 1993, DRE was combined with PSA. Sandblom et al. [37] have reported on the outcome after 15 years of follow-up.

In the screened group, 85 (5.7 %) cancers were detected, 42 (49.4 %) of which were diagnosed in the interval between screening rounds. 292 (3.8 %) cancers were identified in the control group of which 26.7 % ($n=78$) were localized at diagnosis compared to 56.5 % ($n=48$) in the screened group ($p<0.001$). A lower incidence of metastases, regional lymphadenopathy, and higher-grade tumors were found in the screened group ($p<0.05$). Curative treatment was given to 25 % ($n=21$) and 14 % ($n=41$) of the screened and control groups, respectively. With regard to mortality, log rank testing did not show any significant difference in overall survival or cancer-specific survival for men who were screened, but at 15 years, 11 % of the screen-detected patients had died compared to 33 % of patients diagnosed in control group. There are a number of limitations to this study. Originally, it had been intended as a pilot to show how a screening program could be designed, and the study was insufficiently powered to provide a definitive answer. The rate of diagnosis in the screened group was lower than in ERPSC and PLCO, and this may be explained by the use of a fine-needle aspiration biopsy to establish a cancer diagnosis rather than standard needle core biopsy, the latter having a comparatively higher sensitivity for diagnosing PCa [38]. 48.8 % of the group with screen-detected tumors did not undergo treatment. It is unclear how men were randomized, there was no blinding to intervention or assessment of outcomes, and results from the study were disseminated via television, radio, and newspapers, increasing the chance of contamination and self-selection bias, with controls opting to be screened.

### Quebec, Canada, 2004

Labrie et al. [39], in 2004, reported 11-year follow-up data on a prospective RCT of men on the electoral roll of the Quebec City area, Canada. 31,133 men were randomized and invited by letter to annual screening for PCa, of which only 7,348 (23.6 %) accepted and were actually tested. 23,785 (76.4 %) men did not accept the invitation. Of the 15,353 men allocated to the control arm, 14,231 (92.7 %) remained unscreened. At the first screening visit, PSA and DRE were performed. A prostate biopsy was offered if PSA >3 ng/ml or the DRE was abnormal. Ten of the 7,348 screened men died from PCa compared to 74 deaths in the 14,231 unscreened control group. With a median follow-up of 7.93 years, the annual cause-specific death rate incidences were 19.8 and 52.3/100,000 person-years ($p<0.002$), equating to a 62 % reduction in cancer-specific mortality (RR 0.38, 95 % CI 0.20–0.73). The limitations of this study are self-evident including the low rate of acceptance in the screened group (24 %) potentially introducing significant bias, the uncertain level of contamination (PSA testing) in the control group, and, most importantly, the failure to use an intention-to-screen (ITS) analysis, and the study conclusion of a 62 % reduction in death rate has largely been discounted.

### Tyrol, Austria, 2006

Although not a "screening trial" but rather an "observational study," Oberaigner et al. [40] analyzed the PCa mortality over time in the population of Tyrol, Austria, comparing it to "Austria without Tyrol." The study design arose from the fact that PSA testing was introduced on a routine basis into the Tyrol in Austria in 1988–1989 and, since 1993, had been offered free to all men aged 45–74, leading to approximately 75 % of men having at least one PSA test. However, in "Austria without Tyrol," PSA was not offered in free health checks, and thus the study aim was to assess whether the mortality rate was lower in a region with a high rate of PSA testing. The analysis of mortality time trends was based on age-cohort modeling and Poisson regression for mortality data covering three decades, 1970–2003. The authors reported a significant reduction in PCa mortality in Tyrol during the last 5 years with a risk ratio (RR) of 0.81 (95 % CI 0.68–0.98). For "Austria without Tyrol," no reduction was seen with a RR of 1.0 (0.95–1.05), which led the authors to conclude "PSA testing offered to a population free of charge can reduce PCa mortality" (Fig. 27.5). However, due to the design of the study and lack of any prospective randomization of the intervention, the results cannot confirm that screening for PCa has any impact on mortality rates.

### Cochrane Review, 2010

There have been many other published studies examining whether screening for PCa reduces PCa mortality, most of which are of dubious methodological quality. Rather than continuing to try and keep abreast of all published studies on the subject, the epidemiologist Archie Cochrane saw the wisdom in establishing a "critical summary….adapted periodically… of all randomized controlled trials" on many different topics [41]. The initial Cochrane review on screening for prostate

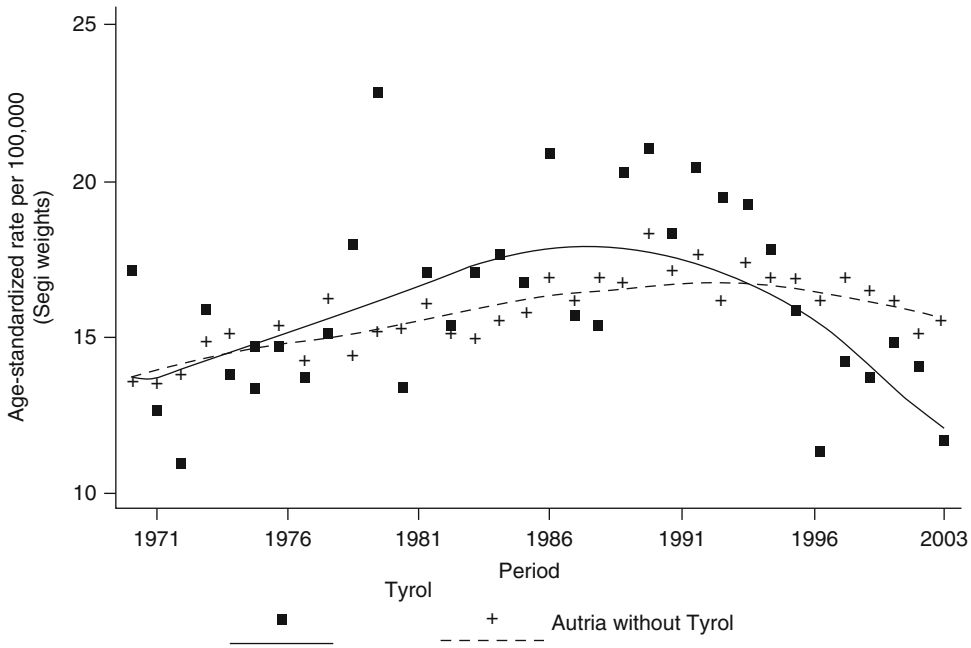

**Fig. 27.5** The age-standardized rate of PCa mortality in Tyrol and in "Austria without Tyrol," mortality data for Austria, 1970–2003. In the last 5 years of this period, there was a significant reduction in PCa mortality (RR 0.81, 95 % CI 0.68–0.98) in Tyrol, while no effect was seen for "Austria without Tyrol." (Reprinted from [40] with permission from Oxford University Press)

cancer was published in 2006 and was reanalyzed and republished in 2010 [42]. Two hundred five potentially relevant studies have been identified, but only 5 RCTs met the review inclusion criteria. The combined RCTs included 341,351 participants, although all but the ERSPC and the PLCO trials were judged to contain a high risk of bias. Reanalysis using the ITS principle and meta-analysis of the results from the 5 RCTs found no statistically significant difference in PCa mortality between men randomized for screening and controls (RR 1.01, 95 % CI: 0.8, 1.29), and the investigators concluded there was "insufficient evidence to either support or refute the routine use of mass, selective or opportunistic screening compared to no screening for reducing PCa mortality." Djulbegovic et al. [43] published their own update of the 2006 Cochrane review and included six RCTs. This meta-analysis of 351,531 patients demonstrated that screening was associated with an increased probability of being diagnosed with PCa (RR 1.46, 95 % CI 1.21–1.77, $p<0.001$) and being diagnosed with localized disease (RR 1.95, 95 % CI 1.22–3.13, $p=0.005$), but there was no effect of screening on death from PCa (RR 0.88, 95 % CI 0.71–1.09, $p=0.25$) or overall mortality (RR 0.99, 95 % CI 0.97–1.01, $p=0.44$).

## The Pitfalls of Screening for Prostate Cancer

Having examined the evidence, one can see the variety of reasons why many consider screening for PCa does more harm than good. There are confounding limitations to the RCT evidence including significant trial contamination, reduced compliance (nonattendance), and limited follow-up. In addition, there are inherent pitfalls of screening with three major types of bias which can occur with any screening program. It would seem appropriate to consider each of these types of bias further and identify how they relate to what we know about screening for PCa.

### Overdiagnosis or Detection Bias

Overdiagnosis is the identification of disease in patients in whom it would never have become apparent or symptomatic in their lifetime [44] or, in other words, disease that does not need diagnosing. Cancer overdiagnosis occurs either because the cancer never progresses or the cancer progresses sufficiently slowly that the patient dies of other causes before he becomes symptomatic. Overdiagnosis contributes to the problem of escalating health costs, and patients are subjected to unnecessary diagnostic tests and unnecessary treatment while also putting them at risk for physical or psychological harm.

Welch and Albertsen [45] obtained data on age-specific incidence from the National Cancer Institute's Surveillance, Epidemiology, and End Results program (SEER) and on age-specific male population estimates from the US census to determine the excessive number of men who are diagnosed and treated for PCa each year following the introduction of PSA testing (1986–2005). Since 1986, an estimated additional 1,305,600 men were diagnosed with PCa of which 1,004,800 were definitively treated. Given the considerable time that has passed since PSA screening began, most of this excessive incidence is thought to represent overdiagnosis.

Draisma et al. [46] developed mathematical models of PCa detection and progression calibrated to incidence data from the SEER program to estimate lead times and the

proportion of overdiagnosed cancers due to PSA screening among US men aged 54–80 years between 1985 and 2000. Among screen-detected cancers that would have been diagnosed in the patients' lifetime, the estimated mean lead time ranged from 5.4 to 6.9 years, and overdiagnosis ranged from 23 to 42 % of all screen-detected cancers. The same authors had previously developed similar models based on the results from the Rotterdam section of the ERSPC trial. For a single screening test at age 55, the overdiagnosis rate was 27 %, and by age 75, the estimates had risen to 56 %. For a screening program with a 4-year screening interval from age 55 to 67, the estimated mean lead time was 11.2 years and the overdiagnosis rate was 48 %. For annual screening from age 55 to 67, the estimated overdiagnosis rate was 50 % and the lifetime prostate cancer risk was increased by 80 % [47]. Etzioni et al. [44] have reported similar computer modeling data based on the SEER database and have estimated that 29 % of cancers in white men and 44 % of cancer in black men are overdiagnosed.

The main threat posed by overdiagnosis is overtreatment of indolent disease. Overtreatment in PCa is a term used to describe the situation when a man undergoes radical treatment for a localized PCa which, untreated, would not have led to clinical detection or altered the man's life expectancy. In other words, we are treating disease that does not need treating or diagnosing in the first instance. This becomes extremely relevant when one considers the potential long-term morbidity of radical treatment, namely, urinary incontinence, erectile dysfunction, and bowel dysfunction [48].

### Lead Time Bias

Lead time bias can be defined as the time by which the date of diagnosis of PCa is advanced by screening from the date when the disease would have been diagnosed clinically. Screening leads to an earlier disease detection date, but the date of death is the same as nonscreened individuals and has no effect on life expectancy or the mortality rate. This causes survival to appear artificially increased given the "lead time" from screening diagnosis to clinical diagnosis. For PCa, the published lead time estimates range from 5 to 12 years [46]. Draisma et al. [47] have published estimates from the Rotterdam section of the ERSPC. For a single screening test at age 55 or 75, the estimated mean lead time was 12.3 years (range: 11.6–14.1) or 6 years (5.8–6.3), respectively. For a 4 yearly screening interval between the ages 55 and 67, the mean lead time was 11.2 years (10.8–12.1). The same authors have more recently estimated the lead time of PSA screening between 1985 and 2000 in the USA, a period that covers the early PSA era [46]. Using several different definitions of lead time and independently developed models, they calibrated each model to the US incidence of PCa during this time. The estimated lead time for cancers destined to be clinically diagnosed was 5.4–6.9 years, but this may be an underestimate. Since 2000, with the revision of national guidelines, there has been an increase in the number of first biopsies performed at lower PSA values, the traditional sextant biopsy technique has been replaced with more extensive core biopsy protocols, and more repeat biopsies are being performed. All of these factors will result in still further overdiagnosis.

### Length Time Bias

Length time bias is a term used to describe how screening overrepresents less aggressive disease. Aggressive, faster-growing PCa has a shorter asymptomatic period than a slower-growing tumor. Thus, they are less likely to be detected by a screening program and more by clinical presentation. However, aggressive PCa is also associated with a poorer prognosis, and this can lead to the overrepresentation of slower-growing tumors in screening programs. This, in turn, can mean screening tests are erroneously associated with improved survival, even if they have no actual effect on prognosis. Length time bias is more pronounced in screening programs with longer screening intervals.

## A Risk-Based Strategy for Early Detection

So where does this information on mass population screening leave the individual patient? An alternative to population screening, where age is the only factor determining whether you should be offered screening, is to target screening according to an individual's risk. Targeted screening may be more appropriate given that not all men with a predefined PSA threshold (whether >2.5 ng/ml, 3 ng/ml, or >4 ng/ml) need a biopsy, not all PCa needs to be diagnosed, and a diagnosis of PCa should not always lead to treatment. An individual risk-based approach improves PSA-driven detection of PCa [49], and tools now exist such as the PCPT risk calculator to guide risk prediction based on 5,519 men from the PCPT placebo arm who all underwent biopsy regardless of DRE and PSA [50].

The main risk factors for PCa include race, age, family history, genetic susceptibility, PSA kinetics (PSA velocity, PSA density, and % free/total PSA ratio), and previous prostate biopsy history. Ideally, all of these should be considered along with the conventional DRE and PSA when recommending further investigation with a prostate biopsy [51].

As the large RCTs of screening for PCa have failed to provide a definitive answer, individual risk assessment and a risk-based strategy in the early detection of PCa would appear to be a better way forward until more specific markers for prostate cancer become available. Furthermore, due to

the ever-expanding field of basic science and molecular biology, an individual's genetic susceptibility to PCa is now becoming more decipherable. There are now a number of candidate PCa susceptibility genes, and two of the best characterized are *HPC1* and *BRCA2* [52, 53]. Chapter 28 gives further information in this area. Studies of families with breast cancer have indicated that male carriers of BRCA2 mutations are at increased risk of PCa, particularly at an early age. Edwards et al. (53) found that 2 % of men with early onset PCa harbor a germline mutation in the BRCA2 gene, and the relative risk of developing PCa by age 56 in men with this mutation is increased 23-fold. The role of targeted PCa screening in men with BRCA2 (or BRCA1) mutations is the focus of ongoing research. Three hundred men aged 40–69, from families with BRCA 1 and BRCA 2 mutations, were offered annual PSA screening over 33 months and compared to 95 nonmutation controls. After baseline PSA screening, 7 % (21 men) have undergone a prostate biopsy for a PSA >3 ng/ml, and of these 21, 11 men have been diagnosed with PCa, giving a prevalence of 3.3 %. Of the 11 men with PCa, 9 (81.8 %) were mutation carriers and 8 (72.7 %) of the cancers were clinically significant [54]. The PPV of PSA screening in this cohort was 52.4 % and supports the rationale for continued screening in this group of high-risk men.

The recent advances in molecular biology and PCa genomics have now reached a point where some are advocating gene-based individualized screening for PCa [55]. Eeles et al. have conducted a genome-wide association study using blood DNA samples from 1,854 men with clinically localized PCa which was either diagnosed before the age of 60 years or where there was a strong family history of prostate cancer and compared this to 1,894 controls with a PSA below 0.5 ng/ml. They analyzed 541,129 single nucleotide polymorphisms (SNPs) and have identified seven new loci associated with PCa. Of the three newly identified loci containing candidate susceptibility genes, microseminoprotein-beta (MSMB) has been nominated as a new urinary biomarker in PCa [56]. Whitaker et al. [57] have demonstrated that in men who carry a specific risk allele, MSMB is significantly less likely to be found in the urine of men who have prostate cancer.

## Summary

The final chapter on screening for prostate cancer has yet to be written. Whether screening for PCa reduces mortality remains controversial and unresolved. We do know that PSA screening can reduce the PCa mortality rate, the presence of metastatic disease at the time of diagnosis, and increase the detection of localized cancer. Nevertheless, the disadvantages of overdiagnosis, overtreatment, and unproven cost-effectiveness, coupled with the probable but as yet unquantified effects on the quality of life of men who have been screened, are cogent reasons not to push for a PSA-based screening program at this time. As we await the development of better prostate cancer biomarkers, most men will still want to know their PSA and an informed risk-based approach to early PCa detection would appear to be the most rational way forward.

## Update

Due to the nature of the ever-evolving debate on prostate cancer screening and early detection, there have been recent amendments to the recommendations of some of the key international regulatory bodies, most notably from the US Preventive Service Task Force (USPSTF). In October 2011, the USPSTF released a controversial definitive position statement in contrast to their previous report which could be considered noncommittal. The USPSTF have concluded prostate cancer screening is not to be advocated for US men regardless of age, and the grade D recommendation states "the USPSTF recommends against prostate cancer screening. There is moderate or high uncertainty that screening for prostate cancer has no net benefit or that the harms outweigh the benefits" [58].

The 2011 update of the online version of the National Comprehensive Cancer Network (NCCN) Prostate Cancer Guideline for Early Detection (www.NCCN.org) also has become slightly more prescriptive. Using its algorithmic design, they continue to advocate thorough discussion between physician and individual patients about the pros and cons of screening, but they now make the following recommendations: (1) for men opting to participate in an early detection program, baseline DRE and PSA testing at 40 is useful; (2) annual follow-up is recommended for men who have a PSA value ≥1.0 ng/ml; (3) men with PSA ≤1.0 ng/ml should be screened again at age 45; (4) regular screening should be offered to all participants starting at age 50; (5) African-American men and men with a first-degree relative with PCa should commence screening at an earlier age ("in their 40s"); and (6) annual screening is also recommended for men receiving 5-alpha reductase inhibitors due to the reported association of high-grade cancer in men taking this medication for preventative reasons. This latter statement is the first time this population of patients have been identified as candidates for active screening due to their perceived risk.

Essentially, the publication of ERSPC and PLCO has probably created more confusion than clarity, but it has certainly stimulated long overdue international debate in the role of PSA as a screening tool, considering PSA is the "best available" serum PCa marker and was identified 40 years ago. However, on the whole, clinicians are unaware or

unwilling to acknowledge the limitations of PSA as a sensitive and specific marker for PCa. As with everything in life, opinions differ and the controversy of PSA-based screening will continue indefinitely or until a much needed improved biomarker for PCa is discovered.

# Next Generation Screening Tests

# 28

Jack A. Schalken and Agus Rizal A.H. Hamid

## Introduction

Cancer screening intends to increase the chances of successful treatment through early cancer detection and then reduce cancer-specific mortality [1]. Cancer screening is performed on healthy/nonsymptomatic population. A cancer screening test must be considered as intervention protocol, so measurement of benefit and harm must be outweighed before introduced into the population [2–4]. Screening can be performed through three methods, which are mass (in entire population), selective (in high-risk populations), or opportunistic (incorporated as part of a medical consultation) [1]. Contrary to opportunistic screening, mass screening is endorsed by the health care officials and governmental bodies [5]. There are ten general requirements to be fulfilled to qualify a disease for a screening program (Table 28.1) [6].

Prostate cancer (PrCa) is one the most common cancers in men worldwide. PrCa has also become the second and third most common cause of cancer mortality in the USA and Europe [7–9]. These data indicate that PrCa is a major health problem that fulfills the first requirement as disease that needs screening [10, 11]. Even as it did not fulfill all disease screening criteria, almost all medical organization have encouraged PrCa screening. PrCa screening is then only recommended after a patient was clearly informed about the decision-making process, and as such it is not for mass screening [4, 12–18].

Currently, PrCa screening is based on the serum PSA test [19]. The incidence of PrCa has rapidly increased after the introduction of the serum PSA test. There is also a clear stage migration in that PrCa is predominantly diagnosed as localized disease [20]. PSA-based screening effects on PrCa specific mortality are still controversial. The European Randomized Study of Screening for Prostate Cancer (ERSPC) study showed a 30 % decrease in PrCa-specific mortality [21]. But this decrease in PrCa-specific mortality was also seen in countries with limited use of PSA screening [22, 23]. Another factor that should be considered is the improvement of effective localized PrCa treatment [23, 24]. Meanwhile, other randomized study did not show a beneficial effect probably because of poor methodology [25]. Even though the controversy on the effectiveness of population-based screening has not been resolved, it is clear that due to the overtreatment, the number needed to treat is unacceptably high, and there is no recommendation for screening by the European urological association (EAU) [16].

**Table 28.1** Criteria for disease that need screening program [6]

| |
|---|
| 1. The condition sought should be an important health problem. |
| 2. There should be an accepted treatment for patients with recognized disease. |
| 3. Facilities for diagnosis and treatment should be available. |
| 4. There should be a recognizable latent or early symptomatic stage. |
| 5. There should be a suitable test or examination. |
| 6. The test should be acceptable to the population. |
| 7. The natural history of the condition, including development from latent to declared disease, should be adequately understood. |
| 8. There should be an agreed policy on whom to treat as patients. |
| 9. The cost of case-finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole. |
| 10. Case-finding should be a continuing process and not a "once and for all" project. |

**Table 28.2** Development screening marker phase [45]

| Phase | Step | Aim |
|---|---|---|
| Phase 1 | Preclinical exploratory | To identify promising marker |
| Phase 2 | Clinical assay and validation | To validate promising marker in clinical assay and assess its ability to distinguish subjects with cancer from subjects without cancer |
| Phase 3 | Retrospective longitudinal | To evaluate the capacity of the marker to detect preclinical disease |
| Phase 4 | Prospective screening | To determine detection rate, false referral rate, and practical feasibility in a relevant population |
| Phase 5 | Cancer control | To estimate the reductions in cancer mortality afforded by the screening test |

## The "PSA Dilemma"

The limited or conditional screening recommendation is due to several limitations of PSA as a screening test [1]. A major limitation of PSA is the low specificity (high false-positive rates). PSA levels are highly variable and influenced by several factors, such as benign enlargement, inflammation, and prostatic manipulation (i.e., catheterization and DRE) [11, 26]. The low specificity of the PSA test can lead to 70–80 % of negative biopsies [11, 21, 27]. In the "gray area" (PSA 4–10 ng/ml), the positive predictive value (PPV) was only 25 %. Furthermore, controversy about the PSA cutoff level to be used to distinguish PrCa from benign tissue is also unresolved [4]. The prostate cancer prevention trial (PCPT) study showed that 25 % of PrCa cases are found in patients with a PSA level below 4 ng/ml [28, 29]. This study recommended the PSA level was not a dichotomous value but it reflects a continuum for PrCa risk [30]. An attempt to discard all PSA cutoff level will result in more overdiagnosis and thus overtreatment, so different PSA-based nomograms are needed to decrease unnecessary biopsies and reduce over diagnosis/treatment [31, 32].

Risk of overdiagnosis in PSA-based screening was almost 50 % [1, 24]. This risk is higher than for any other cancer for which screening is commonly recommended. For example, the overdiagnosis probability is estimated to be about 10–25 % in breast cancer screening [33]. This overdiagnosis was due to the high incidence of latent PrCa and was in fact predicted by autopsy studies. Therefore, there is a large pool of indolent PrCa cases that could potentially be detected by screening [2, 24]. ERSPC study showed that one needed 1,410 cases to screen and 48 additional cases to treat to prevent one PC-specific mortality case [21]. False-positive results will increase anxiety, especially cancer-specific anxiety preoccupation with symptoms and increased use of health services. It might last long to reassure the diagnosis [24, 34, 35]. Overdiagnosis and overtreatment can also increase almost twofold of cost for repeated screenings, biopsy, and treatment [11, 36]. Thus, there are biomarkers needed to generate several ways to overcome these PSA limitation.

## Novel Biomarkers

It is clear that novel PrCa biomarkers are urgently needed that can identify patients with clinically significant PrCa. Current advancements in molecular profiling technology have enabled the discovery and development of novel biomarkers. Molecular alterations in cancer can be discovered by using these technologies that assess changes at the genomic/DNA level, its transcriptome (RNA), the production of proteins (proteome), or the synthesis of various metabolic products. Biomarkers can be categorized into DNA-based (genomic), RNA-based (transcriptomic), protein-based (proteomic), and metabolic-based (metabolomic) biomarkers [37–40]. By DNA microarray analysis, thousands of DNA variations can be assessed at high throughput as potential biomarker simultaneously. Then potential biomarkers should be further validated either by a quantitative measurement of DNA/RNA levels (northern blot, RT-PCR, or in situ hybridization) or protein levels (immunohistochemistry or Western blot) [41, 42]. Development of microdissection techniques can isolate particular cell populations for analysis and give more specific information. This technique can overcome disadvantages of the use of heterogeneous cells population used in the past [41].

However, the road from the initial discovery of a biomarker to widespread clinical application involves several steps [43]. Five conceptual steps of biomarker development have been suggested, as seen in Table 28.2 [38, 44]. Most common pitfalls in moving from the discovery phase to the validation phase are the need for a standardization assay and a well-designed multicenter prospective studies. Validation of biomarkers should also focus on "doing no harm" and includes psychosocial, ethical, and economic assessment [45].

The widespread use of the PSA test complicates novel biomarker evaluation because biopsy work-up is usually triggered by elevated PSA [46]. The observed sensitivities and specificities typically reflect the diagnostic value over and above the commonly used primary screening tests rather than the diagnostic value in a primary screening situation [47].

## PrCa Screening Biomarker Criteria

There are several basic requirements for a screening marker that are different from those for a diagnostic marker [10, 12, 38, 44]. These requirements are:

1. Highly specific
   Maintaining high specificity (low false-positive rates) is a high priority for screening test. It is due to the low prevalence of cancer in the general population, a lot of participants, and cost-effectiveness [44, 48, 49]. There are only 5–10 % PrCa cases detectable in a screening setting during life [2]. An almost absolute specificity (at least 95 %) and good sensitivity would be required for screening of an apparently healthy population. A simple calculation shows that in ideal conditions (1 % incidence of the disease, 99 % sensitivity and specificity), the frequency of false positive is already 50 % [48]. So ideally, a substance as potential marker must be secreted only from cancer tissue, not secreted by non cancer tissue [44].
2. Easily obtainable specimens/noninvasive
   Several substrates for a PrCa biomarker can be considered, that is, prostate tissue, blood, urine, or seminal fluid [50]. Serum and urine can easily be obtained. In contrast, prostate tissue sampling requires a minimally invasive procedure. Many studies though used tissue in phase 1 to identify the potential marker. The paradigm of direct detection of cancer cells in biological fluids then becomes opportune due to the expected specificity improvement. Detection of cancer cells in blood is considered to be specific for patients with advanced PrCa [51]. Prostatic cells and biomolecules, however, can be released directly into urine. Thus, urine was expected to have exfoliated cancer cell even in early cases. Manipulation of the prostate would mobilize PrCa cells into the urethra, so sediments from urine collected following a DRE would be enriched in prostate borne cells. Another advantage of urine is that it contains cancer cells that come from multiple foci within the gland. So urine sample was a yet-unexploited high-potential substrate for PrCa tests albeit that one had to anticipate the potential problems with respect to sample stability [27, 52, 53].
3. Simple and cost-effective test
   In a population-based setting, there are many participants and therefore considerable amounts of money are needed. So the test should be easily distributed to laboratories and readily interpretable by a clinician [49, 54].
4. Ability to differentiate indolent (low risk) from aggressive cancers
   Overdiagnosis is arguably the most important harm associated with early cancer detection. The impact of overdiagnosis can be lifelong and affects patients' sense of well-being, their ability to get health insurance, their physical health, and even their life expectancy. Recent criteria for indolent PrCa are no Gleason grade 4 or 5, organ confined, and cancer volume was less than 0.5 $cm^3$ [55]. It was found that indolent PrCa constitutes up to 30–50 % of all newly diagnosed PrCa [23, 49, 56].
5. Ability to detect PrCa at an early stage
   PrCa cases can be found at any PSA level. Novel biomarker should be significantly increased (or decreased) in the related disease condition and have no or limited overlap in values. It should also differentiate between healthy control subjects and untreated patients [38].

Recently, so many new markers have been suggested as PSA alternative. But there is only one PrCa specific marker that is already used in a clinical setting (PCA3) [57]. Furthermore, another PrCa specific gene rearrangement, commonly referred to as ETS gene fusions, has a high potential due to its PrCa specificity.

## PCA3

PCA3/DD3 was recently clinically implemented and is thus the first biomarker after PSA to predict outcome of prostate biopsies [58]. PCA3 as marker was identified in 1999 by using differential display analysis, a PCR-based technique that compares mRNA expression patterns. PCA3 is a noncoding RNA and is only expressed in the prostate. Its expression was much higher in PrCa than BPH or normal prostate tissue; hence, it is close to being PrCa specific. Because no protein product has been detected from PCA3 RNA, PCA3 assays were developed using RNA detection methods. The next big step forward was the detection of PCA3 transcripts in urine, which is a clear benefit for routine analytical procedures [59]. An RT-PCR-based PCA3 test was developed to evaluate the utility of PCA3 to detect PrCa cells in post-DRE urine [60]. The proof of principle was delivered with an early urinary RT-PCR-based test by Hessels et al.; PCA3 could be useful to predict biopsy outcome, with high specificity, in patients with a PSA <10 ng/ml. The assay was a robust RUO test, yet too time consuming for widespread implementation in clinical laboratories. The PCA3 test was then developed on an IVD technology platform based on transcription-mediated amplification (TMA). This technology is more simple, faster, and sensitive enough to be used in a clinical laboratory. All assay steps can be done in a single tube and completed within 6 h [54]. The PCA3 score was calculated by the ratio of PCA3 mRNA and PSA mRNA. PSA mRNA was used to normalize the PCA3 value for the expected variations in cell numbers in urine. The apparent specificity of PCA3 was 66–83 % in a population of patients that had a PSA >2.5 ng/ml. In the "gray PSA range," its specificity increased to 71–91 % [59, 61]. The commercial PCA3 test has already been studied in several multicenter studies and showed similar specificity as the RUO test [62].

In recent studies, the potential of the PCA3 test to predict the presence of clinically significant PrCa was tested. The PCA3

score correlated with PrCa volume measured in the subsequent radical prostatectomy specimen. This was confirmed by several studies and only one study failed to show a difference between PCA3 score and pathology outcome [63]. This might be attributed to the highly selected population typically seen in an academic referral situation. The general picture that emerges is that PCA3 can discriminate indolent from significant cancers, but that within the group of patients with significant cancers, there is no further discriminative value of the test. This could be explained by the fact that these significant cancers all shed cells in the urine and that the absolute expression levels do not vary much between Gleason grades [64]. The next phase was measuring effectiveness of PCA3 in a screening study. This has so far not been reported. The only study in a screening cohort (ERSPC) unfortunately used an already-multiple-times-prescreened population. In that study, a biopsy indication was used as PSA >2.5 ng/ml or PCA3 score >10. This study showed PCA3 decreased the number of missed PrCa cases compared to PSA. Adding PCA3 to the decision to biopsy resulted in detecting 64 % additional cases of PrCa in men with PSA levels <3.0 ng/ml, of which 15 % could be considered as potentially life threatening if detected at a later stage [61, 65]. There are still more general study to establish cutoff values before its use in screening test study [66]. The evaluation of PCA3 in a screening setting is thus still to be expected and eagerly awaited.

## TMPRSS2:ETS Gene Fusions

For over 30 years, genetic rearrangements have been recognized as key events in hematological malignancies and sarcoma development. A surprising report was that of the frequent occurrence of gene fusions in PrCa in 2005. This discovery was based on using microarray data, combined with a novel bioinformatic algorithm. Traditional microarray analysis methods only prioritize genes commonly activated across a class of cancer samples, and these methods will fail to identify rare/outlier events. A novel bioinformatic algorithm called the cancer outlier profile analysis (COPA) was developed to analyze outliers in gene expression profiles (those markedly overexpressed in a subset of cases). COPA identified high outlier profiles for the v-ets erythroblastosis virus E26 oncogene homolog (ERG) gene and the ETS variant 1(ETV1) gene. This high ERG or ETV1 outlier expression led to the identification of fusions of the 5-untranslated region of the prostate-specific-androgen-induced transmembrane protease serine 2 (TMPRSS2) gene to the ETS gene. This fusion is only found in cases with over expression of ETS gene and was not detectable in benign prostate tissues. TMPRSS2:ERG fusions in PrCa tissue have been reported in approximately 50 % cases, which represents the prevalence in PSA-screened cohorts worldwide [42]. These TMPRSS2:ERG fusions are highly specific for PrCa [67]. Based on detection of PCA3 in post-DRE urine, to detect PrCa, it was an obvious next step to measure gene fusions in urine. Detection of TMPRSS2:ERG transcripts by quantitative RT-PCR in post-DRE urine can be found in 42 % of PrCa cases. The gene-fusion-based test had a sensitivity of 30–50 % with specificity >90 % in PSA-screened cohorts [42]. Recently, gene fusion scoring using ERG mRNA expression and PSA mRNA expression was proposed. This score gave same sensitivity and specificity as previous results [68]. A review of the literature demonstrated an association between gene fusions to both more and less aggressive PrCa cases. Thus, there were conflicting results on associations between gene fusions and aggressive PrCa features. This discrepancy is yet not fully explored. The gene fusion based test is currently being evaluated for their positioning in the diagnostic armamentarium for PrCa.

## TMPRSS:ERG

Thus, it seems clear that none of the new tests is proven to be better than serum PSA measurements; however, based on the high specificity, the combination of the strengths of the serum PSA test with the PrCa specific PCA3 and gene fusion tests bears the promise to come to a better diagnostic algorithms for clinically significant prostate cancer that are so eagerly needed for PrCa.

## Targeting Screening on High-Risk Population

Screening can be targeted to a group of men who have a higher incidence of disease [69]. After an age, the strongest PrCa risk factor is a family history. Risk factor of family history has already been reported in 1974. There were approximately 10–20 % of PrCa cases having a significant family PrCa history [70]. One meta-analysis data showed the average PrCa risk will increase 2.5-fold if men had one first degree relative with PrCa. It will increase if men had more than one affected family member [71]. Although men who had a family history of PrCa are at a substantially greater risk for developing the disease, recent studies showed no difference in clinical presentation and prognosis by biochemical progression compared to sporadic cases, with the exception of PrCa cases among BRCA2 carriers (as describe below) [72, 73]. Meanwhile, an increased diagnostic activity among men with a family PrCa history had also contributed to a detection bias [74]. Thus, there is a controversy whether PSA-based screening should be offered to all men with a family PrCa history.

## Gene Variants

Many genetic linkage studies and genome-wide association studies (GWAS) have been reported to explain the hereditary basis of PrCa. These investigations enabled the prediction of

risk of men to develop PrCa based on gene variants [69, 75]. There are indications that up to 90 % of men that had a familial history of PrCa were interested in undergoing genetic testing [70].

GWAS try to identify genes involved in human disease using single nucleic polymorphism (SNP) covering the entire human genome. GWAS have identified at least 40 reported SNPs that are associated with PrCa risk [75–77]. But each SNP had very low odds ratio (OR) between 1 and 1.3. The combination of the 30 selected SNPs only explained 13.5 % of the total genetic variance in the European population associated with PrCa risk [78]. Another study showed that a combined set of SNPs associated with an OR of 2.5 was found in only present 1.3 % of the population [77]. Another challenge is more SNPs will be detected as sample sizes increase and additional populations are studied [75].

Recently, at least two risk prediction models using combined panel of SNPs and family history were tested. These models identified about 0.5–1 % of men have 41–52 % risk for developing PrCa between ages 55 and 74 years. The limitation of this risk prediction model still could not define aggressive PrCa risk. This was due to the fact that the panel of SNPs used was not correlated to aggressive PrCa features. It was expected that increasing novel SNP finding can improve risk prediction model [79].

GWAS also found at least six SNP variants that are related to PSA level. This study evaluated the combined relative effect of the SNPs variants primarily associated with PSA levels to variation in PSA levels among individuals. This study found that unnecessary biopsies are more likely to be performed on individuals with elevated PSA levels due to genetic variants factors. Then this study proposed a personalized PSA cutoff value, based on genotype variants, to decide a prostate biopsy [80]. Genetic variants test for PrCa risk is already commercially available, but it still needs further validation study. The cost-effectiveness and the utility for the individual patient remain the main challenge for SNP-based selection to identify high-risk populations.

## BRCA2 Carrier

Another gene that was shown to be related to PrCa risk is BRCA2. Men with BRCA2 mutations have been reported to have 4.7 relative risk of PrCa, more aggressive disease, and a high mortality rate. Men with BRCA1 mutations are reported to have lower relative risk of PrCa than those with a BRCA2 mutation. A large international study is ongoing to study the effect of PSA-based PrCa screening in BRCA mutation carrier men. Preliminary report of this study showed higher population incidence of PrCa, as observed particularly in BRCA2 mutation carriers, that can affect the PPV of screening [69, 81].

## Risk Calculator for Biopsy-Detectable PrCa

PSA was considered as a range of risk. PrCa occurs in men at all PSA ranges and a significant number of men with "normal" PSA levels (<2.5 ng/ml) have high-grade PrCa. PSA by itself may not be the only factor to consider when selecting men for prostate biopsy. This led to the development of a biopsy-detectable PrCa predictive risk calculators (or nomograms), which combined several risk factors with PSA level [30, 82, 83]. These combinations will improve the diagnostic value of PSA by increasing its sensitivity and specificity and provide individual risk estimation of having a biopsy-detectable PrCa [32, 84, 85]. Mathematically, a nomogram is a graphic calculating scale design to provide an approximate calculation of a function. In clinical practice, a nomogram is used as an algorithm to predict the probability of an outcome [86]. Recently, there are two online biopsy-detectable PrCa risk calculators available, which come from ERSPC study based on European population (http://www.uroweb.org or http://www.prostatecancer-riskcalculator.com/via.html) and PCPT study based on United States (US) population (http://deb.uthscsa.edu/URORiskCalc/Pages/uroriskcalc.jsp) [49]. These risk calculators have already proved to support in individualized clinical decision-making and reduced the number of unnecessary biopsies with a marginal loss of potentially aggressive PrCa [85].

The main limitation of these risk calculators is their development depends on population characteristic. It is well known that ERSPC risk calculator was based on Dutch section of ERSPC; meanwhile PCPT risk calculator was based on US population. PrCa characteristics may not be the same in Europe as in the USA [84]. Indeed, the PCPT risk calculator that had been applied retrospectively to the ERSPC has been found to be miscalibrated and gave a higher risk. It is also questionable whether the risk calculator based on European population can be applied to a US population. Thus, validation of the risk calculator on a variety of different population is needed [87].

