Peter Paul Rickham (1917–2003)

This textbook is dedicated to Peter Paul Rickham, pioneering surgeon, who co-founded the world's First neonatal surgical unit at Alder Hey Children's Hospital Liverpool, United Kingdom.

Foreword

Peter Paul Rickham graduated in medicine from Queens' College, Cambridge, and St Bartholomew's Hospital, London, in 1941. He trained in paediatric surgery at the Hospital for Sick Children, Great Ormond Street, London, under Sir Denis Browne and under Isabella Forshall at Alder Hey Children's Hospital, Liverpool, where he was appointed consultant paediatric surgeon in 1953.

At Alder Hey, Rickham established the hospital as a regional centre for neonatal surgery, he instituted a neonatal transport system for the safe transfer of surgical neonates from a wide area around Liverpool to Alder Hey and he inaugurated the world's first neonatal surgical intensive care unit which was the prototype emulated at centres throughout the world. As a result of the developments, neonatal surgical mortality decreased from 78% to 26% over a period of only 3 years. The subject of his MD thesis was "The Metabolic Response of the Newborn to Surgery".

Rickham remained in Liverpool until 1971 when he was then appointed Professor of Paediatric Surgery at the University Children's Hospital, Zurich, Switzerland, where he remained until retirement in 1983. At Alder Hey he trained numerous surgeons throughout the world particularly from the United States, Japan, Europe, Asia and South Africa.

He was the recipient of many awards and distinctions including the Denis Browne Gold Medal of the British Association of Paediatric Surgeons of which he was founder member and later President, the Legion d'Honneur, France, the Commander Cross, Germany, Ladd Medal Surgical Section of the American Academy of Pediatrics and two Hunterian Professorships from the Royal College of Surgeons of England.

The first edition of *Neonatal Surgery* co-edited with J. Herbert Johnston was published in 1969. It was the first textbook devoted entirely to neonatal surgery based on the accumulating experience of newborn surgery carried out at Alder Hey Children's Hospital from 1953 to 1968. It was, in its time, the "bible" of neonatal surgery and I read it from cover to cover before, during and after my time as a Smith and Nephew Fellow studying under Peter Paul Rickham in 1970. Two subsequent editions of *Neonatal Surgery* were later published in 1978 and 1990. The scope of these publications was expanded, and new contributions from a range of experts of international repute were included.

It is pleasing now to witness a major new international textbook launched from Alder Hey titled *Rickham's Neonatal Surgery* edited by Paul Losty

(Liverpool, UK), Alan Flake (Philadelphia, USA), Risto Rintala (Helsinki, Finland), Naomi Iwai (Kyoto, Japan) and John Hutson (Melbourne, Australia). This new textbook has a truly international list of distinguished contributors covering the full range of neonatal surgical conditions and related topics. Among many key themes comprehensively included in the new book attention also focuses on advances in fetal surgery, minimal invasive surgery, long-term outcomes and evidence-based surgery.

The textbook is a fitting tribute to the life and work of Peter Paul Rickham who was my mentor and good friend.

London, UK Lewis Spitz

Editors' Preface: Rickham's Neonatal Surgery

In 1969, Peter Paul Rickham and Herbert Johnston published the first edition of Neonatal Surgery from Alder Hey Children's Hospital Liverpool which for many paediatric surgeons was considered to be one of the leading textbooks in the world dedicated to newborn surgery. The huge success of the first edition was followed with further editions of this landmark textbook published in 1978 and 1990. Peter Paul Rickham is credited with establishment of the world's first neonatal surgical unit at Alder Hey in 1953 co-founded together with Isabella Forshall. Indeed, it is perhaps then no great surprise that several generations of young paediatric surgeons travelled to Liverpool to work with Rickham and the team of surgical staff based at Alder Hey. Peter Rickham was fortunate to also have Jackson Rees a pioneer in neonatal anaesthesia as a consultant colleague during that era. The "impossible became possible". Many young surgeons who visited Alder Hey later advanced to become world leaders in paediatric surgery across four continents.

This new textbook "Rickham's Neonatal Surgery" is dedicated to Peter Paul Rickham including past and present staff at Alder Hey. The team of editors have assembled leading experts with co-authors to provide state-of-the-art chapters covering the speciality field of neonatal surgery and its related disciplines including fetal medicine, fetal surgery, radiology, newborn anaesthesia, intensive care, neonatal medicine, medical genetics, pathology, cardiac surgery and urology. Contributions from the basic sciences and laboratory research are highlighted in the textbook reflecting steady progress in our current working knowledge and understanding of many neonatal surgical disorders. Evidence-based studies and "best practice" provide the reader wide-ranging information including the latest developments in many chapters. As huge advances have been made in neonatal surgery with improved survival particularly in the past decade(s), ethical issues, long-term outcomes and quality of life are also emphasised by the individual contributors. We hope the textbook will be an authoritative reference for surgical residents in training, consultant surgeons, general surgeons with an interest in paediatric surgery, neonatologists, paediatricians, intensive care specialists and nursing staff. The editors are greatly indebted to the many authors from across the world for their excellent contributions and for some their lifelong professional associations having trained or worked as surgeons at Alder Hey.

Special thanks must go to Barbara Lopez Lucio who worked tirelessly with all authors, editor-in-chief and editorial team to make the project possible. We greatly value and appreciate the skills of the artist(s) and illustrators

for their high-quality work. Finally, enormous gratitude is owed to Julia Megginson, Wyndham Hacket Pain and Melissa Morton at Springer, London, UK, for the final production of the textbook.

Medical Law as Applied to Neonatal Surgery

1

Robert Wheeler

Abstract

Medical law as applied to neonatal surgery, when considered in terms of the number of requests for legal or ethical opinions, is mainly concerned with the withdrawal or withholding of treatment. However, this must be placed into the context of the chronological opportunities for law to intervene in clinical care. For that reason alone, this chapter commences with the unborn child, passing through the stage of birth, initial decisions on viability (and acquiring a legal parent); before progressing to the 'baby cases', and subsequent guidance when considering the withdrawal of care in neonatal surgery.

Ethics • Medical law • Neonatal surgery • Paediatric surgery

Medical law as applied to neonatal surgery, when considered in terms of the number of requests for legal or ethical opinions, is mainly concerned with the withdrawal or withholding of treatment. However, this must be placed into the context of the chronological opportunities for law to intervene in clinical care. For that reason alone, this chapter commences with the unborn child, passing through the stage of birth, initial decisions on viability (and acquiring a legal parent); before progressing to the 'baby cases', and subsequent guidance when considering the withdrawal of care in neonatal surgery.

Contained within a book emerging from one of the founding centres of neonatal surgery in the British Isles, it is unsurprising that this chapter rests squarely on the common law in England and Wales. However the judges creating that law constantly survey the decisions of their colleagues in North America, Canada and Australasia which in turn influences the English decisions. Since the commencement of the Human Rights Act 1998, our courts are also constrained by the European Convention of Human

Rights, so that the law pertaining to neonatal surgery described in this book is derived from broad international experience.

1.1 Wrongful Birth

International experience is nowhere better reflected than in wrongful birth. This is a topic which mainly relates to foetal medicine, rather than to neonatal surgery. Applicable only to the precursor of the newborn child, it is included for completeness. But many of us provide antenatal counselling to prospective parents, and it is instructive to reflect on the consequences that could, in principle, flow from this.

Parents of children born with an affliction that could and should have been detected in utero have been suing their clinicians for some years. An early case [1] in the New York Court of Appeals found that parents could claim the costs of institutional care of their child who was born with Down's syndrome, following their doctor's failure to recommend amniocentesis to the 37 year old mother. Courts immediately found such cases difficult due to conflicts of interest. There was public policy to consider; of favouring life over abortion; to be weighed against a woman's prerogative of control over her own body. What emerged was a rule accepted in at least 30 US states that valid claims for wrongful birth will succeed [2].

In the United Kingdom, the action is also allowed, with evidence that many are settled without recourse to the courts [3]. Nevertheless, litigation over failure to diagnose a wide field of diseases that are identifiable antenatally, including congenital rubella syndrome, Duchenne muscular dystrophy and Down's syndrome have been reported.

In addition, in a Scottish case [4], a father was been awarded damages for the shock and distress he has suffered as a result of the birth of an affected child. This was unusual, since such damages have usually been limited to the mother, and evidence of psychiatric harm has previously been required. Neither of these applied in McLelland.

1.2 Proposed Guidelines for Instituting Intensive Care at Birth

In a report [5] commissioned by the Nuffield Council on Bioethics, guidelines were proposed for deciding as to whether babies of certain gestational age should have limitations placed on their resuscitation and intensive care. These proposals were based solely on judgement of the best interests of a premature child, irrespective of the wider issue of whether clinical resources were available to support this aspect of neonatal medicine. The working party concluded that below 22 weeks of gestation, no baby should be resuscitated, unless this was taking place within all the safeguards of a clinical research study. For babies between 22 weeks and 22 weeks 6 days of gestation, "…standard practice should be not to resuscitate a baby, (and that) … resuscitation would normally *not* be considered or proposed". In this group, parents' views might lead to a reversal of this approach, after a thorough discussion of the risks and prognosis with an experienced clinician. In babies between 23 weeks 0 days and 23 weeks 6 days, precedence should be given to the views of the babies parents, but there is no clinical obligation to embark on treatment that is 'wholly contrary' to clinical judgment.

This brief description does not do justice to a 250 page report of great quality. However, it is cited as an illustration of the national efforts being made to define some limits to treatment at the commencement of extra-uterine life, based on a balance between the importance of preserving life, whilst at the same time acting a in a child's best interest.

1.3 Parental Responsibility

Parental responsibility is conferred by statute [6] and is defined as 'all the rights, duties, powers, responsibilities and authority which by law, a parent of a child has in relation to the child …. ' Included is the right to provide consent for

treatment where necessary. The child's mother (the woman who gave birth to the baby, rather than the person who provided the egg from which he was conceived, if different) automatically gains parental responsibility. The child's father gains parental responsibility automatically if married at the time of the birth registration. Since 2003, unmarried fathers also get parental responsibility automatically, when they register the birth.

If the father subsequently marries the mother, he acquires parental responsibility, an acquisition described as 'legitimation' [7].

Alternatively, parental responsibility can be acquired by the unmarried father either with the agreement of the child's mother, or by application to a court.

Parental responsibility is passed to adoptive parents on legal adoption. It may be shared with guardians appointed by parents; with local authorities; and is linked to various legal orders [8].

The person with parental responsibility who provides consent for a child's surgery must act in the child's best interests in so doing. These are usually self evident, and the agreement between parents and surgeon is reached after full disclosure of the relevant information.

1.4 The 'Baby Cases'

Medical law is a relatively modern discipline. In some respects, it has been built upon cases considering whether a child with congenital malformations should be treated, or allowed to die without operation. It should be remembered that these 'withdrawal' cases only get to court if there is dissent; between surgeons, physicians, nurses or parents. Provided all agree that withdrawal (or continuation of treatment) is in a baby's best interest, the effects of their joint decision attract no public attention. It is only where one or other group powerfully disagree over the management plan that litigation occurs, and it is helpful to begin with the English cases, in chronological order.

1.4.1 Baby Alexandra, and the Question of Life's Sanctity

In a case known as Re B,[1] the parents of a newborn with Down's syndrome and duodenal atresia wished to allow their child to die, rather than undergo surgery. Her doctors disagreed, and the local authority was given care and control of the baby. The court authorised surgery, but when the child was transferred for operation, the surgeons were unwilling to operate, in view of the parents' objections. The local authority returned to court, but the judge, after hearing the parents' views, withdrew authorisation for the surgery.

The case was then considered by the Court of Appeal, which was told that other surgeons would be prepared to operate. This court found that the judge had placed too much emphasis on the wishes of the parents, and that it was the *best interests* of the child that should prevail. To determine these best interests, the appeal court created a test: Was Alexandra's life "…. demonstrably going to be so awful that in effect she should be condemned to die, or whether the life of this child is still so imponderable that it would be wrong for her to be condemned to die?"

Concluding that the surgery would give her the chance to live the normal life expectancy of a child with Down's syndrome, the court allowed the appeal, and Alexandra's surgery was performed. However, in his leading judgment, Templeman LJ acknowledged that "… there may be cases … of severe proved damage where the future is so certain and where the life of the child is so bound to be full of pain and suffering that the court might be driven to a different conclusion". The court thus established two cornerstones of modern jurisprudence. That there was no absolute parental right to control the fate of a child in these circumstances; and that there was no absolute right to life for a child.

Thus the foundations were laid for the *quality of life* to be used as a yardstick of the success of

[1] Re B (A Minor) (Wardship: Medical Treatment) (1982) FLR 117.

therapy, rather than merely the preservation of life, irrespective of its quality.

Furthermore, the case provided an early example of a balancing exercise that must be employed when determining the best interests of children. Such an exercise is as applicable to surgical decision-making as it is to judicial deliberation.

1.4.2 Dr. Arthur

No account of neonatal law can ignore the case of Dr. Leonard Arthur [9], who was charged (initially) with the murder of a child with Down's syndrome.

It must be understood that this famous case is a legal anomaly. It is a solitary criminal case nestling amongst a group of private civil medical law cases, and the outcome was unexpected.

Dr. Arthur's patient was a baby boy with uncomplicated Down's syndrome who had been rejected by his mother. On the basis that neither parent wished the child to survive, Dr. Arthur prescribed 'nursing care only', together with dihydrocodeine as required, 5 mg four hourly. The child died 2 days after birth; the cause of death being attributed to bronchopneumonia resulting from Down's syndrome.

The prosecution alleged that Dr. Arthur decided to cause the death of the child. The jury disagreed, and acquitted him after 2 h deliberation. A successful conviction had been anticipated. The case caused a furore, commentators roundly criticising [10] the judge's presentation of the legal issues to the jury. In particular, the judge failed to apprise the jury of Dr. Arthur's homicidal intent.

It could be inferred from the facts of the case that Dr. Arthur administered dihydrocodeine in order to end his patient's life. This element of intention to kill is crucial in obtaining a conviction for murder. How Dr. Arthur escaped this remains a matter of speculation amongst lawyers, who almost invariably point out [11] that the case holds no value as a precedent for future decisions.

Dr. Arthur was represented at trial by George Carman QC, the foremost defence counsel of his generation. Controversially, he advised his client *not* to give live evidence at the trial. Carman's biographer [12] reveals that in the barrister's view, "if Leonard Arthur had been asked 'When you decided on the way to treat this baby, what did you intend to happen?', Arthur would have replied 'I intended it to die'. End of story".

The case was therefore highlighted as an anomalous criminal judgement, but together with a reported case a few weeks preceding it [13], (that no action being taken against a doctor who had allegedly refused to sustain a baby with spina bifida), it brought non-treatment of newborns to the public attention. It also caused consternation amongst doctors, (some of whom) failing to appreciate the distinction that was being made between withholding treatment from a dying patient, as opposed to depriving hydration and nutrition from a child who was otherwise healthy. This error was encapsulated in a statement from the President of the Royal College of Physicians: "… I say that with a child suffering from Down's and with a parental wish that it should not survive, it is ethical to terminate life … [14]".

In reality, Dr. Arthur's mistake, in retrospect, was to conflate 'futility' with an obligation to accede to the parents' wishes that their child should not be treated. One of the legal mistakes was to allow the jury to believe that the doctor's duty to a child with Down's syndrome could be different from, and lower than, that owed to a child without the syndrome. That was and is quite wrong. The doctor's obligation is to do what is reasonable in all the circumstances of his or her patient.

1.4.3 Re C, and the Emergence of the Best Interests of the Child

Baby C was born prematurely in 1988 with hydrocephalus; at birth, her doctors considered her to be terminally ill, due to associated cerebral structural damage. However, a shunt was inserted at 2 weeks to prevent enlargement of her head. The question arose as to whether and how she should be treated in the event of shunt blockage,

or infection. It was the disparity of the advice between the local authority's social and legal services that lead to a review of the case in the Court of Appeal [15]. The child's social worker concluded that the doctors should treat C in a way "appropriate to a non-handicapped child". The legal department concluded differently, that C should "… receive treatment as is appropriate to her condition". The leading judge in the Court of Appeal was firmly in agreement with the latter view:

"You do not treat a blind child as if she were sighted, or one with a diseased heart as if she was wholly fit" [16].

The Court of Appeal was careful to issue directions that were not explicit, authorising the hospital "… to treat the minor to allow her life to come to an end peacefully and with dignity".

Re C is the case that Lord Templeman had anticipated during his judgement in Baby Alexandra. Baby C was dying, untreatable, with a quality of life far removed from that which a child with Down's syndrome could reasonably expect. Baby C's physical limitations could be predicted to lead to the demonstrably awful and intolerable life of suffering that Alexandra would hope to avoid.

The decision confirmed that there is no absolute right to life; and the full judgement provides powerful reassurance [17] that English law refuses to countenance killing patients.

1.4.4 Re J, and 'Substituted Judgements'

In the case of a 27 week premature baby [18] with severe brain damage, the question for the court was how the child should be managed in the event of a further collapse. J was born at 1.1 kg, and required ventilation for 4 weeks. Oxygen-dependent for a further 6 weeks, he was discharged home at 3 months of age, but had a cyanotic collapse at home a few days later. This acute illness, which necessitated 3 more weeks of ventilation, caused parenchymal brain damage; the prognosis was of severe spastic quadriplegia.

In an initial approach to the court, following the diagnosis of the brain damage, an order was made that it would not be in J's best interests to reintubate him "unless to do so seemed appropriate given the prevailing situation. If he developed a chest infection treatment with antibiotics and maintenance of hydration was recommended, but not prolonged ventilation" [19].

Representing the public interest, the Official Solicitor appealed this decision, on the grounds that a court was never justified in withholding consent to life-saving treatment to a child, irrespective of the quality of life which it would afterwards experience. The Court of Appeal held that a medical course of action which failed to prevent death could still be in a child's best interests. Furthermore, that there was no absolute rule that, (except when a child was already dying), neither the court nor any responsible parent could approve the withholding of life-saving treatment on the basis of the quality of the child's life". This judgement, and those that preceded it, established a precedent in English law for the withdrawal of treatment on the basis of a poor quality of life.

The court in Re J also reviewed the 'demonstrably so awful' test that had emerged in baby Alexandra's case. There was concern that this test allowed courts to determine the patient's quality of life by their own standards, whilst having no understanding of the situation from the patient's own perspective. Thus, the restrictions that severely disabled people face in their daily activities might not be as incompatible with a rewarding and fulfilling life as many judges might assume.

From this idea flowed the proposal that the anticipated quality of life that the child might have to endure should be judged *from the viewpoint of the child*; as to whether it would be intolerable *for him*.

This is described as the 'substituted judgement' test. The Court thus emphasised that any assessment of the forthcoming quality of life should be made from the assumed view of the child patient, rather than that of the adult decision-maker.

This was a radical view from a legal system based upon judges arriving at their own view of a

child's best interests, and drew wide criticism [20]. Not least, because it involves the creation of a legal fiction: Baby J had no capacity to create a 'viewpoint', so there was no way in which his supposed views could be predicted. Any assumed view would thus be entirely a creature of the judge's imagination. Nevertheless, the substituted judgement was an important milestone in the jurisprudence of withdrawal, and its effects remain visible today.

1.4.5 Re C, and the Reassertion of Parental Rights?

This case from 1996 concerns a baby with biliary atresia [21]. C underwent a Kasai procedure at three and a half weeks, but biliary drainage was not achieved. His parents were influenced by the pain and distress their son experienced in preparation for, and subsequent to, the surgery and resolved that if the Kasai was unsuccessful, they did not wish him to undergo a liver transplant. The clinicians looking after C provided a unanimous prognosis that without transplant, he would die; and thus it was in his best interests to receive a new liver when one became available.

After the failure of the portoenterostomy was recognised, C's parents left the jurisdiction, taking jobs in a distant Commonwealth country. The clinicians, via the local authority, applied to the courts seeking three decisions; (i) whether it was in C's best interests to undergo liver transplantation; (ii) permission to perform transplantation notwithstanding his mothers refusal to consent; (iii) for the child to be returned to England for this purpose. When C was 17 months old, the High Court granted all three requests, ordering his return to this country within 21 days.

C's parents appealed, and the Court of Appeal handed down the judgement 5 weeks later.

This court distinguished C from previous cases, which it asserted had been decided largely upon the *medical* best interests of the children concerned. Butler-Sloss LJ, a judge in the appeal, considered that insufficient emphasis had been given to "the enormous significance of the close attachment between the mother and baby [and whether it was]. .in the best interests of C … to direct the mother to take on this total commitment where she [did] not agree with the course proposed".

The court thus expanded the concept of 'best interests' to incorporate non-medical considerations, such as how a decision might have impact upon the relationship between a child and his parents; and arguably, on the interests of the mother.

The ruling was mainly criticised on this basis; that there was a failure sufficiently to differentiate the interests of the child and his mother … which arguably, could be in conflict. For instance, cases may occur when parents wish to move to a distant country only for reasons of employment … irrespective of the harm to their child, now unable to get access to necessary therapy. Commentators [22] suggest that the emphasis this case gives to (enhanced) parental rights is reminiscent of the situation in England in the nineteenth century. Nevertheless, the case does emphasise the need to consider the wider aspects of a child's best interests when deciding cases of treatment withdrawal.

1.4.6 Re A; Conjoined Twins, and the Impact on the Influence of Parents

In a case [23] from September 2000, the Court of Appeal was faced with the onerous task of balancing the opposing interests of two babies. Born conjoined, these ischiopagus twins shared a common aorta. The court heard that Mary, the weaker child, would die during the proposed separation from Jodie, who was given a good prognosis if separated. The court was also told that if separation was not performed, death of both twins would be inevitable in a matter of months, due to heart failure.

The reason for the approach to court was that the parents of the twins, who were Maltese, were devout Roman Catholics; they were unwilling to provide consent to allow one twin to be sacrificed in order that the other might live.

In this unusual situation, the court had to decide the correct principle to apply when there

was an overt conflict between the rights of the two girls; and between their rights, and those of their parents. Furthermore, the criminal law problem; that Mary's inevitable death would raise the inescapable inference that the surgeons had intended her death.

In respect of the conflicting rights between the babies, the majority of the judges held that their interests should be balanced, and the least detrimental alternative should be chosen. Since surgery would offer Jodie the chance of a relatively normal life, whilst not affecting Mary's fate, the court sanctioned the operation.

Considering the conflict between the interests of the girls and their parents, the court reiterated the principle that the parents' views were not determinative. In doing so, the court rejected the approach in Re C, above. In finding that the parents' religious views were not of decisive importance when considering the jeopardy a child's life, the court reaffirmed the general principle that it is the *child's* welfare that is of paramount importance. Crucially, what the Court of Appeal *did not do* was reject the wider principle in Re C; that evaluation of the child's best interests should not be confined to medical best interests.

In terms of the criminal law, the difficulty of the situation before the court was reflected in the variety of the solutions found to assert that separation, resulting in Mary's death, would be lawful. The judges were searching for a defence to what would otherwise be murder. One judge construed this as a form of self-defence; seeing "… no difference between … resort to legitimate self defence and removing the threat of fatal harm to [Jodie] presented by Mary's draining her life blood".

The court, agonising, concluded that the surgery could lawfully be performed.

In Bainham's words [24], the case:

> "[Is] one rather stark demonstration of the lack of a shared morality about these life and death decisions. For the Roman Catholic parents it was morally wrong to kill Mary. For others it was morally wrong not to bring about her death since there was a moral duty to save Jodie".

This series of cases provides the common law background for our current handling of withdrawal of care in neonatal surgical cases. These, together with statutory and professional influences have provided the principles by which we are guided in clinical practice.

1.5 Statutory Guidance

The Children Act 1989 is the cornerstone of modern children's legislation in England and Wales, and was intent on placing the child's interests, rather than those of the parents, at the centre of decision making. At the opening line of the Children Act 1989 [25] is the *paramountcy* principle:

"When a court determines any question with respect to:

(a) the upbringing of a child … the child's welfare shall be the court's paramount importance"

The Act provides, in addition, for a welfare 'checklist', by which a court must evaluate the effect of any proposed decision that will affect the child. These include:

(a) the ascertainable wishes and feelings of the child concerned (considered in the light of his age and understanding);
(b) his physical, emotional and educational needs;
(c) the likely effect on him of any change in his circumstances;
(d) his age, sex, background and any characteristics of his which the court considers relevant;
(e) any harm which he has suffered, or is at risk of suffering;
(f) how capable each of his parents, and any other person in relation to whom the court considers the question is relevant, is of meeting his needs;
(g) the range of powers available to the court under this Act in the proceedings in question.

It can immediately be seen that not every heading on the checklist is applicable to surgical

babies. But some headings from this checklist form an aide memoire for reminding us all of the matters that we should be considering when we decide whether the clinical management we propose is in the child's best interest; reminiscent of the expansion from solely medical best interests that the court in *Re C* alluded to. It should be emphasised that although the welfare checklist is applicable to withdrawal of treatment (as a "decision that will affect the child"), in the vast majority of cases, the checklist will be employed in lesser decisions.

As an example, faced with the decision as to whether stoma formation is the correct approach in a baby with NEC, the main consideration will undoubtedly be on 'surgical' grounds of safety and efficacy. However, if the result of that initial determination still leaves you in equipoise, the ability of the nurses (or the parents) to manage the stoma; the cultural implications of exteriorised bowel; and the potential problem this may cause with bonding with his parents may also require some thought. In considering these influences, you have adhered to the principles behind the creation of the welfare checklist.

1.6 Practical Application

As neonatal surgeons, we are sometimes faced with a neonate who has lost all the small bowel. It may be instructive to consider how we deal with the next steps, upon this discovery.

It is self evident that it is far better to anticipate such findings, and discuss the ramifications of total gut loss before you start the surgery on their child. Nevertheless, once the diagnosis is made at operation, it is likely that you will need to return to the parents, further to discuss the clinical situation, before making a final decision on treatment. The correct surgical decision will depend on the circumstances, but options such as central venous catheter insertion and long term parental nutrition, or prompt withdrawal of treatment are likely to be discussed.

In reality, if the clinicians (surgeons, neonatologists and nurses) and the parents are all in complete agreement as to the correct next step, the opportunity to embark upon a discussion of ethical or legal principles does not arise. However, any decision to withdraw treatment should be made only after consideration of the relevant guidelines from the Royal College of Paediatrics & Child Health [26].

These are currently undergoing revision, but provide various categories of clinical situations where it may be legal and ethical to consider withholding or withdrawing life sustaining treatment. Included in theses categories is the "No Chance" situation, where treatment will only delay death, and will not alleviate suffering; and the "No purpose" situation, where the degree of mental or physical impairment would be so great that it would be unreasonable to expect the patient to bear it.

Originally designed to assist clinicians' categorise and thus better understand the wide variety of case they face, these guidelines now begin to feel outdated, hence their revision.

It is to be expected that any unanimous decision will coincide with the best interests of the child, her welfare being paramount, and this will be enacted.

It is only when there is disagreement, with any one of these four parties failing to support the clinical decision, that further exploration of ethics and law may have to begin. In some circumstances, the disagreement is based upon an incorrect belief; and a full discussion between clinical staff and the parents may resolve this.

If the disagreement is based on fundamental differences over the child's prognosis, or over which treatment most closely corresponds with the patient's best interests, it is prudent to obtain an early second clinical opinion. This may be from within the unit, or from an adjacent hospital. If the second opinion does not resolve the disagreement, an opinion from the local clinical ethics committee (CEC) may be helpful, if only to clarify precisely the grounds of conflict.

A member of the CEC may be able to identify options that the clinicians, or parents, regard as sufficiently common ground to allow resolution of the conflict. Even if this is not achieved, a formal review by the CEC will be construed as an important and necessary step, should review by a

court later become necessary. Further consideration by experts within speciality organisations or Royal Colleges may also aid resolution. However, experience indicates that in situations where the CEC review fails to resolve the disagreement, the intervention of a court is likely to become necessary.

This is surprisingly easy to arrange, using the Trust solicitor as a starting point, to clarify the question(s) that the court is asked to decide. Referral to a court should not be seen as a failure. The court is simply another form of second opinion, and its decision will usually be welcomed by those on both sides of the disagreement, since this will bring certainty to the next clinical step, both for clinicians and parents. It should be noted that courts in England and Wales will not usually insist that any identified clinician follows a particular course of treatment. The court merely identifies the child's best interests, and clarifies what further steps would be lawful. If the judgement prescribes treatment that doctors are unwilling to provide on clinical grounds, their obligation will be to refer the patient to a centre that may be prepared to embark on the proposed treatment, and maintain the patient's condition until a transfer can be achieved.

It should be noted that referral to the medical defence organisations is not advocated in this process, since these bodies exist to promote the interests of the doctors, rather than those of the patients. It is submitted that the mechanism described will cater thoroughly for the needs of the neonatal surgical patient; if you feel that recourse to your defence body is prudent, that is clearly a matter for you.

In summary, the common law has provided us with clear guidance in resolving some of the dilemmas in caring for neonatal surgical patients, and this is strongly reinforced by statutory guidance, identifying the child's best interests as paramount.

It will rarely be possible (or proper) to solve dilemmas of treatment limitation without first establishing a broad consensus of opinion that includes those of the baby's parents. In the absence of such unanimity, recourse to the courts for a 'second opinion' will usually be of great assistance, and should be viewed as a positive step.

Conclude … the courts may have an increasing role in resolving these uncertainties.

Embryology of Surgical Birth Defects

2

Dietrich Kluth and Roman Metzger

Abstract

Today, the embryology of numerous congenital anomalies in humans is still a matter of speculation. This is due to a number of reasons which include:

- Misconceptions and/or outdated theories concerning normal and abnormal embryology.
- A shortage of study material (both normal and abnormal embryos).
- A shortage of explanatory images of embryos and developing embryonic organs.
- Difficulties in the interpretation of serial sections.

In recent years, a number of animal models have been established which helped to overcome the shortage of both, normal and abnormal embryos. However, a general agreement on when, why and how abnormal development takes place, still does not exist. As a result, many typical malformations are still not explained satisfactorily and pediatric surgeons of all specialties are still confused when they are confronted with the background of normal and abnormal embryologic development.

2.1 General Remarks on Embryology and The Embryology of Malformations

Today, the embryology of numerous congenital anomalies in humans is still a matter of speculation. This is due to a number of reasons which include:

- Misconceptions and/or outdated theories concerning normal and abnormal embryology.
- A shortage of study material (both normal and abnormal embryos).
- A shortage of explanatory images of embryos and developing embryonic organs.
- Difficulties in the interpretation of serial sections.

In recent years, a number of animal models had been established which helped to overcome the shortage of both, normal and abnormal embryos. However, a general agreement on when, why and how abnormal development takes place, still does not exist. As a result, many typical malformations are still not explained satisfactorily and pediatric surgeons of all specialties are still confused when they are confronted with the background of normal and abnormal embryologic development.

Our understanding of the normal and abnormal development of embryos is still influenced by two theories:

- The 'biogenetic law' after HAECKEL [1].
- The theory of 'Hemmungsmissbildungen' [2].

According to Haeckel's 'biogenetic law', a human embryo recapitulates in its individual development (ontogeny) the morphology observed in all life-forms (phylogeny). This means that during its development an advanced species (a human embryo) seems to pass through stages represented by adult organisms of more primitive species [3]. This theory has been used to 'bridge' gaps in the understanding of normal embryonic development and still has an impact on the nomenclature of embryonic organs. This explains why human embryos have 'cloacas' like adult birds and 'branchial' clefts like adult fish.

The term 'Hemmungsmißbildung' stands for the theory that malformations actually represent 'frozen' stages of normal embryonic development. This theory too has been used to 'bridge' gaps in the understanding of normal embryonic development in a manner which could best describe as 'reversed embryology'. As a result, our knowledge of normal embryology stems more from pathological-anatomic interpretations of observed malformations than from proper embryological studies. The theory of the 'rotation of the gut' as a step in normal development is a perfect example for this misconception [4]. Others are: 'failed fusion of the urethral folds' [5], 'failed closure of the pleuro-peritoneal canals' (congenital diaphragmatic hernia [6],) or 'persistent cloaca' [7].

Today, a growing number of animal models exists which allows embryological studies in various embryological fields. This includes studies in normal as well as in abnormal embryos. Especially for the studies of esophageal and anorectal malformations, a number of animal models had been established.

Advanced technology in a number of fields gives much better insights into human development. This includes ultra sonography of fetuses as well as magnetic resonance imaging (MRI). For detailed embryological studies, scanning electron microscopy is still a very useful tool. STEDING published a scanning electron microscopic atlas of human embryos which provides detailed insights into normal human embryology [8]. Scanning electron microscopy is the perfect tool to document embryonic structures:

- Serial sectioning of embryos and time-consuming three-dimensional reconstructions are not necessary.
- The embryo can be studied in all three dimensions 'on-line'.
- The images and photographs are of superior quality (Fig. 2.1).

Although a number of specific tasks demand the serial section of embryos, the difficulties in the interpretation must not be underestimated. Three dimensional (3D) reconstructions, although feasi-

ble, are tainted with a loss of information, not only caused by the sectioning itself but also by the use of 3D image software.

2.2 Animal Models Used for Applied Embyology

Over the last two decades a number of animal models had been developed with the potential to gain a better understanding of the morphology of not only of malformed but also of normal embryos. These annual models can be grouped in 5 subgroups:

(a) Embryos of different species for the study of normal embryology.
(b) Surgical models.
(c) Chemical models.
(d) Genetic models.
(e) 'Spontaneous' malformations of unclear cause.

Human embryos are rare. Human embryos displaying typical anomalies are extremely rare. Therefore, it makes sense to study specific developmental processes in embryos of animals with human like abnormalities. However, in all cases of animal models, the detailed study of normal embryos of the same species is mandatory.

We used scanning electron microscopy (SEM) in chicken, rat and murine embryos in order to study certain embryological processes of the normal embryology of the foregut, the hindgut, the midgut, the testicular descent and the development of the external genitalia. The advantage of chicken embryos is the high availability at low costs. They are easily accessible in the eggshell and further breeding is possible when the eggs are treated accordingly. Embryos of rats and mice can be obtained in comparable large numbers; however, local regulations may limit the usage of mammalian embryos.

- The chicken embryo was used to study fore gut development. The aim was to clarify weather lateral ridges occur in the developing foregut or not and, when present, if they fuse to form the trachea-esophageal septum [9, 10].
- Rat embryos were used to study i.e. developmental processes during testicular descent [11], to clarify if 'rotation' takes place during gut development [12, 13] (Fig. 2.2a), to assess the question if 'cloacas' actually exist in rat embryos and how the differentiation of the developing hindgut takes place [12, 13] (Fig. 2.2b).
- Mouse embryos where studied in the SD-mouse model (Fig. 2.3). Here, normal and abnormal hindgut development was studied [14].

In the past, the chicken was an important surgical model to study embryological processes. As mentioned above, the easy access to the embryo, its broad availability and its cheapness makes it an ideal model for experimental studies. It has been widely used by embryologist especially in the field of epithelial/mesenchymal interactions [15–17]. Pediatric surgeons have used this model to study morphological processes involved in intestinal atresia formation [18, 19], gastroschisis [20] and Hirschsprung's disease [21]. The Czech embryologist LAMEZ [22] used chicken embryos in order to induce tracheal agenesis with tracheo-esophageal fistula (Fig. 2.4).

(**a**) Schematic drawing of the technique, (**b**) arrows indicate the area were the clips were positioned (SEM picture of a chicken embryo). SEM Picture and schematic drawing © Dietrich Kluth

Apart from these purely embryonic models, a large number of fetal models had been developed in the last 30 years. Although they were mainly created to study the feasibility of fetal interventions [23], they also added to our current knowledge of normal and abnormal fetal development and fetal organ systems.

It is well known that a number of chemicals (drugs, chemical fertilizers) can alter normal development of humans and animals alike. Some of these had been used to induce malformations similar to those found in humans. Most important are today:

(a) Adriamycin [24–26]
(b) Etretinate [27, 28]
(c) All-trans retinoic acid (ATRA) [29–31]
(d) Ethylenethiourea [32, 33]
(e) Nitrofen [34–38]
(f) Suramin and Trypan [39, 40]

Models (a-d) have been used to study atresia formation in the esophagus, the midgut and the anorectum. Model (e) was developed to study malformations of the diaphragm, the lungs, the heart and kidneys (hydronephrosis). Model (f) was used in chicken embryos to study the formation of cloacal extrophies.

We used the nitrofen model to study the morphology of diaphragmatic hernia formation in rat embryos (Fig. 2.5).

Many aspects make genetic models the ideal model for the studies of abnormal development. In the past a number of genetic models had been used for embryological studies of malformations. While older models were mostly the product of spontaneous mutations, newer models are, in most instances, the result of genetic manipulations mainly in mice (transgenic mice). The following models had been used by pediatric surgeons:

(a) Models of spontaneous origin: The SD-mouse model [41, 42]. In the SD-mouse model ano-rectal malformations are combined with anomalies of the kidneys, the spine and the external genitalia (Fig. 2.3).

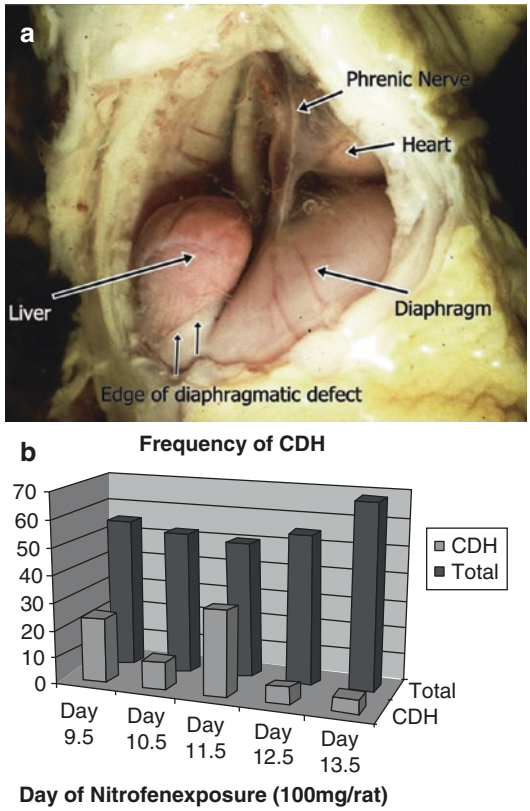

Fig. 2.5 Animal models: The nitrofen model of diaphragmatic hernia. (**a**) Newborn rat with diaphragmatic hernia after nitrofen exposure at day 11.5. (**b**) Results of nitrofen exposure on days 9.5, 10.5, 11.5, 12.5 and 13.5. Most hernias were seen after nitrofen exposure on day 11.5. Picture © Dietrich Kluth

(b) Inheritance models: the pig model of anal atresia [43, 44]. In pigs, ano-rectal malformations are seen quite frequently. One out of 300 newborn piglets present with ano-rectal malformations without evidence of genetical alterations.
(c) 'Knock-out' models.
(d) Viral models.

The number of transgenic animal models is currently growing fast. For pediatric surgeons those models are of major importance, which result in abnormalities of the fore- and hindgut. Here, interference with the Sonic hedgehog (Shh) pathway has proven to be very effective [45–47]. There are two ways to interfere with that pathway:

- Targeted deletion of Sonic hedgehog [45, 46].
- Deletion of one of the three transcription factors Glil, Gli2 and Gli3 [46, 47].

It has been demonstrated, that targeted deletion of Sonic hedgehog resulted in homozygous Shh null mutant mice in the formation of foregut malformations like esophageal atresia/stenosis, tracheo-esophageal fistulas, and tracheal/lung anomalies [48]. In the hindgut, the deletion of Sonic hedgehog caused the formation of 'cloacas' [46], while Gli2 mutant mice presented with the 'classic' form of anorectal malformations and Gli3 mutants showed minor forms like anal stenosis [46, 47]. Interestingly, the morphology of Gli2 mutant mice embryos resembles that of heterocygous SD-mice embryos while Shh null mutant mice embryos had morphological similarities with homocygous SD-mice embryos. It is interesting to note that after administration of adriamycin abnormal pattern of Shh distribution could be demonstrated in the developing foregut [48].

Recently, BOTHAM et al. studied developmental disorders of the duodenum in mutations of the fibroblast growth factor receptor 2 gene (*Fgfr2IIIb*) [49]. They noted an increased apoptotic activity in the duodenal epithelium of *Fgfr2IIIb −/−* embryos at day 10.5, followed by a disappearance of the endoderm at day 11.5. Interestingly, the duodenal mesoderm also disappeared within 2 days and an atresia was formed. Similar processes had been observed in newborn piglets whose esophageal epithelium was removed via endoscopy [50, 51]. This procedure resulted in esophageal atresias in these piglets.

In humans, viral infections are known to cause malformations. Animal models that use viral infections important for pediatric surgeons are very rare. One exception is the murine model of extra hepatic biliary atresia (EHBA) [52]. In this model, newborn Balb/c mice are infected with rhesus rotavirus group A45. As a result, the full spectrum of EHBA develops as it is seen in newborn with this disease. However, this model is not a model to mimic failed embryology. But it highlights the possibility that malformations are not caused by embryonic disorders but caused by fetal or even postnatal catastrophes.

In chicken embryos, a number of spontaneous malformations can be observed. It is not quite clear which processes cause them. One reason may be a prolonged storage (more than 3 days) in fridges below 8° C before breeding is started [53].

Spontaneous malformations of the head anlage (i.e. double anlage of the head), the anlage of the heart as well as abnormalities of the embryonic position (hererotaxia) are frequently seen [53].

This part on embryology and animal models highlights not only the importance to study embryos with experimental malformations but also the study of normal animal embryos. Today, much information in current textbooks on human embryology stems actually from studies done in animals of varies species. Many of these are outdated. The wide use of transgenic mice in order to mimic congenital malformations makes morphological studies of the organ systems in normal mice mandatory. Otherwise the interpretation of the effects by deletion of genetic information can be very difficult or even misleading.

2.3 Scanning Electron Microscopic Atlas of Normal and Abnormal Development in Embryos

In this section we want to present examples of normal and abnormal development as we have seen them in our studies in our labs over the past 30 years using scanning electron microscopy (SEM). We use the form of an embryological atlas following the old motto 'A picture says more than a thousand words'. We focus on the following developmental processes:

- Normal and abnormal foregut development (chicken embryos).
- Normal and abnormal development of the diaphragm (rat embryos).
- Development of the midgut (rat embryos).
- Normal and abnormal development of the hindgut (mice and rats).
- The development of the external genitalia and the urethra (rat embryos).
- Testicular descent (rat embryos).

2.3.1 Normal Foregut Development

Traditionally, foregut malformations like esophageal atresias and trachea-esophageal fistulas are explained by a faulty formation of the so-called 'tracheo-esophageal septum'. It is believed that normal septation takes place in two steps:

1. Lateral endodermal ridges appear in the primitive foregut which fuse and form the trachea-esophageal septum.
2. This solid endodermal septum is partly removed by apoptosis and substituted by mesenchymal cells.

This theory had been described in detail by ROSENTHAL [54] and SMITH [55]. However, neither ZAW TUN [56] nor O'RAHILLY and MÜLLER [57] were able to confirm these sequences of embryological events. According to them, the term 'separation' is a misnomer as the formation of the trachea is simply the result of the down growth of the respiratory diverticulum [58].

Using SEM, we studied the normal development of the foregut in chicken embryos [9, 19, 59].

The first goal of these studies was to see if lateral endodermal ridges appear inside the foregut and if they fuse (Fig. 2.6). However, in our studies we were unable to identify ridges in the lateral foregut wall. Furthermore, signs of fusions of lateral foregut components were also not seen. As no signs of fusion can be demonstrated in the foregut, theories dealing with improper formations of the trachea-esophageal septum are obsolete [56].

The second goal was to visualize the early formation of the lung bud (Fig. 2.7). In our series of embryos we could demonstrate that after the formation of the early lung anlage two lung buds appear, which are the forerunners of the bronchi. The anlage of the trachea itself is seen later as the floor of a 'common foregut' chamber [10]. Thus, not the trachea but the bronchi are the first organs of the respiratory tree that develop. This speaks against the idea of a simple down growth of the tracheal anlage as assumed by ZAW TUN and O'RAHILLY and MÜLLER [56, 57].

The third goal was to identify possible mechanisms of differentiation of the foregut into larynx, pharynx, trachea and esophagus. In our embryos, we could identify typical markers in the foregut (Fig. 2.8). In the dorsal aspect of the foregut a fold appears which

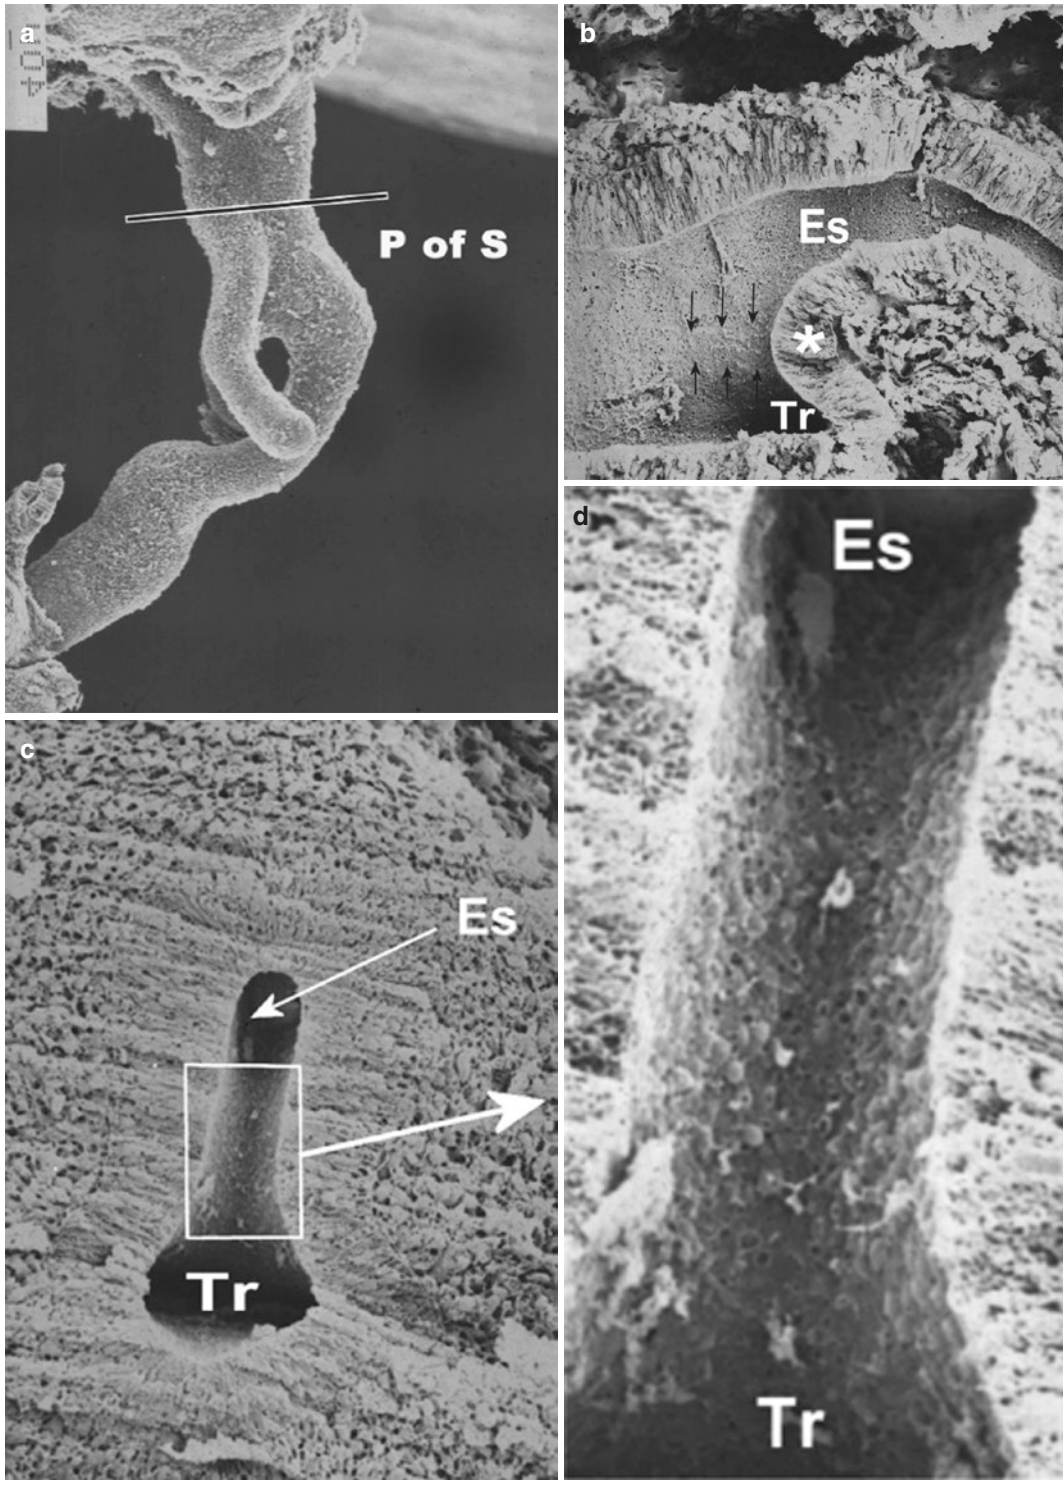

Fig. 2.6 Embryology of the esophagus: SEM studies in chicken embryos. (**a**) Foregut of a chicken embryo of stage20/21, 3.5 days old. (**b**) The foregut is opened from lateral. The inner surface of the foregut is seen. Notice the absence of lateral folds (*arrows*). *ES* esophagus, *TR* trachea, *Asterisk* (*) tip of the trachea-esophageal fold. (**c**) View into the foregut from cranial. The tip of the trachea-esophageal fold can be seen. Notice the absence of fusion (higher magnification in D). *ES* esophagus, *TR* trachea. Fig. 2.7 Embryology of the esophagus: Formation of the respiratory tract. (**a**) Lung buds are the forerunners of the bronchi (LB). *CF* common space of foregut. (**b**) The bronchi start to develop (L Br). A trachea is not visible yet. *CF* common space of foregut. (**c**) The trachea (Tr) is still part of the common foregut. *LaF* larynxanlage, *ES* esophagus, *L Br* bronchi, *St* stomach, *Double Asterisk* fold which marks the border between pharynx and esophagus. SEM Pictures © Dietrich Kluth

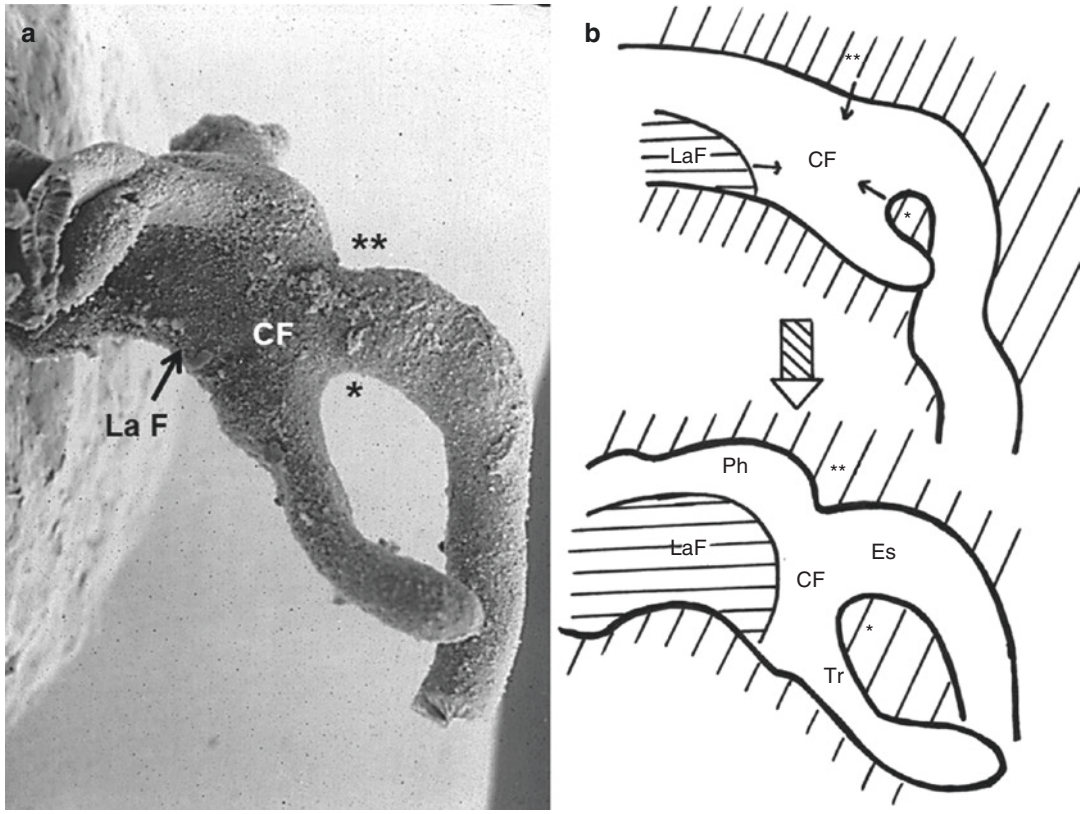

Fig. 2.8 Embryology of the esophagus: The common space of the foregut is reduced in size by a system of folds. (**a**) The trachea is still part of the common space (CF). *LaF* Larynxanlage. (**b**) The size of the common foregut (CF) is reduced by the growth of folds, which are formed by the larynx fold (LaF) from cranial, the trachea-esophageal fold (*asterisk*) from caudal, and the fold between phayrynx and esophagus (*double asterisk*) from dorsal. SEM Picture and schematic drawing © Dietrich Kluth

marks the borderline between pharynx and esophagus. Cranially the larynx develops and caudally, a fold appears between the developing trachea and the esophagus. In the next developmental steps these folds approach each other but do not fuse. As a result, the area of the common foregut is reduced in size and later forms the pharyngo-tracheal canal [5].

2.3.2 The Formation of Esophageal Atresia

Although a number of models for abnormal foregut development exist, a clear morphological description of the embryological events that finally lead to esophageal atresias, are still missing. Based on our observations, the development of the malformation can be explained by disorders either of the formation of the folds or of their developmental movements [9, 10, 59]:

- Atresia of the esophagus with fistula (Fig. 2.9c1):
- The dorsal fold of the foregut bends too far ventrally. As a result the descent of the larynx is blocked. Therefore the common tracheo-esophageal space remains partly undivided and lies in a ventral position. Due to this ventral position the common space differentiates into trachea.
- Atresia of the trachea with fistula (Fig. 2.9c2):

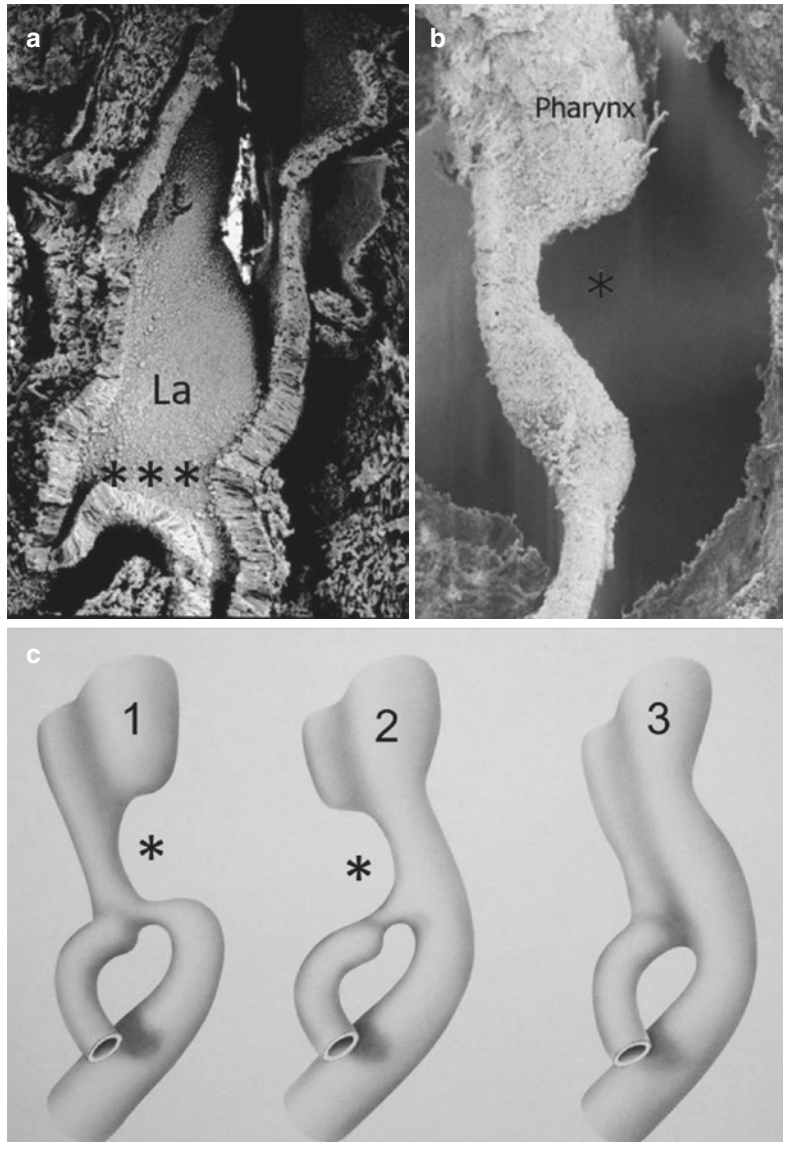

Fig. 2.9 Embryology of the esophagus: Hypothetical formation of foregut malformations. (**a**) Normal foregut of a chicken embryo, view from lateral into the foregut. Notice the reduced size of the common foregut space (*Triple Asterisk*) due to the development of the folds. *La* Larynx. (**b**) Chicken embryo with a spontaneous foregut malformation. The Pharynx ends blindly. Part of the trachea is in normal position and of tracheal size. The dorsal part of the common foregut space is missing (*Asterisk*). (**c**) Hypothetical explanation of foregut maldevelopment. (C1) The dorsal fold (*Asterisk*) between pharynx and larynx grows too deep into the common foregut space. Consequently the rest of the common space develops into trachea and an esophageal atresia with lower fistula develops. (C2) The common foregut space is reduced in size from ventral (*Asterisk*). Consequently the rest of the common space develops into esophagus and a tracheal atresia with fistula occurs (very rare). (C3) Impaired development of the dorsal fold and the tracheo-esophageal fold leads to an undivided common foregut space and a laryngo-tracheo-esophageal cleft. SEM Pictures and schematic drawing © Dietrich Kluth

- The foregut is deformed on its ventral side. The developmental movements of the folds are disturbed and the tracheo-esophageal space is dislocated in a dorsal direction, where it differentiates into esophagus.
- Laryngo-tracheo-esophageal clefts (Fig. 2.9c3): Faulty growth of the folds results in the persistence of the primitive tracheo-esophageal space.

In our collection of chicken embryos we came across an embryo with abnormal foregut features (Fig. 2.9b). When compared to normal embryos of the same age group (Fig. 2.9a), the following statements can be made: (a) obviously, the pharynx ends blindly. (b) The dorsal part of the common foregut space is missing. (c) the ventral part of the common space has the size of a trachea. (d) This foregut looks like the hypothetical form C1 in Fig. 2.9.

2.3.3 Normal Diaphragmatic Development

The traditional theories of diaphragmatic development have been summarized by KLUTH et al. [60]. Using SEM, we have recently restudied the diaphragmatic development. For practical reasons, it is essential to note that the early diaphragm consists of two parts:

- The septum transversum which, in young embryos, is identical to the floor of the pericardium.
- The structures that surround the pleural cavity. They are:
  - The Post Hepatic Mesenchymal Plate (PHMP) [38], which covers the dorsal aspect of the liver and is in continuity to the septum transversum ventrally and cranially.
  - The pleoro-peritoneal fold (PPF) which separates the pleura from the peritoneal cavity. This fold connects ventrally to the septum transversum and the PHMP and dorsally to the mesonephric ridge [61]. This PPF is a structure that is identical to the pleuro-peritoneal membrane of the old literature [60].
  - The dorsal mediastinum which contains the esophagus, the trachea and the Aorta.

According to our SEM studies, the PHMP plays the most important role in normal diaphragmatic development. In Figs. 2.10 and 2.11 the closure process of the pleuro-peritoneal openings (PPO) is depicted. At embryonic day (ED) 13,

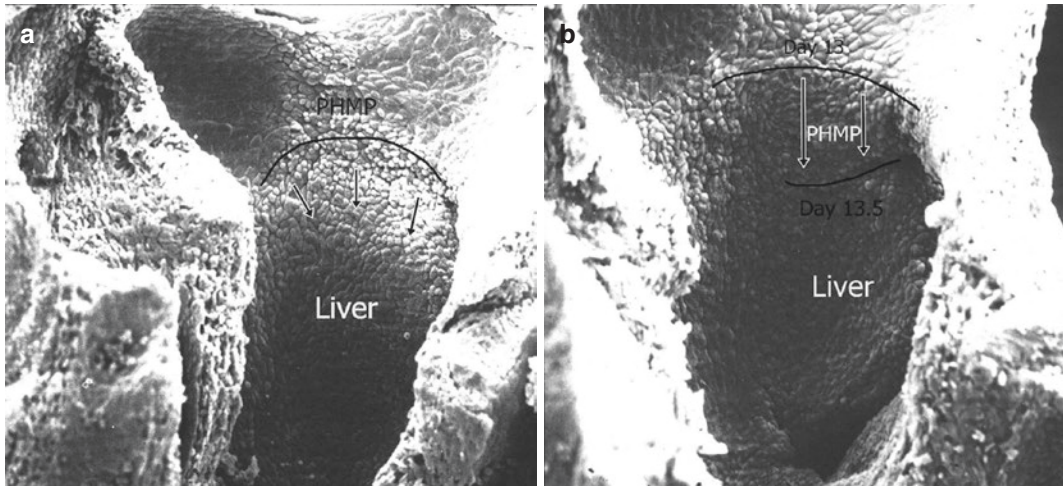

Fig. 2.10 Normal development of the diaphragm: Caudal growth of the posthepatic mesenchymal plate (PHMP) [38]. (**a**) Rat embryo, ED 13. View at the dorsal part of the diaphragm. The dorsal diaphragm is short. The black line in marks the caudal border of the PHMP. Arrows indicate the direction of future PHMP growth. Note the large area of liver still uncovered by the PHMP. (**b**) Rat embryo 13.5 days. Note the caudal growth of the PHMP within 12 h (second dark line). The uncovered liver is markedly smaller. SEM Pictures © Dietrich Kluth

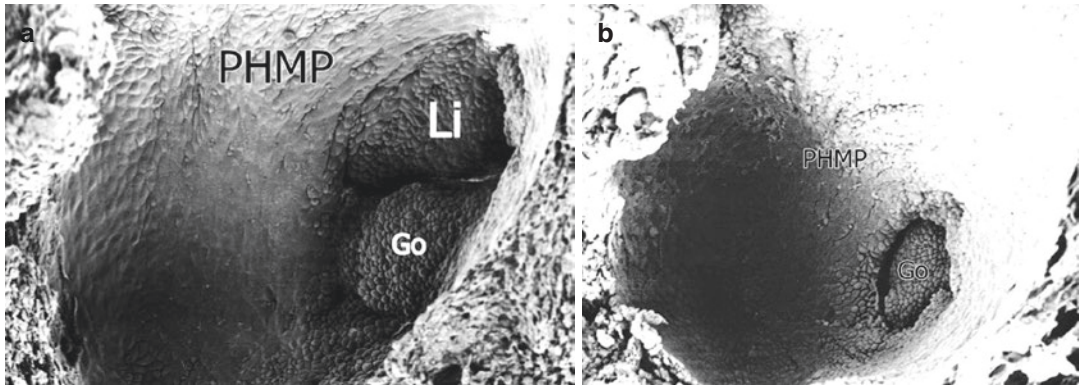

Fig. 2.11 Normal development of the diaphragm: Closure of the pleuroperitoneal openings (PPO). Rat ED 15 (**a**) and ED 16 (**b**). Most of the liver (Li) is covered by the posthepatic mesenchymal plate (PHMP). At ED 16 the only intra-abdominal organ seen is the tip of the gonads (Go). SEM Pictures © Dietrich Kluth

the formation of the PHMP and its lower border can be seen (Fig. 2.10a). The PHMP then expands dorso-laterally at embryonic day 13.5 (Fig. 2.10b), establishing a new lower border.

In Fig. 2.11 the final closure of the PPO is shown. In this process the PHMP starts to cover the last free areas of the liver (Fig. 2.11b). In this process, the PPF plays only a minor role.

In the literature, the nomenclature of the various parts of the diaphragm is confusing. We use the term PPF for a structure which was formally known as pleuro-peritoneal membrane [60, 61]. The term PPF is used differently by GREER and co-workers [62]. Their PPF is very similar to the PHMP as described by IRITANI and us but seems to include the ventral part of our PPF.

2.3.4 Abnormal Diaphragmatic Development

In the past, several theories were proposed to explain the appearance of postero-lateral diaphragmatic defects:

- Defects caused by improper development of the pleuro-peritoneal membrane [63, 64]
- Failure of muscularization of the lumbocostal trigone and pleuro-peritoneal canal, resulting in a 'weak' part of the diaphragm [64, 65]
- Pushing of intestine through postero-lateral part (foramen of Bochdalek) of the diaphragm [66]
- Premature return of the intestines into the abdominal cavity with the canal still open [64, 65]
- Abnormal persistence of lung in the pleuro-peritoneal canal, preventing proper closure of the canal [67]
- Abnormal development of the early lung and posthepatic mesenchyme, causing non-closure of pleuro-peritoneal canals [38]

Of these theories, failure of the pleuro-peritoneal -membrane to meet the transverse septum is the most popular hypothesis to explain diaphragmatic herniation. However, using SEM techniques [60, 61] we could not demonstrate the importance of the pleuro-peritoneal membrane for the closure of the so-called pleuro-peritoneal canals (Fig. 2.11).