Tools that were developed in a different era may not provide equally accurate predictions in contemporary patients. So this nomogram should be updated and developed [84]. The latest development in risk calculator is the use of a PCA3 score [49, 66, 82, 88]. As at least half of PrCa cases detection in screening was an indolent PrCa, more discussion recently also move to the development of risk calculator to predict indolent PrCa as effect of screening [49, 89].

### Conclusion

A rather diverse recommendation for PrCa population-based screening is due the low specificity of the serum PSA test. The way forward is to find new biomarkers that are better than PSA or can complement serum PSA in its weak characteristics, particularly the low specificity.

The development of new high-throughput molecular tools has given the way to find such novel markers. Biomarker assays for urine have expanded the (screening) marker panel for PrCa. It so far has taken a long time to bring a discovery of a new marker into the realm of routine clinical. For PCA3, for example, it has taken more than 7 years to develop it into a clinical test. However, the valuable experiences now enable a much faster translation from bench to bench, like for the gene-fusion-based tests. In the mean time, targeted population screening can be an option. The risk calculator approach is the closest option to overcome PSA limitation, integrate all clinical and laboratory parameters, and include new tests.

# Diet and Prostate Cancer: A Holistic Approach to Management

29

Philippa J. Cheetham and Aaron E. Katz

## Introduction

Prostate cancer foci are believed to exist in 30% of men >50 years and in 75% of men >80 years [1]. Most of these foci remain latent and do not grow or spread to any significant extent, and the occurrence of such foci is fairly consistent worldwide.

There is now increasing evidence from epidemiologic surveys and from laboratory, intervention, and case-control studies that diet and lifestyle play a crucial role in prostate cancer biology and tumorigenesis. This applies to both the development and progression of prostate cancer, although in many cases the specific initiating factors in the diet are poorly understood. Many nutrients and herbs also show significant promise in helping to treat prostate cancer by slowing progression and reducing recurrence, ultimately reducing the risk of morbidity and mortality from the disease. Furthermore, for all grades of prostate cancer, nutritional interventions complement conventional treatment to improve response and quality of life.

With high incidence (currently affecting one in six men in the United States), a long latency period, and strong environmental influences, prostate cancer is an ideal target for chemopreventative approaches. In this context, the term chemoprevention is used to describe nutritional interventions (i.e., changes in diet and the use of specific nutritional supplements) to slow or reverse the progression of premalignant lesions (i.e., high-grade prostate intraepithelial neoplasia [PIN]). Reversing PIN with chemopreventative agents could be the best primary defense against prostate cancer, preventing it from occurring in the first place.

The information given in this review about prostate cancer chemoprevention will benefit the health of every man, whether he has prostate cancer or not. Most nutritional chemoprevention agents also have the added benefit of being beneficial for the cardiovascular system, bone health, and for the prevention of other cancers.

## Epidemiology

African American men in the United States have the highest risk of prostate cancer on the planet, with a much greater risk of advanced, invasive prostate cancer and prostate cancer death. Caucasian and African American men have a prostate cancer incidence that is 5–50 times greater than that of Japanese men residing in Japan [2, 3].

Furthermore, migration studies reveal that risk shifts in men who move from low-risk to high-risk countries. When a man adopts the lifestyle and diet of a high-risk country, his risk rises correspondingly. Risk of prostate cancer thus increases substantially within a single generation in lower risk men who relocate to the United States. The incidence of prostate cancer in Japanese immigrants to the United States is four times that of their native Japanese counterparts. The risk of prostate cancer in Indian men in the United States is comparable to that of native-born American men. These changes in risk are linked to changes in diet and lifestyle that most immigrants adopt when they make the United States their home. These men exercise less and eat a diet heavier in fats, alcohol, and meat and lower in fiber. As more of the planet eats like Americans, the incidence of prostate cancer is rising even in relatively low-risk countries. This, along with marked racial and cultural disparity, indicates that diet plays a strong role in prostate cancer risk.

## Evidence for Dietary Intervention

In research conducted at the Preventive Medicine Research Institute at the University of California, San Francisco, Ornish et al. [4] demonstrated the power of diet and lifestyle changes in 87 men with prostate cancer (prostate-specific antigen [PSA] 4–10 ng/mL; Gleason score <7) who chose not to undergo conventional treatments during a 1-year period. Subjects were enrolled either in a program of extensive, comprehensive lifestyle changes, including a low-fat, vegetarian, soy-rich diet and nutritional supplements; exercise; psychosocial support; and stress reduction, or in a usual case-control group. Not one of the men in the experimental group required conventional treatment during the study period, but six control subjects required such treatment. This study and other research studies strongly suggest that if men who would otherwise be told to watch and wait were offered the information and motivation they need to enter into a focused chemoprevention program, we could have a significant impact on disease progression, as well as on other important aspects of men's overall health. Following a nutritional plan also gives men the power to do much more than watch and wait; active holistic surveillance that incorporates diet and lifestyle changes along with some of the herbs, supplements, and other holistic interventions to promote the body's natural defenses against cancer growth and spread gives men the tools they can use to heal themselves proactively.

## Diet and Prostate Cancer Risk

Fat content of the diet, overall caloric intake, the ratio of omega-6 to omega-3 fatty acids in the diet, and consumption (or lack thereof) of meat, antioxidants, and soy foods are the major factors that appear to correlate most closely with risk of prostate cancer and risk of death from this disease. These dietary factors may act as late-stage promoters rather than initiators transforming a relatively harmless, latent prostatic neoplasia into a more aggressive form.

### Dietary Fat

Fat intake, especially from animal sources, has been linked to an increased risk of developing prostate cancer in several studies. In a 31-country study, investigators also found a close correlation between fat intake and prostate cancer mortality [5, 6]. Within populations with a low risk of prostate cancer, such as Chinese men, the percentage of fat in the diet is strongly predictive of whether they will ultimately develop the disease [7]. Another case-control study, which was performed in Utah, found that men with high-fat intake had the highest risk of developing aggressive prostate tumors [8].

The exact mechanism by which dietary fat induces prostate carcinogenesis is unclear. Possible explanations include the effects of dietary fat on serum testosterone levels, oxidative stress, or increases in the hormone insulin-like growth factor-1 (IGF-1) with those on a high-fat diet having higher IGF-1 levels. On the other hand, more fat in the diet may boost conversion of testosterone to estrogens, which may have protective effects against cancer progression.

### Obesity

Men who are obese have an increased risk of developing prostate cancer. Obesity has also been strongly implicated as an independent risk factor for high-grade prostate cancer and prostate cancer mortality [9–11]. Obesity is not only a risk factor for prostate cancer; it can also increase the risk of recurrence. In some cases, obesity may be correlated to high-fat intake, although the more likely culprit is high-caloric intake.

### Physical Activity

The increased risk of prostate cancer in obese men is related to changes in hormone balance. Excess body fat alters estrogen and testosterone activity, and lower testosterone is associated with lower PSA at diagnosis. Tymchuk et al. [12] found that when obese men were put on a very-low-fat (<10% of calories from fat), high-fiber diet, and exercise programs, all of those men who had high PSA levels (>2.5 ng/mL) saw those values fall. Sex hormone-binding globulin (SHBG) rose and free testosterone levels dropped, possibly decreasing growth-promoting effects on the prostate. Another hazard of obesity—one that increases risks of all cancers, as well as heart disease—is that it exacerbates both inflammation and oxidative stress. Obese men are also more likely to have high insulin levels and high blood sugar levels.

Refined carbohydrates also fan the flames of chronic inflammation. Food sources rich in refined carbohydrates (or saccharides) include table sugar, corn syrup, fruit, white bread, white pasta, fizzy drinks, and cakes. Carbohydrates, particularly those with a high glycemic load, consumed in excessive amounts, result in a state of relative hyperinsulinemia and obesity. This has been postulated to increase the risk of developing prostate cancer through higher bioavailability of circulating estrogen and IGF-1 [13]. None of this bodes well for a man's prostate; it exacerbates both inflammation and oxidative stress. Further studies and randomized controlled trials are thus urgently required to investigate the potential role of carbohydrate consumption in prostate cancer in humans.

## Saturated and Trans Fat

Before the advent of highly processed diets, the ratio of omega-6 to omega-3 fats in typical diets was about two or three to one. Today's standard processed-food American diets, however, yield a ratio as high as 40:1. An American high-fat diet is high in omega-6 polyunsaturated fatty acids (PUFAs) and trans fats.

A high intake of saturated fatty acids (SFA) (from red meats, processed meats, egg yolks, whole fat dairy foods), trans fatty acids (from processed, hydrogenated vegetable oils), and omega-6 PUFAs, particularly arachidonic acid (AA) and linoleic acid (LA), have been associated with both an increase in the incidence of prostate cancer and of mortality. All authorities agree that trans fatty acids should be avoided completely. Saturated fats are probably not intrinsically carcinogenic. There are, however, chemical toxins found in most sources of saturated fat, as a result of modern factory farming methods. Toxins that can raise cancer risk concentrate in the fat of animals that eat a diet laced with pesticides and herbicides. Even higher concentrations of these toxins accumulate in dairy products and eggs.

Conversely, higher intake of the omega-3 fatty acids docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA), and alpha-linolenic acid (ALA) is associated with a reduced risk of prostate cancer. The protective effects of omega-3s (found in oily fish such as salmon and mackerel) may be prostate cancer protective by reducing inflammation. In a Swedish study, those subjects who ate oily fish more than three times a week had almost half the risk of metastatic prostate cancer compared with those who ate fish less than twice a month. Each additional daily intake of 0.5g of marine fatty acid from food was associated with a 24% decreased risk of metastatic cancer [14].

Unrefined vegetable oils rich in phytosterols, including beta-sitosterol and campesterol, are also believed to reduce the risk of prostate cancer; Asian and Mediterranean diets, both rich in phytosterols, thus confer reduced risk compared with the standard American diet, with its abundance of cholesterol, refined oils, and saturated fats.

Olive oil in the diet, a source of neutral omega-9 fatty acids, has been found to be protective against many cancers, including prostate cancer.

## Dairy Products

Clinical studies assessing dairy intake and risk of prostate cancer have shown conflicting results. A large meta-analysis of 45 observational studies showed no evidence of increased risk [15]. Other large meta-analyses have showed that men who consume more dairy products have an 11–39% higher risk of prostate cancer [16, 17]. The most likely explanation for this increased risk is a high dairy diet resulting in increased levels of plasma calcium, which in turn cause suppression of 1,25-dihydroxyvitamin D3 [18]. Other researchers have suggested that the increased risk is attributable to the high amount of saturated fat present in dairy, as well as increased circulating IGF-1 levels which have also been implicated in an increased risk of prostate cancer [13, 19, 20]. There is very limited data assessing the effect of dairy intake and prostate cancer progression, although some studies have suggested a low dairy diet may prolong PSA doubling time [21].

## Exercise and Weight Management

Studies demonstrated that physical activity is important in preventing prostate cancer. In one large prospective study, men over 65 who exercised the most had the lowest risk of prostate cancer [22]. Exercise also helps maintain normal body weight and obesity is a risk factor. In one study involving men who previously had prostate cancer, those with the highest BMI had the highest risk of developing the disease. Improving physical and psychological health has also shown promising results in prostate cancer survivors. Physical activity for at least 30 minutes a day and lifting weights or performing resistance exercises several times a week has a positive effect on reducing the side effects of androgen deprivation therapy (ADT). Exercise reduces the risk of weight gain, reduces insulin resistance, and minimizes bone loss, all of which are so prevalent in men on ADT.

## Meat

There is considerable evidence across populations that the more red meat a man eats, the higher his risk of developing prostate cancer. Meat contains high amounts of arachidonic acid. Some byproducts of arachidonic acid have promoted prostate cancer in animals [23]. Preliminary reports have suggested that frequently eating well-done steak or cured meats is a risk factor. Meat contains high concentrations of heterocyclic amines (HCAs) (in particular meat that has been cooked at high temperatures and is thus well done or charred, creating poly-aromatic hydrocarbons). Cured meats contain nitrosamines because meats contain amines, and sodium nitrite, a source of nitrosating agents, is added to cured meats as a preservative. These chemicals concentrate preferentially in the prostate gland, where they enhance free radical production and trigger carcinogenesis. Colli and Colli found strong correlations between prostate cancer mortality and intake of meat, reported in two retrospective population studies assessing prostate cancer mortality in 71 countries [24, 25]. Marinating meats in a mixture of olive oil, vinegar, and protective spices like garlic, rosemary, or turmeric reduces the

production of carcinogenic substances during cooking. Eating plenty of crucifer vegetables (broccoli, cauliflower, and cabbage) further helps by neutralizing the effects of heterocyclic amines in the body.

## The Ideal Prostate Cancer Chemoprevention Diet

Slowing the growth of latent foci of prostate cancer is best achieved with a combination of dietary and nutritional supplements. Current evidence supports the notion that the most effective prostate cancer protective diet is low in red meat and dairy and high in fruits, vegetables, whole grains, herbs (especially Asian herbs like turmeric and ginger), and green tea.

Overall, the best diet for prostate cancer chemoprevention most closely resembles the traditional diets of the southern Mediterranean and Japan. Fish and soy foods take the place of red meats, and dairy products are kept to a minimum. When oils and fats are called for, they are included in the form of oils that help reduce the omega-6 to omega-3 balance. Whole grains are favored over refined grains and foods made with flour and sugar. Both diets contain abundant fiber. Yet these two diets differ in many important ways: The Mediterranean diet is rich in tomatoes, which are the best source of cancer-fighting lycopene. Its main source of fat is olive oil, which (in its extra-virgin form) is high in important antioxidants. Olive oil is high in omega-9 fatty acids, which do not promote inflammation, and contains a compound called oleocanthal that has anti-inflammatory properties. The Japanese diet includes a variety of medicinal mushrooms that have great value for cancer prevention. Japanese diets also incorporate sea vegetables. Soy foods and ginger are important parts of Japanese cuisine; Mediterranean cuisine is often flavored with rosemary and oregano. All of these foods have cancer-fighting properties.

Fruits and vegetables have high concentrations of various phytochemicals, antioxidants, and fiber and are therefore promoted not only in healthy populations for the prevention of cancer but also in cancer survivors. Red meat should be a small part of the diet, if consumed at all, and grass-fed, organic beef, free-range poultry, game, eggs, and wild-caught ocean fish are the best options for flesh foods. Tempeh, tofu, and miso are good alternative protein sources.

Whole grains in the diet have an inverse relationship with prostate cancer risk. They are rich in fiber that helps remove carcinogens from the body. Grains should be chosen in a form as close as possible to the ones in which they occur in nature: brown rice instead of white and whole-grain or sprouted-grain crackers and breads, for example. Nuts and seeds are good additions to the chemopreventive diet; unrefined extra-virgin olive oil and ground flaxseeds are positive additions to the diet, particularly when stirred into organic, low-fat, and live-culture yogurt (the best choice of dairy product) or oatmeal. Flour and sugar intake should be minimized, as well as the consumption of trans refined fats and other highly refined vegetable oils, which promote the proinflammatory eicosanoid cascade.

Research suggests that the following natural substances may be of some benefit in prostate cancer prevention:

### Fruit and Vegetables

An antioxidant-dense diet made up primarily of whole plant foods (vegetables, fruit, whole grains, nuts, and seeds) provides a good antioxidant foundation. Certain foods like pomegranates, tomatoes, dark leafy greens, deeply colored fruits, and cruciferous vegetables (broccoli, cauliflower, and the like) are especially dense with protective antioxidants.

### Phytoestrogens

Phytoestrogens are a group of biologically active plant compounds with a chemical structure similar to estradiol, of which isoflavones are the most important. Foods rich in isoflavones include soy bean, tofu, kidney beans, lentils, chick peas, and peanuts.

There is conflicting information on soy and soy isoflavones and prostate cancer risk. Current evidence indicates a possible protective effect of dietary soy in prostate cancer prevention [26]. The effects of concentrated soy extracts and other phytoestrogens are less clear.

Differences in the level of consumption of traditionally prepared dietary soy foods (i.e., miso, tofu, tempeh, natto) is believed to contribute to the significant difference in prostate cancer incidence and mortality between Asian and American men. A large-scale epidemiologic study by Hebert et al. [27] of 59 countries found that soy-derived products offered highly significant protection against prostate cancer. Animal studies reveal that soy isoflavones, particularly genistein, inhibit prostate cancer growth in cell cultures [28]. In rat models, genistein has been found to offer significant chemopreventive activity against advanced prostate cancer. Possible mechanisms of action include estrogenic properties (binding to estrogen receptors thus suppressing cellular proliferation and promoting differentiation *in vitro* and in vivo) and inhibition of 5α-reductase (5AR). Soy foods contain protease inhibitors, saponins, and phytates, which have putative anticarcinogenic effects.

Some of the conflicting information on soy may be due to the fact that men eating a Western diet (full of meat and low in vegetables) have a different population of bacteria inhabiting their gut. These bacteria may not effectively break down soy into its active metabolite, genistein. Men eating a traditional Japanese diet tend to experience greater benefit from soy in

terms of preventing prostate cancer because they have been eating soy foods as a part of their daily diet for years. They are therefore more likely to have a population of gut bacteria that effectively metabolize soy isoflavones into genistein: men who incorporate soy foods in the diet abruptly may not receive the same benefit.

### Tomatoes and Other Lycopene–Rich Foods

Lycopene is a bright red carotenoid pigment found in tomatoes, watermelons, pink grapefruit, and papaya. A number of small studies indicate that regular consumption of lycopene (from eating raw tomato and cooked tomato products) may help prevent prostate cancer [29], as well as reducing the risk of progression in those who have the disease [13, 18–30] Cooked tomatoes and tomato sauce are better than raw tomatoes because cooking them releases lycopene from their storage sites. *In vitro*, lycopene has been shown to exert its antiproliferative effects on various cancer cell lines by causing cell cycle arrest and inducing apoptosis [31]. It also increases IGF-1 binding proteins thus resulting in a reduction in serum IGF-1, which has previously been associated with increased risk of prostate cancer [32]. However, no studies have proven that taking lycopene in supplement form can decrease the risk of prostate cancer. Further, well designed large-scale studies are required to establish the role of lycopene in the prevention and treatment of prostate cancer [33, 34].

### Silymarin

This phytochemical found in the herb milk thistle was shown *in vitro* to inhibit prostate cancer cell growth [35]. Silymarin actually refers to several different flavonoid compounds with similar structures: silibinin, the most prevalent form, has been entered into phase I and phase II clinical trials with prostate cancer patients [36].

### Delphinidin

Delphinidin from berries caused apoptosis of prostate cancer cells along with significant inhibition of tumor growth in an animal study [37].

### Quercetin

A preliminary cellular study in the journal of Carcinogenesis demonstrated that the flavonoid quercetin has potential as both a preventive agent and a complementary treatment for prostate cancer [38, 39].

### Fiber and Lignan Intake

Lignans are found in seeds, whole grains, vegetables, fruit, and legumes, but the richest dietary source of lignans is flaxseed. Diets rich in this and other fibers have consistently been associated with reduced prostate cancer risk [40]. Duke University investigators added 30g of ground flaxseed/day for an average of 34 days (21–77 days) to the diets of 25 patients scheduled for prostatectomy. The men were also placed on a 20% fat diet for the study's duration. During the study, testosterone and free androgen levels fell, proliferation rate fell, and cell apoptosis was enhanced [41]. To enhance lignan intake, patients may be advised to supplement their diets with three tablespoons of flaxseed daily; the seed meal can be added to yogurt, hot cereals, soups, stews, or nut butters. The seeds also can be ground in a coffee grinder, or they can be purchased already ground.

### Cruciferous Vegetables

Consumption of cruciferous vegetables from the Brassicaceae family, including broccoli, cauliflower, and cabbage, is inversely related to the incidence of prostate cancer. Broccoli in particular has been shown in clinical trials to help prevent prostate cancer. Sulfur-containing glucosinolate breakdown products indole-3-carbinol (I3C) and sulforaphane are phytochemicals found in crucifers, and both have been demonstrated to reduce the proliferation of prostate cancer in vivo in a dose-dependent manner. I3C reduces the proliferation of cancer cells and increases cell apoptosis; some investigations have found that supplemental doses of this nutrient chemosensitize chemoresistant prostate cancer cells, aiding in the treatment of hormone-resistant cancers [42]. Supplements of I3C and sulforaphane are available, such as BroccoProtect®; however, more research is needed to determine whether these supplements are more useful chemopreventives than the foods from which they are derived.

### Fish and Fish Oils

The long-chain ω-3 fats DHA and eicosapentaenoic acid (EPA) are abundant only in fish, crustaceans, and some forms of algae. They have been found to suppress cancer initiation, induce cell apoptosis, and decrease proliferation of several cancers including prostate cancer, causing decreased PSA doubling time in a mouse model. This appears especially true when the overall diet is altered to reduce intake of red meat, dairy products, hydrogenated oil, and highly unsaturated vegetable and seed oils, which are staples of the standard American processed-food diet and sources of saturated fats, ω-6 polyunsaturated fats, and trans fats [43, 44]. These

three classes of fat have been linked with increasing incidence of cancer in the prostate and breast.

The short-chain ω-3 fat found in plant foods such as flaxseeds, which contain ALA, has not matched DHA and EPA in its chemopreventive effects; to act as a substrate for the production of anti-inflammatory eicosanoids, ALA must first be converted to long-chain ω-3 PUFAs, an inefficient process. Flaxseeds, walnuts, and soybeans, the most important dietary sources of ALA, are still good foods to include in the chemoprevention diet, but they should not be relied upon as sole sources of ω-3 fats.

Numerous investigations have found that the consumption of fish three to four times per week confers a significant reduction in prostate cancer occurrence (a two- to threefold reduction in one study and a 40–44% reduction in risk in two other studies) [14, 45, 46].

The evidence in favor of fish oil supplementation is adequate to make general recommendations for patients to consume one each day and to use a fish oil supplement that has been purified (pharmaceutical grade or molecularly distilled), contains an antioxidant, such as vitamin E or rosemary oil, to prevent rancidity, and that comes from small, oily cold-water fish, such as anchovies or sardines. Current guidelines indicate that patients may benefit from 1,000 to 3,000 mg/day of combined EPA and DHA, with higher EPA than DHA content.

## Green Tea

Green tea is derived from the plant Camellia sinensis. The tea leaves are very rich in polyphenols, known as catechins, of which epigallocatechin-3-gallate (EGCG) makes up 10–50% of the total catechin content. EGCG inhibits cellular proliferation primarily by acting as a very potent antioxidant scavenging free radicals along with 51 other compounds present in green tea that have anti-inflammatory activity. Other modes of antitumorigenic action include apoptosis and cell cycle arrest via alterations in the mitogen-activated protein kinase, phosphatidylinositol-3-kinase (PI3K)/Akt, and protein kinase C pathways; inhibition of inflammatory pathways (nuclear factor-kB and cyclooxygenase-2(COX-2)); and modulation of the insulin-like growth factor and androgen receptor axes [47].

In oriental cultures in which green tea plays a major role in diet, the incidence of and mortality from prostate cancer is significantly lower. Several studies have confirmed green tea as a potent agent against many cancers, including prostate cancer [48]. A recent small double-blind human trial demonstrated that green tea was effective at treating high-grade prostatic intraepithelial neoplasia (HGPIN) with a significant reduction in the incidence of prostate cancer [49]. Researchers at Louisiana State University conducted a study involving 26 cancer patients. Prior to their scheduled surgery, the patients were given a green tea extract containing 800 mg of EGCG (equivalent to 12 cups daily) for an average of 34.5 days. The patients had significant reductions in blood levels of PSA, VEGF, and HGT, all of which are correlated with prostate cancer growth [50]. Furthermore, in a population study published in 2008, researchers looked at data on 49,920 men (ages 40–69) and found that consumption of green tea was linked to a dose-dependent reduced risk of advanced prostate cancer in men who drink more than five cups of green tea per day [51]. Most men will not drink 6 cups per day of green tea; therefore, supplementation with a concentrated extract appears to be an important aspect of herbal chemoprevention [49–52].

*Essiac Tea*—a combination of four herbs (*Rheum palmatum*, *Trifolium pretense*, *Arctium lappa*, *and Rumex acetosella*) has also been found *in vitro* to inhibit prostate cancer cell growth.

## Pomegranate Juice

Pomegranate is a rich source of polyphenolic compounds, including anthocyanins and hydrolysable tannins. It has a reportedly higher antioxidant activity than green tea and red wine as well as anti-inflammatory properties. Recent studies show that anatomically discrete sections of the pomegranate fruit acting synergistically exert antiproliferative and antimetastatic effect against prostate cancer cells. Furthermore, pomegranate fruit extract treatment of highly aggressive PC-3 cells resulted in a dose-dependent inhibition of cell growth/cell viability along with induction of apoptosis coupled with corresponding laboratory effects on prostate cancer *in vitro* cell proliferation and apoptosis, as well as oxidative stress [53].

Pomegranate juice has also been shown to increase mean PSA doubling time. A human clinical trial featuring men with rising PSA levels demonstrated that drinking just 8 oz of pomegranate juice daily was effective at stabilizing PSA levels up to four times longer than normal, potentially delaying the growth of prostate cancer cells [54].

## Eicosanoids and Anti-inflammatory Chemoprevention

Inflammation is mediated by hormone-like chemicals called eicosanoids. Some eicosanoids encourage chronic inflammation; others discourage it. They impact the action of the immune system as well as the constriction of blood vessels, blood clotting, stomach acid secretion, and the intensity and longevity of pain and fever. Eicosanoids are built from polyunsaturated fats. Fats dictate the action of

enzymes that build eicosanoids. Certain enzymes make "good," anti-inflammatory eicosanoids; others make "bad," proinflammatory eicosanoids. "Good" eicosanoids are made from omega-3 fats, found in fish, walnuts, flaxseeds, and leafy green vegetables. "Bad" eicosanoids are made from omega-6 fats, found in many vegetable oils used to make processed foods, including oils made from corn, soybeans, sunflower, safflower, and cottonseed. Meats and dairy products, which come mostly from animals that are fed a grain-rich diet, also are high in omega-6s. The body's production of eicosanoids depends in large part on the balance of these fats in the diet.

In prostate cancer, the eicosanoid-building enzymes that seem to have the greatest impact on progression are *cyclooxygenase-2* (COX-2), *5-lipoxygenase* (5-LOX), and *12-lipoxygenase* (12-LOX). These enzymes lead to the production of proinflammatory eicosanoids like *prostaglandin E2* and *leukotriene B4*. COX-2 overexpression is a predictor of a worse prostate cancer outcome [44].

Other studies have suggested that angiogenesis is orchestrated in part by increased COX-2 activity and ensuing prostaglandin production, a hypothesis supported by the effects of some COX-2 inhibitor drugs (i.e., celecoxib) on the biochemical measures of apoptosis.

The anti-inflammatory aspect of chemoprevention appears to be a pivotal one, particularly in cases of PIN, which can appear up to 10 years before diagnosable cancer and which coexists with cancer in >85% of cases. PIN also offers investigators the opportunity to apply chemopreventive measures when dysplasia is present and the point at which prostate carcinogenesis may be at its earliest stage.

Manipulation of proinflammatory eicosanoids can be achieved in two ways: (1) with manipulation of fatty acid intake, providing the body with increased substrate for the production of anti-inflammatory eicosanoids, which then competitively inhibits formation of proinflammatory eicosanoids and (2) with manipulation of COX and lipoxygenase (LO) enzyme isoforms, inhibiting those that promote the inflammation that encourages prostate carcinogenesis. So far, it appears that fatty acid intake is a safe and effective intervention in this regard. Manipulating COX and LO with pharmaceutical agents, however, has proven to be a less promising avenue for chemoprevention. Recent case–control studies have found significant risks regarding long-term COX-2 inhibitor therapy, with increases in mortality and risk of heart failure and gastrointestinal (GI) bleeding.

Herbal anti-inflammatory agents have a broader, less specific effect and the research community is beginning to recognize their therapeutic value. Many researchers have explored a variety of natural plant extracts and other natural products to elucidate their specific and nonspecific effects on COX and LO. Curcumin (turmeric), ginger, holy basil, resveratrol (concentrated in grape skins), and berberine (from barberry and Chinese goldthread) are among the most promising candidates in the burgeoning field of herbal anti-inflammatory agents.

A novel compound under further study, Zyflamend (New Chapter, Brattleboro, VT), is composed of these and a few other herbs, most of which have a nonselective COX inhibitory effect. Each of the mixture's components has been found to have anti-inflammatory, antioxidant, or antiproliferative effects; some are even antiangiogenic. In 2005, Bemis et al. [55] published the results of an analysis of Zyflamend's effects on LNCaP cells—significant decrease in both COX-1 and COX-2 activity; increased p21 expression; attenuated cell growth; and induced cell apoptosis. A phase 1 clinical trial is currently being conducted at Columbia University in men with PIN to determine whether Zyflamend can influence the progression of biopsy-proven high-grade PIN to prostate cancer. Preliminary results are promising [56].

## Curcumin

Curcumin, or turmeric, has been found to be a potent radiosensitizer that enhances radiation-induced clonogenic inhibition in tumor cells [57]. A recent in vivo study showed that curcumin can help prevent prostate cancer. Dorai et al. [58] found that curcumin modulates proteins that suppress cell apoptosis and interferes with growth factors that promote cancer progression [59].

## Ginger

Ginger flavors many cuisines and has been a herbal medicine since antiquity, used to treat nausea, motion sickness, upper respiratory infections, and intestinal parasites. Modern investigators have discovered >20 phytochemicals in this rhizome that inhibit COX-2 and 5-LO. Ginger constituents have potent antioxidant and anti-inflammatory activities; some, particularly shogaols and vallinoids [6]-gingerol and [6]-paradol, exhibit cancer-preventive activity in experimental carcinogenesis. The chemopreventive effects of ginger have been illustrated in a variety of experimental models [60].

Prostabel, a herbal combination containing extracts of pao pereira (an Amazonian tree) and Rauwolfia vomitoria (from the bark of a sub-Saharan plant), was created by the late molecular biologist Mirko Beljanski. These plants have been used in indigenous medical traditions for centuries; Beljanski found that they had anticancer activities in various cancer cell lines, including prostate cancer. Research has revealed that both Rauwolfia and pao extracts suppress prostate tumor cell growth in culture and in vivo. Patients with elevated PSA and negative biopsy results are now being

enrolled in a phase 1 study of this herbal medicine. Results are awaited [61].

The herbs discussed in this review are relatively free of interactions with prescription drugs. Turmeric, however may potentiate antiplatelet activity in patients on antiplatelet agents; ginger and turmeric may potentiate the effects of anticoagulants. Patients should be advised that herbs and drugs can interact in harmful ways and that they should reveal the use of all medications and supplements to their physicians so that these adverse interactions can be avoided.

## Individual Micronutrients as Chemopreventatives

Vitamins are a group of structurally and functionally unrelated organic compounds that are essential for the normal functioning of the body and are present in various different food sources. According to a survey by the American Institute of Cancer Research (AICR), roughly half of adults >45 years take multivitamins specifically to lower the risk of developing cancer. In this same survey, 23–36% of subjects reported using other supplements for the same purpose [62]. No single nutrient has been found to stand alone as a chemopreventive agent. Notwithstanding current evidence in favor of individual nutrients from animal and *in vitro* models, the synergistic action and interaction of wide spectrum of micronutrients are the most likely reasons for the health benefits of disease-preventive foods, not the isolated action of any one or two nutrients in those foods.

The evidence does point strongly to the supplemental use of a handful of nutrients, in addition to a diet composed of beneficial and nutrient-dense foods in prostate cancer prevention. Vitamin E, selenium, vitamin D, and calcium all appear to play roles in prostate health. Supplementation of some vitamins and minerals may be appropriate as part of a chemopreventive program.

## Vitamin E

Vitamin E is a general term referring to a class of related compounds, including α-, P-, Σ-, and ψ-tocopherol and α-, P-, Σ-, and ψ-tocotrienols. α-Tocopherol has the highest biologic activity of all these compounds. In foods, vitamin E exists as a mixture of these various compounds, each of which has unique and interactive effects. The inhibitory effect of vitamin E on prostate carcinogenesis is probably attributable to its potent antioxidant effect in membrane phospholipids. It is the major hydrophobic chain-breaking antioxidant that protects membrane lipids from oxidation. Animal and preclinical studies have found that vitamin E also has direct antiproliferative effects unrelated to its antioxidant capacity [63], including inhibition of protein kinase C (PKC) activity, which plays an important role in proliferation, adhesion immune response, free radical production, and gene expression. Vitamin E also appears to interfere with hormone signaling, which is particularly relevant to prostate carcinogenesis.

Several RCTs have evaluated the role of Vitamin E either alone or in combination with other vitamins. In the large α-Tocopherol, B-Carotene (ATBC) RCT study, 29,133 male smokers received daily doses of 50 mg α-tocopherol (Vitamin E), 20 mg B-carotene (Vitamin A), both, or a placebo for 5–8 years. Although B-carotene had no effect on prostate cancer risk and it increased the risk of lung cancer and total mortality in this cohort, α-tocopherol supplementation reduced the risk of prostate cancer by 32% [64, 65]. Other research by the same Finnish investigators found that higher circulating concentrations of α-tocopherol and ψ-tocopherol, the major vitamin E fractions, correlated with a reduced risk of prostate cancer [66]. A role for α- and ψ-tocopherol in prostate cancer chemoprevention is further supported by the results of serum case-control studies. Follow-up analysis of the cohort involved in the ATBC studies found that the risk ratio for prostate cancer rose again to 0.94 in the 6 years following the end of the supplementation protocol, suggesting that continual supplementation with vitamin E is necessary to maintain its chemopreventive effects in the prostate. Men should take a minimum of 240 international units (IU) of vitamin E daily as mixed tocopherols (α and ψ in particular).

The selenium and vitamin E chemoprevention trial (SELECT), the largest prevention trial ever undertaken using a drug or nutrient, involved over 35,000 men randomized to one of four arms (to receive either 200 μg selenium, 400 IU of Vitamin E, both nutrients, or two placebo capsules alone). This large double-blind placebo-controlled trial closed enrollment in 2004. The trial was terminated early as interim results failed to show any benefit with either of the components in reducing prostate cancer risk [67]. The evidence supporting vitamin E is a chemoprotective agent in prostate cancer thus remains controversial.

## Selenium

Selenium is an essential trace mineral that gives reduction/oxidation (redox) potential to vitamin E. It is found in Brazil nuts and certain seafoods such as tuna, swordfish, and oysters. Furthermore, the amount of selenium obtained in any diet can vary widely because of variations in the selenium content of soil in different parts of the world where food is grown. Population studies consistently show that men with higher intake of selenium have a lower risk of prostate cancer and that men with prostate cancer have lower selenium levels than men who do not have the disease.

In 1996, the nutritional prevention of skin cancer study found that although daily supplementation with 200 μg selenium did not prevent recurrence of skin cancer in men with a previous history of skin cancer, it did result in a substantial reduction in the incidence of prostate cancer [68]. Supplementation for 6.5 years correlated with a 60% reduction in the number of new cases of prostate cancer compared with placebo, and 7.5 years of supplementation yielded 52% fewer cases compared with placebo. These investigators used a form of selenium that had been fermented with *Saccharomyces cerevisiae* yeast, a process that increases the nutrient's bioavailability [68]. These results and the overall reduction in the risk of other cancers were so promising that the control arm of the trial was stopped early.

Other studies demonstrate that selenium supplementation alone may slow prostate cancer growth or aid in the prevention of recurrence. In one study, 974 men with a history of prostate cancer received 200 μg selenium/day or placebo. With about 4.5 years of treatment and a 6.5-year follow-up, the authors concluded that selenium treatment was associated with a 63% reduction in prostate cancer recurrence.

Laboratory studies have determined that selenium inhibits angiogenesis and cellular proliferation [69], as well as inducing apoptosis *in vitro* [70]. Selenium also potentiates vitamin E-induced inhibition of prostate cancer cell growth [71]. Vitamin E combined with selenium has been found to induce cellular arrest in abnormal cells. Five of six biomarker-based studies found an association between selenium intake and either a reduced risk of prostate cancer or a nonsignificant trend toward a lower risk of the disease [72–76].

The studies above initially raised the prospect of using selenium supplementation for chemoprevention of prostate cancer. The interim results of the SELECT trial, however [67] were disappointing, showing no benefit of selenium alone or when combined with vitamin E for prevention of prostate cancer, which led to the early closure of this trial, however, Recently, the results of another large multicenter phase III RCT using selenium vs placebo in men with HGPIN has proved equally disappointing with no benefit seen in the intervention group receiving selenium supplementation [77]. The role of selenium supplementation in men with an already established diagnosis of prostate cancer was recently studied by Chan et al. [78]. The authors concluded that selenium supplementation in certain patients may result in a more aggressive prostate cancer phenotype especially when patients have an altered genotype for the manganese superoxide dismutase (SOD2) enzyme. These results taken together now challenge the previous notion of a protective role of selenium supplementation with some studies even suggesting the converse. Further investigations into selenium for chemoprevention are ongoing [79–81].

## Calcium

Current guidelines for calcium intake for osteoporosis prevention recommend that men >50 years take 1,200 mg calcium daily. Yet, in epidemiologic studies of calcium intake from diet and supplements, men with the highest intake of calcium have a significantly elevated risk of prostate cancer [18, 82]. The calcium intake found to raise the risk of prostate cancer was >1,200 mg; however, calcium intake of >2,000 mg/day from food and supplements elevated men's risk of the disease to varying extents, with risk ratios for prostate cancer ranging from 1.2 in the 86,404 men enrolled in the Cancer Prevention Study II (CPS-II) Nutrition Cohort to 1.71 in the Physicians' Health Study. The risk ratio for metastatic disease was found to be 2.97 in the latter investigation. A small proportion of men (1% of study subjects) consumed enough calcium to raise their risk of prostate cancer, but the link does exist and it is consistent. Physicians should thus ensure that patients recognize the upper limit for calcium intake. If the patient consumes significant amount of dairy products along with a calcium supplement, it may be prudent to evaluate the patient's diet to reduce calcium intake.

The interplay between vitamin D and calcium is probably the reason behind this association. High calcium intake reduces the production of $1.25(OH)_2$ vitamin D, which has antiproliferative, differentiating, and antimetastatic effects [83].

## Vitamin D

Several studies have demonstrated that vitamin D can inhibit prostate cancer growth by promoting cellular differentiation and inhibiting proliferation, invasiveness, and metastases [84]. In areas of the world where sun exposure is low and thus vitamin D deficiency is more prevalent, prostate cancer rates increase [85] and geographical distribution of CaP mortality is the inverse of that of UV radiation [86].

An international placebo-controlled randomized trial is looking into whether vitamin D has benefits for those with prostate cancer. In a pilot study, PSA levels decreased or remained unchanged after patients were given 2,000 IU (50 mcg) of cholecalciferol daily. This was sustained for as long as 21 months. Also, there was a statistically significant decrease in the rate of PSA rise after administration of vitamin D. The doubling time for PSA was increased by approximately 50% in the men taking vitamin D [87, 88]. A recent study of 3,763 urology patients revealed that 68% were deficient in vitamin D [89]. It thus seems appropriate to measure 25-hydroxy vitamin D in patients to check they have normal levels between 30 and 70 ng/mL. Randomized phase III clinical trials are necessary to determine the optimal dose

and most optimal vitamin D analogue along with route and schedule of administration.

## Active Hexose Correlated Compound (AHCC)

Active hexose correlated compound (AHCC) is a mushroom mycelium extract derived from a liquid culture of basidiomycetous mycelia of *Lentinula edodes* (shiitake mushroom). It was developed by Amino Up Chemical Co. Ltd (Sapporo, Japan) in 1989 and has been used throughout the world for its antitumor effects through the purported upregulation of the innate and adaptive immune responses [90]. Its main active component is a mixture of oligosaccharides with an average molecular weight of 5,000 kDa, with about 20% of them being of the α-1, 4glucan type, which is likely to be the molecule responsible for the therapeutic effects of AHCC [91–93]. In studies to date, AHCC has been shown to have some biological response modifier-like activity in certain cancer patients.

AHCC has a number of effects at the cellular level on immune function. AHCC has been shown to significantly increase the number of total dendritic cells (DCs) [93]. AHCC has also been shown to have direct anticancer activity against certain tumor cell-lines [94] as well as increasing natural killer (NK) cell activity which is important in the elimination of tumor cells. AHCC was also found to increase production of IFN-y, TNF-α, and other cytokines important in the activation of effector cells, which translates into antitumor activity in the cancer microenvironment. These results may indicate that AHCC can improve immunological competence in cancer patients, many who are already on therapies that cause immunosuppression. Despite the relative lack of large-scale randomized controlled trials, the existing literature has shown AHCC to be effective in the treatment of numerous cancers including breast [95], liver [96], and prostate [97].

The only studies in the existing literature utilize the reduction of prostate-specific antigen (PSA) as the primary end point to indicate the effectiveness of AHCC in treating prostate cancer. Case reports, although not conclusive, have shown AHCC to be an effective treatment option for prostate cancer showing that PSA levels drop significantly as early as 1–2 months and reach normal levels by 4 months [94]. But the relatively small number of patients in AHCC studies, as well as lack of controls and statistical analysis, greatly limits their power.

Although based on the two small clinical studies, AHCC does not appear to lower PSA scores of the general population of prostate cancer patients, but it has potential to lower PSA levels in older patients and in patients with advanced disease, which should be confirmed in larger trials focusing on these population groups. Case studies also indicate that patients with certain characteristics may benefit from supplementation with AHCC. Besides looking at PSA values as a standard of efficacy, other clinical correlates should be analyzed, such as using imaging techniques to assess for resolution of cancer, as well as eliciting overall symptom response and assessment of patients' physical and psychosocial improvement. Given the strong safety profile of this natural compound and its apparent lack of side effects, supplementation with AHCC holds much potential to help certain prostate cancer patients, but further studies need to be conducted in order to support this.

Because, thus far AHCC has not been shown to be harmful and is not associated with any significant adverse effects, its clinical utility can still be assessed with little overall risk to the patient. Although AHCC appears to be a promising alternative treatment in patients with malignancy, there is a need to conduct randomized controlled double-blind trials on a larger scale to understand its true implications in prostate cancer patients. To date, PSA has been used as the primary outcome measure to quantify the effectiveness of AHCC, but the utility of this measure needs to be considered against other clinical outcomes. By performing studies with higher statistical power and including the measurement of other clinical end points while controlling for prostate cancer grade and stage, AHCC may be confirmed as a safe, natural, and effective alternative to standard medical therapy for prostate cancer.

### Conclusions

The popularity of complementary and alternative medicine continues to grow in prostate cancer management. Nutritional and herbal interventions in early prostate cancer and high-grade PIN have strong support in the published research. Furthermore, they show significant promise in helping to slow progression and reduce recurrence of prostate cancer. The interventions described in this review are beneficial for multiple body systems, including the endocrine, cardiovascular, immune, and central nervous systems. In all grades of prostate cancer, diet and supplements complement conventional treatment to improve response and quality of life and help empower the patient to be proactive and play their role in taking control of their disease.

In a series of studies, Demark-Wahnefried et al. [98] of the Duke University Program of Cancer Preventive, Detection, and Control Research have pointed out the growing role of oncologists as advisors and supporters of cancer patients who will greatly benefit from long-term diet and lifestyle changes. According to their review article on the subject, cancer survivors frequently initiate diet, exercise, and other lifestyle changes after the wake-up call of cancer diagnosis but that older men and less well-educated men are less likely to do so. In reviewing relevant studies from 1966 to the present, Demark-Wahnefried and

colleagues found that only 25–42% of cancer survivors consume adequate fruit and vegetables and that approximately 70% of prostate and breast cancer survivors are obese or overweight. They conclude that "oncologists can play a pivotal role in health promotion, yet only 20% provide such guidance."

With the number of cancer survivors continually rising as the result of early detection and improved treatments and with our increasing understanding of the benefits of dietary changes and nutritional interventions in early-stage cancers, the time has come for urologists to disclose all pertinent information regarding their knowledge of specific foods and nutritional supplements to their patients. Accountability and responsibility are required of both doctor and patient.

At this writing, clinical research into the use of such therapies in early prostate cancer and high-grade PIN is relatively new. Much more of this kind of research is imperative for the creation of consistent and effective protocols for chemoprevention, not just of prostate cancer but of other cancers as well. Recommendations for standardization and dosages of herbal medicines are often frustratingly difficult to determine because of the lack of this research. Even so, the benefits of herbal and nutritional chemoprevention appear to greatly outweigh any harm that could come to a patient, particularly in the earliest stages of detectable disease, in whom active surveillance would be the most likely first intervention.

# Estrogens in Prostate Cancer

30

Giuseppe Carruba

## Introduction

Although prostate cancer represents a major health issue in men in Western countries, being a common cause of morbidity and mortality after the age of 50, it ought to be preventable and curable. Notwithstanding, despite the most recent advances in both basic and translational research, the molecular basis of prostate cancer remains poorly understood. In particular, the mechanisms underlying development and progression of this neoplasm appear to be complex: genetic and environmental factors (notably lifestyle and diet), along with endogenous sex hormones and host immune and inflammatory response, are likely to be interconnected in the pathogenesis of the disease.

As for breast cancer, dietary factors are thought to profoundly affect levels of endogenous hormones and their metabolism, eventually leading to prostate cancer development and/or progression [1]. In this context, sex hormones may act as intermediaries between exogenous factors, either environmental or nutritional, and biomolecular targets in both development and progression of prostate malignancies. Fascinatingly, breast and prostate cancer share many similarities, in terms of geographical distribution, risk factors, biomolecular determinants, and natural history. In a figurative way, cancer of the human prostate and breast can be viewed as brother and sister tumors, where dietary factors and hormones, especially estrogens, represent key interrelated players in many biological and pathological processes. In this framework, both breast and prostate cancer may be primarily considered, as elegantly proposed by Coffey [2], an acquired nutritional disease that could be prevented through changes of lifestyle and dietary habits.

Although estrogen regulation of prostatic development, growth and function is generally recognized, the potential role of estrogens in human prostate cancer has been mistakenly neglected for decades and only recently reconsidered [3]. It has been long time remarked, but lately acknowledged, that neither androgens nor estrogens have a sexual selectivity, the former being implicated in breast and the latter in prostate, either normal or malignant, cell growth. This concept is nicely presented in a paper by Kuiper and colleagues where estrogen is described as a male and female hormone [4].

## Epidemiological Studies

Prostate cancer is the commonest non-skin tumor and the second leading cause of cancer death in men in the United States, with an estimate of 241,740 new cases and 28,170 deaths from this disease expected in the year 2012 [5]. Between the late 1980s and 1990s, incidence rates of prostate cancer have increased dramatically in USA, Europe, and in many other Westernized countries with a peak in 1992 as a consequence of the introduction of prostate-specific antigen (PSA) blood test as a diagnostic tool for prostate cancer screening. The causes of the subsequent decline of prostate cancer incidence, that is present solely in men aged 65 years and older, remain indefinite. In addition, mortality rates of prostate cancer have been consistently decreasing in Western countries since the late 1990s. Notwithstanding, human prostate carcinoma continues to represent a major health and socioeconomic issue especially because mechanisms underpinning prostate carcinogenesis and tumor progression are largely unclear and, hence, new strategies for prevention, early diagnosis, and personalized treatment have only been rarely developed and implemented in clinical practice.

Both incidence and mortality rates for prostate cancer vary greatly worldwide, with as much as 50-fold and a 12-fold [6] difference, respectively, between African American and Caribbean men and men in Eastern Asia (China, Korea) and Africa (Egypt, Somalia). In European

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_30, 

countries, incidence of prostate cancer is markedly higher in Northern (80.1/100,000) than in southern Europe (44.7/100,000), with Sweden having the highest rates (139.3/100,000) and Greece the lowest (43.4/100,000).

Although several aspects may account for these large geographic variations, there is an overall consensus that lifestyle and, notably, diet play a key role, while environmental and genetic factors may only have a limited impact on prostate cancer incidence. A small proportion (5–9%) of prostate cancer cases can be in fact associated with heritable genetic defects, while familial prostate cancer may represent up to 20% of cases [7]. However, even in men who carry strong cancer-susceptibility genes, the contribution of environment and lifestyle appears to be critical for the manifestation of disease.

An increased risk of developing prostate cancer has been reported in relation to a high fat diet, high protein and energy intake, low intake of fiber and complex carbohydrates, and a sedentary lifestyle [8–10]. However, the statistical significance of this association is low, and age, ethnicity, and family history remain the few, well-established risk factors for prostate cancer [11].

Previous studies on migrant populations who moved from countries with low incidence/mortality rates of prostate cancer (i.e., China or Korea) to countries with higher prostate cancer rates (Unites States) showed, within a generation, a significant increase in prostate cancer incidence/mortality as compared with their peers in the countries of origin [12, 13]. On the other hand, prostate cancer incidence is rising rapidly in countries that have been historically characterized by low rates especially Asian countries such as China and Japan, as oriental populations gradually adopt Western diet and lifestyle. This evidence suggests that environmental and, especially, lifestyle factors play a dominant role in prostate cancer development.

Several studies have hypothesized that plant hormones contained in Asian diets, particularly the phytoestrogens present in soy products, might act as natural hormone antagonists and anticancer agents and that their intake could be associated with a decrease of prostate cancer risk. A recent review [14] of epidemiological studies on the association of soy and other nutrients containing phytoestrogens with the risk of developing prostate cancer showed contradictory results with only a few studies reporting a risk reduction associated with the intake of soy food, legumes, and isoflavones. In a meta-analysis of eight epidemiological studies, Yan and Spitznagel indicated that the consumption of soy food was related to a nearly 30% reduction of prostate cancer risk, despite only three studies in the analysis showed statistically significant lower risk of prostate cancer [15]. Several studies in Asian men have also reported a trend toward decreased prostate cancer risk with increased equol (a gut bacterial product of the isoflavone daidzein). In addition, lower equol concentrations or a lower prevalence of equol producers have been observed in Asian populations among men with prostate cancer compared with controls, whereas studies in European populations have reported no association [16].

Interestingly, after World War II, lifestyle and dietary habits in Asian countries, especially Japan, have drastically changed, and these changes have been accompanied by a marked increase of both testicular and prostatic tumors [17]. In particular, the introduction of milk in a no-meat/no-milk dietary culture produced a significant, unprecedented source of saturated fats and estrogens that could have, in turn, favored prostate cancer development and progression. In this respect, Ganmaa and colleagues claim that the 20-fold increase of milk consumption seen in Japan after the war should be taken into account to explain, at least in part, the increase of prostate cancer incidence and mortality that has recently occurred in this country.

An explanation of the linkage between environmental and/or lifestyle factors and prostate cancer risk may lie in the potential impact of these factors on both levels and biotransformation of endogenous sex steroids, particularly estrogens. It is noteworthy that environmental and dietary factors are highly likely to induce significant changes in circulating hormones, their intraprostatic levels and metabolic patterns, eventually leading to prostate cancer development and/or progression.

## Circulating Sex Steroids

Doubtlessly, the human prostate gland is dependent upon androgen for its development, function, and homeostasis. On the other hand, the potential implication of androgens in prostate carcinogenesis and tumor progression remains a common assumption (the “androgen hypothesis”), to such a point that prostate cancer is universally recognized as a prototype of age-related, androgen-dependent tumor. This assumption is based also on the fact that a high proportion of patients having locally advanced prostate tumors initially respond to hormone treatment, while they frequently develop an androgen-refractory condition after a relatively short time (usually within 2 years from presentation).

Both total and free serum testosterone significantly decline with age, eventually leading to an inverse relationship between testosterone levels in blood and prostate cancer risk. Thus, we are facing a seeming paradox whereby the higher the circulating testosterone, the lower the risk of developing prostate cancer.

In men, the balance between circulating levels of androgens and estrogens changes significantly with age [18]. In the aging male, a reduced production by the testes and increased levels of sex hormone-binding globulin (SHGB)

combine to lower free circulating testosterone. While plasma androgens decline, estrogen levels remain fairly constant, also as a consequence of an age-related increase of adipose tissue where estrogens are produced through the aromatization of androgens [19]. The ultimate result is a marked increase of the estrogen to androgen ratio and, hence, a potential increase of estrogenic activity on prostate gland that may eventually lead to abnormal growth and subsequent malignant transformation [20].

Apart from aging, males are exposed to relatively higher levels of circulating estrogens solely during in utero development. Several studies have indicated exposure of prostate cells to elevated estrogens early in uterine or perinatal life (a process referred to as developmental estrogenization or estrogen imprinting) may induce permanent disorders of prostate development that may in turn result in a higher propensity of prostate to develop precancerous or malignant lesions [21–23]. In addition, perinatal or neonatal exposure of prostate gland to endogenous estrogen and/or environmental estrogen-like endocrine disruptors may directly impair androgen-driven prostate development or result in functional and morphological prostate alterations that may in turn predispose the tissue to an earlier onset of disease, including cancer [24, 25]. One could speculate that developmental estrogenization generates important changes in the pool of embryonic stem cells that may, in turn, give rise to a population of adult "imprinted" prostate stem cells having a high susceptibility of developing cancer. All other things being equal, an increased adult prostate stem-cell pool would elevate the risk that one stem cell might become initiated [26].

The association between circulating androgens and prostate cancer risk has been explored by several studies, but the resulting data have been inconsistent and largely conflicting the "androgen hypothesis." None of the numerous prospective studies that have investigated the relationship between absolute plasma levels of testosterone and the risk of developing prostate cancer have shown any significant association. The subsequent meta-analyses by Eaton and colleagues [27] and Hsing et al. [28], respectively presenting quantitative reviews of the data from 8 and 12 available prospective studies, clearly revealed no significant differences in circulating hormones, either androgens or estrogens, between men who subsequently develop prostate cancer and those who remain free of disease. Only one study, the Physician's Health Study [29], reported a significant rise of prostate cancer risk with increasing plasma testosterone levels and an inverse association of estradiol with risk after adjusting for reciprocal levels and sex hormone-binding globulin (SHBG). However, this study found no significant difference in the risk of prostate cancer between men in the highest and the lowest quartiles of serum total testosterone.

Only a few earlier studies have investigated the correlation of serum levels of free testosterone and the risk of prostate cancer. Again, no significant association has been reported when the free fraction of this androgen was measured directly [30, 31].

The Rancho Bernardo study, conducted in California, revealed an association of elevated plasma estradiol and estrone with an increased risk of prostate cancer [32]. Two more recent nested case-control studies on serum levels of both androgens and estrogens failed to show any association with prostate cancer risk [33, 34]. Interestingly enough, one of the two studies has reported a positive association of plasma total testosterone with low-grade disease and an inverse association with high-grade disease [33].

Recently, a limited but significant decrease of prostate cancer risk has been associated with increasing serum levels of total testosterone [35]. In a study on hypogonadal men, Morgentaler and colleagues [36] reported that subjects with PSA levels <4.0 ng/mL had a 15% overall rate of prostate biopsies positive for cancer. Interestingly, subjects with plasma levels of testosterone <250 ng/dL had a prostate cancer rate of 21% as opposed to 12% for men with a testosterone level >250 ng/dL. Furthermore, the probability of cancer in men in the lowest tertile was over twice as much as that in men in the highest tertile of both total and free testosterone.

Several studies have scrutinized the relationship between pretreatment serum levels of testosterone with clinical stage of prostate cancer and patient survival, suggesting that low serum testosterone could be used as a negative prognostic predictor for this neoplasia. In the last decade or so, a number of papers have emphasized that low serum testosterone is associated with prognostically adverse characteristics of prostate cancer, including high-grade [37, 38], poor clinical outcome [39], advanced pathological stage at surgery [40, 41], and shorter survival [42].

Based on the above inconsistency, investigators have raised the question why it has been so problematical to demonstrate that plasmatic androgens are related to the risk of developing prostate cancer. The most obvious answer to this question is that circulating androgens are simply not associated with prostate cancer risk.

It should be taken into consideration, however, that several issues related to measurement of plasma steroids, both androgens and estrogens, could be contemplated to explain this large inconsistency of data. They include the low statistical strength of most studies, the limited number of incident cases in prospective studies, the minor differences in sex steroid serum levels between cases and controls, and the rather large intra- and inter-assay laboratory variations of serum hormone measurements [43]. On the other hand, several other variables, including obesity, physical activity, diabetes, metabolic syndrome, and benign prostatic hyperplasia, that might have an impact on serum levels of hormones and have been related to prostate cancer have not been adjusted for in previous nested case-control studies [44].

In any case, it is unlikely that a single assay of plasmatic androgens can be regarded as descriptive of average androgen levels over an etiologically relevant period of life. In this respect, since the length of prostate carcinogenesis and tumor progression can span 35–40 years or longer, the timing for the carcinogenetic activity of androgen and/or estrogen on human prostate should be counted 20–30 years (or even earlier) prior to the clinical manifestation of the disease, when serum androgens are higher and, hence, could be biologically relevant.

All the above issues might contribute to justify, at least in part, the inconsistency of data on the association of plasmatic androgens and prostate cancer risk. However, a major problem remains whether or not plasma levels of steroids can be considered representative of the respective intraprostatic concentrations. Intratissue levels of sex steroids in target organs, including breast and prostate, have been reported to be markedly greater (10- to 100-fold) than the respective values in plasma [45, 46]. Furthermore, both normal and malignant steroid target tissues are equipped with a repertoire of enzymes of steroid metabolism, including a superfamily of hydroxysteroid dehydrogenases, two 5α-reductases, several hydroxylases, sulfotransferases, sulfatases, and aromatase. A different expression and/or activity of these enzymes may result in a different accumulation of bioactive metabolites, eventually leading to patterns of intratissue steroids that may substantially diverge from the plasmatic figure. Simpson and colleagues [47] have emphasized that estrogens circulating in men and in postmenopausal women are not the drivers of estrogen action, but they represent a reflection of estrogen uptake and biotransformation at extragonadal sites, including prostate. In other words, they are *reactive* rather than *proactive* [48].

## Tissue Biosynthesis and Metabolism

As pointed out above, the balance between androgens and estrogens in individual target tissues may be significantly different from that in plasma, being dependent on several factors including uptake from the circulation, binding to steroid receptors and cofactors, and, notably, expression and/or activity of steroid enzymes, including 5α-reductase and aromatase. In this context, the ultimate biological impact of parent sex steroids and their derivatives could be assessed only through the evaluation of their local biosynthesis and metabolism. This issue has become increasingly important for a better understanding of the potential role of estrogens in breast and prostate cancer, also because abnormal levels of estradiol and/or estrone and, especially, of some of their hydroxylated tissue derivatives have been implicated in tumor development and progression [49].

As compared to breast, only a few early studies have assessed intraprostatic levels of sex hormones [50, 51]. Although these studies present some interesting preliminary observation on how prostate cells, either epithelial or stromal, metabolize androgens, they are largely insufficient and not significant enough to draw any conclusive inference.

In androgen target tissues, such as skin and prostate, testosterone is converted into its bioactive metabolite dihydrotestosterone (DHT). DHT binds in turn to androgen receptors and localizes in the nuclei of prostate epithelial cells as a dimer to regulate transcriptional activity of androgen-sensitive genes and DNA synthesis. The extent of DHT formation, that is governed by the 5α-reductase enzyme(s), produces DHT tissue levels markedly higher than those of testosterone, leading to a totally reversed testosterone:DHT ratio with respect to plasma (1:6 vs. 10:1, respectively) [52, 53]. In humans, two isozymes (type I and II) of the 5α-reductase exist, having distinct enzyme kinetics and tissue distribution. The type 1 isoform (encoded by *SRD5A1*) is expressed predominantly in skin and hair, while the type 2 enzyme (encoded by *SRD5A2*) is located primarily in androgen target tissues, including skin and prostate [54].

Results of the Prostate Cancer Prevention Trial (PCPT) indicate that the use of finasteride, a 5α-reductase inhibitor, for chemoprevention of prostate cancer results in a decrease of the overall number of incident cases but increases the proportion of high-grade prostate tumors [55]. Correspondingly, Nishiyama et al. [56] reported significantly lower levels of intraprostatic DHT in men with prostate cancer having a 7–10 Gleason score (GS) as compared with prostate cancer of ≤6 GS, suggesting that locally advanced, aggressive disease can progress even in a low-androgen environment. The authors also found no correlation between plasma levels of testosterone and/or DHT and intraprostatic levels of DHT. Indeed, Freedland and associates [57] have reported that circulating testosterone could not be mirroring intraprostatic androgenicity, and, hence, comparison of men having low and high testosterone levels could not be useful for a better understanding of the association between low androgen and aggressive prostate tumors.

Tissue estrogen biosynthesis occurs primarily through androgen aromatization. Since results of several studies suggest that human prostate gland is a primary target for estrogen action and that local synthesis of estrogen may be significant in prostate cancer, it would be important to determine whether or not aromatase is expressed in prostate tissues and to investigate the association between aromatase alteration and prostatic disease(s), including cancer. In this respect, the aromatase enzyme may act as a critical regulator of the balance between androgens and estrogens in target tissues and plasma. In the last decades, consistent evidence has accumulated to support the hypothesis that abnormal aromatase may play a critical role in development and/or

progression of human breast cancer. The *normal* prostate expresses aromatase in the stromal compartment, while aromatase expression is induced in malignant prostate through an abnormal promoter utilization, eventually leading to an altered T:E ratio that is associated with the development of disease [58]. Interestingly, lifelong exposure of aromatase knockout (ArKO) mouse to elevated androgens resulted in the development of prostatic hyperplasia, although no malignant changes could be detected in the prostate at any time, supporting a pivotal role of local estrogen biosynthesis in prostate cancer development [59]. In addition, significant expression and activity of aromatase have been detected in LNCaP, DU145, PC3 prostate cancer cells, and microdissected prostate epithelial tumor cells, while the enzyme could not be detected in *nonmalignant* prostate epithelial cells [60]. However, the potential implication of aromatase in either nontumoral or malignant human prostate remains today equivocal.

Estrogen patterns in target tissues and cells are much more assorted than one could expect on the basis of circulating estrogen profiles. The two major plasmatic estrogens, estradiol (E2) and estrone (E1), are readily interconverted in the tissue through the action of a superfamily of 17β-hydroxysteroid dehydrogenase enzymes (17β-HSDs) having distinct catalytic preferences and tissue distributions [61]. The hydroxylation of these "classical" estrogens at the C2/C4 positions through cytochrome P450 enzymes encoded by the CYP1A1 and CYP1B1 genes generates the so-called catecholestrogens (CCE), namely, the 2-hydroxy and 4-hydroxy derivatives of E2 and E1. Until are further metabolized by the catechol-O-methyltransferase enzyme into inactive methoxy derivatives, CCE may produce reactive oxygen species (ROS) that are in turn responsible of oxidative DNA damage.

Two mutually exclusive pathways, the 16α- and the 16β-hydroxylation, may act to produce a series of additional metabolites of either of as yet undefined biological activity. In particular, 16α-OHE1, along with other hydroxylated estrogens, has been repeatedly implicated in human breast carcinogenesis [49]. In a recent study, estrogen derivatives produced through either 16α-hydroxylation (e.g., 16α-OHE1 and 17-epiestriol) or 16β-hydroxylation (e.g., 16β-OHE1) have been reported to be comparable to classic E2 or E1 not only in terms of estrogenic potency but also for tumorigenicity in young adult mice [62].

Unfortunately, however, no direct unequivocal evaluation of estrogen intraprostatic levels has been so far provided.

In a recent randomized, dietary intervention study (the MeDiet study), we have ascertained that a traditional Mediterranean diet markedly reduces (over 40%) urinary levels of estrogens in healthy postmenopausal women [63]. It is of interest to note that, in this study, the majority of urinary estrogens was represented by hydroxy and methoxy derivatives of either E2 or E3 (notably 2-OHE2, 17-epiestriol, and 16-ketoE2), while *classical* estrogens (namely, E2 and E1) accounted for a mere 0.5% of total endogenous estrogens in urine. This pattern is cognate to what we have found by measuring intratissue levels of estrogens in both *nontumoral* and malignant human breast, whereby hydroxy estrogens accounted for the majority (more than 80%) of all estrogen metabolites in either condition [46]. In other words, metabolic profiles of estrogens in urine appear to be comparable to those obtained by measurement of their intratissue concentrations. This, incidentally, reinforces the suggestion that urinary estrogens can be used as indirect indicators of patterns of intratissue estrogens. In this respect, we have reported that a lower risk of developing prostate cancer is associated with a higher ratio of 2-hydroxyestrone (that has been originally proposed to act as anticancer estrogen and named accordingly *the good estrogen*, [64]) to 16α-hydroxyestrone (that has been claimed to be genotoxic, [65]) in urine [66].

Aiming to determine the impact of local metabolism on the distribution of bioactive steroids to malignant prostate cells, a few studies have assessed both expression and activity of key steroid enzymes in cultured human prostate cancer cells.

Recently, Vihko and colleagues [67], using both androgen-sensitive and androgen-independent LNCaP prostate cancer cells as a model system, have suggested that progression of prostate cancer to an androgen-refractory state is associated with a significant decrease of oxidative activity and a corresponding increase of reductive activity of the 17β-HSD enzyme(s). As a consequence, reduced bioactive estrogen (namely, estradiol) would accumulate in androgen-independent cells, while oxidized estrogen (namely, estrone) would become prevalent in androgen-sensitive cells.

We have originally established and optimized a rapid, simple approach to measure simultaneously the activity of several steroid enzymes in *intact* cultured cells [68]. Using this approach, we have assessed rates and direction of androgen metabolism in human prostate cancer cells [69]. Shortly, androgen-responsive LNCaP cells show consistent conversion of testosterone into the bioactive androgen DHT and its derivatives, 3α/3β-androstanediol, along with 17-βreduction of E1 to E2, while androgen-resistant PC3 cells exhibit a massive 17β-oxidation, leading to the predominance of oxidized androgen (androstenedione) and estrogen (estrone) derivatives. We have subsequently revealed that these highly divergent metabolic patterns are a consequence of a different expression and activity of several steroid enzymes, including 17β-HSDs, 3α-/3β-HSDs, and 5α-reductase, in the two cell lines [70]. This finding is of outmost importance since it corroborates the view that local steroid formation and metabolism is critical to determine the respective amounts of individual bioactive metabolites and, hence, the ultimate biological impact of sex steroids in target tissues and cells.

Our previous studies have revealed that aromatase activity is present in LNCaP prostate cancer cells even though to a significantly lesser extent than that observed in MCF7 human mammary carcinoma cells [71]. More recently, Ellem and Risbridger [72] have assessed aromatase RNA, protein, and enzyme activity in benign and malignant human prostate tissues, as well as in human prostate cancer cell lines. While aromatase was expressed solely in the stromal compartment of nontumoral prostate tissues, it was detected in microdissected epithelial tumor cells and prostate cancer cell lines.

Genes encoding for steroid enzymes are highly polymorphic in nature. Gene polymorphisms, along with epigenetic silencing or structural alteration, may all be associated with an increased risk of prostate cancer. To date, however, a relatively finite number of epidemiologic studies have been conducted to address this issue, and only limited, inconsistent evidence of the association between prostate cancer risk and gene polymorphisms has been provided.

As far as androgen metabolism is concerned, polymorphisms of genes involved in androgen biosynthesis (CYP11A1, CYP17A1, CYP19A1, CYP17A2), DHT formation (SRD5A2), and androgen inactivation and excretion (CYP3A4, HSD3B1, HSD3B2) have all been related to risk of developing prostate cancer [73–79]. In particular, several polymorphic regions are present in the SRD5A2 gene that encodes for the type 2 5α-reductase enzyme. Polymorphisms of this gene have been studied with special interest since its enzyme product presides over DHT formation in prostatic tissues. However, the present evidence indicates only a weak to modest increase of prostate cancer risk and, hence, does not apparently support the implication of DHT in prostate cancer development and progression [80].

As for estrogen metabolism, three different polymorphisms of the CYP1A1 gene, encoding the 2-hydroxylase enzyme, have been associated with an increased risk of prostate cancer, while only one single nucleotide polymorphism (SNP) has been reported to have an opposite impact by reducing prostate cancer risk in Japanese and a Caucasian-American population [81, 82]. Comparable finding was obtained for the CYP1B1 gene that encodes the 4-hydroxylase enzyme [83]. It is noteworthy that these polymorphisms result in a prolonged half-life and activity of either enzyme, and, hence, produce a sustained exposure of prostate cells to their products, respectively, 2- and 4-hydroxy estradiol, amplifying their carcinogenetic potential.

In a recent paper, Mononen and colleagues have identified a novel SNP of the CYP19A1 gene that encodes for a variant aromatase enzyme having higher activity and that is significantly associated with prostate cancer risk [79]. The reported evidence implies that this SNP results in lower androgen levels and greater amounts of tissue estrogens, supporting the potential implication of estrogen in prostate cancer development and growth.

Although some of these gene polymorphisms could be relevant in prostate carcinogenesis and tumor progression, their significance is still unclear and remains fairly speculative. Many issues may concur to make results of these studies inconsistent, but probably the most important is the lack of information on the combined effect of these polymorphic genes on prostate cancer risk [84]. Further studies on haplotypes and diplotypes are being conducted to determine the ultimate effects of polymorphic genes on the production and/or activity of steroid enzymes in relation to individual risk of prostate cancer.

## Estrogens in Prostate Tumor Development and Growth

Since the pioneering work of Charles Huggins, the concept that human prostate cancer represents a paradigm of androgen-dependent tumor has endured for decades against a bulk of experimental evidence suggesting that estrogens and other growth factors may be at least equally important in prostate carcinogenesis and tumor progression (reviewed in 3).

### Estrogens in Tumor Initiation

Recent experimental evidence suggests that prostate cancer originates from precancerous lesions, such as chronic proliferative inflammatory atrophy (PIA), as a consequence of prostate tissue injury [85]. Normally, in response to tissue injury, the prostate stem cell niche, that represents a minority (1–3%) of basal epithelial cells and has been located at the basement membrane of the prostatic glandular epithelium, would give rise a population of transit-amplifying/intermediate cells that would, in turn, terminally differentiate and generate luminal secretory and neuroendocrine epithelial cell types. It is speculated that tumor-initiating cells could arise during the prostate regeneration process within the pool of prostate stem cells when their differentiation ability is somehow impaired by a mutation activating oncogenic and/or abrogating tumor-suppressor signaling pathways [86]. The resulting progeny of cells would clonally expand and undergo the promotion and progression phases of the multistep carcinogenetic process, eventually leading to create a population of cancer stem cells featured by unrestricted replicative potential and reduced apoptosis. In this context, estrogens have been reported to upregulate both expression and activity of telomerase in human prostate epithelial cell lines, an event that is generally associated with unlimited cell proliferation [87].

Cavalieri and Rogan [88] have produced consistent experimental evidence in support of their hypothesis that selected tissue estrogen metabolites, notably the electrophilic catechol

estrogen-3,4-quinones, may react with DNA and generate depurinating estrogen-DNA adducts. After adducts are released from DNA, error-prone base excision repair of the resulting apurinic sites may eventually lead to mutations that can be critical to initiate breast, prostate, and several other human cancers.

## Experimental Animals

Early studies have reported that long-term administration of testosterone to rats induces the development of prostate tumors, suggesting that testosterone act as a complete carcinogen on the rat prostate, though in a limited proportion of cases and in some but not all rat strains [89–91]. However, when Noble rats were used as model system, the administration of testosterone and estradiol, in sequence or combined, resulted in the occurrence of both ductal and acinar epithelial dysplasia, followed within 1 year by the development of adenocarcinomas of the dorsolateral prostate in 90–100% of the animals [92]. If rats were treated with androgen alone, the incidence of prostate cancer dropped to 35–40% [93].

The mechanisms underpinning the hormonal carcinogenesis in the rat prostate remain largely undefined, but there is evidence to suggest that both receptor-mediated and *nonreceptor* effects may be implicated. As far as estrogens are concerned, the development of dysplastic lesions in the dorsolateral prostate of rats exposed for 16 weeks to a combination of testosterone and estradiol was almost completely abrogated by the simultaneous administration of the pure antiestrogen ICI-182,780 [94]. However, since ICI-182,780 also induces a block of the hyperprolactinemia produced in rats by estrogen treatment, it is difficult to establish whether the effects of this estrogen antagonist are a consequence of binding to estrogen receptor or not.

Other studies have revealed that Noble rats treated with testosterone and estradiol or with testosterone and the synthetic estrogen diethylstilbestrol (DES) for 16 weeks accumulate estradiol and the estrogenic androgen 5α-androstane-3β,17β-diol (3α-androstanediol, 3α-diol), respectively, in dorsolateral and ventral prostate [92, 95]. This evidence suggests that androgen and estrogen treatment of animals creates an estrogenic milieu in the rat prostates, eventually leading to the development of epithelial dysplasia and adenocarcinoma in the Noble rat prostate model. In an elegant study, Wang et al. [96] rescued pelvic organ rudiments of Rb KO mice and grafted them under the renal capsule of male adult nude mice to develop functional prostatic tissue. When Rb-/-prostate epithelium was combined with wild-type urogenital mesenchyme to construct chimeric tissue recombinants, dysplastic and malignant lesions occurred 5–8 weeks after host animals received silastic implants containing testosterone (25 mg) and estradiol (2.5 mg).

Although most studies on hormonal carcinogenesis of the prostate have been conducted on rodents, it ought to be emphasized that the rat prostate, consisting of dorsal, lateral, ventral, and anterior lobes, has embryology and anatomy distinct from human and dog prostates. Therefore, results of these studies should be interpreted with caution.

## Endocrine Disruptors

Accumulating evidence from both epidemiological and animal studies suggests that environmental exposure to endocrine-disrupting chemicals may be important for development or progression of human prostate cancer. These compounds may disturb estrogen signaling by interfering with either ER or enzymes of steroid metabolism, eventually leading to significant changes of levels of individual estrogen derivatives having distinct biological activity. Endocrine disruptors include pesticides, polychlorinated biphenols (PCBs), polyhalogenated aromatic hydrocarbons (such as bisphenol A, BPA), phthalates, arsenic, cadmium, and UV filters. Most of them have estrogen-like activity and are also referred to as xenoestrogens; many have been associated to an increase of prostate cancer risk (reviewed in [97]). The accumulation and the assortment of xenoestrogens in the environment have enormously increased in recent years, and this has also been related to the persistent increase of estrogen-related diseases, including breast and prostate cancer, neurodegenerative disorders, endometriosis, premature puberty, cryptorchidism, and many others. It is important to note that sensitivity of prostate tissues to endocrine disruptors appears to be prominent through critical developmental phases, notably in uterine life, at birth, and during puberty. A sustained exposure to xenoestrogens during these periods may be responsible for an increased susceptibility to develop prostate cancer later in life.

## In Vitro Studies

Both epidemiological and experimental evidences presented herein support the view that prostate cancer arises in the aging male in an estrogenic environment. However, the ultimate biological impact of sex steroids, particularly estrogen, on prostate cancer cells is difficult to dissect as it is strictly dependent upon several variables, including the estrogen:androgen ratio in both plasma and prostate, the expression and activity of steroid enzymes, the binding to intracellular and/or membrane receptors, the exploitation of genomic and/or nongenomic mechanism(s) of action.

Previous studies have assessed the proliferative effects of sex hormones in cultured prostate cancer cells. Although several reports have shown that androgens markedly stimulate

prostate cancer cell growth [98, 99], unequivocal evidence for a direct increase of DNA synthesis brought about by bioactive androgens in prostate tumor cell lines is surprisingly rare and often conflicting. The inconsistency of the results obtained in cell model systems does not allow to draw any truthful interpretation also because different variables including culture and experimental conditions, age of cultured cells, and exposure to endogenous hormones and growth factors may considerably affect the results.

Various in vitro studies carried out on LNCaP cells have indicated that both androgen and antiandrogen stimulate growth of these cells [100]. We have previously reported that exposure to physiological estrogen concentrations may either stimulate or decrease growth of androgen-responsive LNCaP or androgen-refractory PC3 prostate cells, respectively, and that these effects are predominantly receptor-mediated being completely abrogated by the simultaneous addition of the pure estrogen antagonist ICI-182,780 [101, 102]. This evidence implies that estrogen may affect proliferative activity of prostate cancer cells even if the cells have become androgen resistant. This finding is also corroborated by the significant rates of clinical response to the systemic administration of estrogens observed in prostate cancer patients having a metastatic, androgen-refractory disease [103]. Other authors have revealed that tamoxifen (mixed antiestrogen) and ICI-182,780 (pure antiestrogen) inhibit growth of both DU145 and PC3 prostate cancer cell lines and have cytotoxic effect on DU145 cells. This latter effect could be prevented by the pretreatment of cells with an estrogen receptor (ER) β antisense oligonucleotide, suggesting that antiestrogens may accomplish their antitumor effects also through this type of ER [104]. Based on the finding that the proliferative effects of estrogens on human prostate cancer cells in culture appear to be typically receptor-mediated, it would be important to assess ER content and the balanced expression of different ER types and their variants.

## Estrogen Receptors and Prostate Cancer

Several in vivo or in vitro studies have repeatedly pointed out that classical effects of sex steroids are mediated through specific intracellular receptors that belong to the superfamily of nuclear receptors [105]. However, there is accumulating evidence that estrogens and their receptors may combine or act unconnectedly to exploit an amazing array of both genomic and nongenomic, either ligand-dependent or ligand-independent, activities [106].

Two major ER types, the classical ERα and the more recently discovered ERβ, have been identified. The two receptor types are encoded by separate genes, respectively *ESR1* and *ESR2*, located on different chromosomes. In addition, several ERα and ERβ splicing variants and deletion mutants have been isolated in both *nontumoral* and diseased target tissues and cells [107]. However, these ER species are habitually coexpressed with wild-type receptors, and, hence, their potential role in either physiological or pathological processes is difficult to dissect.