It is still speculated, that delayed or inhibited closure of the diaphragm will result in a diaphragmatic defect that would allow herniation of gut into the fetal thoracic cavity. In a series of normal staged embryos, we measured the width of the pleuro-peritoneal openings and the transverse diameter of gut loops [68]. On the basis of these measurements we estimated that a single embryonic gut loop requires at least an opening of 450 μm size to herniate into the fetal pleural cavity. However, in none of our embryos the observed pleuro-peritoneal openings were of appropriate dimensions. This means that delayed or inhibited closure of the pleuro-peritoneal canal cannot result in a diaphragmatic defect of suffi-

cient size. Herniation of gut through these openings is therefore impossible. Thus the proposed theory about the pathogenetic mechanisms of congenital diaphragmatic hernia (CDH) development lacks any embryological evidence. Furthermore the proposed timing of this process is highly questionable [66].

2.3.5 Animal Model

Recently, an animal model for diaphragmatic hernia has been developed [34–38] using nitrofen as noxious substance. In these experiments CDHs were produced in a reasonably high percentage of newborns [36]. We collected a number of affected embryos of different age groups and studied these using SEM [68, 69]. Our results (Figs. 2.12 and 2.13) are as follows:

- Timing of diaphragmatic defect appearance. IRITANI [38] was the first to notice that nitrofen-induced diaphragmatic hernias in mice are not caused by an improper closure of the pleuro-peritoneal openings but rather the result of a defective development of the post-hepatic mesenchymal plate (PHMP). In our study in rats, clear evidence of disturbed

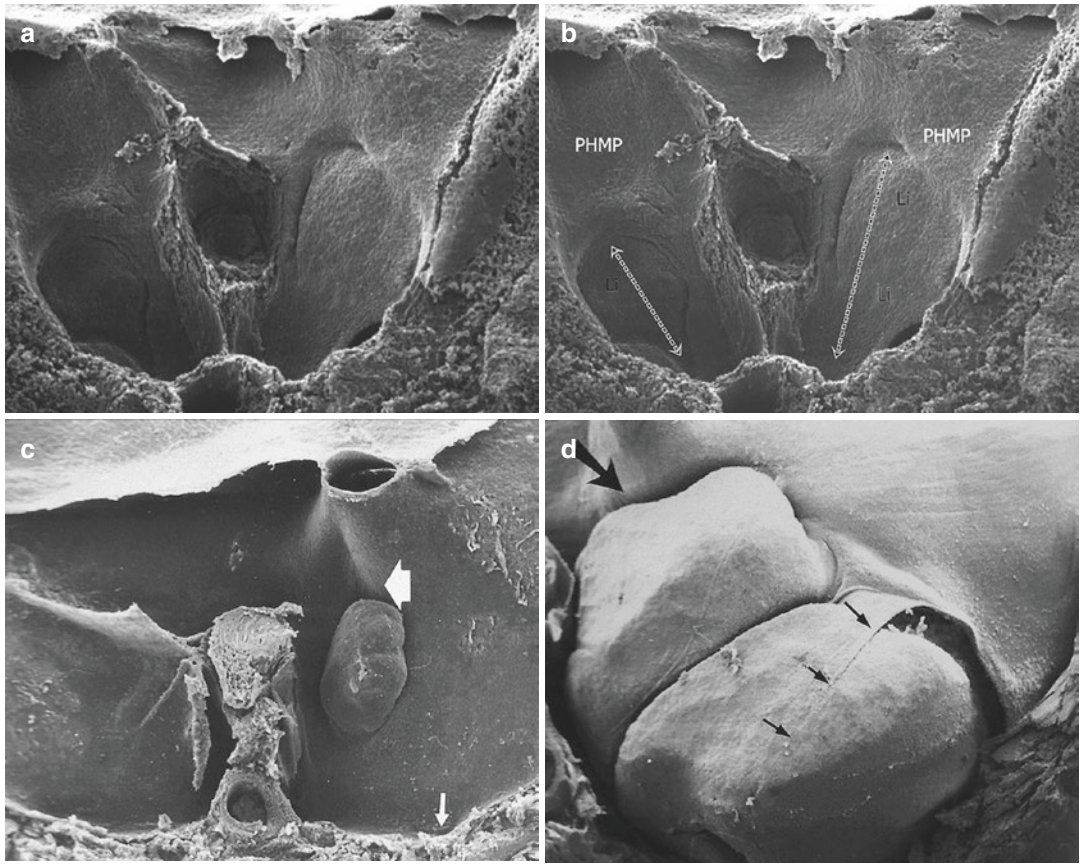

Fig. 2.12 Dorsal diaphragms after nitrofen exposure at rat ED 11.5. (**a**, **b**) Rat embryo at ED 14. The abnormal anlage of the right diaphragm is easy to see. Dotted arrows mark the diameter of the uncovered liver (Li). On the left, the development of the posthepatic mesenchymal plate (PHMP) is normal. On the right, the PHMP stopped to grow to caudal. (**c**) Rat ED 17. A small hernia (liver) can be seen. Note the position close to the vena cava (*large arrow*). The small arrow points to the closed pleuroperitoneal openings (PPO). (**d**) Rat ED 18. The hernia is big. Two lobes of liver project into the thorax. The big arrow points to the vena cava. *Small arrows* mark the border of the PPO, which is open due to the ingrowth of the liver. Note that the size of the diaphragmatic defect is much larger than the PPO itself. SEM Pictures © Dietrich Kluth

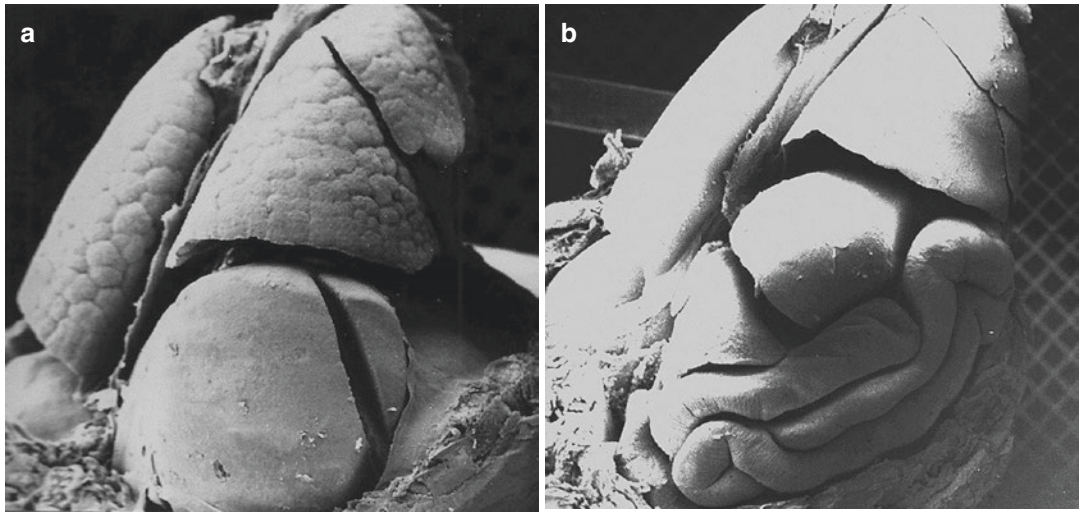

Fig. 2.13 Huge diaphragmatic hernias after nitrofen exposure. (**a**) Rat ED 20. In none of our embryos, gut could be found in this age group. (**b**) Rat ED 21. In this age group and older animals, gut can be found inside the thoracic cavity. SEM Pictures © Dietrich Kluth

development of the diaphragmatic anlage was seen on ED 13 on the left and ED 14 on the right diaphragm anlage (Fig. 2.12) [68, 70]. In all embryos affected, the PHMP was too short. This age group is equivalent to 4–5 week old human embryos [68, 69].

- Location of diaphragmatic defect. In our SEM study, the observed defects were localized in the area of the PHMP (Fig. 2.12). We identified two distinct types of defects: (1) large 'dorsal' defects and (2) small 'central' defects [68, 69]. Large defects extended into the region of the pleuro-peritoneal openings. In these cases, the closure of the pleuro-peritoneal openings was usually impaired by the massive ingrowth of liver (Figs. 2.12 and 2.13). If the defects were small, they were consistently isolated from the pleuro-peritoneal openings which closed normally at the 16th or 17th day of gestation. Thus, in our embryos with CDH, the region of the diaphragmatic defect was a distinct entity and was separated from that part of the diaphragm where the pleuro-peritoneal 'canals' are localized. We conclude therefore that the pleuro-peritoneal openings are not the precursors of the diaphragmatic defect.
- Why lungs are hypoplastic? Soon after the onset of the defect in the 14-day-old embryo, liver grows through the diaphragmatic defect into the thoracic cavity (Fig. 2.12). This indicates that from this time on the available thoracic space is reduced for the lung and further lung growth is hampered. In the following stages, up to two- thirds of the thoracic cavity can be occupied by liver (Fig. 2.13a). Herniated gut was found in our embryos and fetuses only in late stages of development (21 days and newborns) (Fig. 2.13b). In all of these, the lungs were already hypoplastic, when the bowel entered the thoracic cavity [68, 69].

Based on these observations, we conclude that the early ingrowth of the liver through the diaphragmatic defect is the crucial step in the pathogenesis of lung hypoplasia in CDH. This indicates that growth impairment is not the result of lung compression in the fetus but rather the result of growth competition in the embryo: the liver that grows faster than the lung reduces the available thoracic space. If the remaining space is too small, pulmonary hypoplasia will result.

2.3.6 Normal Hindgut Development

As in the foregut, a process of septation has been postulated for the proper subdivision of the 'cloaca' into the dorsal anorectum and the ventral sinus urogenitalis. Disorders in this process of differentiation are thought to be the cause of cloacal anomalies such as persistent cloaca and anorectal malformations [7].

However, for many years, this process of septation has been under dispute. Some authors [71, 72] believe that the descent of a single fold separates the urogenital part from the rectal part by ingrowth of mesenchyme. Others [73] think that lateral ridges appear in the lumen of the cloaca, which progressively fuse along the midline and thus form the septum. Van de PUTTE [74] denied the existence of any process of septation.

In the recent years we studied the cloacal development in rats and SD-mice embryos using SEM techniques [13, 14, 75].

The first goal of these studies was to see if lateral ridges appear inside the 'cloaca' and if these actually fuse to form an endodermal septum (Fig. 2.14). As in the foregut of chick embryos, we were unable to see lateral ridges (Fig. 2.14c)

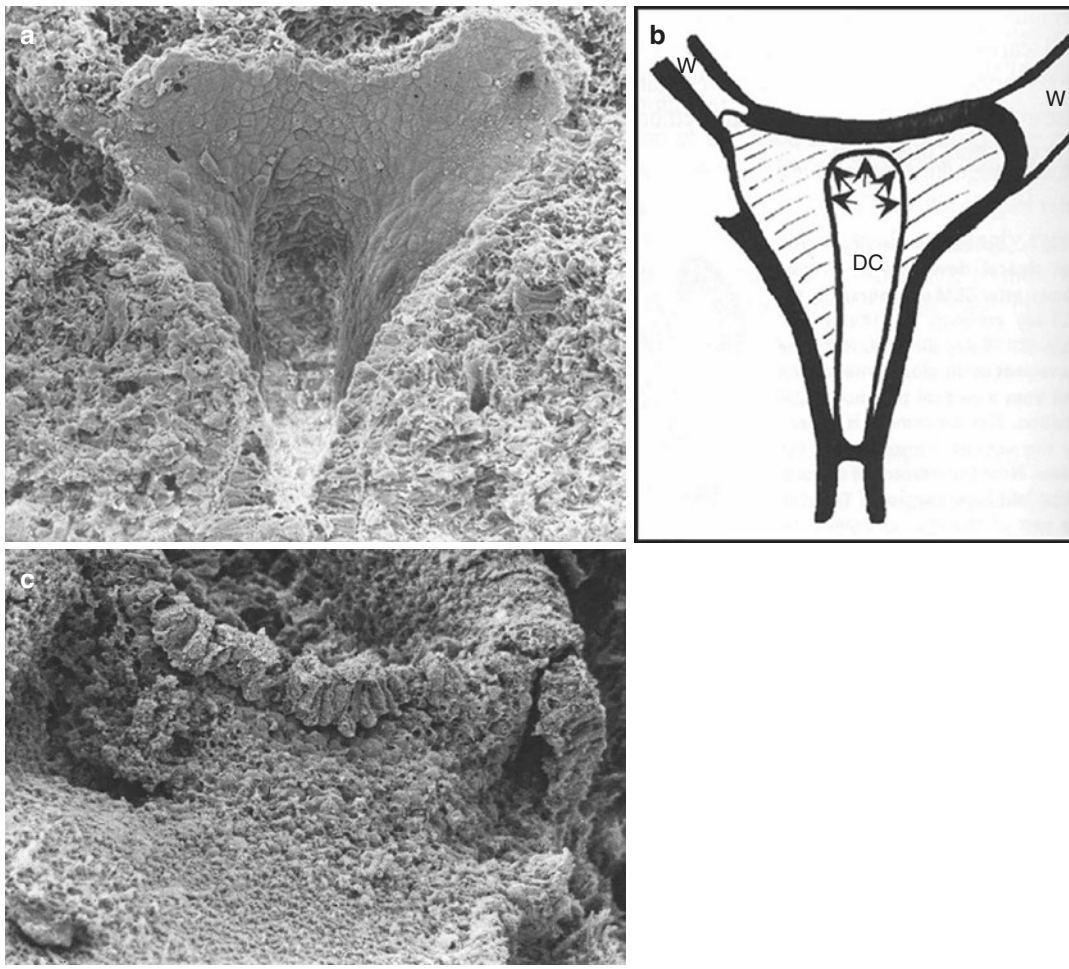

Fig. 2.14 Normal development of the hindgut. Rat ED 14. (**a**) The ventral part of the cloaca is removed. As in the foregut, signs of fusion are lacking. (**b**) Schematic drawing of the situation in A. (**c**) After removal of the lateral wall of the cloaca, internal ridges which could form an uro-rectal septum, are not detectable. SEM Pictures and schematic drawing © Dietrich Kluth

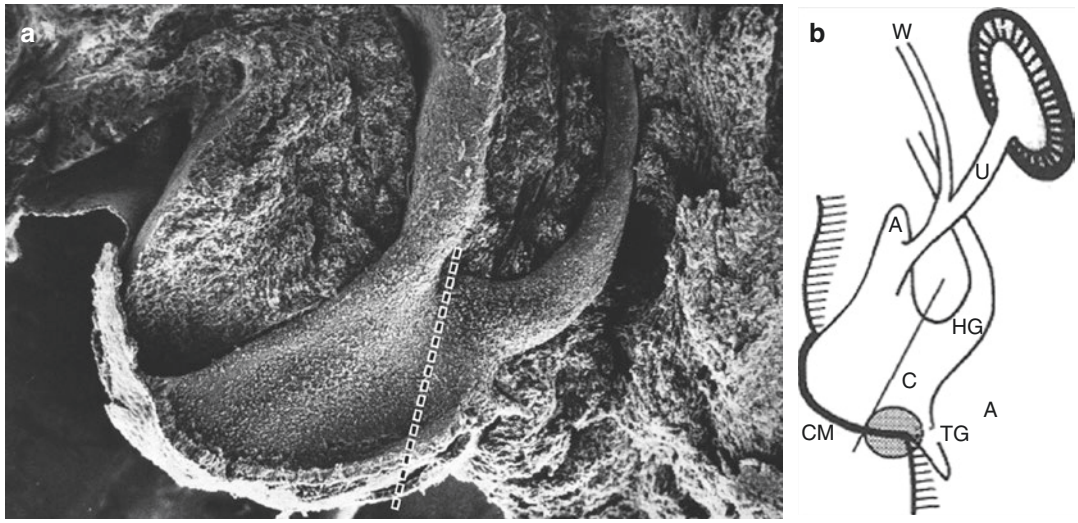

Fig. 2.15 Normal development of the hindgut. (**a**, **b**) The 'cloaca' (C) in a rat embryo ED 14.5 has the following features: Proximal urethra (PU), distal urethra (DU), rectum (HG), tail gut (TG), cloacal membrane (CM). The line marks the border between rectum and urethra. The schematic drawing shows the situation in a rat embryo ED 14. Note that the 'cloaca' is not equally divided by the line. The gray area in the schematic drawing marks the area of the future anus. It lies in the dorsal part of the cloacal membrane close to the tail fold. SEM Pictures and schematic drawing © Dietrich Kluth

projecting into the cloacal lumen. Signs of median fusion of lateral cloacal parts were also lacking (Fig. 2.14a,b). However, in contrast to Van de PUTTE [74] our SEM studies indicate that down growth of the tip of the uro-rectal fold takes place (Fig. 2.15a,b), although it is probably not responsible for the formation of cloacal malformations.

Our findings on normal embryology of the hindgut were:

- The 'cloaca' is not subdivided into two equal parts (Fig. 2.15a, b). The much larger ventral part gives rise to the future distal urethra.
- The dorsal 'cloaca' contains the future ano-rectal region. The future anal opening is situated in the dorsal part of the 'cloacal' membrane, close to the tail fold (Fig. 2.15b).

2.3.7 Abnormal Hindgut Development

As already mentioned, a number of animal models exist which allow embryological studies of abnormal hindgut development. In our studies we used embryos obtained from SD-mice. The SD-mouse is a spontaneous mutation of the house mouse, characterized by a short tail (Fig. 2.3). Homozygous or heterozygous offspring of these mice show skeletal, urogenital and ano-rectal malformations [42]. Therefore, these animals are ideal for detailed studies of ano-rectal malformations.

In all affected embryos we made the following observations (Fig. 2.16):

- Compared to normal embryos (Fig. 2.16a, b) we found abnormally shaped cloacas. The dorsal part was always missing (Fig. 2.16c, d).
- The cloacal membrane was always too short (Fig. 2.16c, d). In all cases the dorsal part of the cloacal membrane was absent.
- The proximal hindgut joined the cloaca at an abnormal position (Fig. 2.16c, d).

In Fig. 2.17 the developmental processes are summarized in a sketch.

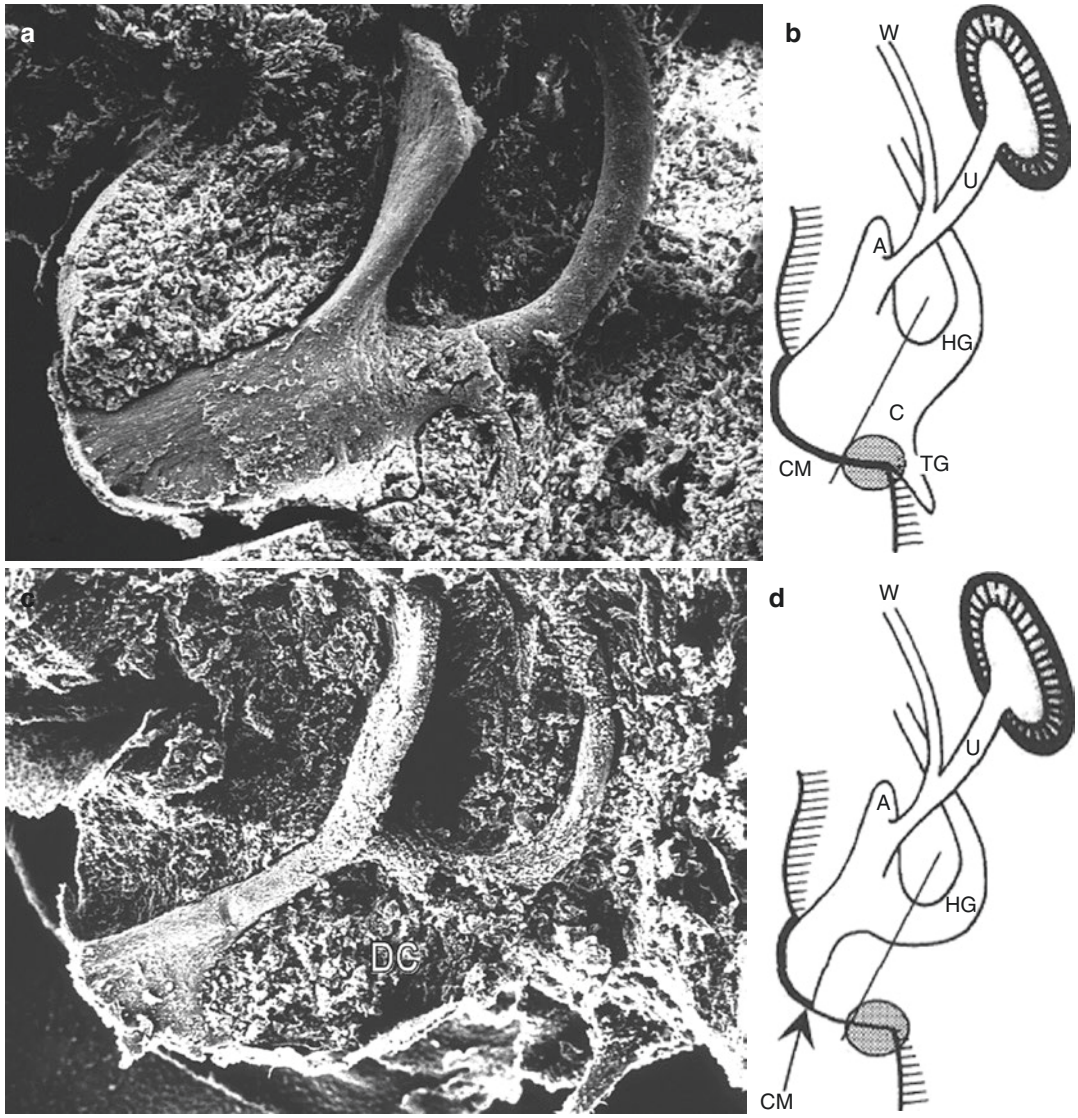

Fig. 2.16 Normal (**a**) and abnormal hindgut (**c**) in heterozygous SD-mouse embryos. Note that in the abnormal hindgut, the dorsal cloaca (DC), which contains the area of the future anus, is completely missing. As a result, the rectum keeps in contact with the urethra too high (so-called fistula). The cloacal membrane (CM) is too short. In B and D the findings are summarized in schematic drawings. *A* future bladder, *U* ureter, *W* WOLFF duct, *HG* rectum (hindgut), *C* 'cloaca', *TG* tail gut. SEM Pictures and schematic drawing © Dietrich Kluth

2.3.8 Normal Development of the External Genitalia

Many investigators [75–77] believe that the urethra develops by fusion of the paired urethral folds which takes place following the disintegration (rupture) of the ventral part of the cloacal membrane, the so-called 'urogenital membrane'. Impairment of this process of fusion is thought to result in the different forms of hypospadias [78, 79]. In order to get more information about this process, we studied the formation of the external genitalia in staged rat embryos and fetuses [80, 81].

This study was carried out in normal rat embryos and fetuses between embryonic day 17.5 (Fig. 2.18) and embryonic day 20.

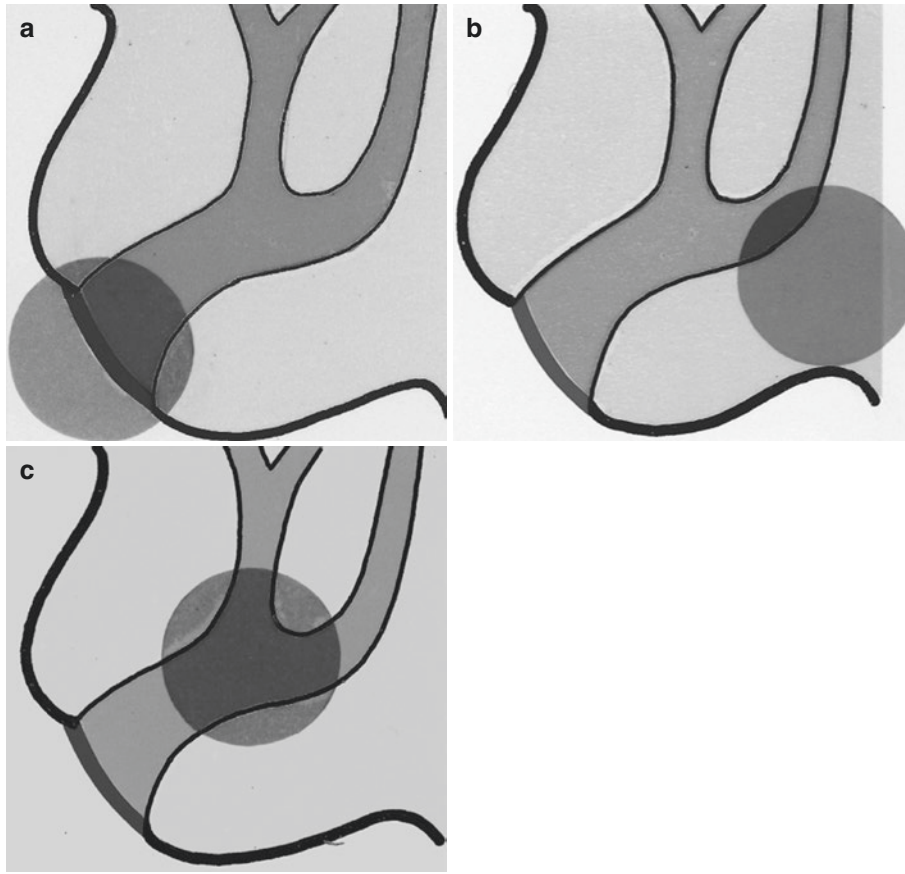

Fig. 2.17 Hypothetical line of events in anorectal malformations: (**a**) In young embryos, the cloacal membrane is too short. (**b**) As a result, the dorsal part of the 'cloaca' is missing, which normally contains the area of the future anal canal. (**c**) The rectum remains attached to the future urethra. Schematic drawing © Dietrich Kluth

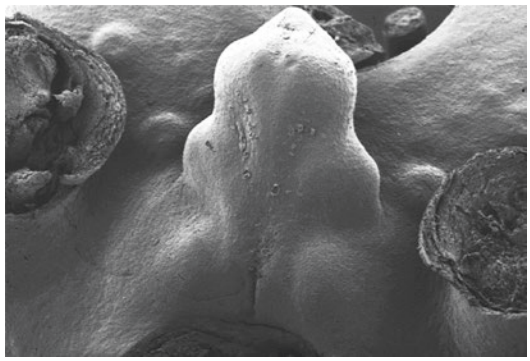

Fig. 2.18 Normal genital development. It is a common assumption that the 'cloacal membrane' ruptures not only in the dorsal (anal) part but also in the ventral (urethral) part [5]. However, the SEM picture of the phallus of a normal rat embryo (ED 17,5) shows only partial rupture of the "cloacal membrane" in its dorsal (anal) region. In this age group the sex of the embryo can't be estimated by the appearance of the outer genitals. SEM Picture © Dietrich Kluth

- Rupture of the cloacal membrane (Fig. 2.19). At embryonic day 17.5 the dorsal disintegration of the cloacal membrane can be seen (Fig. 2.19a, b). The ventral (urethral) part of the cloacal membrane remains intact. In Fig. 2.19c this process of disintegration is seen in more detail. The ectodermal part of the cloacal membrane shows clear signs of disintegration. The tip of the uro-rectal fold is seen which later forms the perineum. Ventral to the tip of the uro-rectal fold an opening is seen which is in connection to the distal urethra. Dorsally the anal opening is seen. At this time point, the external genitals allow no differentiation between the sexes.
- Further development of the external genitalia. A rupture of the ventral part of the cloacal membrane can't be seen in older embryos and fetuses. In males, the transient urethral open-

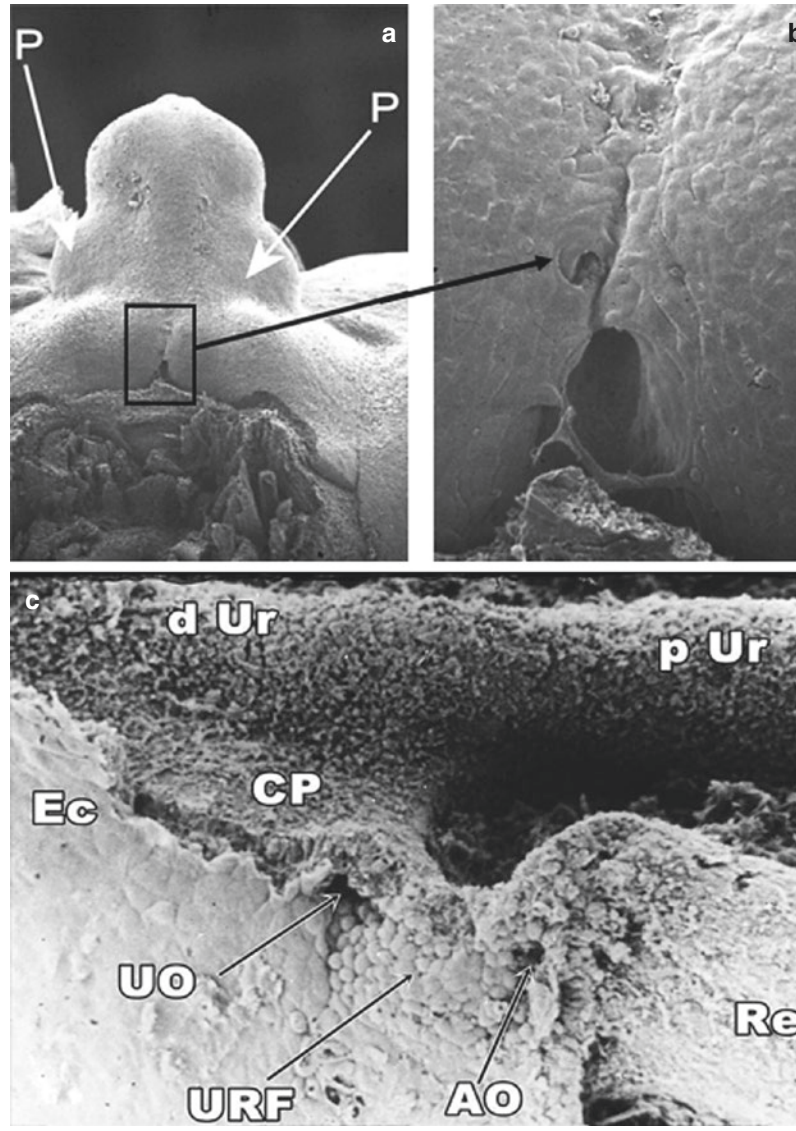

Fig. 2.19 Rupture of the dorsal cloacal membrane in a rat embryo (ED 17.5). (**a**, **b**) The rupture of the membrane is clearly seen. (**c**) In high magnification the situation is visible in detail. Half of the genitals is removed by micro preparations. The Tip of the urorectal fold can be seen (URF). Ventrally the opening of the urethra is seen (UO). The rectum (Re) opens dorsally (AO). Fusion of the URF with the cloacal membrane, as assumed by some researchers, does not take place. *EC* ectoderm, *CP* cloacal plate, *d Ur* distal urethra, *p Ur* proximal urethra. SEM Pictures © Dietrich Kluth

ing disappears. Later a 'raphe' is seen in this position (Fig. 2.20a). In females, this 'raphe' is missing (Fig. 2.20b).

- Special dissections of a rat embryo at embryonic day 18.5 allow the following statements (Fig. 2.21a–c): The urethra is composed of two parts, the proximal and the distal part. The epithelium of the distal part reaches to the tip of the phallus. It is interesting to see that the urethra is connected to the perineal region by a short canal, the so-called 'cloacal canal'. In our opinion this is the future female urethra.

Summarizing our results we found:

- In rats, the urethra is always present as a hollow organ during urethral embryogenesis and that it is always in contact with the tip of the genitals.
- Initially a double urethral anlage exists. The differentiation in female and male urethra happens in rats more than 18.5 days old.
- We had no evidence for the disintegration of the urogenital cloacal membrane, and a fusion of lateral portions within the perineum.

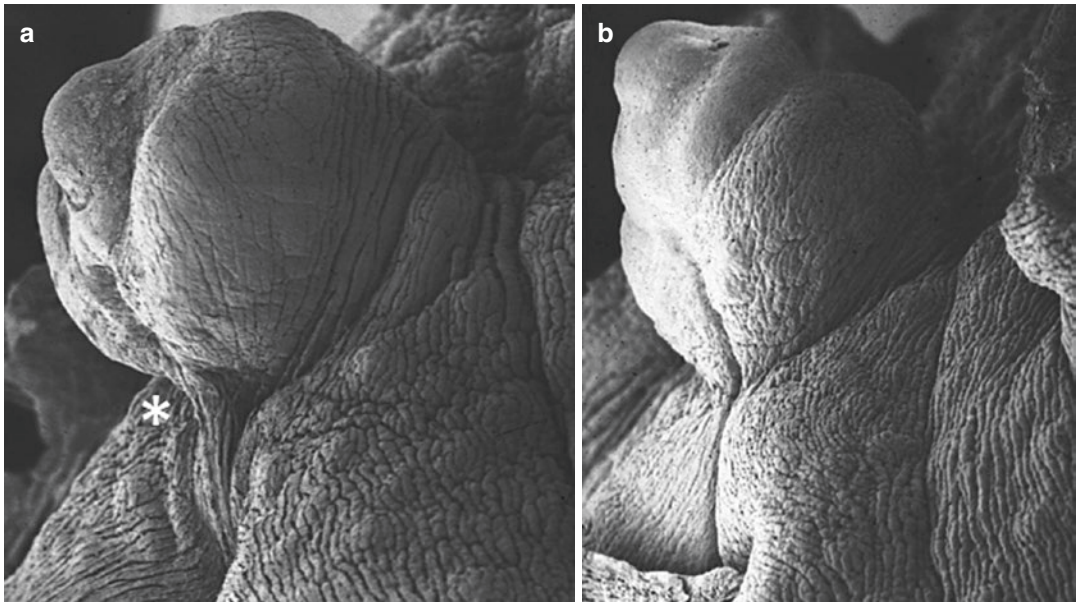

Fig. 2.20 Rat fetuses ED 20, (**a**) male rat, (**b**) female rat. The sex is discernable by external inspection of the genitals. Note the 'raphe' (*Asterisk*) in A, which is typical for the male phallus. This raphe is not the result of fusion, as generally believed. In female rats this 'raphe' is missing. SEM Pictures © Dietrich Kluth

2.3.9 Abnormal Development of the External Genitalia (Hypospadia Formation [80, 81]

In our opinion, more than one embryological mechanism is at play in the formation of the hypospadia complex. The moderate degrees, such as the penile and glandular forms, represent a developmental arrest of the genitalia. They take their origin from a situation comparable to the 20 days old embryo. Consequently the penis, not the urethra, is the primary organ of the malformation. Perineal and scrotal hypospadias are different from the type discussed previously. Pronounced signs of feminization in these forms suggest that we are dealing with a female type urethra. Origin of this malformation complex is an undifferentiated stage as may be seen in the 18.5 days old rat embryo.

2.3.10 Normal Midgut Development

2.3.10.1 Traditional Theories

Traditionally, the midgut development is described as a process of 'rotation'. In this process the following parts are involved: The distal part of the duodenum, the small bowel and most parts of the big bowel. The process of rotation takes place in two phases [82, 83]:

- In the first phase, the midgut loop develops inside the umbilicus (so-called 'physiological herniation of the midgut'). Here, a 90° anti-clockwise rotation around the axis of the mesentery is thought to take place.
- After the 'return' of the midgut into the abdominal cavity, another anti-clockwise 'rotation' of 180° is thought to take place inside the abdominal cavity (second phase). As a result, the region of the cecum moves to the right, thus overcrossing the mesenteric root, while the flexura duodeno-jejunalis is pushed to the left beneath the root of the mesentery [82, 83]. These two phases sum up 270°. In contrast to this description, GROB [84] subdivides this intra-abdominal process of rotation into two steps of 90° each.

2.3.10.2 Own Observations

We studied midgut development in rat embryos using SEM (Figs. 2.22, 2.23, and 2.24) [12, 85,

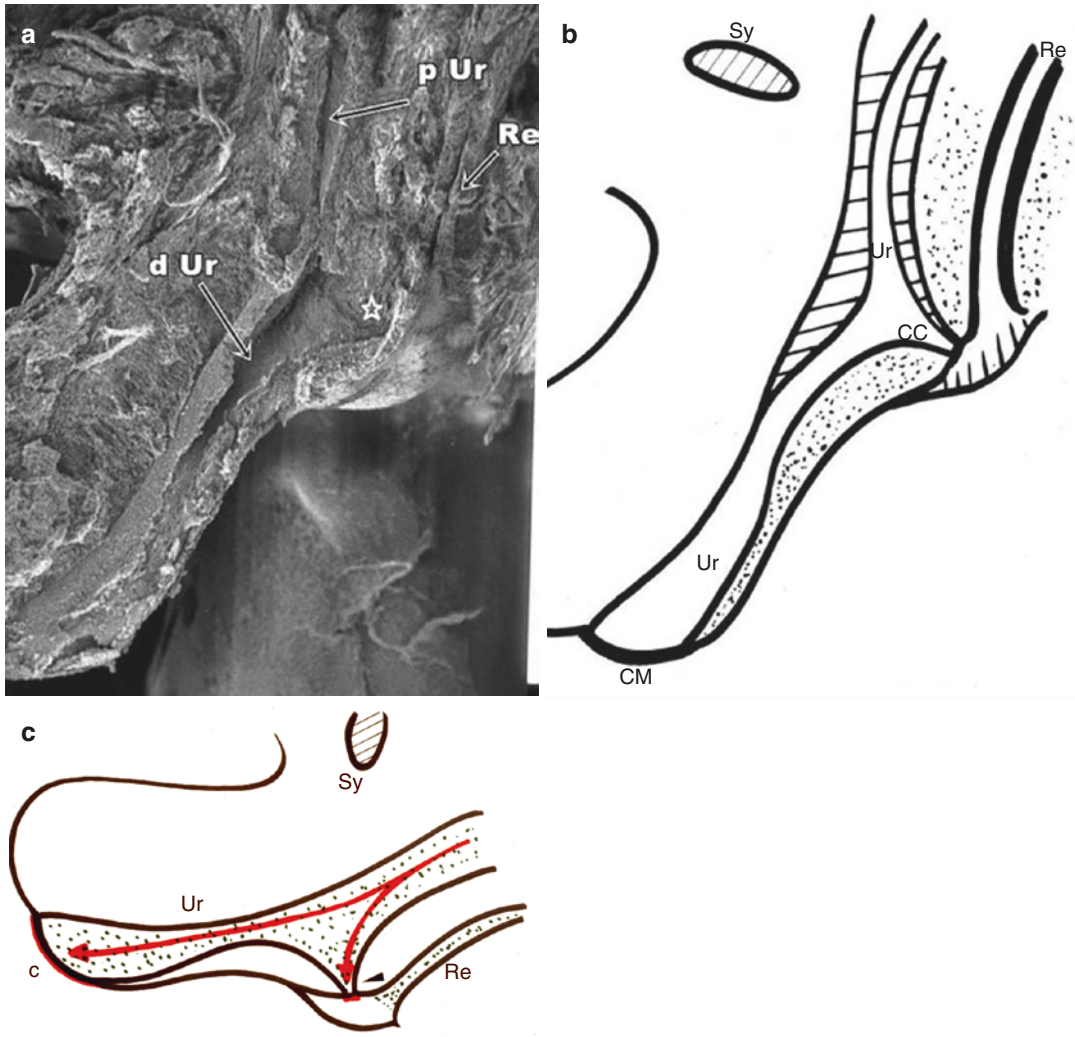

Fig. 2.21 Phallus of a rat ED 18.5. (**a**) The sex is not discernable by external inspection. The lateral portion of the phallus and the lateral wall of the urethra are removed. *p Ur* proximal urethra, *d UR* distal urethra, *Re* rectum. (**b**) The sketch describes the situation in A: *p Ur* proximal urethra, *d UR* distal urethra, *CC* urethral opening in females. Note that the urethra in this stage is not sexually determined. The female urethra is short and ends at the CC opening. (**c**) The male urethra is formed by the distal urethra, which extends to the tip of the pallus. *Sy* symphysis, *Ur* urethra, *C* cloacal membrane, *Re* rectum. SEM Pictures and schematic drawings © Dietrich Kluth

86]. Starting at embryonic day 13, the following parts of the midgut loop can be seen (Fig. 2.22a):

- A central part with the duodenum and the distal colon close to the root of the mesentery.
- A ventral part inside the extra embryonic coelom of the umbilicus (so-called 'physiological herniation'). Here the cecum and the distal small bowel can be identified.
- A middle part which connects the central part with the ventral part inside the umbilicus. Here the umbilical vessel, the small bowel on the right and the proximal part of the colon on the left can be seen (Figs. 2.22b, and Fig. 2.23d).

In the further development (ED 14—16) growth activities are seen in the area of the duodenum and inside the extraembryonic coelom.

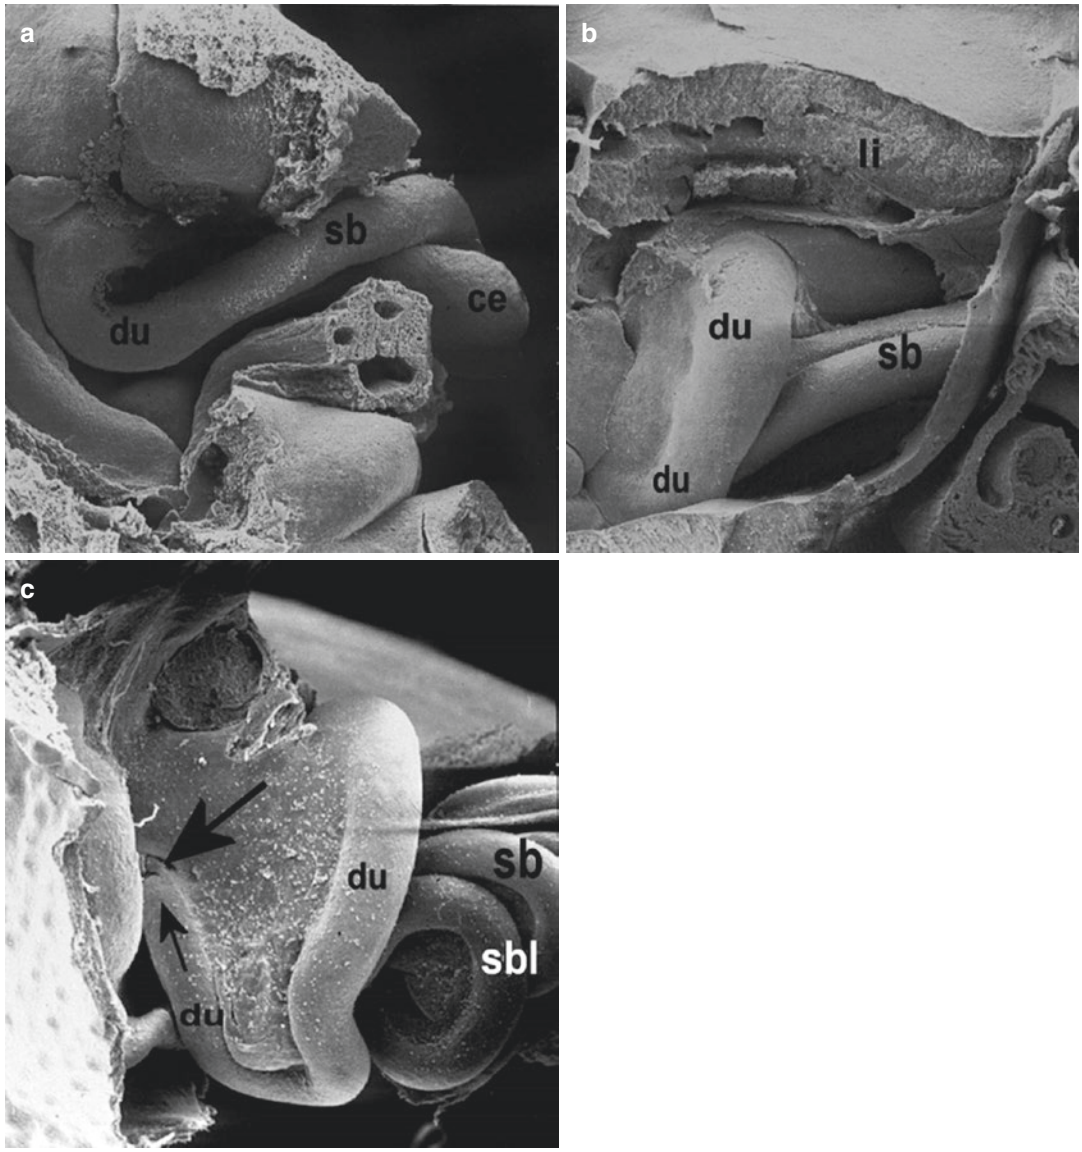

Fig. 2.22 Normal development of the midgut. (**a**) Rat embryo ED 13. The early midgut consists of three parts: A central part with the primitive duodenal loop (du), an extraembryonal part in the extraembryonic sac of the umbilicus (ce) and a straight part in between (sb). (**b**, **c**) The development of the central part, the duodenal loop (du), is seen. Note that the duodeno-jejunal junction is pushed beneath the root of the mesentery (*arrows* in **c**). This is caused by longitudinal growth of the duodenum. *sb* small bowel loops, *li* liver. SEM Pictures © Dietrich Kluth

In Fig. 2.22 the steps important for the duodenal developmental are shown. In Fig. 2.22b (rat embryonic day 15) the duodeno-jejunal loop has been formed due to longitudinal growth of the duodenum. Further growth pushes this loop beneath the root of the mesentery (Fig. 2.22c).

In Fig. 2.23, the development of the intraumbilical loops is shown. These loops are the result of longitudinal lengthening of the small gut. Note the absence of any signs of rotation around the axis of the mesentery in Fig. 2.23d in a phase of active loop development inside the extra embryonic coelom.

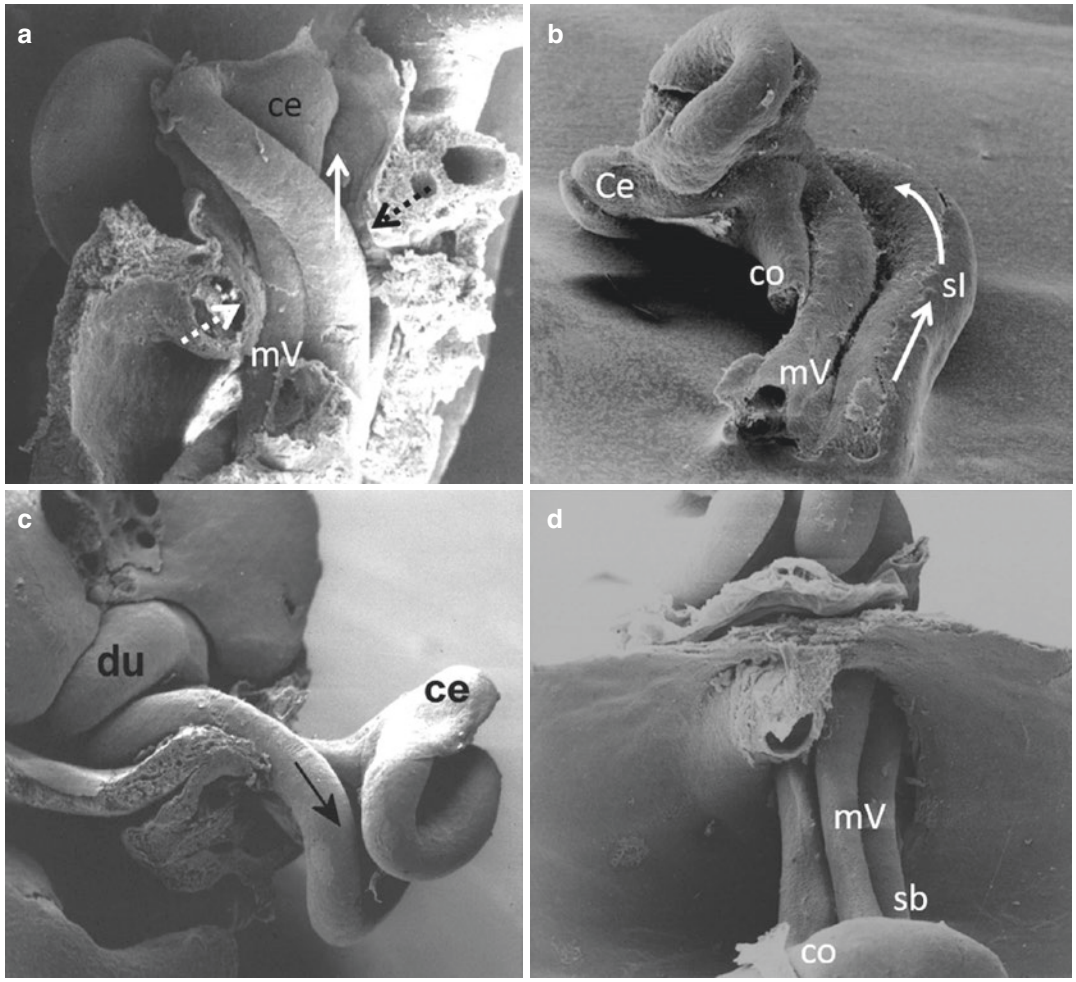

Fig. 2.23 Normal development of the midgut. (**a**) Rat ED 13. The cecum and the most distal part of the small gut are seen in the extraembryonic sac of the umbilicus. *Dotted arrows* indicate the border between extraembryonic and intraembryonic coelom. (**b**, **c**) Rapid lengthening of the small bowel leads to the formation of loops inside the extarembryonic sac of the umbilicus. Arrows indicate the direction of growth. (**d**) Note that during this process rotation around the axis of the mesentery does not take place. *ce* cecum, *sb* small bowel, *co* colon, *mV* mesenteric vessel. SEM Pictures © Dietrich Kluth

In Fig. 2.24, the 'return' of the midgut into the abdominal cavity is shown. The cecum is seen inside the abdominal cavity in a ventral position close to the abdominal wall (embryonic day 17). The colon is entirely to the left in this phase of development. It's a small bowel loop which is still extra embryonic inside the umbilicus. In this phase of small bowel 'return', the bowel loops have already developed locally inside the abdominal cavity (Fig. 2.22c).

We conclude from our observations that the midgut can be subdivided in three parts, of whom the central and the ventral part are of mayor importance. Localized longitudinal growth in the area of the duodenum leads to the formation of the duodeno-jejunal loop and its final position beneath the root of the mesentery. At the same time, localized growth of the small bowel has led to the formation of bowel loops inside the umbilicus and, later, inside the abdominal cavity. The

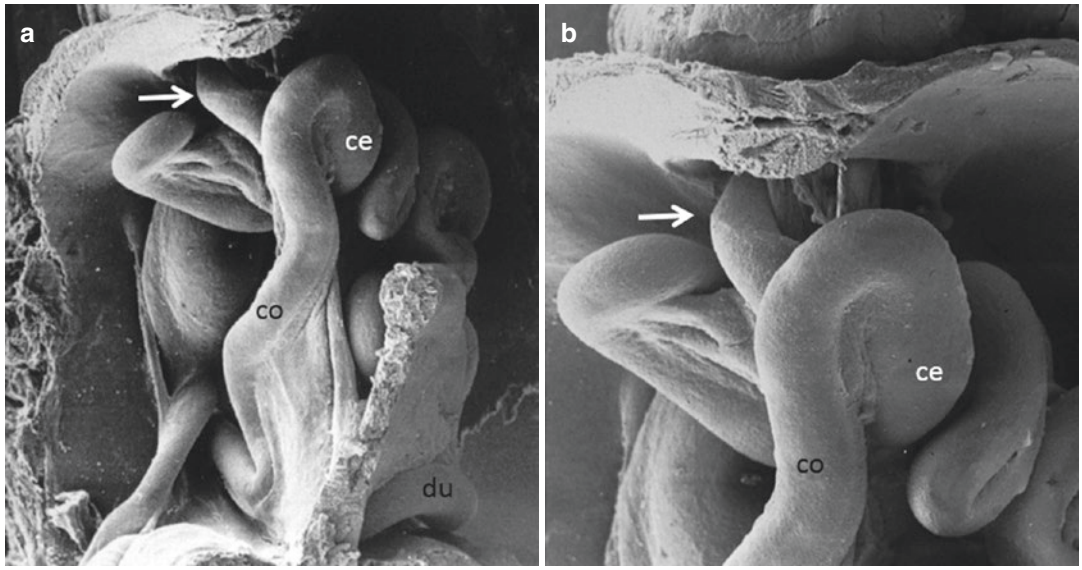

Fig. 2.24 Normal development of the midgut. Rat ED 17. (**a**) The Cecum (ce) is found in the abdominal cavity. A small bowel loop is still outside in the umbilical sac (*arrow*). *Co* colon, *du* duodenum. (**b**) Higher magnification of the area of the ventral body wall. *Ce* Cecum, *co* colon. SEM Pictures © Dietrich Kluth

growth activity of the large bowel is minimal, compared to that of the small bowel. Neither in the phase of loop formation inside the extra embryonic coelom of the umbilicus, nor in the phase following the 'return' of the gut into the abdominal cavity, rotation of the gut around the axis of the mesentery can be observed. All processes in midgut development are the result of longitudinal lengthening of gut.

2.3.11 Normal Testicular Descent

Since JOHN HUNTER in 1762, many researchers studied the embryology of testicular descent. In many of these studies, the importance of the gubernaculum during this process has been highlighted. However, a clear illustration of this rather simple process is still lacking [87].

Today, most researchers in the field [88–90] see two developmental phases during testicular descent:

- The intra-abdominal descent: In this phase, the testis, which initially lies in close contact to the kidney, moves into the inguinal area.
- The inguinal descent: In this phase the testis moves into the area of the scrotum.

We [11, 91] studied the morphology of testicular descent in rat embryos between embryonic day 15 and 20 using SEM in order to illustrate in detail the various steps of the testicular development. While in rat embryos at embryonic day 15, male and female gonads look still identical (Fig. 2.25a) they become clearly distinguishable in rats of embryonic day 16 (Fig. 2.25b). The male gonad is getting thicker and slightly shorter than the female gonad, but both gonads are initially in close approximation to the kidneys.

Starting at embryonic day 16.5, the testis moves away from the lower pole of the kidney. On ED 19 the testis is located between the lower kidney pole and the roof of the bladder (Fig. 2.26a) and moves towards the bladder neck at ED 21 (Fig. 2.26b). This brings the intra-abdominal descent to an end and the inguinal descent starts.

At the end of the intra-abdominal descent (ED 22), the bulb of the gubernaculum is still visible. (Fig. 2.27a). A little later, around birth (embryonic day 22), the bulb disappears partially and the pro-

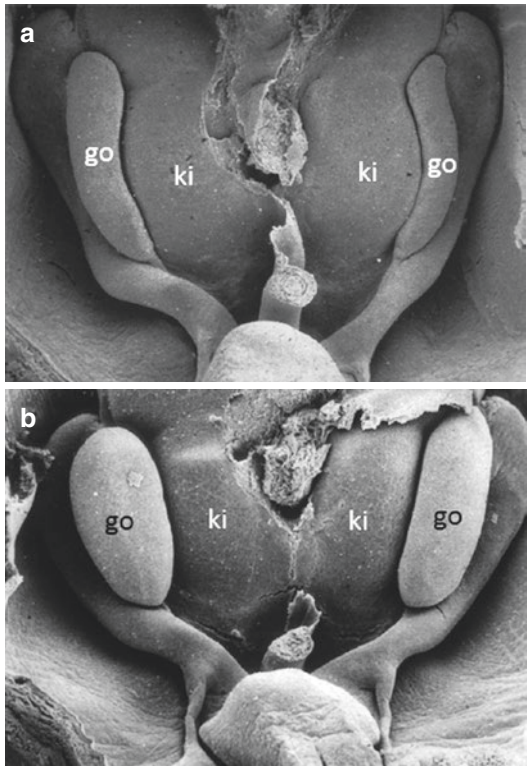

Fig. 2.25 Descensus of the testis. Rat ED 15, female rat in (**a**), male rat in (**b**). Notice the difference in the size of the male and female gonads (go). Both gonads lie in close approximation to the kidneys (ki). SEM Pictures © Dietrich Kluth

cessus vaginalis peritonei (PVP) develops (compare with Fig. 2.27b). Notice the rest of the bulb at the lower pole of the PVP. In this phase, the corda of the gubernaculum is still visible and attached to the caudal part of the epididymis, which has entered the PVP. At birth and later, the testis finally enters the PVP (Fig. 2.27c).

2.3.12 The Role of the Gubernaculum

In our series, we studied the formation and the fate of the gubernaculum (Fig. 2.28). In rat embryos at embryonic day 16 the gubernaculum consists of two parts, the gubernacular bulb and the corda of the gubernaculum (Fig. 2.28a). The corda is rather attached to the lower anlage of the epididymis (Fig. 2.28a, c) than to the testis, as it is often described in the literature. Furthermore, it is often assumed, that the testis is pulled downwards by corda and bulbus. While this—in initial stages—seems to be morphologically possible, we identified later stages, where testis and gubernaculum were positioned in such a way that pulling of the testis by the gubernaculum seems to be impossible (Fig. 2.28c, e).

Thus in our findings we cannot support the opinions about the role of the gubernaculum

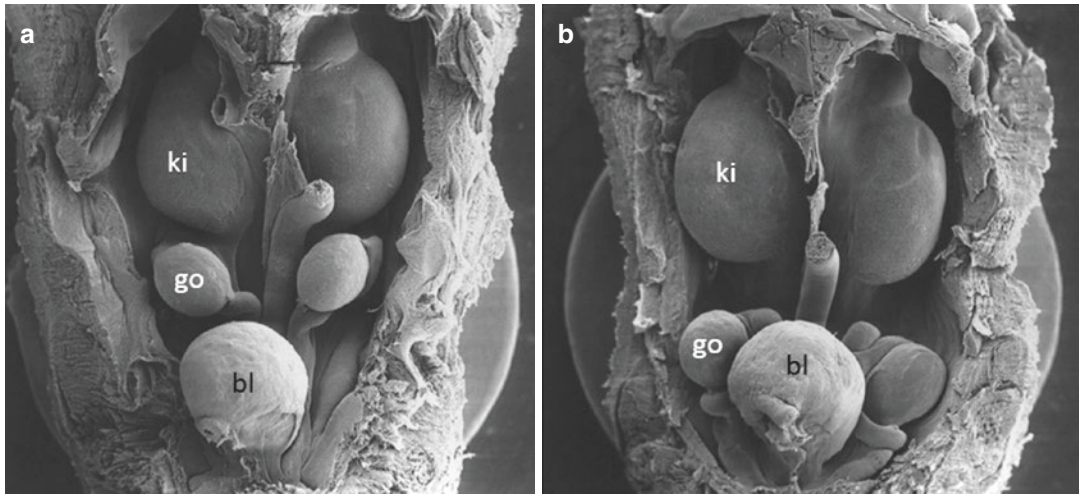

Fig. 2.26 Testicular descent: Intraabdominal descent (first phase). (**a**) Male rat, ED 19. The gonads (go) have lost contact to the lower pole of the kidneys (ki) and lie in the middle portion between kidney and bladder (bl). (**b**) Male rat, ED 21. The gonads are now close to the bladder in the inguinal area. This movement relative to the urinary bladder can't be attributed to the relatively ascent of the kidneys. SEM Pictures © Dietrich Kluth

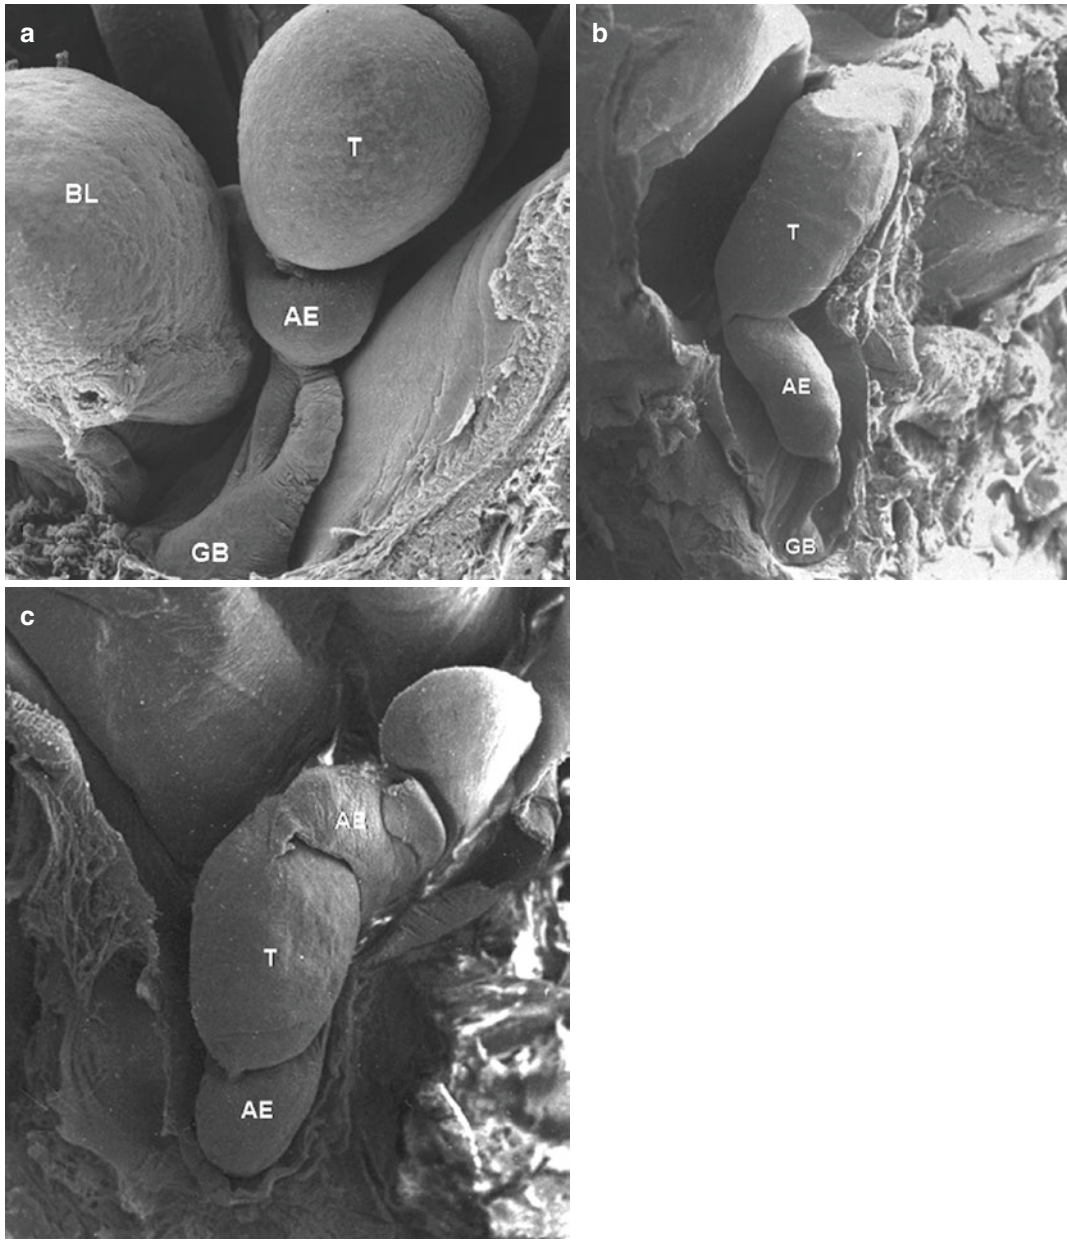

Fig. 2.27 Testicular descent: Inguinal descent (second phase). (**a**) male rat ED 21. The testis (T) has reached a position close to the inguinal region. The bulbic gubernaculum (GB) is still present. *BL* bladder, *AE* epididymis. (**b**) Male newborn rat, D 0. The bulbic part of the gubernaculum (GB) disappeared and the processus vaginalis peritonei is formed (PVP). The border between peritoneal cavity and PVP is marked by *arrows*. The epididymis has entered the PVP. The corda of the gubernaculum is still visible. (**c**) Male newborn D 1-5. Not only the epididymis but also half of the gonads (T) has entered the PVP. The gubernaculum has completely disappeared. *Arrows mark* the border between the peritoneal cavity and the PVP. *AE* epididymis. SEM Pictures © Dietrich Kluth

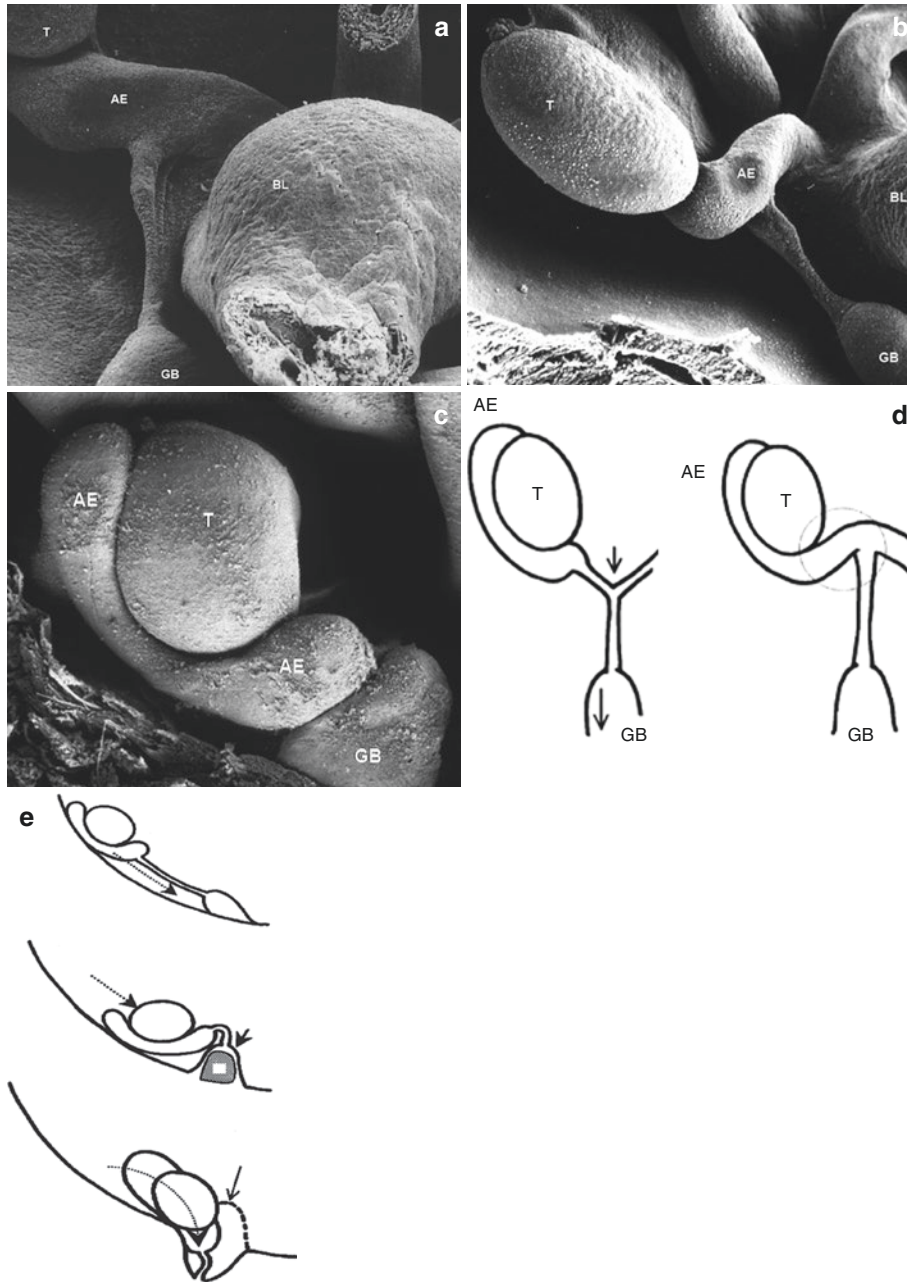

Fig. 2.28 Testicular descent: In this series of SEM pictures, the morphology of the gubernaculum is shown (rat ED 19). (**a**, **b**) Here the gubernaculum consist of two parts, the corda of the gubernaculum (*arrows* in **a** and **b**) and the bulbus of the gubernaculum (GB). The corda inserts rather into the caudal anlage of epididymis (AE)/ mesonephric ridge than into the testis (T), as often assumed. *BL* bladder. (**c**) While in A and B tension caused by the gubernaculum seems to be theoretically possible, C demonstrates that the testis (T) is rather blocked by the bulb of the gubernaculum (GB) than pulled. Rat ED 21, *AE* epididymis. (**d**) Many researchers believe that tension caused by the corda is at play during testicular descent. However, the morphology of the insertion zone of the corda into the anlage of the epididymis shown in A and B speaks against this assumption. Sketch on the left shows expected morphology (traction!) vs. observed morphology on the right. *AE* epididymis, *T* testis, *GB* bulbus of the gubernaculum. (**e**) The sketch summarizes our morphological data on the developmental sequence of the testicular descent. SEM Pictures and schematic drawing © Dietrich Kluth

during the testicular descent. Its main role seems to be its transformation into the PVP. We believe that intra-abdominal pressure probably plays an active role at least in the phase of the inguinal phase of testicular descent.

Surgery research • Newborn surgery • Animal models • Regenerative medicine • Innovation

3.1 Introduction

Pediatric surgeons have the privilege to care for patients at every stage of human development, from the fetus to the fully developed young adult. As such, we must cultivate and advance an all-encompassing knowledge base ranging from obstetrics to pediatrics to adult medicine and surgery. This unique, sweeping perspective on human disease requires an equally broad approach to research, which in our field is as vast and varied as it is stimulating.

Yet, despite the appeal of research in such a diversified and vibrant spectrum, the relative proportion of pediatric surgeons performing research appears to have been dwindling in recent years. While different factors can be debated as implicated in this scenario, perhaps one should be emphasized, namely the increasingly restricted exposure to research during training. The greater significance of this trend lies in the fact that, unlike most other components of this conjuncture, it has career-long consequences, rendering the unexposed trainees essentially unable to develop as independent investigators once they become practicing pediatric surgeons, notwithstanding the eventual will to do so. Regrettably,

fewer and fewer countries and institutions can afford the time and resources necessary for surgical trainees to develop a strong research background.

While the recent emphasis on a multidisciplinary approach to research has allowed for many developments that would not have been possible in isolation, we must aspire to a central role within research groups related to our specialty. Clinical expertise is often a pre-requisite for one to provide consequential guidance to the powerful scientific methodology currently available and the perspective offered by the pediatric surgeon cannot be replaced. By the same token, only we can protect and expand the role of research in the education of our future peers. This chapter is aimed at tendering some support, however limited, to this need.

It would be beyond the scope of any book chapter to present a comprehensive, exhaustive review of all the possible developments applicable to research in Pediatric Surgery. Here, we present a summarized overview of different aspects involving both laboratory- and clinical-based research that should be of interest to both trainees and practicing colleagues, through select examples representative of the far reach of our field. Our focus will be on translational research, as this is typically the chief dominion of the pediatric surgeon, as opposed to that of the basic scientist.

3.2 Animal Models

Although much can be learned from *in vitro* analyses of intracellular processes and defined cellular manipulations, especially in light of recent developments in cellular reprogramming, the complexity of organ systems or whole organisms cannot yet be substituted. Both developmental and interventional research pursuits still depend heavily on animal models, which remain the workhorses at most pediatric surgical laboratories.

There is now an overwhelming variety of animal models for research, spanning widely across taxonomic groups [1]. A few basic considerations should guide animal selection for a given experiment. One is of course the degree of correspondence to the human disease or biological process of interest. The options here are perhaps surprisingly broad, depending on the subject, not infrequently including significantly less prescient species, such as in the zebra fish model of lymphatic malformation, in addition to more predictable mammals. At the same time, species-specific variations in physiology and anatomy can render certain higher species essentially irrelevant to a given human disease process. For example, a swine model of naturally occurring congenital diaphragmatic hernia (CDH) (*Sus scrofa*) does not include pulmonary hypoplasia, virtually ubiquitous to CDH in human infants.

Another consideration is the availability of genetic tools conducive to in depth molecular and pathway-specific analyses of mechanisms behind the phenomena being studied. Mice (*Mus musculus*) constitute the prime representative of that set of considerations, not the least due to the plethora of knockout and knock-in murine models, though the thornier rat knockouts have also become options in the last several years. The International Mouse Phenotyping Consortium is striving to create viable strains of identical genetic background mice in which only one of the approximately 20,000 genes in the mouse genome can be selectively deactivated for systematic phenotypic screens, further expanding the scope of the murine genetic manipulation platform [2]. The more recent development of the first cloned rat also paves the way for the establishment of overexpression rat models based on targeted insertions [3].

Yet another consideration of special appeal to pediatric surgery is tolerance to fetal manipulation/intervention. While this can be accomplished in a number of species, sheep (*Ovis aries*) deserves special attention due to their inordinately high tolerance to such manipulations, the size of their fetuses and newborns, and the easily manageable gestational times. The ovine model can also be an asset to an additional aspect to be taken into consideration when selecting an animal model, namely is fast growth rate combined to the fact that their sizes are comparable to that of humans, from infancy to adulthood.

Meaningful growth is often a pre-requisite to pediatric surgical research, for example in projects involving different forms of structural repair.

Expectedly, as always, logistical and financial constraints come into play as well. The following is a brief review of select animal models of interest to certain specific groups of pediatric surgical diseases, as representative illustrations of the breadth of animal research in our field. Other lists equally focused on our specialty, though based on somewhat different criteria, should also be of particular interest to the reader [4].

3.2.1 Abdominal Wall Defects

Not infrequently, a given structural congenital anomaly can be modeled in animals by either of five methods: surgery; genetic manipulation; drugs/chemicals; other environmental manipulations; or it may be naturally occurring. Selecting which one best correlates with the clinical disease is not always straightforward, especially when the etiology of the human condition is unknown. Animal models of gastroschisis and omphalocele illustrate that scenario.

There is an inbred mouse strain, namely HLG/Zte, in which gastroschisis occurs spontaneously. The typical prevalence of 3% can be increased with irradiation during pre-implantation development [5]. Studies with these animals have identified a region of the mouse chromosome 7 as a responsible locus [6]. Further similar studies may shed more light on genes eventually involved in the development of abdominal wall defects.

Abdominal wall defects can also be induced experimentally with a variety of teratogens. However, these agents typically lead to inconsistent results, as well as multiple associated anomalies. Aminpyrine causes omphalocele when given to pregnant mice at midgestation [7]. This can be augmented by supplementation with barbital [8]. In rats, omphaloceles have been induced with maternal exposure to DA-125 (anthracycline antineoplastic agent) [9], beta-aminoprpioitrile [10], or flubendazole [11]. Additional teratogenic agents have been explored in assorted species, including doxorubicin hydrochloride [12], ethanol [13, 14], nitrous oxide [15], ethylene glycol [16], scopolamine hydrobromide [17], acetazolamide [18], and cyclooxygenase inhibitors [19]. The rate of gastroschisis in this studies, however, is somewhat limited, ranging from 3.7 to 19.8%. In guinea pigs, a daily period of maternal hyperthermia can result in abdominal wall defects, among other abnormalities [20].

Various species have been used in surgical models of gastroschisis, the most prominent of which are sheep, rabbit, and the chicken embryo. Haller et al. first described a sheep model of gastroschisis by operating on fetal lambs at midgestation and excising a full thickness disk of abdominal wall lateral to the umbilical cord [21]. The exposed intestine in surviving fetuses was edematous and matted, similar to the findings in humans. Langer and colleagues later modified this model by placing a silastic ring in the abdominal wall defect [22–24]. Though this design was associated with a relatively high rate of spontaneous abortion, it demonstrated that intestinal damage correlates with the time of exposure to the amniotic fluid. Less costly rabbit models of gastroschisis have also been described [25, 26]. Improvements in experimental fetal surgery have improved the success rate of this model to the range of 80–90% [27, 28]. An interesting modification of the leporine model has been described so as to remove the effect of amniotic fluid exposure on the intestinal damage during fetal development [29]. The least costly models for gastroschisis involve chicken embryos. The chicken embryo is enveloped in amniotic fluid and a number of membranes. After confirming fertility of an egg, a 1 cm defect is created in the shell. Using the allantoic vessels and the umbilical cord as landmarks, the physiologic umbilical hernia sac can be incised in order to create a gastroshisis [30]. Using this model, the effects of amniotic fluid exchange as a means to reduce the severity of intestinal damage have been studied [31–33].

3.2.2 Biliary Atresia

Multiple theories have been proposed to account for the varied spectrum of pathology in biliary

atresia, ranging from putative congenital malformations of the bile ducts to the presence of a causative infectious agent. Reflecting this diversity, several types of models have been described.

Lampreys provide an arguable natural model for biliary atresia. Adult lampreys are the only vertebrates with an absence of a bile duct system in their livers. This occurs through programmed degeneration of the biliary tract during normal morphogenesis [34]. As the biliary tract regresses, the adult lamprey develops progressive cholestasis and bile pigment accumulation. The spectrum of pathology resembles the human form of the biliary atresia with the accumulation of luminal debris, basement membrane thickening, disorganization of hepatic architecture, extra-hepatic bile duct atresia, and shrinkage or loss of the gall bladder [35]. These animals live for several years after biliary tract regression allowing for studies on compensatory response to cholestasis as well as changes in the evolution of biliary atresia at the molecular level [36].

Bile duct injury has been induced with several agents in an attempt to mimic histological features of biliary atresia. After having identified low levels of L-proline in the serum of patients with biliary atresia, Vacanti and Folkman were able to induce bile duct enlargement with a continuous intraperitoneal infusion of L-proline [37]. 1,4-phenylenediisothiocyanate (PDT), an antihelminthic agent, can be employed to induce bile duct inflammation [38, 39]. The bile duct pathology is related to the timing of exposure to this agent. When gavaged in the postnatal period, PDT causes bile duct enlargement. When gavaged to pregnant rats, PDT causes fibrosis in the bile ducts. However, with a combination of gavage to the pregnant rats and during the postnatal period, the bile ducts exhibit wall thickening with stenosis and atresia. Further study of this temporal relationship may aid in the understanding of bile duct development. Another agent, phorbol myristate acetate (PMA), has been infused directly into the gallbladders of adult rats with a subcutaneous pump [40]. After a 28-day infusion, portal fibrosis and neo-cholangiogenesis were observed. PMA is a nonspecific activator of inflammation and may lead to insights on the role of inflammation in the development of biliary atresia.

Surgical models involving ligation of the fetal bile duct have been described in sheep [41]. Although the distal bile duct can become atretic, similarly to what is found in the human form of biliary atresia, the same does not apply to the impact on the liver, which does not correlate with what is found in the human disease. More recently, it has been shown, also in the ovine model, that occlusion of the fetal bile duct and the consequent hyperarterialization of the liver actually/instead significantly affects hepatic hematopoiesis, leading to a new perspective into the mechanisms that govern hematopoiesis in general, illustrating the potentially far reaching impact of fetal surgical models [42].

3.2.3 Congenital Diaphragmatic Hernia

Multiple animal models of congenital diaphragmatic hernia (CDH) have been described, however only few bear relevance to the human disease.

A model of familial CDH has been described in pigs which were originally bred to produce anorectal malformations, with a prevalence of approximately 10% [43]. Animals show herniated intra-abdominal organs within the thoracic cavity, but not the pulmonary hypoplasia characteristic of CDH. Several genetically manipulated mice models have also demonstrated CDH in combination with other associated malformations. If both murine retinoic acid receptors are deleted, mice have a high incidence of cranial, vertebral, limb, cardiac, foregut and pulmonary malformations, in addition to occasional CDH [44, 45]. Mutations in the homeobox *Hlx* gene result in CDH with large lungs and small livers [46]. Homozygous inactivation of *WT-1* causes CDH and major defects in the urogenital system [47]. Knockout mice homozygous for *Slit3* deficiency exhibit CDH in a ventral midline location with herniation of the liver and gallbladder, along with renal and ureteral agenesis [48].

The first surgical model of CDH was described by De Lorimier using third trimester fetal lambs [49]. Through a maternal hysterotomy and a fetal thoracotomy, a large defect was created in the left dome of the diaphragm. This model resulted in hypoplastic lungs, however with essentially normal pressure-volume curves. Further studies using an inflatable balloon in the fetal chest produced significantly reduced tidal volume and pulmonary compliance compared with control animals [50, 51]. Deflation of the balloon *in utero* improved these pathophysiologic effects and improved newborn survival [50]. In another variation of fetal manipulation, the diaphragmatic defect was created in the second trimester rather than the third, in order to more closely mimic the human disease [52]. In these animals, the lungs were hypoplastic, had abnormal airway branching, and a smaller and more muscularized pulmonary arterial tree when compared with controls [53, 54]. The fetal surgical model of CDH has also been described and further explored in rabbits [55–57]. As these surgical models are created during fetal life, they hold limited significance to the embryogenesis of CDH.

Experimental CDH can also be produced in other animal species through different interventions, other than surgical creation of the defect, including: exposure to diet deficient in either vitamin A [58, 59], zinc [60], or cadmium [61]; administration of either thalidomide [62], anti-rat rabbit serum [63], 2,4-diclorophenil-p-nitrofenilic ether (nitrofen, a herbicide) [64–66], or polibromate biphenils [67, 68]; and genetic manipulations, such as FOG-2, COUP-TFII, and GATA-4 mutations [69–71]. However, with the possible exception to the nitrofen model, there's been no conclusive relationship between these experimental models and clinical/epidemiological data in humans. The nitrofen model has been increasingly accepted as the most relevant to clinical CDH due to the fact that, in that model, the pulmonary hypoplasia precedes the diaphragmatic defect and is independent from the latter. This is in accordance with today's favored notion that the primary defect is not in the diaphragm, but rather in the developing lung buds, with the diaphragmatic defect being actually secondary to a primary pulmonary hypoplasia. Such pulmonary hypoplasia, in turn, could be made worse by the herniated content into the chest.

Laboratory developments in CDH include a peculiar facet which further epitomizes the impact that fetal intervention models can have in our understanding of not only a given disease, but also of germane biological processes. In the sixties, Carmel and colleagues used a healthy leporine model to demonstrate that fetal tracheal occlusion induced lung growth [72]. In the seventies, Alcorn et al. suggested, in a healthy ovine model, that fetal tracheal occlusion and drainage led to hyperplasia and hypoplasia of the lungs, respectively [73]. It was not until the early nineties, however, that Wilson et al. showed, also in sheep, that fetal tracheal occlusion could actually be a means to reverse the pulmonary hypoplasia associated with both CDH and fetal nephrectomy [74–76]. Wilson's sentinel studies on therapeutic fetal tracheal occlusion have triggered one of the most fertile experimental and clinical development sprees of recent memory in our specialty, with ramifications that have crossed the boundaries of our field.

3.2.4 Hirschsprung's Disease

A number of animal species have naturally occurring aganglionic megacolon, including mice, rats and horses [77–79]. In 1966, Lane described two strains of mice with autosomal recessive aganglionosis [79]. The lethal spotting (ls) mice have approximately 2 mm of aganglionosis while piebald lethal (s^l) mice have approximately 10 mm of aganglionosis. Lane and Liu also described megacolon associated with a dominant spotting gene (Dom) in mice, characterized by distal colonic aganglionosis and a long hypoganglionic transition zone [78]. Ikadai and Agematsu described an autosomal recessive total colonic aganglionosis in a strain of rats [77]. These animals have a high mortality rate and are only able to survive for 3–4 weeks after birth, eventually succumbing to severe bowel obstruction and enterocolitis. Histological studies using acetyl cholinesterase whole-mounts in all these rodent

models are virtually identical to the human histopathology [80].

Various genes have been actively disrupted in mice, producing phenotypes similar to human Hirschsprung's Disease (HD). The Ret gene encodes a receptor tyrosine kinase, which has four ligands: glial cell line derived growth factor (GDNF), neurturin (NTN), artemin (ATM) and persephin (PSP) [81]. The complete receptor complex includes the Ret receptor tyrosine kinase and a glycosylphosphatidylinositol-anchored binding component (gfrα1, gfrα2, gfrα3 or gfrα4). This receptor has been suggested to function as an adhesion molecule, which is required for neural crest migration and could also play a role in either differentiation or survival of the neural crest cells which have stopped migrating [82, 83]. Ret (−/−) transgenic mice have a homozygous, targeted mutation of the tyrosine kinase receptor resulting in a loss of its function. These mice exhibit total intestinal aganglionosis and renal agenesis [84]. The Ret gene has been demonstrated to be a major gene causing HD in humans. Mutations of Ret account for 50% of familial and 15–20% of sporadic cases of HD [85–88]. GDNF, one of the Ret receptor ligands, stimulates the proliferation and survival of neural crest derived precursor cells in the embryonic gut [89, 90]. Mice homozygous for null mutation in Ret, GDNF and gfrα1 have almost identical phenotypes characterized by failure of enteric nervous system development distal to the esophagus and absent kidneys [84, 91–95]. Although a causative role for GDNF mutations in some patients with HD has been suggested, the occurrence of such cases is uncommon. It is more likely that the GDNF mutations are involved via its interaction with the Ret receptor [96, 97]. No gfrα1 mutations have been identified in patients with HD [98].

Endothelins are intercellular local messengers that comprise four members to date: ET-1, ET-2, ET-3 and VIP. They transduce a signal via two cell surface transmembrane receptors: ENDR-A and ENDR-B [81]. Both ET-3 and ENDR-B genes have been disrupted and have been identified as the cause for the natural mutants lethal spotting mice and piebald lethal mice, respectively [99, 100]. Moreover, a transgenic mouse ENDR-B knockout has a phenotype identical to the piebald lethal mouse [101]. As the connection between mutations in the Ret receptor and familial HD was established, ET-3 and ENDR-B mutations were also implicated in the disease [99, 100, 102]. However, these mutations have been demonstrated in less than 10% of the cases of HD in humans [103]. Endothelins are initially produced as an inactive proendothelin that has to be activated by a specific enzyme, the endothelin-converting enzyme (ECE). Two ECE genes have been described, ECE-1 and ECE-2 [81]. ECE-1 knockout mice show craniofacial and cardiac abnormalities in addition to colonic aganglionosis [104]. A heterozygous ECE-1 mutation has been identified in a patient with HD who also had craniofacial and cardiac defects [105].

Sox10 is a member of the SRY-related family of transcription factors that is expressed by enteric nervous system precursors before and throughout colonization of the gut mesenchyme [81]. Disruption of the Sox10 gene has been demonstrated to be the cause of the Dom mouse natural mutant [106, 107]. Interestingly, both homozygous and heterozygous animals produce a lethal HD-like phenotype [108]. Mutations in Sox10 have been identified in Waardenburg syndrome associated with HD [109].

Phox2B is a transcription factor that is essential for the development of the neural crest derivates as it regulates the Ret expression in enteric nervous system precursors [110, 111]. Targeted Phox2B gene disruption leads to a complete absence of enteric nervous system in the mice, a phenotype that is very similar to that of the Ret knockout mouse [110]. Garcia-Barcelo et al. reported that Phox2B deficiency might predispose to HD in humans [112].

Pax3 is a member of the paired-box containing family of nuclear transcription factors that is expressed in neural cell precursors giving rise to enteric ganglia and synergizes with Sox10 to activate an enhancer in the Ret gene [113]. In the mouse, Pax3 mutations result in a phenotype characterized by deficient enteric ganglia in the heterozygous state. Homozygous deficient embryos die during mid-gestation

with neural tube defects, cardiac defects and absence of enteric ganglia [113]. So far, no Pax3 mutations have been identified in patients with HD, though.

Most surgical models of HD have involved chick embryos because they are easily accessible and the development of their enteric nervous system has been well studied. In that species, aganglionosis can be caused by surgical ablation of the premigratory neural crest [114]. This model is useful for the investigation of possible treatment strategies. It has been used to recolonize aganglionic bowel with neural crest cells by transplanting tissue obtained from the dorsal neural tube [115–117]. It has also been employed to show that neurons from more proximal regions of bowel are capable of recolonizing distal bowel and forming enteric ganglia [115, 118].

Sato and colleagues described a chemical model of HD [119]. They created segmental aganglionosis by applying benzalkonium chloride topically to the colon and rectum in rats. This model has been reproduced in mice and guinea pigs [120, 121]. It has also been used in the distal esophagus as a model of achalasia [122]. Benzalkonium chloride causes cell damage and death by producing an irreversible depolarization of the cell membrane. Due to the high cell membrane negative charge of neurons, they are more intensely affected then other cells. As a result, benzalkonium chloride induces a selective neuronal ablation in the intestinal wall eliminating almost all myenteric neurons and glia in treated segments [121]. Although the aganglionic bowel does not show hypertrophic nerve bundles and the chemical does not affect the number of submucosal neurons, the treated part does become narrowed and the rectoanal reflex is abolished [119]. Compared to the other models of HD, this technique is inexpensive, easy to perform and the animals can survive longer. It has been used to study functional and structural changes in the bowel resulting from loss of these neural elements. It could also be used to study the chronic changes caused by the aganglionic segment, as well as the long-term effects of different surgical treatments [123–128].

3.2.5 Necrotizing Enterocolitis

To date, no true animal model for necrotizing enterocolitis (NEC) has been described. Nevertheless, as multiple factors have been implicated in the pathogenesis of NEC, several animal models exist that may provide useful platforms for the study of different aspects relevant to the pathophysiology of this disease.

The ischemia/reperfusion model involves direct occlusion of mesenteric vessels or the superior mesenteric artery for varied periods of time followed by reperfusion. It has been performed in different species. In one study in neonatal piglets, the mesenteric vessels were tied off at different points near the distal ileum for 48 h [129]. There was a higher chance of intestinal injury when the occlusion was closer to the ileocecal junction. The degree of injury was greatest in low birth weight piglets as measured by ulceration, vascular engorgement, pneumatosis intestinalis, full-thickness necrosis, and ulceration with perforation. In normal birth weight piglets no injury was observed. This model allows for the investigation of eventual differences in the intestinal response to injury dependent on developmental stages. In mice, the time for the development of ischemic injury following vascular occlusion is substantially less than in low birth weight piglets. For example, occlusion of the superior mesenteric artery for 20 min in adult mice can result in the development of ischemic intestinal lesions in 50% of the animals by 48 h [130].

Studies in human infants with NEC have shown that, within the intestinal lumen, the pH was generally less than 5.0, the protein content less than 5 g/dL, and sufficient carbohydrate and bacteria were available to produce organic acids by fermentation [131]. Based on these data, investigators have created a rabbit model of NEC using a bovine casein formulation acidified with propionic acid [131, 132]. In weanling rabbits, either saline or a solution of 10 mg/mL casein and 50 mg/mL calcium gluconate acidified to a pH of 4.0 was instilled into isolated intestinal loops triggering increased intestinal blood flow, mucosal permeability and histamine release. After 3 h,

the villa were blunted, the lymphatic vessels dilated and edema was observed [133]. After 16 hours, several rabbits had hemorrhagic necrosis and died. Advantages of this model include its simplicity and reproducibility as well as the fact that assorted animals at varied stages of development can be evaluated as to their response.

3.2.6 Short Bowel Syndrome

Perhaps not surprisingly, many models of short bowel syndrome (SBS) have been described. For example, intestinal resection and subsequent gut adaptation have been characterized in the pig [134, 135], dog [136–138], rat [139, 140], and mouse [141]. Warner and colleagues have shown that the murine model can be particularly useful for the study of various genes germane to intestinal adaptation [141]. In this model, a proximal resection is preferred, as adaptive changes are most pronounced in the distal intestine. Large animal models such as the pig are more useful for the development of new surgical bowel lengthening techniques [142–144].

3.2.7 Parenteral Nutrition

Now exceedingly rare due to animal welfare regulations, canine models were instrumental to one of the most relevant achievements not only in pediatric surgery, but in all of medicine and surgery, namely the ability to sustain life exclusively by parenteral nutrition, chiefly through the work of Dudrick and colleagues [145]. In their original study, the aim was to support growth and development in beagle puppies for 10 weeks [146]. Small lipoid pigment deposits and hemosiderin pigment were present in the liver, so dosages of fat and iron were reduced. These results lead to a subsequent study in which 6 beagle puppies were fed entirely by central venous infusion for 72 to 256 days and compared with their littermates [147]. These puppies exceeded their orally fed control littermates in weight gain and matched them in skeletal growth, development, and activity for the study period. The longest-term animals, fed for 235 and 256 days, more than tripled their body weight and developed comparably to their control littermates. These studies first demonstrated that it was both possible and practical to feed animals entirely by vein for prolonged periods of time without excessive risks or compromise of growth and development. Soon thereafter, Dudrick and colleagues administered total parenteral nutrition to six severely malnourished adult patients with chronic, severe gastrointestinal disease for up to 48 days [148]. Positive nitrogen balance was achieved in all of them, along with weight gain, normalized wound healing, and increased activity. All patients were eventually discharged from the hospital. The first neonatal administration occurred in that same year, in an infant with near-total small bowel atresia who underwent a massive intestinal resection [149].

3.2.8 Vacter and Other Models

As previously stated, this was not to be an all-inclusive list, but rather one illustrative of the different development avenues offered by a variety of animal platforms. Other models applicable to the pediatric surgical diseases discussed above, as well as models of interest to other pathological processes, will be discussed in their respective chapters. A special note must be mentioned on the remarkable variety of models of the VACTER (vertebral, anorectal, cardiac, trachea-esophageal, and renal) association, both as far as mechanism of action, as well as variability within the broad spectrum of this "syndrome" [4, 150–159].

3.3 Cell-Based Research

Cell-based therapies remain largely experimental, yet cell-based research has undergone dramatic growth and diversification over the last few decades. Certainly, in light of recent advances in stem cell biology, tissue engineering, gene manipulations, and other so-called regenerative medicine strategies, it is reasonable to speculate that these therapies may become alternatives, if not preferred treatment modalities, for a number

of structural congenital anomalies and other diseases within the realm of pediatric surgery in the not so distant future [160, 161]. The following is a much summarized outline of a few aspects of this burgeoning field that are of particular consequence to our specialty.

Prenatal stem cell and gene therapies have tremendous potential to treat a range of disorders that can be diagnosed or predicted before birth, stemming from the unique environment present during fetal developmental, which can facilitate and enhance cellular engraftment. A notable example is *in utero* hematopoietic stem cell transplantation (IUHSCT). While few disorders have a compelling rationale for IUHSCT based on the prevention of irreversible damage to the fetus before birth, such as for example glycogen storage diseases with neurologic involvement, this methodology can be a powerful means to induce tolerance to transplantation later in life. Flake and colleagues have developed germane work in this area aimed at maximizing chimerism through a variety of strategies so as to achieve complete or near complete replacement of host hematopoiesis by donor cells without toxicity or graft versus host disease in rodent models [162–164]. Consistent results in preclinical large animal models are now being pursued by that group and others [165].

Fetal tissue engineering is another notable development. It constitutes a novel therapeutic concept in perinatal surgery, involving the procurement of fetal cells, which are then used to engineer tissue *in vitro* in parallel to the remainder of gestation, so that an infant, or a fetus, with a prenatally diagnosed birth defect could benefit from having autologous, expanded tissue readily available for surgical implantation in the perinatal period. The fetus is a prime tissue engineering subject, both as a donor and as a host. The many exclusive characteristics of fetal cells, in conjunction with the developmental and long-term impacts of engineered graft implantation into a fetus or a newborn, add new dimensions to tissue engineering generally. Also, the fact that certain congenital anomalies present as perinatal surgical emergencies further justifies the fetal tissue engineering principle. Our group and others have been developing this notion in a variety of animal models of structural congenital anomalies, typically employing the amniotic fluid as a preferred source of fetal cells [166–180]. Preclinical studies have been reported and the first clinical trials are expected for the near future [181–183]. Another facet of fetal cell-based treatments of structural anomalies being developed experimentally is the use of fetal neural stem cells for the repair of spinal cord damage in the setting of neural tube defects, such as spina bifida [184]. Additionally, select fetal cells have also been proven valuable experimentally in studies on wound healing modulation [185].

Tissue engineering techniques have already been used to repair congenital anomalies postnatally in children. Shin'oka and colleagues have accumulated considerable clinical experience with the use of engineered conduits as vascular replacements in low-pressure systems, in children with varying forms of complex congenital cardiovascular anomalies [186–190]. Further clinical experience with tissue engineering in pediatric surgery beyond the more prevalent anecdotal reports is expected in the coming years.

More recently, transamniotic stem cell therapy (TRASCET) has emerged experimentally as a novel therapeutic strategy for the treatment of different birth defects. It is based on the principle of harnessing/enhancing the normal biological role of mesenchymal stem cells that are naturally occurring in the amniotic fluid for therapeutic benefit. Specifically, we have recently shown that amniotic fluid-derived mesenchymal stem cells (afMSCs) play a central role in fetal wound healing, widely known to be enhanced when compared with postnatal repair of tissue damage [185]. This germane finding was not only the first demonstration of a biological role for any amniotic cell, it has also provided validation for the use of afMSCs in regenerative strategies, in that these cells already play a regenerative role in nature. More recently, we have also shown, in different animal models, that the simple intra-amniotic delivery of afMSCs in large numbers can either elicit the repair, or significantly mitigate the effects associated with major congenital anomalies, putatively by boosting the activity

that these cells normally have. For example, concentrated amounts of these cells injected into the amniotic cavity can induce partial or complete coverage of experimental spina bifida by promoting the local formation of a host-derived primitive skin, thus protecting the spinal cord from damage [191, 192]. Placenta-derived MSCs also seem to be a suitable option for TRASCET, at least in experimental spina bifida [193]. In another example, TRASCET has been shown to significantly alleviate the bowel damage associated with gastroschisis [194]. Many other applications of this practical therapeutic concept, involving a variety of congenital anomalies, are currently being investigated.

3.4 Clinical Research

Clinical research has evolved appreciably, particularly over the last two decades. It has essentially become a science deserving of a whole book, rather than a segment of a book chapter. The several aspects that make up clinical research need careful planning and execution if a study is to be any relevant. More specifically, conceiving the research question(s); establishing the appropriate study/trial format; defining randomization criteria when suitable; choosing and recruiting the research subjects; estimating sample size and power; assessing control/independent variables and/or causal interference; designing questionnaires and interviews; organizing and managing databases; analyzing data; implementing quality control; and addressing ethical issues are just some of the components that need to be tackled before one can embark on a meaningful project. By the same token, as the clinical research endeavor becomes more refined, it expectedly subdivides, perhaps more notably between clinical trials and outcomes research.

As critical as it is to any medical/surgical field, the overall adequacy of clinical research design and reporting in our specialty has been rather inconsistent over time [195]. Fortunately, however, pediatric surgeons have grown increasingly more discerning of late, progressively driving our scientific journals and professional societies to implement enhanced and more standardized peer-review guidelines which ultimately should be of great benefit to the field as a whole [195–199].

3.5 Final Considerations

The history of our young specialty is already rich in original translational initiatives which have shaped clinical practice both within and across the boundaries of our field. Among the many of these, perhaps one should stand out as an inspiration to all of us. A pediatric surgeon, Dr. M. Judah Folkman, was the first to propose and coin the term "antiangiogenesis" as a potential therapeutic approach to cancer and other conditions in his landmark paper of 1971 [200]. With this seminal insight, he established a new perspective on cancer biology by expanding the focus beyond the tumor cells to their microenvironment. The concept that proliferating endothelial cells may be better therapeutic targets than the neoplastic cells themselves represented a momentous shift of focus and triggered an enormous research enterprise. Folkman's direct and rational approach to angiogenesis redefined cancer biology, as well as multiple other processes in health, embryonic development, and other diseases [201]. It has been predicted that angiogenesis-related therapies can eventually benefit half a billion people worldwide [202].

As Dr. Folkman used to say, "science goes where you imagine it". Let us hope that more and more of our colleagues can be drawn by that inspirational vision and manage to incorporate either of the many forms of pediatric surgical research into their daily activities and ambitions.

4 Antenatal Diagnosis: Current Status for Paediatric Surgeons

Ryan Hodges, Luc De Catte, Roland Devlieger, Liesbeth Lewi, Tim Van Mieghem, and Jan Deprest

Abstract

In this chapter we review antenatal diagnosis and obstetric management of fetal conditions that are relevant to paediatric surgeons. We restrict our discussion to fetal conditions that have been shown to, or have the potential to, benefit from in utero surgical therapy.

Keywords

Prenatal diagnosis • Fetal medicine • Fetal surgery

4.1 Introducing the Fetal Patient

The ascendancy of antenatal imaging and genetic biotechnology has transformed fetal medicine in the modern era. In current clinical practice, women are offered a raft of early pregnancy screening options for aneuploidy, placental disorders and increasingly earlier diagnosis of fetal abnormalities. The introduction of first trimester ultrasound for nuchal translucency measurement as part of Down syndrome screening also potentiates early diagnosis of several major structural malformations [1–6]. For pregnancies categorized as higher risk based on this early screening or on past or familial history, invasive genetic diagnostic testing can be pursued and further highly specialized diagnostic fetal ultrasound and echocardiography can be offered from 16 weeks gestation [7–9]. Furthermore, fetal magnetic resonance offers additional imaging capabilities to further define anatomical defects detected on ultrasound screening. Most recently, the stage is now set for non-invasive prenatal diagnosis, whereby free fetal DNA is extracted from maternal plasma during pregnancy, to radically change our approach to antenatal diagnosis as high resolution genome wide evaluation becomes available [10]. Multidisciplinary counselling, therefore, must assume even greater

clinical importance if we are to effectively assist pregnant women to navigate through the increasingly complex information and myriad of choices that come with improved antenatal diagnosis.

In this regard, for some very selected abnormalities, fetal surgical intervention may prove beneficial. It is indeed possible that early antenatal diagnosis will allow timely *in utero* surgical correction of an anatomic defect or reverse a pathophysiologic process, which may then permanently alter the trajectory of growth and development in a positive way. For this to be successful, however, strict criteria have been proposed as a means of justifying the implicit risks to the mother and fetus by surgically invading the amniotic cavity during pregnancy (Table 4.1, [11]). Of paramount importance in this selection is accurate antenatal diagnosis with a clearly defined antenatal and postnatal course. In recent years, we have made some headway in defining these parameters for certain pathologies. Furthermore, detailed sonographic diagnostic criteria, often complemented by fetal MRI, have developed novel predictive indices to better delineate the likely *in utero* progression of disease, health at birth and even in the neonatal period. This has allowed patient selection for fetal intervention to be refined [12]. In addition, the literature has transcended from heterogeneous, small observational studies of fetal surgical interventions to successful multicentre randomised trials for instance on twin-twin transfusion syndrome [13], myelomeningocoele [14], congenital diaphragmatic hernia [15, 16] and lower urinary tract obstruction [17]. Notwithstanding the maternal burden, we are now in a better position to provide counselling to parents to determine whether fetal surgery is likely to rescue abnormal fetal development or not. There remains more to be done. It should be remembered the inspiration and translation of fetal surgery has all come from the careful antenatal examination and meticulous description of the fetal patient.

Table 4.1 Criteria for fetal patient selection

1. Accurate diagnosis, staging where relevant, with exclusion of associated anomalies
2. Well documented natural history and prognosis of the disease
3. No effective postnatal therapy
4. *In utero* surgery shown to be feasible and effective in animal models
5. All interventions performed in dedicated multidisciplinary fetal treatment centres with strict protocols, local Ethics Committee approval and informed consent of mother or parents.

Adapted from Harrison, M.R. and N.S. Adzick, The fetus as a patient. Surgical considerations. Ann Surg, 1991. 213(4):279–91; discussion 277–8; used with permission

Herein lies the focus of this chapter, where we review antenatal diagnosis and obstetric management of fetal conditions that are relevant to paediatric surgeons. We restrict our discussion to fetal conditions that have been shown to, or have the potential to, benefit from *in utero* surgical therapy.

4.2 Lower Urinary Tract Obstruction

4.2.1 Definition and Epidemiology

Lower urinary tract obstruction (LUTO) refers to a heterogeneous, pathological group of disorders that directly affect the urethra. The presence of posterior urethral valves (PUV) is most common, whereby a Mullerian or cloacal embryological membranous remnant is responsible for the obstruction. Obstruction can also be caused by urethral atresia, urethral stenosis, ectopic insertion of a ureter, perivesical tumours and prune belly syndrome [18]. The incidence of LUTO is reported at 2.2 cases in 10,000 births, with PUV occurring in 1 in 7031 births [19]. Most cases are in males (PUV are exclusively male), whereby in females urethral atresia is more common and consideration should be given to rarer cloacal plate pathologies such as megacystis-microcolon-hypoperistalsis-syndrome (MMHS).

4.2.2 Genetics

Most cases are sporadic; in some, cases have been associated with polymorphisms of genes expressed during development of the urinary tract [20]. Recurrence risk is low. MHHS syn-

drome is an exception, which has an autosomal recessive inheritance pattern. Chromosomal abnormalities, in particular trisomies 13, 18 and 21 have been reported in 12% of cases [21]. Genetic testing is therefore mandatory.

4.2.3 Pathophysiology and Natural History

LUTO results in bladder distension with compensatory smooth muscle hypertrophy of the bladder wall. With increasing pressure and distension, the bladder wall eventually loses its natural elasticity and poor tone and function develops. Increasing backpressure from vesico-ureteric reflux drives bilateral hydronephrosis above, with enlarging pyelectasis and calyectasis then responsible for progressive compression of the vulnerable developing renal parenchyma. This pressure-induced mechanism of injury may act in concert with premature activation of the renin-angiotensin system causing vasoconstriction and further hypoxic injury [22]. Fibrosis to the renal medulla and renal cortex results in renal dysplasia and eventually renal insufficiency. Some have suggested dysplasia may even result from other abnormal embryological communication unrelated to the obstruction [23]. Regardless, urine production fails and oligohydramnios ensues. This results in the development of pulmonary hypoplasia [24]. Oligohydramnios inhibits lung expansion up to 20%, primarily a result of altered fetal posture and narrowing of the fetal thorax, with reduced fetal respiration [24]. Respiration is considered an important factor in stimulating lung growth. Decreased airway branching may occur and alveoli numbers are reduced and may be structurally immature with reduced collagen and elastin [25]. Depending on gestational age and severity, respiratory embarrassment at birth is the norm, yet the condition can also be lethal.

Prognosis is dependent on the degree of renal insufficiency and the presence and degree of pulmonary hypoplasia. Mortality for antenatally diagnosed cases is 45%, but rises to 95% for those with persistent oligohydramnios [26]. For survivors at birth, one third will develop renal failure necessitating dialysis and is the leading cause of childhood renal transplantation [27]. Voiding problems happen as well.

4.2.4 Antenatal Diagnosis

The sensitivity of ultrasound for detecting LUTO is 95% with 80% specificity [27]. The diagnosis is usually made at the 18–20 week ultrasound, although in some may be evident at the 11–13 week ultrasound and confirmed, if persistent, at 16 weeks [28]. The classical sonographic feature is the "key hole" sign (Fig. 4.1), whereby the dilated proximal urethra above the obstruction extends into the dilated and thick walled bladder (greater than 2 mm is considered pathologic) [22]. The dilated bladder, or *megacystis,* may occupy much of the abdomen, and even spontaneously rupture and produce urinary ascites. Ureterectasis, caliectasis and hydronephrosis are all evident sonographically (Fig. 4.2). Bilateral renal dysplasia appears as increased echogenicity of the renal parenchyma and subcortical cysts are indicative of particularly poor prognosis [26]. Similarly, the presence of oligohydramnios signifies major obstruction, and if present prior to 24 weeks is associated with a

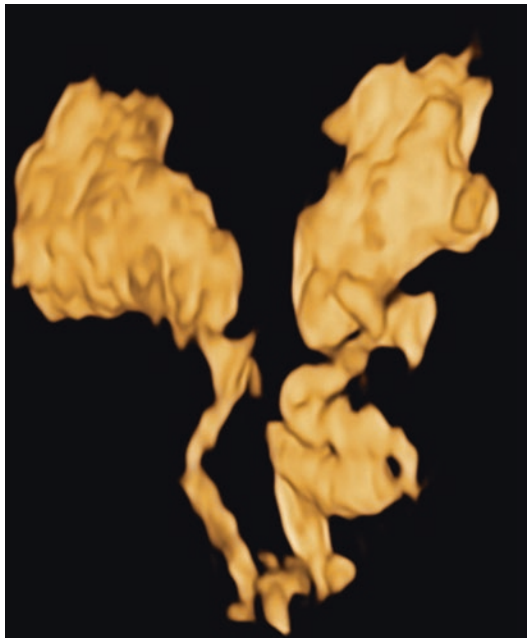

Fig. 4.2 Lower urinary tract obstruction later in gestation with bilateral ureterectasis and hydronephrosis and caliectasis, clearly displayed by 3Dinverted rendering. This modality extracts the fluid filled higher urinary tract, dilated into its intrarenal portions. Image: courtesy and copyright UZ Leuven

higher prevalence of renal dysplasia and pulmonary hypoplasia [21]. Oligohydramnios with an absence of caliectasis may suggest such severely damaged dysplastic kidneys that they are no longer capable of producing demonstrable urine [22]. Where possible, the bladder should be observed during voiding for the presence of vesicoureteric reflux. Fetal sex should also be determined. Of note, Potter's facies and club feet can be seen in chronic cases. A thorough search for features of trisomy 13, 18 and 21 must also be undertaken and a detailed examination for the presence of other abnormalities.

The limitation of ultrasound is in accurately defining the specific aetiology of the LUTO as well as to predict renal function. Amnioinfusion may be required to explore structural integrity. Fetal MRI may offer additional information, particularly when oligohydramnios prevents adequate resolution. Fetal MRI has been shown to modify the diagnosis of LUTO in 5 of 16 cases in the third trimester [29] and to better define subcortical cysts, potentially aiding prenatal counselling.

4.2.5 Antenatal Prediction of Prognosis

Much effort has been expended to define antenatal determinants of fetal and postnatal renal (and therefore respiratory) function, with a view to identify candidates for *in utero* intervention. Unfortunately, in the present day, the waters remain somewhat muddied. Momentum developed in the late 1980s following experimental animal studies that demonstrated rescuing renal function by decompressing the obstructed bladder *in utero* [30, 31]. The rationale for this approach is that renal development is complete at birth, rendering postnatal surgical strategies largely ineffective. This raised the possibility that relieving the obstruction *in utero*, particularly during the peak of nephrogenesis (20–30 weeks gestation), may be beneficial [22]. Several observational series have since highlighted the importance of appropriate patient selection, whereby the risks of surgical invasion (most commonly preterm prelabour rupture of membranes, premature birth and chorioamnionitis) are applied only to a fetus that has potentially salvageable renal function. To predict this, there is now a large body of work examining the performance of urinary and serum electrolytes to quantify fetal renal function (Table 4.2) [18]. It has become apparent that serial measurements of urinary electrolytes (via vesicocentesis) are more representative of fetal renal function, as urinary stasis may confound the initial measurement [32]. However, in a 2007 systematic review, Morris and colleagues [33] argued that no particular fetal urinary analyte could accurately predict poor postnatal renal function. Profiling fetal serum obtained by cordocentesis for beta 2 microglobulin may improve this

Table 4.2 Fetal urine prognostic tresholds based on different series

Electrolytes	Good prognosis	Poor prognosis
Sodium	<90 mmol/L	>100 mmol/L
Chloride	<90 mmol/L	>100 mmol/L
Osmolality	<180 mOsm/L	>200 mOsm/L
Total protein	<20 mg/dL	>40 mg/dL
Beta 2 microglobulin	<6 mg/L	>10 mg/L

assessment. It is not possible to measure directly fetal urea and creatinine due to their small molecular size and placental filtration between fetal and maternal circulations, however beta 2 microglobulin has a larger molecular size and appears to reflect fetal glomerular filtration rate more reliably [34, 35]. Furthermore, repeated measurements are possible even after the placement of a shunt, which is not possible for urinary electrolytes [36]. Some groups have even suggested renal biopsy [37]. Our group uses a combined algorithm of sonographic features (kidney echogenicity and presence of cortical cysts, amniotic fluid volume), urinary electrolytes and serum beta 2 microglobulin. We simultaneously perform amniocentesis for karyotype, vesicocentesis for urinary electrolytes and cordocentesis for beta 2 microglobulin to help select potential candidates for a vesicoamniotic shunt (Fig. 4.3) and inform our prenatal counselling. In some cases of severe oligohydramnios, an amnioinfusion is required to complete this diagnostic work up. Candidates for prenatal intervention are generally considered if they are male fetuses with "good" prognostic features and worsening oligohydramnios. Regrettably, there are probably some fetuses with a favourable renal function profile but with normal amniotic fluid that, although currently not considered for shunting, do deteriorate later, sometimes even in infancy. Predicting this group remains problematic. Furthermore, shunting in utero intervention in female fetuses is usually not successful owing to the complexity of LUTO in this group [18]. Overall, several observational studies in males with LUTO have now suggested shunting seems to prevent neonatal death from lethal pulmonary hypoplasia, but the effect on improving renal function in survivors is less clear [21, 32, 38]. The most recent systematic review was in 2010 by Morris and colleagues [39], who examined 20 studies including 369 fetuses with LUTO. At that time there were no randomised trials and several studies were of poor methodological quality in accounting for bias and in reporting the techniques used. In their meta-analysis of 12 studies, they found that antenatal bladder drainage improved perinatal survival compared with no treatment (OR 3.86, 95% CI 2.00–7.45) and appeared most beneficial in a subgroup of fetuses with a poor predicted prognosis (OR 12.85, 95% CI 1.25–153.03). However, when examining survival with normal renal function in seven studies,

a key component in prenatal counselling with parents, the analysis favoured no intervention. This may suggest that the reduced number of survivors with normal renal function following antenatal intervention compared to those without fetal treatment, may represent a group of fetuses with severe renal disease who would have died *in utero* from pulmonary hypoplasia if they had not received intervention. This may also suggest, as discussed above, that additional mechanisms are responsible for renal parenchymal damage other than an entirely pressure-mediated process from obstruction. When the authors examined a subgroup of fetuses with LUTO and good predicted renal function from urinalysis, there was a trend to favour intervention but this did not reach statistical significance. No fetuses with poor predicted prognosis survived. Caution must be applied in interpreting this data however, particularly subgroup analysis, given the observational nature of this research. With regard to longer term follow up, Biard and colleagues [40] recently reported long-term follow up of 20 male fetuses with LUTO and oligohydramnios who were shunted antenatally. Renal function was acceptable in 45% of cases, with 22% having renal impairment and 33% with end-stage renal disease necessitating transplantation. Of note is that the self-perceived qualtiy of life of survivors fell in the normal range. Hence, despite several decades of research, a robust prospective randomised trial was still in the making.

The Birmingham group in 2007 designed the PLUTO trial [17], whereby fetuses with LUTO were randomized to either vesicoamniotic shunt placement or observation when the treating clinician was uncertain of the need for a shunt. Key to this study design was the demonstration of clinical equipoise, which was attempted by surveying paediatric nephrologists, paediatric urologists and maternal fetal medicine subspecialists [41]. After demonstrating clinical equipoise, the PLUTO trial study design did not stipulate an algorithm to formally evaluate fetal renal function prior to randomisation and instead relied on the clinician's uncertainty as to whether the fetus would benefit from a vesicoamniotic shunt placement or not. Disappointingly, the trial was stopped early in 2012 due to poor recruitment and many questions remain unresolved [42]. They concluded that survival seemed to be higher after shunting, but the size and direction of the effect remain uncertain, such that benefit could not be conclusively proven. Also, the chance of newborn babies surviving with normal renal function seems very low irrespective of whether or not vesicoamniotic shunting is done. A further advance may yet come from fetal cystoscopy (Fig. 4.4). Cystoscopy potentially offers an attractive combination of improved diagnosis, and thereby improved patient selection, and potentially even definitive treatment. Fetoscopic antegrade catheterization and hydro- or laser ablation of urethral valves has now been described, but technical challenges of instrument size and manoeuvrability limits percutaneous access to the bladder neck. Nevertheless, Ruano and colleagues have recently reported the largest prospective series of 23 fetuses with LUTO managed with the option of fetal cystoscopy [43]. The procedure, which can be done as early as 16 weeks of gestation, allows a more robust diagnosis, and in case of urethral valves, definitive treatment by laser fulguration may be attempted. A recent systematic review of four fetal cystoscopy studies [44] demonstrated that the initial diagnosis of posterior urethral valves changed in 32% (6/19) typically towards urethral atresia. In terms of postnatal survival, cystoscopic ablation of the valves was superior to expectant management yet comparable to shunting. The latter procedure is neither without any risk for collateral damage to pelvic floor structures.

4.2.6 Obstetric Management

Patients should be referred to a fetal medicine referral centre for diagnosis and multidisciplinary counselling with maternal fetal medicine specialists, paediatric urologists, paediatric nephrologists and neonatologists all considered essential. In most cases, delivery at a tertiary centre is appropriate. A detailed sonographic assessment should be undertaken as described above, and given the presence of chromosomal abnormalities in 12% of cases [21], fetal karyotype should be offered. As described earlier, for mild cases where fetuses have normal amniotic fluid and no evidence of

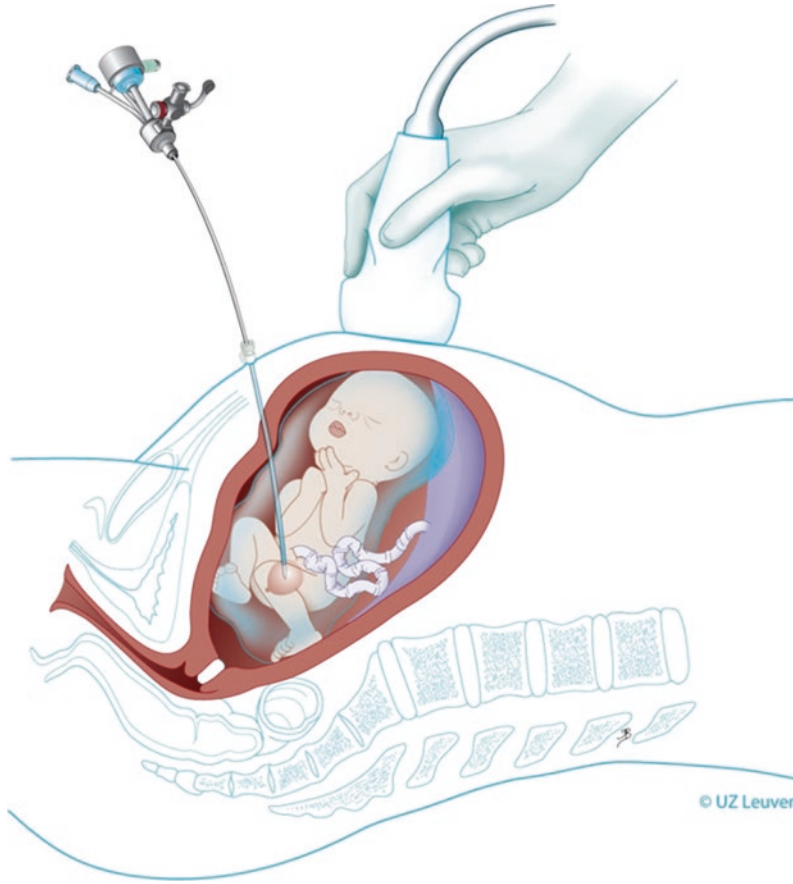

Fig. 4.4 Schematic drawing of fetal cystoscopy. *Insert*: Through a 7 Fr cannula a semi-flexible endoscope has been inserted into the bladder to visualize the bladder outlet (reproduced with permission from the UZ Leuven, Belgium)

renal dysplasia on ultrasound, they should be observed closely for evidence of reducing amniotic fluid or signs of renal dysplasia. If renal function remains stable, there should be no respiratory problems at birth, and thus timing and mode of birth should be guided by usual obstetric considerations. Post-natal surgical evaluation and correction is then undertaken. Should there be sonographic signs of failing renal function, then management is guided by gestational age. If the pregnancy is more than 32 weeks, elective delivery (covered by glucocorticoids for fetal lung maturity when appropriate) is advised to pursue postnatal repair [22]. When less than 32 weeks gestation, we would offer investigational fetal MRI to aid in the examination for signs of renal dysplasia and recommend formal evaluation of fetal renal function by both urinary electrolytes and serum beta 2 microglobulin. In the good prognosis group, we will offer parents the option of vesicoamniotic shunting and/or fetal cystoscopy after through counselling of the limitations discussed earlier and close ongoing surveillance. In the poor prognosis group, or in those who present early with severe chronic obstruction, oligo- or anhydramnios and renal dysplasia evident on ultrasound, we would counsel the parents regarding termination of pregnancy or expectant care. Expectant care should be clearly defined by obstetric and neonatal physicians, including advising no intervention for fetal heart rate abnormalities in labour, providing intermittent auscultation of the fetal heart rate at maternal request only, no indication for cardiotocograph monitoring in labour and no active resuscitation at birth. Parents should be well counselled regarding comfort care of the neonate after birth, post mortem and diagnostic investigations and support services for the family should be initiated. The place of active management is as described above.

4.3 Sacrococcygeal Teratoma

4.3.1 Definition and Epidemiology

Sacrococcygeal teratomas (SCT) are tumours derived from the totipotent Hensen node of the primitive streak, thereby retaining a full differentiation repertoire down ectodermal, endodermal or mesodermal cell pathways [45]. It is the most common tumour in the fetus with an incidence of one in 40,000 births with more females than males affected (4:1) [46], although malignant change is more common in males. The American Academy of Pediatrics Surgical Section classification system is shown in Table 4.3, [47] which describes SCTs according to their relationship with the sacral region. Note that this classification is a surgical description and does not reflect prognosis.

4.3.2 Genetics

Considered sporadic. Rare autosomal dominant inheritance in some families has been reported [26]. Rarely associated with aneuploidy.

4.3.3 Pathophysiology and Natural History

Given SCT's are of totipotent origin, cells can differentiate into embryonic (mature and immature teratomas) or extraembryonic (choriocarcinoma and yolk sac teratoma) tumours. Most commonly, gastrointestinal, respiratory and nervous tissue material is present [26]. SCT's show a paraxial or midline distribution usually from the brain to the sacral region, thereby reflecting aberrant migration of the primordial germ cells. Other less common sites are the anterior mediastinum, pineal area, retroperitoneal area, neck, stomach, and vagina [18]. SCT's are the most common presentation at birth. They represent an extragonadal form that arise in the presacral area, which, as demonstrated by the classification presented in Table 4.3, can extend into the pelvic and abdominal cavity or develop more exteriorly. They are heralded for imposing vascularity and the propensity for rapid growth *in utero*, which can risk fetal survival through the development of high output cardiac failure and/or fetal anaemia, non-immune hydrops, destructive processes to adjacent viscera or obstetric complications. The condition can also cause maternal problems (Ballentyne Syndrome). Most SCT's are benign, however can recur following surgical resection and do have malignant potential in around 10% of neonates born with SCT, particularly in more immature and in type IV tumours [22].

Table 4.3 Type of tumour as per the American Academy of Pediatrics, Surgical Section (AAPS)

Tumour type	Description
Type 1	Predominantly external, with minimal intra-pelvic extension
Type 2	Mainly external, with significant intra-pelvic extension
Type 3	Visible external, but predominantly internal
Type 4	Internal, although external parts may be visible

From Altman, R.P., J.G. Randolph, and J.R. Lilly, Sacrococcygeal teratoma: American Academy of Pediatrics Surgical Section Survey-1973. Journal of pediatric surgery, 1974. 9(3):389–98; used with permission

4.3.4 Antenatal Diagnosis

SCT is usually diagnosed at the 18–20 week ultrasound, although occasionally reported at the 12-week ultrasound [6]. Alternatively, patients may present later with the clinical sequelae of polyhydramnios, such as large for dates, uterine irritability, preterm labour or preterm prelabour rupture of membranes. Sonography reveals a mixed solid and cystic mass, often with calcification, arising from the distal spine and sacral region (Fig. 4.5). A SCT is considered destructive to the spine, whereas as a myelomeningocoele will widen the spine and is likely to have additional cerebral signs [26]. A thorough description of the external and internal pelvic components of the tumour is necessary. The latter may benefit from fetal MRI to more accurately delineate the degree of pelvic extension and distortion of local

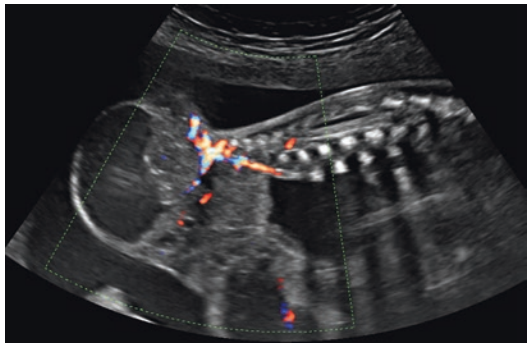

Fig. 4.5 Sacrococcygeal teratoma. Sagittal section on the midline with the lumbosacral vertebrae visible. A tumor orginates at its distal end, and with Doppler ultrasound the feeding vessels from the presacral area. The echogenicity of the tumor varies, with cysts as well as within the solid parts. Image: courtesy of and copyright UZ Leuven

anatomy, where acoustic shadowing from pelvic bones on 2D ultrasound may be bothersome [48]. Bladder elevation, ureteral dilatation and hydronephrosis with the potential for renal dysplasia from compression forces may occur. Similarly, gastrointestinal dilatation may result from obstruction. Rectovaginal fistula and imperforate anus may also develop from direct tumour spread. Danzer and colleagues (2006) [48] evaluated their experience with additional fetal MRI compared with sonography alone. In their series of 24 patients, MRI was superior to sonography for assessing colon displacement (n = 11), urinary tract dilatation (n = 9), hip dislocation (n = 4), intraspinal extension (n = 2), and vaginal dilation (n = 1). In fetuses with sacrococcygeal teratoma types II and III, MRI was again superior to sonography in demonstrating the cephalic extent of the tumor. In two referred cases, MRI led to a changed diagnosis (healthy, $n = 1$; myelomeningocele, $n = 1$). They concluded additional anatomic resolution from MRI resulted in more accurate antenatal counselling and preoperative planning for surgical resection.

SCT's are renowned for their impressive vascularity, often jeopardising fetal cardiac integrity. This can be simply visualised with 2D colour Doppler or more recently has been evaluated with 3D power Doppler, allowing calculation of the vascular volume of the tumour relative to the heart [49]. Cardiac failure and non-immune hydrops may develop, usually from high output cardiac failure following rapid growth of the tumour with extensive arteriovenous shunting. Furthermore, if the tumour outgrows its blood supply and becomes necrotic it can rupture, resulting in haemorrhage and fetal anaemia [22]. Fetal anaemia can be observed by an increase in the middle cerebral artery Doppler peak systolic velocity [50]. High output failure can be diagnosed sonographically and with fetal echocardiography, demonstrating increased inferior vena cava diameter (reflecting increased venous return), dilated ventricles, increased cardiac output and descending aortic flow velocity, and absent or reversed end diastolic flow of the umbilical artery from vascular "steal" from the umbilical artery to the placenta [22, 26, 51]. Olutoye and colleagues (2004) [52] suggested reversal of end diastolic flow may indicate "backwash" of flow into the low resistance vascular bed of the tumor. Polyhydramnios, placentomegaly, hepatomegaly, increased skin thickness and fluid within fetal compartments may then be recognised consistent with hydrops. Fetal hydrops is considered a pre-terminal sign. Fetal growth restriction may also be apparent. A thorough examination for additional abnormalities should be undertaken, although most are usually the direct result of tumour extension.

4.3.5 Antenatal Prediction of Prognosis

Overall, fetal SCT confers a reasonable prognosis, however a particular subset of fetuses is at great risk. The mortality rate for those who present for the first time as neonates is around 5%, considerably better when compared to those who present antenally who have 50% mortality [53]. Similarly, those who present earlier in gestation have a higher mortality rate of up to 90% less than 30 weeks, compared to 15% in later pregnancy [26, 54]. Accordingly, reliable antenatal prediction of disease progression and survival is imperative to counsel parents. A rapidly growing tumour places enormous burden on the fetal heart and the presence of hydrops should confer grave

concerns for the survival of the fetus. Flake and colleagues (1986) [53] described the presence of hydrops and polyhydramnios being associated with a mortality of seven out of seven fetuses and in a series by Bond and colleagues (1990) [54], they reported ten out of ten hydropic fetuses and nine out of nine fetuses with placentomegaly died. There have been some occasional cases of survival with early delivery and post-natal resection reported since then [55, 56] (Robertson 1995, Nakayama 1991), however this appears uncommon. Some fetal deaths may also occur in fetuses without demonstrable hydrops [57], although abnormalities of absent or reversed end diastolic flow of umbilical artery Doppler may herald impending fetal loss [52].

It would seem reasonable that tumour size would be predictive of the risk of cardiac failure and thus, mortality. Wilson and colleagues (2009) [58] reported tumour growth rates approaching 150 cm^3 per week as a predictor of increased perinatal mortality. However, Westerburg and colleagues (2000) [59] did not confirm that tumor size to be predictive of demise, but instead found the most vascular tumours, regardless of size, had the worst prognosis. In 2006, Benachi and colleagues [60] devised a combined classification system based on tumour diameter, vascularity and rate of growth determined by ultrasound (Table 4.4). This was from a series of 44 fetuses with SCT mostly diagnosed on second trimester ultrasound. The fetal and neonatal loss rates were similar (12% and 13% respectively) and half were born preterm. Group one and three did very well, delivering at term with all fetuses surviving. Group two had the worse prognosis, delivering at 31 weeks on average with a 52% perinatal mortality rate; about half dying *in utero* and half dying in the neonatal period. Surprisingly in this series, most who died were not hydropic. It is worth mentioning that in survivors, morbidities included intraventricular hemorrhage, pulmonary hypertension (and other steal syndromes), acute renal failure and three infants had a rectal perforation or sepsis requiring colostomy. For smaller tumours, a good prognosis is generally expected, presumably due to less circulatory demand. Makin and colleagues [61] reported in 2006 on 29 cases of SCT diagnosed antenatally. The long-term outcome for fetuses not requiring intervention (n = 17) was excellent, with constipation in one child the only reported outcome at 39 months. Of note in this series, six of the seven cases of hydrops resulted in fetal or neonatal demise.

Most recently, Rodriquez and colleagues (2011) [62] have proposed tumour volume to fetal weight ratio (TFR) as an early prognostic classification for fetal SCT. In a retrospective series of ten cases, a TFR greater than 0.12 measured at less than 24 weeks gestation either by ultrasound or fetal MR, was predictive of poor outcomes with a sensitivity of 100% and a sensitivity of 83%. A TFR less than 0.12 predicted an uncomplicated course with 100% survival. All hydropic fetuses

Table 4.4 Proposed classification based on prenatal tumor development, according to Benachi et al. [60]

	Number	Mean gestational age at diagnosis	Prenatal interventions in this case series	Mean gestational age at birth
Group 1: small tumors (<10 cm) with a poor vascularity and slow growth	n = 13	24.0±1.6	no fetal intervention.	38.0 ± 0.47
Group 2: large (>10 cm) and fast growth (>8 mm/week) and high vascularity OR high output cardiac failure (cardiomegaly and increased diameter of inferior vena cava)	N = 21	23.2±0.9	One embolization and one cyst puncture for obstetrical reason	31.0 ± 1.03
Group 3: large (>10 cm) tumors, but predominantly cystic, poorly vascularized or slowly growing tumors	N = 10	22±1.2	None apart from cyst puncture for obstetrical reasons	37 ± 0.3

and all fetuses that died had a TFR greater than 0.12, with just 20% of fetuses having an uncomplicated outcome above this threshold.