The ERα and ERβ are characterized by tissue-specific distribution and exploit a variety of physiological activities in several human tissues [108]. Both receptors typically act as nuclear transcription factors with the ultimate biomolecular effect of estrogen on target cells being dependent on their respective expression levels and balance in individual tissues, ligand binding, heterodimerization, transactivation, and estrogen response element (ERE) activity. In this respect, an alteration of ERα and ERβ balance may be implicated in the etiology of various diseases, including prostate cancer.

Both ERα and ERβ are expressed in the adult human prostate, although ERα is generally located in the stromal compartment, while ERβ is located predominantly in the basal cell layer of the glandular epithelium. Various studies have inspected the expression of ERα and ERβ (at both transcript and protein level) in *nontumoral*, hyperplastic, and malignant human prostate tissues and cells. The resulting data have consistently revealed a marked decrease of ERβ expression in the malignant prostate as compared with benign (hyperplastic) or normal tissues, while ERα expression remains unchanged or even increased. There is convincing evidence that the two receptors are mutually regulated, with ERβ limiting cell proliferation by direct (ERβ-specific) effects on gene transcription and/or indirect activity through modulation of ERα. In this respect, loss of ERβ expression may represent a crucial step in estrogen-related mechanisms of prostate cancer progression (reviewed in [109]).

Previous studies based on estrogen receptor knockout (ERKO) mice model systems have provided important insights for a better understanding of ER role in both normal and diseased prostate. In particular, the adult ERβ knockout (βERKO) mouse has been associated with the onset of prostatic epithelial hyperplasia, while no prostatic alteration could be observed in the ERα knockout (αERKO) mice [110]. This evidence reinforces the assumption that ERβ may play a protective role against prostate malignant cell growth. Interestingly, both synthetic antiestrogen (toremifene) and natural phytoestrogen (genistein) prevent prostate cancer development in the transgenic adenocarcinoma mouse prostate (TRAMP) model acting as ERβ agonists [111, 112].

Cancer progression is hallmarked by the acquisition of genetic and epigenetic changes that eventually lead to the generation of a phenotypically diverse progeny of cancer cells. In this framework, hypermethylation of CpG islands in the promoter region of tumor-suppressor genes is a common mechanism of gene silencing during tumor progression. Loss of ERβ expression has been reported in both primary cultures

of human prostate cancer cells and prostate carcinoma tissues [113, 114]. Conversely, metastatic lesions of prostatic carcinomas frequently display high expression levels of ERβ [115]. This combined evidence apparently indicates that while loss of ERβ is an important event in prostate carcinogenesis, its re-expression in metastatic disease could even provide some survival advantage to prostate malignant cells. However, hypermethylation of the promoter region and silencing of the genes have been reported to occur for both ERα and ERβ in prostate cancer tissues and cells [116]. In addition, direct acetylation of ERα by the coactivator p300 at well-conserved lysine residues in the hinge/ligand domain of the receptor has been associated with both hypersensitivity to estradiol and contact-independent growth in cancer cells [117, 118]. All the above changes may be crucial in determining the net biological effects of estrogen in either normal or diseased prostate gland.

A few studies have investigated polymorphisms of both AR and ER genes in relation to prostate cancer risk. It has been experimentally observed that the length of the polymorphic glutamine (CAG) trinucleotide repeat in the AR gene affects both transactivation of AR and transcriptional activity of androgen target genes, hence having a potential on prostate cancer development and growth [119, 120]. In contrast, Platz and colleagues [33] revealed that neither circulating steroids nor length of the AR gene CAG repeat is associated with prostate cancer, supporting the view that these factors do not significantly contribute to prostate carcinogenesis and tumor progression.

A positive association with prostate cancer of the T/T variant of the PvuII site in the ERα gene and the TC or CC variant alleles of ERβ has been reported in case-control studies [121, 122].

Little is known about the expression and the functional meaning of splice or deletion variants of ER in the human prostate. There is evidence that two ERα splice variants, hERα46 and hERα36, are potent inhibitors of the wild type hERα66 transactivation. In particular, hERα46 is located almost exclusively in cell nuclei, while hERα36 is predominantly associated to the plasma membrane where it transduces both estrogen and antiestrogen signaling, including activation of mitogen-activated protein kinase [123, 124]. On the other hand, several relatively abundant ERβ isoforms have been described. In particular, hERβ2 and hERβ5 have been reported to inhibit transcriptional activity of ERα [125]. Presently, no ERα variant has been described in prostatic tissues, while both hERβ2 and hERβ5 have been detected in prostate cancer, with the combined expression of the two receptor variants being a prognostic indicator of patients having shorter disease-free survival [126]. In a recent report, Taylor and colleagues have indicated that expression of the ERαΔ5 deletion variant is significantly greater in tumor-adjacent prostate samples as compared to benign tissues [127].

Results of further studies on ER variants in both normal and malignant human prostate are awaited with interest to provide important insight into the role of ER and estrogen signaling in prostate cancer development and progression.

In the recent years, selective estrogen and androgen receptor modulators have attracted interest for their potential use in the management of various human diseases (reviewed in [128]). In particular, selective estrogen receptor modulators (SERMs) have been used to prevent bone fractures, to treat ER-positive postmenopausal breast cancer patients, and to induce ovulation in infertile women [129]. On the other hand, selective androgen receptor modulators (SARMs), a newcomer category of agents that are currently being investigated mostly at basic and preclinical level, have been proposed for both prevention and treatment of human prostate cancer [130]. SERMs, including raloxifene, lasofoxifene, and arzoxifene, selectively bind ERα and ERβ to accomplish either estrogenic or antiestrogenic activities in a variety of human tissues. It has been suggested that SERMs induce a conformational change of ER, dissociate the receptor from the heat-shock protein complexes, release ER in a monomeric form, and permit its translocation to nuclei of cells where it binds as a homodimer to the regulatory sequences of target genes to either initiate or suppress transcription [131]. Today, research on SARMs is largely in its infancy, with no SARM approved for clinical use and a few agents completing phase I and II trials. Their potential efficacy in prostate cancer remains to be established and again based on an "androgen hypothesis" that has been by far disputed more than convincing. On the other hand, the loss of ERβ expression during prostate cancer progression and its re-expression in metastatic prostate cancer cells raise the possibility of using ERβ-specific ligands in triggering cell death in these malignant cells. In this context, SERMs, along with synthetic estrogen receptor ligands and antagonists, have recently emerged as promising agents in both prevention and treatment of human prostate cancer [132].

## Perspectives

In spite of the recent, significant advances in the research on prostate cancer, mechanisms underpinning development and progression of the malignant prostate remain undefined. Several networked factors, including the balance of estrogen and androgen, changes and polymorphisms in the enzymes responsible for biosynthesis and transformation of intraprostatic hormones, alteration of hormone signaling or local balance between estrogen receptor types and variants, are all markedly affected by lifestyle factors (notably diet), genetic determinants, and exposure to environmental chemicals and may play a critical role in human prostate cancer.

Presently, the lasting conception that androgens are the key determinants in prostate carcinogenesis and tumor progression appears to be a never-ending persuasion that has, faultily, led to neglect different areas of research with promising perspectives for both treatment and prevention of this disease.

In particular, steroidogenic enzyme inhibitors [133], ER subtype-selective agonists/antagonists or SERMs [134, 135], have been in turn proposed as potential agents for both chemoprevention and treatment of prostate cancer.

In a recent intriguing paper, Williams [136] has combined apparently distant evidence from epidemiology, basic research, animal model systems, and clinics to design a unifying hypothesis for the increasing prevalence of global disease worldwide. The controversial breakthrough presented by the author proposes that several distinct factors may significantly affect hormone balance in the organism through upregulation of the P450 aromatase enzyme and the resulting unopposed excess of endogenous estrogen, alteration of insulin receptor machinery and leptins, and exposure to elevated environmental xenoestrogens. This unbalanced hormonal milieu may represent a common condition for development of life-threatening diseases, including cancer, diabetes, obesity, Alzheimer's disease, that are currently pandemic.

In this respect, we have been forerunner in approaching and emphasizing the potential implication of estrogen not only in endocrine-related tumors, including prostate cancer, but also in several other human diseases [137]. A better understanding of estrogen-driven mechanisms in different processes related to health and disease would be of primary importance to design and exploit original preventive and therapeutic strategies also in prostatic carcinoma.

# Vitamin D and Prostate Cancer

31

Naomi Smith and Alejandro Nolazco

## Introduction

Vitamin D was first recognized for its role in bone health. It is now known to have a number of important physiological effects, and vitamin D levels have been implicated in the pathology of a wide range of diseases including cardiovascular disease, hypertension, cancer, and autoimmune-based pathologies such as multiple sclerosis [1]. Aside from prostate cancer, vitamin D deficiency has also been linked to colorectal cancer [2], and there is evidence to suggest a role in skin and breast cancers. Elevated levels of vitamin D have been associated with worse outcomes from breast, esophagus, and pancreatic cancer [3].

The interest around vitamin D and prostate cancer began in 1990 when Schwartz and Hulka published epidemiological data describing the association between risk factors for vitamin D deficiency (black race, age, northern latitude) and clinically significant prostate cancer [4]. Schwartz and Hanchette subsequently published evidence demonstrating that mortality rates from prostate cancer in counties within the United States (US) were inversely correlated with the availability of ultraviolet (UV) radiation, one of the key factors in vitamin D production [5].

Considerable research has been carried out on the role of vitamin D in the pathophysiology of prostate cancer and its potential role in chemoprevention or as an adjunct to treatment. In this chapter, we will describe the physiology of vitamin D metabolism, the results of in vitro research with prostate cancer models, epidemiological research on the association between vitamin D and prostate cancer before finally reviewing the clinical trials of vitamin D in treatment of prostate cancer carried out to date.

## Vitamin D Metabolism

The term "vitamin D" is used to describe a group of fat soluble "secosteroids" (a steroid based structure with a broken ring). Physiologically, the two most important forms are vitamin D2 (ergocalciferol) available from fish, eggs, meat, and fortified dairy products and vitamin D3 (cholecalciferol) synthesized in the inner layers of the epidermis from 7-dehydrocholesterol in a reaction facilitated by UVB radiation, that is, sunlight exposure. Both forms are subsequently hydroxylated in hepatocytes by the enzyme D-25-hydroxylase to form the prohormone calcidiol (25(OH)D) which can be stored in tissues or released bound to alpha globulin [6]. It is calcidiol, a relatively stable circulating form of vitamin D which is usually measured in the serum since it has the advantage that it reflects both the vitamin D ingested as well as that produced in the skin. Circulating levels however may not always accurately reflect body stores, especially in obese individuals [7].

Calcitriol (1,25(OH)2D), the biologically active form, is produced by a further hydroxylation step carried out by 1-alpha-hydroxylase in the proximal tubules of the kidney and other organs including the prostate and colon [8, 9]. The conversion of calcidiol to this active form, calcitriol, is increased by parathyroid hormone (PTH) and low serum calcium or phosphate levels. The level of calcitriol is thus carefully controlled by these influences, falling only in very severe vitamin D deficiency.

The expression of renal 1-alpha-hydroxylase is upregulated by PTH and inhibited by calcitriol, forming a negative feedback loop. In contrast, extra renal 1-alpha-hydroxylase is thought to be constitutively active, suggesting that tissues

expressing this enzyme, which could include certain tumors, may experience local levels of calcitriol which directly reflect circulating calcidiol levels rather than being under the tight control of the feedback loop [10].

Calcitriol is transported bound to vitamin D-binding protein (VDBP) and is the ligand for the vitamin D receptor (VDR). On binding this nuclear receptor, calcitriol promotes its association with the retinoic acid X receptor (RXR), and the complex formed acts as a transcription factor, binding to DNA sequences called vitamin D response elements (VDREs) and modulating the expression of target proteins such as calbindin (increases calcium uptake in the gut) [11] and osteoclastin (regulating bone metabolism) [12]. Many proteins affecting the cell cycle, cell proliferation, differentiation, and apoptosis have also been found to be VDREs, most notably the cell cycle regulator p21 [13], insulin-like growth factor [14], fibronectin [15], and tissue necrosis factor-alpha [16]. VDRs have been found not only in the gut but in the brain, heart, skin, gonads, prostate, and breast supporting the emerging evidence for the many and varied effects of this steroid hormone not just on calcium balance but on the immune system, insulin secretion, blood pressure regulation, and cell cycle, cell differentiation and proliferation.

## Vitamin D Deficiency

Severe vitamin D deficiency causing rickets in children and osteomalacia in adults is generally only seen with serum calcidiol levels of less than 10 ng/ml [17]. While levels of greater than 15 ng/ml have historically been considered sufficient for good health, this cutoff came from average levels found in healthy populations, and emerging evidence suggests that PTH levels and calcium absorption are not optimized until levels of approximately 30 ng/ml [18]. Using this value, it is estimated that approximately one billion people worldwide are vitamin D deficient [19].

People with dark skin, the elderly, pregnant and lactating women, and breast fed infants are at increased risk of deficiency. Certain medical conditions also predispose to vitamin D deficiency such as obesity, fat malabsorption syndromes, inflammatory bowel disease, and renal disease [19].

Conversely vitamin D toxicity, usually due to excessive supplementation, manifests as hypercalcemia and its clinical effects (gastrointestinal disturbances, renal stones, and bone pain). This is typically seen with calcidiol levels greater than 150 ng/ml and unlikely to occur in healthy people receiving less than 10,000 IU/day [20].

In November 2010, the US Institute of Medicine updated the dietary reference intake for vitamin D. The committee stated that the evidence for health outcomes other than bone health were not sufficiently robust to influence their recommendations and therefore advised 600 IU a day between the ages of 1 and 70 years and 800 IU a day for those 71 years and over (intake sufficient to achieve a serum calcidiol level greater than 20 ng/ml in at least 97.5 % of the population). In the European Union (EU), the recommended daily allowance is 5mcg per day (equivalent to 200 IU) [21].

## Effect of Vitamin D on the Prostate

Both in vitro and in vivo studies have provided evidence for the antitumor effects of vitamin D and its metabolites in prostate cancer cell lines and animal models.

Experiments with human prostate cancer cell lines have demonstrated that vitamin D has an antiproliferative effect and may also act to increase differentiation of tumor cells as suggested by an increase an in PSA secretion [22]. This effect is also shown by vitamin D analogs [23]. Furthermore, calcitriol and synthetic analogs have also been shown to decrease the invasiveness of prostate cancer cell lines, an effect that is probably mediated by a selective inhibition of type IV collagenase secretion [24].

These in vitro observations are supported by in vivo work using the Dunning rat model of prostate cancer. Both calcitriol and a synthetic analog inhibited tumor growth and decreased the number of lung metastases when prostate cancer cell lines were implanted into the flank of rats. Analysis of the treated cell lines showed a growth inhibitory and differentiating effect, with significantly more cells in the G0/G1 phase of the cell cycle compared with controls [25]. Using a murine model of prostate bone metastases, mice fed a vitamin D-deficient diet were found to develop larger lesions with increased mitotic activity [26].

In preclinical studies VDR ligands have been shown to potentiate the activity of many other antitumor agents. Calcitriol and its analogs act synergistically with conventional chemotherapeutic agents (e.g., docetaxel [27], paclitaxel [28], cisplatin, carboplatin [29], and mitoxantrone [30]) and enhance radiation-induced apoptosis [31] in prostate cancer models. Steroids [32] and nonsteroidal anti-inflammatory drugs [33] also increased cell cycle arrest and apoptosis in cell lines treated with vitamin D.

## Epidemiological Studies of Vitamin D and Prostate Cancer

A number of epidemiological studies have attempted to define the relationship between vitamin D and prostate cancer risk. These studies have focused on the dietary intake of ergocalciferol, sunlight exposure (known to be associated in a nonlinear fashion with levels of cholecalciferol), and serum levels of calcidiol. The results of these epidemiological studies remain contradictory. One of the key complicating factors

is that the association between the measurable variables is not related in a simple manner to the level of the active form calcitriol. Furthermore, there have been a number of confounding factors in these epidemiological studies that have been difficult to exclude, for example, reliance on self-reporting of dietary patterns and the use of single assessments of dietary intake or serum level may which may not adequately reflect lifetime exposure to vitamin D.

More recent research includes study of the role of polymorphisms in the genetic sequence of the vitamin D receptor and how these may influence the function of vitamin D hormone axis and the downstream effects of vitamin D in the prostate. Advancing techniques in genomics will no doubt continue to expand further into this field.

## Intake

In Schwartz and Hulka's 1990 paper proposing vitamin D as a risk factor for prostate cancer, they identify an increased incidence of prostate cancer in migrant Asians as they adopt a Western diet and decrease their intake of oily fish (rich in vitamin D). Hanchette and Schwartz later highlighted a ten-fold difference between prostate cancer rates in the United States and Japan where the traditional diet is high in fatty fish rich in both vitamin D and omega-3 fatty acids (which raise serum levels of active vitamin D metabolites by dissociating them from their binding proteins).

Many subsequent studies carried out to investigate the influence of dietary vitamin D on prostate cancer risk have included other food groups which may affect risk indirectly via their effect on vitamin D levels. For example, low serum levels of calcium and phosphate promote production of calcitriol, fructose can transiently reduce circulating phosphate levels, and high animal protein intake lowers serum pH, decreasing the activity of 1-alpha-hydroxylase [34].

A number of large questionnaire-based studies have failed to show an association between vitamin D intake and prostate cancer but have found associations with dairy intake and vitamin D from supplemental sources.

The National Health and Nutrition Examination Epidemiologic Follow-up Study included 3,612 men, 131 of whom developed prostate cancer during the 8–10-year study period. Increased risk was associated with dietary calcium (third tertile compared with first: RR 2.2, 95 % CI 1.4–3.5, $p=0.001$) and dairy intake (third tertile compared with first: RR: 2.2, CI 1.2–3.9, $p=0.05$). Low fat milk was associated with increased risk, while whole milk was not. Neither vitamin D nor phosphorus was independently associated with risk [35].

These results are supported by EPIC, a large multinational observational study (153,457 male participants across ten European countries), which found a significant association between prostate cancer and dairy protein intake and with calcium from dairy products [36]. The Multiethnic Cohort Study (82, 483 men; 4,404 prostate cancer patients were identified over 8 years) found no association between prostate cancer risk and calcium or vitamin D intake, but in the food group analysis, the risk of localized low-grade tumors was found to be increased with low fat and decreased with whole milk [37].

Interestingly the Prostate, Lung, Colorectal and Ovarian Screening Trial (29,509 patients; 1,910 developed prostate cancer) found that dietary vitamin D was not associated with prostate cancer risk, but that a greater intake of vitamin D from supplemental sources was associated with a decreased risk. In men who took >600 IU of vitamin D in the form of supplements, the risk of developing prostate cancer was 40 % lower [38]. However, the Prostate Cancer Prevention Trial examined nutritional risk factors in 9,559 participants using a questionnaire and serial PSA and digital rectal examinations (prostate biopsy was recommended to patients if either was abnormal and offered to all participants at the end of the study; 1,703 cancers detected). There was no association found with supplement use of any kind. Dietary calcium was positively associated with low-grade cancer but inversely associated with high-grade cancer (quartile 4 vs. quartile 1, OR 1.27, 95 % CI 1.02–1.57 and OR 0.43, 95 % CI 0.21–0.89, respectively) [39].

The reported association of prostate cancer with dairy intake remains controversial. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (27,062 Finnish smokers) found no association with any of the studied food groups, nutrients, or minerals in the entrance food use study questionnaire and the 183 incident prostate cancers diagnosed in the study period [40].

A review meta-analysis conducted in 2008 including 26,769 patients from 45 observational studies looking at dairy products, calcium, and vitamin D intake in relation to prostate cancer risk found no relationship between vitamin D intake and prostate cancer risk [41].

## Serum Levels

Large trials carried out to investigate the association between serum calcidiol and calcitriol concentrations have not shown a consistent association with prostate cancer risk.

Li and colleagues working in the United States carried out a nested case–control study within the Physician's Health Study. Comparing serum calcidiol and calcitriol levels between 1,066 prostate cancer patients and 1,618 controls (matched for age and smoking status), they concluded that men with calcidiol and calcitriol levels below the median had a significantly increased risk of aggressive prostate cancer (OR = 2.1 95 % CI 1.2–3.4). As expected median plasma levels of calcidiol varied for season (25 ng/ml in winter or spring and 32 ng/ml in summer or autumn) but serum levels of calcitriol did not [42].

However, a nested case–control study within the multinational European Prospective Investigation into Cancer and Nutrition (EPIC) compared serum calcidiol levels in 652 prostate cancer patients with 752 age-matched controls over 4 years and found no significant association with prostate cancer risk (highest vs. lowest quintile: odds ratio = 1.28, 95 % confidence interval: 0.88–1.88) [43].

In a large, nested case–control study carried out within the prospective Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial that included 749 cases and 781 controls, there was no trend between serum calcidiol levels and rates of nonaggressive prostate cancer. However, serum calcidiol levels greater than the lowest quintile were associated with aggressive disease ($p = 0.05$ for trend) [44].

Further evidence to support the possibility of a J- or U-shaped association between calcidiol serum levels and prostate cancer risk comes from a 2004 Scandinavian study which compared serum calcidiol levels in 622 prostate cancer patients with 1,451 matched controls. Low serum calcidiol levels (<19 nmol/L) were associated with an increased prostate cancer risk (RR 1.5, 95 % CI 0.8–2.7) as were high levels (>80 nmol/L) (RR1.7, 95 % CI 1.1–2.4) [45]. The J-/U-shaped association hypothesis is also supported by work in other cancers [3].

A meta-analysis of publications investigating the relationship between circulating levels of calcidiol (14 studies) or calcitriol (7 studies) and prostate cancer risk published in 2010 found little evidence to support a role for vitamin D in the risk of or progression of prostate cancer. Using $I^2$, a statistical test of heterogeneity in meta-analyses, the authors concluded that differences in the analyzed studies were unlikely to be genuine [46]. They suggested that differences the analyzed studies were instead attributable to variation in study design and other factors [47].

## Sunlight Exposure

Hanchette and Schwarz's 1992 publication analyzed the relationship between the distribution of UV radiation and prostate cancer mortality in 3,073 United States counties. They reported a significant inverse correlation ($p < 0.0001$)[5] [5]. This association has subsequently been supported by numerous further investigations.

Thirteen thousand five hundred and forty-one skin cancer patients from the Netherlands were found to be at decreased risk of developing prostate cancer compared with the general population (standardized incidence ratio (SIR) 0.89, 95 % CI 0.78–0.99). The risk of advanced cancer was significantly decreased (SIR 0.73, 95 % CI 0.56–0.94), suggesting a possible "antiprogressive" effect of UV radiation on prostate cancer [48].

Using mathematical models to calculate UVB levels from forecasted ozone levels, cloud levels and elevation researchers in the United States found an inverse correlation between UVB levels and prostate cancer incidence and mortality in white men (RR-0.42, $p < 0.01$: RR-0.53, $p < 0.001$), but only for prostate cancer incidence in black men (RR-0.40, $p < 0.05$). Interestingly these correlations were strongest with UVB levels in autumn and winter for white men and for UVB levels during the summer for black men [49].

## Vitamin D Receptor

The existence of genetic factors in the pathogenesis of prostate cancer is well accepted and supported by evidence from twin studies and familial clustering of disease [50, 51]. Given that the effects of calcitriol, the active form of vitamin D, are mediated via the vitamin D receptor, it is biologically plausible that VDR gene polymorphisms could affect the binding of vitamin D to its receptor and its downstream effects. The genetic differences in the VDR could also contribute to some of the differences seen in prostate cancer between ethnic groups.

The six most studied VDR polymorphisms are the restriction sites: *Apa*I, *Bsm*I, Cdx2, *Fok*I,*Taq*I, and the poly( A) microsatellite. Early findings of such differences were observed in the 1990s including an association between the *Bsm*I VDR polymorphism and both circulating levels of calcitriol and bone density in 1994 [52], the first report of a VDR polymorphism in prostate cancer in 1996, and subsequently a case–control study showing the presence of the *Taq*I tt genotype in 8 % of 108 men undergoing a radical prostatectomy compared to 22 % of controls [53].

Subsequent research has yielded often contradictory results, and a meta-analysis performed in 2006 of 26 heterogenous studies (1996–2005) looking primarily at *Taq*I but also at *Apa*I, *Bsm*I, *Fok*I, and the poly( A) found no significant association between VDR polymorphisms and prostate cancer susceptibility [54]. Similarly a population-based case–control study published in 2009 analyzed 48 single nucleotide polymorphisms (SNPs) in genes coding for the VDR, vitamin D-activating enzyme 1-α-hydroxylase, and deactivating enzyme 24-hydroxylase in 827 prostate cancer patients and 787 age-matched controls. Researchers found no association between these SNPs and the risk of prostate cancer or tumor aggressiveness [55].

It may be that VDR subtypes play a greater role in disease susceptibility when other environmental factors are taken into account. For example, Luscombe et al. found positive associations between *Fok*I,*Taq*I, and *Bgl*I in men with ultraviolet radiation exposure above the median arguing for an important gene-environment interaction [56].

## Vitamin D in Treatment of Prostate Cancer

A number of clinical trials have been carried out to investigate the potential for calcitriol, the biologically active form of vitamin D, and other vitamin D derivatives as therapeutic agents in prostate cancer.

In vitro research results suggest that expression of proteins with antitumor effects caused by the activated VDR bound to its ligand occur at high calcitriol concentrations and in a dose-dependent manner [57]. In vivo achievable concentrations are limited by the hypercalcemia and hypercalciuria associated with high doses of calcitriol. However, phase I clinical trials suggested that the tolerable dose could be increased by varying the dosing schedule. The first trials used doses of 0.5–2.5 μg daily with reported effects, showing considerable variation [58, 59]. Weekly oral calcitriol allowed significant dose escalation (up to 2.8 μg/kg), achieving plasma concentrations of 3.7–6.0 nM without dose-limiting toxic side effects, but the pharmacokinetics of the available formulation were found to be nonlinear at higher doses [60, 61].

Novacea Inc. subsequently developed DN-101, a calcitriol formulation available in larger dose capsules and with linear pharmacokinetics over a wide dose range. Concentrations up to 14.9 nM have been achieved with this preparation. ASCENT, a placebo-controlled randomized trial, compared DN-101 and docetaxel to placebo and docetaxel in 250 androgen-insensitive prostate cancer patients. PSA response rate, the primary end point, showed a trend toward the experimental arm (63 % compared to 52 %) but did not reach statistical significance ($p=0.07$) [62]. However, survival (secondary end point) was improved in the treatment group (HR 0.67).

A phase 3 trial ASCENT-2 commenced recruitment and was to compare 45 μg DN-101 and 36 mg/m$^2$ of docetaxel with 75 mg/m$^2$ and prednisolone. This trial was halted early due to an excess of deaths in the experimental arm, and the Food and Drug Administration placed a temporary hold on the studies of DN-101 [63]. Unfortunately due to changes in clinical practice, this study did not compare similar chemotherapy regimens, making interpretation difficult.

Given the potential side effects of calcitriol when used as a therapeutic drug for prostate cancer, there has been interest in synthetic VDR ligands. Researchers in Israel have reported the development of a synthetic calcitriol analog (BGP-15) which has shown anti-tumor activity in androgen-dependent prostate cancer cell lines (LNCaP). BGP-15 is derived from calcipotriene, a synthetic calcitriol analog which is already in use for the treatment of psoriasis and does not show any calcium-related side effects with long term use [64].

Phase I clinical trials of another synthetic vitamin D analog 1-alpha-hydroxyvitamin D2 found that 12.5 mg did not cause any toxic side effects. A phase II trial subsequently recruited 70 patients with androgen-insensitive prostate cancer and randomized them to receive docetaxel with or without 1-alpha-hydroxyvitamin D2. The response rates, time to disease progression, and toxicity were similar in both arms of the study [65].

### Conclusion

Evidence exists for the antitumor effects of vitamin D in prostate cancer cell lines and animal models and the inverse association of UVB exposure and prostate cancer incidence. However, epidemiological research has failed to define the association between vitamin D intake or serum levels and the risk of prostate cancer or its subsequent clinical course. The many and varied effects of vitamin D on different health outcomes and emerging evidence that response to vitamin D may follow a "J- or U-shaped curve" make the potential use of vitamin D a complex issue.

Clinical trials of high levels of vitamin D in the treatment of prostate cancer were initially promising but complicated by the outcome of the ASCENT-2 trial. Clearly there is a need for further large-scale research studies in this area.

Currently there is insufficient evidence to recommend vitamin D supplementation to the general population or prostate cancer patients.

# The Role of 5α-Reductase Inhibitors (5-ARIs) in Prostate Cancer Chemoprevention

32

David Margel and Neil Fleshner

*Prostate cancer (PCa)* is the most common male malignancy in the Western world. The traditional treatments, such as surgery or radiation, are associated with significant adverse events and can negatively affect the quality of life of patients and their families [1–3]. The negative effects of the treatments combined with potentially long latency of the disease, late-age onset, and high prevalence make PCa an ideal target for disease prevention.

*5α-reductase inhibitors* (*5-ARIs*). The rationale for the specific use of 5-ARIs as chemopreventive agents is based on the androgenic nature of prostate cancer and the uniform absence of prostate cancer among men with congenital deficiency of 5α-reductase [4]. The enzyme 5α-reductase resides in prostatic tissue and converts circulating testosterone to localized dihydrotestosterone (DHT), a more potent agonist of androgen receptors in prostatic cells. 5α-reductase has two isoforms: Type II 5α-reductase is the isoform common in benign prostatic tissue; type I predominates in localized PCa [5]. Finasteride is a selective inhibitor of the type II enzyme, while dutasteride inhibits both isoforms [6].

*Preventive medicine or preventive care* refers to measures taken to prevent diseases, (or injuries) rather than curing them or treating their symptoms. Preventive medicine strategies are typically described as taking place at the primary, secondary, and tertiary levels:

1. *Primary prevention* strategies intend to avoid the development of disease.
2. *Secondary prevention* strategies attempt to diagnose and treat an existing disease in its early stages before it results in significant morbidity.
3. *Tertiary prevention* aims to reduce the negative impact of established disease by restoring function and reducing disease-related complications.

In this chapter, we will consider the role of 5-ARIs in chemoprevention of prostate cancer at the primary and secondary levels. Whether primary PCa prevention is truly primary or tertiary can be debated, given that histological evidence suggests that microscopic disease can be found in 1 of 3 men in their 30s—well before the average PCa patient is diagnosed [7]; but for the purposes of this chapter, "primary prevention" refers to the prevention of clinically detectable disease.

*5-ARIs for primary prevention*. There are two published large, prospective randomized controlled studies examining the role of 5-ARI in PCa prevention. The first was the Prostate Cancer Prevention Trial (PCPT) [8]. The PCPT randomized 18,882 men with low risk for prostate cancer development (normal digital rectal examination and prostate specific antigen [PSA] ≤3.0 ng/ml) to 5 mg finasteride daily or placebo for 7 years. Primary analysis demonstrated a 25 % reduction in the prevalence of prostate cancer among men treated with finasteride compared to the control arm. Secondary analysis showed an unexpected greater absolute number of high-Gleason-grade cancers in the finasteride arm. To put it simply, for every 1,000 men, finasteride reduced the number of prostate cancers from 60 to 45; however, the number of high-grade cancers would increase from 18 to 21[9]. This has raised concern of the potential causal relationship of finasteride to high-grade cancer. Does the increase in high-grade cancers reflect a real risk of finasteride or merely confounding factors?

Several subsequent analyses addressed this question. At first, the reliability of the Gleason score in patients treated with a hormonal agent such as finasteride was questioned. There was some concern that morphologic changes caused by finasteride may mimic high-grade cancer and therefore produce a false higher Gleason reading. However, pathologic review eliminated the questions of morphologic artifact [10].

The next possible explanation was sampling error induced by the recognized effect 5-ARIs have on prostate volume.

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_32, 

Finasteride decreases prostate volume by approximately 30 % [11, 12]. Indeed, modeling studies incorporating prostate volume suggest that the increase in high-grade cancers in the PCPT may be accounted for by higher detection and not tumor transformation or induction [13]. In fact, in the pathologic specimen of subjects who underwent radical prostatectomy in the placebo and finasteride arms of the study, the rates of more aggressive disease were not in concordance with the biopsy results [14]. A higher number of patients in the placebo arm than in the finasteride arm displayed high-grade disease (8.2 % vs. 6.0 %) [14].

The third hypothesis by which high-grade tumors were seen more frequently has to do with the differential effects of 5-ARIs on PSA between men with low- and high-grade diseases. In the PCPT, PSA was corrected according to a changing ratio to keep for-cause biopsies similar among both treatment arms. Post hoc analyses revealed that the utility of PSA is better for higher grade disease [15]. The implication of this is that men randomized to finasteride and had high-grade disease were more likely to get a for-cause biopsy than men with low-grade disease. Although one might think that these cases would be found at study exit biopsies, in fact, fewer men randomized to finasteride had exit biopsies. Despite these hypotheses, a causal relationship between high-grade PCa and finasteride treatment cannot be eliminated. Although, most believe that a true causal association is unlikely.

The results from the PCPT provided the proof in principle for 5-ARIs as an effective prostate cancer chemopreventive strategy. The next big step was the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial [16]. This trial was a large prospective randomized controlled study, published in the New England Journal of Medicine 2010. It was designed to assess the specific benefit of dutasteride, a 5-ARI that inhibits both type 1 and type 2 isoforms of 5α-reductase, in the prevention of PCa. As mentioned earlier, the type 1 isoform of 5α-reductase is enhanced during prostate cancer development. Table 32.1 displays the main differences between PCPT and REDUCE. The primary end point for both PCPT and REDUCE was prostate cancer incidence. The REDUCE patients were a higher risk population. Specifically, eligibility criteria included men aged 50–75 years with a baseline PSA level between 2.5 and 10 ng/ml, a prostate volume of less than 80 $cm^3$, and a prior negative biopsy performed "for cause" within 6 months before enrollment. Unlike the PCPT trial, the REDUCE trial required subjects to have a negative prostate biopsy [no PCa, high-grade prostatic intraepithelial neoplasia (PIN), or atypical small acinar proliferation] within 6 months of starting the trial. This requirement aimed to limit for-cause biopsies (protocol independent). Perhaps, one of the most important design features was the plan to require biopsies at 2 and 4 years to further minimize for-cause biopsies as a result of the increased PSA and DRE sensitivity previously noted with therapy using 5-ARIs. In REDUCE, approximately 12 % of patients had a for-cause biopsy, compared with 35 % of patients in the PCPT.

**Table 32.1** Comparison between 5-ARI primary prevention trials

The results of the REDUCE trial parallel those of the PCPT (Table 32.1). The 22.8 % reduction in PCa diagnosis with dutasteride at the end of 4 years was similar to that with finasteride (24.8 %) at the end of 7 years. Consistent with the PCPT trial, the effect of dutasteride on PCa incidence occurred in all subgroups (age, PCa family history, body mass index, prostate volume, etc.) suggesting good utility in a wide range of men. Men randomized to dutasteride also demonstrated significantly better outcomes with respect to benign prostatic hyperplasia, such as decreased prostate volume, fewer episodes of urinary retention, fewer episodes of urinary tract infections, and decreased benign prostatic hyperplasia-related surgery. Dutasteride was generally well tolerated with a small but significant decrease in libido, loss of libido, and increased erectile dysfunction in the dutasteride arm when compared with those receiving placebo. Of concern was an increase in all types of cardiac events in the dutasteride arm. Nonetheless, when compared with the total number of patients in each arm, the absolute numbers were very small (30 of 4,105 in the dutasteride group, 16 of 4,126 in the placebo group), and this outcome, a composite of several cardiac-related conditions, was not homogeneous.

In the REDUCE trial, there was no statistically significant overall increase of high-grade cancer among patients receiving dutasteride, although in the 4-year arm, there were more high-grade tumors in the cohort of men receiving dutasteride. The REDUCE authors noted that, by 2 years, 141 more patients with Gleason 5–7 disease were removed from the placebo arm than from the dutasteride arm as a consequence of PCa diagnosis. Conceivably, a significant number of those patients would have advanced to Gleason 8–10 if continued in the study for another 2 years, thereby offsetting the higher number of Gleason 8–10 patients in the dutasteride arm. In addition, like the Prostate Cancer Prevention Trial, men receiving 5-alpha-reductase inhibitor had a lower incidence of high-grade PIN (prostatic intraepithelial neoplasia) and in REDUCE, a lower incidence also of ASAP (atypical small acinar proliferation). Both ASAP and high-grade PIN are considered to be precancerous or precursors of prostate cancer.

Unpublished reanalysis of the REDUCE results (personal communication with Dr Fleshner, 2012) using the modified Gleason (as opposed to the traditional system) scoring system has revealed a slightly higher statistically significant rate of high-grade cancers among men randomized to dutasteride.

The results of these trials prompted a combined American Urological Association and American Society of Clinical Oncology guidelines and a systematic review on PCa prevention with 5-ARIs [17]. The panel arrived at the following conclusions:

1. Asymptomatic men with a prostate-specific antigen (PSA) less than 3.0 ng/mL who are regularly screened with PSA or are anticipating undergoing annual PSA screening for early detection of prostate cancer may benefit from a discussion of both the benefits of 5-ARIs for 7 years for the prevention of prostate cancer and the potential risks (including the possibility of high-grade prostate cancer).
2. Men who are taking 5-ARIs for benign conditions such as lower urinary tract [obstructive] symptoms (LUTS) may benefit from a similar discussion, understanding that the improvement of LUTS relief should be weighed with the potential risks of high-grade prostate cancer from 5-ARIs (although the majority of the panel members judged the latter risk to be unlikely).
3. A reduction of approximately 50 % in PSA by 12 months is expected in men taking a 5-ARI; however, because these changes in PSA may vary across men and within individual men over time, the panel cannot recommend a specific cut point to trigger a biopsy for men taking a 5-ARI. No specific cut point or change in PSA has been prospectively validated in men taking a 5-ARI.

Recently, the Oncologic Drugs Advisory Committee (ODAC) of the US Food and Drug Administration (FDA) recommended against PCa chemoprevention labeling for the 5α-reductase inhibitors finasteride (Proscar) and dutasteride (Avodart) because both agents increase the likelihood of high-grade tumors when given as preventive agents to healthy men.

Panelists and FDA reviewers shared 3 main concerns about the drugs:

1. The risk of exposing currently healthy people to an increased risk for high-grade tumors.
2. The fact that risk reduction was only in low-grade tumors.
3. The doubt that the supporting clinical studies are generalizable to clinical practice in the American population.