4.3.6 Obstetric Management

All patients with suspected SCT should be referred to a tertiary fetal medicine centre for evaluation and multidisciplinary counselling. Maternal fetal medicine specialists, neonatologists and paediatric surgeons are essential members of this team. A detailed sonogram, echocardiogram and fetal MRI are recommended to confirm the diagnosis and exclude additional abnormalities. If SCT is confirmed, a detailed evaluation of the extent of internal pelvic extension, additional visceral involvement and fetal haemodynamic state is required. Classification according to Benachi [60] and the TFR discussed above [62] could be considered. Karyotype is generally not required, unless additional abnormalities are present. Termination of pregnancy should be discussed with parents, particular for a large or rapidly growing SCT, the presence of dysplastic renal involvement and if cardiovascular compromise is evident on ultrasound. The presence of hydrops should be conveyed as a particularly ominous prognostic feature. If termination of pregnancy delivery is planned, it is important that the delivery team consider possible labour dystocia. An intact fetus is preferable for thorough post mortem pathological examination.

For ongoing pregnancies, close surveillance is mandatory. Serial sonography is recommended every 1–2 weeks to identify progression of disease. It must be remembered that SCT's can grow very rapidly and the fetal cardiovascular system may come quickly into jeopardy. Sonographic and echocardiographic signs of hydrops should be pursued, including measurements of a high output circulation such as the inferior vena caval diameter (>1 cm), descending aorta flow velocity (>120 cm/s) and the umbilical artery Doppler waveform [22]. The middle cerebral artery Doppler peak systolic velocity should be examined for signs of anaemia [50]. The renal and gastrointestinal tract should be examined for signs of obstruction. Amniotic fluid volume should be measured for polyhydramnios, and if present, a cervical length measurement to predict preterm labour is advised. Obstetric complications may evolve with advancing pregnancy. In a series by Hedrick and colleagues in 2004 [57], in 26 women with fetal SCT who did not undertake termination of pregnancy, 81% experienced obstetric complications. These included polyhydramnios in seven women, oligohydramnios if four women, preterm labour in 13 women, pre-eclampsia in four women and gestational diabetes, HELLP syndrome and hyperemesis each occurring in one woman. Maternal mirror syndrome has also been reported in cases of SCT with hydrops.

Antenatal fetal intervention for SCT may be an option for selected cases. Dr. Flake and colleagues discuss fetal surgical resection for SCT in detail in Chap. 10. For our purposes in this Chapter, we will briefly discuss additional interventions in the antenatal period, and how this is informed by antenatal diagnosis. In general terms, antenatal intervention is reserved for fetuses at high risk that are still remote from term. Drainage of polyhydramnios is a simple and safe procedure that may help resolve uterine irritability and maternal discomfort. Similarly, if fetal anaemia is detected by increased peak systolic velocity of the middle cerebral artery Doppler signal, intrauterine blood transfusion is a feasible option [63]. In cases of renal tract obstruction from pelvic extension of the SCT, a vesicoamniotic shunt may protect the renal parenchyma from injury in much the same way as fetuses with LUTO [60, 61, 64]. Clinical experience, however, is scarce to formally evaluate these strategies. Open resection with cardiac monitoring, thermocoagulation and radiofrequency ablation of the tumour is discussed elsewhere in this book.

Timing of birth is usually dictated by either fetal or maternal complications. The presence of fetal haemodynamic compromise mandates immediate delivery. For small tumours in healthy fetuses, vaginal delivery may be possible. Delivery in a tertiary centre is essential. Cyst aspiration and decompression does not seem beneficial to aid vaginal delivery [26]. There have, however, been reports of fetal death after

tumour rupture, avulsion and asphyxia following complications of vaginal birth [22]. Close surveillance in labour with continuous cardiotocography monitoring and the presence of senior obstetric and neonatal staff are necessary. For tumours more than 4.5 cm, or in cases of fetal haemodynamic compromise, caesarean section is advised to prevent labour dystocia and reduce the chance of tumour rupture and fatal haemorrhage [26]. This approach requires meticulous planning with obstetric, anaesthetic, neonatal, haematologic and paediatric surgical teams. The caesarean should take place in an elective setting with fetal lung maturity assisted by glucocorticoids when less than 37 weeks gestation [65]. Depending on tumour size, consideration should be given to maternal general anaesthesia to aid uterine relaxation for careful manipulation and delivery of the fetus. The uterine incision should be generous to facilitate an atraumatic delivery of the fetus, particularly in cases with a large mass. A classical (vertical) uterine incision may be advisable to increase the surgical field of exposure, especially in more preterm gestations where a lower uterine segment may not be sufficiently formed and where delivery is anticipated to be difficult. Intraoperative cyst aspiration of 2 L in one case has also been reported to aid delivery [66]. Uterine bleeding from extension of the incision during delivery of the fetus or from atony must be anticipated in advance and oxytocics be used readily, if not prophylactically. Neonatal intensivists and haematologists should be prepared for resuscitation of the neonate and extreme care must be taken when handling the tumour, especially if a "stalk" is present with a risk of torsion [26]. Even superficial bleeding can result in life threatening haemorrhage [26]. Tumour rupture and neonatal death have been reported even from handling during caesarean delivery [67]. In the absence of haemorrhage at birth, surgical excision can generally be delayed to allow stabilisation of neonatal circulation and further imaging to be undertaken in the neonatal intensive care to inform definitive surgical plans. When there is hemodynamic instability, immediate neonatal surgery, even restricted to debulking, may be required to arrest the steal effect. In that case an adjacent operation suite must be available.

4.4 Fetal Congenital Thoracic Malformations

4.4.1 Definition and Epidemiology

Fetal congenital thoracic malformations (CTMs) constitute a heterogeneous group of pathologies involving the airways and/or lung parenchyma. Fur our purposes in this chapter, we will focus our attention on congenital cystic adenomatoid malformation (CCAM), and the related pathology, bronchopulmonary sequestration (BPS). CCAM's are defined as benign, multicystic, dysplastic lung tumours with an overgrowth and proliferation of terminal bronchioles that receive their blood supply from pulmonary vessels. BPS on the other hand, refers to a distinct mass of non-functioning lung tissue that is not in communication with the normal lung architecture and receives its blood supply from an anomalous systemic vessel. Both lesions may also coexist together referred to as a hybrid CCAM-BPS [22, 68].

The European Surveillance of Congenital Anomalies (EUROCAT) population-based registry [69], in 2008 reported on 222 fetuses with CTMs, with an incidence of 4.44/10,000 (i.e. including live births, fetal deaths and terminations of pregnancy). Of these 222 cases, 52 had CCAM alone with an incidence of 1.04/10,000. With regard to live births, the incidence was 3.52 and 0.94 per 10,000 live births in 2008 for all CTMs and CCAMs respectively in EUROCAT countries. The reported annual incidence of BPS ranges between 0.15 and 6.45% of all CTMs [68].

4.4.2 Genetics

Sporadic inheritance. When isolated, not associated with aneuploidy.

4.4.3 Pathophysiology and Natural History

CCAM's (Fig. 4.6) may be the result of failed maturational processes during the psuedoglandular stage of lung development [70], represent-

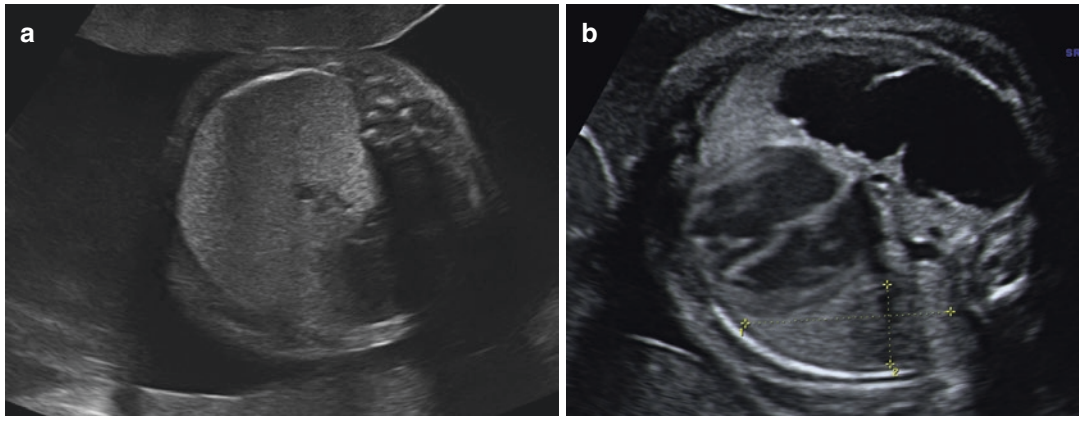

Fig. 4.6 Congenital Cystic Adenomatoid Malformation. *Left*: microcystic type, with uniform more echogenic lung tissue; *right*: macrocystic type, next to remnant lung tissue measured with the calipers. Images courtesy and copyright UZ Leuven

ing focal dysplastic regions [71] or related to airway obstruction [72]. Importantly, to help differentiate them from BPS, they derive their vasculature directly from pulmonary vessels. CCAM's are almost always unilobular, with bilateral tumours occurring in less than 2% of cases. About one in four are associated with additional fetal abnormalities, such as pectus excavatum, renal agenesis, congenital diaphragmatic hernia, bowel atresia and non-immune hydrops [26]. The natural history and progression is rather variable but overall prognosis is good. Small lesions are largely asymptomatic, while larger lesions can result in mediastinal shift, compression of systemic venous return, resulting in hydrops and risking fetal death. Pulmonary hypoplasia may also be evident, but difficult to predict. The haemodynamic state may in turn be worsened by a leakage of proteins into the amniotic fluid and thereby reducing systemic oncotic pressure [73]. Polyhydramnios may occur due to mechanical compression of the fetal oesophagus inhibiting swallowing, and occurs in 70% of cases [74]. The risk of preterm prelabour rupture of membranes and/or preterm birth naturally follows. However, in some fetuses, the CCAM may reduce in size and resolution of the lesion may occur. This has been observed in between 5 and 10% of cases [74]. CCAM's tend to plateau in their rate of growth around 26 weeks gestation, and furthermore, resolution via involution may eventually occur if the tumour outgrows its vascular supply.

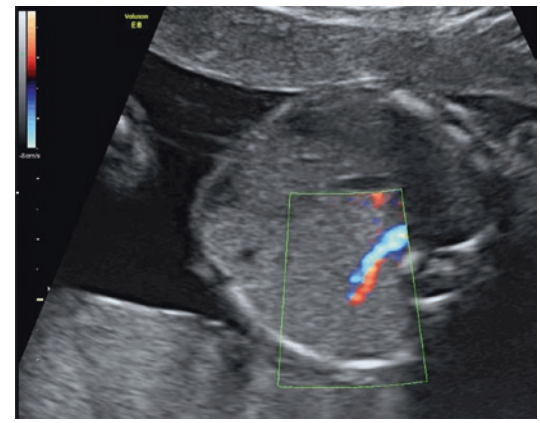

Fig. 4.7 Bronchopulmonary sequestration: hyperechogenic pathologic lugn tissue, feeding vessel being demonstrated by Doppler ultrasound. Images courtesy and copyright UZ Leuven

BPS is generally thought to represent ectopic pulmonary buds, which can be either intralobular or extralobular (Fig. 4.7). This difference is explained embryologically. Intralobular sequestration develops early, before the development of the pleura, and the ectopic buds become incorporated within the adjacent lung, almost exclusively in the lower lobe (98%). Extralobular sequestration develops later and is less common (25%), whereby the pulmonary bud is separated from the adjacent lung and has its own pleural covering. This is more likely to be associated with additional abnormalities than intralobular sequestration (50% versus 10%), particularly congenital heart disease, and is most common on the left

side of the thorax (90%) [26]. In both cases, the ectopic bud is thought to develop caudal to the lung and migrates in a caudal direction along with the oesophagus [22]. Up to 10% of extralobular sequestrations may lie inferior to the diaphragm [26]. Around 75% of antenatally diagnosed BPS may resolve, most likely from outgrowing their blood supply or infarction mediated by vascular torsion of their pedicle. However, in some fetuses, there exists a considerably poorer outlook. Torsion of the extralobular pedicle may then obstruct venous and lymphatic drainage and result in ipsilateral hydrothorax, which may then place the mediastinum under tension. Without intervention, hydrops and fetal death are likely. If there is an abdominal extralobular BPS, hydrops is less likely, however polyhydramnios may occur from impaired swallowing due to gastro-oesophageal compression. Similarly, for intralobular BPS, hydrops may be the result of high output circulation from a "left to left" ateriovenous shunting between the anomalous arterial supply and pulmonary veins [22].

4.4.4 Antenatal Diagnosis

In the antenatal period, there has been a shift in recent years away from pathological diagnosis to descriptive appearances based on imaging. The original histological classification system for CCAM was by Stocker and colleagues in 1977 [70], which they more recently updated in 2002 [75] (Fig. 4.6). In their most recent classification, five types of lesions are suggested that attempt to present a spectrum of abnormalities across consecutive airway types (Table 4.5). In other words, lesions are described as moving down the bronchial tree from bronchial, bronchiolar, alveolar and to peripheral. However, this system has not been embraced universally. Applying a histopathological classification system to a condition that is increasingly recognized and diagnosed antenatally, may not be useful in predicting prognosis and guiding clinical management decisions. Furthermore, it appears likely that types 0, 3 and 4 represent different pathogenetic processes. More recently, the Children's Hospital of Philadelphia published a simplified classification

Table 4.5 Comparison of two proposed classifications of CCAMs

Congenital pulmonary airway malformation: a new name for and an expanded classification of congenital cystic adenomatoid malformation of the lung. [75] (Stocker classification)	New concepts in the pathology of congenital lung malformations (Langston 2003) [72]
Type 0 CCAM—Acinar atresia	**Bronchogenic cyst**
Type 1 CCAM—Cysts up to 10 cm. The cysts are lined by pseudostratified ciliated cells that are often interspersed with rows of mucous cells	**Bronchial atresia** • Isolated • With systemic arterial/venous connection (intralobar sequestration) • With connection to GI tract • Systemic arterial connection to normal lung
Type 2 CCAM—Sponge-like multiple small cysts (<2 cm) and solid pale tumour-like tissue. The cysts resemble dilated bronchioles separated by normal alveoli. Striated muscle seen in 5%	**CCAM, large cyst type (Stocker type 1)** • Isolated • With systemic arterial/venous connection (hybrid/intralobar sequestration)
Type 3 CCAM—Solid. Excess of bronchiolar structures separated by small air spaces with cuboidal lining (foetal lung)	**CCAM, small cyst type (Stocker Type 2)** • Isolated • With systemic arterial/venous connection (hybrid/intralobar sequestration
Type 4 CCAM—Cysts up to 10 cm. The cysts are lined by flattened epithelium resting upon loose mesenchymal tissue	**Extralobar sequestration** • Without connection to GI tract • With connection to GI tract
	Pulmonary hyperplasia and related lesions • Laryngeal atresia • Solid or adenomatoid CCAM (Stocker Type3) • Polyalveolar lobe
	Congenital lobar over-inflation
	Other cystic lesions Lymphatic cysts, Enteric cysts, Mesothelial Cysts, Simple parenchymal cysts, Regressed type 1 pleuropulmonary blastoma

of microcystic (solid sonographic appearance) and macrocystic (single or multiple cysts >5 mm) types. It is likely this can be more useful clinically [76]. Sonographic examples of this classification of CCAM are shown in Fig. 4.6. It is important to visualise the vascular supply by colour Doppler to help differentiate with BPS, whereby an anomalous systemic vessel commonly arising from the descending aorta will be seen feeding a solid echogenic mass (Fig. 4.7). In both cases of CTM, sonographic features of hydrops, mediastinal shift and the presence of additional fetal abnormalities should be sought. Polyhydramnios is commonly encountered, in which case a cervical length measurement may be informative. Fetal MRI may have additional value is cases where the diagnosis is uncertain, in particular with CCAM versus congenital diaphragmatic hernia, or when they coexist [77].

4.4.5 Antenatal Prediction of Prognosis

A significant proportion of lung lesions may regress; nevertheless cautious frequent observation is required to identify a large or enlarging CCAM that imposes pulmonary compression and risks the development of hydrops. The presence of fetal hydrops alerts a poor prognosis and its detection is essential to guide counselling and management. This is demonstrated by a large series reported by Adzick and colleagues [74] in 1998 of 134 fetuses diagnosed antenatally with CCAM. In 25 fetuses with a large CCAM causing hydrops, there was a 100% mortality rate. This is in stark contrast to non-hydropic fetuses, who experienced 100% postnatal survival. In 2002 Crombleholme and colleagues [78] developed a prognostic measure for the development of hydrops. They defined the ratio of the mass area to head circumference as the CCAM volume ratio (CVR). This is sonographically measured (in milliliters) by using the formula for an ellipse: CCAM volume/Head Circumference = (length × height × width × 0.52)/HC (Fig. 4.6). It is gestational age independent. They found when the CVR is higher than 1.6, there was an 80% risk for fetal hydrops. Sonographic follow-up frequency based on the CVR has been also proposed, with weekly follow-up for CVR less than 1.2, twice a week for CVR 1.2–1.6, or even more for CVR greater than 1.6, but this protocol remains to be validated in larger studies.

4.4.6 Obstetric Management

All cases of a suspected CTM should be referred to a tertiary fetal medicine referral centre for diagnostic work up, counselling and management. The multidisciplinary team should comprise maternal fetal medicine specialists, paediatric surgeons and neonatologists. A detailed ultrasound and echocardiographic examination should be performed to define the CTM, its vascular supply, the presence of mediastinal shift or signs of hydrops. The potential for coexisting abnormalities should be excluded, in particular cardiac abnormalities such as truncus arteriosus and Tetralogy of Fallot [22]. Amniocentesis for karyotype is not necessary when isolated. We suggest performing a CVR for cases of CCAM and followed serially as described above. Fetal MRI may be required when the diagnosis is uncertain, in hybrid CCAM-BPS cases or in the presence of CDH. To our knowledge there are no series demonstrating predictive value of lung size in terms of pulmonary hypoplasia, which overall is uncommon. Termination of pregnancy is an option when there are additional severe abnormalities or in the presence of hydrops.

Alternatively, for hydropic fetuses with macrocystic CCAM (unilocular or multilocular), fetal intervention should be discussed with parents as an option to try to reverse hydrops, potentially protect residual fetal lung parenchyma. Expectant management offers a nearly hopeless prognosis and risks maternal complications. The rationale for intervention is to decompress a dominant cyst or resect or involute a larger solid mass to resolve mediastinal compression, restore fetal haemodynamic equilibrium and thus improve cardiac function. Minimally invasive intrauterine puncture or shunting of macrocystic masses (Fig. 4.8) is the treatment of choice when possible, now that its efficacy has been demonstrated.

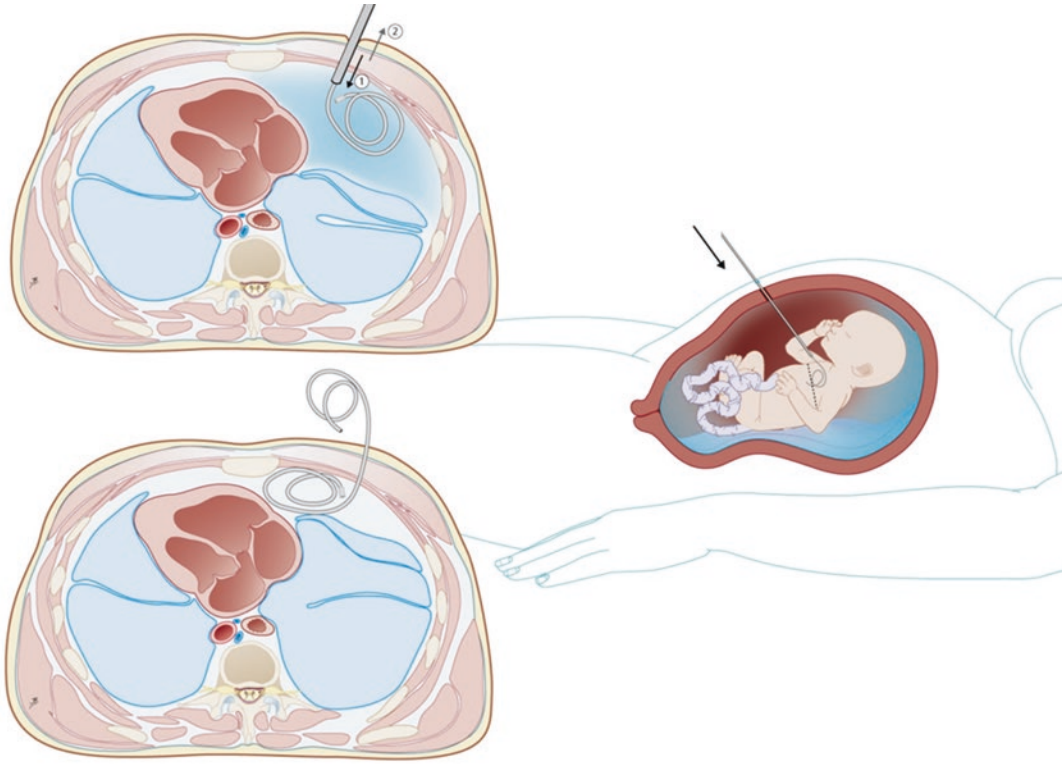

Fig. 4.8 Schematic drawing of thoracic shunt being deployed in the chest. First the pig tail loops in the effusion are deployed, and thereafter the tail is deployed in the amniotic cavity. Drawing Myrthe Boymans; copyright UZ Leuven

Despite an evidence gap of randomised trials, the systematic review by Knox and colleagues [79] showed *in utero* therapy was associated with significantly improved survival in hydropic fetuses (OR 19.28, 95% CI 3.67–101.27), particularly at preterm gestations. With regard to thoracoamniotic shunting in particular, Wilson and colleagues (2006) [80] described 23 cases from CHOP at a mean gestational age of 21–22 weeks. The mean CVR in this group was 2.4, which reduced considerably to 0.7 after shunting. The survival was 74%, with one fetal and five neonatal deaths. In a review by Witlox and colleagues [81] in 2011, summarizing 68 shunted cases including 44 hydropic and 24 non-hydropic fetuses, whereby a large cyst was causing major mediastinal shift. For hydropic fetuses, 89% (39/44) were live born, nine infants died in the neonatal period, giving an overall perinatal survival of 68% (30/44). For non-hydropic fetuses (n = 24), all were live-born, three died in the neonatal period due to pulmonary hypoplasia, giving an overall perinatal survival of 87.5%. Thoracic deformation has been reported but seems rare [82]. Shunting is typically performed until 32 weeks gestation, although more recently has been reported for hydropic fetuses up until 37 weeks [81]. The risk of intervention at later gestations, mostly preterm prelabour rupture of membranes, is less troublesome when compared to the considerable neonatal risks of delivering a preterm hydropic infant. The potential to mitigate hydrops *in utero* and thereby gain further lung maturation before birth would seem likely to translate into improved respiratory function during transition to air breathing and even during postnatal surgery. This approach requires validation.

Not all hydropic fetuses will have a dominant or large cyst(s) amenable to drainage, in particular fetuses with microcystic CCAM. However, most interestingly, several authors have now observed

resolution of hydrops following glucocorticoid therapy [83, 84]. This has occurred at standard dosages given for fetal lung maturation. Curran and colleagues (2010) [85] recently updated Tsao's initial series from 2003 and reported 13 fetuses with microcystic CCAM and hydrops or a CVR>1.6 receiving glucocorticoids. Hydrops resolved in 78% of cases and survival was 85%. It is hypothesised that glucocorticoids may accelerate maturation or involution of the tumour. The same group has now embarked on a randomized controlled trial (clinical-trials.gov NCT00670956) to investigate this more specifically, however in the meantime, glucocorticoids seem a reasonable first-line therapy or medical adjunct for these hydropic fetuses. Their role in non-hydropic fetuses has not been examined. Other fetuses may have solid lesions not suitable for drainage. These are best treated by open fetal surgery and lobectomy, as reviewed by Flake et al. in this book. In the largest fetal surgery series available today, survival rate was 50% [76].

Hydropic fetuses with BPS theoretically may benefit from minimally invasive techniques as well, although this is less defined. In particular occlusion to the anomalous systemic feeding vessel using thermocoagulation by laser or electrosurgery, or sclerosing agents have been reported in a very small number of high-risk fetuses with good outcomes [81, 86–89].

In non-hydropic fetuses, mode of delivery is determined by usual obstetric factors, with spontaneous vaginal delivery at term in a tertiary centre generally favoured.

4.5 Fetal Hydrothorax/Pleural Effusion

4.5.1 Definition and Epidemiology

Pleural effusion can be defined as primary or secondary. Primary pleural effusion is more correctly termed *hydrothorax* antenatally and is due to lymphatic or "chylous" leak with resultant fluid accumulation in the thorax. This may be unilateral or bilateral. After birth, *chylothorax* becomes the more common terminology. In the more common secondary pleural effusion, the effusion harbingers underlying pathology often part of widespread fluid accumulation from immune or non-immune hydrops. The overall incidence is around 1 in 15,000 pregnancies [26].

4.5.2 Genetics

Chromosomal abnormalities can be present. In the most recent series, Ruano and colleagues (2011) [90] reported 23 of 56 (41%) fetuses with pleural effusion had underlying chromosomal abnormalities. Turner's syndrome (45 XO) was the most common in 15 of 56 fetuses (65%) followed by Down syndrome in five fetuses (22%). However, Yinon and colleagues (2010) reported a much smaller association with anuploidy, with four from 88 fetuses being abnormal [91]. A number of genetic syndromes have also been reported, such as Caffey's cortical hyperostosis (autosomal dominant) and Opitz-Frias hypertelorism hypospadius syndrome (autosomal recessive) [26]. Males appear twice as likely to be affected than females.

4.5.3 Pathophysiology and Natural History

Small effusions may remain stable or even regress. Aubard and colleagues [92] observed spontaneous resolution in 22% of 204 cases of primary fetal hydrothorax (Fig. 4.9). However, large (or enlarging) effusions have the potential to cause mediastinal shift, compromised venous return and lung compression, risking pulmonary hypoplasia, hydrops fetalis and intrauterine death (Fig. 4.9). Bigras and colleagues [93] demonstrated by echocardiography a cardiac tamponade effect from rising intrathoracic pressure, whereby ventricular dimensions decreased and the inferior vena cava dimensions consequently increased, reflecting impaired ability of the heart to accommodate venous drainage. Oesophageal compression and impaired fetal swallowing will result in polyhydramnios, which in turn increases the likelihood of preterm prelabour rupture of membranes and preterm birth. When bilateral, pulmonary

Fig. 4.9 Bilateral hydrothorax. Image: courtesy UZ Leuven

lymphangiectasia should be expected and the prognosis is poor even despite fetal treatment, because abnormal lymphatics preclude normal gas exchange in the lung [18]. Furthermore, lung development appears most sensitive to compression effects during the cannalicular phase of lung development; this corresponds to an increased risk of pulmonary hypoplasia between 16 and 24 weeks gestation [94].

Ruano (2011) [90] attempted to define the natural history of fetal pleural effusions without antenatal intervention. In their observational study on 56 fetuses, they divided their cohort into three groups: Group 1 included 14 (25%) fetuses with isolated pleural effusion without other structural abnormalities; Group 2 included 19 fetuses (34%) with a pleural effusion and additional anomalies but normal karyotype; Group 3 included 23 fetuses (41%) with a pleural effusion and an abnormal karyotype. The overall perinatal mortality was 42/56 (75.0%), with fetal death observed in 38 (68%) and neonatal death in 6 (10.7%) cases. Group I demonstrated a significantly higher rate of neonatal survival (64%), less fetal death (29%) and less neonatal death (7.1%) when compared to Group II (0, 78.9 and 21.1%, respectively) and Group III (13.0, 82.6 and 4.3%, respectively).

4.5.4 Antenatal Diagnosis

Pleural effusions may be evident on ultrasound from as early as the first trimester, however these are more commonly associated with aneuploidy. Most cases are diagnosed in the third trimester. Effusions are seen as anechoic regions surrounding and usually compressing the lung, which can be unilateral or bilateral. A classic "bat wing" appearance may become evident. The diaphragm may appear flattened or everted. The mediastinum can come under tension with shifting to the contralateral hemithorax. In this case, ventricular diameters decrease, inferior vena cava diameters widen and pulmonary artery Doppler peak velocities increase [93]. An effusion ratio has been reported, which is a ratio of the cross-sectional area of the effusion to that of the thorax [94]. Furthermore, the severity of left ventricular compression correlates with the effusion ratio [93].

Once an effusion is identified, differentiating between primary and secondary causes is important. Primary pleural effusion is a diagnosis of exclusion. Additional structural abnormalities are found in over a third of cases [90] and a detailed fetal echocardiography is mandatory. A large effusion with mediastinal shift may make visualisation of cardiac anatomy difficult, however this may improve after drainage. Concomitant pulmonary pathologies such as CDH, CCAM and BPS are secondary causes that should be especially sought. Signs of hydrops should be looked for in other fetal compartments and the amniotic fluid index measured for polyhydramnios. Sonographic features of congenital infection, aneuploidy and anaemia should be examined. In practice however, a fetal thoracocentesis (pleural aspiration) is required to confirm the diagnosis. This can be performed in a single pass following amniocentesis for karyotype. A pleural fluid that is predominantly lymphocytic (>80%) is considered pathognomic for chylothorax or primary pleural effusion [22, 94].

4.5.5 Antenatal Prediction of Prognosis

The presence of hydrops has consistently shown to predict poor prognosis [90, 92, 94].

In the presence of fetal hydrops, the estimated survival rate falls steeply from 80% to 30%. Fetuses with a secondary pleural effusion fare considerably worse than those with a primary hydrothorax. In Ruano and colleagues' recent series [90], mortality for hydropic fetuses in Group 1 was 50% versus 100% mortality for hydropic fetuses in Group 2. Other predictors have been suggested, but do not appear consistently across studies: bilateral effusions [90], effusion ratio [95] and gestation at diagnosis [96]. Furthermore, prognosis after thoracoamniotic shunting is often related to the resolution of hydrops [97].

Most recently, fetal total lung volumes as assessed by three-dimensional ultrasonography were used to predict perinatal outcomes in cases of primary pleural effusion. In a cohort of 19 fetuses, the observed to expected total lung volumes were significantly correlated with perinatal outcomes such as respiratory morbidity and perinatal death, and to bilateral effusions and hydrops [98]. The place for this measurement in clinical management will need to be examined in larger studies.

4.5.6 Obstetric Management

A referral to a dedicated fetal medicine tertiary centre is required. The diagnostic work up is similar to that of hydrops. A detailed sonogram and echocardiogram for structural abnormalities and signs of aneuploidy and infection is performed. The middle cerebral artery peak systolic velocity is examined for anaemia. Maternal blood is analysed for serological evidence of infection (toxoplasmosis, rubella, cytomegalovirus, herpes, parvovirus B19, varicella, syphilis), red cell group and antibodies for immune hydrops, haemoglobin electrophoresis, and Kleihauer–Betke test of fetomaternal haemorrhage. Parents should be counselled for amniocentesis for genetic testing and congenital infectious screen (culture and PCR) [94]. Thoracocentesis should be considered at the same time, especially in cases of presumed primary hydrothorax. If a large effusion is evident, then delivery should occur at a tertiary centre. Multidisciplinary counseling with maternal fetal medicine specialists, neonatologists, paediatric surgeons and geneticists are appropriate.

Small effusions nevertheless require close follow up every 1–2 weeks to watch for volume expansion, mediastinal shift, hydrops, polyhydramnios and cervical shortening. A small stable effusion can be managed conservatively with good outcome (survival between 75–100%) [92, 99]. The same cannot be said, however, for fetuses that become hydropic. Survival rates are universally poor without intervention. Hydrops therefore represents the principal indication for fetal intervention. The systematic review of Knox [79] mentioned earlier concluded that in the presence of hydrops therapy seems warranted. Survival rates improve to 45–66% [79, 94, 97]. One may start with thoracocentesis however the effusion may be expected to reaccumulate over several days. Thoracoamniotic shunting can be performed using a double-pigtail catheter (Fig. 4.10). Alternatively, serial thoracenteses can be performed [100]. There is no evidence of a difference in outcome between the two approaches [101]. The complication rate of shunting is about 15% for iatrogenic rupture of membranes [102] and 5–10% for direct fetal loss. Shunt dislodgment has been reported, however posterior insertion may prevent the fetus from dislodging it. Preterm birth is common, with a mean gestational age at birth of 34–35 weeks. At birth the shunt is usually left, however needs obviously to be clamped.

Larger effusions risk pulmonary hypoplasia and respiratory distress at birth and ventilatory support may be needed. There is some discussion in the literature about thoracocentesis immediately prior to delivery to improve the transition to air breathing and facilitate resuscitation measures at birth. Others advocate thoracocentesis after birth, as they believe fluid reaccumulation can be rapid and render the fetus hypovolaemic and compromise resuscitation efforts at birth. Thoracocentesis can instead be performed once circulatory access has been established and fluid therapy initiated [22, 103].

4.6 Congenital Diaphragmatic Hernia

4.6.1 Definition and Epidemiology

The prevalence of congenital diaphragmatic hernia (CDH) ranges between 1 and 4 per 10,000 births, qualifying it as a rare disease. The exact etiology of the condition remains unknown. The vast majority of cases are left sided (LCDH), 13% are right sided (RCDH), and bilateral lesions, complete agenesis and other rarities comprise less than 2%. CDH can occur in association with other anomalies (in which case the mortality is over 85%) (Table 4.6), or as an *isolated* condition [104, 105].

Table 4.6 Non-limitative list of anomalies often associated to CDH, in descending order [104, 105]

Identified genetic defects and syndromes
Trisomy 13, 18, 21, XO, Partial Trisomy 5, 20, Tetraploidy 21, Tetrasomy 12p Syndromes: Fryns, Fraser, Stickler, Pierre Robin, Goldenhar, Beckwidth Wiedeman, Apert, Klippel-Fiel, Rubenstein Taybi, Brachman de Lange, Coffin-Siris, Pentalogy of Cantrell VACTERL or CHARGE association
Structural defects (descending order of occurrence)
Cardiovascular, Gastrointestinal, Urogenital, Musculoskeletal, Respiratory, Central Nervous System, Craniofacial

4.6.2 Genetics

CDH most likely is caused by disruption of common developmental pathways, by several genes spread across the genome [106]. We recently reviewed the genetic factors underlying CDH, including evidence from genetic & teratogenic animal models of CDH and differential expression analysis [107]. Though all these fetuses with isolated CDH are routinely karyotyped, identification of (novel) submicroscopic imbalances and novel genes and/or therapeutic targets, requires the use of high resolution diagnostic methods. Several large centers do so, both from a clinical perspective as well as for research. We custom designed a high resolution array for comparative genomic hybdrization (CGH) [108]. The next step will be to use exome sequencing techniques in selected familial cases. Given the high probability of a mutation(s) segregating with the CDH phenotype, this approach will likely reveal the underlying gene(s) involved in the pathogenesis of CDH for each family studied. Advanced genetic testing in large populations with (apparently) isolated CDH, will lead to a better understanding of the genetics of this condition [109].

4.6.3 Pathophysiology and Natural History

Isolated CDH refers to the surgically correctable defect in the diaphragm, but the key problem is its consequence for lung development. Already from

the first trimester the abdominal content herniates into the thorax, interfering with lung development. This causes hypoplasia of both lungs, i.e. fewer airway branches and abnormal pulmonary vessels, as well as a lesser lung compliance. At birth this causes ventilatory insufficiency and pulmonary hypertension, which can be lethal before the defect can be surgically repaired. The condition remains lethal in up to 30%, despite prenatal referral to a high volume center offering standardized neonatal care [110–112]. Survivors may have several morbidities, such as bronchopulmonary dysplasia and persistent pulmonary hypertension, gastro-esophageal reflux and other feeding problems, less frequently they have thoracic deformations after successful repair or other issues. Eventually most lead a life very close to normal provided when managed in a multidisciplinary follow up program [113, 114].

4.6.4 Antenatal Diagnosis

As ultrasound screening programmes have become widely implemented, one would expect the diagnosis is made before birth. In reality around two out of three cases are picked up before birth [115, 116]. The most striking signs become obvious on a cross section of the thorax, with compression and in left sided cases obvious displacement of the heart, by abdominal organs. In left CDH the stomach is often more posterior, viscera as well as spleen may be herniated (Fig. 4.11). An important feature is the presence of liver into the thorax. Right CDH is more difficult to recognize, because only the liver may be herniated, and echogenicity of the liver may be confused with that of the lung. Assessment of liver position is done by Doppler interrogation of

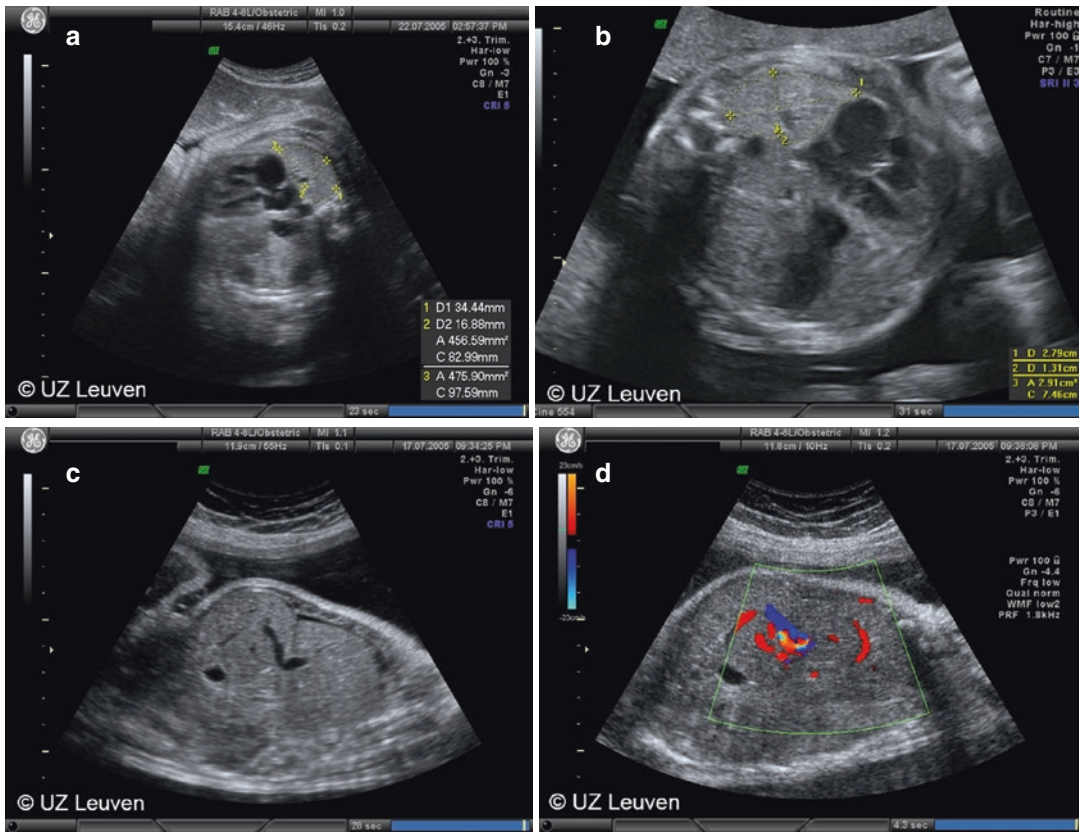

Fig. 4.11 Fetus with left CDH before and after fetal therapy. (**a**) lung measurement at the four chamber view with the so-called "longest axis method" as well as "tracing method". These dimensions will be used to calculate the Lung to Head Ratio. (**b**) measurement of the lung 1 day after balloon insertion, with changed echogenicity and dimensions. (**c**) Herniation of the liver. (**d**) visualization of the major vessels help in its identification. Copyright UZ Leuven; (From Deprest et al., Treatment of Congenital Diaphragmatic Hernia. In: Fetal MRI. Prayer D (Ed). Springer Verlag, Heidelberg 2011, 528 pp.)

the umbilical vein and liver vessels, as well as the position of the gall bladder (Fig. 4.11). Indirect signs of CDH are polyhydramnios and a smaller abdominal circumference. Differential diagnosis includes essentially other pulmonary pathology with cystic features, such as cystic adenomatoid malformation, bronchogenic cysts, rarely enteric or neuroenteric cysts, mediastianal teratoma and thymic cysts, or bronchopulmonary sequestration or bronchial atresia.

Prenatal diagnosis of CDH should prompt referral to a tertiary centre experienced in assessing this anomaly and managing CDH in the perinatal period. A comprehensive diagnostic and prognostic work up comprises advanced imaging, genetic testing and multidisciplinary counselling, so that parents can take a well informed decision. In view of the options, an individualized prediction of outcome is crucial.

4.6.5 Antenatal Prediction of Prognosis

Most frequent quoted predictors of outcome are the presence of associated anomalies, and for isolated cases, lung size, position of the liver and the stomach, and to a lesser extent assessment of lung vasculature. Herein we will focus on the best validated predictors; however research on improved prediction is actively ongoing.

The Lung-to-Head Ratio (LHR) consists of measurement of the lung contralateral to the defect, at the level of the four chamber view. It is divided by the head circumference as measured in the standard biparietal view [117] (Fig. 4.11). The most accurate method for measuring is by tracing the lung contours [118, 119]. The LHR is a function of gestational age, because the lung grows four times more than the head over the entire gestation. To overcome this problem, we proposed to express the LHR of the index case as a function of what is expected in a gestational aged control (observed [O]/expected [E] LHR). The expected value can be calculated using formulas specific for the side of the lesion [120], which are also available on line (www.totaltrial.eu). The prognostic value of the O/E LHR was validated in 354 fetuses with unilateral isolated CDH, that were evaluated between 18 and 38 weeks gestation; later meta-analyses have confirmed this [121]. The O/E LHR is predicting mortality as well as early neonatal morbidity (Fig. 4.12) [122, 123].

Lung size can also be estimated by volumetric techniques, either using 3D ultrasound or fetal Magnetic Resonance Imaging (MRI). Because the ipsilateral lung is not always visible on 3D

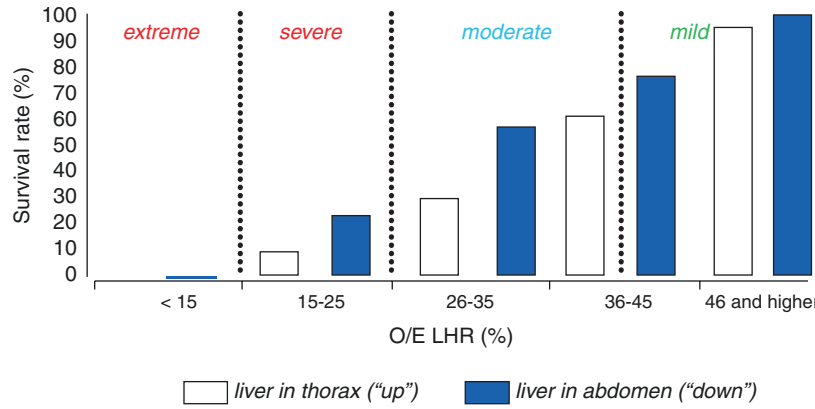

Fig. 4.12 Survival rates of fetuses with isolated left-sided congenital diaphragmatic hernia, depending on measurement of the observed/expected lung:head ratio (O/E LHR) and position of the liver position as in the antenatal congenital diaphragmatic hernia registry. From: Jan A. Deprest et al., Antenatal prediction of lung volume and in-utero treatment by fetal endoscopic tracheal occlusion in severe isolated congenital diaphragmatic hernia, Seminars in Fetal & Neonatal Medicine (2009), doi:https://doi.org/10.1016/j.siny.2008.08.010 (Deprest, Flemmer et al. 2009); with permission of authors and publisher

US, we do prefer MRI [124] (Fig. 4.13). Again measured fetal lung volume must be expressed as a function of what one expects for a gestational age- or weight-matched control [125, 126]. A recent meta-analysis has shown its predictive value [127]. Though we feel fetal MRI will become the method of choice, there is currently no proof for superiority over ultrasound yet [128].

The presence of liver herniation is also predictive, but whether it can be used as a sole feature remains a matter of debate [127, 129]. Liver herniation is easily visualized by ultrasound, using

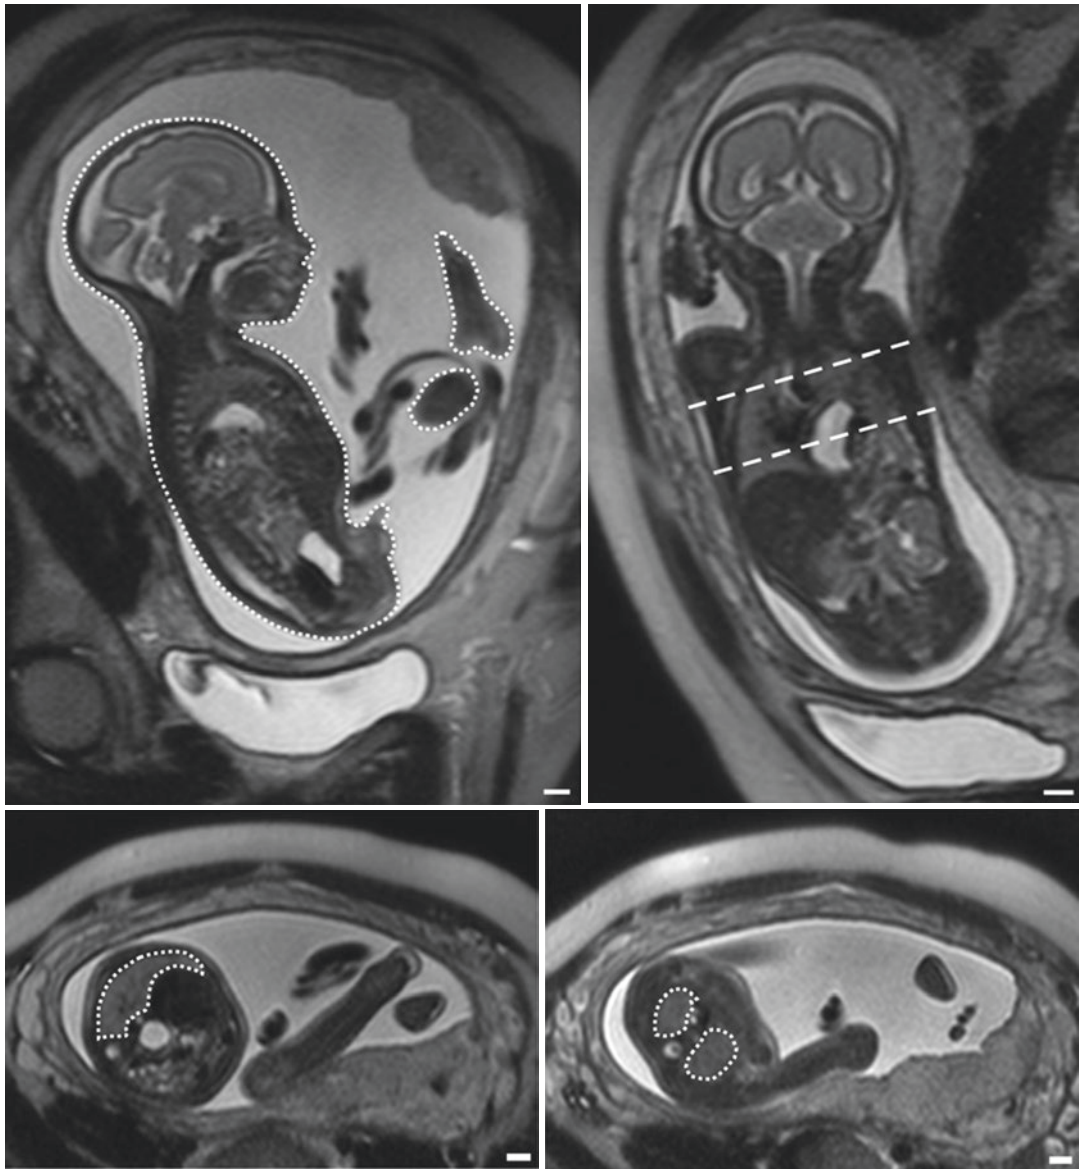

Fig. 4.13 T2 weighted images of fetus with left sided CDH at 26 weeks without liver herniation. Top left, sagittal section with tracing of the body contours. *Top right*: coronal view of the fetus demonstrating the level at which the two axial images are made (*bottom*). Lung tracing (*dotted line*) on the two axial views. *Scale*: white bar in right lower corner is 1 cm (From Deprest et al., Treatment of Congenital Diaphragmatic Hernia. In: Fetal MRI. Prayer D (Ed). Springer Verlag, Heidelberg 2011, 528 pp.)

the umbilical vein as a landmark. We and others have proposed to use MRI to quantify the degree of liver herniation more accurately, but we refer to the literature for further details [130] (Fig. 4.14). Position of the stomach is in Japan accepted as a predictor of outcome, based on its position as up or down [131, 132] or more specifically on its location in the thoracic cavity [133]. Several classification systems have been devised for standardized determinations of the stomach position such as by Kitano et al. [133], and more recently by Cordier et al., yet the latter on ultrasound [134]. Another less studied factor is pulmonary vascular assessment, for which again we refer to the literature (reviewed in [130]). Eventually more accurate prediction can be expected by combining techniques [135, 136], especially when they assess different aspects of the disease, such as parenchymal lung measurement and evaluation of the pulmonary vascularization.

4.6.6 Antenatal Management

CDH has been the sentinel condition proposed for fetal surgery. We refer to a recent review for the history of fetal surgery for this condition [137, 138]. Initially in utero anatomical two step repair was proposed. Since this includes reduction of the liver which causes umbilical vein kinking, the majority of cases are not amenable for fetal surgery. Now prenatal intervention consists of percutaneous Fetoscopic Endoluminal Tracheal Occlusion (FETO) (Fig. 4.15). Tracheal occlusion prevents egress of lung fluid, increasing airway pressure, causing proliferation, increased alveolar airspace and maturation of pulmonary vasculature (reviewed in [139]). The current timing of insertion and removal of the balloon is based on observations in sheep experiments, with a recent trend for later insertion to reduce the impact of preterm delivery, mainly due to ruptured membranes. Sustained TO, though inducing lung growth, reduces

the number of type II pneumocytes hence surfactant expression. This can be improved by in utero release ("plug-unplug sequence") [140]. Perinatal steroid administration has also been shown to beneficial [141]. Ideal balanced lung growth and maturation is however obtained experimentally by 47 resp. 1 h cycles of occlusion and release, but this is yet clinically impossible [142].

Several occlusion methods have been described, but an endovascular balloon is what currently is used [143]. This technique is amenable for a percutaneous approach under local anesthesia [144]. Also purpose designed instruments were developed with support of the European Commission (reviewed in [145]). Over time, invasiveness was reduced by moving away from general over locoregional to local anesthesia, with fetal analgesia and immobilization [146]. The FETO task force proposes for severe cases insertion of the balloon at around 28 weeks, and reversal of occlusion at 34 weeks. In utero reversal is achieved either by fetoscopy (50%) or ultrasound guided puncture (19%). Prenatal (>24 h) removal of the balloon has been shown to increase survival and decrease morbidity [147]. Removal at birth can be done on placental circulation or less ideally after birth. Peri- or postnatal retrieval should not be underestimated and problems with this have been the cause of neonatal death [146, 148, 149].

We have reported outcomes of 210 interventions, in fetuses with liver herniation and an O/E LHR <27–28%. Compared to historical controls from the antenatal CDH registry, FETO increased survival in severe cases with left-sided CDH from 24.1 to 49.1%, and in right-sided from 0 to 35.3% ($p < 0.001$) [122]. The strongest predictors of survival were observed/expected LHR *prior* to the procedure (OR, 1.490; $P = 0.019$) and gestational age at delivery (OR 1.024; $P = 0.007$). Early delivery typically is the consequence of Preterm Premature Rupture Of the Membranes (PPROM), occurring within 3 weeks occurred in 16.7% cases. Mean gestation at delivery was 35.3 weeks; only one in three delivers prior to 34 weeks. Interestingly, survival for those delivering at 32–33 weeks is equal to that at 34 weeks

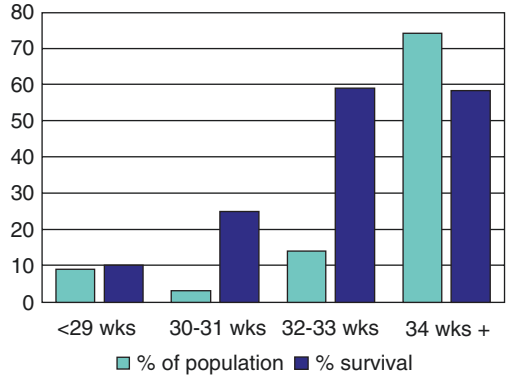

Fig. 4.16 Graphical display of number of patients delivering (*light blue bars*) and number of fetuses surviving (*dark blue bars*) as a function of gestational age. Modified from Deprest J, Nicolaides K, Done E, et al.: Technical aspects of fetal endoscopic tracheal occlusion for congenital diaphragmatic hernia. or later (60%; left sided cases only) (Fig. 4.16). Short term morbidity in survivors is better than expected: it is close to that of cases with *moderate* pulmonary hypoplasia, that were managed expectantly during pregnancy [147].

The early clinical experience has shown few demonstrable clinical side effects of the balloon on the developing trachea, except in very early occlusions and complications arising at the time of removal [48]. However, the neonates and infants do have obvious tracheomegaly, that does not seem to have a clinical impact, except for a barking cough on effort [48, 49]. Over time, the widening seems to become less important [49]. Most newborns require surgical patching of the diaphragm, indicating the rather large size of the defect in this selected group. The use of patch has previously been shown to be a predictor of outcome. High patch rates will increase the number of patch related complications, so that we felt research on engineering a diaphragmatic patch is now really required [150].

4.6.7 Trials on FETO Versus Expectant Management

Our initial experience has meanwhile been confirmed in other hands [151–153]. There is even one Brazilian randomized trial that showed an increased survival following FETO, though the survival rate in expectantly managed cases was very low (5%), which is not representative for most institutions [154]. Also right and left sided cases were pooled, which does not seem appropriate. In Europe there are now two trials ongoing (www.totaltrial.eu) (Table 4.7). One is in severe hypoplasia, with insertion of the balloon at 27–30 weeks and its removal at 34 weeks (NCT01240057). This protocol is based on our existing experience. A few items are worth mentioning. (1) We have slightly moved the time point of insertion from 26–28 to 27–30 weeks. This will lessen the risk for delivery prior to 32 weeks, the latter having a negative impact on survival (Fig. 4.16). The reason why we do not insert the balloon later, is that we have evidence for a less vigorous lung response with insertion beyond 30 weeks [155]. (2) We chose for in utero balloon removal (3) at 34 weeks. Prenatal removal was associated with a higher survival

Table 4.7 Criteria for fetal intervention for left sided CDH, as used in the TOTAL trial (www.totaltrial.eu). In that trial, FETO needs to be done within a certain window of gestation, as specified. Right CDH has been treated as well based on poor survival rates observed in the CDH antenatal registry [122]

Isolated left sided congenital diaphragmatic hernia	
Severe hypoplasia	Moderate hypoplasia
Severity: O/E LHR <25%, irrespective of liver position	Severity: O/E LHR 25–34.9% (included) irrespective of the liver position, or O/E LHR 35–44.9% (included) with intrathoracic herniation of the liver
Gestational age at randomization[a]: At the latest 29 weeks + 5 days → FETO between 27 weeks + 0 day and 29 weeks + 6 days	Gestational age at randomization[a]: At the latest 31 weeks + 5 days → FETO between 30 weeks + 0 day and 31 weeks + 6 days
Isolated right sided congenital diaphragmatic hernia	
Severe pulmonary hypoplasia

[b]Based on observations in the antenatal CDH registry [122]

[145, 147]. Moreover survival does not increase with gestation at delivery, once beyond 34 weeks. Timely and elective balloon removal avoids unexpected emergency balloon retrieval. However, in the two Brazilian series there was no apparent difference in survival with balloon removal at the time or prior to birth. The trial in foetuses with moderate hypoplasia has started earlier (NCT00763737)(Table 4.7). In this group occlusion is done at 30–32 weeks. For both trials, our neonatal colleagues from all over Europe designed a standardised consensus postnatal management protocol [156] (Table 4.8). In right sided cases, the cut off is at O/E LHR <45%.

4.7 Fetal Cardiac Interventions

Antenatal interventions for congenital heart disease remain experimental, despite a well-defined rationale, with only a few expert centres worldwide developing expertise. The Children's Hospital of Boston has led this research. In this Chapter, we will review critical valvular aortic stenosis with evolving hypoplastic left heart syndrome (HLHS) in the fetus, which is considered the sentinel pathology for potential intervention. For readers interested in the experimental intervention for pulmonary atresia and hypoplastic right ventricle, we refer to the Boston group's two recent publications as well as one from Linz [157–160].

4.7.1 Definition and Epidemiology

Critical aortic stenosis is a congenital obstruction to the left ventricular outflow tract. It occurs most commonly as a result of fusion or one or both aortic commissures, thereby reducing leaflet mobility [26]. The incidence is 3.5 in 10,000 births, and represents 5% of childhood cardiac disease. HLHS is a lethal congenital heart abnormality, whereby the left ventricle is unable to support the systemic circulation. It usually occurs due to obstruction to left ventricular outflow, with aortic atresia the most common (Fig. 4.17). The degree of the ventricular hypoplasia is proportional to the

Table 4.8 Summary of the most important items in the postnatal treatment of patient with CDH according, based on the consensus statement of the CDH-EURO consortium [156]

Treatment in the delivery room	• No bag masking • Immediate intubation • Peak pressure below 25 cmH_2O • Nasogastric tube
Treatment on the NICU/PICU	• Adapt ventilation to obtain preductal saturation between 85–95% • pH > 7.20, lactate 3–5 mmol/L • Conventional ventilation (CMV) or high frequency oscillation (HFOV) maximum peak-pressure 25–28 cmH_2O in CMV and mean airway pressure 17 cmH_2O in HFOV • Targeting blood pressure: normal value for gestational age • Consider inotropic support
Treatment of pulmonary hypertension	• Perform echocardiograhy • Inhaled nitric oxide (iNO) first choice in case of non response stop iNO • In the chronic phase: phosphodiesterase—inhibitors, endothelin antagonist, tyrosine kinase inhibitors
ECMO (extracorporeal membrane oxygenation)	• Only starting if the patient is able to achieve a preductal saturation > 85% • Inability to maintain preductal saturation above 85% • Respiratory acidosis • Inadequate oxygen delivery (lactate>5 mmol/L) • Therapy resistant hypotension
Surgical repair	• Fraction of inspired oxygen (FiO_2) below 0.5 • Mean blood pressure normal of gestational age • Urine output >2 mL/kg/h • No signs of persistent pulmonary hypertension

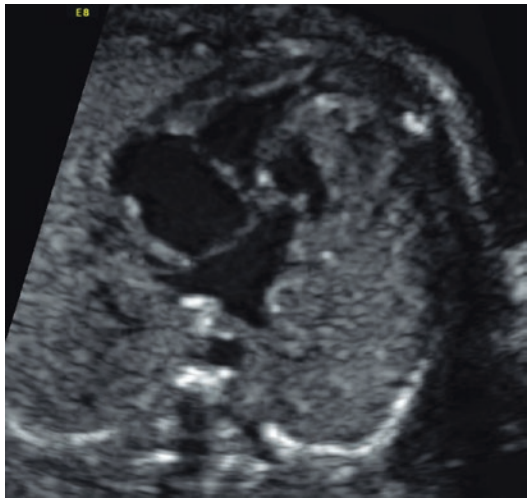

Fig. 4.17 Hypoplastic left heart syndrome

degree of outlet obstruction, unless an escape mechanism exists such as a ventricular septal defect [161].

4.7.2 Genetics

Aortic stenosis is associated with Turner, Noonan and William's syndrome. Aneuploidy is present in 5% of cases of congenital heart disease [22]. It is more common in males, 4:1. Recurrence is 2% with one affected sibling and 6% with two affected siblings. HLHS occurs in 10,000 births, with males twice as likely as females to be affected [22]. It is most commonly sporadic.

4.7.3 Pathophysiology and Natural History

Most fetuses with aortic valve stenosis will not sustain fetal compromise during pregnancy. However, a subset with critical stenosis (ductus dependent) may result in decreased right to left shunting between atria and thereby retard normal left ventricular development and result in HLHS. A pressure effect from the obstructed outflow tract first enlarges the left ventricle, coronary perfusion falls and cardiac function is impaired. Chronically raised ventricular pressures cause endocardial fibroelastosis and left sided structures such as the aortic root, mitral valve and left ventricle then fail to develop with advancing gestation [22, 162, 163]. Indeed, a preferential return of oxygenated blood towards the right ventricle and lower body rather than towards the left ventricle and the brain may also lead to suboptimal brain oxygenation *in utero*, which may be in part responsible for poorer neurodevelopmental outcomes [164, 165]. Significant restriction of the foramen ovale is present in 22% of patients with HLHS [166] and in 6% the atrial septum is completely closed. This drives increased pulmonary vein pressure and left atrial hypertension, as well as to pulmonary venous arterialization (abnormal vascular musculature) and hydrops. After birth, pulmonary venous return to the left atrium is increased, and obstruction to pulmonary venous drainage results in a further rise in pulmonary pressure, with severe hypoxemia, pulmonary oedema and haemorrhage. Emergency atrial septostomy is required.

About 5% of HLHS develop in the second trimester and are progressive [167]. Intrauterine growth restriction and hydrops may similarly develop. In Sharland and coauthors' series of 30 fetuses with left ventricular dysfunction, five fetuses with aortic stenosis developed into HLHS. There appears to be an overlap of diseases of primary left ventricular endocardial fibroelastosis, critical stenosis of the aortic valve and the HLHS [163].

Despite improvements in neonatal surgical and intensive care, the outcome of fetuses with hypoplastic left heart syndrome (HLHS) remains poor. Postnatal surgery, which for many results in a far from perfect single ventricle Fontan-type circulation [168], has a significant mortality rate, leading to a total survival of less than 65% [167]. Without it survival is not possible. The surgical choice is Norwood's three staged procedure or neonatal transplantation. For some fetuses with critical aortic stenosis, biventricular repair remains a possibility, with the therapeutic options including open and balloon valvulotomy [169].

4.7.4 Antenatal Diagnosis

Critical aortic valvular stenosis may be diagnosed antenatally, however sonographic features

for milder forms may be unreliable [22]. An early clue may include dilatation of the ascending aorta [26]. With critical obstruction, the left ventricle becomes hypokinetic and may appear dilated and hypoplastic on a standard 2D four chamber view. With advancing gestation however, ventricular size will become relatively smaller. Endocardial fibroelastosis may become evident. In cases of aortic and mitral atresia, the ventricle has a "slit" like appearance or may even appear absent, whereas aortic stenosis with mitral stenosis there is a small and very round or "tense" left ventricle, with the apex of the heart formed by the right ventricle [170]. Colour Doppler will reveal poor or absent filling of the diminutive ventricle. The aortic valve leaflets may be thickened with reduced motion and reveal turbulent and increased antegrade velocity on Doppler imaging. An absence of antegrade flow across the aortic valve confirms atresia. With severe stenosis, there may be hypoplasia of the mitral valve and aortic arch, or mitral stenosis and coarctation [26]. Mitral regurgitation can be determined by colour Doppler. The right ventricle and tricuspid valve should be inspected for regurgitation. The patency of the foramen ovale should be demonstrated by colour Doppler. Flow may become reversed across the atria, from left to right, with consequences for the pulmonary vasculature [26]. Doppler examination of the pulmonary veins then complements this assessment. In fetuses with a restrictive foramen ovale, the venous *a wave* is increased and peaked, with reversal of flow in the pulmonary veins during atrial systole [170]. Moving the transducer to the sagittal view will demonstrate retrograde flow in the ascending aorta and transverse aortic arch. Here, a coarctation may be visualised. At the three-vessel view, colour Doppler will show flow in the opposite direction of the adjacent pulmonary artery and arterial duct, confirming retrograde flow in the transverse aorta from the arterial duct. The Doppler profile in the arterial duct will similarly be altered. It is important to note here that the brain receives oxygenated blood via retrograde filling of the head and neck vessels from the arterial duct. Accordingly, the middle cerebral artery Doppler pulsatility index should be examined for central redistribution, or a fall in resistance, in an attempt to maintain fetal cerebral perfusion and guard against cerebral hypoxia. Fetal growth and amniotic fluid index may indicate IUGR. Sonographic evidence of additional abnormalities, aneuploidy and hydrops should all be meticulously sought.

4.7.5 Antenatal Prediction of Prognosis

For fetuses with critical valvular aortic stenosis, accurate prediction of evolving HLHS is imperative for parental counselling regarding continuation of the pregnancy, antenatal care, timing and patient selection for potential fetal intervention, to plan resuscitation and postnatal surgery. Mäkikallio and co-authors [171] from the Children's Hospital in Philadelphia, recently published anatomic and physiological variables in the mid gestation fetus with aortic stenosis and normal left ventricle size that are predictive of progression to HLHS. In their study on 43 fetuses diagnosed with aortic stenosis and normal left ventricular length at less than 30 weeks gestation, there were 23 live-born patients of which 17 developed HLHS and six having a postnatal biventricular circulation. All fetuses that progressed to HLHS had retrograde flow in the transverse aortic arch, 88% had left-to-right flow across the foramen ovale, 91% had monophasic mitral inflow, and 94% had significant LV dysfunction. With regard to all six fetuses who successfully achieved a biventricular circulation postnatally, they had antegrade flow in the transverse aortic arch, biphasic mitral inflow and normal LV function. These echocardiographic indices may help refine patient selection and assist prenatal counselling for progression of aortic stenosis to HLHS.