We believe that both the REDUCE and PCPT provide level I evidence to the following:

- 5-ARIs prevent biopsy-detected prostate cancer.
- These drugs are generally safe, with reversible sexual dysfunction as the major AE.
- The performance of PSA and DRE for the diagnosis of prostate cancer is improved with 5-ARIs.

At present, we believe that it is reasonable to offer 5-ARI chemoprevention to patients who are at increased risk for developing prostate cancer, especially men with concomitant symptoms due to prostate enlargement. The decision to pursue 5-ARI chemoprevention must be made in concert with the patient and must take into consideration the benefits and risks associated with treatment. During this discussion, patients must be made aware of the potential sexual-related side effects associated with treatment. In addition, patients must be willing to accept the burden of cost of the medication.

*5-ARIs in secondary prevention*. A more appealing strategy than exposing healthy men to long-term medication would be to use 5-ARIs to delay progression in those men already diagnosed with PCa. There are currently two studies examining the role 5-ARI to prevent progression in men with low-risk, localized prostate cancer. The first study is a single-institution retrospective cohort study comparing men taking a 5-ARI versus no 5-ARI while on active surveillance for PCa [18]. The primary end point was pathologic progression defined as Gleason score >6, maximum core involvement >50 %, or more than three cores positive on a follow-up prostate biopsy. A total of 288 men on active surveillance with a median follow-up of 38.5 months were included in the analysis. Men taking a 5-ARI experienced a lower rate of pathologic progression (18.6 % vs. 36.7 %; $p=0.004$) and were less likely to abandon active surveillance (20 % vs. 37.6 %; $p=0.006$). On multivariable Cox proportional hazards analysis, lack of 5-ARI use was most strongly associated with pathologic progression (HR: 2.91 95%CI 1.5–5.6).

This concept of the use of 5-ARIs to prevent clinical progression in patients on active surveillance for low-risk PCa was also studied in a randomized controlled study. Our group has led the Reduction by Dutasteride of Clinical Progression Events in Expectant Management (REDEEM) trial [19]. In this trial, 300 subjects with biopsy-proven, low-risk, localized

prostate cancer were randomized to receive dutasteride 0.5 mg/day or placebo for 3 years while on active surveillance. Eligible men were between 50 and 80 years of age, had clinical stage T1c–T2a prostate cancer, a Gleason score of less than or equal to 6, and serum PSA less than or equal to 10 ng/mL. Entry biopsy of at least ten cores had to be performed within 6 months of screening and was repeated at 1.5 and 3 years. The primary end point of REDEEM was time to disease progression. This was a composite outcome defined as the earliest of the following events: receipt of primary therapy for prostate cancer (e.g., prostatectomy, radiation, hormonal therapy) or pathologic progression (≥4 cores involved, ≥50 % of any core involved, or any Gleason score ≥7). The initial results of this study were presented as an abstract in the 2010 SUO [20]. Forty-nine percent (71 patients) progressed in the placebo group compared to 38 % in the dutasteride group (51 patients), translating to a relative risk reduction of 38.9 %. Furthermore, subjects treated with dutasteride were more likely to have no cancer detected on follow-up biopsies (23 % in the placebo arm vs. 36 % in the dutasteride arm). The authors conclude that among men followed up for prostate cancer with active surveillance, dutasteride may delay the time for cancer progression and may provide a useful adjunct to active surveillance.

In summary, the concept of prevention dates back to Benjamin Franklin, whose aphorism—"an ounce of prevention is worth a pound of cure"—has withstood the test of time. 5-ARIs seem ideal drugs for cancer prevention since they are safe with only minimal side effects which seem to disappear upon drug discontinuation. The question remains who is the ideal candidate for PCa prevention and in what setting should we offer such a strategy. For example, 5-ARIs have been demonstrated to be effective in men older than 50. However, primary prevention should most probably start earlier in life, since PCa starts its growth during a man's fourth decade. Secondary prevention, preventing progression in men already diagnosed with PCa, may be a more appealing option. We believe 5-ARIs show great promise in secondary prevention and may in the future have a role in any active surveillance protocol.

# Other Pharmaceutical Agents in the Chemoprevention of Prostate Cancer

33

Vivekanandan Kumar

## Introduction

Prostate cancer is the most commonly diagnosed cancer in the Western world and second commonest cause of death in males. Clinically significant prostate cancer takes two decades to develop. This long natural history of the disease lends itself well to modification by agents—dietary and therapeutic. Prostate cancer represents an ideal target for nutritional prevention due to its long latency, high incidence, tumor marker availability (prostate-specific antigen, PSA), and identifiable preneoplastic lesions and risk groups.

There are three broad categories of chemoprevention for prostate cancer: hormonal, dietary, and anti-inflammatory. Most studies have focused on hormonal interventions, which manipulate sex steroid hormone pathways, and dietary interventions, which alter the balance of nutritional intake. As 5-ARI's role is discussed in the previous chapter, we will restrict this chapter to chemoprevention by statins, anti-inflammatory drugs, dietary supplements, and estrogen pathway modulators.

## Statins

### Rationale and Mechanism

Statins work by inhibiting the enzyme 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting step in the biosynthesis of cholesterol.

Studies have shown a possible role for statins in prevention of cancer. Statins reduces mevalonate synthesis which is a product of HMG-CoA reductase. Mevalonate is indirectly responsible for the activation of RasG protein. Lack of mevalonate inhibits further downstream molecules like farnesyl pyrophosphate and geranyl pyrophosphate, which are responsible for translocation of Ras and Rho to cell membrane—essential component for cell proliferation and migration. Further cholesterol is a main component of cell membrane, and its lack affects key regions (lipid rafts) involved in cell growth, survival, and migration. Protein kinase B is important in intracellular signaling pathway, the level of which gets altered on statin therapy. p21 and p27 also accumulates in cells, due to inhibition of cyclin-dependent kinase 2 by statins, resulting in growth inhibitory effect, retarding cancer cell mitosis.

### Epidemiological Studies

Some observational studies support the role of statins in prostate cancer. Graaf et al. found a nonsignificant reduction in incidence of prostate cancer (risk reduction 65 %) among 300,000 Dutch residents who were on statins [1]. Similarly, Shanon et al. found 65 % reduction in risk of prostate cancer among 100 prostate cancer patients compared to controls who were recruited upon referral for biopsy [2]. The risk reduction was with patients with Gleason score $\geq 7$. Similarly, in a retrospective review of veterans database, Singal et al. found that statin use was associated with protective effect on prostate cancer (OR 0.46).

In the Finnish Prostate Screening Trial [3], long-term statin use appears to support a lower total incidence of prostate cancer in relatively dose-dependent fashion. A factor that confounds these analyses is that long-term statin use appears to decrease serum prostate-specific antigen. While this seems to be the case, it is unlikely to be the cause of the observed differences in lowering the risk of aggressive or overall prostate cancer. From the studies, it also appears that short-term statin use is probably not sufficient to have any impact on the development or treatment of prostate cancer.

Dale et al. performed a meta-analysis of 26 randomized trials involving statins with a mean duration of follow-up

DOI 10.1007/978-1-4471-2864-9_33, © Springer-Verlag London 2013

of at least 1 year, enrolling a minimum of 100 patients, and reporting data on either cancer incidence ($n=20$ studies) or cancer death ($n=22$ studies) [4]. In the meta-analyses, there were 6,662 incident cancers and 2,407 cancer deaths. Statins did not reduce the incidence of cancer (OR, 1.02; 95 % CI, 0.97–1.07) or cancer deaths (OR, 1.01; 95 % CI, 0.93–1.09). No reductions were noted for any individual cancer type. This null effect on cancer incidence persisted when only hydrophilic, lipophilic, naturally derived, or synthetically derived statins were evaluated. The strength of this study includes large patient numbers, multiple randomized studies, and rigorous methodology. There were few limitations for this meta-analysis as well. Variation in cancer reporting and surveillance strategy among different studies included could have had an effect on the results. The authors have excluded the cancer incidence from Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) from this analysis because it only reported the cumulative number of cancer diagnoses. Further, the study was not standardized for confounding factors like smoking, though randomization would have distributed these factors evenly.

Breau et al. [5] analyzed the data from a longitudinal population-based cohort. The statin intake was self reported, and the prostate biopsy and cancer-related information was obtained through community records [5]. Statin use was associated with a decreased risk of undergoing prostate biopsy (HR 0.31; 95 % CI, 0.24, 0.40), receiving a prostate cancer diagnosis (HR 0.36; 95 % CI, 0.25, 0.53), and receiving a high-grade (Gleason 7 or greater) prostate cancer diagnosis (HR 0.25; 95 % CI, 0.11, 0.58) (Figs. 33.1 and 33.2). Statin use was also associated with a nonsignificantly decreased risk of exceeding a prostate-specific antigen threshold of 4.0 ng/ml (HR 0.63; 95 % CI, 0.35, 1.13). In addition, a longer duration of statin use was associated with a lower risk of these outcomes (all tests for trend $P \leq 0.05$). In this study, the authors have suggested that longer duration of statin use is associated with protective effect, and the RCTs/ cohort studies which did not show the association typically had 3.9–6 years of exposure to statins. In their study, they also found strongest association in patients who were on statins for more than 9 years. This study also had detailed discussion on limitations including bias on screening, selection, and standardization of the groups.

Dietary fat intake has been shown in observational studies to increase the risk of prostate cancer. Hence, the effect of statins could be merely due the effect of treating hyperlipidemia than direct effect of cancer cells. However, a study comparing statin group versus bile acid-binding resin group showed a positive association for only statins in reducing prostate cancer risk.

**Conclusion**

Statins are widely used, and initial research demonstrates they may have a role in prostate cancer prevention. Further research is needed before clinical recommendations.

## COX-2 Inhibitors

### Rationale

Evidence of chronic inflammation is found in the prostate along with prostate cancer commonly. It is possible for the prostatic inflammation to contribute to the etiology of prostate cancer. Chronic inflammation can cause oxidative stress which could lead to accumulation of DNA damage during the aging process which has been implicated in the genesis of malignancy. Inflammatory cells in the prostate produce a number of compounds such as superoxide, hydrogen peroxide, oxygen-free radicals, and peroxynitrite that cause DNA damage. The inflammatory response also results in the production of bioactive lipids such as prostaglandins. Cyclooxygenase enzymes (COX-1 or COX-2) catalyze the rate-limiting step in prostaglandin synthesis, which is the conversion of arachidonic acid to PGH2. COX-2 expression is highly inducible and regulated by a number of inflammatory or mitogenic stimuli, such as bacterial lipopolysaccharides, proinflammatory cytokines (IL-ip, IL-2), tumor necrosis factor, epidermal growth factor, and androgens. Prostaglandins generated at sites of inflammation mediate a variety of responses to tissue injury and hypoxia, including inhibition of apoptosis, cell growth, increased cell migration, inhibition of the immune response, and stimulation of angiogenesis [6].

### In Vitro Studies

Epithelial proliferation has been shown to arise in the inflammatory foci, and it has been found that COX-2 is expressed at high levels at these sites [7]. However, the presence of COX-2 in prostatic lesions is highly variable [8]. The studies on expression of COX-2 in prostate cancer had shown conflicting results. NSAIDs have been shown to exert growth inhibitory effects through non-COX-2 inhibition effect like inhibition of proinflammatory gene induction by arachidonic acid metabolites in prostate cultures as well [9]. These studies show possible inhibition of prostate carcinogenesis by NSAIDs.

## Epidemiological Studies

A Canadian nested case–control study had shown NSAIDs/coxibs were associated with a reduced likelihood of prostate cancer occurrence (odds ratio [OR], 0.71; 95 % confidence interval [CI], 0.58–0.86), as was exposure to aspirin (OR, 0.84; 95 % CI, 0.74–0.96) in patients over 65 years of age. Longer duration exposure to NSAIDs increased the protective effect [10].

A systematic meta-analysis performed in 2004 and subsequently in 2006 identified 24 studies examining the association between NSAID use and prostate cancer [11, 12]. Ten of them were cohort, and 14 were case–control studies. There were no randomized control trials. Majority of the studies assessed the intake of drugs once only by asking the patients. Studies that assessed the effect of aspirin use on total prostate cancer had a pooled odds ratio (POR)

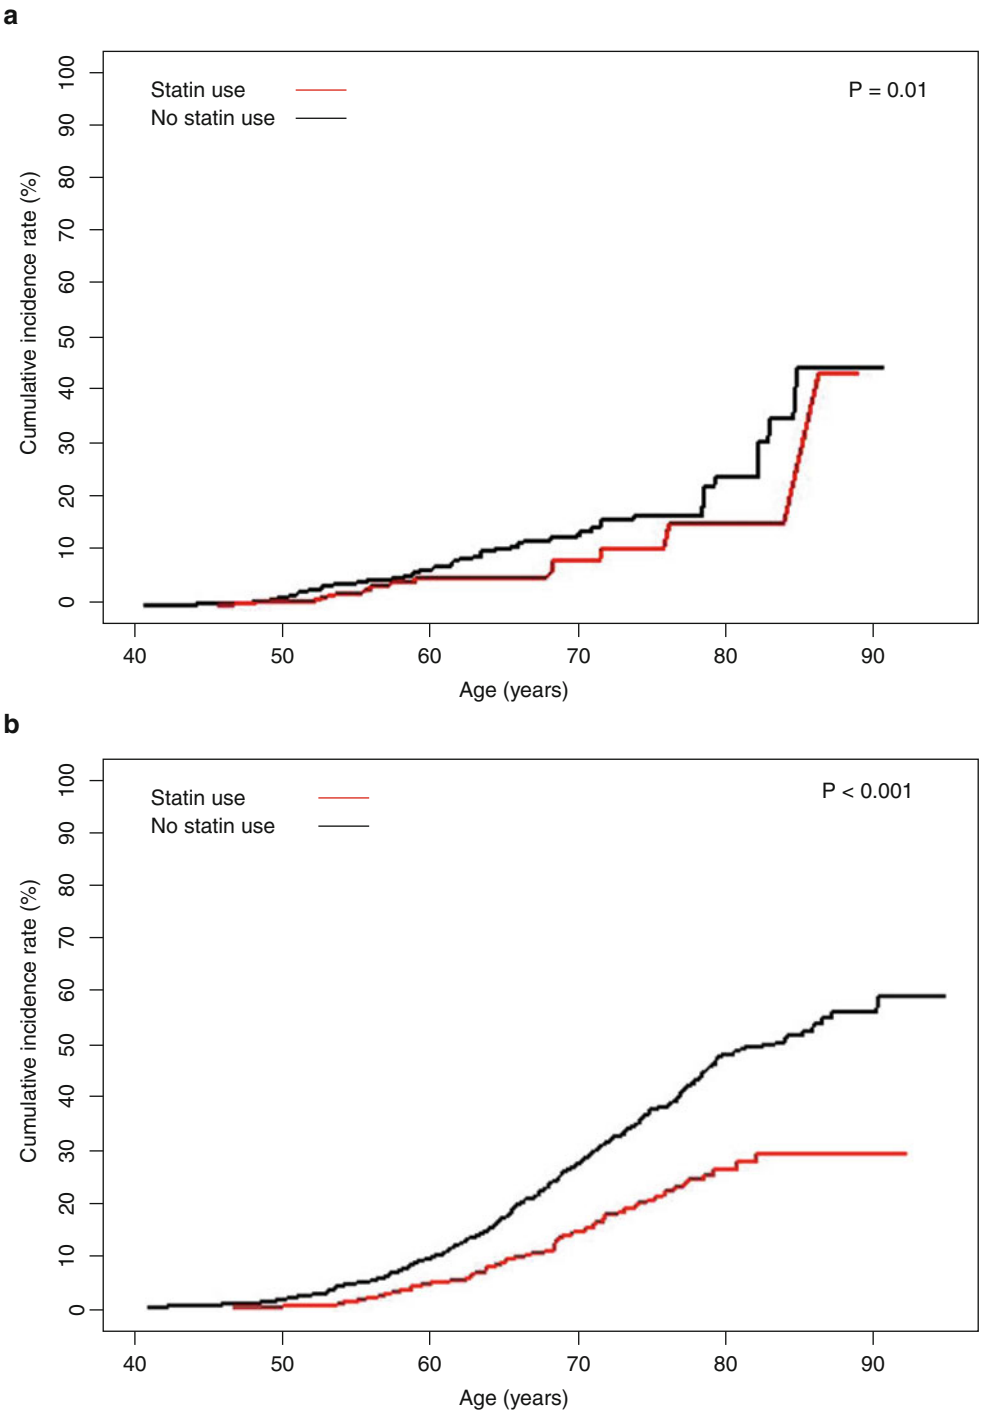

**Fig. 33.1** Cumulative incidence of exceeding age-specific PSA reference range (**a**) of prostate biopsy (**b**), of prostate cancer (**c**), and of high-grade prostate cancer (Gleason 7 or greater, **d**) (Reproduced from [5])

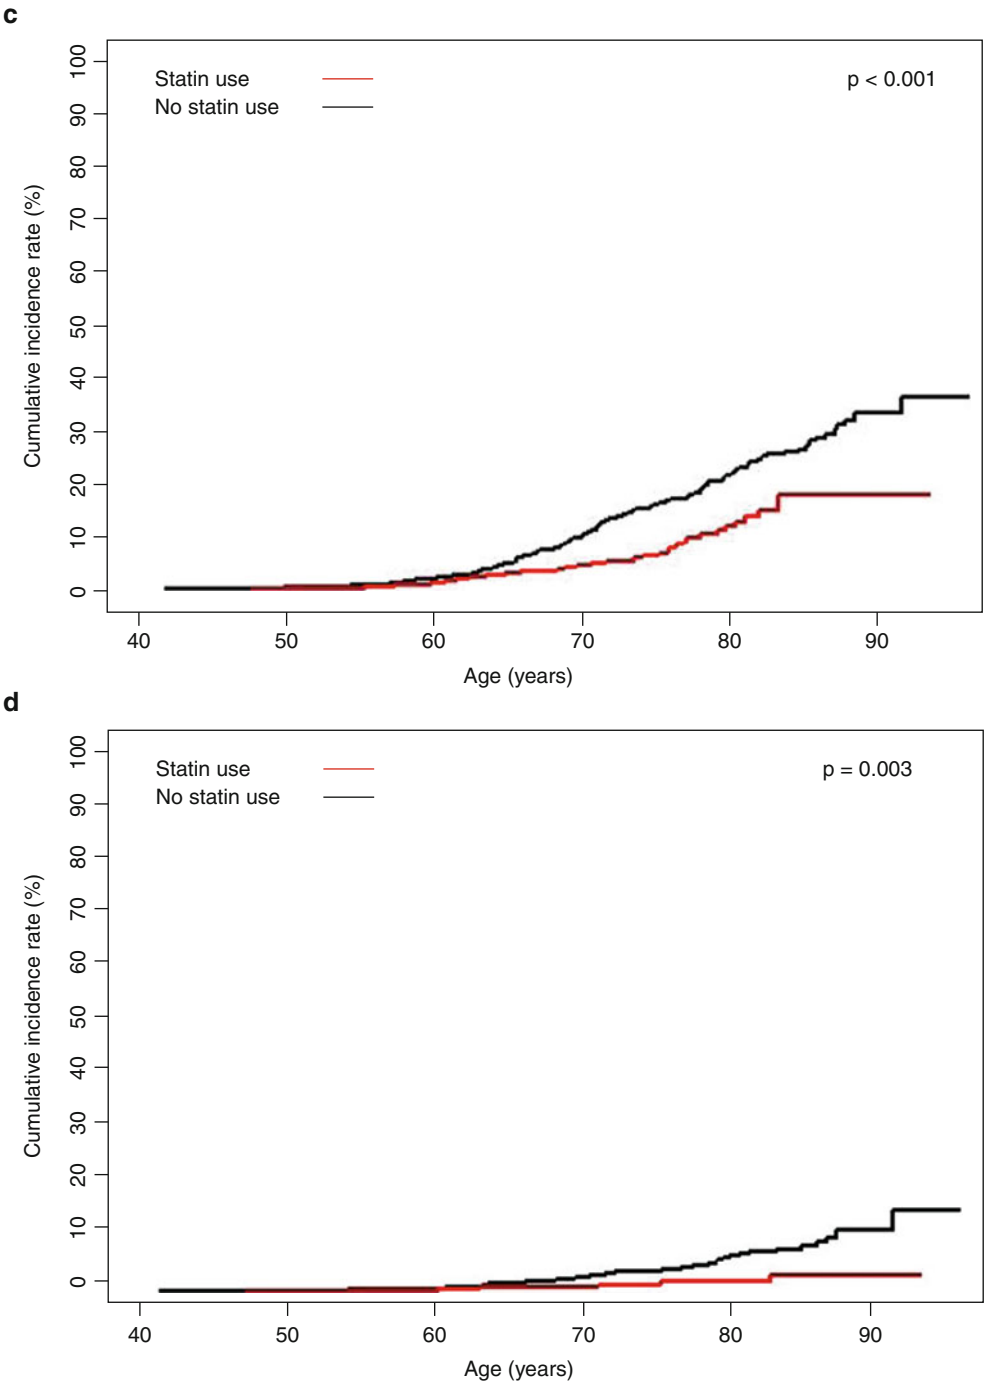
**Fig. 33.1** (continued)



of 0.83 (95%CI: 0.77–0.89), whereas those that assessed the effect of aspirin on advanced prostate cancer had a POR of 0.81 (0.72–0.92). Studies that examined the effects of nonaspirin NSAIDs or all NSAIDs were less consistent but still suggestive of reduced risks. Exposure misclassification, limited information on dose and duration of drug use, and the possibility of uncontrolled detection bias are limiting factors (Fig. 33.3).

## Conclusion

NSAIDs are a commonly used group of drugs, and they cause various gastrointestinal side effects, namely, dyspepsia, gastric ulceration, and bleeding. Every year, there are several reported cases of death due to these side effects. Selective COX-2 inhibitors (coxibs) were developed to reduce these side effects, and they indeed reduced the gastrointestinal side effects by 50 %. However, in

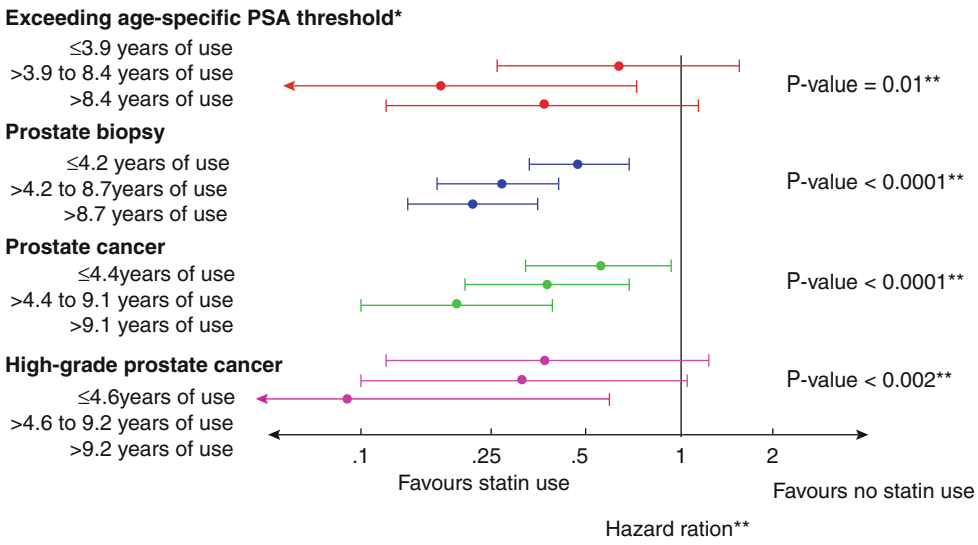


**Fig. 33.2** Associations between duration of statin use (stratified by tertiles) and outcome using nonstatin users as referent group. *P* values represent tests for trend. *Asterisk* indicates PSA outcomes only for 634 men who participated in in-clinic examinations. *Double asterisk* indicates adjusted for age, diabetes, hypertension, CHD, and NSAID, 5-alpha-reductase inhibitor, and α-blocker use (Reproduced from [5])

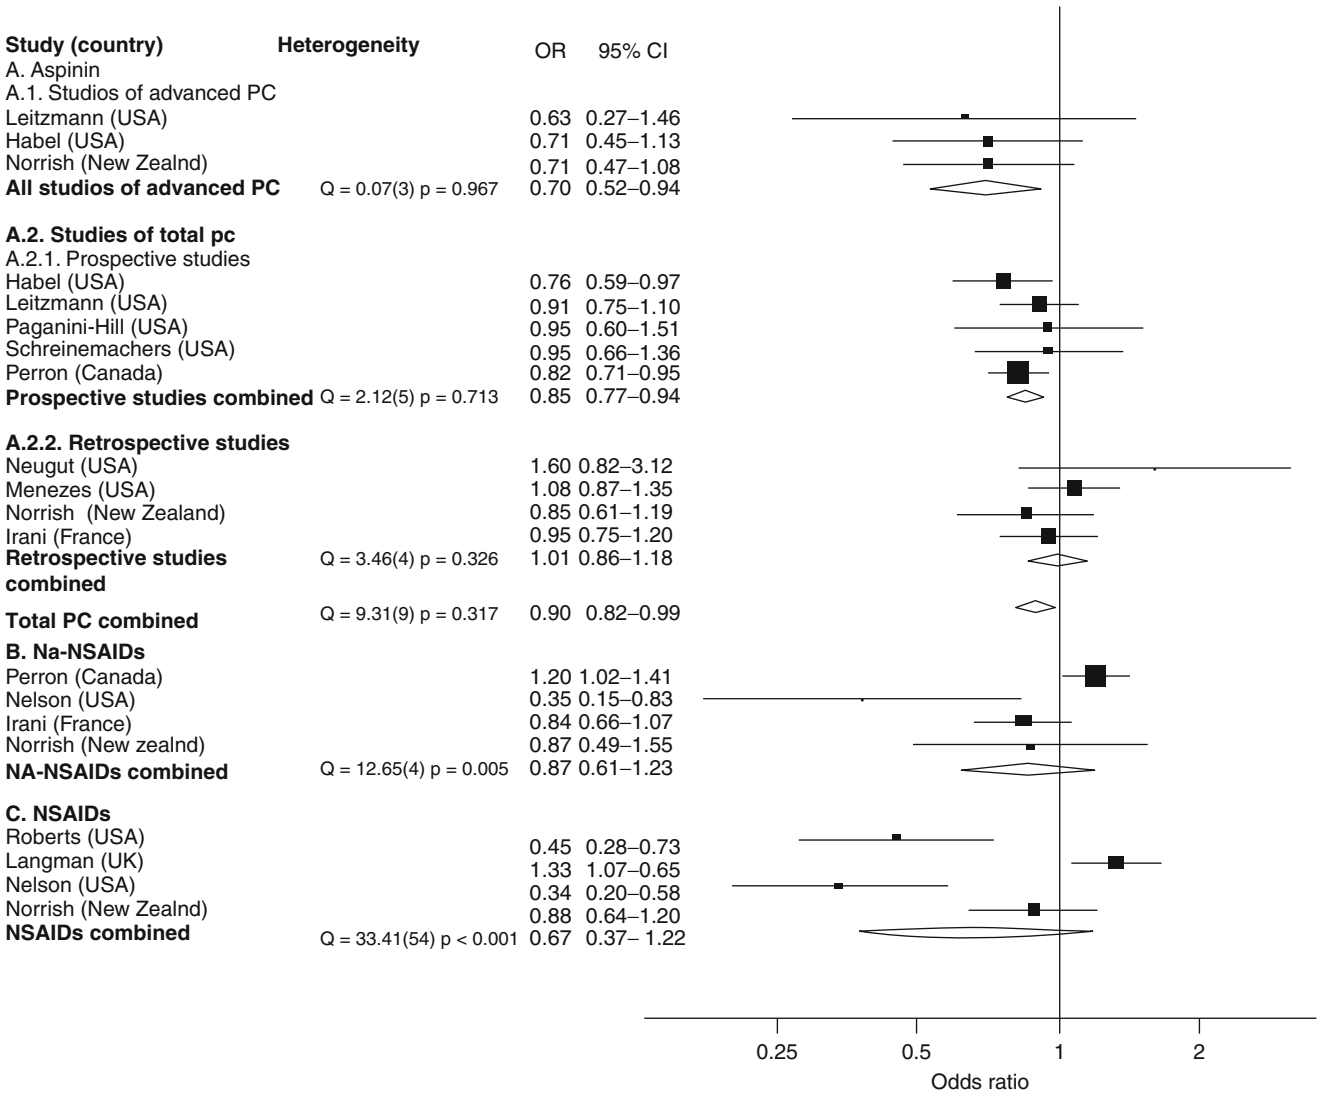

**Fig. 33.3** Relative risk estimates and summary of odds ratio by NSAID type (Reproduced with permission from [12])

cancer prevention studies, selective COX-2 inhibitors were found to be associated with increased risk of cardiovascular toxicity. This has caused a great deal of concern and hampered the progress in this field. Moving forward, it seems that a balance between the risk of disease and risk of taking NSAIDs or aspirin should be carefully taken into account when formulating recommendations.

## Selenium and Vitamin E

### Rationale

*Vitamin E* is used to refer to a group of fat-soluble compounds that include both tocopherols and tocotrienols (ref). There are many different forms of vitamin E, of which γ-tocopherol is the most common in the North American diet. γ-Tocopherol can be found in corn oil, soybean oil, margarine, and dressings. α-Tocopherol, the most biologically active form of vitamin E, is the second most common form of vitamin E in the North American diet. This variant of vitamin E can be found most abundantly in wheat germ, sunflower, and safflower oils. It is a fat-soluble antioxidant that stops the production of reactive oxygen species formed when fat undergoes oxidation.

*Selenium* is a nonmetal chemical element found in sulfide ores such as pyrite, where it partially replaces the sulfur. The chief commercial uses for selenium today are in glassmaking and in chemicals and pigments. Selenium salts are toxic in large amounts, but trace amounts are necessary for cellular function in many organisms. It is a component of the enzymes glutathione peroxidase and thioredoxin reductase (which indirectly reduce certain oxidized molecules in animals and some plants). It is also found in three deiodinase enzymes, which convert one thyroid hormone to another.

Preclinical and epidemiological data have suggested that selenium, vitamin E, and beta-carotene prevent prostate cancer. Cell line studies have shown that vitamin E inhibits the growth of LNCaP prostate cancer lines [13]. Further studies have also shown that selenium causes apoptosis in DU145 prostate cancer cell lines [14] and has an effect on prostate cancer cell growth [15].

### General Cancer Prevention Studies

Nutritional Prevention of Cancer: This was a North American randomized, placebo-controlled, crossover cancer prevention trial. 1,312 subjects with nonmelanomatous skin cancer were randomized to placebo or 200 μg of selenium. Patients were treated for a period of 4.5 years and mean follow-up of 6.4 years. Results from secondary end point analysis suggested that supplemental selenium reduced the incidence of several cancers including prostate cancer. However, selenium did not protect against development of skin cancers [16].

ATBC Cancer Prevention Study: A randomized, double-blind, placebo-controlled, primary-prevention trial to determine whether daily supplementation with alpha-tocopherol, beta-carotene, or both would reduce the incidence of lung cancer and other cancers. A total of 29,133 male smokers, 50–69 years of age from southwestern Finland, were randomly assigned to one of four regimens: alpha-tocopherol (50 mg/day) alone, beta-carotene (20 mg/day) alone, both alpha-tocopherol and beta-carotene, or placebo. Follow-up continued for 5–8 years. As a secondary end point, the participants who received alpha-tocopherol had fewer cancers of the prostate and colorectum than those who did not receive alpha-tocopherol, whereas more cancers of the bladder, stomach, and other sites combined were diagnosed in the participants who received this supplement [17].

### Specific Prostate Cancer Prevention Trials

A randomized, placebo-controlled trial (Selenium and Vitamin E Cancer Prevention Trial [SELECT]) of 35,533 men from 427 participating sites in the United States, Canada, and Puerto Rico randomly assigned to four groups (selenium, vitamin E, selenium and vitamin E, and placebo) in a double-blind fashion. Baseline eligibility included age 50 years or older (African-American men) or 55 years or older (all other men), a serum prostate-specific antigen level of 4 ng/mL or less, and a digital rectal examination not suspicious for prostate cancer. Intervention included oral selenium (200 μg/day from L-selenomethionine) and matched vitamin E placebo, vitamin E (400 IU/day of all-rac-alpha-tocopheryl acetate) and matched selenium placebo, selenium and vitamin E, or placebo and placebo for a planned follow-up of minimum of 7 years and a maximum of 12 years. At a median overall follow-up of 5.46 years (range 4.17–7.33 years), hazard ratios (99 % confidence intervals [CIs]) for prostate cancer were 1.13 (99 % CI, 0.95–1.35; $n=473$) for vitamin E, 1.04 (99 % CI, 0.87–1.24; $n=432$) for selenium, and 1.05 (99 % CI, 0.88–1.25; $n=437$) for selenium and vitamin E versus 1.00 ($n=416$) for placebo. There were no significant differences (all $P=0.15$) in any other prespecified cancer end points. There were statistically nonsignificant increased risks of prostate cancer in the vitamin E group ($P=0.06$) and type 2 diabetes mellitus in the selenium group (relative risk, 1.07; 99 % CI, 0.94–1.22; $P=0.16$) but not in the selenium and vitamin E group. Selenium or vitamin E, alone or in combination at the doses and formulations used, did not prevent prostate cancer in this population of relatively healthy men (Fig. 33.4).

| Selenium + vitamin E | 8700 | 8585 | 8371 | 8097 | 7428 | 4894 | 2580 |

**Fig. 33.4** Cumulative incidence of prostate cancer detected each year by intervention group. Compared with placebo, there was as statistically nonsignificant increase in prostate cancer in the vitamin E group ($P = 0.06$) and not in the selenium + vitamin E group ($P = 0.52$) or the selenium group ($P = 0.62$) (Reproduced from [18])

**Conclusion**

SELECT suggested vitamin E, alpha-tocopherol, or combination did not prevent development of prostate cancer in spite of strong secondary evidence. There could be several reasons to account for this. The dosage (vitamin E dose of 400 IU vs. 50 IU) and formulations (L-selenomethionine vs. selenized yeast) used in the SELECT were different from ATBC or NPC. Nevertheless, the authors had a strong clinical evidence to use the dosage and formulations used in SELECT. Further, the results of NPC could be skewed due to low sample size, and the result could be chance finding due to multiple testing.

## Estrogen Receptor Modulators (Also See Chap. 30)

### Rationale

Estradiol contributes to the development of HGPIN and prostate cancer. Toremifene is an estrogen receptor modulator and has the potential to reduce the incidence of HGPIN and prostate cancer [19, 20]. Animal studies in transgenic mice had shown toremifene reduced the incidence of HGPIN and prostate cancer [21].

### Epidemiological Studies

A phase II dose-finding double-blind study involving 514 subjects had been conducted in subjects with HGPIN but not biopsy-proven prostate cancer. This was a 12-month prospective study, and patients were randomized to daily dosage of 20, 40, or 60 mg of toremifene. There had been 22 % reduction in cumulative risk of prostate cancer in patients on 20 mg of toremifene compared to placebo (24.4 % vs. 31.2 %, $P < 0.05$). The point incidence of prostate cancer was reduced by 48.2 % with 20 mg of toremifene compared to placebo in patients who did not have biopsy evidence of prostate cancer at baseline and 6 months [22]. Although it is unclear why only the 20-mg arm showed a significant reduction in the risk of prostate cancer, the authors hypothesize that it was the greater selectivity and inhibition of a subtype of the estrogen receptor which stimulate prostate growth.

**Conclusion**

A phase III study is ongoing comparing toremifene 20 mg with placebo, and the initial results indicate no statistically significant difference in incidence of the prostate cancer between the two groups [23]. However, final results are awaited. Until then, given current clinical recommendations for HGPIN, toremifene should not be considered for prostate cancer prevention at this time [24].

## Lycopene

### Rationale

Lycopene is a carotenoid that gives tomatoes their red color. Although lycopene is the major bioactive compound, there is a possibility of synergistic action with other compounds like glycoalkaloids (tomatine), phenolic compounds (quercetin), salicylates, phytoene, and phytofluene. Although it is established that lycopene is readily taken up by the prostate, most of the lycopene in the human prostate gland has been found to be primarily in the cis form, despite being available largely in the trans form in the food sources, although the significance of the transformation is still poorly understood [25, 26].

### Mechanisms

Lycopene exerts its effect by several possible mechanisms. It is an antioxidant and prevents oxidative damage to cellular protein, lipid, and DNA. Lycopene had been shown to modulate intercellular communication. Some studies have shown increased gap junction intercellular communication, decreased oxidative damage to DNA, and increased apoptosis. Lycopene had been shown to inhibit both androgen dependent and independent cell lines. Lycopene has been shown to impact IGF-I signaling, cell cycle progression, and cellular proliferation and to have an inhibitory effect on deoxyribonucleic acid (DNA) synthesis in primary prostate epithelial cell cultures in vitro [27].

Although in vitro studies have demonstrated several cellular effects, which are both genomic and nongenomic, to date, the molecular mechanism for the cancer-preventive effects of lycopene is not clearly understood. This may be due to the fact that chemopreventive agents have multiple chemoprevention-associated molecular activities. Some of these activities may be interrelated. Also, a single activity, even if it is the agent's predominant pharmacologic activity, may not be the most important or the only one effecting chemoprevention. Thus, although observing chemopreventive effects at the cellular and tissue levels is a key approach to identifying potential chemopreventive agents, future clinical trials must complement these studies by examining the molecular targets of these agents.

### Epidemiological Studies

Ten epidemiological studies have been found to be examining the relation between lycopene and prostate cancer. Six of them investigated the relation between dietary lycopene intake and risk of prostate cancer. Four studies examined the relation between blood lycopene levels and prostate cancer risk. Eight out of the ten studies have shown inverse association between lycopene and the risk of prostate cancer.

The possible importance of dietary lycopene in the etiology of prostate carcinoma was highlighted by the Health Professionals Follow-up Study. This showed that of all the dietary factors investigated, including several carotenoids and vitamin E, only high levels of dietary lycopene were associated with a decreased risk of developing prostate cancer.

Giovannucci reviewed the role of lycopene and lycopene-based dietary factors in relation to the risk of various cancers including prostate cancer [28]. Among 72 studies identified, 57 reported statistically significant inverse associations between tomato intake or blood lycopene level and the risk of cancer in defined anatomic sites including the prostate [29]. The Physicians' Health Study revealed lycopene was the only antioxidant found at significantly lower mean levels in patients with cancer than in matched controls [30]. None of the associations was confounded by age, smoking, body mass index, exercise, alcohol use, multivitamin use, or plasma cholesterol level. Furthermore, early clinical trials of short-term lycopene supplementation, either in the form of an oleoresin or in tomato pasta sauce, in patients before radical prostatectomy have shown significant decreases in PSA level, together with evidence of downregulation of cancerous cell activity.