As with other fetal pathologies, the presence of hydrops suggests a bleak outlook. Similarly, the presence of tricuspid regurgitation conveys a poor prognosis for both survival and postnatal surgical success [170]. An added layer of complexity comes with a restrictive foramen ovale. Fetuses with a restrictive or intact foramen have a worse prognosis and may not respond to medical therapy in the postnatal period. This is a result of

abnormal pulmonary vasculature that develops from high atrial pressures. Hypoxaemia can develop quickly at birth and cardiovascular collapse is likely without immediate balloon atrial septostomy or surgery. Antenatal prediction of emergency atrial septostomy (or fetal intervention described below) is therefore essential to plan resuscitation and cardiac intervention at birth. The Cincinnati group have developed a pulmonary venous Doppler forward/reverse velocity time integral (FR VTI) ratio, that when less than three, optimizes specificity for predicting emergency atrial septostomy [158]. Others have performed a maternal hyperoxygenation challenge to study the response of the fetal pulmonary vasculature. Less than a10% decrease in the branch pulmonary artery pulsatility index after 10 min of 60% inspired oxygen administered to the mother is a non-reactive test and is predictive of emergency intervention at birth [172].

Furthermore, as introduced earlier, half of the long-term survivors have poor neurodevelopmental outcome [173], which may in part have an antenatal origin. Reduced middle cerebral artery pulsatility index may be a marker of such cerebral hypoxia, however this has not been specifically correlated with neurodevelopmental follow up in infants with HLHS.

4.7.6 Obstetric Management

Referral of suspected cases to an expert tertiary centre is required. Multidisciplinary counselling with maternal fetal medicine specialists, neonatologists, paediatric cardiologists and cardiothoracic surgeons are necessary. The diagnosis should be confirmed by fetal echocardiography as discussed above, including predictive indices. Additional abnormalities should be excluded and an amniocentesis performed to evaluate chromosomes. After counselling, termination of pregnancy should be offered to parents due to the poor prognosis and significant surgical morbidity that is necessary to sustain life. Expectant management may also be offered, whereby the pregnancy is conservatively cared for without intervention to spontaneous labour. At birth, comfort care to the neonate is offered. A clear plan from neonatology colleagues and parental support is clearly necessary. This may become more of an option as the pregnancy continues and repeat echocardiograms from 28 weeks gestation reveal progressive HLHS.

In some cases of evolving HLHS due to outlet valve obstruction, timely fetal balloon valvuloplasties offer the attractive rationale of ventricular recovery *in utero* and further growth (Fig. 4.18).

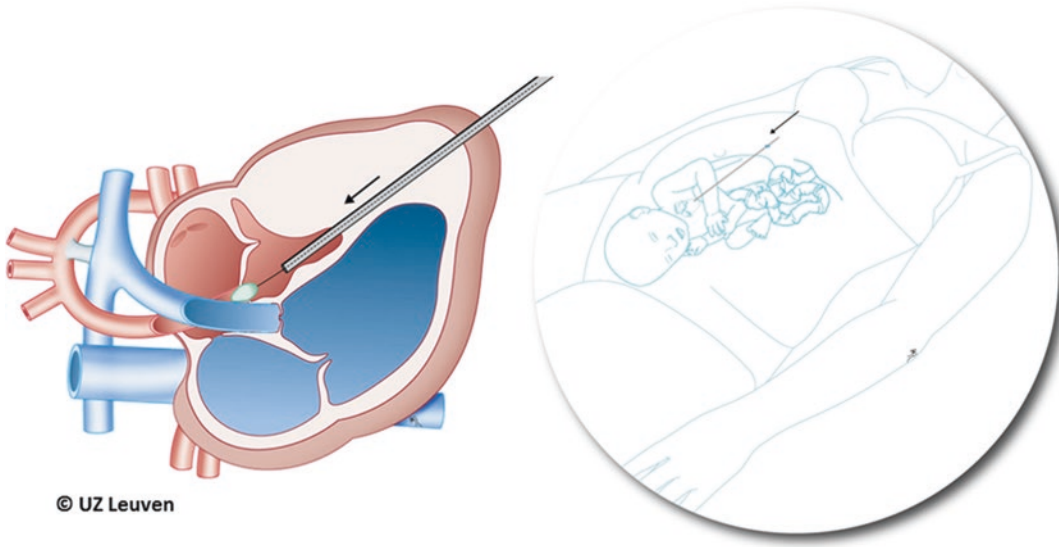

Fig. 4.18 Schematic drawing of in utero percutaneous aortic valve dilatation. Drawing: Myrthe Boymans. Reproduced, with permission from the UZ Leuven

Antenatal intervention theoretically reduces intraventricular pressure, improves coronary perfusion, reduces pulmonary pressures, promotes ventricular growth, and avoids development of myocardial fibroelastosis, thus all enabling improved cardiac function and potential biventricular postnatal repair [18].

Standardised needle-based procedures to access the fetal heart have been developed from groups in Boston (Massachusetts, US) [174] and Linz (Austria) [159]. A cardiocentesis is performed using a Seldinger technique to advance the working sheath into the target area under ultrasound guidance. Most cases can safely be performed under maternal local or locoregional anesthesia with fetal analgesia and immobilization. Maternal laparotomy rates are now therefore uncommon, falling from 27 to 10% in the Boston experience [160]. For the procedure, an 18 or 19 gauge needle is inserted into the fetal left ventricle at the level of the apex and in alignment with the left ventricular outflow tract (Fig. 4.18). A guide wire and a catheter with a coronary dilatation balloon are advanced through the aortic valve, which is dilated to 120% of the valve annulus. Fetal valves differ to children's valves, in that they are less complex structures, difficult to dilate and likely to re-stenose. Fetal resuscitation with inotropic medication, other vasoactive agents, or blood must be anticipated early to correct fetal acidosis or anaemia. Fetal complications include bradycardia requiring fetal resuscitation (17–38%), hemopericardium (13%), ventricular thrombosis (15–20%) and fetal death (8–13%) [159]. Maternal morbidity is rare, except when uterine exposure is needed for the procedure or emergency delivery. Rupture of membranes occurs in 2–7% of cases [175, 176].

In their largest series published in 2009 [174], the Boston group examined prenatal aortic valvuloplasty in 70 fetuses with aortic stenosis and evolving HLHS. The intervention was technically successful in 52 (74%) of treated fetuses, of whom 17 (33%) achieved biventricular circulation postnatally. However, prenatal aortic valvuloplasty altered the growth and function of some left heart structures (aortic valve, ascending aorta, mitral valve), but surprisingly did not change the growth velocity of the left ventricle. This may alter the approach to fetuses with evolving HLHS. Nevertheless, in fetuses with a larger left ventricle at enrolment, aortic valvuloplasty did increase the likelihood of a biventricular circulation. The authors developed a multivariate threshold scoring system of valvular and ventricular size and pressure to predict fetuses able to survive postnatally with a biventricular circulation. This may improve patient selection for fetal intervention. Of note, *in utero* atrial septoplasty for a highly restrictive foramen ovale has also been described, however the numbers remain small at this stage [177].

For otherwise continuing pregnancies, the fetal heart should be examined at 28 weeks gestation and then fortnightly thereafter for progression and the development of hydrops. The pregnancy should otherwise be allowed to continue to term. Delivery should occur in an experienced tertiary centre with immediate neonatal, cardiology and cardiothoracic surgery teams present. There appears to be no significant advantage of caesarean delivery when compared to vaginal birth. The Children's Hospital of Philadelphia compared 79 cases of HLHS delivered either vaginally or by caesarean section [178]. They found those delivered by elective caesarean had lower pH and higher partial pressure of CO_2 on arterial cord blood gas analysis, however no other differences in 1- and 5-min Apgar scores, markers of end organ function, echocardiographic parameters, length of hospitalization, and survival to discharge. It is even possible that vaginal delivery may prove advantageous, given that the fetus has a relatively fixed stroke volume and relies on heart rate to drive cardiac output. The physiological demands from vaginal delivery may protect the fetus by augmenting cardiac output from the single functioning ventricle [178]. Some centres plan induction of labour close to term to ensure a neonatal intensive care bed and appropriate staff are available and prepared to care for the neonate.

Others however, have advocated planned caesarean section for cases with restricted foramen ovale. It is argued a scheduled delivery facilitates immediate transfer of the neonate to an already well-prepared

team for emergency atrial septoplasty [158, 179]. An ex-utero intrapartum treatment (EXIT) procedure has also been reported to initiate extracorporeal membrane oxygenation before placental separation. Once stabilized, the neonate then underwent radiofrequency perforation of the atrial septum with a good outcome [180].

Prostaglandin E_1 therapy, often in conjunction with inotropes and correction of acidosis, is required for severe stenosis and HLHS [26]. If the stenosis is less severe and left ventricular function appears adequate and the condition is not duct dependent, the ductus arteriosus is allowed to close under close supervision.

4.8 Amniotic Band Syndrome

4.8.1 Definition and Epidemiology

Amniotic band syndrome (ABS) is a group of disruptive abnormalities and limb amputations; the likely consequence of early rupture of the amnion [26]. The reported incidence is 1 in 1300 live births.

4.8.2 Genetics

Considered sporadic. Associations with Ehlers-Danlos syndrome and osteogenesis imperfecta have been reported [22, 26]. There is no known risk of recurrence in future pregnancies.

4.8.3 Pathophysiology and Natural History

At first glance of our simple definition of early amnion rupture, one might expect the pathophysiology to be rather simple. However, there is a wide range of clinical manifestations and several theories have been developed to try and understand the observed complexity. Indeed there is a spectrum of many anomalies involving limbs, craniofacial structures, trunk, constrictive bands, and visceral and body wall abnormalities [22]. It is fair to say the exact cause remains unclear.

Of the proposed theories, Streeter in 1930 [181] suggested an intrinsic defect in the embryonic germinal disk and amniotic cavity, which resulted in later amniotic bands. This explains central anomalies of viscera, limb body wall complex and craniofacial structures, but is less satisfactory for extremities [182]. Torpin in 1965 [183] described an extrinsic theory, whereby early rupture of the amnion partially dislodges the fetus to the extra-amniotic space, with secondary amniochorionic mesodermal bands developing. A vascular disruption theory has also been proposed [184]. Most recently Moerman and colleagues [185] in Leuven, synthesised this work by proposing three distinct lesions: constrictive amniotic bands, amniotic adhesions and limb-body wall complex. This was based on their pathological study of 18 cases of ABS. In this series, four cases had constrictive bands presumed to be from amnion rupture that resulted in limb entanglement in shrivelled amniotic strands. This type may also be associated with cord entanglement and fetal death. In other cases, adhesive bands were observed to be the result of a broad fusion between disrupted fetal parts (mostly cephalic) and an intact amniotic membrane, while the limb-body wall complex is likely the result of vascular disruption. The authors suggest that the observed craniofacial defects (encephalocoeles and/or facial clefts) in these fetuses were not caused by constrictive amniotic bands, but were the result of a vascular disruption with or without cephalo-amniotic adhesion. Accordingly, the theories of Streeter and Torpin are not mutually exclusive and in fact may overlap. Timing of amnion rupture may also help to explain the variation in clinical manifestations. Huang and colleagues [186], suggested more severe visceral and skull abnormalities are likely to occur if rupture occurs before 45 days gestation.

Chorioamniotic separation, although considered normal until 16 weeks gestation, may occur either spontaneously, or following extrachorionic haemorrhage or invasive procedures such as amniocentesis, amnioreduction or fetal surgery [22, 187]. This may also increase the likelihood of ABS [188].

The natural history is difficult to predict. The degree of developmental disruption will determine the clinical outcome. Not unexpected with a definition of ruptured membranes is preterm

birth, with an average gestational age of 32 weeks in cases of ABS [22]. Low birth weight is also more common [189].

4.8.4 Antenatal Diagnosis

Sonographic features may be either isolated or appear in combination, reflecting the numerous forms of ABS. The bands themselves may be evident sonographically (Fig. 4.19), or more commonly, their effect on the fetal tissue can be seen. For example, bands may be inferred by absent or amputated digits or portions of limbs and constrictive bands from swollen distal limbs (Fig. 4.20). Similarly Doppler ultrasound may reveal compromised flow. Clubfeet or hands may occur. Craniofacial abnormalities may include cleft lip and palate, microphthalmia, encephalocoele and anencephaly. Encephalocoele can be attributed to ABS when they occur off the midline and anencephaly when some portion of the calvarium is present [22]. Gastroschisis, omphalocoele (less commonly) and limb body wall complex can all be associated with ABS [26]. Severe spinal defects, particularly when associated with abdominal wall defects, are consistent with ABS. Umbilical cord Doppler flow is essential to exclude cord involvement.

The sonographic presence of amniotic bands is not necessary to complete a diagnosis of ABS however, provided characteristic features are present. Fetal MRI has also been shown to be complementary to routine ultrasound [190].

Fig. 4.19 Amniotic band syndrome, evidenced by ultrasound. Image: courtesy UZ Leuven

4.8.5 Antenatal Prediction of Prognosis

Prediction of prognosis is not well established, however is likely to be proportionate to the

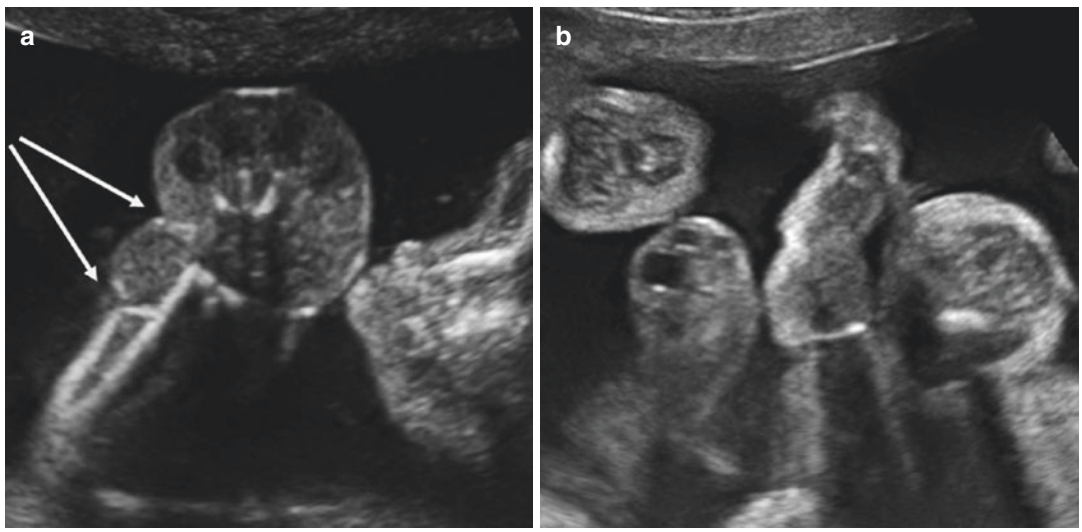

Fig. 4.20 Limb in Amniotic band syndrome. (**a**) Right forearm at 23 weeks: significant edema at the distal part and visualization of two notches created by the amniotic band (*arrows*). (**b**) Ultrasound image of the right arm and hand 1 month after fetoscopic release of the band. There is a decrease of the edema, with still two notches visible due to the amniotic band (*arrows*). c. At birth, there is still amniotic band tissue present around the arm, infiltrating into the subcutis. Images: courtesy UZ Leuven

Fig. 4.20 (continued)

Table 4.9 prenatal classification of Amniotic Band Syndrome by Hüsler (2009)

1. Amniotic bands without signs of constriction
2. Constriction without vascular compromise (normal vascular Doppler studies compared to opposite site)
(a) Without or only mild lymphoedema
(b) With severe lymph oedema
3. Severe constriction with progressive arterial compromise, flow measurements distal and proximal of the constriction band
(a) Abnormal distal Doppler studies when compared to contralateral extremity
(b) No vascular flow to extremity
4. Bowing or fracture of long bones at constriction site
5. Intrauterine amputation

complexity of the ABS. Tadmor and colleagues (1997) [191] serially observed lower limb amputation from 21 weeks gestation, with evolving sonographic signs of a constriction ring, oedema, patent then absent limb arterial Doppler, bending, breaking and finally resorption of both tibia and fibula. However, other reports have shown resolution [192]. Serial Doppler ultrasound forms an important part of clinical assessment, particularly with regard to cord involvement. Reversed end diastolic flow of the umbilical artery Doppler may become evident with worsening constriction [193]. Hüsler and colleagues (2009) [194] proposed a prenatal classification to reflect stages of ABS involving extremities, which is based on Weinzweig's postnatal classification [195] (Table 4.9).

4.8.6 Obstetric Management

Referral to a dedicated fetal medicine centre is appropriate. A detailed sonographic survey and fetal echocardiogram is essential. Amniocentesis for karyotype is recommended for cases of diagnostic uncertainty. Obstetric management is dependent on whether the ABS is isolated or more complex. For isolated cases, expectant management is the norm. Weekly Doppler surveillance in comparison to the contralateral side for constrictive progression seems appropriate. When progression is identified, fetoscopic intervention may salvage the developing limb. However, given the natural history is not well established, patient selection is not established. Compromised but present flow is probably the appropriate time for intervention. Richter and colleagues (2012) [182] recently reviewed all published cases of intrauterine release of amniotic bands to rescue fetal limbs. The outcomes were generally favourable, although it might not always be possible to visualize and/or dissect and cut the bands, without risk for collateral damage. The bands may be covered within a constrictive ring in an oedematous area. After the procedure partial to full disappearance of the signs, flow and/or functional recovery may be obtained, but postnatal surgery remains often necessary. In their series of ten cases, preterm prelabour rupture of the membranes occurred in 78% prior to 34 weeks, with 67% of cases delivering preterm. Ruptured membrane rates were higher following fetoscopic band release when compared with fetoscopy for other indications, which may be related to the inherent pathology of ABS. In 90% of cases (8/9), the band could be cut to some extent, but only in three cases (33.3%) there was complete release possible. Functional salvage of the limb occurred in 6/9 cases (67%). In the other three, secondary postnatal amputation was required in one and in two cases there was persistent reduced mobility.

For more complex ABS with multiple abnormalities, multidisciplinary counselling with geneticists, neonatologists and paediatric surgeons are essential. Options of expectant management and termination of pregnancy should be discussed with parents.

4.9 In Conclusion: From Tinkering to Translation

For the field of fetal intervention and surgery to continue to translate into improved and meaningful outcomes for our fetal and neonatal patients, training and research collaborations between maternal-fetal medicine specialists, neonatologists and paediatric surgeons must become fluid across multiple centres. Effective collaboration is necessary to ensure cohorts of fetal patients with rare diseases are identified and streamlined into formalised trials in specialised centres to evaluate our novel interventions. This chapter is but one example of the necessary dialogue needed across different medical specialties if we are to help improve the lives of our unborn fetal patients.

How Pathology Helps the Neonatal Surgeon

5

Michael Ashworth

Abstract

It is axiomatic that good pathology is essential for good patient care. For too long, pathologists have viewed their central role in diagnosis and clinical management as self-evident to all. Alas, the benefits of high-quality pathological investigation are not always self-evident, and much good work has gone unrecognized or unappreciated. To some extent we have ourselves to blame in that there has been a retreat of the pathologist to the autopsy room or the laboratory with a consequent lack of visibility in the clinical arena. The reduction in the volume and scope of pathology teaching in some undergraduate curricula has led to a lessening of the background pathological knowledge of many clinicians and, thus, the common meeting ground of clinician and pathologist has diminished. In pediatrics perhaps as nowhere else, is the need for a commonality of interest so great. Fortunately, in pediatrics the pathologist, by and large, is more visible in the clinical arena than in any other area. It is necessary for us all to strive to increase the commonality of interest for the benefit of the patient.

Pathology • Newborn surgery • Paediatric surgery

5.1 Introduction

It is axiomatic that good pathology essential for good patient care. For too long, pathologists have viewed their central role in diagnosis and clinical management as self-evident to all. Alas, the benefits of high-quality pathological investigation are not always self-evident, and much good work has gone unrecognized or unappreciated [1]. To some extent we have ourselves to blame in that there has been a retreat of the pathologist to the autopsy room or the laboratory with a consequent lack of visibility in the clinical arena. The reduction in the volume and scope of pathology teaching in some undergraduate curricula has led to a lessening of the background pathological knowledge of many clinicians [2] and, thus, the common meeting

ground of clinician and pathologist has diminished. In pediatrics perhaps as nowhere else, is the need for a commonality of interest so great. Fortunately, in pediatrics the pathologist, by and large, is more visible in the clinical arena than in any other area. It is necessary for us all to strive to increase the commonality of interest for the benefit of the patient.

5.1.1 Biopsy Handling

Ideally the sample should be submitted to the pathology laboratory fresh and as soon as possible after removal from the patient. It is important that the tissue is contained in a sterile container labelled with the patient's details and that it is accompanied by a request form giving basic demographics, a short summary of the clinical history and any notable features together with any particular points that the surgeon wishes to be addressed [3].

Submission of fresh tissue permits taking of samples for microbiological culture, for molecular biological analysis and for electron microscopy, all important and all increasingly being used for diagnosis and prognostication. The temptation on the part of the surgeon to open the specimen to have a sneak preview should be firmly resisted! This distorts the anatomy, particularly if the specimen is then placed in fixative, and makes assessment of resection margins very difficult, if not impossible.

5.1.2 Frozen Sections

The standard method of dealing with tissues for histopathological examination is fixation in formalin, followed by dehydration of the specimen in graded alcohols and embedding in paraffin wax to permit cutting of sections at 3–5 μm thickness. While this gives excellent preservation of detail for the pathologist, it does have several disadvantages:

Time. Fixation is a slow process with penetration of the tissues by the fixative at the rate of only several millimeters per day. Very small specimens fix rapidly; larger ones do not. To a certain extent this difficulty can be obviated by rapid fixation techniques such as microwaving where urgency is required [4]. However, even with the best techniques several hours are required. Where more rapid diagnosis is required the frozen section must be used.

Loss of enzyme activity and antigenicity with fixation. Enzyme activity is abolished with formalin fixation and if an enzyme histochemical technique is required the sample must be received fresh and then frozen. Some antigens are lost, or their expression is greatly reduced, by fixation. Newer techniques are being developed and antibodies optimized and antigen retrieval systems perfected to permit antigens previously undetectable on paraffin sections now to be seen [5]. Nonetheless the optimum expression is still seen on frozen section. Immunofluorescence techniques also still require frozen section.

In the frozen section technique the tissue is rapidly frozen to prevent ice crystal formation;, Ice crystals destroy tissue morphology and make the specimen worthless. Isopentane and liquid nitrogen are the most commonly used materials for rapid freezing. Once frozen the specimen needs to be cut in a special freezing microtome—the cryostat. Frozen sections are cut at a greater thickness than conventional paraffin section. This means that the cellular detail is not so good. Also tissues that contain a lot of air (such as lung) can become very distorted on frozen section [6].

In routine pediatric practice frozen sections are used for:

- assessment of ganglion cells on rectal suction biopsy
- acetylcholinesterase staining of rectal suction biopsies
- Identification of level of aganglionic zone in Hirschsprung pull-through
- muscle enzyme histochemistry
- intra-operative assessment of clearance of surgical resection margins

5.1.3 Histochemistry

Enzyme activity in a tissue is preserved after removal and can be detected by cutting frozen sections of the tissue and applying the enzyme

substrate, permitting the enzyme to work and then demonstrating the enzyme product by means of a color marker.

This is used most specifically for muscle biopsy where oxidative enzymes are employed and ATPase is used to identify fiber types. Latterly, immunohistochemistry is being increasing used in this field [7]. The demonstration of acetylcholinesterase activity in rectal suction biopsies is very useful in the assessment of Hirschsprung disease [8]. Multiple other enzymes can be demonstrated but their use is limited to large specialist, or research, centers.

5.1.4 Immunohistochemistry

The past 30 years has seen histopathology revolutionized by the introduction of immunohistochemistry. This employs the antibody-antigen interaction by using antibodies labelled with a coloring system and directed at specific antigens in the tissues. There are a vast number of antigens that can be identified and the list grows almost daily. The significance of demonstrating antigens in the tissue lies in the possibility of using an antigen profile to identify the origin of the tissue and yield diagnostic and prognostic information about its behavior. Nowadays most immunohistochemical techniques can be used on formalin fixed paraffin embedded tissue, although a few still require fresh frozen tissue. It is important to realize that a single antigen rarely, if ever, is specific to a single diagnosis and that panels of antibodies are required and even then must be interpreted in the context of the case [9].

5.1.5 Molecular Techniques

Molecular techniques can now be applied to tissue [10]. Again the point must be emphasized that the results of all these tests must be interpreted in the context of the case. If this is not followed then mistakes will be made [11]. The two most commonly employed techniques in molecular diagnosis are Fluorescent In-situ Hybridization (FISH) and Reverse-transcriptase Polymerase Chain Reaction (RT-PCR). High quality nucleic acid is required usually from fresh or frozen tissue, although techniques are now available for use on formalin fixed and paraffin embedded tissue. FISH can be used on tissue imprints, frozen sections or paraffin embedded sections. It requires the target DNA to be denatured and then hybridized with fluorescent-labelled DNA probes for target specific sequences of DNA. This technique is suitable for detection of translocations by using sequences that flank the breakpoint; if a translocation is present in the tissue then the probe sequences are separated. If fusion probes are used, then if a translocation is present the probes will be brought together. FISH can also be used for detection of amplification or regions of DNA, DNA gain or DNA loss.

In RT-PCR RNA is extracted from the tissue and the extracted nucleic acid is mixed with oligonucleotide primers and the enzyme DNA polymerase. This leads to amplification of large quantities of DNA highly specific to the primers used. This amplified product is then visualized by various techniques such as gel electrophoresis, restriction fragment length polymorphisms, Southern blotting or sequence analysis. The technique is exquisitely sensitive, and great care must be taken to avoid contamination with even minute amounts of extraneous nucleic acid. This requires meticulous attention to detail and use of appropriate controls.

FISH and PCR detect slightly different things and in practice are complementary techniques, each supplying the others deficiencies.

Pediatric tumors in which molecular biology is used routinely in the clinical setting [10] include neuroblastoma where the MYCN status of the tumor is used for prognostication, rhabdomyosarcoma where detection of the PAX-FKHR fusion transcript permits the diagnosis of alveolar rhabdomyosarcoma and primate neuroectodermal tumor (PNET) where the detection of EWS gene fusion transcripts is used in diagnosis.

5.1.6 Team Work

Running through all that has been written above is the need for teamwork. The pathologist is part of the clinical team. The information available to the pathologist needs to be of the best to permit

them to select the correct techniques of examination and correctly to interpret their result. There needs to be dialogue between surgeon, radiologist, pediatrician/neonatologist and pathologist in formulating diagnosis and approach to treatment and its monitoring. Constant feedback and regular meetings are essential for all to permit the maximum effectiveness of the team.

5.2 Developmental Disorders of the Gastrointestinal Tract

5.2.1 Oesophagus

True maldevelopments of the esophagus include esophageal atresia (with or without tracheoesophageal fistula), diverticula, webs and duplication cysts.

5.2.1.1 Esophageal Atresia and Tracheoesophageal Fistula

Esophageal atresia (OA) has an incidence of 1:3000–1:5000 live births and there is a high incidence of associated maternal polyhydramnios (50%). The commonest variants are proximal OA with distal tracheoesophageal fistula (TOF) (85%), OA without fistula (10%), "H-shaped" TOF without atresia (3%). In proximal OA with distal TOF, the esophagus is a blind ending pouch, ending a short distance from the cricoid cartilage [12]. The gap is in the order of 1–2 cm and the fistula usually takes origin from the carina posteriorly (Fig. 5.1). In Pure OA the gap much wider than with above. There is a high incidence of trisomy 21. The "H" type usually do not have associated abnormalities. Diagnosis is usually late.

Fig. 5.1 Oesophageal atresia with tacheo-oesophageal fistula. A hand-drawn illustration from the Archives of Great Ormond St Hospital for Children. This is a child who presented in 1901 with regurgitation after feeding. Attempts to place a tube in the stomach failed and a gastrostomy was fashioned. He died aged 5 days of pneumonia. A post-mortem was performed and the hand-written report (still extant) reads "a probe passed from the stomach up the oesophagus appeared through the larynx. A probe passed down the oesophagus from above was stopped one half-inch above the bifurcation of the trachea". The illustration shows the blind-ending upper oesophageal pouch behind the larynx, and the distal oesophagus taking origin from the carina of the trachea. Of the two probes in the larynx, one emerges from the left main bronchus and the other through the stomach wall close to the cardia

5.2.1.2 Esophageal Diverticulum

Congenital diverticula are rare and most are acquired. Histologically they consist of all layers of esophageal wall.

5.2.1.3 Esophageal Stenosis and Webs

These are very rare and usually have tracheobronchial remnants in the wall of the esophagus. True congenital lesions are akin to esophageal

atresia. They may be associated with OA or TOF. Webs are commoner in mid esophagus and stenosis commoner in lower esophagus. Webs consist of mucosal and submucosal tissue only.

5.2.1.4 Duplication Cyst

This may present with respiratory distress or feeding difficulties [13]. They may be detected antenatally [14]. Doubling of the esophagus may be tubular or spherical (Fig. 5.2). The cyst has a muscle coat (usually with two layers) and the lining epithelium is ciliated, non-ciliated, squamous or gastric or combinations of these. For the purposes of classification, if a duplication cyst is associated with vertebral defect it is best regarded as a neurenteric cyst. If the wall of the cyst contains cartilage the lesion is best classified as a bronchogenic cyst. (Fig. 5.3).

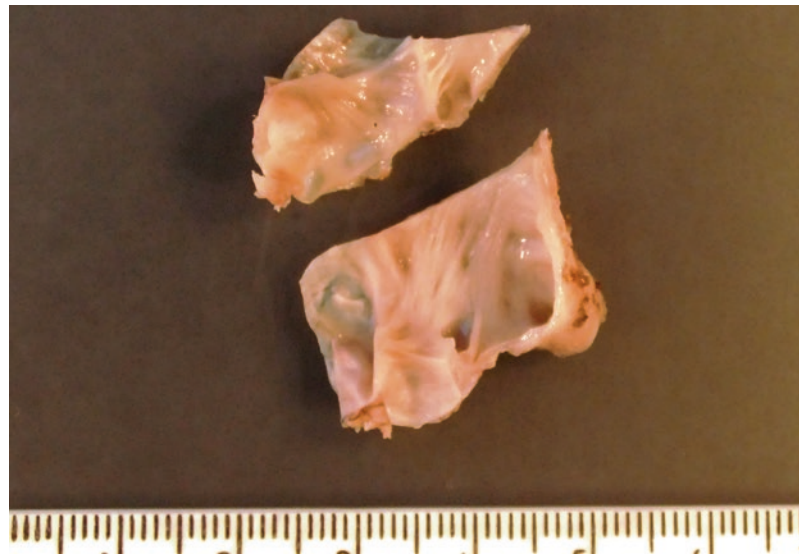

Fig. 5.2 Oesophageal duplication cyst. A 7-month old boy with a right-sided mediastinal cyst. The cyst was a mass 3.5 × 3.0 × 3.0 cm and contained thick mucus. The lining is white and trabeculated. Histologically it was covered by respiratory and squamous epithelium. The wall contained smooth muscle but no cartilage

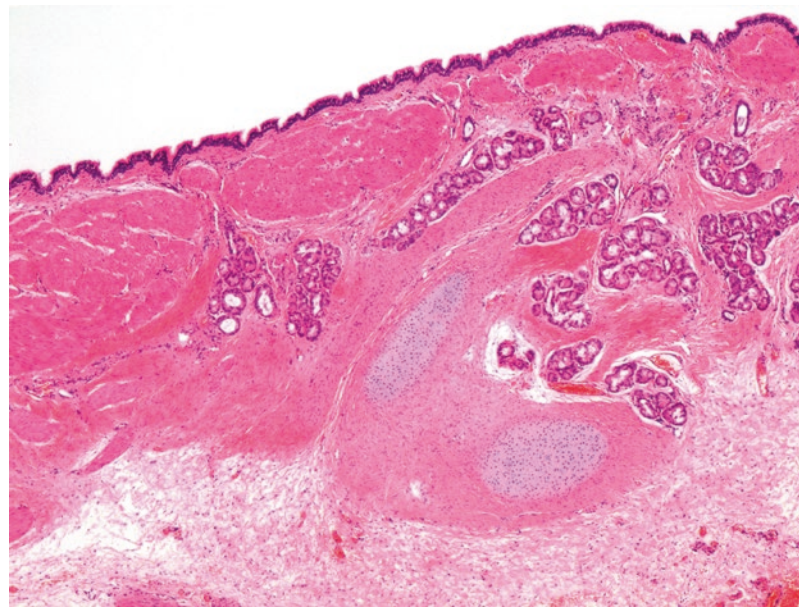

Fig. 5.3 Bronchogenic cyst. A left-sided chest mass 3.0 cm in diameter that has a wall composed of smooth muscle with sero-mucinous glands and hyaline cartilage. The lining is of ciliated respiratory epithelium

5.2.2 Stomach

5.2.2.1 Gastric Duplication Cysts

These are rare and may present as gastric outlet obstruction [15], abdominal mass, abdominal pain or failure to thrive. They are associated with duplication of esophagus or duodenum and vertebral abnormalities. Histologically they have a smooth muscle coat in continuity with that of the stomach wall and the cyst lumen may communicate with the gastric lumen. The mucosal lining is usually of gastric mucosa (Fig. 5.4).

5.2.2.2 Heterotopias

These include pancreatic tissue in wall of antrum (usually submucosa or muscle coat) that may cause gastric outlet obstruction. It is sometimes seen endoscopically as a dome-shaped nodule with a central punctum. It consists histologically of pancreatic acini and Brunners glands and may show prominent smooth muscle hyperplasia [16]. If Brunner's glands and smooth muscle alone are seen, the lesion is best termed an adenomyoma [17].

5.2.2.3 Hypertrophic Pyloric Stenosis

In this common condition of infants the pyloric portion of the stomach becomes abnormally thickened. It manifests as gastric outlet obstruction. There are few pathological descriptions; and these describe morphologically unremarkable smooth muscle. There is possible absence of sarcoglycans within hypertrophied pyloric muscle [18].

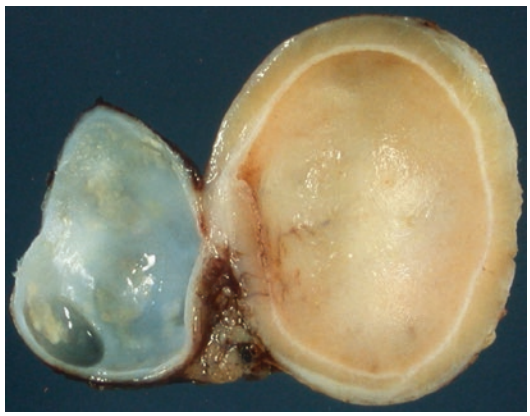

Fig. 5.4 Gastric duplication cyst. A 2.5 cm diameter cyst from the wall of the stomach. It is bi-lobed with a smooth lining and a muscular wall

5.2.3 Small Intestine

5.2.3.1 Intestinal Atresia

Intestinal atresia is an intrauterine process resulting in an incomplete bowel lumen. Duodenal atresia is mainly associated with trisomy 21. Usually it is treated with duodeno-duodenostomy and only rarely submitted for pathological assessment. Intestinal atresia is presumed to be due to intrauterine insult, either an ischemic or a hypotensive episode. The jejunum and ileum may also be affected. It may be isolated or multiple. Jejuno-ileal atresia is more commonly submitted for pathological assessment, because it is treated with resection and anastomosis. The specimen (Fig. 5.5) shows a discontinuous lumen and the atretic segment shows fibrosis [19] with focal muscularis replacement, dystrophic calcification and pigment-laden macrophages (Fig. 5.6).

5.2.3.2 Meckel's Diverticulum and Related Vitello-Intestinal Remnants

The vitellointestinal duct in the embryo joins the lumen of the midgut to the yolk sac. It is usually obliterated early in development. It can persist as a fistula between umbilicus and ileum; only parts of it may persist, the proximal part as Meckel's diverticulum or the distal part as an umbilical sinus or cyst. Meckel's diverticulum is present in between 1 and 4% of the population. It may be completely asymptomatic. There are symptoms in about one-fifth of cases: there may be ulceration either in the diverticulum or adjacent small bowel. It may cause hemorrhage, it may perforate or a foreign body may lodge in it to cause perforation. It may form the lead point for intussusception or it may have fibrous attachment to umbilicus and cause constriction of bowel with obstruction or volvulus [20]. The diverticulum is situated on the antimesentreic border of terminal ileum approx. 30 cm from

Fig. 5.5 Jejunal atresia. A 5-day old male infant with multiple segments of jejunal atresia. The specimen shows four pieces of small intestine. The longest is 14 cm long and it shows areas of thread-like narrowing. The other pieces also show tapered ends

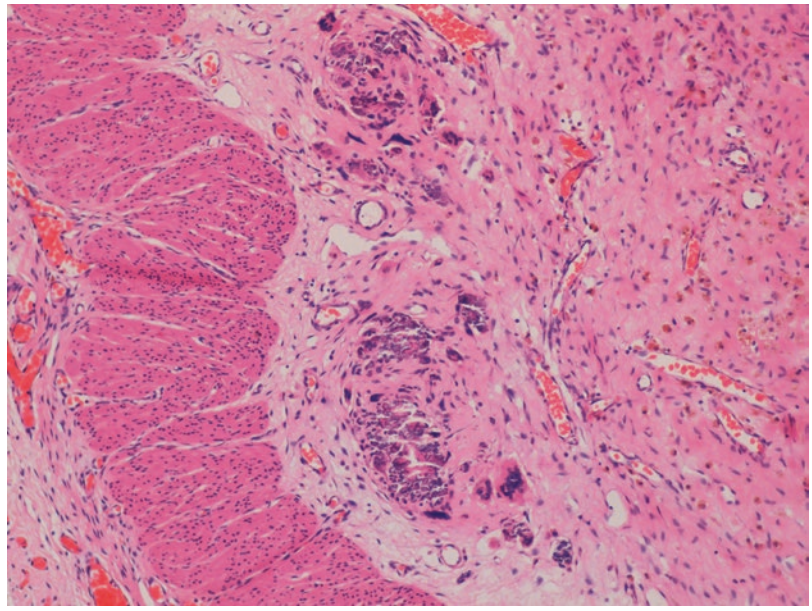

Fig. 5.6 Ileal atresia. Six-day old male infant with mid-ileal atresia. A 5 cm length of small bowel was resected that ended blindly. The section from the blind end shows that the muscle coat is still intact, but there is fibrous obliteration of the lumen and the presence of dystrophic calcification and haemosiderin-laden macrophages

ileocaecal valve. The diverticulum may be up to 8 cm long, but is usually much shorter (Fig. 5.7). It may be long and tubular or squat and almost cystic. The tip may be bifid or nodular. All components of normal bowel wall are present. The muscle coat may be very attenuated at the tip or distorted by heterotopic tissue. It is lined, usually, by ileal mucosa, but may have gastric body mucosa lining it [21]—Helicobacter organisms may colonise it. Rarely, colonic tissue is present or one may see ulceration or a bleeding point. There may be nodules of pancreatic tissue (including islets) in the wall and the serosa may show fibrosis or inflammation (Fig. 5.8).

5.2.3.3 Omphalomesenteric Cysts and Sinus

These present as umbilical discharge or granulation tissue. They are lined by small bowel, gastric or colonic mucosa (Fig. 5.9) and may contain pancreatic tissue. The lesions may ulcerate with replacement of the lining by granulation tissue to form an umbilical granuloma [22].

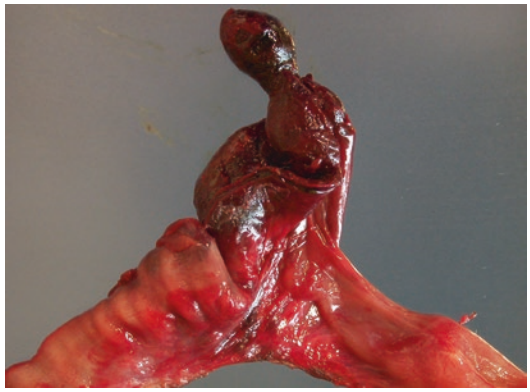

Fig. 5.7 Meckel's diverticulum. A 2-month old girl who underwent laparotomy for irreducible intussusception. A segment of ileum 21 cm long was resected. Protruding from the antimesenteric borer there is a Meckel's diverticulum 1.5 cm long and 0.8 cm in diameter that has undergone haemorrhagic infarction

5.2.3.4 Duplication Cysts

The cysts have a two-layered muscularis propria with outer layer fused with normal intestine (Fig. 5.10). The muscle coat contains a myentric plexus. The mucosal lining is usually enteric mucosa, but gastric mucosa is also common.

5.2.4 Large Bowel

5.2.4.1 Anorectal Anomalies

These are complex developmental defects with variable anatomy. While the treatment is largely operative, it is not usual for the pathologist to receive surgical specimens from these operations. Small segments of stenotic anal canal or rectum or small fistulae may be received showing disorganized musculature with variable fibrosis. Nephrogenic elements are sometimes seen in the distal bowel wall [23].

5.2.4.2 Currarino Triad

This is an autosomal dominant condition with incomplete penetrance comprising: teratoma, meningocoele, anorectal malformation and sacral bony defect. Approx. 50% of the cases also have Hirschsprung disease [24].

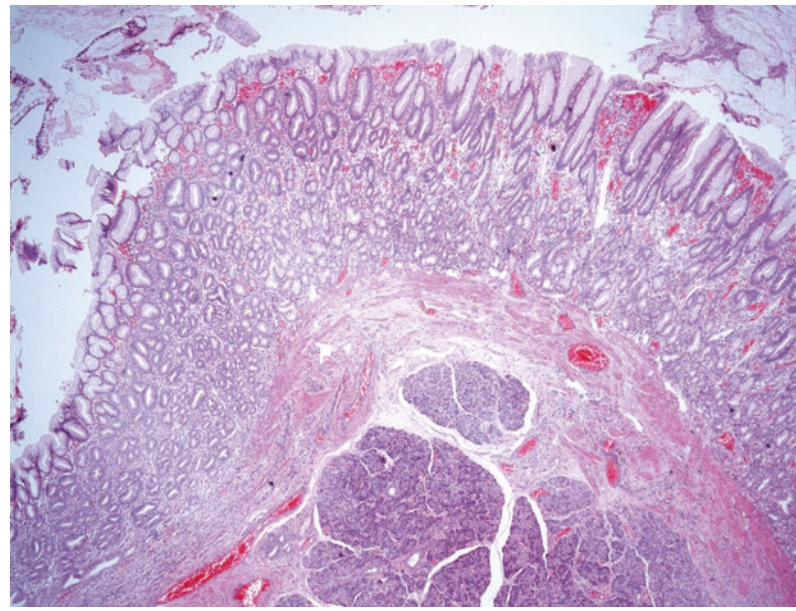

Fig. 5.8 Meckel's diverticulum—heterotopic pancreas. A 5-month old girl with ileo-colic intussusception. The lead point was a Meckel's diverticulum and histological examination of the tip of the diverticulum shows that it is lined by gastric antral type of mucosa, beneath which there is a nodule of heterotopic pancreatic tissue. The pancreatic tissue extended through the muscle coat of the diverticulum to its serosa

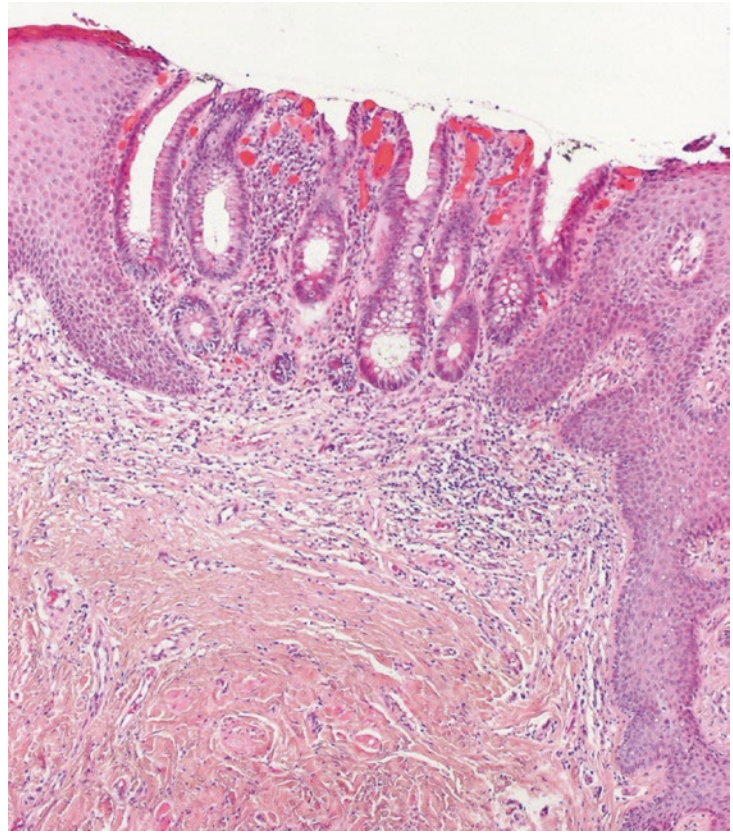

Fig. 5.9 Umbilical polyp—omphalomesentreic duct remnant. A polyp, partly covered by skin and partly by small bowel mucosa showing superficial capillary congestion and deeper chronic inflammation. Although the tissue may appear red and weeping, it is not, in fact, ulcerated

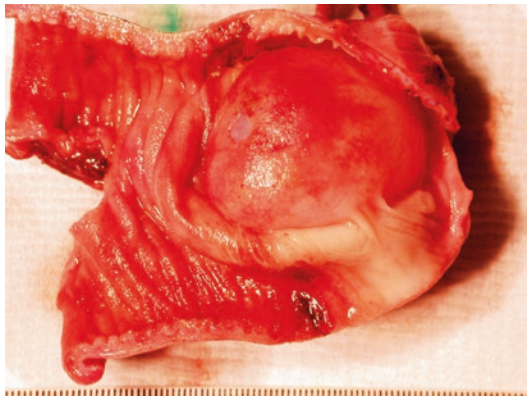

Fig. 5.10 Ileal duplications cyst. A 5-month old boy who presented with intestinal obstruction and at examination had an ileo-caecal mass. At laparotomy the mass was resected. The illustration shows the opened specimen. Protruding into the bowel lumen is a smooth-domed mass 3 cm in diameter that represents the cyst. Histologically it was composed of a two-layered muscularis propria with the outer layer fused with the normal bowel wall. The mucosal lining of the cyst was an admixture of simple cuboidal enteric-type mucosa and non-specialised gastric-type epithelium

5.3 Intestinal Obstruction

5.3.1 Intussusception

Although intussusception is rare in neonates, it does occur [25] and, especially in the premature infant may be misdiagnosed as necrotizing enterocloitis [26]. Only those cases that cannot be reduced medically come to pathological attention. The resected mass comprises:

- an outer layer of thinned distended bowel—the intussuscipiens
- an inner layer of everted, invaginated bowel—the intussusceptum

The mesentery of the intussusceptum is stretched and congested. The lead part of the intussusceptum may show a mass that may be lymphoid hyperplasia, sometimes secondary to infection with Adenovirus. It may also be due to

a polyp, a Meckel's diverticulum, a duplication cyst, a tumor or heterotopic pancreas (Figs. 5.11 and 5.12). The intussusceptum is frequently infarcted and hemorrhagic.

Histologically the intussusceptum shows edema and hemorrhagic infarction. Adenovirus inclusions may be seen in hyperplastic bowel surface epithelium. Other pathology associated with the cause of the mass may be recognized. The cause may not be identified other than lymphoid hyperplasia. The intussuscipiens shows thinning of its wall and it may also show hemorrhage.

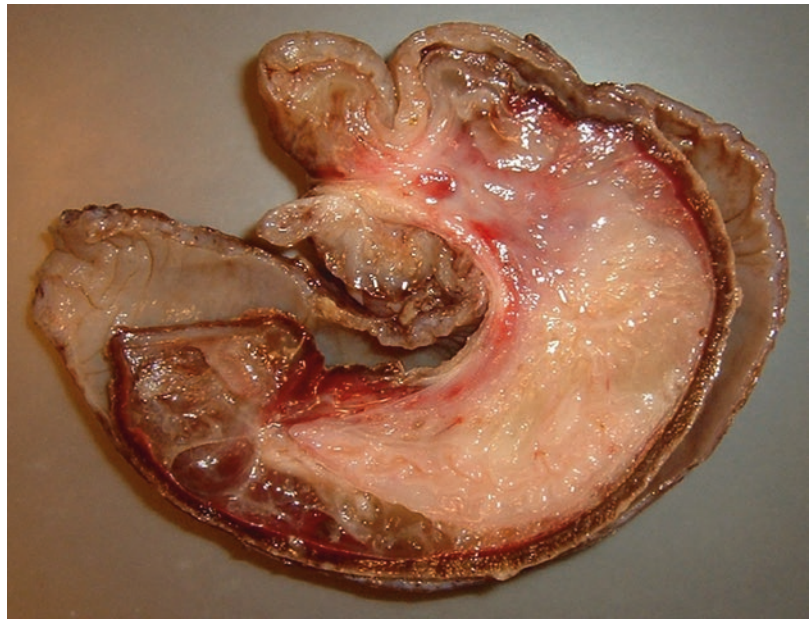

Fig. 5.11 Intussusception. A 5-month old girl with failed reduction of ileo-colic intussusception. The opened specimen shows the invaginated and everted small bowel contained within a sleeve of large intestine. The intussusceptum is infracted and there was a Meckel's diverticulum at its lead point that contained heterotopic pancreas in its wall

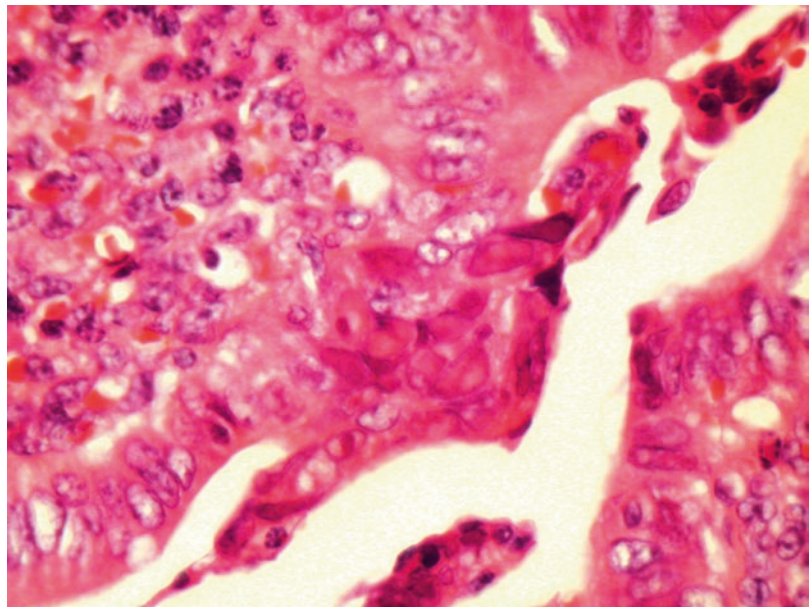

Fig. 5.12 Intussusception. An 8-month old boy with ileo-colic intussusception. The resected specimen showed lymphoid hyperplasia. A high-power view of the mucosal surface of the small bowel shows epithelial cell hyperplasia and numerous Adenovirus intranuclear inclusions

5.3.2 Volvulus

This refers to twisting of the bowel on its mesentery to such an extent as to compromise the mesenteric blood supply. It is associated with malrotation [27] with abnormally long mesentery showing a short attachment to the abdominal wall, with congenital bands or inflammatory adhesions. It may be fatal. Pathologically, the affected bowel is distended and shows hemorrhagic infarction with sharp demarcation from the unaffected bowel (Fig. 5.13). It is rare for the pathologist to identify a cause of volvulus in the submitted specimen.

5.3.3 Meconium Ileus

This refers to neonatal bowel obstruction due to impacted meconium, most commonly in the terminal ileum. There may have been intrauterine obstruction or perforation. Meconium ileus is typically associated with cystic fibrosis, affecting about 15% of neonates with cystic fibrosis. However, about 10–20% of apparent meconium ileus cases do not have cystic fibrosis. Very low-birth weight and premature infants especially can develop meconium obstruction in the absence of cystic fibrosis [28]. The clinical picture may be mimicked by total colonic aganglionosis.

The resected surgical specimen show secondary features of perforation and meconium peritonitis with granulation tissue, dystrophic calcification and fetal squames, as well as pigment (Fig. 5.14). The intestinal lumen characteristically is filled with inspissated meconium, the mucus extending deep into crypts (plugging). A similar histological picture may be seen in premature infants with meconium plugging who do not have cystic fibrosis [29] (Fig. 5.15).

Fig. 5.13 Volvulus. An 11-month old with intestinal obstruction. Laparotomy showed volulus caused by adhesions because of previous Nissen fundoplication. A 25 cm length of bowel was resected. The image shows the resected bowel. The serosal surface is congested and shows a shaggy appearance caused by fibrinous exudate. The middle part of the specimen shows haemorrhagic infarction with very dark disclouration and haemorrhage. A perforation on the antimesenteric border is evident at bottom left. Note the sharp demarcation between infracted and non-infarcted bowel

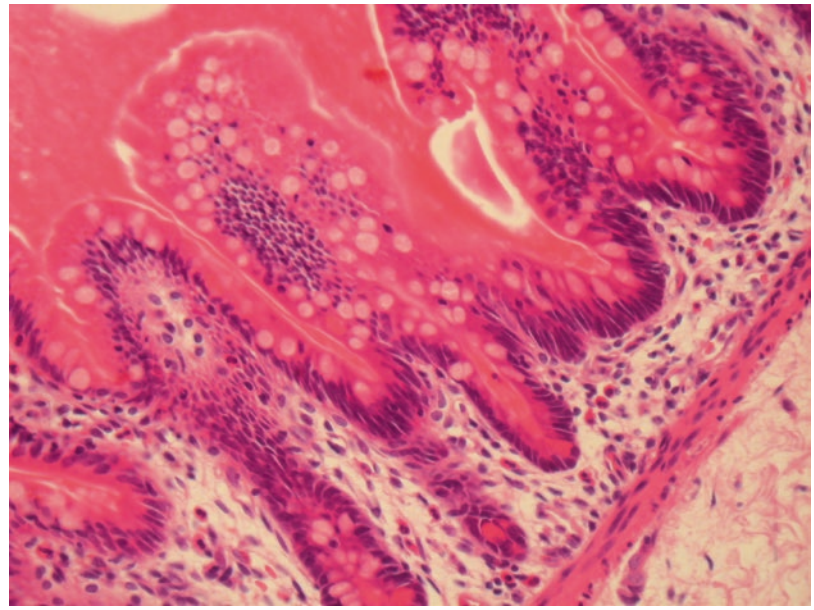

Fig. 5.14 Meconium ileus cystic fibrosis. Two day old boy with cystic fibrosis gene mutation who presented with meconium ileus and microcolon. There was associated ileal atresia. The resected specimen shows small bowel mucosa with inspissated mucus in the crypts

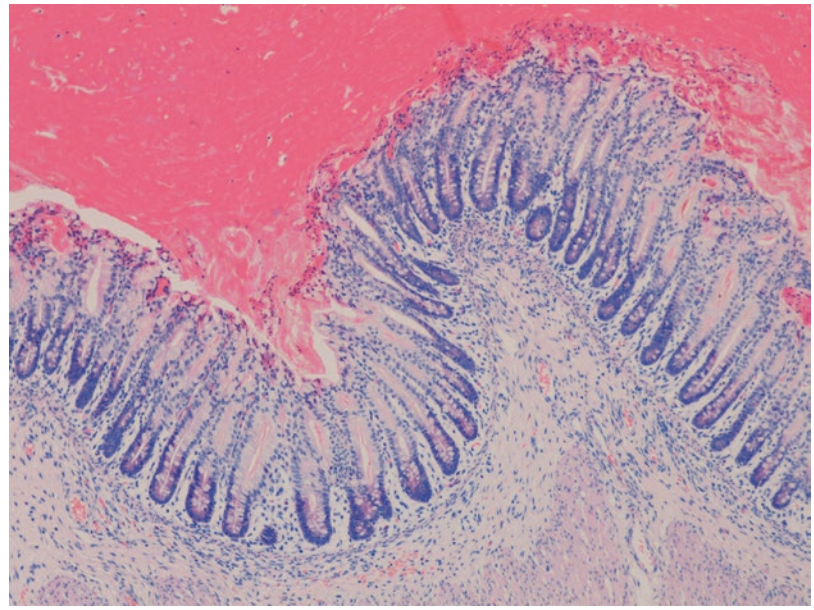

Fig. 5.15 Meconium ileus in a premature infant. Five day old premature male infant with meconium ileus. Cystic fibrosis screening negative. The histological section of the resected bowel shows dilated bowel with inspissated meconium in the crypts, identical to that seen in patients with cystic fibrosis

5.4 Hisrchsprung Disease

Hisrchsprung disease is a developmental disorder in which there is absence of ganglion cells in the distal rectum and a variable length of contiguous proximal bowel. Caused by failure of neural crest cells to migrate, proliferate, and/or differentiate during development of the enteric nervous system.

In most cases of Hisrchsprung disease the diagnosis is straightforward, but in a small number the diagnosis can be difficult to the extent of being one of the most difficult areas in pediatric pathology practice. This area is the commonest cause of litigation in pediatric pathology practice. Meticulous examination and documentation are essential. Pitfalls abound for the unwary.

There are three stages in the care of Hisrchsprung disease in which there is histopathological involvement:

1. primary diagnosis
2. intraoperative guidance of resection of the aganglionic segment
3. evaluation of the resected bowel

The histopathologist may, of course, also be involved in further evaluation if the patient continues to have symptoms after the definitive surgical procedure.

5.4.1 Primary Diagnosis on Rectal Suction Biopsy

The diagnosis of Hisrchsprung disease is made or excluded on rectal suction biopsy: the quality of the biopsy sample critically depends on the skill and experience of the operator. The diagnosis rests on demonstrating the absence of submucosal ganglion cells in an adequate sample (Fig. 5.16), with or without accompanying hypertrophic submucosal nerves (diameter greater than 40 μm). An abnormal acetylcholinesterase (AChE) staining pattern is diagnostic—there are increased numbers of coarse fibers in the muscularis mucosae and lamina propria mucosae with transversely running nerve fibers in lamina propria (Fig. 5.17).

Laboratories differ in their approaches to these biopsies. Acetylcholinesterase staining can be demanding and difficult and cannot be employed on formalin fixed, paraffin embedded tissue. It is not used in all laboratories. Many laboratories rely on H&E staining of serial paraffin sections; In some, enzyme histochemical staining for lactic and succinic dehydrogenase and nitric synthase are also used [30]. Some groups use enzyme histochemical staining for nicotinamide adenine dinucleotide phosphate (NADPH)-diaphorase [31]. Immunohistochemical staining for many

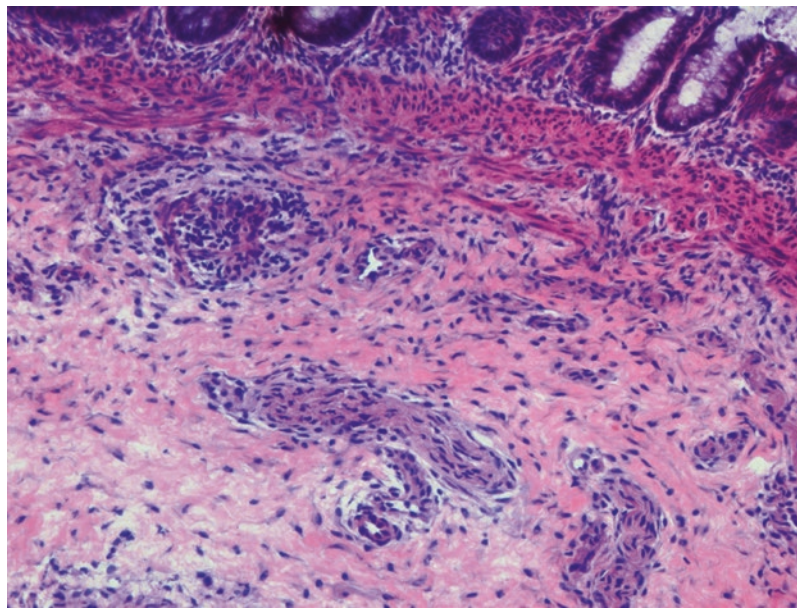

Fig. 5.16 Hirschsprung disease—rectal suction biopsy. The image shows an H&E stained section of a rectal suction biopsy in a neonate with Hirschsprung disease. The bases of the mucosal crypts and the muscualris mucosae are visible in the upper part of the image. The rest of the field represents submucosa. As is normal in the neonate the tissue is cellular, but there are no ganglion cells. There are however, multiple, abnormally thick submucosal nerves. While this picture is typical of Hirschsprung disease, in reality, multiple serial sections need to be viewed to be certain of the absence of ganglion cells. Acetylcholinesterase staining greatly assists the interpretation

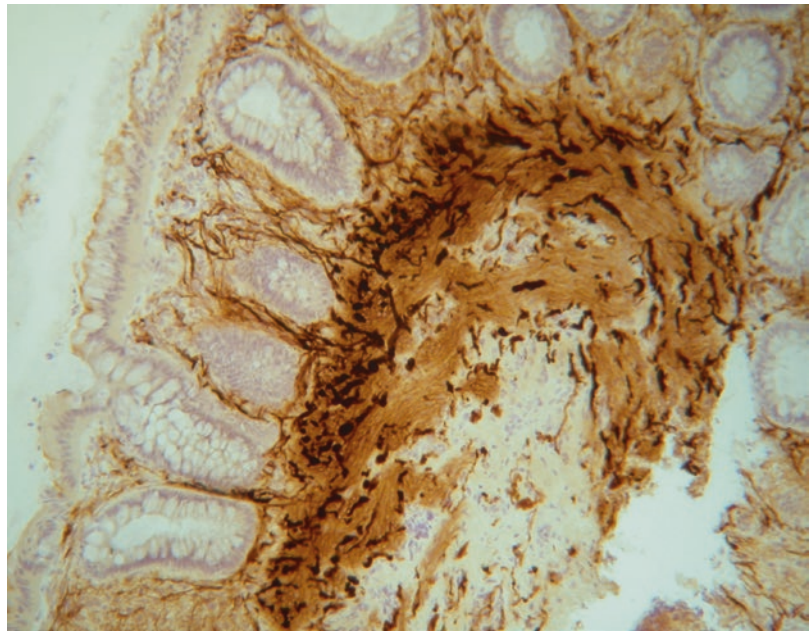

Fig. 5.17 Hirschsprung disease—acetyl cholinesterase. Neonatal rectal suction biopsy snap frozen, sectioned and stained for acetlycholinesterase activity. Positive reaction product is stained *dark brown*. There are large irregular and knotty nerve fibres in the muscularis mucosae and a marked increase in fibres in the lamina propria mucosae, including nerve fibres running parallel to the biopsy surface. This appearance is characteristic of Hirscshsprung disease

different antigens has been described. Most facilitate recognition of ganglion cells, but in practice add little to the H&E-based interpretation of an experienced pathologist. Recent interest has centered on Calretinin immunohistochemistry [32]. Loss of calretinin immunoreactive nerves correlates spatially with aganglionosis (Figs. 5.18 and 5.19). This has the advantage of being employable on formalin fixed paraffin embedded tissue. Many laboratories have switched to this technique and are pleased with the results. The technique, however, does have the theoretical disadvantage that it relies on absence of staining for a positive result.

At least two rectal suction biopsy specimens at different levels above the dentate line (e.g. 2, 3, 5 cm) are required and should be received fresh on saline-moistened filter paper. If an urgent diagnosis is required, the specimens are processed immediately. The specimen from the lowest level (distal) should be cut first. Specimens are oriented with the submucosal side up, frozen rapidly and serial sections cut without trimming. Rapid H&E staining is performed and when many sections with submucosa are present, the slides are passed to the pathologist. Two further frozen sections are then cut and a rapid Acetylcholinesterase stain is performed (45 min). If the specimen is ganglionic, a standard acetylcholinesterase stain is performed later. A report can be issued to the surgeon in less than 1 h from receipt of the specimen. After the acetylcholinesterase stain is reported, the remainder of specimen is fixed in 10% buffered formalin for paraffin processing. A ribbon of at least 60 serial sections is cut with the specimen orientated in usual way and stained with H&E.