However, in the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, the intake of 25 tomato-related foods in 29,361 men was prospectively assessed, and lycopene intake was not associated with prostate cancer risk nor were reduced risks found for total tomato servings or for most tomato-based foods, although inverse associations were suggested for some processed tomato products commonly cooked with fats [31]. No association was observed between serum lycopene and total prostate cancer, whereas high serum beta-carotene concentrations were associated with increased risk for aggressive PCa [32].

A systematic review of lycopene supplementation on post diagnostic prostate cancer progression identified

eight interventional studies [33]. Five studies did not have a control, and one had unmatched control. There were two randomized studies. The studies also had widely different groups of patients and included a range of different outcome measures. The outcome measures reported in the studies include changes in PSA levels, cancer-related symptoms, evidence of progression from bone scans, survival, and toxicity. Six of the eight studies showed inverse association in biochemical response with PSA on lycopene supplementation. Kucuk in a small RCT examined short-term supplementation of lycopene for 3 weeks before radical prostatectomy, and he did not find significant change in percentage PSA. However, in a larger RCT, Ansari et al. examined the effect of lycopene supplementation on metastatic cancer patients treated by orchidectomy [34]. They used lycopene at a dose of 4 mg/day for 2 years. The intervention arm showed a significantly low mean PSA ($P < 0.001$) compared to nonintervention group and complete PSA response in 78 % versus 40 % in nonintervention group ($P < 0.05$). One RCT and another before–after study showed amelioration of cancer-related symptoms, namely, bone pain [35] and urinary symptoms [34] objectively. They have also shown higher proportion of patients with complete response by bone scan with corresponding decrease in bone pain and use of analgesics. The before and after study by the same group had shown 25 % reduction in overall metastatic lesions. Ansari group also reported survival advantage at a mean follow-up of 25.5 months. Out of 19 deaths, 12 happened in control group compared to seven in the intervention group ($P < 0.001$). However, there was no information on long-term survival.

Toxicity was examined in six out of eight studies. None of the studies reported severe intolerance according to the National Cancer Institute Common Toxicity criteria. In the RCTs, no adverse effect was reported during and after supplementation. The common side effects reported in the before–after studies were GI related, including nausea, vomiting, diarrhea, flatulence, anorexia, and dyspepsia. As these studies did not include control, it is difficult to definitely attribute the side effects to lycopene.

**Conclusion**

Studies indicate that lycopene is well tolerated and is not harmful. It is premature to recommend lycopene in primary chemoprevention of prostate cancer due to heterogeneity of the studies. However, lycopene supplements are already available in the market with specific reference to prostate cancer and men's health.

The trails considered so far do not provide sufficient evidence to recommend the use of lycopene supplements in routing clinical practice for patients diagnosed with prostate cancer. Further research should also consider other active components in tomato apart from lycopene.

## Zinc and Citrate

### Rationale and Mechanism

The primary function of the prostate gland is the production and secretion of prostatic fluid. The major component of the prostatic fluid is its extraordinarily high concentration of citrate, which ranges from ~40 to 150 mM as contrasted with ~0.2 mM citrate in blood plasma. The function of prostate citrate production is achieved by the activity of highly specialized glandular epithelial cells. The prevention of citrate oxidation by the prostate cells is the key event that is responsible for net citrate production. The cellular accumulation of zinc results in high levels of mitochondrial zinc that inhibit m-aconitase activity and citrate oxidation resulting in high prostatic citrate level. The inhibition of m-aconitase truncates the Krebs cycle at the first step of citrate oxidation, which provides the most efficient metabolic alteration for synthesized citrate to accumulate for secretion.

It is now well established that citrate and zinc levels [36] are markedly decreased in malignant versus normal prostate tissue (Figs. 33.5 and Table 33.1). In the absence of high cellular zinc levels, m-aconitase activity is no longer inhibited, and citrate oxidation proceeds via the Krebs cycle. Thus, zinc-accumulating citrate-producing normal prostate epithelial cells get metabolically transformed into citrate-oxidizing cells that have lost the ability to accumulate zinc. Zinc accumulation in normal prostatic epithelial cells results in citrate production, inhibits respiration and terminal oxidation of prostate mitochondria, inhibits growth and proliferation of prostate epithelial cells, induces apoptogenesis, and inhibits the invasive capabilities of malignant prostate cells. These effects of zinc accumulation are inhibitory to and incompatible with the prostate malignant process and can be defined as "tumor suppressor" effects of zinc. This leads to a rational expectation that the restoration of zinc accumulation in the malignant prostate cells should arrest the malignancy and cause the death of the tumor cells. Moreover, if zinc accumulation is restored in the neoplastic/premalignant stage, overt malignancy should be prevented.

### Epidemiological Studies

Based on this experimental evidence, several studies that relate the use of dietary zinc supplementation to prostate

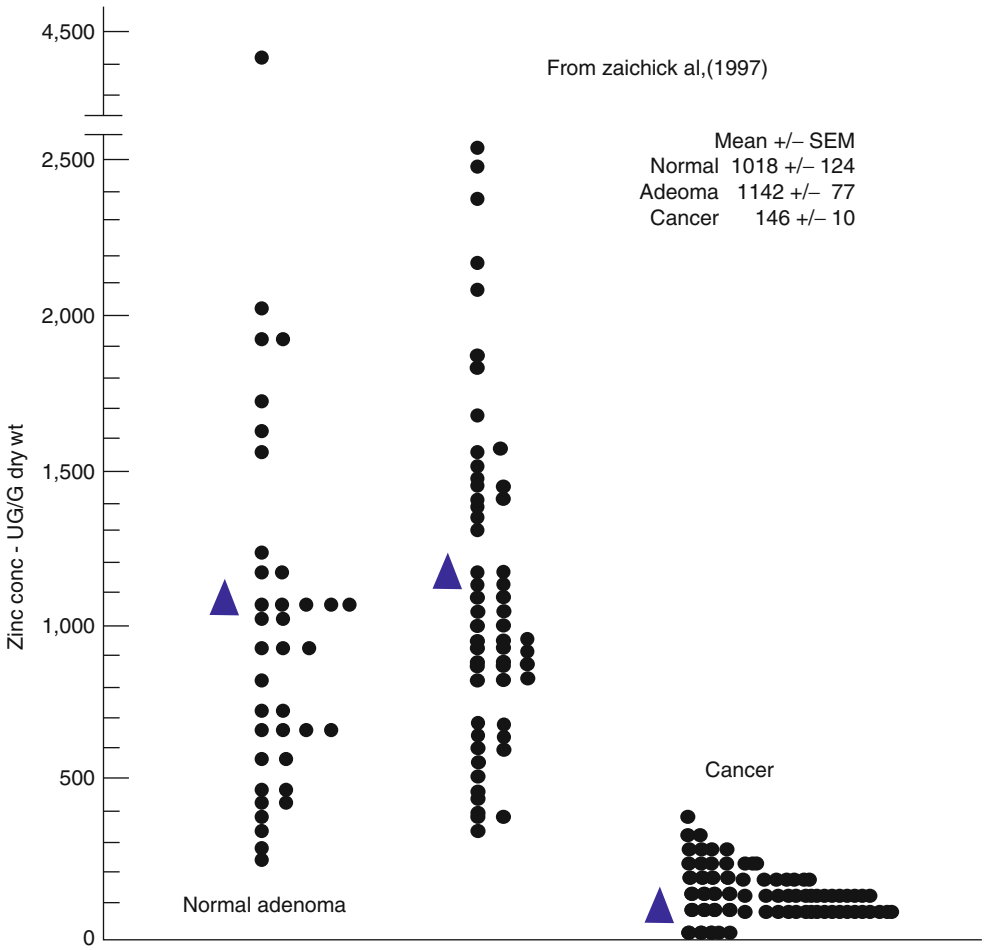

**Fig. 33.5** Zinc levels in normal, benign, and prostate cancer tissues (Reproduced from [37])

**Table 33.1** Zinc level in prostate from 17 published studies

| | Mean values | % Change from |
|---|---|---|
| Normal | Mean ± SEM | Mean (SEM) |
| Normal | 755 ± 158 | – |
| BPH | 1,270 ± 273 | +65 (45)% NS |
| PCA | 276 ± 48 | −68 (3)% $P < 0.001$ |

Reproduced from [37]
% Change from normal is obtained from the sum of the changes observed in each study that included normal values (15 reports)

cancer have been reported. Epidemiological studies regarding dietary zinc effects on prostate cancer have been conflicting and confusing. One study demonstrated that in vivo treatment of zinc increased zinc accumulation and citrate production in PC-3 cell-induced tumor tissues and inhibited tumor growth in nude mice [38]. Excess intake of zinc, especially with individual supplements, may however have the potential to encourage the transition of prostate conditions from benign prostatic hyperplasia to cancer. Health Professionals Follow-up Study examining the risk of prostate cancer in 46,974 supplemental zinc users found supplemental zinc intake at doses of up to 100 mg/day was not associated with prostate cancer risk. However, compared with nonusers, men who consumed more than 100 mg/day of supplemental zinc had a relative risk of advanced prostate cancer of 2.29 (95 % confidence interval = 1.06 to 4.95; $P$ trend = 0.003), and men who took supplemental zinc for 10 or more years had a relative risk of 2.37 (95 % confidence interval = 1.42 to 3.95; $P$ trend < 0.001) [39]. Large doses of zinc can inhibit the benefits of bisphosphonate drugs [40], increase testosterone level, increase cholesterol, reduce levels of "good cholesterol" (high-density lipoprotein), and can promote immune dysfunction [41].

## Conclusion

More research is needed in this area, but in the meantime, the intake of larger concentrations of zinc for most individuals need to be discouraged until adequate research resolves this controversial issue [42]. There is a consis-

tency in all the reports that the use of moderate levels of zinc supplement does not impose any additional risk; and in some reports, it could be efficacious against prostate cancer. In the elderly male population, supplemental zinc would be efficacious in maintaining a normal plasma zinc level. This should be incorporated into or along with any other interventions [37].

## Green Tea

### Rationale

Green tea is obtained from drying fresh tea leaves from tea plant *Camellia sinensis*. More than two-thirds of the world population consume this beverage. It contains characteristic polyphenol compound epigallocatechin 3-gallate (EGCG). EGCG is a more potent antioxidant, and it is 25–100 times more potent than vitamin C or E [43]. Many studies have shown decreased risk or reduced progression of prostate cancer [44, 45] associated with consumption of green tea.

### Mechanism

EGCG in prostate cancer cell lines have shown growth inhibition and induction of apoptosis primarily through p53-dependent pathway [46]. Combination of EGCG and a COX-2 inhibitor resulted in expression of pro-caspase-6 and pro-caspase-9 and poly(ADP-ribose) polymerase (PARP) cleavage, inhibition of peroxisome proliferator activated receptor (PPAR)-γ, and inhibition of NF-κB compared with the additive effects of the two agents alone, suggesting a possible synergism[47]. EGCG also specifically inhibited proteasomes resulting in accumulation of proteasome substrates KIP1/p27 and IκBα followed by growth arrest in the G(1) phase of the cell cycle[48].

### Animal Studies

Animal studies have been done employing TRAMP (transgenic adenocarcinoma of the mouse prostate) mice. Oral infusion of GTP at human achievable dose (six cups of green tea/day) significantly inhibited prostate cancer development and increased tumor-free and overall survival of mice. In the TRAMP mice ventral prostate, EGCG significantly reduced cell proliferation, induced apoptosis, and decreased androgen receptor (AR), insulin-like growth factor 1 (IGF-1), IGF-1 receptor, phospho-ERK1/2, COX-2, and inducible nitric oxide synthase (iNOS) [49]. In athymic nude mice, implanted with CWR22Rυ1 cells, treatment with GTP, water extract of black tea, EGCG, and theaflavins resulted in significant inhibition in growth of implanted prostate tumors, reduction in the level of serum PSA, induction of apoptosis accompanied with upregulation in Bax and decrease in Bcl-2 proteins, and decrease in the levels of VEGF protein [50].

### Epidemiological Studies

Six studies examined the role of green tea in prostate cancer. The trial setting, study design, population studied, and the end points were highly heterogeneous. Two studies have shown minimal or limited antineoplastic activity in castrate-resistant prostate cancer [51, 52]. In a phase II trial, tumor response, defined as a decline in the baseline PSA value, occurred in a single patient or 2 % of the cohort and was not sustained beyond 2 months. The median change in the PSA value, from baseline for the cohort, increased by 43 % at the end of the first month. Green tea toxicity, usually grade 1 or 2, occurred in 69 % of patients; however, six episodes of grade 3 toxicity and one episode of grade 4 toxicity also occurred. In a Japanese public health study, green tea consumption was associated with dose-dependent decrease in incidence of advanced prostate cancer. The multivariate relative risk was 0.52 for men drinking five or more cups/day compared with less than one cup/day. Green tea was not associated with localized prostate cancer [53]. A phase II proof of principle clinical study on HGPIN volunteers, green tea catechin (GTC)-treated men showed no significant change in PSA but a decreased incidence of prostate cancer and improved IPSS in patients with coexistent BPH. Further prostate mapping was done for 2 years in these subjects. It showed long-lasting inhibition of prostate cancer progression after 1 year treatment with GTC [54]. A Chinese case–control study examined the association between green tea intake and prostate cancer in 130 prostate cancer patients and 274 controls. Green tea intake was assessed using structured questionnaire by interview. The prostate cancer risk declined with increasing frequency, duration, and quantity of green tea consumption; and the dose–response relationships were also significant, suggesting that green tea is protective against prostate cancer.

There were no randomized studies examining the association of green tea and prostate cancer. There were very few or no studies examining the risk of prostate cancer in high incidence geographical locations like Europe or North America.

**Conclusion**

Further studies are needed to determine the role, if any, of green tea in prostate cancer prevention.

## Phytotherapy

### Rationale

Soya product intake is one of the major differences in diet between East and West inversely correlating with incidence of prostate cancer. A limited amount of clinical evidence points to a beneficial role of soy products in reducing male sex hormone levels and exhibiting weak estrogen and antiestrogen-like properties [55, 56]. The beneficial effects of soya product have been attributed to isoflavanoids. Experimental evidence is available regarding antitumor effect of isoflavanoids, namely, genistein and daidzein. Phytochemicals differ from what are traditionally termed nutrients because they are not a necessity for normal metabolism nor will their absence result in a deficiency disease.

### In Vitro Studies

Genistein blocked the cell cycle progression at G1, inhibited PSA expression, and modulated cell cycle gene regulation [57]. Genistein also inhibited endothelial cell proliferation and angiogenesis and induced apoptosis in androgen-dependent cell lines.

Aronson et al. demonstrated a reduced growth rate of LNCaP cells in nude mice fed with low fat plus soy protein and isoflavone extract [58]. In animal models, genistein has been demonstrated to inhibit angiogenesis through inhibition of endothelial cell proliferation and several enzymes promoting cell growth (e.g., tyrosine kinase, topoisomerases I and II).

### Animal Studies

A study with Lobund–Wistar rats that received a high-isoflavone diet showed a significant reduction of prostate tumor growth compared to the control group receiving a low-isoflavone diet [59]. Another study with TRAMP mice fed on a genistein-rich diet also found reduction of tumor incidence [60].

### Epidemiological Studies

The first prospective cohort study was conducted in 1994 and showed that flavonoid intake was not associated with mortality from cancer [61]. This was confirmed in a cross-national study of seven countries with 16 cohorts. A positive effect on coronary heart disease but not cancer mortality might be attributed to flavonoid intake [62]. Another cross-national study [63] which is a case–control study was done in 59 countries ($n = 24{,}213$). It showed that soy products are found to be significantly protective with an effect at least four times as large as any other dietary components. A substantial review of studies that have assessed the direct relation between the individual dietary intake of soy products and the risk of prostate cancer was done by Ganry in 2005 where he analyzed epidemiological studies providing data on (1) dietary soy intake or flavonoid intake, (2) urinary excretion of isoflavones or lignans, or (3) blood measurements of isoflavones or lignans. Soy was used as a marker for isoflavone intake. Overall, the results of these studies did not show protective effect. Only four of these studies were prospective, and none of them found statistically significant prostate cancer reductions [64].

Perabo et al. reviewed the role isoflavones in prostate cancer patients [65]. There were no randomized studies examining the relationship. Ten studies analyzed the relationship between isoflavone intake and prostate cancer. Four of them were case–control studies, and six of them were cohort studies. All the studies had few patients, short duration of isoflavone intake, and variable end points, some of which were not clinically relevant. All of them suggested isoflavones are well tolerated with minimal low-grade toxicity. The end points include PSA response (50 % PSA decrease, % change in PSA levels), cholesterol level, p105erB-2 proto-oncogene level, serum DHT level, micronucleus frequency, and serum isoflavone levels. De Vere White et al. determined if supplemental dose of isoflavone would lower the PSA by more than 50 % and found 0 % complete response and 17 % partial response and 67 % disease progression among 62 prostate cancer patients. To date, major prospective interventional randomized studies are lacking in this area to have any meaningful application in day-to-day clinical practice.

#### Conclusion

The protocols chosen for the clinical phase I and II trials make interpretation of data quite difficult. Dose and concentrations of the drug/substance used in the studies were empirically derived, and the manufacturing and preparation of the product were not standardized. Some analysis combined patients without stratification for androgen-dependent and androgen-independent tumors; some had small patient numbers, short treatment duration (6 months), or did not have sufficient statistical power. It is difficult to make definite statements or conclusions because of the great variability and differences of the study results. Although some results from clinical genistein studies seem encouraging, reliable data on tumor recurrence, disease progression, and survival are unknown. A major setback remains the problematic design and definition of end point criteria assessing the value of genistein in cancer therapy. The presented data may potentially allow recommending patients in favor of the use of genistein with the intention to prevent development of prostate cancer. At this stage, there is not enough

clinical evidence by clinical trials that genistein has an effect in the treatment of prostate cancer [64, 65]. To establish the influence of a nutritional compound such as genistein on cancer genesis, promotion, or progression, carefully designed, larger scale, prospective randomized trials should further support the epidemiological and experimental data.

## Conclusion

We have reviewed salient agents that were examined in chemoprevention of prostate cancer. Some of them are commonly used medications, and the remaining are dietary-derived products. All of them showed promising results in the experimental studies. Some of them have showed promising results in both epidemiological and observational studies. However, none of them have shown a significant chemopreventive effect in well-designed randomized control studies with clinically relevant end points. Selenium, vitamin E, isoflavones, and cyclooxygenase inhibitors are not recommended for chemoprevention until any future RCT suggests an association. The role of green tea and lycopene in chemoprevention is promising though the former was not examined in a randomized setting. Both these dietary derivatives are well-tolerated and well-designed RCTs needed to provide appropriate recommendation. Supplemental zinc has not shown consistent protective effect on prostate cancer. However, the association between zinc and prostate cancer is more complex than simple deficiency. The epidemiologic studies cannot and should not be interpreted as evidence that contradicts the clinically and experimentally established relationships. Intraprostatic zinc deficiency does contribute to the development of prostate cancer. More research is needed to elucidate the genetic/metabolic relationships in prostate malignancy and to provide an understanding of the onset of prostate cancer. Further research concentrating on intracellular transportation of zinc and other approaches in alteration of prostate metabolism also needs to be performed. Similarly, vitamin D deficiency is found to be associated with prostate cancer. However, the complex relation between sunlight, exogenous vitamin D intake, calcium intake, and endogenous vitamin D synthesis needs to be clearly understood in relation to prostate cancer. Large prospective observational and randomized studies are needed targeting these areas to fully utilize this unique compound in chemoprevention of prostate cancer.

## Introduction and Philosophy of Early Detection of Prostate Cancer

Prostate cancer (PCa) is a significant health problem both for individuals, doctors, and public health systems. The received wisdom for the management of cancer problems in general has been that the earlier that a cancer diagnosis is made, the better the outcome for the patient. While it is true that the time to cancer death may often be increased, there has also been much debate about whether the increases in life expectancy after diagnosis of a cancer problem by screening simply represent a lead-time bias where life expectancy after diagnosis is increased by moving the time of diagnosis back to an earlier time point rather than a genuine increase in length of life.

While individuals and their physicians may believe that they would be best served by early diagnosis and treatment, this may not be an essential part of successful PCa management. Indeed, the impact of screening for prostate cancer using digital rectal examination and serum prostate-specific antigen (PSA) has been modest with number needed to screen, in the order of 1,410 unselected men screened to save 1 life [1].

The impact of treatment on mortality in screen-detected prostate cancer has also been questioned. Twelve-year follow-up data presented in the 2011 AUA meeting from the PIVOT study of 731 men treated for screening-detected prostate cancer showed no benefit in terms of cancer-specific or overall survival to men randomized to radical treatment over watchful waiting [2]. However, the benchmark SPCG-4 study [3] demonstrated a survival advantage to radical prostatectomy in clinically detected cancers in the pre-PSA era. This advantage equated to one life saved for seven patients undergoing radical prostatectomy in the under-65 age group. These data suggest that an unselective screening and treatment process may increase the number of patients treated and hence dilute the effects of treatment by increasing the number of treatments for clinically indolent disease. It will also increase the number of men exposed to the toxicities of treatment including the potential for erectile dysfunction, incontinence, or other urinary problems and psychological morbidity.

Taking these data as a whole might suggest that PSA-based screening is not justified. This is the conclusion of the European Association of Urology (EAU) and United Kingdom National Screening Committee (UK NSC) and the United States Preventative Services Task Force (USPSTF). Other bodies in the USA have generally supported the slightly stronger statement that PSA screening may be attempted in well-informed men with the necessity to proceed with the test and/or biopsy determined after an appropriate discussion with the patient (discussed in Chap. 27).

Early diagnosis (using newer methods other than digital rectal examination and serum PSA followed by a transrectal ultrasound and prostate biopsy) may however offer both alternatives to PSA screening and a further additional determination of risk prior to proceeding to biopsy or treatment. Costs and the morbidity of treatment and/or investigation are the major barriers to an effective screening/case-finding program. Thus, a "smarter" approach with both novel markers of risk and a more effective assessment of patient risk of non-cancer mortality may help us to deliver more individualized prostate cancer treatment in the future.

In addition, early detection using sensitive techniques is usually applied to patients who are undergoing their first tests for prostate cancer but may equally be applied to men with initial negative biopsies and men who have received treatment with curative intent but where there is a suggestion of recurrence.

## Current Areas for Development of Early Detection Include

1. Whether newer biomarkers (serological, urinary, and histopathological) could give prognostic information on risk of cancer diagnosis, morbidity, or mortality
2. Whether newer imaging modalities can provide prognostic information to risk stratify early-stage disease
3. Whether standard 12-core transrectal ultrasound-guided biopsy gives adequate diagnostic yield to detect clinically significant cancers compared with transperineal prostate biopsy

## Prostate-Specific Antigen, Biomarkers, and Early Detection

Since its discovery over 30 years ago, the use of prostate-specific antigen (PSA) has transformed the detection, surveillance, and follow-up of patients with PCa worldwide. Because PSA is specific to prostatic epithelial tissue rather than purely to PCa, it is often that elevated PSA is due to pathology unrelated to cancer such as infection or inflammation due to instrumentation or urinary retention. Thus, PSA, while an excellent marker of advanced disease or of recurrence after radical surgery or effective ablation where there is no benign tissue left, is less helpful in differentiating prostate cancer from inflammation of the prostate in an early-diagnosis situation.

When an "abnormal" PSA value is chosen, it is necessarily a compromise between sensitivity and specificity where when one rises, the other falls. In order for a PSA screening program to produce the reductions in metastatic and advanced disease that have been identified by studies of screening such as the ERSPC [1], early-stage disease must be identified which means choosing a value with reduced specificity.

Efforts to allow sensitivity to be maintained while increasing specificity have led to studies of variations in PSA kinetics/metrics (Table 34.1). These include age adjustment, PSA density, free to bound PSA ratios, PSA doubling time, and PSA velocity [22].

These and a number of alternative markers (Table 34.1) have been developed with the aim of reducing the number of patients who need to proceed to prostate biopsy and to monitor disease activity. Nevertheless, in current clinical practice, the only widely used markers have remained PSA and PCA3.

## Prostate Cancer Antigen 3 (PCA3)

PCA3 is a commercially available, prostate-specific, non-coding messenger RNA detected in the urine after vigorous prostate massage. It has been used as a primary diagnostic tool with a reference value chosen which offers increased specificity for the same sensitivity values as PSA. This has recently been extended to secondary diagnostic use (in patients with prior negative prostate biopsy) with or without the addition of ETS fusion gene analysis. The PCA3-RNA complex is mapped to chromosome 9q21-22 [23], and under normal circumstances, a low level of the biomarker is expressed specifically by prostate tissue compared to other tissue types [24].

Groskopf et al. evaluated the PCA3 molecular urine test by collecting whole urine specimens after digital rectal examination from three groups: men scheduled for prostate biopsy, healthy men (<45 years with no known prostate cancer risk factors), and men who have undergone a radical prostatectomy. PCA3 and PSA were isolated, amplified, and quantified in each group. PCA3 results yielded a sensitivity of 69 % and specificity of 79 % in the pre-biopsy cohort compared to 28 % specificity with serum PSA assay. PCA3 and PSA were both undetectable in the cohort of recurrence-free post-prostatectomy urine specimens [25]. Data published by Hesse in 2008 demonstrated that PCA3 reference ranges could be chosen that offered additional specificity above F/T PSA but that this information added additional value to that offered by F/T PSA in that a high PCA3 assay result conferred greater positive predictive value in the low F/T PSA ratio group of patients who were identified as already being at greater risk of a cancer diagnosis [26].

PCA3 performance in different groups of men has also been used to determine whether synergistic use of the PCA3 score with other clinical information can predict biopsy outcome. It found that PCA3 is independent of prostate volume, serum prostate-specific antigen level, and the number of prior prostate biopsies. The percent of biopsy-positive men identified increased directly with the PCA3 score. An adapted quantitative PCA3 score correlated with the probability of a positive biopsy. Logistic regression results showed that the PCA3 score could be incorporated into a nomogram for improved prediction of biopsy outcome [27]. This is now clinically available via the PCPT nomogram website [28], and a similar nomogram has been published by Chun [29].

Interestingly, there is no correlation between PCA3 score and Gleason score or the expression of the immunohistochemical markers for PCa biological aggressiveness, though it was associated with clinical T2 (vs. impalpable) disease [26, 30]. PCA3 is probably advantageous to use as in combination with PSA; however, it requires prostatic massage to test which adds physician as well as laboratory costs to diagnostic workup which may represent as much as a tenfold cost increase in clinical practice. This is likely to limit its clinical utility in all but the best-funded health-care systems. It is also disappointing that there is, as yet, little evidence that the metrics of PCA3 predict outcome after prostate cancer diagnosis better than standard care once the diagnosis has been established.

**Table 34.1** Biomarkers in early prostate cancer

| Marker type | Marker | Sensitivity/specificity | Current uses | References |
|---|---|---|---|---|
| Serum/plasma markers | PSA | Sensitivity: 90 % | PSA continues to be the primary diagnostic investigation in the diagnosis of prostate cancer. As a continuous parameter: the higher the value, the more likely is the existence of prostate cancer | [4, 5] |
| | | Specificity: 10–31 % | Several modifications of serum PSA value have been described, to improve specificity of PSA. They include:<br>PSA density<br>PSA density of the transition zone<br>Age-specific reference ranges<br>PSA molecular forms<br>However, these derivatives have limited usefulness in the routine clinical setting | |
| | PSA isoforms | *Free to total PSA ratio*<br>Sensitivity: 90 %<br>Specificity: 10–45 % | The free to total PSA ratio is the concept most extensively investigated and most widely used in clinical practice to discriminate between benign prostatic hyperplasia and prostate cancer | [4] |
| | | *Human kallikrein 2/pro-PSA*<br>Sensitivity: 90 %<br>Specificity: 31 % | Limited studies/utility when PSA value is greater than10 ng/mL | [5, 6] |
| | | *Combination of total PSA, percentage-free PSA, and percentage sum – proPSA*<br>Sensitivity: 90 %<br>Specificity: 44 % | | [7] |
| | PSA kinetics | *PSA velocity*: (cutoff of 0.75 ng/ml/years) | PSA velocity and doubling time useful in monitoring patients with treated prostate cancer | [8–10] |
| | | Sensitivity: 72 % | Limited role in prostate cancer diagnosis due to background noise (total volume of prostate, BPH), the variations in interval between PSA determinations, and acceleration/deceleration of PSA velocity and PSA doubling time over time | |
| | | Specificity: 95 % | Prospective studies have shown that these measurements do not provide extra information compared to PSA alone in the diagnosis of prostate cancer | |
| | | *PSA doubling time:*<br>Sensitivity: 36.6 %<br>Specificity: 60.7 % | | |
| | Early prostatic cancer antigen (EPCA) | Sensitivity: 94 % | EPCA was specifically in prostatic intraepithelial neoplasia in addition to prostate cancer | [11, 12] |
| | | Specificity: 92 % | Although EPCA appears not to be present in patients devoid of prostate cancer, it has been detected in surroundings tissue, adjacent to the cancer | |
| | | | Currently, further investigation is needed to further characterize the protein as a suitable biomarker to diagnose prostate cancer | |
| | Circulating nucleic acids (microRNA) | Sensitivity: 60 % | Currently is used as a noninvasive diagnostic tool and for disease monitoring | [13] |
| | | Specificity: 87–100 % | The search for microRNA biomarkers for prostate cancer is still in its infancy, and only a small number of microRNA profiling studies using clinical samples have been published to date | |
| | | | A research tool only to date | |

(continued)

**Table 34.1** (continued)

| Marker type | Marker | Sensitivity/specificity | Current uses | References |
|---|---|---|---|---|
| Urine markers | DNA markers: hypermethylation, glutathione S-transferase P-1 (GSTP1) | Hypermethylation of GSTP1 has been detected in more than 90 % of prostate tumors | Reduced expression of the GSTP1 gene due to hypermethylation of the promoter has been shown consistently in prostate cancer and has been measured in urine sediment to determine the need for biopsy | [14] |
| | | Sensitivity: 73 % | GSTP1 has been shown to be acutely sensitive in detecting the presence of prostatic intraepithelial neoplasia and prostate cancer, thereby distinguishing patients with these diseases from patients with benign prostatic hyperplasia | |
| | | Specificity: 98 % | This assay has predominantly been used in the research setting although assays are increasingly filtering through to clinical practice | |
| | RNA markers: prostate cancer antigen 3 (PCA3), E-twenty-six (ETS) gene fusions | *PCA3*:<br>Sensitivity: 67 %<br>Specificity: 83 % | PCA3 alone as a diagnostic tool is limited in clinical practice. Increasingly, it is being used combined with serum PSA and/or urinary alpha-methylacyl-CoA racemase (AMACR). Both have shown improved sensitivity and accuracy | [15] |
| | Protein markers: sarcosine, telomerase, metalloproteinases (MMPs), urinary PSA | Sarcosine:<br>Sensitivity: <7 %<br>Specificity: 100 %<br>Telomerase:<br>Sensitivity: 58 %<br>Specificity: 100 % | Although early data has shown promise for sarcosine as a urinary marker, subsequent research has concluded that measuring sarcosine in urine fails as a marker in prostate cancer detection and identification of aggressive tumors. Subsequent review of the literature reached a similar conclusion | [16, 17] |
| | Alpha-methylacyl-coenzyme A racemase (AMACR) | Pairwise comparisons demonstrate significant differences in staining intensity between clinically localized prostate cancer and benign prostate tissue<br>Sensitivity: 82–100 %<br>Specificity 79–100 % | This is one of the few gene products consistently detected, with a high specificity for prostate adenocarcinoma. Considerably more enhanced sensitivity and specificity in prostate cancer patients with mid-range PSA levels have been observed with AMACR antibodies than that with PSA. However, it is a specialized technique limited to few research institutions where it is expensive, and currently, its sensitivity varies from laboratory to laboratory | [18, 19] |
| Tissue markers | Basal cell markers | High molecular weight cytokeratin (HMWCK, 34βE12) and p63 have been demonstrated to be the negative markers that can aid in diagnosis of prostate cancer | Immunohistochemistry plays an important role in diagnosis of prostate cancer | [20, 21] |
| | | The positive 34βE12 or p63 staining in prostatic basal cells may render a definitive diagnosis of benign glands | It helps to differentiate malignant glands from benign lesions, especially for morphologically equivocal glandular alterations in small-core biopsy specimens | |
| | | | Its use has been restricted to larger institutions with the expertise and equipment to process and interpret the data. A combination of HMWCK and AMACR is of great value in combating the morphologically suspicious cases | |

## Prostate Biopsy Techniques and Rates of Detection

The aim of prostate biopsy is to detect those prostate cancers with the potential to cause harm, rather than to detect all prostate cancers [31]. With this in mind, the standard of care for initial biopsy is transrectal ultrasound plus biopsy [31]. Transperineal template prostate biopsy represents a more recent development with a range of potential applications.

## Initial Prostate Biopsy

The UK Prostate Cancer Risk Management Programme and National Institute for Health and Clinical Excellence (NICE) recommended a multiple-core biopsy technique involving at least ten cores, covering all parts of the prostate and performed under ultrasound guidance [32].

Validated nomograms have been developed which predict outcome of biopsies based on preceding PSA and DRE [33], and these may be used to aid a decision on the appropriateness of the biopsy intervention. Total number of biopsies may be varied according to the total size of the prostate. The Vienna nomogram represents a system for deciding on number of cores in proportion to prostate size and inverse proportion to age [34].

The number of cores taken must also take into account the fact that higher numbers of cores seem to result in higher complication rates. A 2006 systematic review suggested that the balance between optimum diagnostic yield and complication rate occurs at 12 cores [35]. Thus, though a higher biopsy number on initial biopsy set (particularly via a transperineal route) might increase the diagnostic yield, there is as yet insufficient evidence that this should be done on a routine basis.

## What Is the Efficacy of Different Forms of Prostate Biopsy?

The first study to compare the two approaches to prostate biopsy was a prospective study of 107 patients with elevated PSA, who underwent both transrectal biopsy (six cores) and transperineal biopsy and suggested superior detection rates from transperineal biopsy [24]. However, a subsequent randomized controlled trial of 246 patients undergoing initial investigation by transperineal template biopsy or transrectal biopsy (12 cores each) reported cancer detection rates of 42 and 48 %, respectively [25]. While these reports confirm the practicality of the transperineal approach, they do not address the need to increase core number when the whole of the prostate gland is targeted with a transperineal template biopsy scheme.

As evidence is as yet lacking in the setting of primary assessment, transperineal template biopsy is not recommended by NICE in preference to the transrectal approach for initial biopsy [36]. However, good evidence is available that increasing core numbers (above 12) do not significantly improve cancer detection with the TRUS route [37].

## When Initial Biopsy Negative but Clinical Suspicion of Prostate Cancer High

Transperineal template prostate biopsy has been shown to be of increased diagnostic yield in patients with negative transrectal biopsy but in whom there remains a high clinical suspicion of prostate cancer. It is under these circumstances that NICE recommends transperineal biopsy [36].

An extended biopsy protocol using the transperineal approach may also be appropriate in cases where there is a rising PSA but equivocal results from transrectal biopsy, including prior biopsies containing higher risk features such as atypical small acinar proliferation [38].

## Transperineal Template Biopsy as a Reference Test for Emerging Imaging Techniques

At present, there is no imaging test that can reliably diagnose prostate cancer. Given its relatively close Gleason score agreement with radical prostatectomy specimens, transperineal template biopsy has become used as a reference test for emerging imaging techniques in the research context [31]. It offers an opportunity to diagnose men within the therapeutic window for radical treatment, particularly in the difficult anterior-only prostate cancer group; however, as with the other described tests, it may increase the chances of diagnosing low-volume low-risk disease which may require monitoring rather than definitive treatment as an initial strategy.

## Emerging Imaging Techniques

MRI scanning and other emerging modalities including computer-aided ultrasonography and PET-CT have been used to assess and stage early-prostate cancer with the hope that eventually less-invasive means to diagnose or risk stratify prostate cancer than biopsy may become available. The ideal test might take men at risk of cancer and identify only those with clinically significant disease for confirmatory biopsy and treatment.

## MRI in Prostate Cancer Early Diagnosis

Until recently, the role of MRI in detecting prostate cancer was limited to providing some evidence on the extent of distant metastasis. The development of multiparametric MRI

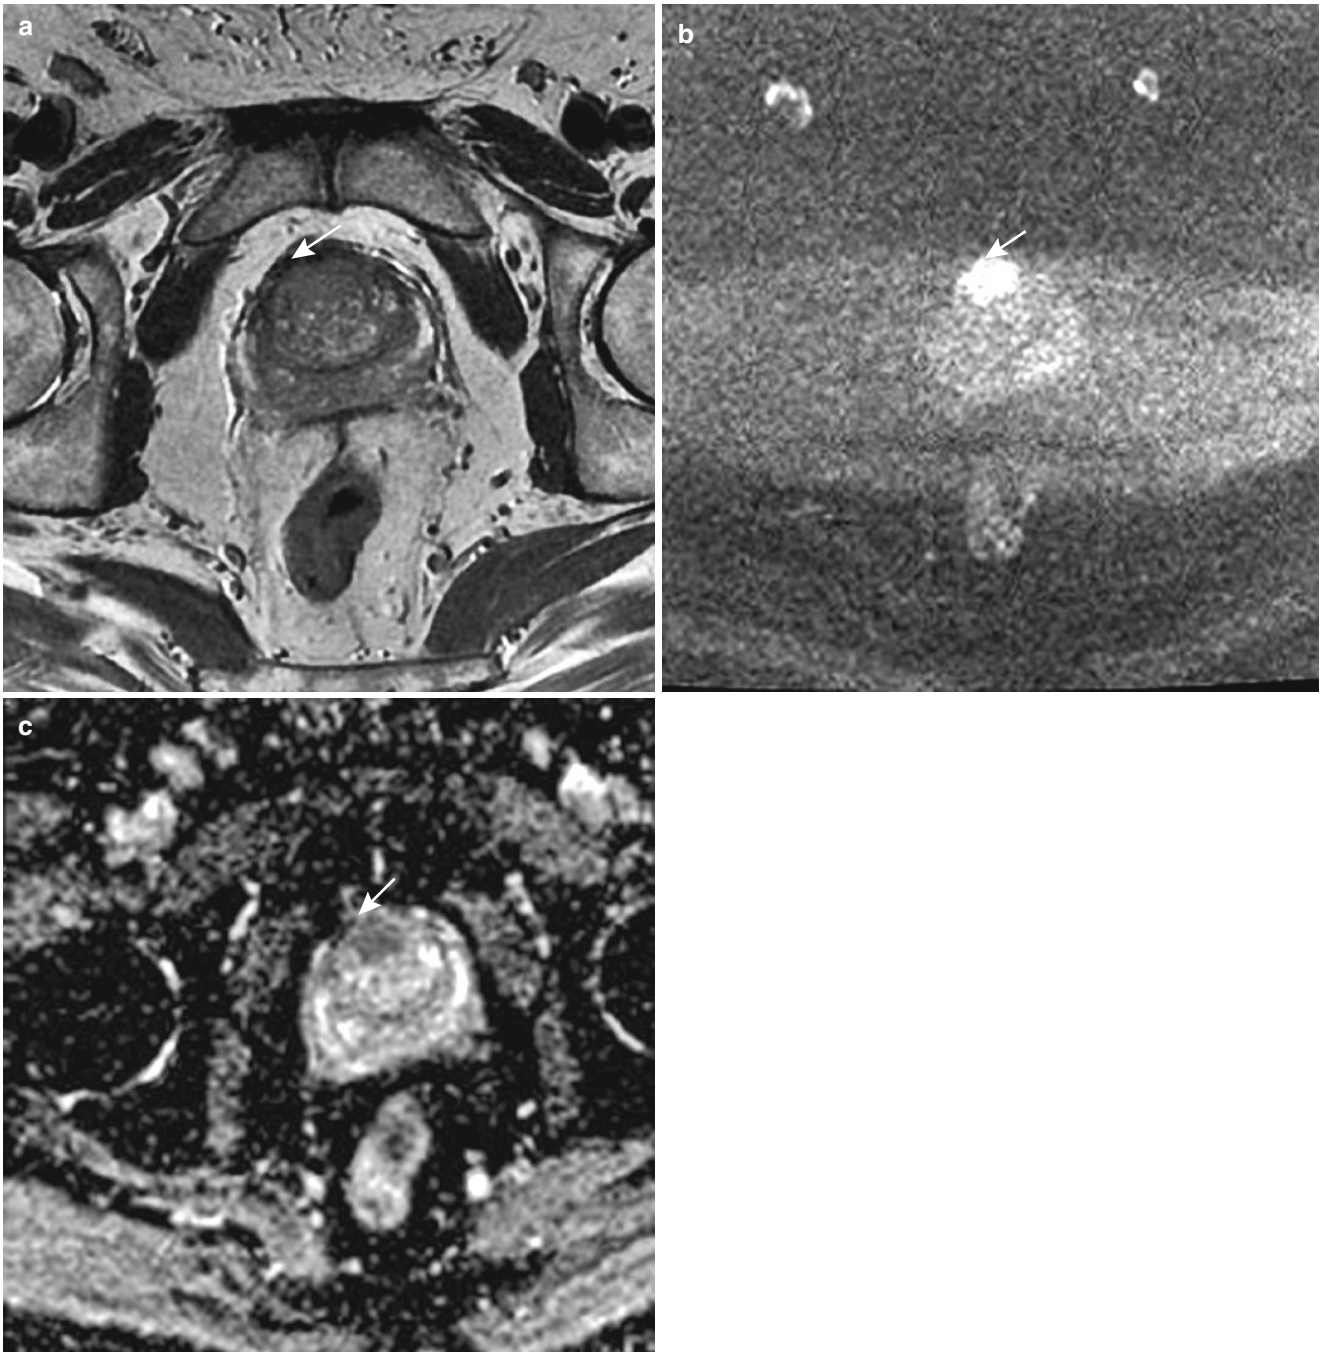

**Fig. 34.1** (**a**) A 70-year-old man presented with repeated negative TRUS biopsies but rising PSA. T2-weighted image demonstrates low signal changes in the bilateral peripheral glands which are negative on TRUS biopsy. (**b**) DWI demonstrates a small area of focal high signal uptake in the right transitional zone. (**c**) ADC demonstrates restricted diffusion in the correlating right anterior transitional zone suggesting tumor, hence explaining the negative TRUS biopsy and rising PSA

which includes both T1- and T2-weighted images, dynamic contrast enhancement, diffusion-weighted imaging (DWI), and proton spectroscopy has extended the use of MRI in the diagnostic pathway of prostate cancer [39].

While histological proof of prostate cancer based on prostate biopsy remains the gold standard, even the most invasive regimes of biopsy by either transrectal or transperineal routes have a false-negative rate [40, 41]. The latest iterative improvements in MRI give some indication of an ability to solve clinical problems in identifying tumor in those patients who have a rising PSA but repeatedly have had negative TRUS biopsies. This is particularly true in the anterior tumor (T2-weighted images Fig. 34.1a, diffusion-weighted images (DWI) Fig. 34.1b, apparent diffusion coefficient (ADC) map shown in Fig. 34.1c).

## Tumor Localization

Published results by Hricak et al. reported an MRI sensitivity of 96 %; however, this study excluded transitional zone tumors, and the analysis was by the presence or absence of tumor in a hemi-prostate.

It is now well established that although transitional zone tumors may be less aggressive, they account for 30 % of prostate cancers [42]. The anterior prostate is a region not biopsied by conventional TRUS biopsy. It is possible to use MRI as a primary "screening tool," decreasing morbidity and costs from patients undergoing TRUS biopsies and directing patients with anterior-only disease on MRI to a primary template biopsy. Clearly, the major disadvantage of this is the potential for false-positive reporting and the additional cost of adding a relatively expensive test or tests into the diagnostic pathway of all patients who are identified as at risk on basic investigation set of PSA and digital rectal examination.

## MRI with Contrast

Dynamic contrast imaging (DCI) techniques can be used to distinguish tumors in the peripheral zone from benign prostatic hypertrophy. Several studies [43, 44] demonstrate that the prostate cancers enhance earlier than the peripheral zone. Ito and Hara et al. have demonstrated 68 % sensitivity and 86 % specificities for detecting prostate cancer in the peripheral zone using dynamic contrast imaging using MRI [45]. Figure 34.2 illustrates the phases of DCI-MRI.

## Diffusion-Weighted Magnetic Resonance Imaging (DW-MRI)

DW-MRI can be a useful in identifying PCa [46, 47]. The cellularity of viable tumor is higher than that of benign tissues, and there may be restricted diffusion of water molecules. Tumors of the peripheral and transitional zone show decreased apparent diffusion coefficient (ADC) compared with their surroundings (see Fig. 34.1c).

In 2005, a study by S*hifousa* showed an increased accuracy for detection of cancer using both DW-MRI and T2W-MRI, using biopsy for confirmation [48].

## Tumor Burden

Studies have confirmed that MRI best detects lesions >10 mm. Only 5 % of tumors <5 mm in diameter were detected compared with 89 % of those >10 mm [49].

## Limitations of MRI

It has been recommended that MRI should be performed 6–8 weeks post biopsy to avoid the hemorrhage artifact, but evidence demonstrates that the hemorrhage is only resolved in 50 % of cases and may delay treatment [50], though the clinical significance of this except as regards psychological morbidity is probably limited. Clearly, pre-biopsy MRI avoids biopsy artifact but increases costs within the patient pathway. In addition, the limited sensitivity of MRI confers problems as 11 % of lesions above 10 mm will be missed, and thus current practice is to use both tests.

The techniques described above, in combination with the advances in technology of 3-T MRI or endorectal coil imaging using a 1.5-T MRI scanner, have extended the potential use of MRI beyond local staging post biopsy . Prospective studies are planned where pre-biopsy MRI is routinely performed before prostate biopsy using the transrectal and transperineal routes. It is hoped that these will confirm the extent of additional information that these techniques add for patients either in the primary diagnostic assessment or in the setting of a negative prostate biopsy with persistent evidence of possible disease such as rising PSA.

## Computer-Aided Ultrasonography

HistoScanning™, or computer-aided ultrasonography, has been assessed as a technique for identifying prostate cancer [51]. Early results suggest that HistoScanning™ may offer more information than standard B-mode ultrasound on cancer size, location, and extent. This may act as a basis for conducting effective biopsy and risk stratification. In a small preliminary study of 29 patients, HistoScanning accurately detected cancer foci of greater than or equal to 0.50 mL (HS).

Detailed scrutiny of the potential for transrectal ultrasound to detect small tumor foci is partially limited by protection of certain proprietary information, regarding, for example, three-dimensional resolution of the ultrasound machine used. Braeckmann et al. [52] point out that there are specific limitations to the HistoScanning algorithm; it is adversely affected by the presence of dense calcification and in the anterior component of a very large gland in which the signal is poor. Further confirmatory publications are still awaited 3 years after the publication of initial study data.

## Positron Emission Tomography (PET)-CT

A recent innovation has been the combination of morphological modalities with functional imaging. Positron Emission Tomography (PET), which can be combined with standard X-ray computed tomography, offers a noninvasive

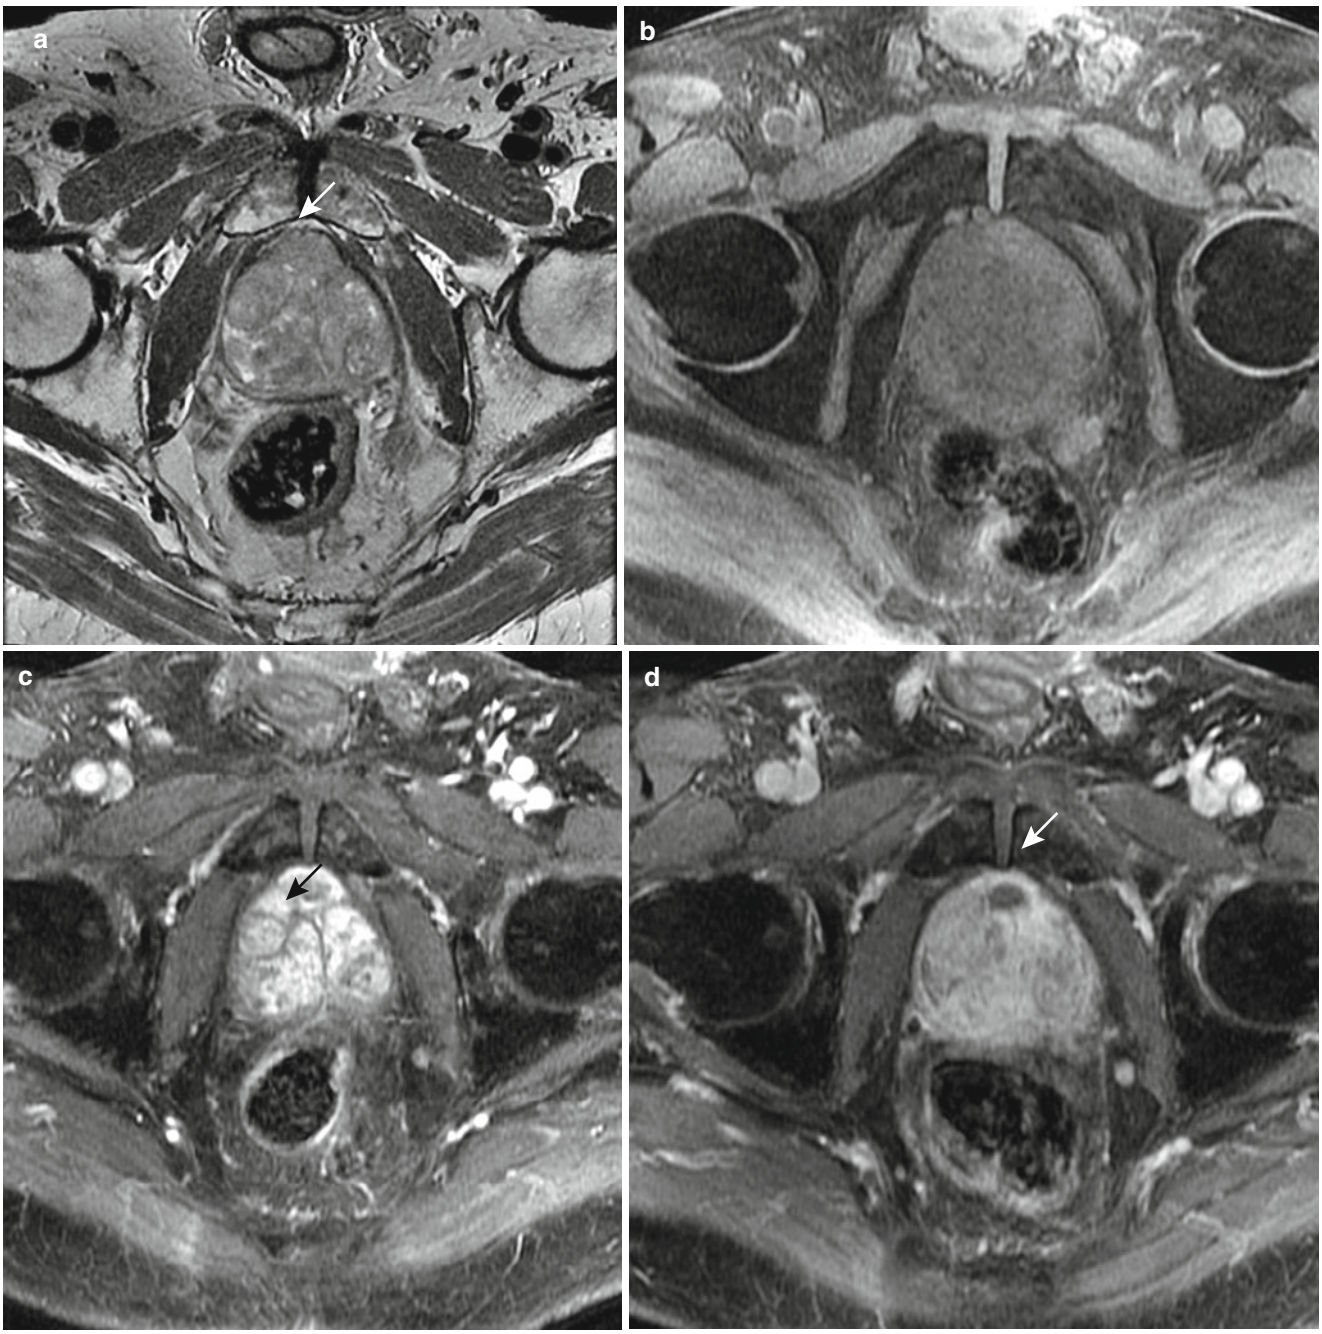

**Fig. 34.2** (**a**) T2-weighted image of low signal in the anterior transitional zone. (**b**) Pre-contrast image of the prostate. (**c**) 30–90-s enhancement of the anterior transitional zone tumor. (**d**) Washout of contrast confirming tumor in the 3–5-min phase of imaging

whole-body modality. PET and PET-CT have been evaluated at various points in diagnosing and treatment planning in prostate cancer, including tumor characterization and staging, restaging (in recurrent prostate cancer), and the monitoring of disease and treatment efficacy (review).

A variety of radiopharmaceuticals continue to be assessed in PET imaging in prostate cancer. $^{18}$Fluorodeoxyglucose is of particularly limited use in imaging the prostate, while $^{11}$C-choline PET has shown the greatest efficacy overall and particularly in the restaging setting. Choline PET-CT now has an established role in restaging prostate cancer, which should be triggered by an increase in PSA following radical treatment for prostate cancer, particularly after radical radiotherapy. Further, it may have a role in the disease and treatment monitoring, though further studies are required.

## Imaging Summary

At the current time, choline PET is useful only in relatively advanced disease, which is rarely present in the setting of early detection. HistoScanning requires further evaluation

before entering routine clinical use, but multiparametric MRI offers additional information, which may be useful in routine practice.

## Patient Factors in Risk Stratification for Early Disease

The assessment of non-prostate cancer related factors in the management of the patient considers the benefits of radical treatment over observation or indeed of watchful waiting. The simplest interpretation of the data from the SPCG-4 study [3] would be that radical prostatectomy has been established as a proven treatment with improved efficacy above watchful waiting.

However, for a number of patients, there will be limited benefit to radical treatment. Grossly, the SPCG-4 showed at a median of 12.8 years follow-up that in the over-65 age group, a significant dilution of the treatment effect occurred. In the over 65 s, no statistically significant treatment effect on all-cause mortality, cancer-specific mortality, or metastasis occurred. It is likely given the 12-year follow-up findings of the PIVOT study that for disease which is predominantly low-volume low-risk disease, there was no significant treatment effect for radical prostatectomy over watchful waiting [2].

Current best practice should choose to consider patient comorbidity as well as chronological age. In the United Kingdom, median life expectancy at age 65 in 2003–2005 was 16.8 years [53] with similar figures of 17.7 years on the Swedish population [54] and in men from the USA (17.2 years) [55]. One might therefore feel it likely that the benefits of treatment for men with limited life expectancy due to their comorbidities might be similarly reduced as they are for the group of older chronological age. While it can be argued that appropriate assessment of comorbidity is what dedicated physicians and surgeons have been doing for many years, it may be the case that there have been relatively limited efforts to risk stratify non-prostate cancer mortality risk in patients with early prostate cancer [56].

In the past, surgical studies have often reported the American Society of Anesthesiologists physical status score to measure comorbidity. Clearly, while these scales have a great practical use in the breadth of surgery, in general, any system which uses only six points to score comorbidity, only four of which relate to planned surgery are so broad that they are unlikely to be helpful in the assessment of chronic disease. Nor do they easily describe differences in outcome from an elective surgical patient group or for patients who are functioning well but have chronic illness.

Other studies have reported Eastern Cooperative Oncology Group (ECOG) performance status [57], which is commonly used in chemotherapy trials to describe comorbidity. ECOG is limited in the assessment of potential surgical or radiotherapy patients as they are generally in good health, and the ECOG scale has only six possible outcomes between completely healthy and dead, which lacks sensitivity in the prostate cancer patient who is being assessed prior to potentially curative treatment. In practice, only three levels of health classification would be likely to apply to any man deemed suitable for treatment of nonmetastatic prostate cancer (healthy – normal activity for >50 % of waking hours). Karnofsky scoring is a less frequently used version which was a precursor of the ECOG system which though it had a greater number of classes has no improvement in sensitivity in the surgical setting [58].

Charlson scoring [59] is a slightly more sensitive system which describes the likelihood of death from 22 serious conditions including solid cancers, heart disease, and diabetes. It allows predictions of estimated 10-year mortality from comorbidities and may also be adjusted for chronological age.

This sort of metric which is more sensitive and robust may help to add objective measures of comorbidity in the clinical trial setting but might also the patient some perspective on the competing risks of their non-cancer diagnoses [60].

In a recent sample of men with low-intermediate-risk prostate cancer, adjusted Charlson score > 3 had a threefold comparative risk of non-cancer death compared with men over age > 75. Despite this in the study of US patients in the Veterans Administration System, the patients with a Charlson score > 3 had fivefold greater risk of receiving radical treatment attempting cure than those of age > 75 [56].

Recently, further work by Litwin's group at UCLA has refined the Charlson score to address other-cause mortality risk in the prostate cancer population [61]. While these calculations demonstrate that current non-cancer mortality risk stratification (based on chronological age and clinical assessment) on when to offer radical treatment is not always based on logical and proportionate assessment of life expectancy, they as yet do not show that any of the scoring systems can be used to tell patients that radical treatment is or is not indicated at their level of risk. The problem with clinical trials may be that they may not include enough patients with comorbidities to allow for accurate risk stratification. It is however encouraging that trial data such as that from the PIVOT study is starting to report and adjust for Charlson score [2]. It is to be hoped that further data will be made available to allow patients and their physicians to make more accurate assessments of the competing risks to their health of prostate cancer and other common comorbidities.

### Conclusion

Early diagnosis of prostate cancer via unselected population screening with currently available tools is unlikely to be either cost-effective or to save significant numbers of lives. However, for well-informed men with good general health and particularly those with increased risk factors

for developing cancer such as a family history, PSA testing may be performed. In this scenario or when initial biopsies are negative but PSA kinetics suggest prostate cancer, the use of cutting-edge tools in early diagnosis can help to separate confirm the diagnosis and risk stratify progression due to higher volumes of cancer or higher Gleason grade.

The combination of more advanced methods of diagnosis and risk stratification of prostate cancer with assessment of the comorbidities of the patient offer the possibility to individualize the treatment of prostate cancer, though once strategies for using these modalities in combination have been developed, they will require testing in large-scale clinical trials with adequate follow-up to establish that they are robust.

They do however offer hope that in future radical therapy may both be applied earlier in clinically significant disease and also less frequently to men at low risk from cancer death either because of indolent disease or marked comorbidity.

# Tumor Markers

35

Diederick Duijvesz and Guido Jenster

## Introduction

A tumor marker in a biomedical setting can be defined as "a biological object present in human tissue and/or body fluids that is capable to differentiate between normal and abnormal biological conditions." The National Institutes of Health added that it should be measured objectively and is evaluated as an indicator of pathogenic processes or biological responses to a therapeutic intervention. With this definition, a wide range of characteristics can be used as a tumor marker, such as easily observable skin lesions or more inconspicuous variables such as proteins or RNA present in tissue, serum, or urine. Nowadays, the term tumor marker is inextricably linked to molecular markers.

So far, different kinds of tumor markers have proven to be a useful diagnostic or prognostic tool for medical doctors when assessing a certain disease, especially within the field of oncology. The presence or an elevation of a marker could indicate the existence of a malignant tumor. Furthermore, it could also have the ability to predict outcome before and after treatment. Also with prostate cancer, tumor markers have been widely used in daily clinical practice. This chapter will discuss multiple types of tumor markers for the diagnosis and prognosis of prostate cancer and will review a selection of markers that have been validated to some extent or are of high interest.

## Different Types of Markers

Tumor markers can be classified into several categories with their own specific purpose. The different kinds of markers can describe the chance of getting a disease (risk marker), the presence of disease (diagnostic marker, early detection, or screening marker), how the course of the disease will be (prognostic marker), and how to estimate the chance of success of a certain treatment (predictive marker) [1]. Furthermore, markers can also be applied to observe therapy efficacy during or after treatment (monitoring marker).

- When using a marker for risk assessment, the disease is not yet (clinically) present or cannot be detected with conventional techniques. Such a marker would be mainly suitable for life-threatening diseases that are typically diagnosed too late. In addition, risk markers can be implemented to identify a subpopulation for regular checkup or screening. In recent years, much research has been dedicated to the identification of genomic changes using genome-wide association studies (GWAS) to identify single-nucleotide polymorphisms (SNPs) associated with the development of a disease [2]. For prostate cancer, it is evident that many of such SNPs are linked to disease development, although none of them individually have a very strong correlation [3].
- Diagnostic markers have the ability to determine the presence or type of malignancy. Such a marker is often used in immunohistochemical examination on tissue specimens or in specific protein/mRNA analysis of patient-derived body fluids.
- Prognostic markers become very useful when it is possible to stratify patients in groups that have different outcomes. Based on this stratification, the physician can choose a specific therapeutic option in order to individualize treatment. Next to the choice of treatment, if aggressive subtypes can be identified, treatment can be initiated earlier [4]. One of the best prognostic markers for prostate cancer is Gleason score, a representation of the organization of tumor glandular architecture [5].

A. Tewari (ed.), *Prostate Cancer: A Comprehensive Perspective*,
DOI 10.1007/978-1-4471-2864-9_35, 

**Table 35.1** Expression of different kind of markers in healthy tissue as compared to malignant tissue

| Healthy tissue | Malignant tissue | Type of dysregulation | Example marker |
|---|---|---|---|
| + | +++ | Upregulated in cancer | AMACR/PCA3 |
| + | + | New distribution due to cancer | PSA |
| – | + | Mutation, oncogene | TMPRSS2:ERG |
| + | – | Mutation, tumor suppressor | PTEN |
| +++ | + | Downregulated in cancer | GSTP1 |

- Predictive markers are used to foretell the responsiveness to or outcome of a specific treatment. Although some markers have been described that predict the efficacy of hormone, radiation, or chemotherapy, these markers are not yet utilized in clinical practice.
- Monitoring markers are measured before, during, and after treatment to determine effectiveness of therapy. Prostate-specific antigen (PSA) is a highly effective and established monitoring marker for efficacy of radical prostatectomy, hormone therapy, and/or radiotherapy [6].

The occurrence, elevation, or modification of tumor markers can be caused by several biological processes. Endogenous cellular products are produced and shed at a greater rate by the abnormal cancerous cells. Also, these markers are released due to a higher apoptosis and necrosis rate in cancer. Furthermore, markers can reveal themselves when the environment of the cells becomes aberrant. An example is PSA, where higher levels in serum can be detected when the blood-prostate barrier is affected. Besides that, products of newly created genes in cancerous cells, such as the TMPRSS2:ERG fusion transcript, are applicable as a marker. Regarding prostate cancer, DNA (genomics), mRNA (transcriptomics), proteins (proteomics), and metabolites (metabolomics) have been the biochemical analytes investigated that could contribute to a better and more precise diagnosis and prognosis.

## Biological Materials for Tumor-Marker Analysis

When searching for new tumor markers, it is important to choose which biological material to explore. The most logical material is the one for which eventually a clinical applicable assay can be generated [7]. Therefore, materials derived with noninvasive techniques and those easily obtainable, such as blood or urine, are the most obvious. Blood is widely used, mainly because of the traditional availability and of the idea that biochemical analytes in plasma might provide important insight in disease-specific characteristics. Unfortunately, discovery of tissue- or cancer-specific marker is hampered by the abundances of all kinds of different analytes. The abundant proteins are identified preferentially and are generally not useful cancer markers. Probably, the most interesting new tumor markers are present in the low abundance range. Unfortunately, for certain technologies such as mass spectrometry, the high-abundance analytes overshadow the detection of the low-abundant ones. This problem is in essence the so-called "dynamic range problem." As an example, the proteome in blood has shown to consist of 3,000 proteins so far, but many more have to be identified. The 22 most abundant proteins account for 99 % of the complete proteome, so the search for new and low-abundant tumor markers is like searching for a "needle in a haystack" [8].

Another issue that arises when using materials such as blood is the origin of the marker. Like most clinically applied cancer markers, it is expected that the disease-specific markers are derived from the cancer cells or organ of origin. When candidate tumor markers are identified in serum, it is difficult to determine from which tissue these markers originate. It becomes slightly less complicated with the use of urine or prostatic fluids/seminal fluids. These materials are more specifically related to the prostate, and the abundance and variety of analytes is generally much less (Table 35.1).

## Identification and Validation of New Markers

### Discovery Phase

Discovery of new markers is an open and unselective search by which the differential expression of specific biochemical analytes between states is first defined [7]. If one wants to identify a specific marker, optionally, two separate states have to be compared without the influence of confounding factors. This comparison and eventual identification are typically performed with state-of-the-art technologies such as mass spectrometry or microarray analysis by using a small training set of samples. Drawbacks from this phase are the costs and the limited number of samples that can be analyzed. Because of the limited number of samples and the large number of analytes tested, many top candidate markers will be false positives, and some genuine markers will not be significantly different (false negative) [7]. With statistical calculations for false discovery rate and multiple testing corrections, these false positively identified analytes can be trimmed down. Eventually, after a list of potential tumor markers is generated, a more focused approach has to be taken where the most promising candidate markers must be validated.

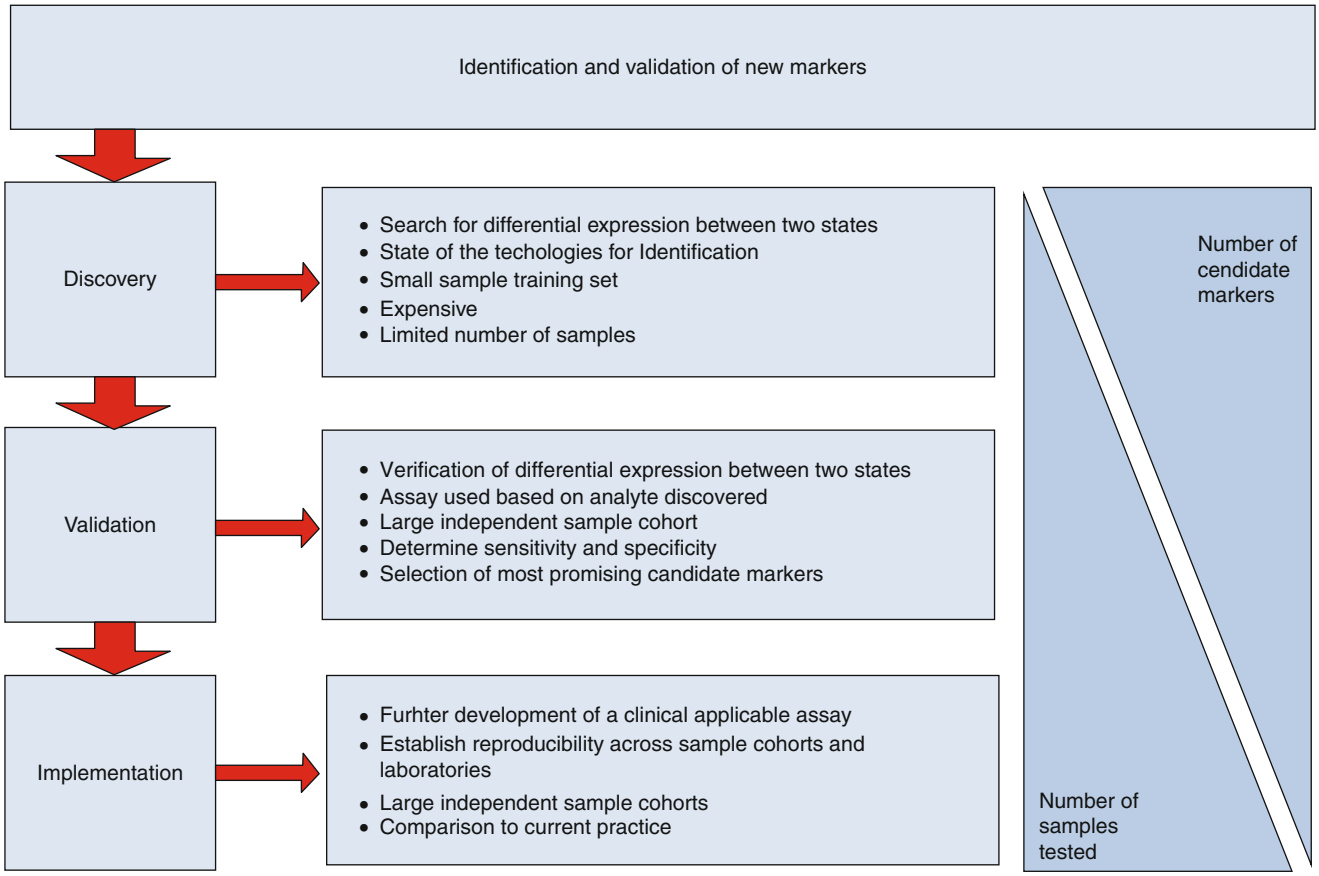

**Fig. 35.1** Identification and validation of new markers

## Validation Phase

The validation phase verifies the differential expression between samples and will give the opportunity to test the candidate tumor marker on an independent cohort (validation set). For this phase, an assay has to be developed that is capable of accurately measuring the candidate markers. The assay that is preferentially used is based on the specific analyte that has been discovered. For example, if a specific protein is identified, an ELISA (enzyme-linked immunosorbent assay) is a very sensitive and reliable test. When RNA is the marker of interest, most likely, the assay that will be used is qPCR (quantitative polymerase chain reaction). Besides these already established and widely used tests, novel techniques can be developed in order to more easily or more accurately detect the new tumor markers [9, 10]. Finally, with a specific and reliable test available, it has to be administered to larger study cohorts in order to test the most promising candidate markers. This cohort has to contain more variables in order to evaluate its restrictions and indicate the exact disease characteristics for which this candidate marker is most suitable. These experiments aim at confirming the previously discovered markers and will show their sensitivity and specificity for that particular disease they have been identified for. Eventually, from this validation step, only a few promising candidate tumor markers submerge. The ones that show a positive correlation with disease-specific characteristics will be used for the development of a clinically applicable assay. Normally, the whole process extends over a time line of at least 5 years, where initially 100–1,000 analytes are identified in the discovery phase. Unfortunately, only very few, if any, will survive the validation phase and reach the clinical implementation phase.

## Implementation Phase

In this phase, the main focus is the further development of a clinically applicable assay that can be used to further validate and implement the tumor marker. With the assay development, it is important to establish reproducibility across independent cohorts and laboratories [11]. By using this test, its operating characteristics are evaluated and a certain clinical cutoff value further tested and adjusted in multicenter prospective studies and compared to current practice. Only after this last phase, a specific test will gain wide acceptance and eventually be applied in a clinical setting (Fig. 35.1).

**Table 35.2** Tumor markers for prostate cancer

| Marker | | Biological function | Biochemical analyte | Marker ability |
|---|---|---|---|---|
| PSA | Prostate-specific antigen | Serine protease with diverse physiological functions | Protein | Screening/diagnosis/prognosis |
| %fPSA | Percentage-free PSA | | Protein | Diagnosis/prognosis |
| PSAD | PSA density | | Protein | Diagnosis/prognosis |
| PSAV | PSA velocity | | Protein | Diagnosis/prognosis |
| [-7],[-5],[-4],[2]ProPSA | PSA isoforms | | Protein | Diagnosis |
| hK2/KLK2 | Human kallikrein 2 | Peptidase, cleaving proPSA to mature PSA | Protein | Diagnosis |
| PCA3 | Prostate cancer antigen | Noncoding mRNA without a functional protein | RNA | Diagnosis |
| ETS | E twenty six gene family | Chromosomal rearrangement without a function | DNA | Prognosis |
| TMPRSS2:ERG | Transmembrane protein serine 2 (TMPRSS2) and ETS-related gene (ERG) | | DNA<br>Protein (ERG) | Prognosis |
| AMACR | Alpha-methylacyl-coenzyme A racemase | Metabolization of fatty acids and bile acid biosynthesis | RNA<br>Protein | Diagnosis/prognosis |
| GSTP1 | Glutathione S-transferase pi 1 (methylated) | Detoxification of carcinogens | DNA | Diagnosis/prognosis |
| PSMA (FOLH1) | Prostate-specific membrane antigen | Peptidase, hydrolyzing peptides in prostatic fluids | RNA<br>Protein | Prognosis |
| PSCA | Prostate stem cell antigen | Membrane-based glycoprotein | RNA<br>Protein | Diagnosis/prognosis |
| CgA | Chromogranin A | Proteolytic protein | Protein | Prognosis |
| B7-H3 | Transmembrane protein family B7, member H3 | Regulation of T lymphocytes | Protein | Prognosis |
| CAV1 | Caveolin-1 | Molecular transport, cell adhesion, and signal transduction | Protein | Diagnosis/prognosis |
| GOLPH2 | Golgi phosphoprotein 2 | Sorting and modification of proteins through the Golgi apparatus | RNA<br>Protein | Diagnosis |
| CRISP3 | Cysteine-rich secretory protein 3 | Unknown | RNA<br>Protein | Diagnosis/prognosis |
| Sarcosine | | Metabolite produced after enzymatic transfer of a methyl group from S-adenosylmethionine to glycine | Protein (metabolite) | Prognosis |
| Exosomes | Nano-sized vesicles, 100 nm in diameter containing RNAs and proteins | Intercellular communication, part of degradation pathway | RNAs and proteins | Diagnosis/prognosis |

## Tumor Markers in Prostate Cancer

Novel tumor markers for prostate cancer are still needed to improve the ability to detect prostate cancer, predict prostate cancer-related morbidity and mortality, and monitor response to treatment. Current markers used in research and even in the clinic remain controversial [12]. The most widely applied biomarker in prostate cancer is PSA. Because of its limitations, multiple new markers have been evaluated to compensate for these limitations. Unfortunately, many of these markers have not made it into the clinic, which shows that identification of better markers remains a challenge [13] (Table 35.2).

### PSA

Since its discovery in 1970, PSA has revolutionized the diagnosis and management of prostate cancer [12]. Subsequently, after its application in urological practice, it has proven to be a valuable tool for (early) detection, staging, and monitoring of men diagnosed with prostate cancer [14, 15]. Especially,

the use of PSA as a screening tool has increased the identification of prostate cancers and also improved curability with treatment.

PSA, also known as KLK3 or hK3, is a member of the human kallikrein family. This gene family consists of 15 members and is described with a distinct nomenclature [16]. The first three members (hK1, hK2, and hK3) encode for serine proteases that have diverse physiological functions. Expression of PSA and some other kallikrein members is androgen regulated. PSA protein has a half-life of 2–3 days and is secreted by prostatic epithelial cells into seminal fluid. Most likely, through tissue leakage, PSA can be found in serum but with a concentration of about $10^6$ times less as compared to seminal fluid.

Initially, PSA is produced as a 261-amino acid preproenzyme with a 17-amino acid signal peptide that is removed during synthesis [17]. After this step, proPSA is formed which contains 244 amino acids, from which subsequently 7 amino acids are cleaved, so it is processed to PSA that contains 237 amino acids. When shed in serum, PSA is unbound (free PSA or fPSA, 5–35 %) or bound (complexed PSA or cPSA) to complexes with the antiproteases α(alpha)1-antichemotrypsin (PSA-ACT), α(alpha)2-macroglobuline (PSA-A2M), or α(alpha)1-protease inhibitor (PSA-API) which inactivate its function [18]. In seminal fluids, it functions as a protease that liquefies semen by interacting with semenogelin and fibronectin [19, 20]. Although PSA is highly specific for prostate epithelial cells, in much smaller concentration, it can be measured in malignant breast cells, salivary gland, bowel, other urological tissues, and renal carcinoma cells [21–23]. Nevertheless, for practical and clinical purposes, PSA is organ specific because after removal of all prostate tissue, PSA values become immeasurable in serum. Although PSA is organ specific, it cannot be ascribed as prostate cancer specific because other urological conditions such as benign prostate hyperplasia (BPH), prostatitis, or mechanical damage also contribute to aberrant PSA values in serum [24]. It is noteworthy that the production of PSA by prostate cancer cells is not higher than benign prostate epithelial cells, but higher serum values are a result of an altered prostate-blood barrier [25]. In fact, production of PSA by prostate cancer cells is generally lower [26].

Large studies showed that 97 % of all men older than 40 years have PSA serum levels lower than 4 ng/mL, which gave rise to the idea that this value should be the threshold when it is used in a diagnostic setting [27]. Furthermore, it was shown that PSA serum values could increase when prostate cancer is present [28, 29]. Initially, PSA was used as a reliable marker to prove residual disease or progression after radical prostatectomy for prostate cancer [30]. Patients with lower values preoperative had higher rates of organ-confined disease [31, 32].

In a screening setting, it has been shown that PSA can increase the detection rate of prostate cancer in men without symptoms [33]. By using PSA, the percentage of men who were found with metastases at diagnosis was reduced from 16 to 4 %, but also late-stage disease and prostate cancer-related mortality was observed to be less [34]. During the last decades, it is shown that with the use of PSA, the detection of prostate cancer has increased dramatically but that prostate cancer mortality was only reduced with 20 %. Therefore, it was concluded that using PSA for the detection of prostate cancer results in a substantial overdiagnosis and overtreatment [35].