5.4.2 Assessment of Rectal Suction Biopsy Specimens for Hirschsprung Disease and Its Pitfalls

Ganglion cells must be identified on H&E stained sections. Ganglion cells in a neonatal biopsy are small with neuroblastic morphology and more difficult to identify than mature ganglion cells (Figs. 5.20 and 5.21). Histiocytes and endothelial cells may mimic them and it is important to check neighboring sections. Cytomegalovirus infected cells in the submucosa can be mistaken for ganglion cells. This may seem an unlikely possibility,

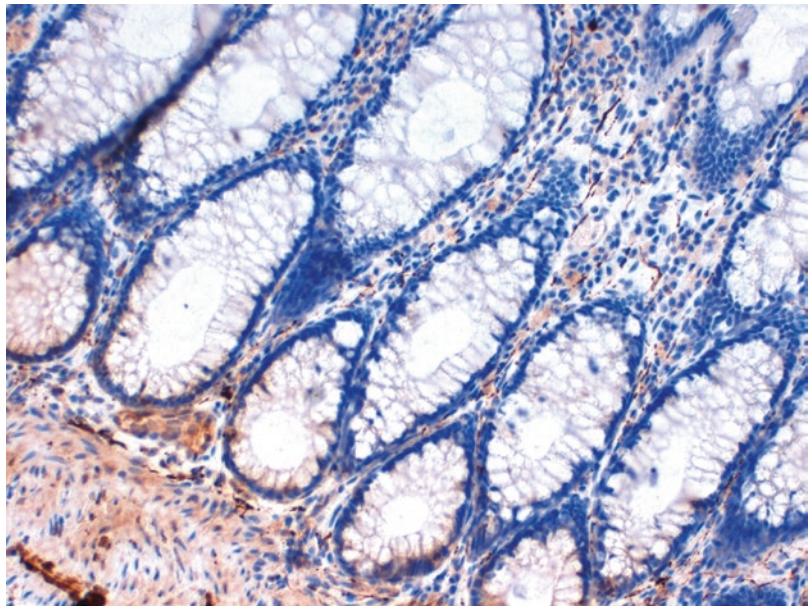

Fig. 5.18 One year old girl with constipation. Rectal suction biopsy to exclude Hirschsprung disease. The specimen was normal A section from the biopsy specimen stained immunohistochemically for Calretinin. The picture shows a view of the mucosa with a small amount of musclularis mucosae and submucosa to the lower left of the field. *Dark brown* nerve fibres are evident in the lamina propria mucosae (running vertically). A few small fibres are evident in the muscularis mucosae and part of the strongly stained body of a ganglion cell is seen at the lower edge of the field

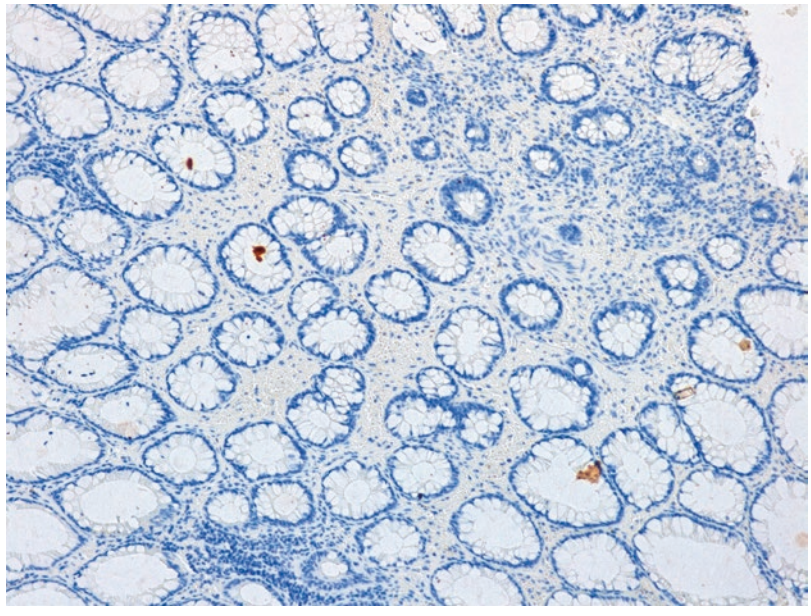

Fig. 5.19 Hirschsprung disease. Five day old boy with Hirschsprung disease. Rectal suction biopsy stained for calretinin. The biopsy is superficial and shows no muscularis mucosae or submucosa, precluding assessment of the presence or absence of ganglion cells. The absence of positive staining of nerve fibres for calretinin indicates that this is a case of Hirschsprung disease. In the absence of submucosa it is not possible to be sure whether this represents aganglionic or transition zone

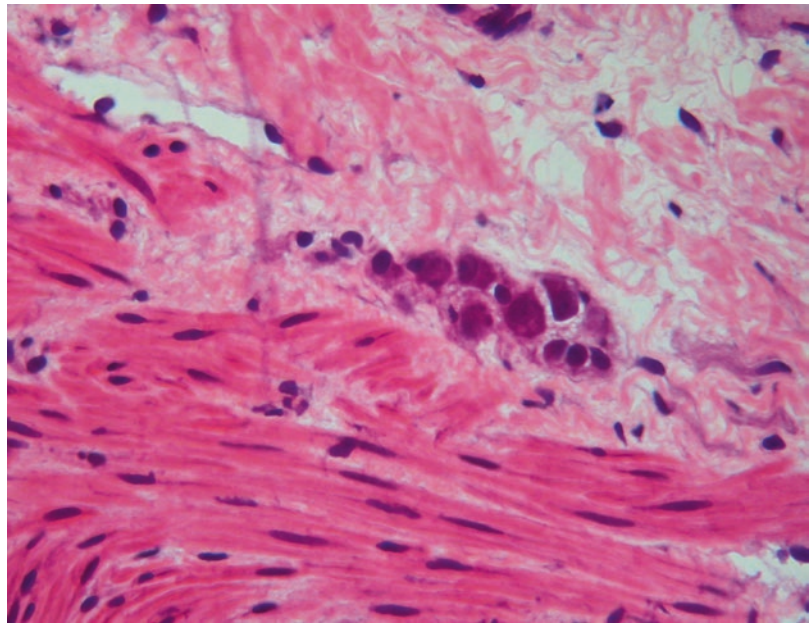

Fig. 5.20 Normal mature submucosal ganglion cells. A high-power view of an H&E stained section of a rectal suction biopsy from an infant without Hirschsprung disease. A group of approximately six ganglion cells is present close to the muscularis mucosae. The characteristics of mature ganglion cells are well seen; large size, basophilic cytoplasm, eccentric, round nucleus, prominent nucleolus and surrounding satellite cells

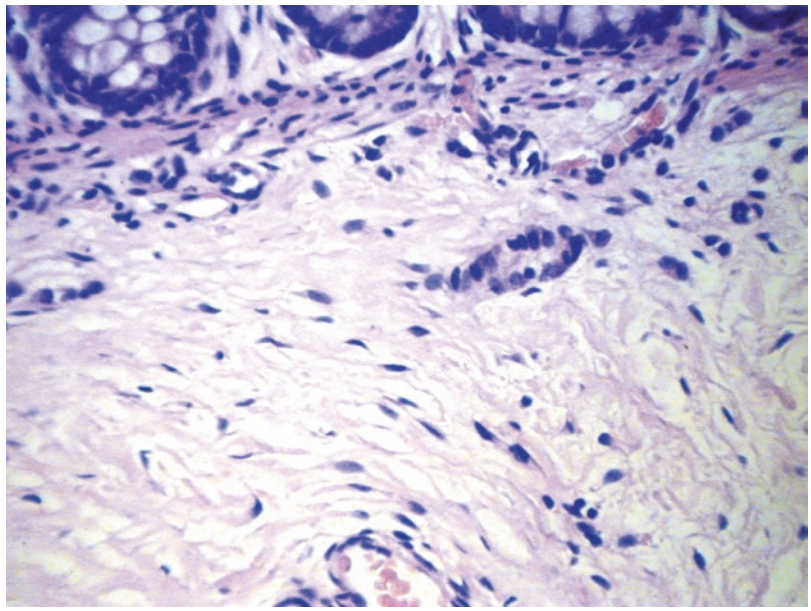

Fig. 5.21 Normal immature submucosal ganglion cells. A high-power view of an H&E stained section of a rectal suction biopsy from a neonate. The bases of the mucosal crypts and the muscularis mucosae are visible at the top of the field. There is a single group of immature ganglion cells lying close to the muscularis mucosae in the centres of the field. In contrast to the mature ganglion cells they show little cytoplasm and the nuclei do not contain prominent nucleoli. When ganglion cells are this immature, they are recognised by their disposition in a characteristic horseshoe pattern. Adjacent sections should be checked to ensure that this structure is not a blood vessel or a group of other cells. Acetylcholinesterase staining greatly aids in the interpretation

but it has happened to me! Such infected cells usually show surrounding inflammatory cells [33].

When ganglion cells are identified with certainty, the report is formulated as "ganglionic at the level of this biopsy" especially if only one specimen is received. This allows for the possibility of short segment disease which may become apparent if symptoms continue and further biopsies are taken at lower levels.

If ganglion cells are present but there are large hypertrophic nerves in the submucosa, the possibility of intestinal ganglioneuromatosis should be suggested.

In a biopsy from the physiological hypoganglionic zone 1–2 cm proximal to dentate line ('low biopsy') there may be extremely sparse ganglion cells, often single rather than in usual clusters. Usually there are associated prominent thick-walled blood vessels. There are also prominent nerves, but they are not hypertrophic. Splayed muscle fibers of sphincter may also give a clue to the low site of the specimen. There may be squamous epithelium or transitional anal mucosa present (Fig. 5.22). The acetylcholinesterase pattern is normal. If no ganglion cells are identified in such a specimen it is reported as: "Morphologic low biopsy. Normal acethylcholinesterase. Repeat biopsy recommended if clinically indicated".

If the biopsy specimen has inadequate submucosa for assessment of the presence of ganglion cells, the acetylcholinesterase staining pattern is crucial. If the acetylcholinesterase pattern in the muscularis mucosae is typical of Hirschsprung disease, then the report to the surgeon is: "Superficial biopsy. No ganglion cells identified. Acetylcholinesterase pattern suggestive of Hirschsprung disease." If the biopsy specimen has inadequate submucosa and the acethylcholinesterase pattern is normal, then the report is: "Superficial biopsy. No ganglion cells identified. Normal acethylcholinesterase. Repeat biopsy advised if clinically indicated" If the acethylcholinesterase staining is equivocal, a repeat biopsy is advised.

There is variability of the morphological patterns. No hypertrophic nerves are present in some cases of Hirschsprung disease.

5.4.3 Short Segment Hirschsprung Disease

The definitions vary. Together with our surgeons we define short segment Hirschsprung disease as

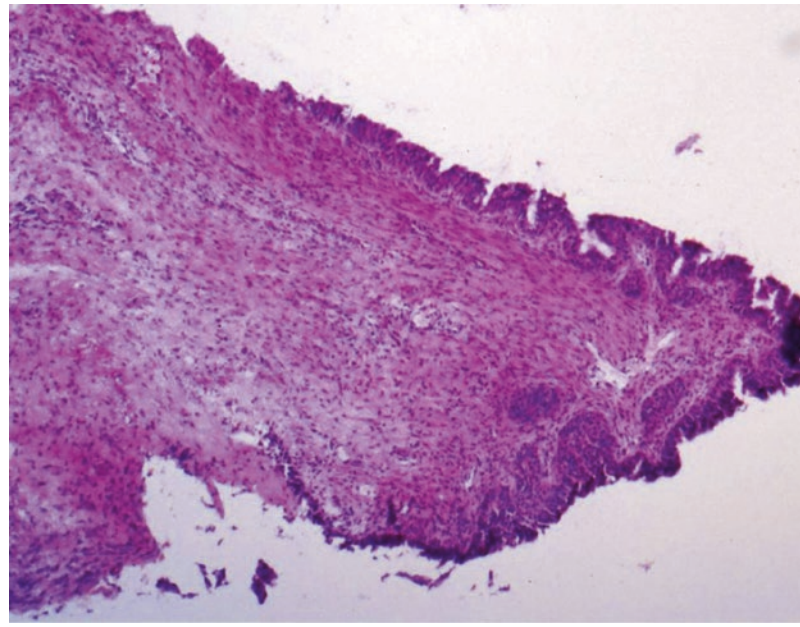

Fig. 5.22 Rectal suction biopsy for suspected Hirschsprung disease. The specimen shows an H&E stained section. It is composed of anal mucosa covered by transitional epithelium. The biopsy is too low for adequate assessment of ganglion cells

Hirschsprung disease in which the length of aganglionic bowel is less than 2 cm. The diagnosis is made when only the most distal rectal suction biopsy or part of the biopsy shows the appearances of Hirschsprung disease. The more proximal biopsies show normal ganglionic bowel with normal acetylcholinesterase staining.

5.4.4 Ultra-short Segment Hirschsprung Disease

Again, definitions vary, but together with our surgeons we define this as a clinical syndrome with functional abnormality of internal anal sphincter (internal sphincter achalasia) diagnosed on anorectal manometry and with no detectable morphological abnormality on rectal suction biopsy.

5.4.5 Intestinal Neuronal Dysplasia (IND)

This has been very controversial over the years. It is now recognized as a morphological description of a normal variant of the submucosal plexus [34, 35]. The finding of 'giant ganglia' containing more than seven nerve cells is a normal feature of biopsies in infants under the age of 1 year. The only situation in which the changes of IND may be of clinical significance is proximal to an aganglionic segment in a patient with Hirschsprung disease.

5.4.5.1 Reporting on Frozen Sections of Intra-operative Biopsies

Treatment of Hirschsprung disease is by surgical removal of the aganglionic segment. The procedure is guided by intraoperative frozen section diagnosis to determine the level at which bowel is ganglionic. Seromuscular biopsies consisting of two layers of muscularis propria and intervening plexus are submitted for urgent frozen section. The level from which the biopsy was taken should be indicated. Submission of appendix for identification of ganglion cells is not recommended since the appendix does not always have a well-defined myenteric plexus and ganglion cells can be difficult to locate in frozen section. For seromuscular biopsy specimens the orientation is such that the two muscle layers can be easily distinguished. A ribbon of serial sections is cut and stained with H&E. A fully ganglionic specimen should contain clusters of readily identifiable ganglion cells with associated neuropil and no nerves (Fig. 5.23). If ganglion cells are present but are accompanied

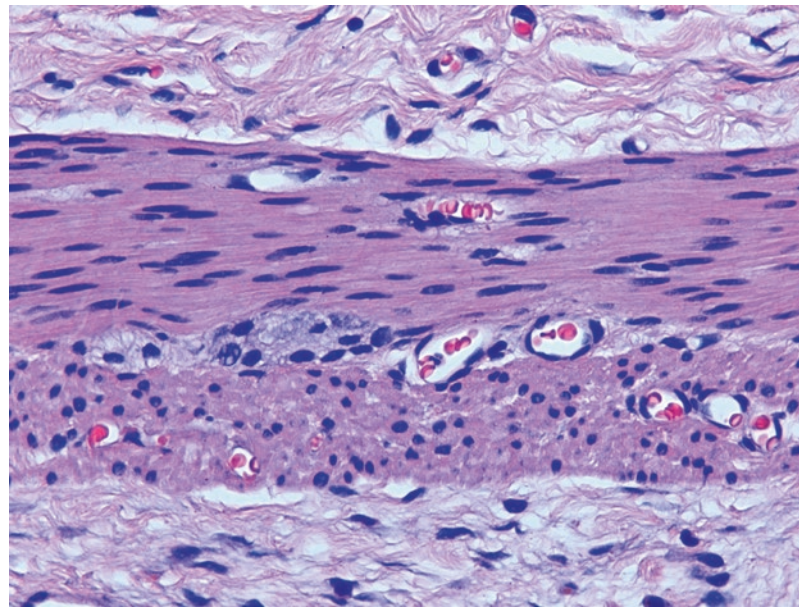

Fig. 5.23 Hirschsprung disease. A neonate with Hirschsprung disease. A section of normally ganglionic myenetric plexus proximal to the aganglionic zone. The two layers of the myenteric plexus are visible, the outer layer running longitudinally in the upper part of the picture and the inner layer in the lower part of the picture. A group of at least two ganglion cells with surrounding support cells is visible between the two layers. There are no enlarged nerves

by hypertrophic nerves, this represents transitional zone (Fig. 5.24) and biopsy from a more proximal level is advised. If ganglion cells appear sparse (i.e. clusters are small or more widely spaced than usual), this also probably represents transitional zone and biopsy from a more proximal level is advised. If ganglion cells are absent, and there are hypertophic nerves biopsy from a more proximal level Is advised. If there are no ganglion cells present, but no hypertrophic nerves and the muscle layers are closely apposed, the appearances are suggestive of long segment disease or total colonic aganglionosis (Fig. 5.25) and biopsy from more proximal level is advised. The pathologist reporting these biopsy specimens must be absolutely confident

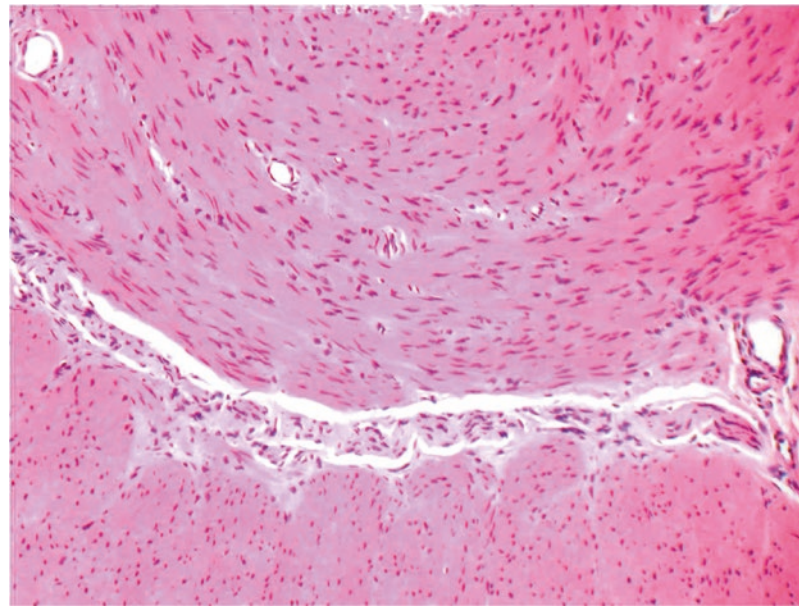

Fig. 5.24 Hirschsprung disease. Seromuscluar biopsy—H&E stained section The myenteric plexus contains enlarged wavy nerves. This appearance may be seen in the aganglionic zone. If ganglion cells are present in addition to enlarged nerves, then this suggests that the specimen is from the transition zone between aganglionic and normal bowel

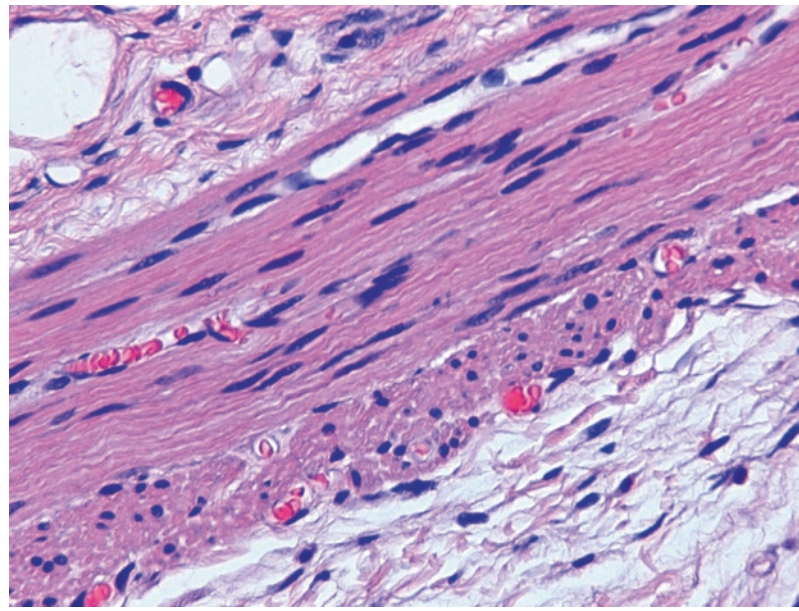

Fig. 5.25 Hirschsprung disease. A seromuscular biopsy from a neonate with total colonic aganglionosis. The outer muscle coat is visible in the upper part of the picture and the inner layer beneath it. They are closely apposed with no intervening tissue and the myenteric plexus is empty. The absence of enlarged nerve fibres is typical of total colonic aganglionosis

that two muscle layers can be distinguished: the serosa can be mistaken for the intermyenteric layer.

5.4.5.2 Evaluation of Resected Bowel

In about 80% of cases of Hirschsprung disease the affected segment is confined to the rectosigmoid. About 10% of cases have long segment disease and 5% have total colonic aganglionosis. The disease may involve small intestine. A further 5% have short segment disease. The transitional zone between normally innervated intestine and aganglionic intestine shows hypoganglionosis and occasional hypertophic nerves. It can be of very variable length. Depending on the clinical circumstances, the resected bowel may be received all in one piece or in multiple parts. Sutures should be applied by the surgeon to indicate orientation. Ideally the specimen should be received fresh, opened on arrival and circumferential samples of proximal margin taken for frozen sections and AChE staining, the remainder should be pinned out and fixed in formalin. Sampling of the proximal margin is most important: we perform circumferential sampling of the proximal end. Since the neuronal population may have spiral architecture, despite intraoperative sections showing ganglionic bowel at one point, the specimen may occasionally reveal transitional zone. There is an association between proximal segment histology and postoperative outcome [36]. ganglionic, this generally predicts good postoperative bowel function, 10% have constipation. If there is intestinal neuronal dysplasia (IND) of the proximal segment, the overall clinical result is unchanged but the constipation rate is higher. If there is proximal segment hypoganglionosis there is impaired postoperative function. If there is proximal aganglionosis there is a complicated postoperative course with secondary bowel resections and episodes of enterocolitis. Acetylcholinesterase activity in the proximal resection margins is a useful indicator [37].

Further sampling of a complete longitudinal full thickness strip of the entire resected bowel documents the lengths of aganglionic segment, transitional zone of hypoganglionosis and occasional hypertrophic nerves and fully ganglionic bowel. Skip segments may be present, recognized as segment of ganglionic bowel in an otherwise aganglionic segment.

5.4.6 Procedures in Other Institutions

Not all laboratories carry out circumferential sampling of proximal resection margins. Some laboratories take representative samples along the resected bowel rather than sampling the entire length.

5.4.7 Assessment of Biopsies from Patients with Failed Pull-through Procedure for Hirschsprung's Disease

One of the reasons for a failed pull -through procedure for Hirschsprung disease is a retained aganglionic segment [38]. Biopsies may be taken to assess whether or not the aganglionic segment has been fully excised. The pathologist needs to be familiar with the surgical pull-through procedure which has been performed. The operation with which we are familiar in our institution is the Duhamel operation [39] in which the anterior wall of the neorectum is aganglionic and the posterior wall is ganglionic. Biopsies are performed of the anterior and posterior rectal wall. It is expected that the anterior rectal wall biopsy will be aganglionic and will show the appearance of Hirschsprung disease. The posterior rectal wall biopsy will be normally ganglionic. If the posterior wall biopsy is aganglionic than the aganglionic segment has not been fully excised.

5.4.8 Hirschsprung's-Associated Enterocolitis (HAEC)

Colitis occurring in children with Hirschsprung disease is a major cause of morbidity and mortality in this group of children [40]. Classic presentation is a neonate with history of constipation. Post-pull through Hirschsprung disease associated enterocolitis is typically seen within 2 years

following pull through. The histopathological features [41–43] show several discrete phases used to grade pathologic severity:

Normal mucosa—grade 0
Crypt dilatation, mucin retention—grade 1
Cryptitis or <2 crypt abscesses/HPF—grade 2
Multiple crypt abscesses/HPF—grade 3
Fibrinopurulent debris and mucosal ulceration—grade 4
Transluminal necrosis or perforation—grade 5
Grade I may show marked mucus streaming from crypts similar to cystic fibrosis. Grades III–V may appear similar to ulcerative colitis (Fig. 5.26)

5.4.9 Hypoganglionosis

The diagnostic criteria are not strictly defined. It is usually a secondary condition being situated proximal to a segment of typical aganglionosis in Hirschsprung disease. Primary hypoganglionosis is rare. The signs and symptoms are indicative of Hirschsprung disease, but the rectal suction biopsy is normal. There are manometric and neurophysiologic tests suggestive of neuropathic process. It is often segmental and may be progressive. It is usually managed by stoma to relieve symptoms. At stoma placement, the surgeon may take a length of full thickness bowel to evaluate for primary hypoganglionosis or other neuromuscular pathology. Pathologically, the submucosal plexus is normal. The myenteric plexus shows a range of appearances including decreased numbers of ganglion cells in ganglion cell clusters, small hypoplastic ganglion cells, decreased numbers of clusters that are widely spaced. There may be decreased numbers of nerves in the muscularis propria on AChE staining [44]. The mean density values of myenteric ganglion cells in childhood is:

jejunum 3.6/mm (TS), 3.7/mm (LS)
ileum 4.3/mm (TS, LS)
colon 7/mm (LS), 7.7/mm (TS)

Ganglion cell density values outside two standard deviations from normal correlate with continuing pseudo-obstructive symptoms [45].

Interpretation in these cases is often subjective and not evidence-based. It is difficult to find normal age-matched controls. Long standing neu-

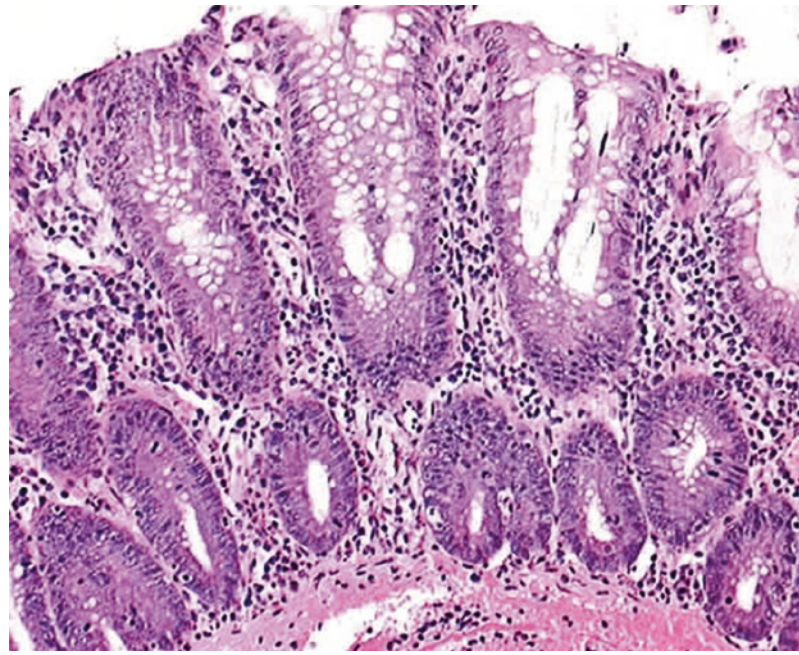

Fig. 5.26 Hirschsprung disease. Enterocolitis. A section from the resected colon shows mucosa with hyperplasia of the crypt epithelium and a diffuse inflammatory cell infiltrate in the lamina propria mucosae. There is also infiltration of the crypt epithelium by inflammatory cell. The histological picture resembles acute ulcerative colitis

ropathy may induce secondary myopathic change and it is consequently difficult to determine which is primary and which secondary process.

5.4.10 Megacystis Microcolon Intestinal Hypoperistalsis Syndrome

A rare, congenital and usually fatal condition of unknown etiology, presenting with abdominal distension, a distended, non-obstructed urinary bladder and intestinal hypoperistalsis resulting in functional intestinal obstruction.

Pathologically, the bowel may appear normal on routine H&E staining. However, connective tissue stains such as Picrosirius Red show that the collagenous fiber network of the muscularis propria is not well-formed [46]. There are vacuolar degenerative changes in the smooth muscle cells of the bladder [47]. There is markedly increased connective tissue between smooth muscle cells of the bladder on Masson Trichrome and van Gieson staining and reduced smooth muscle actin, desmin and dystrophin immunoreactivity in bladder smooth muscle. Electron microscopy shows vacuolar degenerative changes in smooth muscle cells and abundant connective tissue between these cells.

5.5 Necrotising Enterocolitis

Necrotizing enterocolitis is a common medical emergency, particularly in low birth weight infants. The pathogenesis is uncertain but associated risk factors include prematurity, birth weight and enteral feeding, especially milk formula. The pathophysiology is complex and unresolved but involves abnormal or immature gut motility and digestion with abnormal or mature circulatory regulation [48]. There is in addition, abnormal intestinal bacterial colonization, abnormal intestinal mucosal barrier function and abnormal intestinal immunity. About half of all cases require surgical intervention.

The disease can affect any part of the gastrointestinal tract but mainly involves the distal small intestine and right side of the colon. It shows patchy areas of wall thickening and dilatation leading to perforation (Fig. 5.27). There is coagulative necrosis affecting the partial-thickness or full-thickness bowel wall [49, 50]. Intestinal pneumatosis may be evident with representing intramural gas bubbles (Fig. 5.28). If there has been perforation, then acute peritonitis will be evident. There are frequently associated reparative changes with granulation tissue and fibrosis. The lesion heals by fibrosis which may lead to stricture or dysmotility. Healed cases may show features similar to other cases of healed ischemic gut damage, namely loss of muscularis mucosae in areas of previous ulceration, hemosiderin-laden macrophages in the submucosa (indicating previous hemorrhage at this site) or submucosal or muscular coat fibrosis (Fig. 5.29).

Fig. 5.27 Necrotising enterocolitis—bowel perforation. A seven-week old boy born at 31 weeks. Laparotomy and resection of 27 cm of ileum for perforated necrotising enterocolitis. There is extensive necrosis of the wall and the figure shows an area of perforation. Three such perforations were present in the specimen. The wall in the vicinity of the perforation is paper-thin. This patchy thinning is typical of NEC

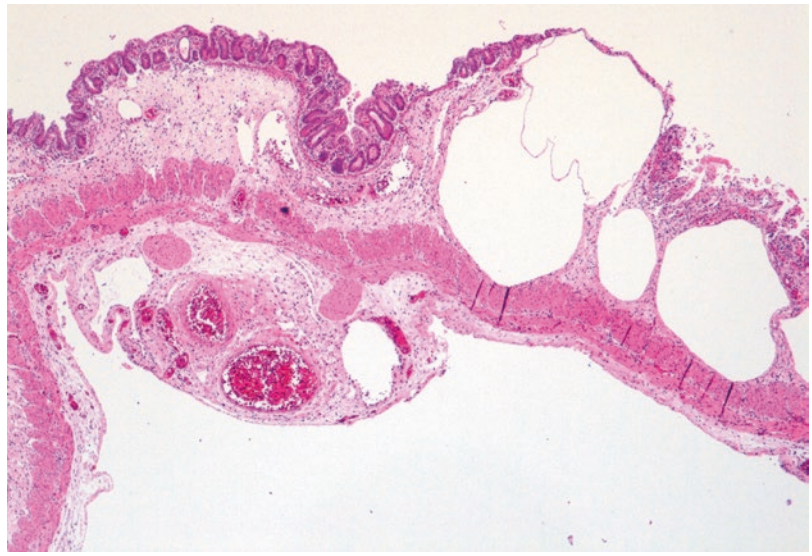

Fig. 5.28 Necrotising enterocolitis. A 28 day old premature female infant with necrotising enterocloitis. A 24 cm segment of ileum was removed. The bowel was pale and thin and appeared "bubbly". A low power H&E section of the affected area shows numerous gas cysts in the submucosa of the bowel, representing Intramural gas. There is ulceration to the right of the field and inflammation with mucosal villous blunting to the left

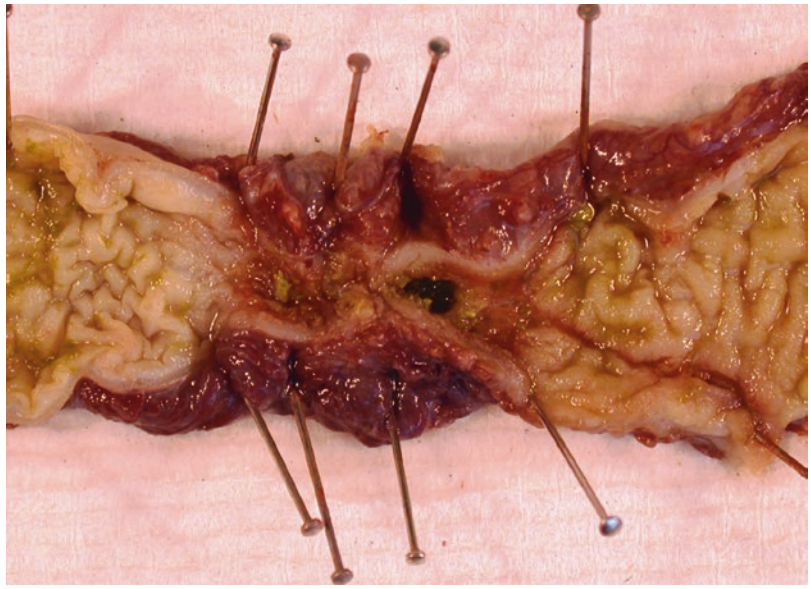

Fig. 5.29 Necrotising enterocolitis—bowel stricture. A 6-week old born prematurely and with intrauterine growth restriction. He developed necrotising enterocolitis that was medically treated, but never managed to establish feeds. He developed abdominal distension and contrast enema suggested right colon hold-up. A 7.5 cm long segment of ascending and transverse colon was resected. The image shows the opened specimen pinned out to permit fixation. There is a central stricture 2 cm long in which the mucosa is ulcerated and the luminal diameter is less than 0.1 cm. The mucosa of the bowel to the right of the stricture shows linear ulcers parallel to the axis of the bowel. Histologically the stricture showed replacement of the mucosa by granulation tissue and fibrous replacement of the muscle coat. Some calcified debris was present in the serosa suggesting possible previous perforation. These appearances are of an iscahemic stricture in keeping with previous necrotising enterocolitis

5.6 Biliary Atresia and Choledochal Cyst

Extrahepatic biliary atresia is characterized by total or segmental obliteration of the extrahepatic bile ducts. Liver biopsy is indicated for the diagnosis. The liver in extrahepatic biliary atresia shows cholestasis with plugging of the small bile ducts [51]. There is proliferation of small ductules at the edges of the portal tracts and there is progressive fibrosis of the "biliary" type. There may be associated giant cell hepatitis with a variable degree of chronic inflammatory cell infiltration in the portal tracts. There is absence or paucity of intralobular bile ducts [52] (Fig. 5.30).

Choledochal cyst is a localized cystic dilatation of the common bile duct. The dilatation may be fusiform or may be present as a diverticulum. There is frequent association with pancreatic or biliary anomalies [53]. The liver biopsy shows features similar to extrahepatic biliary atresia. The cyst wall shows thickening and fibrosis and inflammation with bile staining (Fig. 5.31). There may be dystrophic calcification. There is usually no epithelial lining [54].

5.7 Congenital Neck Cysts in Infants

The majority of such lesions are accounted for by thyroglossal duct cysts and branchial cleft cysts; thyroglossal duct cysts are about three times more common than branchial cleft cysts. Other congenital neck cysts that occur in children are dermoid cyst, cervical thymic cyst, bronchogenic cyst and cystic hygroma.

5.7.1 Thyroglossal Duct Cyst

In the fourth week of embryonic life the thyroid gland develops as an area of epithelial proliferation at the tip of the foramen caecum in the posterior tongue. It migrates inferiorly to its final site in the anterior neck by the seventh week. The thyroid gland remains connected to the foramen caecum by the thyroglossal duct which normally disappears by the end of the fifth week. Failure of involution of this structure gives rise to thyrolossal duct cysts anywhere along the original tract of the thyroglossal duct.

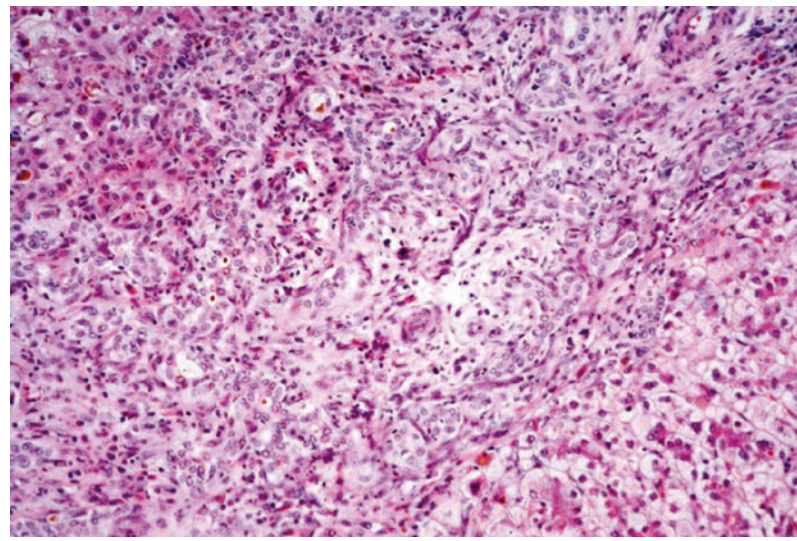

Fig. 5.30 Biopsy of liver from an infant with extrahepatic biliary atresia. The section is stained with H&E. The hepatocytes are swollen and there are bile plugs in canaliculi. A large portal tract at the centre of the field shows oedema and an indistinct demarcation from the surrounding liver. There is proliferation of bile ductules at the periphery of the portal tract

About one-quarter of cases of thyroglossal duct anomalies are sinuses rather than cysts [55]. Sinuses predominant in children and cysts in adults. The thyroglossal duct remnants are located in the midline anywhere between the base of the tongue and the pyramidal lobe of the thyroid gland. Most commonly they are located at the level of, or just, below the hyoid bone. Because of the attachment to hyoid bone, the cysts rise on swallowing or on protrusion of the tongue. They manifest during childhood as asymptomatic neck masses, most commonly before the age of 5 years. The cysts are lined by pseudostratified columnar epithelium in 60% cases and squamous epithelium in 40% (Fig. 5.32). It is important to emphasize that only about 20% have associated, recognizable thyroid tissue (Fig. 5.33). Epithelial tissue is commonly found within the hyoid bone or its periosteum (Fig. 5.34). A sinus may form to the skin surface.

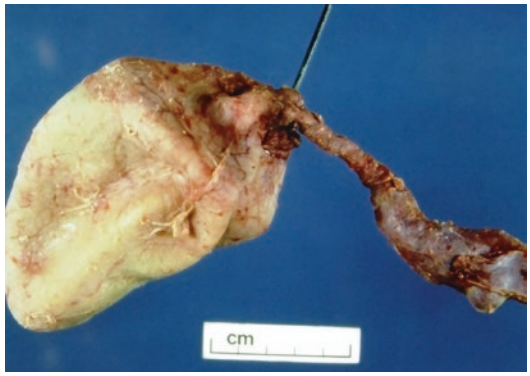

Fig. 5.31 Choledochal cyst. The excised cyst of the bile duct shows a fusiform unilocular swelling up to 12 cm in maximum diameter. The wall was composed largely of fibrous tissue with a haemorrhagic lining

5.7.2 Branchial Cleft Cysts

By the fourth week of embryonic life there are four well developed (and another two rudimentary) pairs of ridges in the cervical area of the embryo; these are termed the branchial arches. Externally the troughs separating the arches are termed clefts and internally (on the endodermal

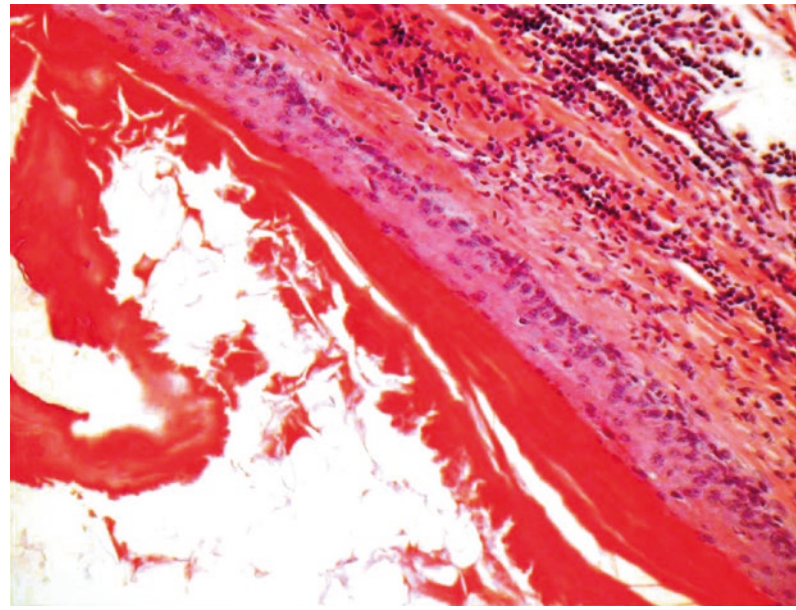

Fig. 5.32 Thyroglossal cyst. A high power view of an H&E stained section of the wall of a thyroglossal cyst. The lining is of keratinising stratified squamous epithelium. The lumen contains keratin, the wall is fibrous and shows a chronic inflammatory cell infiltrate

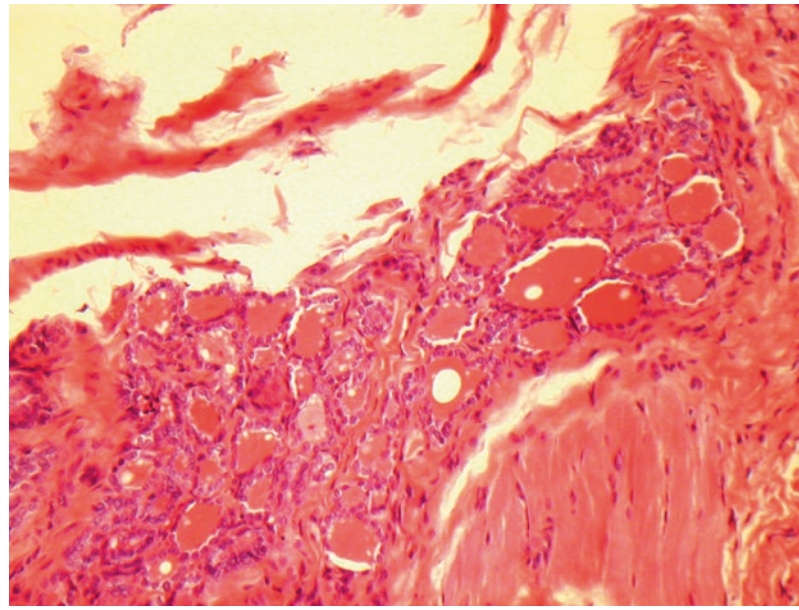

Fig. 5.33 Thyroglossal cyst. An H&E stained section from the wall of a thyroglossal cyst. It shows a collection thyroid follicles identified by heir characteristic content of eosinophilc colloid. Thyroid tissue is identified in only approximately half the case of thyroglossal cyst

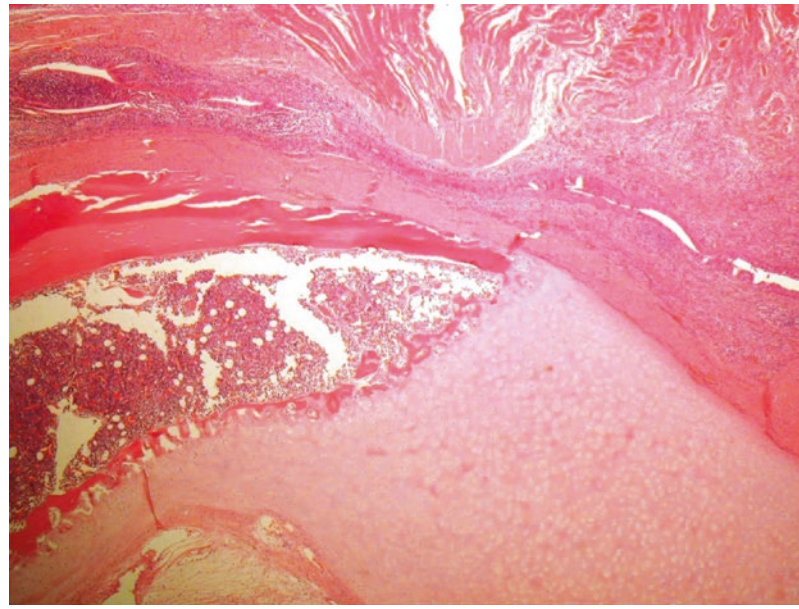

Fig. 5.34 Thyroglossal cyst. A section of the hyoid bone removed with the cyst. The cartilage and the bone are visible and abutting the perisoteum of the bone (in the upper part of the field) is part of the sinus tract. The tract is lined by upper respiratory type of epithelium and shows a lymphocytic infiltrate in its wall. This emphasises the intimate relation of the tract to the bone

surface) the separating depressions are termed pouches. Branchial anomalies are the remnants of the branchial arches and their associated clefts that fail either to regress or to develop normally. Branchial cleft lesions present as either a cyst in the lateral aspect of the neck or as a sinus draining the lower part of the lateral neck. It is the internal opening of the sinus that determines the cleft or pouch of origin. Internally, the first arch derivatives are connected to the external auditory meatus or the middle ear. Second arch anomalies connect internally to the tonsil or supratonsillar area and third and fourth arch derivatives open internally into the pyriform fossa [56].

Lesions derived from the second branchial cleft account for about 95% of all cases; those

derived from the first cleft make up about 1% and the remainder are very rare. Derivatives of the third and fourth arches are almost always left-sided. First cleft anomalies present as a cyst, sinus or fistula opening on the skin between the external auditory meatus and the suprahyoid submandibular area. They are intimately associated with the parotid gland and the branches of the facial nerve. They must be differentiated from preauricular sinuses which are lined only by squamous epithelium and do not communicate with the ear [57].

Second cleft anomalies present as either a fistula or cyst opening along the anterior border of the sternocleidomastoid muscle. Fistulae are commoner than cysts in children. The skin opening is occasionally marked by skin tags or small nodules of cartilage (Fig. 5.35). About 10% of second cleft cysts are bilateral. They are lined by respiratory and squamous epithelium, either alone or in combination. The cysts more frequently show a squamous lining while sinuses and fistulae have a respiratory epithelial type of lining. Other tissues are present in the wall such as lymphoid tissue, sebaceous glands or salivary tissue. The fluid within the cysts contains cholesterol clefts. About one in five lesions has become infected by the time of surgical excision. The

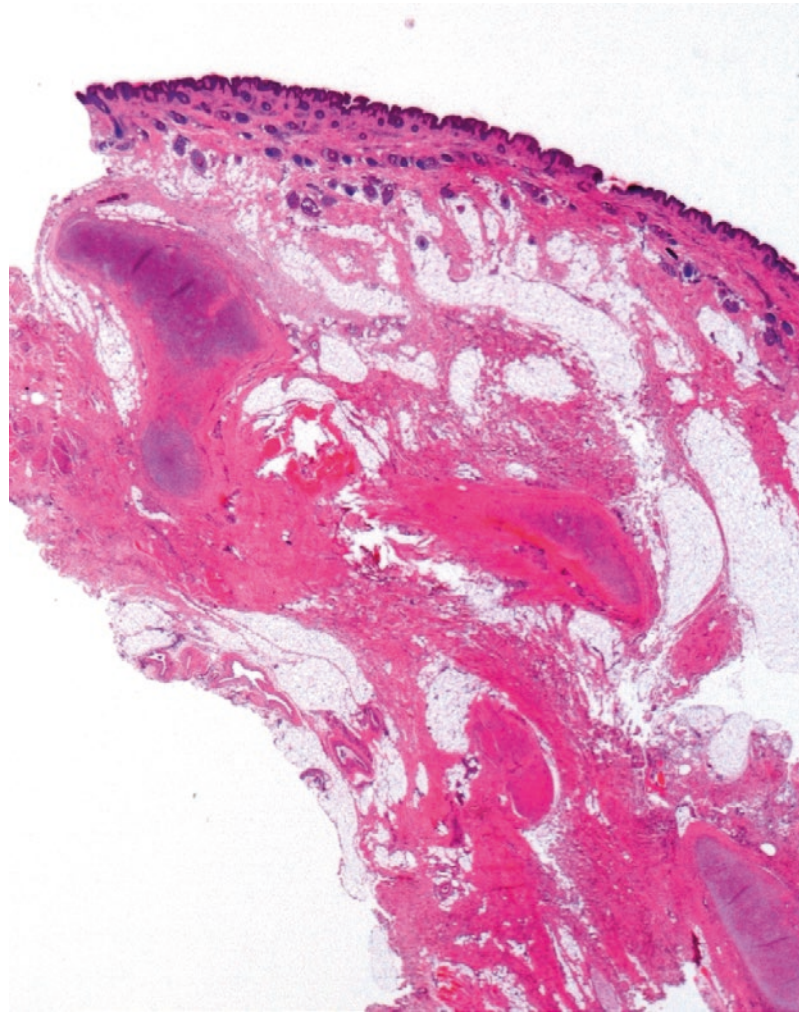

Fig. 5.35 Branchial cleft sinus—A 1 year old boy with a left neck sinus and preauricualr tag. An H&E stained section of the tag shows three plates of elastic cartilage in the subcutaneous tissue

treatment of choice is surgical excision. Incomplete excision results in a high rate of recurrence.

5.7.3 Dermoid Cyst

These account for about 25% of midline cervical anomalies. There are subcutaneous in location and do not move on swallowing or protrusion of the tongue [58]. The cysts, like all dermoid cysts have a lining of keratinizing stratified squamous epithelium and epidermal appendages are present in the wall (Fig. 5.36). The lining may be ulcerated and show a foreign body granulomatous reaction to the keratin contents.

5.7.4 Bronchogenic Cyst

Primarily a lesion of the chest, bronchogenic cyst may occasionally be found in close association with the cervical trachea in the lower neck [59]. It usually indents the trachea and presents with stridor [60]. It is not connected to the tracheal lumen. The cyst is a unilocular, thin-walled paratracheal cyst with a lining of upper respiratory type of epithelium with smooth muscle and sometimes hyaline cartilage (Fig. 5.3).

5.7.5 Cervical Thymic Cyst

They usually present after the age of 2 years, but may present in neonates [61]. They may be found anywhere along the normal descent route of the thymus gland from the mandible to the sternal notch; about half extend into the mediastinum [62]. Most patients are asymptomatic, although respiratory complications may occur. Preoperative recognition is unusual and the diagnosis almost always depends on histology. Histological investigation of the excised specimen shows thymic tissue remnants with Hassall's corpuscles (Fig. 5.37), and cholesterol clefts in the cyst wall [63]. Intact, complete surgical excision remains the treatment of choice.

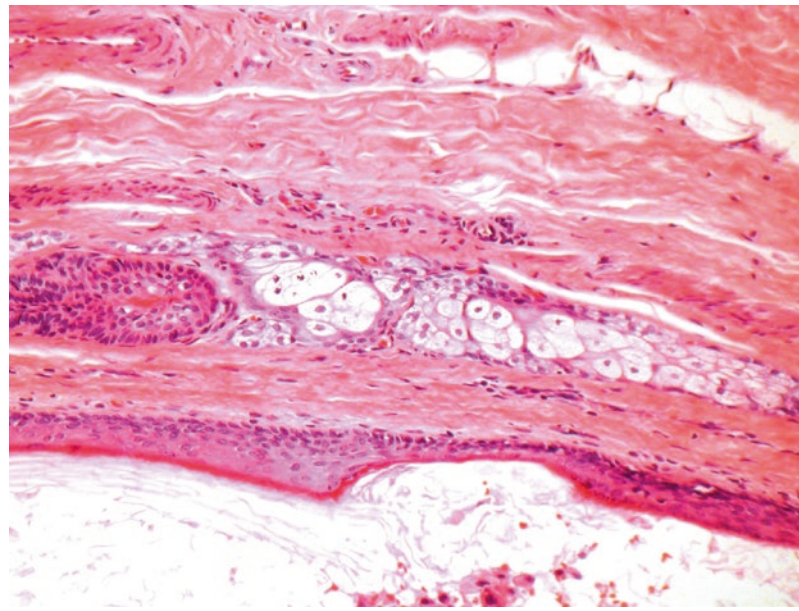

Fig. 5.36 Dermoid cyst. An H&E stained section of the wall of a dermoid cyst showing the characteristic lining of keratinising stratified squamous epithelium with a hair follicle and sebaceous glands in the fibrous wall. Keratin debris fills the cyst lumen in the lower part of the image

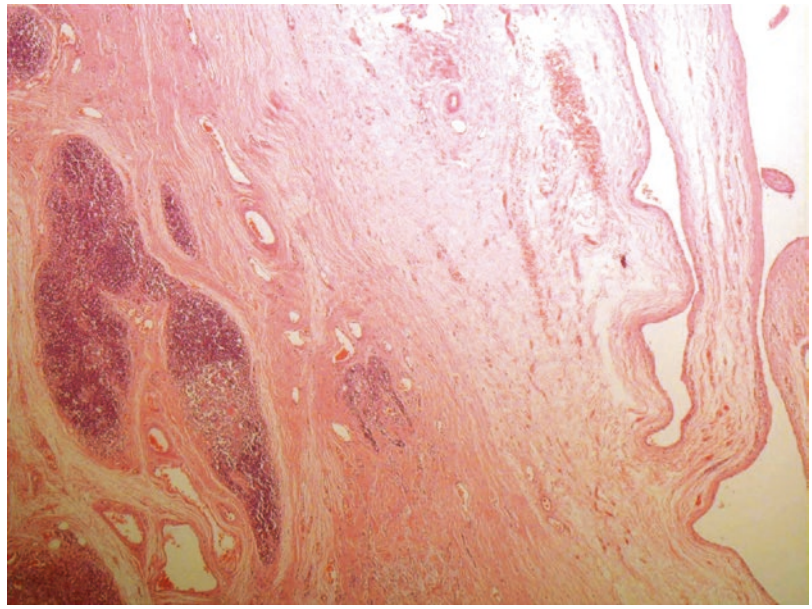

Fig. 5.37 Thymic cyst. An H&E stained section from the wall of a thymic cyst. The lumen is to the left of the picture and the lining is of non-keratinising stratified squamous epithelium. To the right of the field is an area of rather atrophic thymic tissue, composed of lymphocytes and Hassall's corpuscles

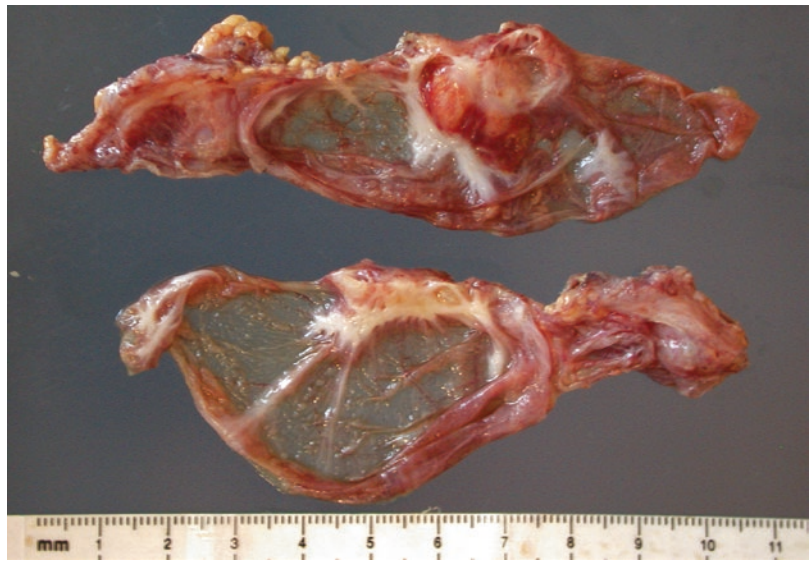

Fig. 5.38 Cystic hygroma. A 3-month old male with a cystic anterior neck mass. A multiloculated cystic mass 7 × 4.5 × 3 cm was resected. The cut surface of the specimen shows the multiple locules of variable size, some with near-transparent walls. Focal fibrous trabeculae are evident in the lining. Histologically the tissue showed multiple cystic spaces with small nodules of lymphocytes in the wall. The features are typical of lymphangioma\cystic hygroma

5.8 Cystic Hygroma

These are malformations of the lymphatic system in the neck [64]. Most present before the age of 2 years, the majority in the first year of life. More than three-quarters are situated in the posterior triangle of the neck. Histologically, they are composed of ectatic lymphatic vessels (Fig. 5.38) and contain small nodules of lymphoid tissue [65].

5.9 Neonatal Lung Pathology

5.9.1 Congenital Lung Cysts

The nomenclature of this group of lesions is confusing [66]; there is overlap of the various entities and similar lesions have been given different names, whereas different lesions have been labelled the same. Many cases are now detected antenatally by ultrasound scanning and followed up [67], permitting assessment of their development. There is disagreement among authorities about the detail and origins of these lesions. It is increasingly becoming apparent that narrowing or obliteration of the bronchial lumen is a common factor in many of them [68].

5.9.1.1 Congenital Pulmonary Airway Malformation

Stocker has provided a near-universally used classification of cystic lung malformations. He originally distinguished cystic lung lesions that he called Congenital Cystic Adenomatoid Malformation (CCAM) types I, II and III [69]. The term CCAM is still in common usage. In 2002, he expanded the original three types to five, termed 0–4 and renamed the entities Cystic Pulmonary Airway Malformation (CPAM) because not all lesions are cystic and with the exception of type 3 they are not adenomatoid [70]. The 2002 classification is based on the putative segment of the bronchial tree that is primarily affected, extending from proximal to distal. Type 0 is said to originate from the trachea\bronchi, while type 4 is said to originate from the pulmonary acinus.

This sometimes causes problems in trying to assign a particular lesion to one or other of these categories particularly in the more immature lung [71]. Type 4 CPAM is claimed by some to be a cystic form of pleuropulmonary blastoma [72].

Type 0 (Acinar Dysplasia)

This lesion is very rare and results in bilateral small firm granular lungs with solid parenchyma (Fig. 5.39) and numerous small spaces less than 0.1 mm diameter. Histologically (Fig. 5.40), the tissue consists of Irregular bronchus-like structure lined by pseudostratified, columnar epithelium, many surrounded by cartilage or smooth muscle. There is prominent, loose mesenchyme containing thin vessels, extramedullary haematopoiesis and basophilic debris. There may be associated cardiovascular abnormalities, renal hypoplasia or dermal hypoplasia. Affected infants usually die shortly after birth.

Fig. 5.39 Congenital acinar dysplasia (CPAM 0). Lungs from a fetus of 22 weeks' gestation with intrauterine growth restriction and fetal hydrops. The lungs are minute. The combined weight was 0.67 g (expected at 22 weeks' gestation is 11 g)

Type 1 (Large Cyst Type)

This accounts for the majority of cases. It may present in utero or postnatally with increasing respiratory distress in the first few days of life. Cysts are limited usually to one lobe with only rare bilateral involvement. The cysts measure 1–10 cm in diameter (Fig. 5.41) and intercommunicate. They are lined by ciliated, pseudostratified columnar epithelium with walls of fibromuscular tissue and cartilage. About half of all cases show small foci of mucinous epithelial cells (Fig. 5.42) in the cyst lining.

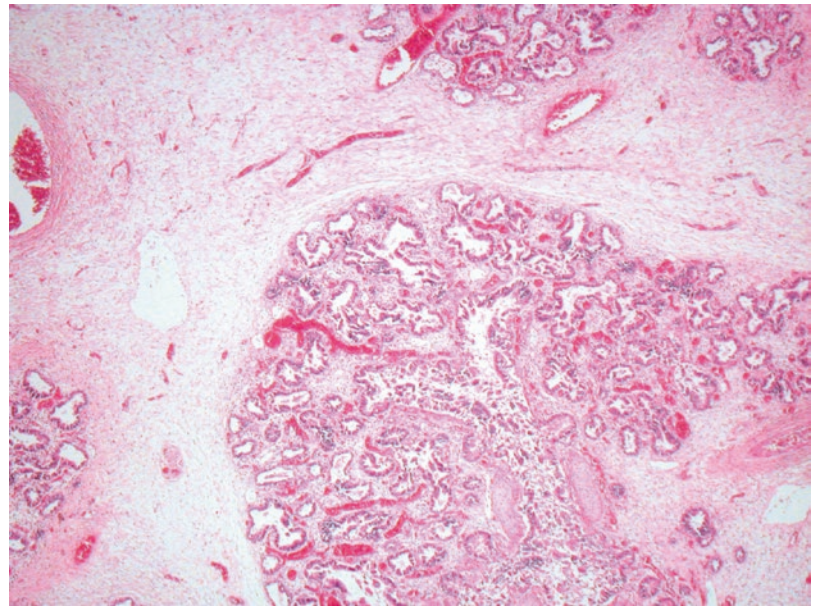

Fig. 5.40 Congenital acinar dysplasia (CPAM 0). Thirteen-day old female with congenital acinar dysplasia. There is oedematous stroma that contains proliferated bronchi, but no more distal differentiation of the lung tissue

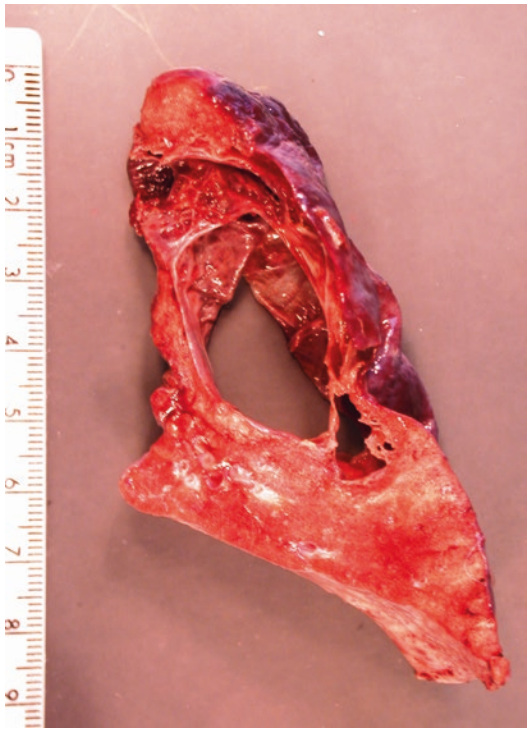

Fig. 5.41 Congenital pulmonary airway malformation Type 1 (CPAM 1). Six-month old boy. With a cyst in the lower lobe of the right lung. The specimen shows the cut surface of the excised right lower lobe. There is a unilocular cyst 5 cm in maximum dimension with a trabeculated lining. The cyst cavity communicated with the surrounding air spaces. Type 1 CPAM may show smaller subordinate cysts in the surrounding lung

Type 2 (Small Cyst Type)

Presents in first weeks of life and is the subtype most commonly associated with other congenital abnormalities. It comprises multiple small cysts (0.5–1.5 cm) (Fig. 5.43) that have back to back dilated bronchiole-like structures with reduction in alveolar structures in between (Fig. 5.44). The intervening parenchyma shows alveolar duct like structures. A subset contains striated muscle in the stroma (rhabdomyomatous dysplasia).

Type 3 (Adenomatoid Type)

This subtype occurs almost exclusively males and is associated with maternal polyhydramnios. It involves an entire lobe or the entire lung and is frequently a bulky mass with mediastinal shift (Fig. 5.45). Grossly, the lesion is firm and bulky and may have small cysts. These have branched bronchiolar or alveolar duct-like structures and are lined by low cuboidal epithelium (Fig. 5.46). There is a virtual absence of larger pulmonary arteries.

Type 4

This subtype present with respiratory distress or tension pneumothorax, and usually affects one lobe. There are large air filled cysts with displacement. The cysts have a flattened epithelial lining. This lesion is controversial [73] and is regarded by some as a type-1 pleuropulmonary blastoma.

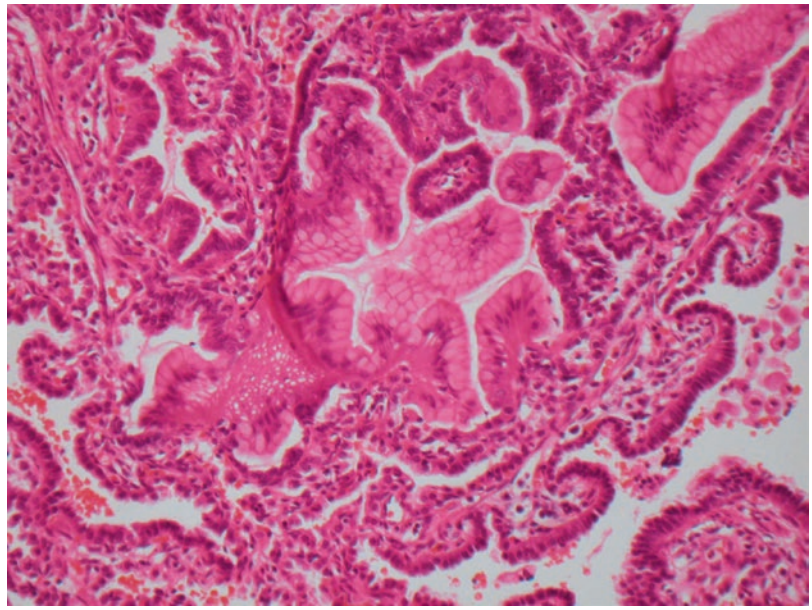

Fig. 5.42 Congenital pulmonary airway malformation Type 1 (CPAM 1). Photomicrograph of the lining of a CPAM type 1. The cuboidal lining typical of this cyst is seen. In addition there are areas of pale, mucin-secreting epithelium, characteristic of Type 1 CPAM

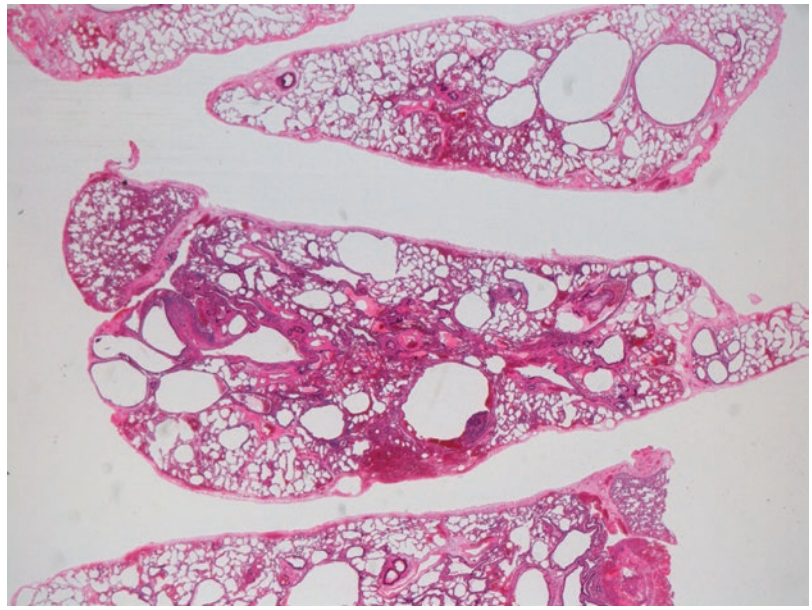

Fig. 5.43 Congenital pulmonary airway malformation Type 2 (CPAM 2). Male with antenatally detected cystic mass in the right middle lobe, removed when aged 5 months. A whole mount section shows that most of the lobe is replaced by multiple small rounded cysts with some intervening normal parenchyma

5.9.1.2 Bronchial Atresia

Can occur at any level from lobar to subsegmental bronchus. There may be a mucocoele at the level of obstruction [66] with an obliterated bronchial lumen. There is dilatation of the distal parenchyma with accumulation of mucus and macrophages in the air spaces. It is becoming increasingly evident that some form of bronchial atresia is present in association with sequestration, congenital pulmonary airway malformation (Fig. 5.47) and lobar emphysema [68].