As a diagnostic tool, PSA has a high sensitivity but low specificity for prostate cancer, where the positive predictive value (>4.0 ng/mL) is limited to 25 % [36, 37]. Serum PSA levels are influenced by tumor grade, volume, and site of origin (primary tumor or metastases), and it is capable to predict pathological features [24]. On the other hand, in 15 % of men with low PSA levels, prostate cancer is present [38]. So, in order to improve identification of prostate cancer and gain specificity, changes in variant forms of PSA have been investigated and introduced into the clinic.

## Free PSA

The proportion of free PSA (%fPSA) is lower when compared to total PSA in healthy men or men with BPH [39–41]. Therefore, %fPSA has been suggested as a marker for prostate cancer [42]. The exact cause for this occurrence is not fully understood, but it is thought that in patients with prostate cancer, PSA "escapes" proteolytic activity and stays bound to ACT, A2M, or API. An extensive meta-analysis that compromised 66 studies showed that %fPSA and cPSA have better diagnostic potential compared total PSA (tPSA) in the intermediate range of 2–10 ng/mL [43]. In studies where %fPSA is combined with serum PSA levels between 2.5 and 4 ng/mL, more specificity can be obtained in diagnosing prostate cancer [44]. The use of %fPSA could contribute to a more reliable diagnosis and therefore maybe reduce biopsies by 20 % and lessen the overdiagnosis [45]. Furthermore, a better stratification could be made of patients who are more eligible to undergo active surveillance and therefore decreases overtreatment.

As a prognostic marker, high %fPSA correlated with smaller and lower grade prostate cancer [45]. Vice versa, low %fPSA resulted in a more aggressive form of prostate cancer, even when measured up to 10 years before diagnosis [46]. Prostate cancers with Gleason scores of >7 and extra capsular extension also showed a correlation with low %fPSA [47, 48].

## PSA Density

In a majority of men with slightly elevated PSA levels, the main contributor is probably BPH and, only in a small percentage

of men, prostate cancer [47]. To differentiate better between these two conditions, a method was introduced that compensated for the increase of serum PSA levels by prostate enlargement [49]. This measurement, PSA density (PSAD) where serum PSA is divided by prostate volume (>0.15), has shown to have a direct relationship with the probability of having prostate cancer, especially with intermediate PSA levels and no abnormalities on DRE (digital rectal exam) [50, 51]. Although these primary reports embrace promising results, this measurement has shortcomings. When PSAD was compared to PSA, it was not able to enhance the predictive value of PSA alone [52]. Furthermore, PSAD is not sensitive enough for prostate cancer detection; almost 50 % of all cancers are missed [53]. The most plausible interpretation of these conflicting results is most likely the heterogeneity of prostate volumes in prostate cancer and BPH. Because PSAD is influenced by prostate volume, the number of epithelial cells has to be a correction for these factors. Correction for transition zone size has shown to be a very specific and sensitive technique to detect prostate cancer, but because of the variability of ultrasound measurements, it has not gained wide acceptance in daily practice [54]. Also as prognostic marker, increased PSAD values were correlated with Gleason scores >7 and a greater risk of organ-confined disease [55].

### PSA Velocity

Another approach for detecting prostate cancer in the intermediate range of serum PSA is by using PSA velocity (PSAV), where the rate of PSA change between two separate measurements is taken into account [56]. As a diagnostic tool, an increase of 0.75 ng/mL or more per year is correlated with the presence of prostate cancer, which has a high specificity with PSA values between 4 and 10 ng/mL (up to 90 %) [56, 57]. To obtain a reliable PSAV result, the interval between the two separate measurement should be at least 18 months [57]. This interval seems not to be optimal for clinical daily practice because it can cause a delay in treatment. Furthermore, based on the characteristics of this marker, its use is limited. When initial PSA values are less than 4 ng/mL, the sensitivity and specificity is dramatically reduced [58]. As a prognostic marker, increased PSAV is significantly related to aggressiveness. One study showed that preoperative PSAV values of >2.0 ng/mL/year resulted in a nine times higher chance of prostate cancer-related mortality after prostatectomy or external beam radiotherapy [59, 60]. A recent study revealed that even a PSAV of >0.35 ng/mL/year correlated with a significant higher chance of biochemical progression [61]. On the other hand, when values of <0.4 ng/mL/year were used, it increased the likelihood of insignificant prostate cancer [62]. Besides these promising results, the exact role of PSAV in the stratification and characterization of specific subgroups of prostate cancer patients remains not fully elucidated. More research has to be performed to maximize its potential as a tumor marker and to establish the most ideal cutoff PSAV value for diagnosis and determining prognosis.

### PSA Doubling Time

Closely related to PSAV, PSA doubling time (PSADT) could also harbor some interesting capacities as a tumor marker. PSADT is defined as the time that serum PSA levels are doubled. As a diagnostic tool, so far, no reports have been published. Nevertheless, the predictive abilities of this tumor marker has been the focus of multiple research efforts, but their results show no relationship between pretreatment PSADT and posttreatment outcomes [63]. As a prognostic marker, it has mainly been measured post prostatectomy and was correlated with survival results. The first study showed that fast PSADT values (<10 months) correlated with lower metastasis-free survival [64]. Others showed that if PSADT was <3 months within a period of 24 months after radical prostatectomy, there was an associated lower cancer-specific survival [65].

### PSA Isoforms

ProPSA is an inactive precursor of PSA that is cleaved by hK2 or hK4, converting it into its active form [66]. The precursor form of PSA contains a 7-amino acid proleader peptide and is therefore named [-7]proPSA. Incomplete cleavage of proPSA results in other subforms, such as [-2], [-4], or [-5]proPSA. Elevated levels of proPSA and its truncated forms were observed in prostate cancer tissue [67, 68]. A possible explanation for this finding was the observation that proPSA is higher expressed in the peripheral zone of the prostate [68].

Mainly in the intermediate range (2.5–10.0 ng/mL) of PSA, ProPSA could early detect more prostate cancers [69–71]. Even when these isoforms were used, it could avoid 59 % of all biopsies taken, as compared to 33 % when only %fPSA was used. Unfortunately, in a prognostic setting, proPSA does not seem to be superior to %fPSA, but when combined, it is correlated with higher Gleason scores and non-organ-defined prostate cancer [72]. All the single subisoforms of proPSA have been investigated and showed no better correlation in diagnosing or determining prognosis as compared to total proPSA or %fPSA [71] (Fig. 35.2).

## KLK2

Human kallikrein 2 (hK2 or KLK2) is also a member of the kallikrein family and shares 80 % homology with PSA. It functions as a peptidase, cleaving proPSA to mature and active PSA [73, 74]. Like PSA, it is highly and specifically expressed in the prostate and is androgen regulated. hK2 levels show a distinct expression pattern on immunohistochemical analysis, which was also observed in serum. These

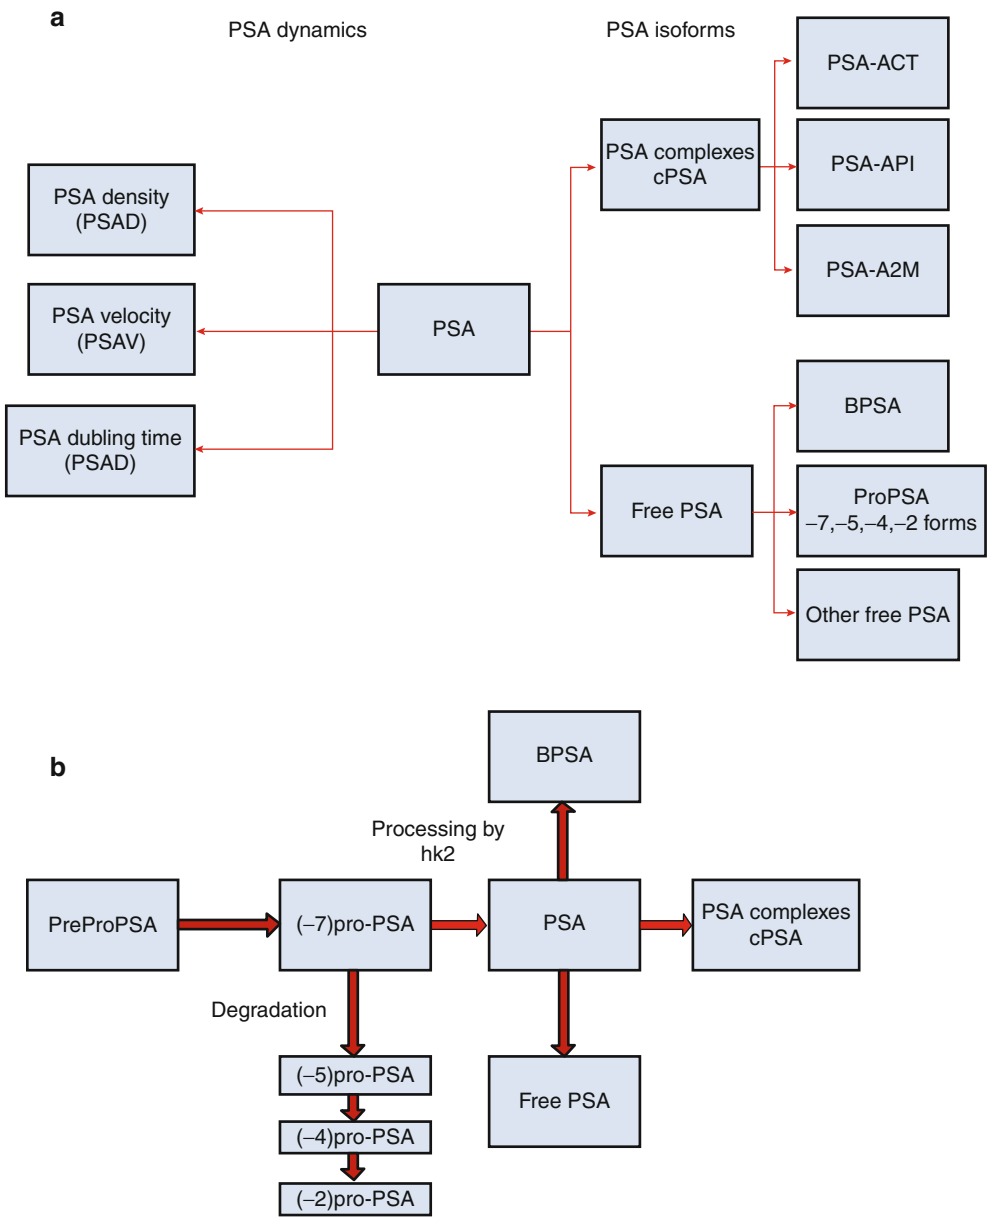

**Fig. 35.2** (**a**) Different measurements contributing PSA including PSA dynamics. (**b**) Processing of PSA to its subforms [295]

findings indicated that this marker could be indicative, independent of PSA [75, 76]. The first studies on hK2 showed no correlation of this marker with prostate cancer. [77–79] Nevertheless, a review that also included all studies on hK2 performed in a later stage revealed a significant higher expression of hK2 in serum from prostate cancer patients [71]. Especially for the intermediate elevated PSA values, it showed a better discrimination as compared to %fPSA. As a prognostic marker, hK2 is capable of differentiating between low and high Gleason scores and also for extraprostatic growth, even prior to radical prostatectomy [80–82]. Unfortunately, when this marker was analyzed in a multivariate model, it had a very limited improvement on prognoses as compared to Gleason score alone [83, 84]. One study revealed that hK2, together with other variables, was significantly predictor of biopsy outcome [85].

## Urinary PSA

In almost all reports, PSA as a tumor marker for prostate cancer was measured in serum. In contrast to serum PSA, also urinary levels of PSA were evaluated as a potential tumor marker for prostate cancer [86]. Although the first report was published in 1985, less is known about this PSA measurement. Just as serum PSA, it was shown that

elevated urinary PSA after radical prostatectomy was correlated with disease recurrence and therefore was suggested as a monitoring marker [87]. In a diagnostic setting, when a ratio was taken of urinary and serum PSA expression, it was shown that it produced higher sensitivity and specificity as compared to serum PSA alone, especially in the intermediate range [88, 89]. Unfortunately, reports on urinary PSA levels are few, and more research is needed to fully elucidate if urinary PSA has any potential as a marker for prostate cancer.

## PCA3

The PCA3 transcript (prostate cancer antigen 3) was discovered in the late 90s as a new promising candidate marker for prostate cancer [90]. The PCA3 gene is located on chromosome 9q21–22 producing a (noncoding) mRNA that does not encode a protein [91, 92]. After its discovery, it was named DD3 (differential display clone 3) as a result of a differential display analysis that was used to compare mRNA expression between healthy prostate tissue and prostate cancer tissue [93]. Ninety-five percent of prostate cancer specimens highly expressed PCA3, compared to no expression in normal prostate, BPH, or other types of cancerous tissues. High-grade PIN also revealed higher expression, up to 96 % of the cases [94, 95]. PCR on similar samples showed a 66-fold increase in PCA3 expression in prostate cancer samples with a sensitivity of 94 % and specificity of 98 % [96, 97]. Furthermore, the expression of this marker is not influenced by age, prostate volume, and infections [93]. The current PCA3 test is mRNA based, and the outcome is a ratio between PCA3 mRNA and PSA mRNA multiplied by 1,000 [97]. This test is preferentially performed on urine samples that are collected after digital rectal examination or prostate massage [98]. When this test is performed on serum, it has less accuracy [99].

Initially, the PCA3 test was launched to predict presence of PCa after negative biopsies. Subsequent reports on the urine test showed a sensitivity of 54–82 % with a specificity of 66–83 %, where PSA has a sensitivity of only 22–47 % for the diagnosis of prostate cancer [93, 95, 97, 99–101]. Multiple studies have shown that increased PCA3 is statistically significantly correlated with more tumor volume [102–104]. PCA3 also outperformed the diagnostic accuracy of %fPSA. This diagnostic accuracy can even further be increased when PCA3 is combined with other (clinical) variables such as PSA, physical characteristics during digital rectal examination, age, and family history [105]. In a screening setting, PCA3 was capable of improving the performance characteristics and identification of serious disease compared with PSA [106].

Although many reports describe the relation and prognostic features, such as histopathological outcome, generally no correlation could be observed between PCA3 and Gleason score and pT staging [107]. With these data, it was suggested that PCA3 could be applied to predict histopathological outcome after biopsy, especially in patients with elevated PSA and a negative biopsy [101, 107, 108]. Furthermore, it was suggested that PCA3 could be used to determine multifocality of prostate cancer lesions and patients that are candidates for active surveillance [93, 109–111]. The exact role of PCA3 in determining diagnosis and prognosis of prostate cancer remains to be further investigated. Since the PCA3 detection assay is RT-PCR (reverse transcriptase PCR) based, the assay needs to be performed by expert labs and is much more expensive than protein-based ELISAs.

## ETS

In prostate cancer, chromosomal rearrangements affecting the ETS (E twenty six) gene family members are common events; around 60–70 % of all cases exhibit such an alteration [112, 113]. In a majority of the rearrangements, there is a fusion between the genes TMPRSS2 and ERG, the so-called TMPRSS2:ERG fusion gene, which is unique for prostate cancer. Both TMPRSS2 and ERG genes are located in the same orientation on the long arm of chromosome 21. They are spaced by approx three million base pairs, and a deletion of this interstitial region can cause fusion of the two genes. Because the TMPRSS2 gene is androgen regulated, a fusion of this gene with ERG results in the androgen-regulated and high expression of ERG. So far, this fusion is never observed in normal tissue and unique to prostate cancer [114].

Multiple gene fusion partners that are related with either the TMPRSS2 part or the ERG part have been identified [115]. Other fusions of the TMPRSS2 gene occur in fewer cases with ETV1, ETV4, and ETV5. Although the TMPRSS2 gene is most often involved, other fusion partners such as the SLC45A3, ACSL3, HERV-K, FOXP1, EST14, KLK2, CANT1, and DDX5 genes can rearrange with ETS family members [116]. All these gene fusions are unique to prostate cancer and seem to play an important role in the biogenesis and development of this disease. Therefore, they could function as marker for diagnosis and prognosis. Recent studies showed that the fusion of TMPRSS2 to ERG is present in the precursor lesions PIN (prostatic intraepithelial neoplasia) and therefore must be an early event in cancer development [117, 118]. Multiple studies that address the prognostic value of this marker have been performed, with several opposing conclusions [113, 116]. Two studies examined 114 and 150 prostates after radical prostatectomy and revealed that expression of ERG or TMPRSS2:ERG correlated with a reduction of biochemical progression [119, 120]. Gleason score are thought

to be lower when TMPRSS:ERG is present [121]. No correlation was observed by other five studies that compromised similar-sized study cohorts [117, 122–125]. Also, the presence of ETV1 rearrangements failed to correlate with progression of disease [126]. Most reports reveal an unfavorable correlation of gene rearrangements with outcome after treatment (radical prostatectomy). These studies showed an increased rate of biochemical recurrence, formation of metastases, or even death [125, 127–135]. Interestingly, one study showed that ERG rearrangement alone was associated with low-grade prostate cancer; present with seminal vesicle invasion, there seemed to be a poorer prognosis [116, 133]. Expression of the TMPRSS2:ERG fusion gene was shown not to be able to predict response to endocrine treatment in hormone dependent and lymph node-positive prostate cancer [136, 137].

Rearrangements of genes from the ETS family are potentially very useful diagnostic markers due to their prostate cancer-specific occurrence if they can be measured in serum or urine. Like for PCA3, a test has been developed to measure fusion transcripts in urine. For prognostic or predictive purposes, fusion gene-based tumor markers remain controversial.

Because measurements of the fusion transcripts and genes are performed with RT-PCR or FISH (fluorescent in situ hybridization) techniques, implementation in daily clinical practice is hampered. Recently, an antibody against the ERG protein was generated that can be used for immunohistochemistry [138, 139]. Although the antibody has some cross-reactivity with FLI1, it gives the opportunity to easily and quickly assess 1,000 of retrospective and prospective patient samples. All three techniques (ERG antibody on protein level, RT-PCR on mRNA level, and FISH on DNA level) provide their own unique information on the status of the fusion event and are likely complementary in their diagnostic and prognostic value.

## AMACR

AMACR (alpha-methylacyl-coenzyme A racemase) is an enzyme that is encoded by the P504S/AMACR gene. In cells, this protein is located in the mitochondria and peroxisomes, and although the function has not been revealed completely, it is related to the metabolization of fatty acids and bile acid biosynthesis [140–142]. The AMACR transcript and protein are known to be highly expressed in a variety of cancers with a very high (up to nine times higher) expression in 86 % off all prostate cancers [143–145]. In 2002, AMACR was introduced as a new marker for prostate cancer [146]. A meta-analysis of multiple mRNA expression arrays revealed that AMACR is overexpressed in prostate cancer with high sensitivity and specificity [147, 148].

In a diagnostic setting, the use of the AMACR protein on immunohistochemical analysis of prostate biopsy samples has been limited to a valuable complement to other known markers [149]. Unfortunately, samples that did not contain prostate cancer also had AMACR expression but generally lower compared to the cancer samples [150]. In 18 % of the prostate cancers, AMACR is false negative [151]. When unusual histopathological subgroups of prostate cancer had to be identified, the increased expression was only limited to 62–77 % [143, 152].

In a prognostic setting, it has been shown that untreated metastasis and hormone-refractory prostate cancers were strongly positive for AMACR. In this specific prostate cancer stages, AMACR has a sensitivity of 97 % and a specificity of 92–100 % [146, 153]. Furthermore, decreased expression of AMACR has been shown to have prognostic value in predicting biochemical recurrence and prostate cancer-related death [154].

In order to assess this marker in noninvasive-derived patient materials (not biopsies) such as serum or urine, expression of AMACR mRNA could also be identified in 69 % of the cases. Unfortunately, AMACR is not specific to cancer of the prostate, because serum levels can also be elevated in other urological disorders like BPH or autoimmune diseases [155]. When used in a diagnostic setting as an additive to PSA, sensitivity and specificity can be increased when measured in urine, especially when the PSA is in the mid-range (4–10 ng/mL) [156–158]. Unfortunately, when AMACR mRNA was normalized to PSA mRNA, AMACR did not accomplish to be a statistically significant predictor of prostate cancer [159]. New promising serum tests for prostate cancer which comprehend the AMACR gene are evaluated. With these tests, a ratio is calculated between the expression of the AMACR gene and the PSA gene [142]. Until now, one report has been published where it was shown that the AMACR protein is detectable in serum with an ELISA, but elevation of this protein was not specific for prostate cancer [160]. Although more research has to be performed, it is also shown that circulating antibodies against the AMACR protein in combination with PSA could function as a useful tool for diagnosis [157, 161].

## GSTP1

During aging, DNA damage occurs as a result of oxidative stress, exposure to chemical substances, or ionizing radiation [162]. These damages can result in mutations or alterations of oncogenes and tumor suppressor genes. In healthy cells, the cytoplasmic enzyme glutathione S-transferase pi 1 (GSTP1) plays an important role in detoxifying the cell from carcinogens. GSTP1 is a member of the glutathione S-transferase family, which contains four different classes.

All these classes are expressed in prostate tissue [163]. Although GSTP1 expression is increased in various cancers, in prostate cancer, GSTP1 is downregulated [164]. This is caused by hypermethylation of the GSTP1 promoter, a mechanism well known in cancer to decrease expression of tumor suppressor genes. Hypermethylation of GSTP1 was observed in all stages of prostate cancer, from high-grade PIN to metastases [165, 166]. Such methylation was not observed in benign prostate epithelial cells [162]. Based on these findings and the presence of methylation in 90 % of prostate cancers and 67 % in high-grade PIN, it was concluded that GSTP1 methylation might function as a tumor marker for prostate cancer [167, 168]. Subsequently, methylation of this gene could be observed in serum, urine, and ejaculate of prostate cancer patients when analyzed by methylation-specific PCR, which gave rise to the idea that it could even be applied in a clinical setting [169–172].

As a diagnostic marker, it was shown that GSTP1 DNA methylation in urine has a sensitivity of 75 % (after DRE) and a specificity of 98 % for prostate cancer and is comparable to its expression in biopsy specimen [173]. Similar values for sensitivity and specificity were observed in other studies. It is notable that sensitivity in urine is increased by collection directly after digital rectal exam or prostate massage and functions independent of PSA [174–176]. To increase sensitivity even more, a relative ratio of GSTP1 methylation over methylated MYOD6 can be determined [164].

For prognostic purposes, 100 % of the locally advanced or metastatic tumors showed hypermethylation. Biochemical recurrence after prostatectomy seems to appear more and faster when the epigenetic alteration is present [177]. In a small study cohort, it was shown that methylation of GSTP1 is a statistically significant predictor for time to recurrence [178]. Androgen-deprivation therapy does not seem to influence GSTP1 methylation in 87 % of the cases [179]. Unlike other genetic alterations, methylation of this gene is reversible after therapeutic intervention. Because no reports have been published which describe this effect, more research is needed.

Methylation of GSTP1 seems to function very well as a diagnostic and prognostic tool, but because the number of reports describing this marker is lacking, we should be careful in jumping to conclusions. As more results are being published, more allusions are made regarding the use of a set of hypermethylated genes for optimal diagnosis and determining prognosis in prostate cancer patients.

## PSMA

PSMA (prostate-specific membrane antigen), or also known as FOLH1, is an androgen-regulated gene that encodes a type II transmembrane glycoprotein. PSMA belongs to the M28 peptidase family and has an intracellular and extracellular domain [180]. Its function is limited to hydrolyzing peptides in prostatic fluid and generating glutamate and also acts as a folate hydrolase [181, 182]. This protein is expressed in a number of tissues such as prostate, nervous system, and kidney [183, 184]. Furthermore, it has been shown to have a higher expression in prostate cancer. This finding could possibly be related to its enzymatic activity and thus invasiveness growth of prostate cancer [185, 186].

In the field of prostate cancer, PSMA has been the focus of many research groups. It has mainly been suggested as a prognostic tool [187]. Immunohistochemical analysis in a group of 232 patients showed higher expression in prostate cancer (79.3 %) and metastases (76.4 %) as compared to benign prostate tissue (46.2 %) [188]. Other studies showed an increased expression in progressive prostate cancer and hormone-independent prostate cancer [189–194]. In serum from prostate cancer patients, the PSMA protein is increased, with a higher expression in advanced stages of cancer [195–197]. Nevertheless, contradicting studies show that PSMA is not prostate cancer specific and does not discriminate between localized prostate cancer and advanced disease [198]. A possible explanation for these different findings could be the fact that in those studies, different types of antibodies have been used in various assays. Also, studies that investigated the expression of PSMA mRNA have shown varying and inconclusive results, probably because of different assays used. The sensitivity of diagnosing prostate cancer with PSMA mRNA is more or less similar to that of PSA mRNA [185]. As a prognostic marker, no correlation was observed between PSMA mRNA, Gleason score, pT staging, and serum PSA. In a study on patients with clinically localized prostate cancer, a combined PSMA/PSA mRNA analysis in peripheral blood samples showed that this could be an independent predictor to biochemical progression after radical prostatectomy [199].

Although PSMA seems to be not prostate and prostate cancer specific, there is an upregulation of PSMA in prostate cancer and probably more in its aggressive forms. Therefore, its function as a marker for prostate cancer is limited. A more promising feature of PSMA is its application in tissue-targeted therapy such as prostate-specific cancer vaccine therapy or radioimmunotherapy [200, 201].

## PSCA

Prostate stem cell antigen (PSCA) is a gene that encodes for a membrane-based glycoprotein. PSCA has been found to be relatively highly present in prostate but also in other cell types such as bladder, placenta, and gastrointestinal tissues [202]. The expression is also elevated in malignant tissues such as prostate cancer, bladder cancer, and gastrointestinal

cancers [203, 204]. In prostate, the expression of the PSCA mRNA is influenced by puberty, androgen deprivation, and androgen restorement [205]. Although the exact involvement of PSCA in prostate cancer is fairly unknown, it was shown that PSCA protein and mRNA are higher expressed from high-grade PIN through all stages of prostate cancer [206, 207]. Nevertheless, knockout of the PSCA gene in mice resulted in a normal urogenital development without an increased risk of prostate cancer [208].

As a diagnostic or predictive marker, it was shown that expression of PSCA in negative biopsies before TURP (transurethral resection of the prostate) is associated with higher risk of having prostate cancer in the TURP specimen, especially when serum PSA levels >4.0 ng/mL or with a suspicious DRE [209].

In a prognostic setting, immunohistochemical analysis showed that expression of the PSCA protein was present in 94 % of all tumors and was significantly associated with adverse prognostic features, such as high Gleason score and extracapsular extension [210, 211]. Furthermore, PSCA was identified in bone metastases and lymph node metastases [212, 213]. These findings suggest that there is a positive correlation of the PSCA protein with advancement of disease status in prostate cancer. When PSCA mRNA was measured in peripheral blood, it corresponded with a reduced disease-free survival time [214]. Compared to PSA and PSMA, it was noticed that specificity and independent prognostic value were very high [214]. Unfortunately, this transcript could only be identified in 13.8 % of the patients, which limited its ability to differentiate between benign and malignant prostate tissue. When this marker was investigated for its post-treatment monitoring value, it was shown that after EBRT, PSCA mRNA is decreased [215]. Therefore, it was proposed as in interesting marker for follow-up after treatment.

Besides the properties of being a possible diagnostic or prognostic marker for prostate cancer, it has also been found that PSCA is a possible target for prostate-specific virus therapy [216, 217]. When PSCA is used, it was possible to inhibit tumor growth and formation of metastases.

## Chromogranin A

Chromogranin A (CgA) is a gene that encodes for a proteolytic protein that is a member of the chromogranin/secretogranin family of neuroendocrine secretory proteins. CgA is one of the most frequently produced proteins in neuroendocrine cells in the prostate and can be easily measured by a radioimmunoassays [218]. Serum levels of chromogranin A could reflect neuroendocrine activity of prostate malignancies, therefore it holds an interesting potential to function as a marker for prostate cancer and especially for neuroendocrine differentiation [219, 220]. Unfortunately, chromogranin A is not prostate specific; it is also elevated in various neuroendocrine tumors and neuroblastomas [221–224]. The exact function of chromogranin A in prostate cancer is unknown, but it has been shown that it influences the growth of prostate cancer cells [225].

Despite conflicting results as a diagnostic tool, when measured in serum, high chromogranin A levels seem to correspond with the presence of (organ-confined) prostate cancer. [216] In combination with PSA, a better diagnostic accuracy could be established [226]. An interesting report showed that chromogranin A is able to predict conversion of hormone-naïve prostate cancer to hormone-refractory disease and the presence of hormone-independent prostate cancer itself [227, 228]. A small prospective study on 50 prostate cancer patients showed that high chromogranin A serum levels prior to radical prostatectomy were able to predict higher Gleason scores, extra capsular extension, and eventually treatment failure [229–231]. Especially in patients with hormone-independent prostate cancer, this marker correlates with adverse outcomes and decreased overall survival [232]. Furthermore, this marker could function as a predictor for chemotherapy response in hormone-independent prostate cancer [233]. In a prognostic setting, high levels of CgA correspond with factors such as a higher Gleason score, advanced pT stage, and metastases [234, 235]. Immunohistochemical analysis showed similar results [236, 237]. No decrease in chromogranin A serum levels were observed after radiotherapy or hormone therapy, therefore the use of this marker as a monitoring tool seems not to be useful [238, 239]. Specific antibodies against chromogranin A can suppress its function through apoptotic pathways, leading to programmed cell death. Therefore, chromogranin A antibody-mediated apoptosis was suggested as an alternative treatment for prostate cancer [225]. A derivate of this marker, chromogranin A velocity was introduced as a marker for predicting time to androgen independence after hormonal treatment [239].

## B7-H3

The transmembrane protein family B7 has gained publicity with its role in regulation of T lymphocytes [240]. Subsequent reports showed that a total of four subtypes (B7-H1, B7-H2, B7-H3, and B7-H4) could be identified in cancers and might play a role in the mechanism by which human malignancies evade host immune responses [241–243]. Higher expression of some of these subtypes are correlated to more aggressive behavior and poor clinical outcome [244, 245]. The B7-H3 has also been identified in healthy placenta and malignant tissues [246]. Although there was expression in benign tissue, the expression in cancerous lesions was significantly higher [241].

B7-H3 could be identified as an independent prognostic factor in 338 patient samples after radical prostatectomy that were followed with a median of 3.9 years. The patients which showed elevated B7-H3 expression had a shorter time to cancer progression [247]. This indicated that B7-H3 could function as a prognostic marker. Furthermore, B7-H3 expression is higher in metastases and hormone-refractory prostate cancer. The expression is not hampered by hormone treatment [248]. Also, this marker could have prognostic value for biochemical recurrence after salvage radiotherapy, especially with low primary TNM staging, low Gleason score, and low pre-radiotherapy PSA [249]. Because this marker is membrane bound in cells, it also harbors a function in targeted therapy. Chemotherapy or radionuclide therapy that is directed against B7-H3 makes it possible to specifically engage prostate cancer cells.

## CAV1 (Caveolin-1)

Caveolin-1, is a major structural component of caveolae. These caveolae are specialized membrane invaginations that are abundant in adipocytes, endothelium, and smooth muscle cells. Caveolae are involved in molecular transport but also in cell adhesion and signal transduction [250, 251]. Caveolin-1 has been linked to prostate cancer since the late 90s, where it was identified as a marker [252]. The exact relation of caveolin-1 and prostate cancer remains unclear, but it is known that caveolin-1 in prostate acts as a tumor suppressor by keeping Akt dephosphorylated in the Akt-pathway [253]. Subsequently, it was shown in in vitro experiments that downregulation of the expression of this gene resulted in cells turning from androgen independent to androgen dependent [254]. This implicated that there is a role for caveolin-1 in the development of castration resistance. It is also known that this protein plays a role in the malignant characteristics of prostate cancer cells by changing the microenvironment and promoting angiogenesis [255]. Studies showed that caveolin-1 is also expressed in normal prostate stromal cells but minimally expressed in normal epithelial cells [256]. The protein expression of caveolin-1 is higher in prostate cancer cells compared to normal prostate epithelial cells [252]. The expression of this marker in epithelial cells upregulates when prostate cancer grading increases [256]. Furthermore, the protein caveolin-1 also has higher serum values in patients with prostate cancer, which makes it possible to measure it with a very sensitive and reproducible ELISA [257]. Median serum caveolin-1 levels are significantly higher in localized prostate cancer compared to men with BPH.

Caveolin-1 levels could harbor a predictive potential in men undergoing radical prostatectomy [258]. Higher expression of caveolin-1 was correlated with an increased risk of developing aggressive recurrent tumors after surgical treatment. Preoperative high caveolin-1 serum levels resulted in a 2.7-fold higher risk of developing biochemical recurrence [259].

When caveolin-1 was investigated as a prognostic tool, in samples retrieved after radical prostatectomy, it was shown that a positive immunohistochemical staining correlates with a significant worse prognosis [260]. In patients with lymph node-negative prostate cancer, caveolin-1 expression is an independent prognostic factor for a Gleason score >7, extraprostatic extension and positive surgical margins. When combined in a multivariate model with other variables such as Gleason score, it is possible to more accurately predict the chance of biochemical recurrence. Unfortunately, another study showed in 1,458 cases no correlation between high postoperative caveolin-1 values in serum and aggressiveness of prostate cancer or adverse prostate cancer events [261].

## GOLPH2

GOLPH2 (Golgi phosphoprotein 2), also known as GOLM1 or GP73, is a type II Golgi membrane protein and involved in the sorting and modification of proteins that are exported from the endoplasmatic reticulum through the Golgi apparatus. Recent findings suggest that changes in structure and function of the Golgi apparatus may play an important role in the development or behavior of malignant cells. This protein has already been shown to be elevated in liver diseases as a result of viral infections but also as a potential marker for hepatocellular carcinoma [262, 263]. Immunohistochemical experiments on prostate cancer samples revealed that the GOLPH2 protein also is upregulated in prostate cancer [264, 265]. An interesting finding was that this specific marker is present, even when AMACR is negative. Therefore, it was mainly introduced as an additive protein marker for prostate cancer, next to other known markers. Preceding mRNA profiling studies, research already showed that GOLPH2 mRNA is upregulated in prostate cancer tissues [266, 267]. When this gene transcript is used in a marker profile to detect prostate cancer in urine, it seems to be capable to outperform PSA measured in serum [159].

## MYO6 (Myosin IV)

Myosin IV is a Golgi apparatus-associated protein that is involved in intracellular vesicle and organelle transport and is required for the structural integrity of the Golgi apparatus. Furthermore, the protein has been suggested as an important factor for cell migration and even cancer invasion [268–270]. Based on a microarray experiment, it was discovered that the

MYO6 mRNA is upregulated in prostate cancer, next to GOLPH2 [271]. Interestingly, expression of the transcript goes down in androgen-independent and more aggressive prostate cancers [271]. With Immunohistochemical analysis, it was shown that a strong protein expression is present in a PIN, the majority of prostate cancer cells, and weak or absent expression in neighboring benign prostate cells [265].. In a prognostic setting, no differences were observed between the different Gleason scores or other pathological indicators for aggressiveness [271]. Based on these results, the transcript could be used as a diagnostic marker, but further research has to be performed to reveal the true potential of this marker and to assess its possible role in prognosis.

## CRISP3

Cysteine-rich secretory protein 3 (CRISP3), also known as specific granule protein 28 (SGP28), has recently been implicated as potential marker in prostate cancer. Relatively, little is known about its function and role in prostate cancer. The CRISP3 mRNA has shown to be present in high concentrations in salivary glands, pancreas, and prostate [271–273]. Furthermore, its expression has been shown in secretory epithelium in the male urogenital tract, including the epididymis and the ampulla of the ductus deferens [274]. Regarding prostate cancer, multiple studies have shown that the expression of the CRISP3 mRNA is higher [275] (20–300 times) in prostate cancer as compared to healthy prostate tissue [273, 276, 277]. Also on the protein level, CRISP3 was shown to be higher expressed [278]. The protein also has been identified by ELISA in multiple bodily fluids, such as serum, saliva, and seminal plasma [279]. Unfortunately, serum concentrations were not different between prostate cancer samples and healthy controls.

As a prognostic marker, immunohistochemical analysis of prostate cancer specimen showed an increase in expression when Gleason scores increased. Expression in normal prostate epithelial cells was weak or absent. A similar analysis on radical prostatectomy samples revealed that expression of CRISP3 eventually positively correlated with biochemical recurrence [280]. In a multivariate analysis, this protein was still associated with recurrence. Nevertheless, when this marker was added in a model with other known markers, such as PSA, no improvement was observed. With the results acquired so far, CRISP3 does not seem to be a good prognostic marker for prostate cancer [275, 281].

An interesting observation was the decrease of CRISP3 after orchiectomy in some patient samples. This could reflect that CRISP3 could be partially androgen regulated and might function as a monitoring marker.

## Sarcosine

The discovery of sarcosine as a marker for prostate cancer has only recently been made. Since a large number of research groups are exploring changes on the level of genomics, transcriptomics, and proteomics, changes in the metabolomic field are novel and few. Sarcosine is a metabolite that is produced by the enzymatic transfer of a methyl group from S-adenosylmethionine to glycine. This reaction is catalyzed by the enzyme glycine N-methyltransferase (GNMT), which is highly expressed in prostate, liver, and pancreas. The first report on sarcosine in prostate cancer showed that sarcosine stimulates malignant growth of prostate cancer cells and has prognostic value [282]. With mass spectrometry, they analyzed blood, urine, and tissue samples from different well-characterized prostate cancer patients and explored them for metabolites. In a relatively small patient cohort, a total of 1,126 metabolites were identified. Sarcosine was highly increased during prostate cancer progression to metastasis and could easily be identified in urine [282]. Subsequently, they showed a decrease in disease progression when glycine N-methyltransferase was knocked down.

Although these results look very promising, subsequent reports showed that sarcosine as prognostic marker is debatable. On tissue samples, the expression in cancerous samples was 7 % higher compared to benign prostate samples. Unfortunately, no statistical differences were seen regarding prostate cancer progression [283]. A drawback of this study was the fact that metastatic samples were not included. Also, sarcosine as a urine marker, normalized to creatinine, could not reproduce the original finding that sarcosine functions as a prognostic marker. [284] When compared to PSA, urine-derived sarcosine was not able to outperform serum PSA on itself. When added to an algorithm with PCA3 or %fPSA, diagnostic performances could be improved [285].

Although sarcosine was promoted as a promising new marker for prostate cancer, its exact clinical value and applicability is unclear. The conflicting reports are mostly based on a limited number of samples with limited follow-up and different technologies to measure this metabolite. In order to resolve these contradictions, we need to control some of the variables, such as the study cohort and tumor marker assays [286].

## Exosomes

Exosomes are small vesicles (50–150 nm) that are shed by almost all cell types in the human body into almost all body fluids. Initially, exosomes were discovered during studies on the loss of the transferrin receptor in sheep reticulocyte maturation [287]. Exosomes are formed by inward budding of the cellular membrane which results in the formation of a large endosome. After formation of the endosome, it is