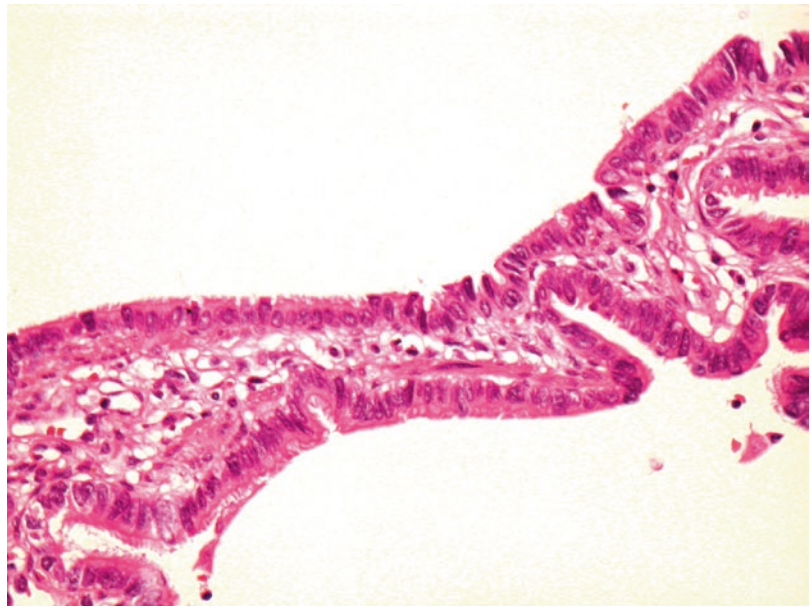

Fig. 5.44 Congenital pulmonary airway malformation Type 2 (CPAM 2). A photomicrograph of a septum separating two cysts. The cysts have a back-to-back arrangement and are lined by bronchiolar type epithelium. Sometimes in type 2 CPAM striated muscle cells are identifiable in the stroma—so-called rhabdomyomatous dysplasia

Fig. 5.45 Congenital pulmonary airway malformation Type 3 (CPAM 3). Two week old female infant with an antenatal diagnosis of right cystic lung mass. There was associated polyhydramnios and hydrops. The right lung shows the lower lobe replaced by a solid mass 8 cm in maximum dimension with a few scattered cysts

5.9.1.3 Pulmonary Sequestration

Pulmonary sequestration refers to lung tissue that lacks a connection to the bronchial tree. Generally there is an anomalous systemic arterial supply [74] (Fig. 5.48). The sequestered segment of lung may be within the lung, where it is termed intralobar sequestration, or outside the lung or even outside the thorax, the lesion then being termed extralobar sequestration. Very rarely, there is a connection to the gastrointestinal tract (usually esophagus) this lesion then being termed a "bronchopulmonary foregut malformation" [75].

Extralobar sequestration usually presents in the first year of life and occurs more commonly in boys. Two-thirds of cases are situated on the left side of the body (thorax, retroperitoneum or even pericardium) and there is a frequently association with diaphragmatic defects. The retroperitoneal examples may be mistaken for tumor e.g. neuroblastoma. Histologically extralobar sequestration is a pyramidal airless mass with a systemic arterial supply, venous drainage to the pulmonary veins, systemic veins or portal veins. It is composed of lung parenchyma, usually covered by pleura. The lung parenchyma shows sec-

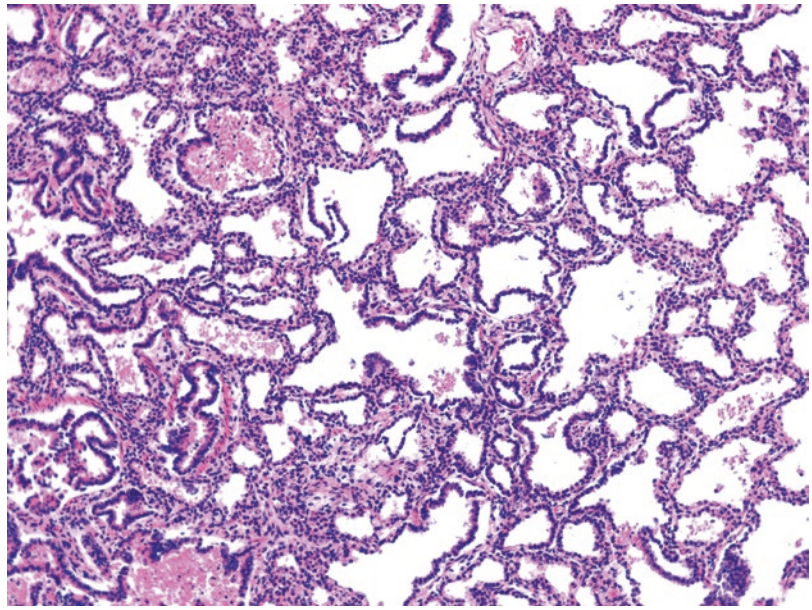

Fig. 5.46 Congenital pulmonary airway malformation Type 3 (CPAM 3). Photomicrograph of the lesion in Fig. 5.45. It is composed of distended air spaces lined by cuboidal epithelium with no normal lung parenchyma

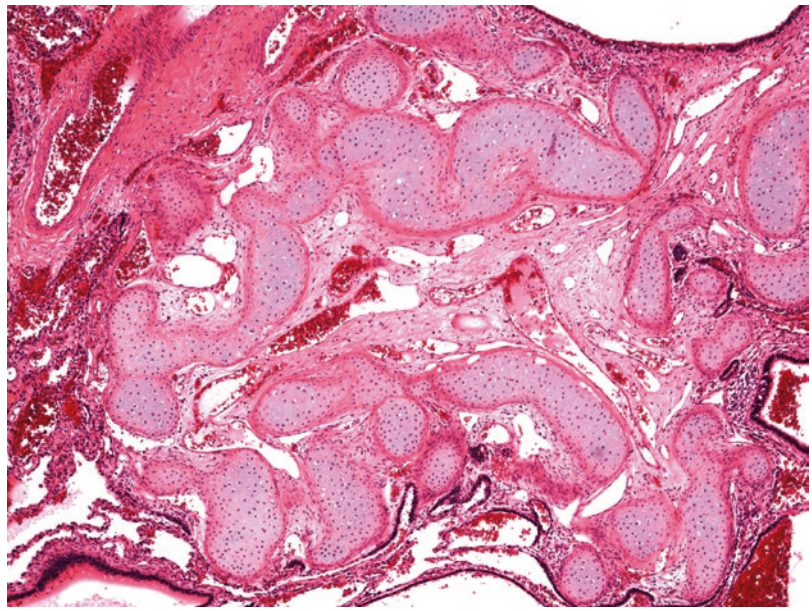

Fig. 5.47 Bronchial atresia. Photomicrograph of a section taken from close to the resection margin of a type 2 CPAM of the right middle lobe in a 6-month old boy. There is a garland of irregular cartilage plates around a fibrovascular core. The appearances suggest occlusion of the lumen of a bronchus

ondary inflammatory changes with secondary lymphangiectasia and may also show features indistinguishable from CPAM [76].

Intralobar sequestration frequently does not present until adult life although antenatal presentation is recorded. It shows no sex preference and affects both sides equally. The lower lobes are most frequently affected. It is situated within the pleural investment of the lung, lacks a demonstrable bronchial connection but contains air. It has a

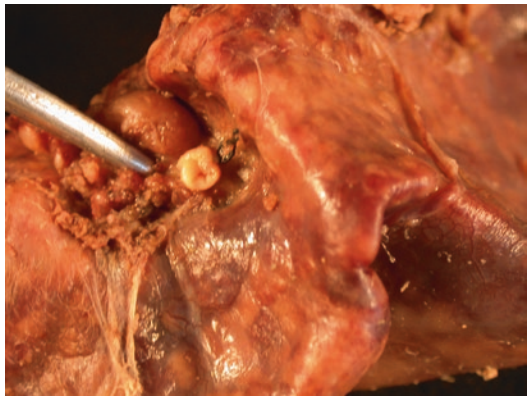

Fig. 5.48 A 7-week old boy with multiple congenital anomalies, including gastroschisis, bladder exstrophy and asplenia, and a left intralobar sequestration causing high-output cardiac failure. Left thoracotomy with excision of the sequestration. The excised specimen shows a large systemic artery entering the lung through the pleural surface well away from the lung hilum

systemic arterial supply (Fig. 5.49) with venous drainage to the pulmonary veins. It frequently shows such secondary changes as, fibrosis and inflammation and may show changes indistinguishable from CPAM. The pulmonary arteries in the sequestered segment may show evidence of pulmonary arterial hypertension [77].

Dr. Langston [66] has proposed an overarching classification of all cystic lung lesions.

5.9.1.4 Congenital Lobar Overinflation

This a more accurate term than the previous designation of congenital lobar emphysema. There is overinflation of a lobe of lung, usually middle or upper lobe, with compression of the surrounding normal lung [78]. It may demonstrate partial bronchial obstruction, but more frequently no anatomical cause can be found for the overdistension. The surgically excised lobe is filled with air and does not collapse after removal. Microscopically, the cut surface shows distended air spaces that may appear normal. Only when compared with an age-matched control lung section is the distended nature of the alveoli apparent (Fig. 5.50).

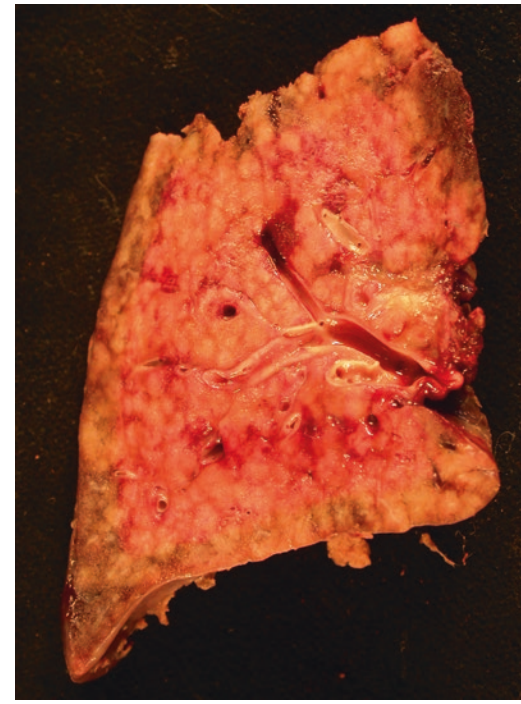

Fig. 5.49 Intralobar sequestration. Same case as Fig. 5.48. The cut surface shows the systemic artery affording the blood supply to the sequestered segment. No connection to the bronchial tree was demonstrated

5.9.1.5 Interstitial Emphysema

This refers to dissection of gas from the respiratory tree into the interstitium of the pleura, interlobular septa and bronchovascular bundles. It is frequently associated with pneumothorax and is usually associated with mechanical ventilation in neonates [79]. A localized form may cause respiratory embarrassment or may mimic CPAM [80] or congenital lobar overinflation. It usually does not require lung resection [81] but may be present in lung removed for other reasons.

It consists of irregular spaces in the lung interstitium around the bronchovascular bundles, veins and pleura that may be cystically enlarged. The lymphatics may be involved. It may be of such severity that bronchovascular bundles apparently 'hang' within clear spaces (Fig. 5.51). It may be confused with lymphangiectasia mor-

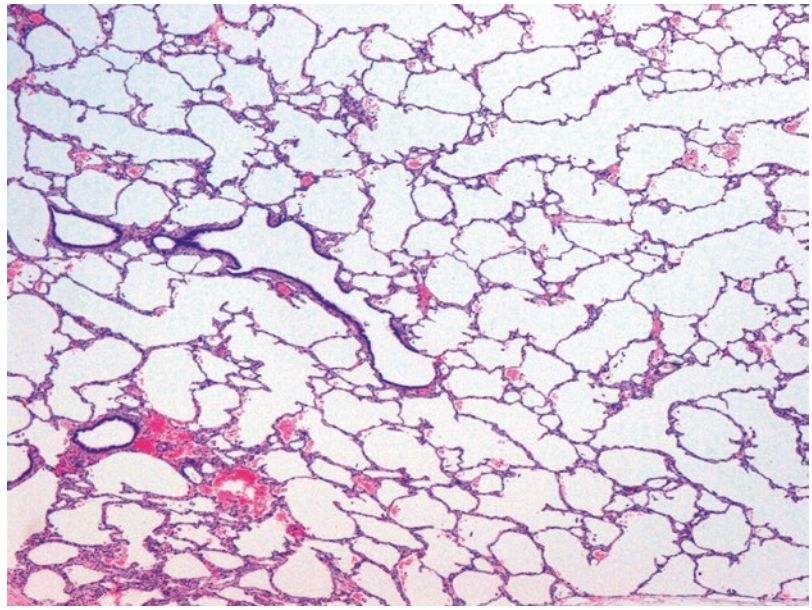

Fig. 5.50 Congenital lobar emphysema (overdistension). A 20 day old male infant who required resection of the right middle and lower lobe. The lung was bulky but without focal abnormality. A photomicrograph shows what appears to be normal lung. The airspaces are, however, distended when compared with a normal lung

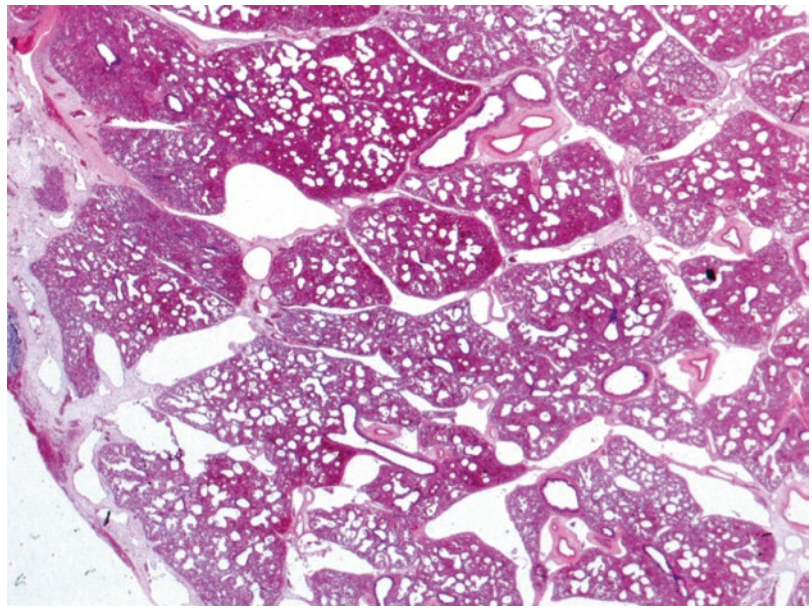

Fig. 5.51 Pulmonary interstitial emphysema. A 1 month old female infant with congenital heart disease, sepsis and multi-organ failure who spent her short life in intensive care and on artificial ventilation. The lung shows extensive pulmonary haemorrhage. In addition, there are large clear spaces in the interlobular septa and around bronchovascular bundles that represent interstitial air—pulmonary interstitial emphysema

phologically. If persistent, a surrounding florid foreign-body giant cell reaction occurs.

5.9.2 Alveolar Capillary Dysplasia

This is one of the commonest indications for neonatal lung biopsy and the condition at present can only be diagnosed on biopsy. The child may have other congenital defects such as congenital heart disease or bowel malformations [82], but from the respiratory point of view, is usually normal at birth. The child develops respiratory difficulty in the subsequent days. Typically, there is extreme difficulty in oxygenation despite ease of ventilation. Death is almost invariable. Familial cases are described. Causative mutations in the FOX F1 gene on chromosome 16q have been described

in cases with associated malformations [83], raising the possibility that in future the condition may be diagnosed on gene testing.

On biopsy, there are two main components:

- Misalignment of pulmonary veins. This can be detected on frozen section. Thin-walled veins run in the same fibrous tissue sheath as the arteries and bronchi (Fig. 5.52). The veins are of a comparable diameter to the arteries they accompany. They should not be mistake for dilated lymphatics that are a common feature of many pulmonary disorders.
- Greatly thickened alveolar septa that contain large numbers of capillary blood vessels not in contact with the overlying alveolar epithelium (Fig. 5.53). If in doubt cytokeratin and CD31

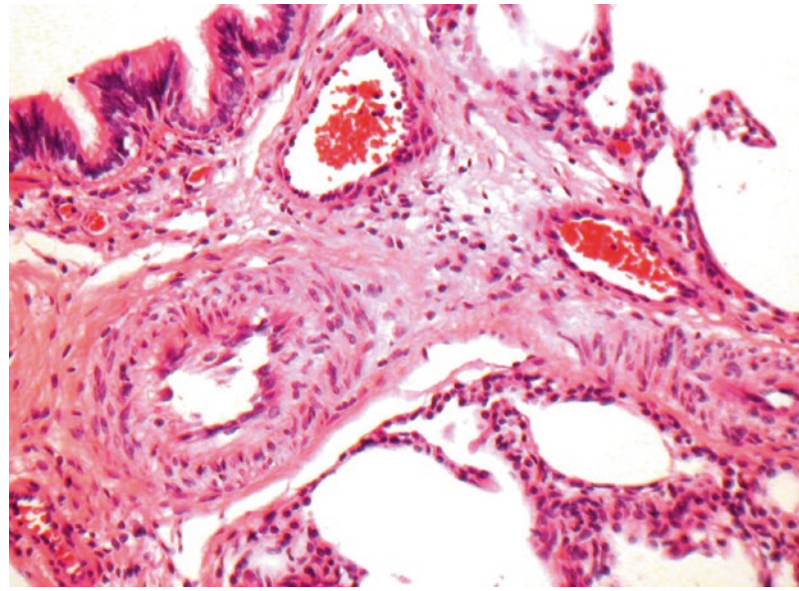

Fig. 5.52 Congenital alveolar capillary dysplasia. Open lung biopsy from a 19-day old female infant with respiratory failure. There is misalignment of the pulmonary veins. A thick-walled intra-acinar artery is present in the centre of the picture and accompanies a bronchiole whose epithelial lining is visible at the top of the field. In addition, two vein branches (filled with blood) accompany the artery. This is abnormal and should prompt a search for alveolar capillary dysplasia

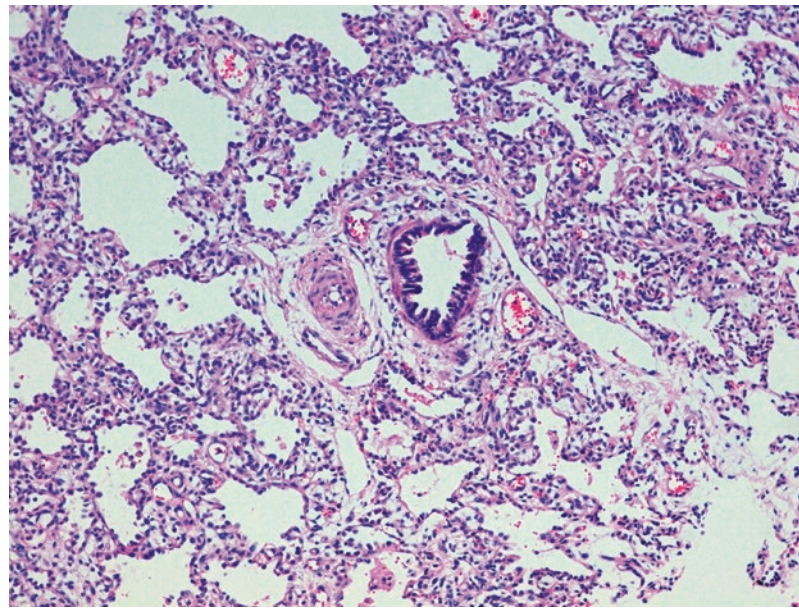

Fig. 5.53 Congenital alveolar capillary dysplasia. A 9-day old male infant with pulmonary hypertension. The section shows lung with misalignment of the pulmonary veins—the vein accompanies the artery and bronchus. In addition, there is thickening of the alveolar septa, and the small alveolar capillaries sit, not immediately beneath the alveolar epithelium, but rather in the centre of the thickened septa—so-called alveolar capillary dysplasia

staining highlights the epithelial and vascular components.

There is pulmonary arterial hypertension with medial hypertrophy in the muscular pulmonary arteries and muscularization of the arterioles.

5.10 Genito-urinary Abnormalities

5.10.1 Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease characteristically presents in the neonatal period or, indeed, antenatally [84]. There is bilateral enlargement of the kidneys by cysts associated with congenital hepatic fibrosis. [85, 86]. There is bilateral massive renal enlargement (Fig. 5.54). There may be severe pulmonary hypoplasia. Histologically there is replacement of the normal renal structure by fusiform cysts extending from the cortex to medulla displayed in radial fashion with preservation of the overall shape of the kidney (Fig. 5.55). The liver shows ductal plate malformation with fibrosis (Fig. 5.56). There may be occasional small glomerular cysts [87], although these are not a prominent feature.

5.10.2 Nephronophthisis

Nephronophthisis is an autosomal recessive condition due to abnormality in the urine concentrating capacity that progresses to end-stage renal failure [88]. An infantile form occurs. Histologically it is characterized by dilated tubules and collecting ducts with the formation of cysts (Fig. 5.57). There is chronic inflammatory change in the interstitium. There may be secondary glomerulosclerosis but glomerular cysts are not prominent.

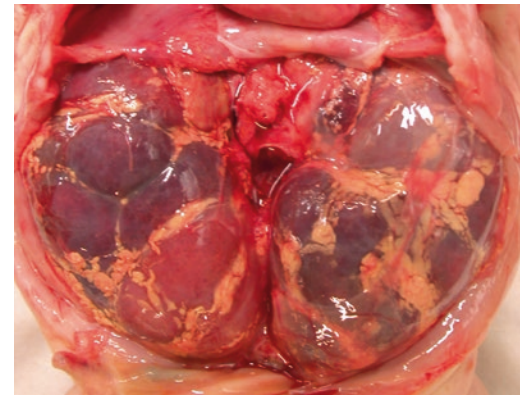

Fig. 5.54 Autosomal recessive polycystic kidney disease. A term infant who died aged 1-day. Renal cystic disease was diagnosed antenatally and there was associated oligohydramnios. The infant died of pulmonary hypoplasia. This is a photograph from the post-mortem showing massive enlargement of both kidneys. The kidneys retain their shape but occupy the entire posterior abdominal wall from diaphragm to pelvis

5.10.3 Renal Dysplasia

Renal dysplasia is a developmental abnormality are also associated with reflux in the ureters or lower urinary tract. [89, 90]. Histologically, the kidneys are small and scarred with numerous immature cysts surrounded by cuffs of immature mesenchyme (Fig. 5.58). There may be metaplastic cartilage in the stroma, a useful histological future (Fig. 5.59). There is often extramedullary hemopoiesis the abnormality may be focal, segmental or affect the whole kidney sometimes associated with hydronephrosis.

5.10.4 Reflux Nephropathy

Reflux nephropathy, is due to vesico-ureteric reflux shows a combination of fibrosis, interstitial inflammation, tubular atrophy and loss of the glomeruli (Fig. 5.60). In utero the features may overlap with those of renal dysplasia. The ureter is usually thick walled.

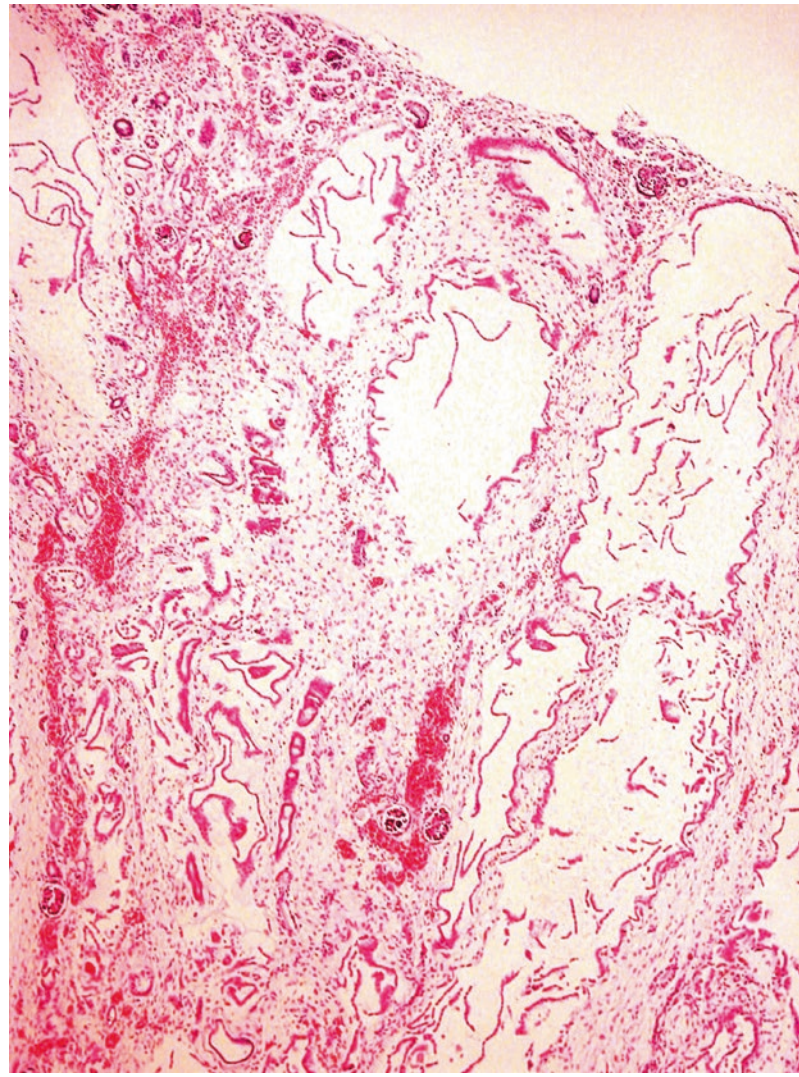

Fig. 5.55 Autosomal recessive polycystic kidney disease. Same case as Fig. 5.54. A histological section of one of the kidneys. The cortex is uppermost, covered by renal capsule. There is post-mortem autolysis. Nevertheless, multiple cystically dilated renal tubules are visible running perpendicular to the capsule. There is focal sloughing of their epithelial lining. The stroma is oedematous with focal haemorrhage. A few glomeruli are visible. The appearance is typical of ARPKD

5.10.5 Testicular Torsion

Testicular torsion is well reported infancy [91] and many cases may represent torsion of the testicular appendage rather the testis itself. If the testis is affected there is congestion and edema and interstitial hemorrhage which progress to frank hemorrhagic infarction of the organ (Fig. 5.61). If the testicular appendage only is affected there is congestion and interstitial hemorrhage although rarely frank necrosis. If the torsion occurs in utero the testicular tissue may regress and no testis may be identifiable (Fig. 5.62). At inguinal exploration a cord like structure is identified with sometimes a small nodule remaining. There is no identifiable normal testicular tissue, although vas deferens and epididymis are identified and histologically there may be scattered areas of hemosiderin laden macrophages or dystrophic calcification [92].

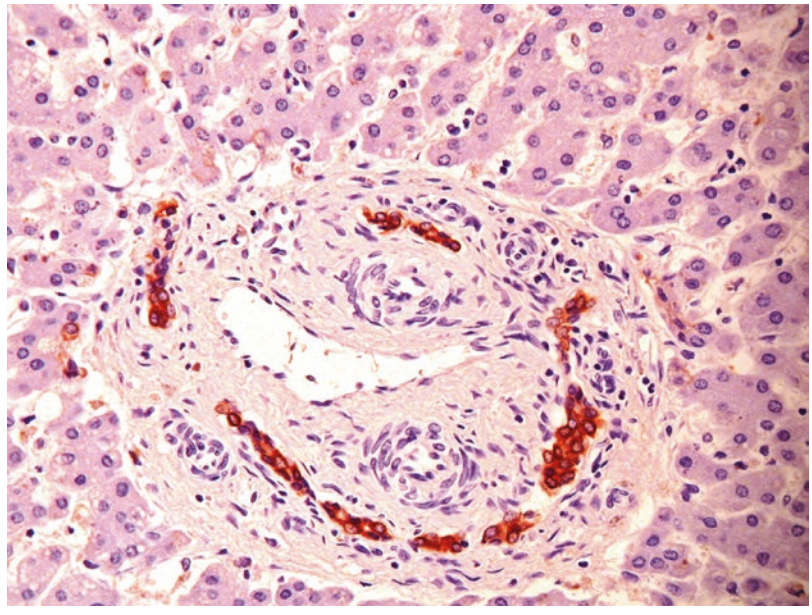

Fig. 5.56 Ductal plate malformation liver. A histological section of the liver stained immunohistochemically for cytokeratin 19. This highlights the biliary epithelium (stained *brown*) in a portal tract. Instead of a single profile of the bile duct to accompany the artery, the bile duct is a garland of tissue around the periphery of the portal tract—the so-called ductal plate malformation. After 16 weeks of gestation this appearance is abnormal and is strongly associated with ARPKD

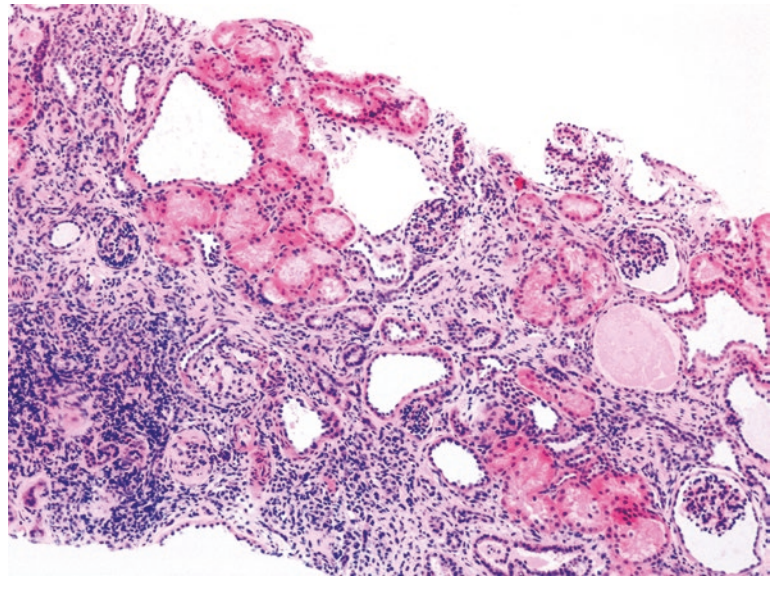

Fig. 5.57 Nephronophthisis. Biopsy from a child with cystic renal disease. There is marked interstitial chronic inflammation and dilatation of tubules. The features are not specific for nephronopthisis and genetic confirmation is required

5.10.6 Cryptorchid Testis

Cryptorchid testis removed during infancy may show minimal or no abnormalities [93].

Fig. 5.58 Renal dysplasia. One-year old female with multicystic renal dysplasia. The excised kidney shows loss of the normal renal tissue and replacement by multiple cysts up to 2 cm in diameter

5.11 Neonatal Tumours

Congenital malignancies are rare [94]. They account for approximately 2% of all childhood cancers. About 40% of congenital tumors are histologically malignant. Of these the commonest are neuroblastoma, leukemia and congenital brain tumors. Neuroblastoma comprises 30–40% of congenital tumors and is the commonest congenital malignancy. Spontaneous regression may occur in 40% of the antenatally detected cases. Congenital acute leukemia is the second, commonest congenital malignancy.

5.11.1 Teratoma

Teratomas in the neonate are usually benign and occur mainly in the sacrococcygeal area (Fig. 5.63) followed by the anterior mediastinum [95]. They may also be found in the peri-

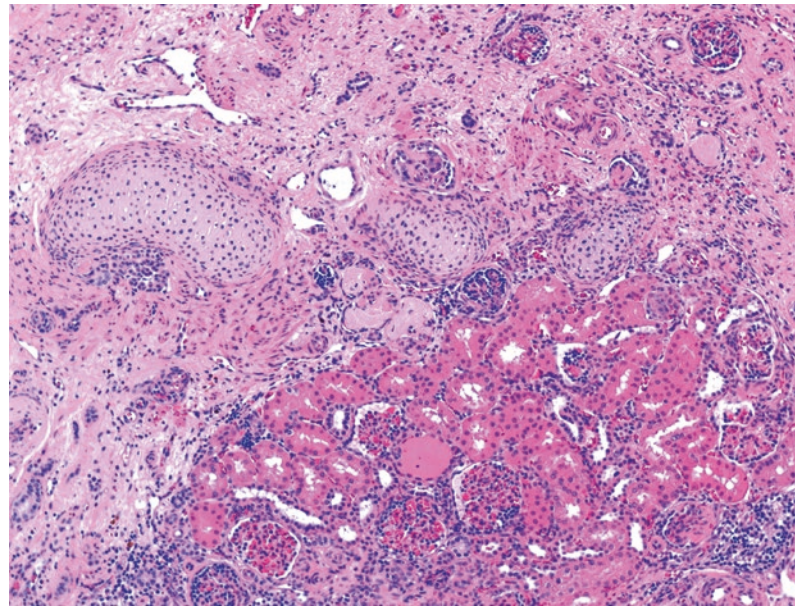

Fig. 5.59 Renal dysplasia. Histological section from a dysplastic kidney (H&E stain). The lower part of the field shows relatively normal kidney. The upper part shows loss of tubules and fibrosis. There are three small irregular bars of hyaline cartilage—feature very typical of renal dysplasia

Fig. 5.60 Reflux nephropathy. Eleven-month old female infant with right duplex ureter and vesicoureteric reflux into lower pole moiety. Resection of lower pole. The cut surface of the specimen shows a normal thickness of cortex but there is blunting of the pyramids, mild calyceal dilatation and marked expansion of the pelvis

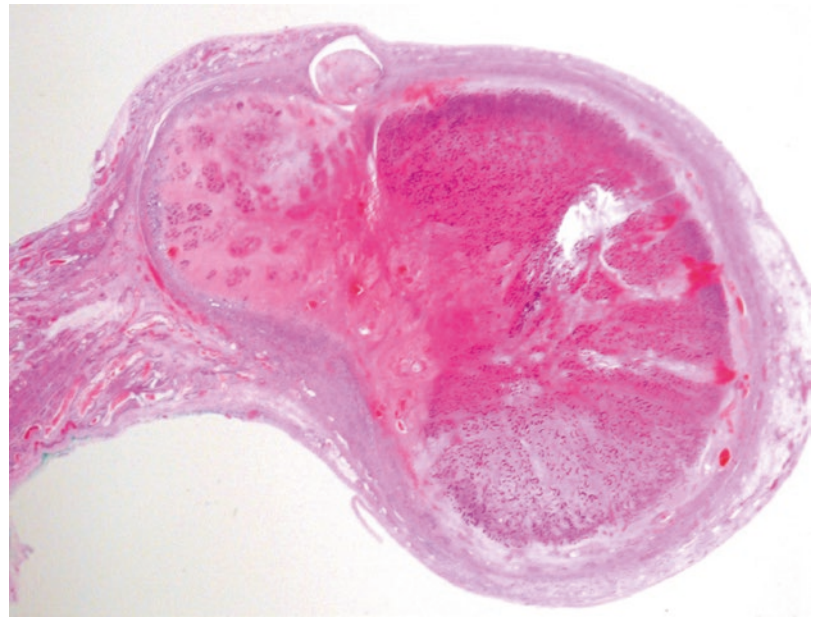

Fig. 5.61 Testicular torsion. Six-month old male with testicular torsion. A section of the entire specimen shows the spermatic cord to the left, the testis to the right and the epididymis and appendix testis in the centre of the field. The tissue is oedematous and shows haemorrhage and necrosis. Much of the cellular detail is obscured because of necrosis

cardium [96]. Diagnosis is usually established prenatally and may require intervention in a compromised fetus. Alpha fetoprotein is the tumor marker of choice and is particularly useful for assessing the presence of residual or recurrent disease. Grossly the tumors may reach a large size (Fig. 5.64) and many are cystic. The cut surface will frequently reveal multiple tissues including adipose tissue, mucus and keratin and frequently hair, cartilage, bone or teeth. Histologically the tumors are composed of tissues derived from all three germ layers. There is usually adipose tissue, skin, mature neuroglial tissue, smooth muscle, glan-

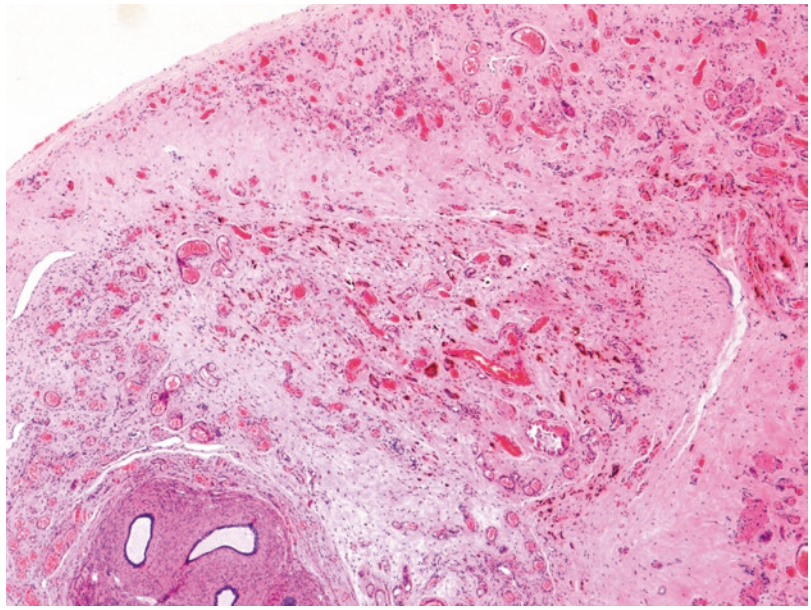

Fig. 5.62 Vanishing testis. Removal of an "atrophic testis" from a 1-year old boy. The specimen was a tubular structure 2.0 cm long and 0.4 cm in diameter. Histologically it consists of vas deferens with epididymis. At the expected site of the testis (shown) there is a nodule of loose vascular tissue with a small focus of calcification and numerous macrophages that contain *dark brown* haemosiderin pigment. No testicular tissue is identified. The appearances are those typical of so-called vanishing testis

Fig. 5.63 Sacrococcygeal teratoma. An antenatally diagnosed sacrococcygeal tumour removed from a 5 day old boy. The specimen weighed nearly 1.5 kg and was 22 cm in maximum dimension. The stretched skin with distended veins over the surface of the tumour can readily be appreciated. Histologically the tumour was a teratoma that contained some immature elements but there was no evidence of malignancy

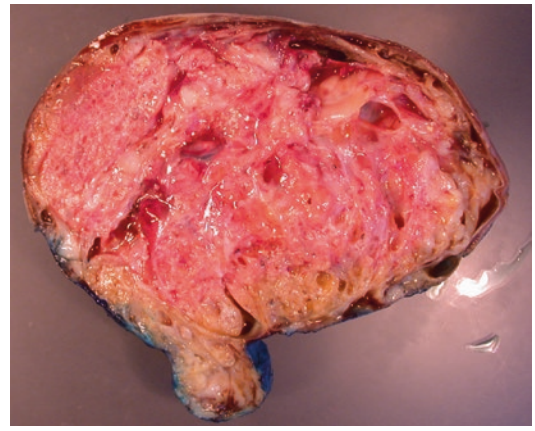

Fig. 5.64 Sacrococcygeal teratoma. The same case as Fig. 5.63. The cut surface of the tumour is predominantly solid, but with cystic areas. There are variable amounts of tissue with a myxoid appearance, while other areas are fleshy and some are fatty

dular tissue, cartilage and sometimes bone (Fig. 5.65). Less frequent are tissues such as retina, pancreas, thyroid and pancreas. About three-quarters of all sacrococcygeal teratomas are benign, containing no immature elements. A further 10–15% will have immature elements, usually immature neural tissue (Fig. 5.66). A small percentage will contain frankly malignant elements, most frequently yolk-sac tumor (Fig. 5.67).

5.11.2 Neuroblastoma

Neuroblastoma is an embryonic tumor that occurs at the site of the sympathetic ganglia from the neck to the pelvis [97]. The adrenals are the most common site with lesser numbers in the abdomen, thorax, head and neck. It is the most common congenital malignancy [94] and the most common intra-abdominal cancer in children. Paraneoplastic syndromes including

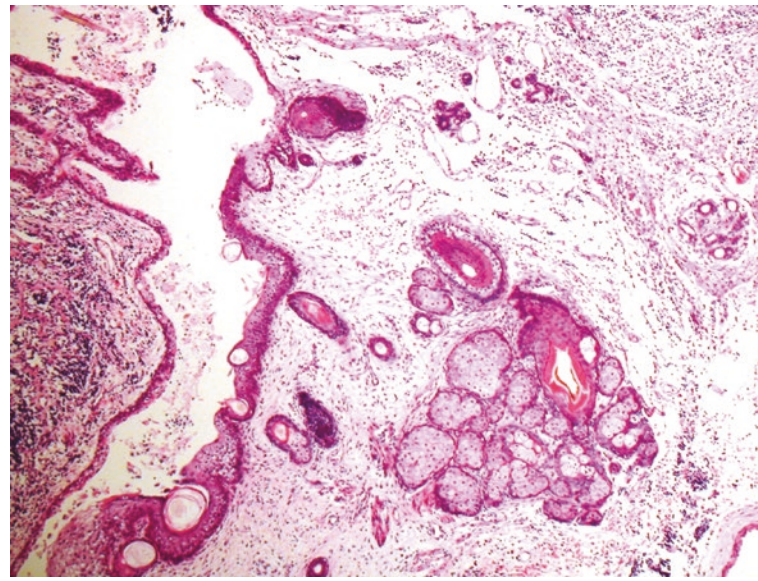

Fig. 5.65 Sacrococcygeal teratoma. A field from a scarococcygeal teratoma showing skin and adnexa, smooth muscle, glandular tissue and loose mesenchyme. There are no immature elements

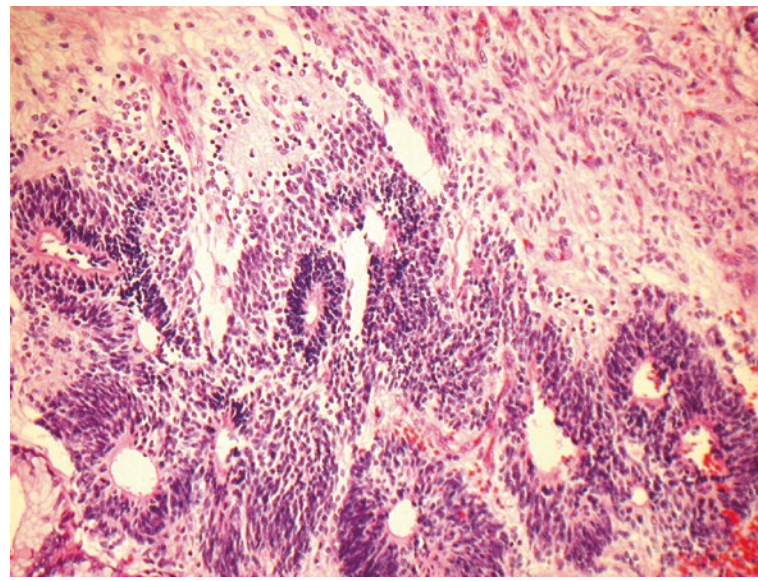

Fig. 5.66 Sacrococcygeal teratoma—immature elements. Another field from the same case showing numerous ependymal rosettes with surrounding immature neural tissue. Such immature neural tissue is frequently found in sacrococcygeal teratomas, and provided the tumour is completely excised, does not adversely affect the outcome

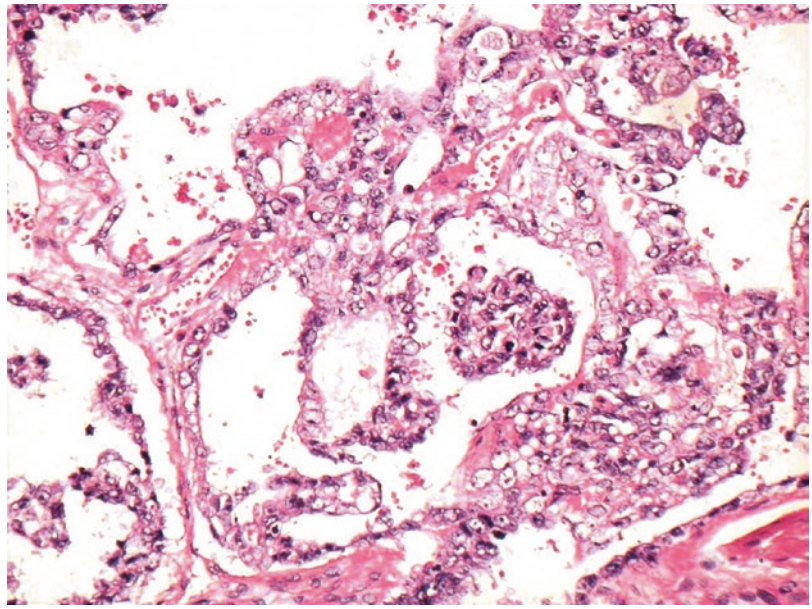

Fig. 5.67 Sacrococcygeal teratoma—1 year old with a sacrococcygeal mass 4 × 3 × 2.5 cm. Raised AFP level. The cut surface was cystic and solid. Histologically there was extensive yolk-sac tumour. A high power view of one such focus shows a cystic space lined by malignant cells and showing a polypoid projection of malignant tissue into the lumen. This is a Schiller-Duval body, diagnostic of yolk sac tumour

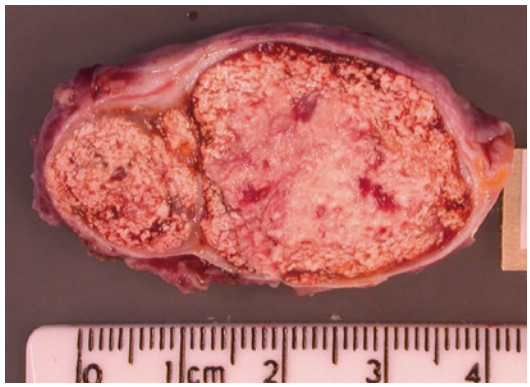

Fig. 5.68 Neuroblastoma. An 11 month old boy with resection of a primary adrenal neuroblastoma—Stage 4—following chemotherapy. The mass weighed 108 g and measured 4 × 3 × 2 cm. The tumour has a fibrous capsule in which remnants of the adrenal gland are visible as bright yellow areas. The tumour is nodular and very heavily calcified with a granular appearance. Histologically there was no viable tumour

hypertension, myclonus and Horner syndrome may be present. Metastasis is to bone marrow, regional lymph nodes and liver. The spinal canal is frequently involved by contiguous spread. Congenital cases may have placental involvement [98].

The tumors are typically bulky and fleshy typically show hemorrhage and are composed of small round blue cells with focal calcification (Fig. 5.68). There is primitive neural tissue with varying maturation. The degree of maturation varies (Fig. 5.69) from totally undifferentiated cells (small round blue cells) to lesions which show abundant Schwann cell differentiation and mature ganglion cells. The poorly differentiated lesions are commoner. By immunohistochemistry the cells stain with antibodies to NSE, NB84 and CD56. The behavior of the tumor depends upon its biological features such MYCN amplification and deletion of chromosomle 1p [99]. In the congenital cases (Fig. 5.70) spontaneous regression may occur in up to 40%. In children under 1 year of age, a particular form of metastatic disease occurs termed stage 4S, where a unilateral tumor shows metastasis limited to skin, liver and bone marrow (but not bone). These tumors have a much better prognosis that neuroblastoma metastatic to other sites [100].

5.11.3 Liver Tumours

Liver tumors account for about 5% of all tumors in the fetus and newborn [101]. The most frequent are benign vascular tumors and mesenchymal hamartoma. Hepatoblastoma is the commonest

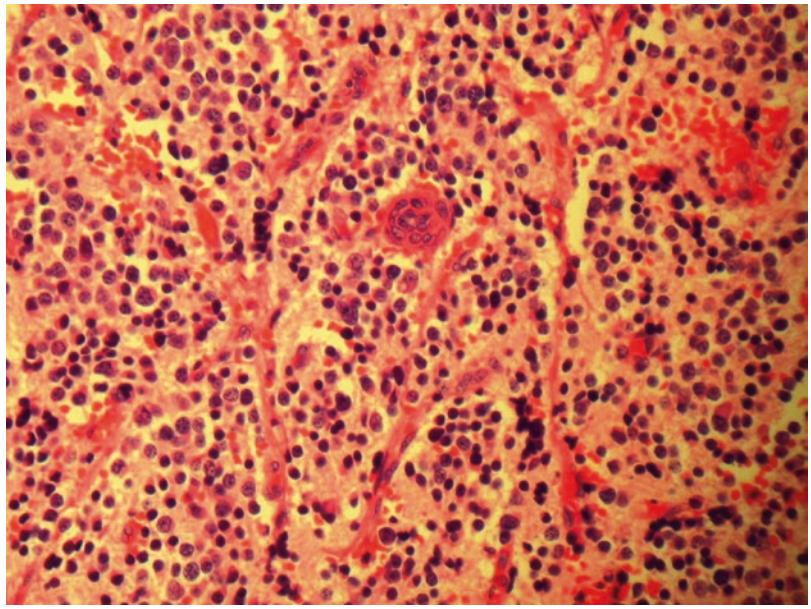

Fig. 5.69 Neuroblastoma—a 10-month old girl with resection of a stage III left adrenal neuroblastoma following chemotherapy. An H&E stained section (high power) shows the packeted arrangement of the tumour cells, separated by incomplete, thin fibrovascular septa. The cells are poorly differentiated neuroblasts and there is a background of fine fibrillary eosinophilic material—neuropil. This appearance is very characteristic of neuroblastoma

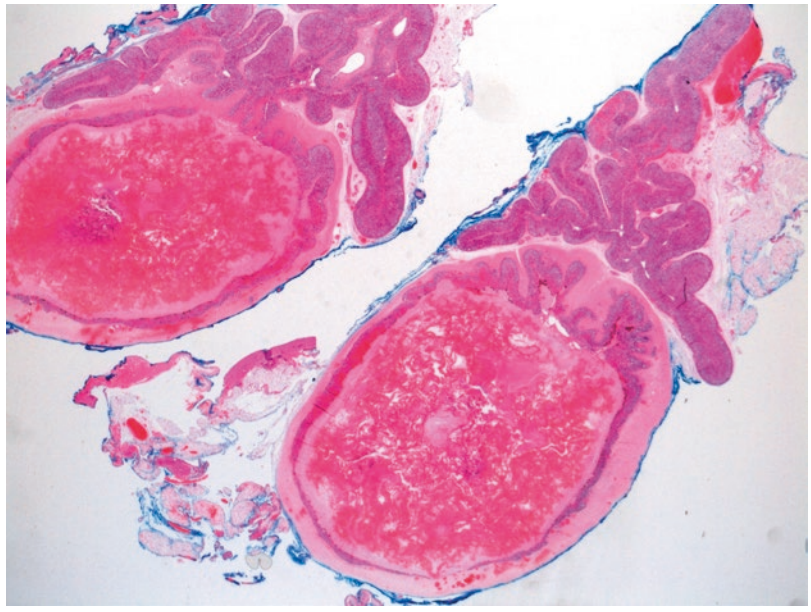

Fig. 5.70 Congenital neuroblastoma. An antenatally diagnosed tumour in the right adrenal gland of a male infant. Removed at 1 year of age. The excised adrenal gland showed a calcified nodule 1.0 cm in diameter. A whole mount section shows the adrenal gland that contains a rounded nodule of necrotic and calcified tissue. No viable elements are seen but the appearance is in keeping with a congenital neuroblastoma. The *blue* colour is ink, painted on the specimen to assess the resection margins

malignant tumor. In utero tumors may be associated with polyhydramnios, fetal hydrops and extreme cases the maternal mirror syndrome. Hepatoblastoma usually presents as a single liver mass (Fig. 5.71), although up to one fifth cases may show multiple lesions. There is usually associated anemia and sometimes raised platelet count. Lung metastasis is present at the time of diagnosis in up to one-fifth of cases. The histopathologic features show great variability. The tumors are predominantly epithelial and generally consists of fetal or embryonal components resembling respectively fetal and embryonic liver (Fig. 5.72). There is a variable amount of associated connective tissue which may show heterologous elements such as osteoid, skeletal muscle and sometimes squamous epithelium or melanocytic epithelium (Fig. 5.73). A small cell undifferentiated type is described. The presence of embryonal or undifferentiated cell types is indicative of a poor prognosis. Many cases are not submitted for pathological examination until after chemotherapy and in these cases there is usually extensive regressive change with fibrosis, necrosis, hemosiderin deposition and frequently a predominance of heterologous elements.

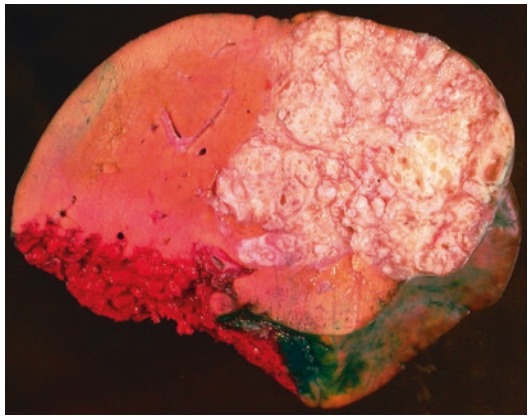

Fig. 5.71 Heaptoblastoma. Nine moth old boy with resection of a liver tumour following chemotherapy. The tumour was in segments IV, VI, VII and VIII. The cut surface shows a heavily calcified nodular pale mass 6 × 5 × 3 cm bulging onto the capsular surface. The *green* and *red* inks are used to identify the resection planes. Microscopically the tumour was predominantly mesenchymal with extensive osteoid. Resection was complete

Mesenchymal hamartoma is solid or cystic and recognized histologically by a myxoid stroma that contains islands of hepatocytes and dilated biliary structures (Fig. 5.74) [102]. There is an association with placental mesenchymal dysplasia [103].

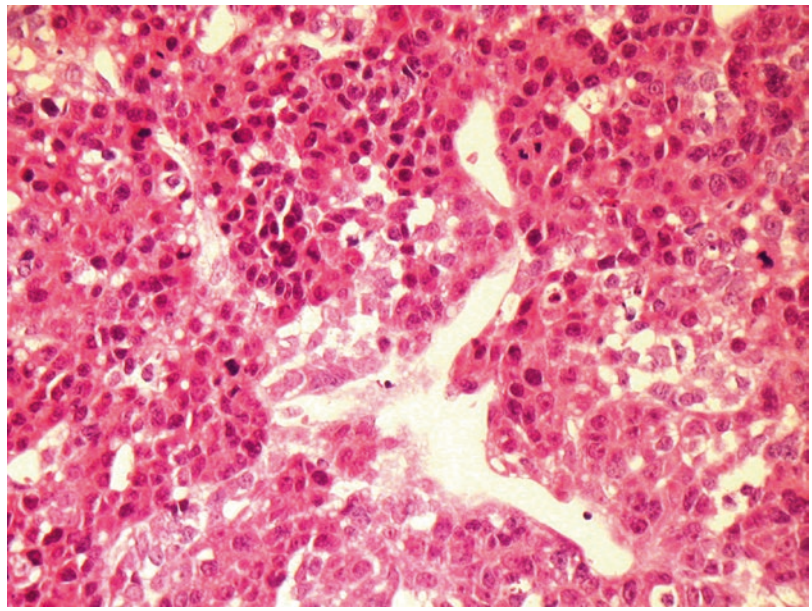

Fig. 5.72 Hepatoblastoma. A 7 month old girl with a mass in the right lobe of the liver and alpha feto-protein level of around 300,000. A needle biopsy core of the mass shows a mixture of embryonal and fetal hepatocytes, typical of hepatoblastoma

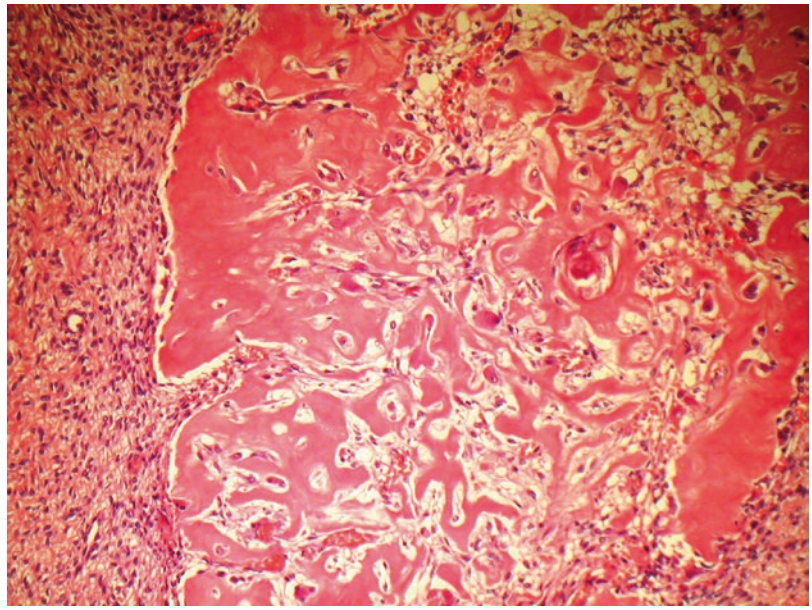

Fig. 5.73 Heaptoblastoma heterologous elements. Same case as in Fig. 5.71. There is extensive osteoid, visible as irregular bands of pink eosinophilic material, set in a spindle cell stroma

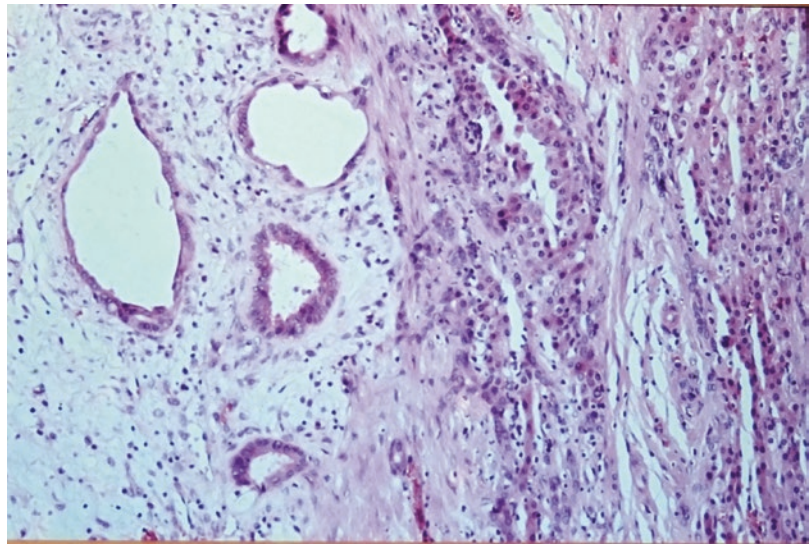

Fig. 5.74 Mesenchymal hamartoma liver. A 6-month old boy with a mass in the right lobe of the liver. A high-power H&E stained section shows dilated biliary structures set in a mesenchymal stroma with enclosed islands of hepatocytes

5.11.4 Renal Tumours

Renal tumors account for approx. 7% of all neonatal tumors [104]. Mesoblastic nephroma (Fig. 5.75) is the most common tumor to be found at this age accounting for between 2 and 5% of all pediatric renal tumors, but Wilms' tumor and other malignant and benign tumors occur.

Congenital mesoblastic nephroma is a tumor of the kidney occurring typically within the first 3 months of life particularly in the neonatal period [105]. The tumor is usually unilateral. Two main subtypes are described—the classical type with a with a distinct resemblance to infantile fibromatosis (Fig. 5.76) and the cellular type that resembles infantile fibrosarcoma (Fig. 5.77) and shares with it the same t(12:15) ETV6-NTRK3 translocation [106]. Macroscopically it has an appearance resembling a uterine fibroid (Fig. 5.75), but with indistinct margins because

of infiltration of the surrounding kidney. Necrosis and hemorrhage are not found but there may, however, be cystic change. It is present at the renal hilum and projects on the medial aspect of the kidney. Microscopically the tumor is composed of spindle cells. Entrapped renal tubules are present within the tumor. There may be immature cartilage, a metaplastic phenomenon.

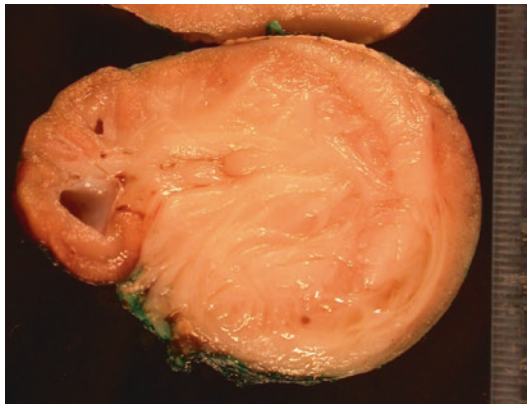

Fig. 5.75 Mesoblastic nephroma. A 17 day old hypertensive female with a congenital left renal mass. The excised specimen weighed 44 g and contained a tumour 5 cm in diameter that bulges from the medial aspect of the kidney. The cut surface has a whorled grey appearance resembling a uterine fibroid. The appearance is typical of congenital mesoblastic nephroma. There is moderate dilatation of the renal calyces

Wilms' tumor (nephroblastoma) is a malignant neoplasm derived from the nephrogenic blastema [105]. The majority of cases are sporadic but there is an association with inherited syndrome some associated with abnormalities of the WT1 gene. Most tumors are unilateral, but may be bilateral. The tumor is a solid mass that is well demarcated from the surrounding uninvolved kidney (Fig. 5.78). Nephrogenic rests may be present in the surrounding kidney. Histologically' Wilms' tumor have a classical triphasic appearance comprising epithelium, stroma and blastema (Fig. 5.79). Blastema refers to cellular immature tissue present in the embryo. The respective proportions of these three elements vary from tumor to tumor. There may be anaplasia in the tumor cells (Fig. 5.80) which may affect any of the three components. Following chemotherapy there is usually marked necrosis and regressive change. The tumor has a tendency to involve the renal vein and spread in that fashion. Local nodes may also be involved. The presence of diffuse anaplasia within the tumor renders it a high-risk tumor. Nephrogenic rests (Fig. 5.81) are abnormally persistent areas of immature cells in the renal cortex. Normally they disappear by 36 weeks of gestation and where they persist they give rise to Wilms' tumor. They are said to have a prevalence of

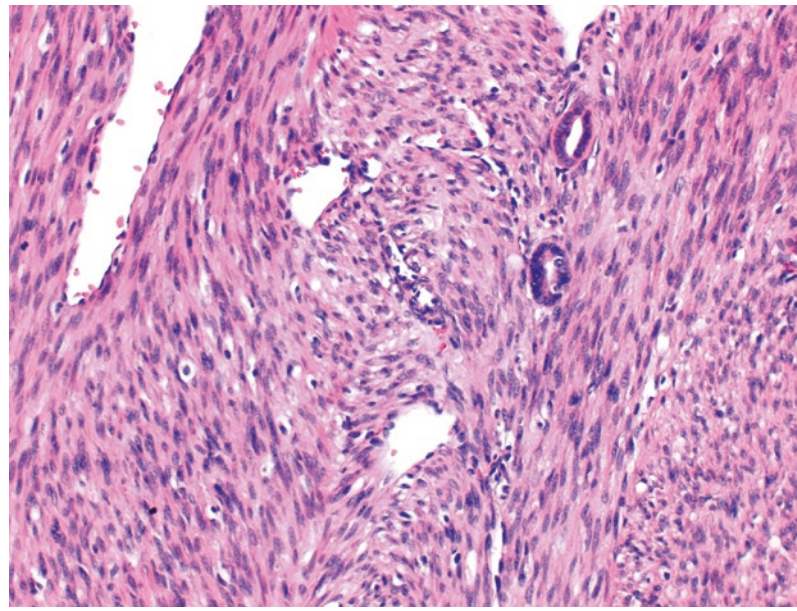

Fig. 5.76 Mesoblastic nephroma. A 7 week old boy with hypertension and a renal mass. A section from the excised kidney (H&E) shows regular fascicles of spindle cells without atypia. There are included entrapped normal, non-neoplastic, renal tubules

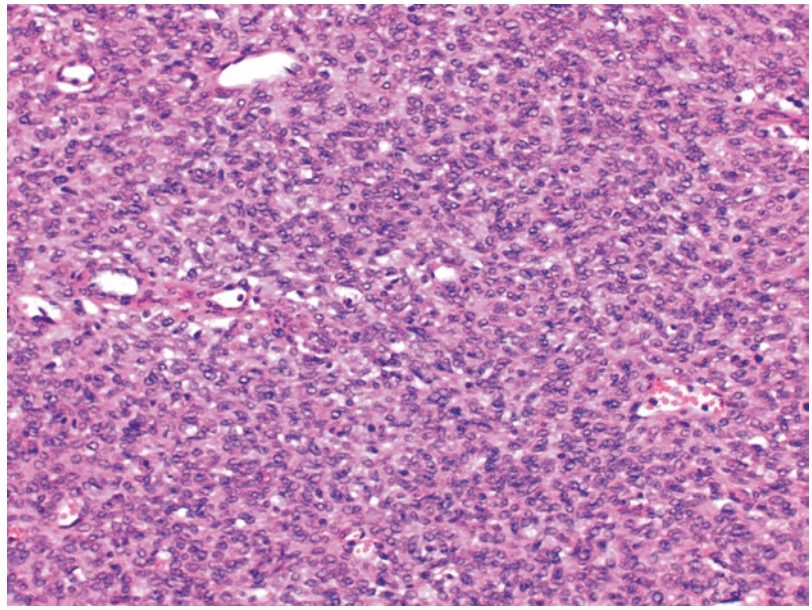

Fig. 5.77 Cellular mesoblastic nephroma. A 6 week old boy with a right renal mass 14 × 13 × 9 cm. A section of the mass taken at the same magnification as Fig. 5.76 shows it to be more cellular than that specimen with numerous mitotic figures. The specimen showed a positive transcript for ETV6-NTRK3 by RT-PCR

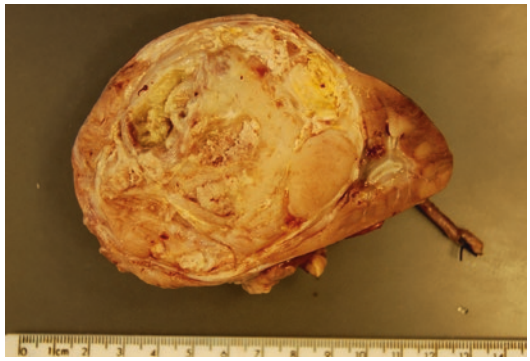

Fig. 5.78 Nephroblastoma (Wilms' tumour). A 3-month old boy with a right renal mass resected after chemotherapy. The excised specimen weighed 244 g and the tumour measures 7 cm in greatest diameter. The tumour is at the upper pole, well circumscribed and demarcated from the kidney by a fibrous pseudocapsule. Its cut surface shows fleshy areas and large areas of necrosis (approx. 60%). Histologically the tumour showed focal extracapsular spread but was completely excised (Stage 2)

approximately 1% in autopsies of children but they are probably much rarer than this.

5.11.5 Brain Tumours

Brain tumors in infants are rare, accounting for less than 5% of all pediatric brain tumors. Most are supratentotiral. These tumors are often histologically benign (teratoma, choroid plexus papilloma), but can be very large and are frequently situated in difficult locations [107, 108].

5.11.6 Tumours of the Chest Wall and Lung

5.11.6.1 Congenital Peribronchial Myofibroblastic Tumor

This is a very rare, but very striking, tumor that presents in utero with polyhydramnios and fetal hydrops [109]. It can present in the neonate as respiratory distress. There is a large mass on chest X-ray occupying most of the lung field. Grossly, there is a well-circumscribed solid mass up to 10 cm in diameter. Microscopically, the tumor is composed of fascicles of uniform spindle cells (Fig. 5.82) without pleomorphism [110]. Mitotic figures are present, but are not atypical. There is a very striking peribronchial infiltration with infiltration of the surrounding lung parenchyma. It has benign behavior, but the infant may die as a consequence of the hydrops [111].

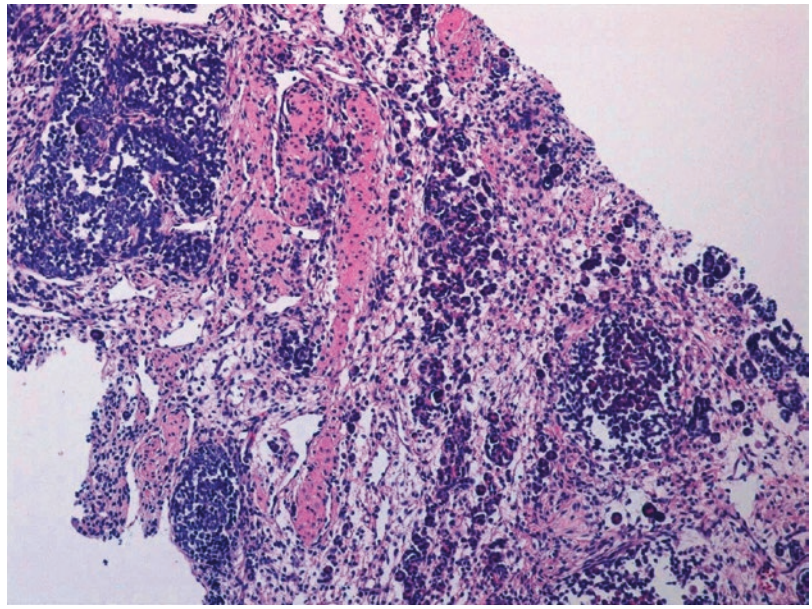

Fig. 5.79 Needle biopsy specimen of a right renal mass in a 1-year old girl. The sections show a high-power view of one of the cores stained with H&E. There is a loose myxoid stroma in which are set primitive tubules and areas of cellular blastema (most evident in the left upper part of the field) The appearance is typical of nephroblastoma (Wilms' tumour). By immunohistochemistry the tumour cell nuclei were stained positively with antibody to WT1

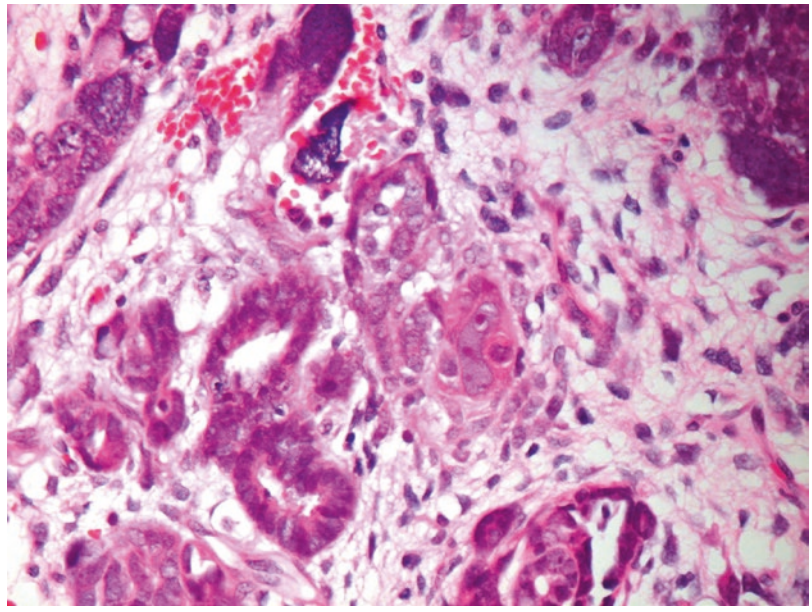

Fig. 5.80 Nephroblastoma (Wilms' tumour) anaplasia. A high-power field from a Wilm's tumour showing that the epithelial elements have bizarre, enlarged and hyperchromatic nuclei—anaplasia. This child was 8 years old. Anaplasia is much commoner with increasing age and is rare in infants

5.11.6.2 Fetal Lung Interstitial Tumor

This entity has only recently been reported [112]. The authors describe ten cases in infant's (seven males and three females) of mixed solid and cystic lung masses. The infants presented with variable respiratory distress developing shortly after birth. Imaging studies showed a well circumscribed mass (right lower lobe × 4, left lower lobe × 2, right upper lobe × 2 and one each in the right middle and left upper lobes). No local recurrence or metastatic disease was noted in up to 3 years of follow up. The mass is described as solid to spongy with well-defined borders. Histologically there was fibrous border between

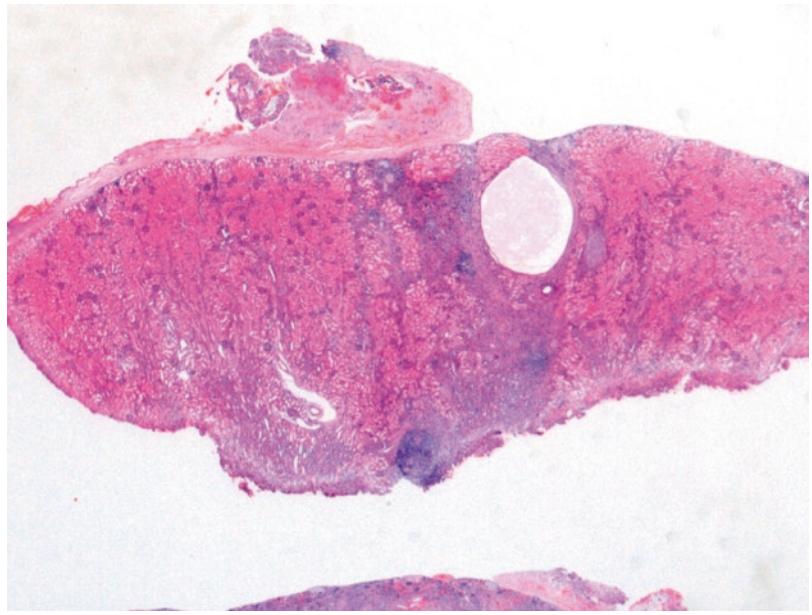

Fig. 5.81 A 1 year old boy with previous resection of nephroblastoma (Wilms' tumour) of the right kidney. A lesion was noted in the left lower pole and excised. It shows a wedge of immature and darkly staining renal tissue 0.8 cm in diameter. There is focal cystic dilatation of some tubules. The appearance is of a nephrogenic rest (H&E stain)

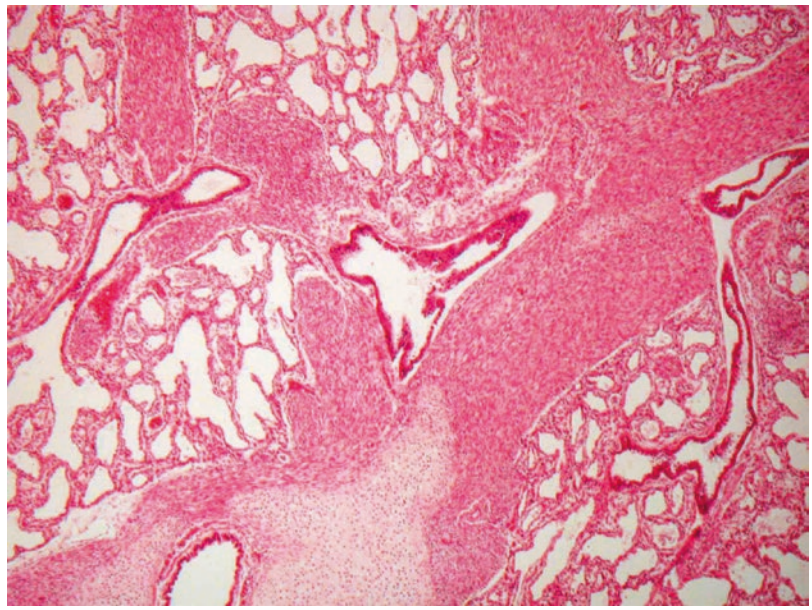

Fig. 5.82 Peribronchial myofibroblastic tumour. A section from the lung of a newborn with hydrops and a large right lung mass. The photomicrograph shows marked expansion of the bronchovascular connective tissue sheaths by thick bundles of bland spindle cells

the lesion and surrounding lung and the tumor is described as resembling fetal lung at 20–24 weeks gestation. There were cystic spaces lined by epithelium and a cellular stroma.

5.11.6.3 Pleuropulmonary Blastoma

The mean age of development of this malignant tumor lies outside the neonatal period but it may, nonetheless, present in the neonate. It is divided, pathologically into three types: I–III corresponding to cystic, solid and cystic, and solid morphology respectively and representing a spectrum of increasing aggressiveness [113]. Type I pleuropulmonary blastoma is the type most likely to present in the neonatal period (its median age of occurrence is 9 months) and is often confused, both on

imaging and pathologically with congenital pulmonary airway malformation (CPAM) [73]. Pleuropulmonary blastoma an association with cystic nephroma [114] and may be part of a familial cancer syndrome associated with mutations in the gene DICER1 [115]. Grossly it is cystic with thin walls (Fig. 5.83). There is no macroscopic thickening or solid areas. The cysts are lined by benign epithelium [72]. Focal subepithelial condensation of primitive cells (Fig. 5.84) may show rhabdomyoblastic differentiation (rhabdomyosarcoma-like). The muscle cells stain with vimentin, desmin and myogenin. The absence of rhabdomyoblastic differentiation does not exclude the diagnosis. There is variable pleomorphism. Primitive cell collections may be very sparse and multiple sections may be required to make the diagnosis and differentiate from type 4 CPAM [73]. The tumor may contain small nodules of immature cartilage which is very useful for diagnosis. It is treated by complete surgical excision with adjuvant chemotherapy. If incompletely excised, it may recur as type II or III pleuropulmonary blastoma.

Fig. 5.83 Pleuropulmonary blastoma type 1. A 6-day old boy with a mass in the lower lobe of the left lung. The resected specimen measured 7 × 5 × 4 cm and had a spongy cut surface

5.11.6.4 Infantile Chest Wall Mesenchymal Hamartoma

This is a very rare, but benign disorder of the ribs that may involve a single rib or more than one rib; it may be bilateral. It occurs in infants and usually present at birth as an asymptomatic chest wall mass or with respiratory distress and cyanosis. It may be fatal because of respiratory impairment, but more usually follows a benign course [116]. Radiology shows a cystic and solid mass with fluid levels in the cysts. Grossly, it is a well-delineated, lobulated mass with blood-filled cystic spaces and areas of cartilage. Histopathologically, it consists of areas of hyaline cartilage, both mature and immature, a spindle cell stroma. Osteoid and aneurysmal bone cyst-like areas.

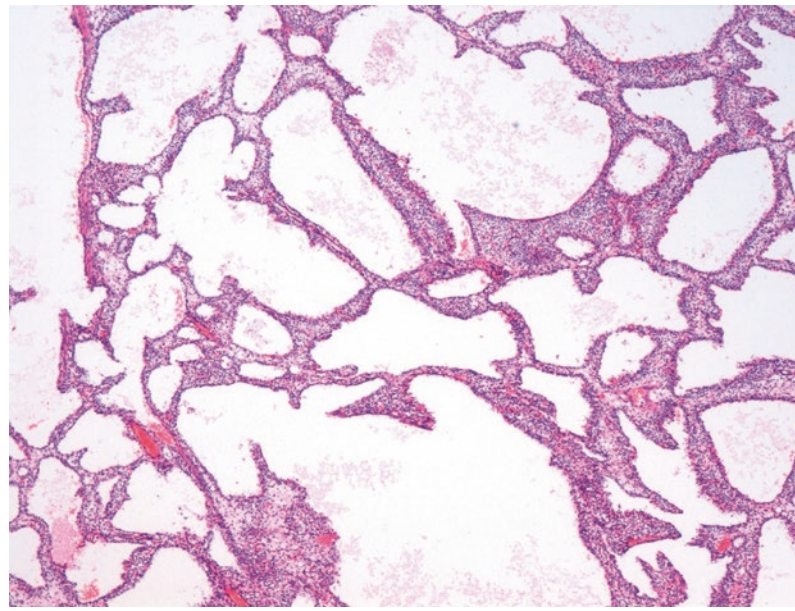

Fig. 5.84 Pleuropulmonary blastoma type 1. Same specimen as Fig. 5.83. The histology shows multiple cystic spaces lined by bland respiratory epithelium. Within the rather rigid septa there is condensation of rather primitive cells beneath the epithelium

5.11.7 Vascular Tumours

Vascular abnormalities are common, occurring about 1% of children. There is considerable confusion about their terminology. They can be broadly classified into hemangiomas and vascular malformations. The hemangiomas represent tumors, they show rapid growth during infancy followed by progressive involution, the basic underlying defect being abnormal endothelial cell proliferation. The vascular malformations, on the other hand, represent lesions that are present at birth (whether evident clinically or not) and grow with the child and do not show spontaneous regression; their basic underlying pathology is abnormal vascular development. Vascular malformations can be further subclassified according to the predominant type of vascular channels present in the lesion, such as capillary, venous, arterial and lymphatic, or a combination of these. They can also be classified according to the blood flow within them as either high-flow or low-flow lesions. The International Society for the Study of Vascular Anomalies, in 1996 produced a classification of vascular anomalies [117] incorporating these distinctions. In the classification, the tumors encompass:

- infantile hemangioma
- congenital hemangiomas (rapidly involuting and non-involuting forms)
- lobular capillary hemangioma (pyogenic granuloma)
- tufted angioma
- kaposiform haemangioendothelioma
- haemangiopericytoma

The malformations are either:

- simple with slow flow (capillary, venous, lymphatic) or high flow (arterial)
- combined lesions with either slow flow (lymphovenous malformation or capillary lymphovenous malformation) or high flow (arteriovenous malformation or capillary arteriovenous malformation).

Infantile hemangioma is the most common vascular tumor of children (Fig. 5.85) [118] characterized pathologically by staining of the lesional endothelium with the antibody GLUT-1 which recognizes the antigen Glucose Transporter Protein 1. The antigen is strongly expressed in all the lesional endothelial cells (Fig. 5.86) at all stages of their natural history [119]. It has greatly simplified the diagnosis of these tumors.

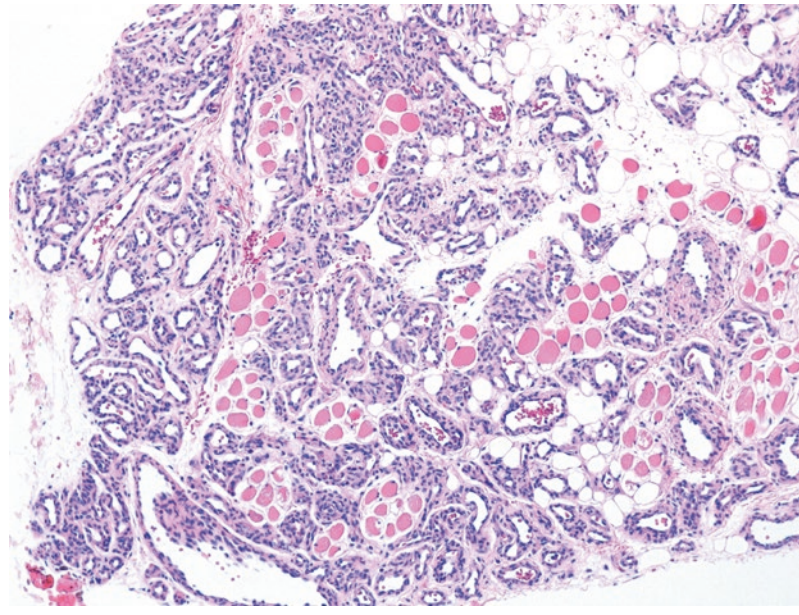

Fig. 5.85 Infantile hamangioma. Needle biopsy of a lump from the left thigh in a 5 month old female infant. The lesion shows multiple, small, capillary-sized vascular channels set among adipose tissue and striated muscle

Kaposiform haemangioendothelioma resembles juvenile hemangioma but shows no tendency to spontaneous regression and is frequently associated with Kasabach-Merritt syndrome, characterized by profound thrombocytopenia and hemorrhage. The lesion is most common in the extremities and is occurs in superficial and deep soft tissues [120]. The lesion is nodular and can resemble infantile capillary hemangioma histologically, but contains spindle cells. The cells are negative for GLUT 1, but are CD31 and CD34 positive. They are focally smooth muscle actin positive, but characteristically show positivity for the lymphatic marker D2–40 [121] (Fig. 5.87).

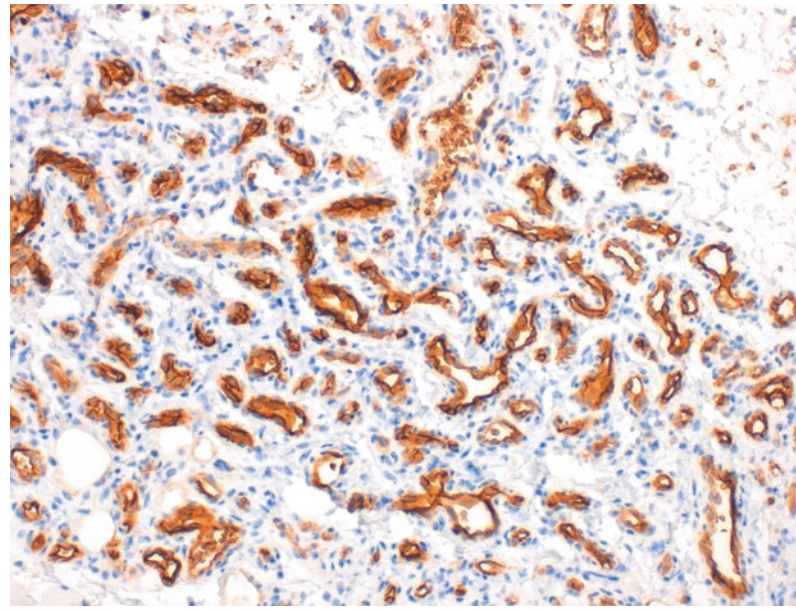

Fig. 5.86 Infantile haemangioma. Same case as Fig. 5.85 stained immunohistochemically with antibody to GLUT1. There is strong staining of the endothelium of the vascular spaces indicating that this is an infantile haemangioma

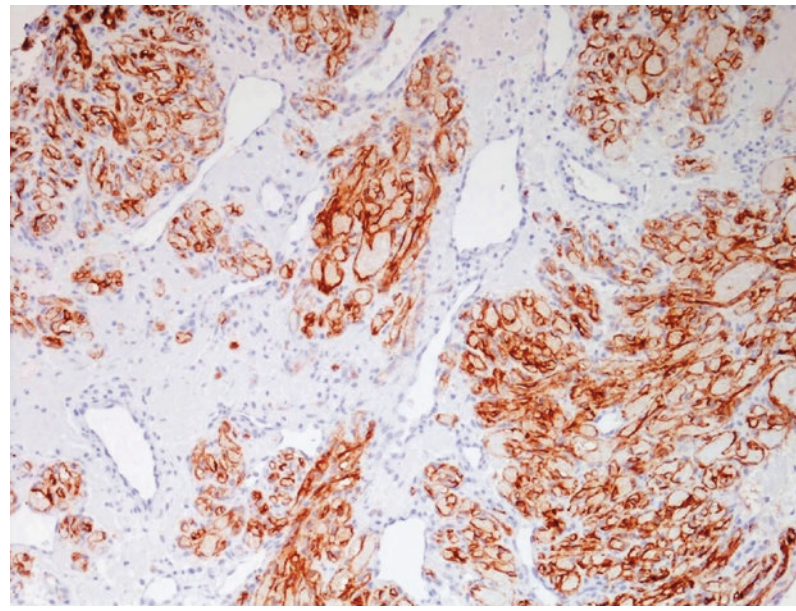

Fig. 5.87 Kaposiform haemangioendothelioma. A lesion composed of spindle cells with vascular spaces that stain strongly with antibody D2–40

5.11.8 Rhabdomyosarcoma

Rhabdomyosarcoma, a malignant tumor with differentiation towards a striated muscle phenotype, is the commonest soft tissue tumor in children, but is rare in the neonate [122]. Nevertheless, it may occur and has even been described in utero [123]. The tumor may arise in many sites but has a predilection to involve the head and neck and parameningeal area, proximal limbs and the viscera including bile duct and genitourinary tract (Fig. 5.88). Two histological subtypes are identified, the embryonic form and the alveolar form, the latter having a more aggressive clinical course. Alveolar rhabdomyosarcoma is characterized by a specific translocation affecting the PAX-FKHR genes [124]. Histologically embryonal rhabdomyosarcoma shows a spindle cell appearance with alternating areas of cellular and myxoid appearance (Fig. 5.89). Rhabdomyoblastic differentiation, that is to say recognizable differentiation toward striated muscle is uncommon, although cells may appear strap-like and have abundant eosinophilic cytoplasm. Cross-striations are not usually seen. The alveolar subtype has a small round blue cell phenotype with aggregation of the cells with a fibrovascular connective tissue stroma. Disaggregation of the cells from the fibrous septa in some cases imparts a pseudo-alveolar pattern that first gave this subtype its name (Fig. 5.90). Immunohistochemically, the tumor cells show strong cytoplasmic staining for the muscle protein desmin and display nuclear positivity for myogenin (Fig. 5.91)—alveolar rhabdomyosarcoma showing a greater percentage of positive nuclei than embryonal rhadomyosarcoma [125]. Increasingly molecular methods are being employed to make the diagnosis of alveolar rhabdomyosarcoma.

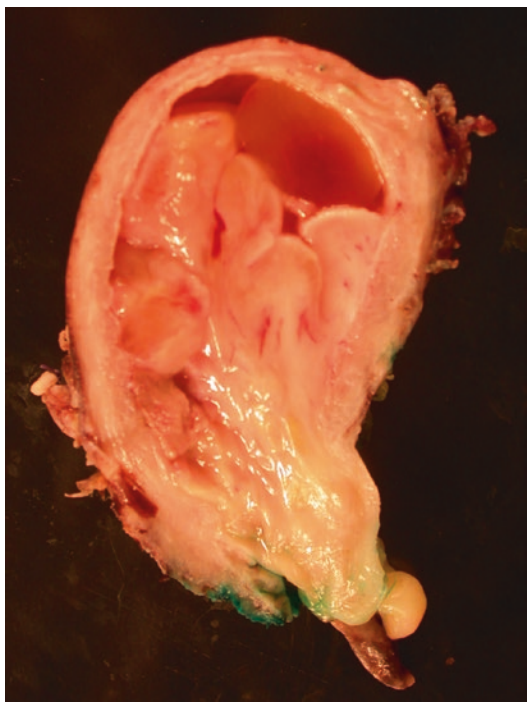

Fig. 5.88 Rhabdomyosarcoma. Two year old boy who had an embryonal rhabdomyosarcoma of the prostate glands treated with chemotherapy and radiotherapy. Cystoprostatectomy following recurrence. The Bladder is sectioned in the sagittal plane. A myxoid, polypoid tumour mass replaces the prostate gland and anterior lower bladder wall and distends the bladder lumen

5.11.8.1 Infantile Fibrosarcoma

This is a tumor of the infant: approximately 50% of cases are congenital. There is a characteristic t(12;15)(p13;q26) translocation resulting in an abnormal ETV6-NTRK3 fusion transcript, that is very helpful for diagnosis [126]. The commonest site is the distal extremities, but other sites may be involved, including head and neck. The lesion presents as a rapidly growing mass and may be mistaken for a hemangioma [127]. Histologically, it comprises interlacing bundles of spindle and ovoid cells (Fig. 5.92). The lesion is responsive to chemotherapy but may recur in up to half of the cases.

5.11.8.2 Infantile Myofibromatosis

Infantile myofibromatosis is a myofibroblastic proliferation and may be solitary or multiple and diffuse. It presents as a superficial painless subcutaneous mass in the head and neck, trunk or extremities. Deeper masses may occur in the muscle or viscera. Histologically it has a nodular appearance with zoning, the central zone showing a haemangiopericytoma-like appearance, while the periphery is more cellular

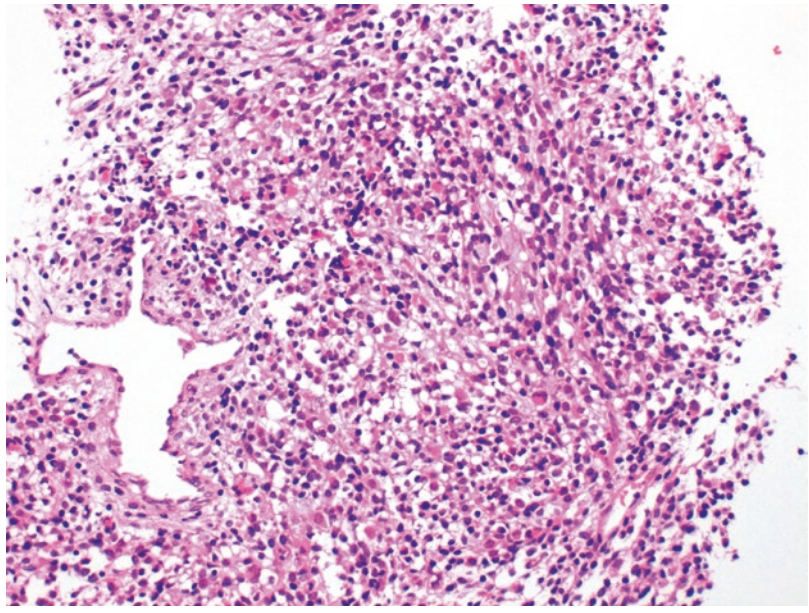

Fig. 5.89 Rhabdomyosarcoma—embryonal subtype. A 9-month old girl with a soft tissue mass in the face, a needle core biopsy shows a cellular lesion composed of spindle cells loosely arranged. Scattered cells with opaque eosinophilic cytoplasm are present, indicating a more mature muscle phenotype. Myogenin staining showed only 30% of tumour nuclei stained positively and there was no FOX01 gene rearrangement

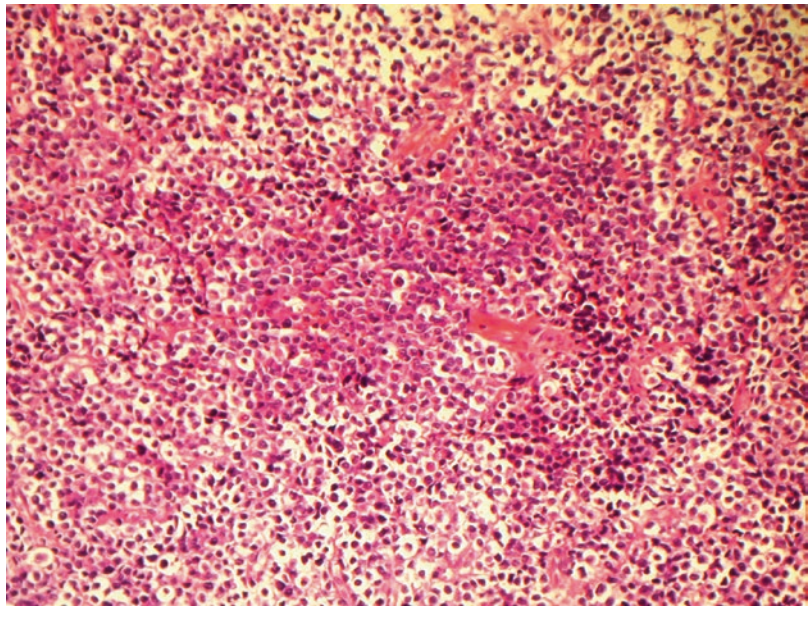

Fig. 5.90 Alveolar rhabdomyosarcoma. A 5-month old girl with a neck mass. A biopsy specimen shows a cellular tumour with a vaguely packeted arrangement of the cells. The centres of the packets show disaggregation of the cells—a feature typical of alveolar rhabdomyosarcoma. The cells showed strong cytoplasmic staining with antibody to desmin and almost all the tumour cell nuclei showed strong staining for myogenin. PCR analysis showed a PAX7-FKHR (t1;13) fusion transcript

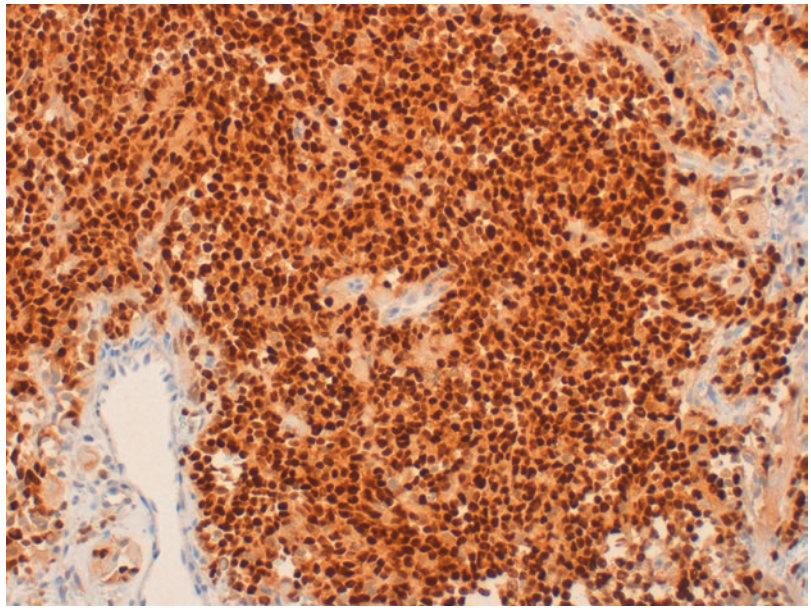

Fig. 5.91 Rhabdomyosarcoma. Immunohistochmical staining of a biopsy specimen with antibody to myogenin. There is nuclear staining of approximately 90% of tumour cell nuclei. Such a high percentage of staining is strongly indicative of the alveolar subtype of rhabdomyosarcoma

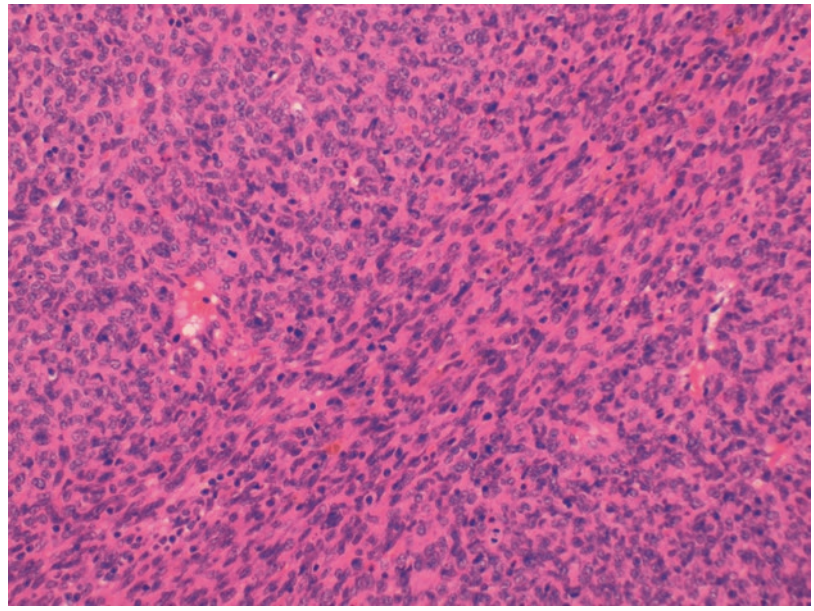

Fig. 5.92 Infantile fibrosarcoma. Twenty-six day old boy with a right thoracic cystic and solid mass, The lesion is composed of spindle cells arranged in fascicles with frequent mitotic figures. PCR analysis showed a ETV6-NTRK3 transcript, confirming the diagnosis of infantile fibrosarcoma

(Fig. 5.93). There is no atypia. There is some histological overlap with haemangiopericytoma and infantile fibrosarcoma [128] but, crucially, it had lacks the typical translocation of infantile fibrosarcoma.

5.12 Autopsy

Inevitably, babies will die of their disease or its complications. In this setting, an autopsy carried out by a competent pediatric\perinatal pathologist

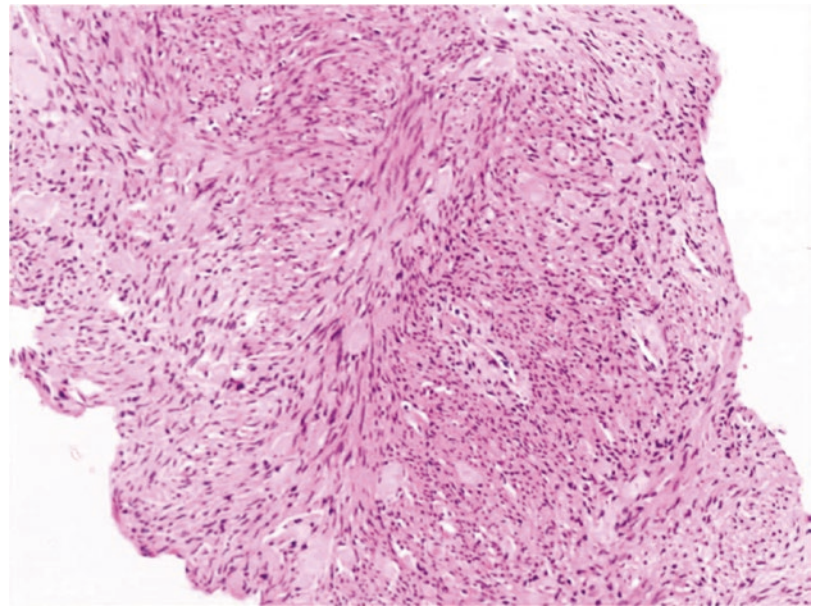

Fig. 5.93 Infantile myofibromatosis. An H&E stained section shows interlacing fascicles of spindle cells with eosinophilic cytoplasm

can be very useful in answering hitherto unanswered questions. It is important to realize that not all questions can be answered by the autopsy—even in the twenty-first century there are areas of biology where understanding is still at a primitive stage. The more precisely formulated the question that the pathologist is posed, the more likely it is that meaningful information can be obtained by the autopsy. Although the preference will always be for a full autopsy, it may well be that the question to a particular query may be answered by a limited post-mortem, for example limited to the operation site, to the heart and lungs or to the brain. This emphasizes again the importance of team work. Possibly nowhere else is teamwork as important as in managing the expectation of the family in relation to post-mortem. Indeed, many of the problems relating to post-mortem have arisen not because of malpractice but because of a lack of appreciation by all parties of the needs and expectations of others.

6 Developmental Physiology and Pharmacotherapy in Pediatric Surgical Newborns

John N. van den Anker and Dick Tibboel

Abstract

Human development consists of a continuum of physiologic events that includes somatic growth, neurobehavioral maturation and eventual reproduction, and is often divided into infancy, childhood, adolescence and early adulthood. Across this period of time organ size and function change as does body composition, protein expression, and cellular function. Some tissues may be more sensitive to effects early in life whereas later in life function may decline. This holds true in particular when organ development has resulted in major congenital anomalies. As these developmental changes in function and form occur, their implications with respect to the clinical pharmacology of drugs and their appropriate place in pediatric therapy must be considered.

Keywords

Newborn physiology • Pharmacology • Newborn surgery

6.1 Introduction

Human development consists of a continuum of physiologic events that includes somatic growth, neurobehavioral maturation and eventual reproduction, and is often divided into infancy, childhood, adolescence and early adulthood. Across this period of time organ size and function change as does body composition, protein expression, and cellular function. Some tissues may be more sensitive to effects early in life whereas later in life function may decline. This holds true in particular when organ development has resulted in major congenital anomalies. As these developmental changes in function and form occur, their implications with respect to the clinical pharmacology of drugs and their appropriate place in pediatric therapy must be considered.

The impact of these developmental changes in drug disposition is largely related to alterations in body composition (e.g. body water content, plasma protein concentrations) and function of organs important in metabolism (e.g. the liver)

and excretion (e.g. the kidney). During the first decade of life, these changes are dynamic and can be non-linear and discordant making standardized dosing inadequate for effective drug dosing across the span of childhood. Consequently, "standard dosing" of many drugs during rapid phases of growth/development where both drug disposition and response may be altered are generally inadequate for the purpose of optimizing drug therapy. This goal can only be achieved through fundamental and integrative understanding of how ontogeny influences pharmacokinetics and pharmacodynamics. Throughout development, the impact of ontogeny on pharmacokinetics and pharmacodynamics is, to a great degree, predictable and follows definable physiologic "patterns" that will be described in the sections that follow. Significant impairment of normal physiology as occurs in intestinal atresias and gastroschisis (absorptive capacity) as well as renal function (obstructive uropathy) have major implications for optimal dosing.

Developmental pharmacokinetics must take into account normal growth and developmental pathways [1, 2]. A better understanding of the various physiologic variables regulating and determining the fate of drugs in the body and their pharmacologic effects has dramatically improved both the safety and the efficacy of drug therapy for neonates, infants, children, and adolescents [3, 4]. The impact of development on the pharmacokinetics of a given drug is dependent, to a great degree, upon age-related changes in the body composition and the acquisition of function of organs and organ systems that are important in determining drug metabolism as well as drug transport and excretion [5, 6]. Although it is often convenient to classify pediatric patients on the basis of postnatal age for the study and provision of drug therapy (e.g., newborn infants aged 1 month or less, infants between 1 and 24 months of age, children between 2 and 12 years of age, and adolescents between 12 and 16–18 years of age), it is important to recognize that changes in physiology that characterize development may not correspond to these age-defined breakpoints and also are not linearly related to age. In fact, the most dramatic changes in drug disposition occur during the first 12–18 months of life, when the acquisition of organ function is most dynamic [3, 4]. Additionally, independent from developmental aspects, it is important to mention that the pharmacokinetics of a given drug may be altered in pediatric patients also due to intrinsic (e.g., genotype, inherited diseases) and/or extrinsic (e.g., acquired diseases, diet, co-medication) factors that may occur during the first months and years of life [7–12]. To study pediatric pharmacokinetics it is very useful to examine the impact of development on those physiologic variables that govern drug Absorption, Distribution, Metabolism, and Excretion [1, 2, 5] which is summarized by the commonly used term ADME. Especially the surgical newborn with major gastrointestinal and/or renal anomalies forms a very complicated patient in this respect.

6.2 Drug Absorption

For therapeutic agents administered by extravascular routes, the process of absorption is reflected by the ability of a drug to overcome chemical, physical, mechanical, and biological barriers. Developmental differences in the physiologic composition and function of these barriers can alter the rate and/or extent of drug absorption [3, 4]. While factors influencing drug absorption are multifactorial in nature, developmental changes in the absorptive surfaces (e.g., gastrointestinal tract, skin) can be determinants of bioavailability [3, 4].

The most important factors that influence drug absorption after oral administration from the gastrointestinal tract are related to the physiology of the stomach, intestine and biliary tract. During the first few years of life there are significant changes in gastric pH related to parietal cell density and function. Parietal cells are present early in fetal life in the antrum and body of the stomach. However, at term only about 20% of neonates possess the same proportion of parietal cells as observed in adults [13]. The highest gastric pH levels (6–8) occur in the neonate immediately after birth and within hours drop to 2–3. These levels return to neutral over the next 24 h, and remain that way for the next 10 days [1].

These initial changes do not occur in premature infants, who seem to have little or no free acid during the first 14 days of life [1]. However, sick preterm infants have been shown to have a lower gastric pH than healthy preterm infants [14]. In addition, one must also consider the impact of feeding on gastric pH and effects on drug absorption. Feedings with infant formula have been found to increase gastric pH, buffering it to levels >4 for up to 90 min after a feeding. As a consequence, the oral bioavailability of drugs that are acid labile (e.g., beta-lactam antibiotics) may be increased due to reduced degradation. With parietal cell maturation over the next few years, gastric pH gradually decreases to adult values by 3–7 years of age.

Gastric emptying rates also show significant ontogenic differences. The time of gastric emptying is delayed in the period immediately after birth for both full term and preterm neonates. It approaches adult values within the first 6–8 months of life [15]. For drugs with limited water solubility (e.g., phenytoin), gastric emptying rate may significantly influence the rate and extent of bioavailability. Delayed gastric emptying can result in delayed absorption of drugs, since most drugs are absorbed in the small intestine.

Especially in newborns following major loss of intestinal length, either congenital or acquired (NEC), hypergastrinemia has a significant effect on stomach function.

Intestinal transit time is prolonged in neonates because of reduced motility and peristalsis, but appears to be reduced in older infants as a result of increased intestinal motility [15, 16]. Other factors that may play a role in intestinal drug absorption are immaturity of the intestinal mucosa leading to increased permeability, immature biliary function, high levels of intestinal β-glucuronidase activity, reduced first-pass metabolism, maturation of carrier mechanisms and variable microbial colonisation [16]. Additionally, the ability to solubilize and subsequently absorb lipophilic drugs can be influenced by age-dependent changes in biliary function. Immature conjugation and/or transport of bile salts into the intestinal lumen result in low intraduodenal levels despite blood levels that exceed those seen in adults.

Unfortunately, few studies have systematically evaluated the effect of developmental changes in gastric emptying and intestinal motility on drug absorption in infants and children. Anderson et al. showed that the oral acetaminophen absorption rate was significantly lower in the first days of life before stabilizing 1 week after birth [17]. Another study showed that the time to reach the maximum concentration (t_{max}) of cisapride was significantly longer in preterm infants compared with term neonates [18]. Generally, the rate at which most drugs are absorbed is generally slower and thus, the time to achieve maximum plasma concentrations is prolonged in neonates and young infants relative to older infants and children. Despite their incomplete characterization, developmental differences in the activity of intestinal drug metabolizing enzymes and efflux transporters have the potential to markedly alter drug bioavailability.

So far only very few studies have systematically evaluated the effect of ultrafast transit time on drug absorption or intestinal hormone profiles such as gastrin, CCK and peptide YY in newborns with short bowel.

Development can also alter the systemic exposure to drugs given by other routes of administration such as dermal, intramuscular, rectal, and intrapulmonary. The morphologic and functional development of the skin as well as factors that influence the penetration of drugs through the skin have been reviewed [19]. Basically, the percutaneous absorption of a compound is directly related to the degree of skin hydration and relative absorptive surface area and inversely related to the thickness of the stratum corneum [19]. The integument of the full-term neonate possesses an intact barrier function and is similar to that of an older child or adolescent. However, the ratio of surface area to body weight of the full-term neonate is much higher than that of an adult. Thus, the infant will be exposed to a relatively greater amount of drug topically as has been proven in case of local application of drugs-containing ointments to protect (giant) omphaloceles for infection in the past (mercury; jodide, etc.). In contrast, data of human skin from preterm infants indicates

an inverse correlation between permeability and gestational age. Permeability rates were 100- to 1000-fold greater before 30 weeks gestation as compared with full-term neonates, with a three- to fourfold greater permeation rate seen beyond 32 weeks [20]. *In vivo* studies suggest that this increased dermal permeability in preterm infants is a short-lived phenomenon with the permeability barrier of even the most premature neonates similar to that of full-term neonates by 2 weeks of postnatal life [20]. There are numerous reports in the literature underscoring the importance of skin absorption in neonates primarily showing toxicity after exposure to drugs or chemicals [21]. These include pentachlorophenol-containing laundry detergents and hydrocortisone [22, 23]. Therefore, extreme caution needs to be exercised in using topical therapy in neonates and young infants.

In infants absorption of rectally administered agents may be reduced due to a greater number of high-amplitude pulsatile contractions in the rectum, relative to adults, leading to premature expulsion of solid rectal drug formulations (e.g., suppositories). In contrast, rectal solutions of drugs such as diazepam are readily and rapidly absorbed in children, achieving therapeutic plasma concentrations within 4 min of administration [24].

Developmental differences in airway surface area, chest wall compliance, functional residual capacity and hypoxic drive have the potential to influence the local and systemic exposure of drugs that are administered via inhalation. For example, lung deposition increases and oropharyngeal deposition decreases with increasing age (lung deposition from same inhaler/spacer combination 1–2% in infants, 4–6% in 2–6 year old children, and 12% in 10 year old child). Aerosol particles are typically designed for adults and older children and these large-particle aerosols are typically not suitable for newborns, infants and toddlers who have smaller pulmonary passages.

6.3 Drug Distribution

Drug distribution is influenced by a variety of drug-specific physiochemical factors, including the role of drug transporters, blood/tissue protein binding, blood and tissue pH and perfusion [1, 3, 4]. However, age-related changes in drug distribution are primarily related to developmental changes in body composition, the concentration of available binding proteins, and the capacity of plasma proteins to bind drugs. Age-dependent changes in body composition alter the physiologic "spaces" into which a drug may distribute [25]. When expressed as a percentage of total body mass, neonates and young infants have significantly higher extracellular fluid and total body water spaces (e.g., 80% in infants vs. 60% in adults). In contrast, the percentage of intracellular water as a function of body mass remains stable from the first months of life through adulthood. Age-dependent changes in body composition can alter the apparent volume of distribution for many drugs, both hydrophilic and lipophilic in character. Larger extracellular and total body water spaces in neonates and young infants, coupled with adipose stores that have a higher water/lipid ratio than in adults, produce lower plasma concentrations for drugs that distribute into these respective compartments when administered in a weight-based fashion. The surgical newborn suffering from ongoing fluid losses in the abdominal cavity (intestinal obstructions, volvulus NEC) in combination with generalized edema can still suffer from intravascular hypovolemia. This has major consequences for renal function. In clinical practice the amount and quantification of changes in extracellular fluids is very difficult. Several hydrophilic drugs such as gentamicin and linezolid have a significantly larger volume of distribution in neonates than in infants or adults [26, 27].

The extent of drug binding to proteins in the plasma may influence the volume of distribution of drugs [1]. Only free, unbound, drug can be distributed from the vascular space into other body fluids and, ultimately, to tissues where drug-receptor interaction occurs.

Albumin, total protein, and total globulins such as α[alpha]1 acid-glycoprotein are the most important circulating proteins responsible for the drug binding in plasma. The absolute concentration of these proteins is influenced by age, nutrition, and disease. Changes in the composition and amount of these circulating plasma proteins can also influence the distribution of highly bound drugs [1, 5]. A low plasma albumin is commonly

observed in newborns with gastroschisis, intestinal atresia, and NEC postoperatively. A reduction in both the quantity and binding affinity of circulating plasma proteins in the neonate and young infant often produces an increase in the free fraction of drug, thereby influencing the availability of the active moiety and potentially, its subsequent hepatic and/or renal clearance. For example, phenytoin is extensively (~94–98%) bound to albumin in adults as compared to 80–85% in the neonate and the resultant six to eightfold difference in the free fraction can result in CNS adverse effects in the neonate when total plasma phenytoin concentrations are within the generally accepted "therapeutic range" (10–20 mg/L).

Other factors associated with development and/or disease such as variability in regional blood flow, organ perfusion, permeability of cell membranes, changes in acid-base balance and cardiac output can also influence drug binding and/or distribution. Finally, drug transporters such as the ABC efflux pump P-glycoprotein (MDR1/ABCB1) can influence drug distribution because these transporters can markedly influence the extent to which drugs cross membranes in the body and whether drugs can penetrate or are secreted from the target sites (e.g., cerebrospinal fluid). P-glycoprotein has been found to be expressed in the human central nervous system as early as 27 weeks of gestation with expression intensity during the neonatal period becoming most prevalent at 33 weeks of gestation. This is particular relevant in the large number of premature born infants treated for NEC. Within the CNS there is also differential expression within various regions of the brain in relation to age [28]. P-gp in the liver also follows a developmental pattern of expression whereby activity increases during the first few months of life and adult levels are reached by 2 years of age [29].

6.4 Drug Metabolism

Drug metabolism exhibits marked developmental dependence, especially during fetal and early postnatal life. Hepatic development begins in the fetus at the fourth week of gestation as a duodenal diverticulum. By the sixth week of fetal life hepatic lobules are present and by the ninth week, the organ represents 10% of the fetal weight [30]. Drug metabolism reflects the biotransformation of an endogenous or exogenous molecule by one or more enzymes to moieties, which are more hydrophilic and thus can be more easily excreted [1, 3, 4]. While metabolism of a drug generally reduces its ability to produce a pharmacologic action, it also can result in a metabolite that has significant potency, and thereby, contributes to the overall pharmacological effect of the drug. A good example being morphine in which the M3-and M6-glucuronide metabolites have extensive anti- and equal morphinomimetic effects. In the case of a pro-drug such as codeine, biotransformation is required to produce the pharmacologically active metabolite morphine. Although drug metabolism takes place in several tissues (e.g., intestine, skin, kidney, lungs, liver), hepatic metabolism has been investigated most intensively and this metabolism has been divided conventionally into two phases [1, 3, 4]. Phase I hepatic metabolism usually results in modifying the therapeutic agent or xenobiotic (e.g., through oxidation) in order to make the molecule more polar. Phase II hepatic metabolism usually results in addition of a small molecule (e.g., glucuronide) to the therapeutic agent in order to make it more polar. As the architecture of the liver develops, so do the families of enzymes responsible for the biosynthesis and metabolism of both endogenous and exogenous substrates. While there are many enzymes that are capable of catalyzing the biotransformation of drugs, the quantitatively most important are represented by the cytochromes P450 (CYP450). The specific CYP450 isoforms responsible for the majority of human drug metabolism are represented by CYP3A4/5, CYP1A2, CYP2B6, CYP2D6, CYP2C9, CYP2C19, and CYP2E1.

Development has a profound effect on the expression of CYP450. Distinct patterns of isoform-specific developmental CYP expression have been observed postnatally. As reflected by recent reviews, distinct patterns of isoform-specific developmental changes in drug biotransformation are apparent for many Phase I and Phase II drug metabolizing enzymes [31–34]. Very recently, Hines [35] has categorized the

development of enzymes involved in human metabolism in three main categories: (1) those expressed during the whole or part of the fetal period, but silenced or expressed at low levels within 1–2 years after birth, (2) those expressed at relatively constant levels throughout fetal development, but increased to some extent postnatally and (3) those whose onset of expression can occur in the third trimester, but substantial increase is noted in the first 1–2 years after birth. Based on literature data CYP3A7, flavin-containing monooxygenase 1 (FMO1), sulfotransferase 1A3/4 (SULT1A3/4), SULT1E1, and maybe alcohol dehydrogenase 1A (ADH1A) belong to the first group. To the second group belong CYP2A6, 3A5, 2C9, 2C19, 2D6, 2E1, and SULT1A1. The third group includes ADH1C, ADH1B, CYP1A1, 1A2, 2A 6, 2A7, 2B6, 2B7, 2C8, 2C9, 2F1, 3A4, FMO3, SULT2A1, glucoronosyltransferases (UGT) and N-acetyltransferase 2 [35–37].

In addition to these *in vitro* data, there has been an explosion in the amount of information generated about metabolism of therapeutic agents in children during the last two decades. *In vivo* data have been generated largely through two means [38, 39]. One is through dedicated ontogeny studies in which a probe drug (e.g., dextromethorphan or acetaminophen/paracetamol) is given to children of various age groups or to the same children over a period of time [38, 39]. The other manner in which these *in vivo* data have been developed is serendipitously over the course of industry-sponsored or investigator-initiated pediatric clinical trials. The most important examples of studies that have resulted in clinically important insight into the ontogeny of drug metabolism are summarized in the following paragraph.

Midazolam plasma clearance, which primarily reflects hepatic CYP3A4/5 activity after intravenous administration [40, 41], increases approximately fivefold (1.2–9 mL/min/kg) over the first 3 months of life [42]. CYP2C9 and to a lesser extent, CYP2C19, are primarily responsible for phenytoin biotransformation [43]. Phenytoin apparent half life is prolonged (~75 h) in preterm infants but decreases to ~20 h. in term infants less than 1 week postnatal age and to ~8 h. after 2 weeks of age [44]. Also for caffeine developmental changes is elimination have been describes [45]. Saturable phenytoin metabolism does not appear until approximately 10 days of postnatal age, demonstrating the developmental acquisition of CYP2C9 activity.

It is well established that infants who are barely into their second trimester of gestational life and are born with a weight of just a few hundred grams (400–500 g) can survive and will develop into a surgical newborn by chance. On the other extreme, by the end of the first month of postnatal life, large for gestational age infants may weigh upwards of several kilograms. Indeed, the 95th weight percentile is approximately 5 kg. No other age groups can be defined in differences measured logarithmically. As one might expect, there are similar tremendous developmental changes in hepatic drug metabolizing enzymes during this time frame. Understanding these implications is important for individualized dosing in critically ill surgical newborns.

6.5 Phase I Enzymes

6.5.1 CYP3A

The CYP3A subfamily represents the majority of CYP total content in the liver. Indeed, it has been shown that over one-half of all drugs administered to pediatric patients (e.g., tacrolimus, midazolam, fentanyl) are metabolized by CYP3A [46]. The CYP3A subfamily consists of CYP3A4, 3A5, 3A7 and 3A43. CYP3A43 is not known to play a significant role in hepatic metabolism. It has been established that CYP3A4 is the predominant CYP3A enzyme in adults, whereas CYP3A7 is the predominant CYP3A enzyme in the fetus and infants. Moreover, there is a great deal of overlap of specificity of ability for CYP3A4 and CYP3A7 to metabolize therapeutic agents. In 2003, Stevens et al. published the results of examining the largest collection of fetal and pediatric liver samples to date [47]. The study included 212 samples. Stevens and colleagues demonstrated that CYP3A7 is highest between 94 and 168 postconceptional days on a pmol/mg basis of total hepatic protein [47]. The

level at birth is less than half that of the high prenatal value. However, it remains higher than that of even adult CYP3A4 levels. Furthermore, these hepatic samples demonstrated that there is minimal CYP3A4 activity prenatally that continues to increase after birth. Nevertheless, CYP3A7 content remains higher than CYP3A4 content until at least 6 months of age. The high activity of CYP3A7 early in fetal life is associated with its function in forming a precursor for estriol biosynthesis, a hormone that is important in fetal growth and timing of child birth. CYP3A4 and CYP3A5 have overlapping substrate specificities and in the case of CYP3A5, polymorphic expression with racial differences in the genotype-phenotype relationship exists that can have significant effects on the biotransformation of drugs that are substrates for this isoform [48]. A clear developmental pattern for CYP3A5 expression has not yet been fully elucidated.

To date, two probe drugs have been researched extensively, which have demonstrated the lower activity of CYP3A4 at birth and in neonates. In 2001, de Wildt et al. published the results of midazolam metabolism given to 24 preterm infants [40]. Only 19 of 24 preterm infants produced detectable levels of 1-OH-midazolam. Furthermore, these results firmly established that premature infants had lower CYP3A4 activity than full-term infants, than did children and adults historically. In conclusion, CYP3A7 activity is very high before birth and continues to have high activity after birth and is even present into adulthood. CYP3A4 possesses very low activity at birth and very slowly increases in the neonatal period. Thus, when designing studies and dosing with substrates for CYP3A4 in young infants and children, great care needs to be taken to adjust for this low activity in order to achieve the goal of the FDA guidance that in children exposure and Cmax are not higher than that in adults.

6.5.2 CYP1A2

One of the first CYP enzymes to be studied utilizing a probe drug in the first year of life is CYP1A2. Two methylxanthines (caffeine and theophylline) have been utilized extensively to evaluate CYP1A2 in vivo in young children [49–51]. Theophylline and caffeine are two commonly utilized medications in neonates for the treatment of apnea. These medications are frequently continued form the neonatal period during the first year of life. At birth, caffeine-3-demethylation, a measure of CYP1A2 activity, is very low. Consequently, Erenberg et al. published that the efficacious dose of caffeine is 10 mg/kg every day [50]. The half-life of caffeine is 72–96 h in infants compared to approximately 5 h in older children and adults. Similarly, 8-hydroxylation of theophylline is reduced at birth. Specific effects on intestinal circulation of premature borns with NEC are not available. Nevertheless, longitudinal data indicate a rapid maturation process for CYP1A2, as it appears to reach adult levels within the first year of life, often within the first 6 months of life.

In conclusion, it is evident that CYP1A2 activity is highly reduced in young infants. Additionally, activity of the enzyme is highly inducible. Finally, maturation of CYP1A2 activity is rapid in the first year of life.

6.5.3 CYP2D6

CYP2D6 is one of the most polymorphically expressed enzymes in humans [52, 53]. Some estimates indicate the fewer than 90% of individuals are homozygous for the wild-type allele. In 1991, Treluyer et al. published the results of liver samples from fetuses aged 17–40 weeks postconception [54]. These results demonstrated that the concentration of hepatic CYP2D6 protein was very low or undetectable in these fetuses. This lack of CYP2D6 activity at birth led to the hypothesis that birth-related events may trigger maturation of the enzyme. In 2007, Blake et al. published in vivo results that provided further understanding of CYP2D6 activity in the first year of life [38]. Dextromethorphan results demonstrate indeed that there is low activity at birth, but that there is rapid acquisition of CYP2D6 activity in the first year of life. Already within the

first 2 weeks of life there is measurable acquisition of CYP2D6 activity. Despite the discussion in the literature about the fact that the increase in renal function might conceal the enzyme development resulting in an apparent plateau of the metabolic ratio after 2 weeks [55], very recent data show that an infant with a postmenstrual age of 52 weeks has already mature hepatic CYP2D6 activity [56].

6.5.4 CYP2C9/CYP2C19

Lee et al. [57] and Koukouritaki et al. [58] have published the most extensive reviews to date on CYP2C activity in humans. They demonstrate that the two main representatives of the CYP2C subfamily of enzymes (CYP2C9 and CYP2C19) conveniently follow the CYP2C rule of 20%. Approximately 20% of hepatic CYP content of adult livers is CYP2C and these CYP2C enzymes metabolize 20% of pharmaceuticals developed to date.

Although not to the same extent as CYP2D6, the two main CYP2C representatives are polymorphically expressed. To date, over ten genetic polymorphisms of CYP2C9 have been identified and at least 15 genetic polymorphisms of CYP2C19 have been reported in the literature [57, 58]. Just as with CYP2D6, these polymorphisms may result in poor metabolizer status, which may confound studies in infants and young children.

The ontogeny of CYP2C9 is much better established than CYP2C19. Indeed, hepatic liver samples have shown that CYP2C9 activity is functionally very low just prior to birth. However, much like CYP2D6, this activity increases quickly in the first year of life. The classic example of the effects of this very low level of CYP2C9 activity at birth can be seen with phenytoin [59]. Indeed, the recommended daily dose for newborns is 5 mg/kg/day, but by 6 months to 3 years of age this increases to 8–10 mg/kg/day consequent to increased CYP2C9 activity.

Two major pharmaceutical classes of drugs (i.e., benzodiazepines and proton pump inhibitors) have major representative therapeutic agents that are metabolized by CYP2C19 [60, 61]. Indeed, characteristic representatives from these classes are used in the literature to indirectly ascertain the ontogeny of CYP2C19 activity. Hydroxylation of diazepam is attributed to CYP2C19 activity and is a classic example of the effects of the maturation process of CYP2C19 [62]. In neonates, the half-life of diazepam is reported to be 50–90 h. Within the first year of life, that half-life of 40–50 h is much closer to the adult value. The surgical ELBW infant with a high risk of CNS-related problems (convulsions; intracranial hemorrhage) can easily be overdosed once these phenomena are not taken into account. More recently, the effects of the ontogeny on proton pump inhibitor metabolism have been reviewed. To date, all proton pump inhibitors other than rabeprazole are metabolized by CYP2C19. Of the drugs in this class, the biotransformation of pantoprazole is predominantly dependent upon CYP2C19 activity. As expected, exposures of the CYP2C19 metabolism-dependent proton pump inhibitors are universally increased in the youngest infants when genetic polymorphisms of CYP2C19 are fully accounted for [61, 62].

Taken together, these results demonstrate an important trend when designing pharmaceutical studies that depend on hepatic metabolism through the two major CYP2C enzyme pathways. It is extremely important to be cognizant of the limited activity of these enzymes in early childhood and its potential differences in case of serious hepatic disease such as biliary atresia and TPN-associated cholestasis. Moreover, much like with CYP2D6, it is important to recognize the impact of genetic polymorphisms when studying individuals who take substrates of these enzymes [63]. Finally, the first 3 months of life represents a dramatic maturation time for the activity of many drug metabolizing enzymes. When considered in the context of a similar dramatic, nonlinear increase in body size (i.e., both weight and length), individualization of drug dose based on pharmacokinetic data is often a real challenge, especially for agents where attainment of critical target plasma concentrations (or systemic exposures) is necessary.

6.5.5 CYP2E1

CYP2E1 is being increasingly recognized for its importance in the oxidative metabolism of a wide variety of pharmaceuticals (e.g., acetaminophen, halothane, and ethanol) [64]. However, only in the last 5 years has the developmental patterns of this important enzyme been well understood [65]. Nevertheless, human hepatic CYP2E1 developmental expression is difficult to appreciate due to the multiple levels of regulation in its activity. Finally, an increasing number of genetic polymorphisms, which lead to lower CYP2E1 protein concentration, have been demonstrated in the literature [66].

To date, Johnsrud et al. have published the largest study of the activity of fetal and pediatric liver samples to determine the ontogeny of CYP2E1 [65]. Measurable CYP2E1 activity was demonstrated in 18 of 49 second trimester livers and 12 of 15 third trimester samples. Moreover, measurements of mean concentrations of CYP2E1 protein as part of total milligrams of microsomal protein found that second trimester infants averaged 0.35 pmol/mg, third trimester infants 6.7 pmol/mg, newborns 8.8 pmol/mg and older infants aged 30–90 days 23.8 pmol/mg, and finally children aged 90 days to 18 years 41.4 pmol/mg. Thus, this implies a rapid maturation starting in late fetal life and continuing through early infancy in CYP2E1 activity. It would appear that these data demonstrate that careful attention would be required in studies of new CYP2E1 substrates in infants under the age of 90 days.

Of the cytochrome P450 isoforms quantitatively important for drug metabolism in humans, all studied till now appear to have a developmental pattern with respect to the attainment of activity.

As with chloramphenicol, morphine, acetaminophen, and zidovudine, all UGT substrates have a requirement for alteration of dosing regimen to compensate for reduced enzyme activity in the first weeks and months of life. In premature infants (gestational age 24–37 weeks) the plasma clearance of morphine was found to be fivefold lower relative to older children. The clearance of morphine, a predominant UGT2B7 and UGT1A1 substrate, generally reaches adult levels between 2 and 6 months of life. However, considerable variability exists [67]. Acetaminophen glucuronidation (a substrate for UGT1A6 and UGT1A9) is present in the fetus and newborn at very low levels (1–10% of adults). Following birth, activity steadily increases with levels approaching (~50%) by 6 months of age and full maturation by puberty.

6.6 Drug Excretion

Drug excretion or elimination in pediatric patients can occur via multiple routes which include biliary excretion, exhalation, and renal clearance. Of these, the kidneys are quantitatively the most important. The kidney is the primary organ responsible for the excretion of drugs and their metabolites. Maturation of renal function is a dynamic process that begins early during fetal organogenesis and is complete by early childhood [68, 69]. The developmental increase in glomerular filtration rate (GFR) involves active nephrogenesis, a process that begins at 9 weeks and is complete by 36 weeks of gestation, followed by postnatal changes in renal and intrarenal blood flow. Following birth, the GFR is approximately 2–4 mL/min/kg in term neonates and as low as 0.6–0.8 mL/min/kg in preterm neonates [70]. GFR increases rapidly during the first 2 weeks of life followed by a steady rise until adult values are reached by 8–12 months. This increase in GFR in the first weeks of life is mainly because of an increase in renal blood flow. Similarly, tubular secretory pathways are immature at birth and gain adult capacity during the first year of life.

There is a clear controversy regarding the use of serum creatinine to predict renal function in children [71]. Serum creatinine depends on many factors and residual maternally derived creatinine interferes with the assay in the first days of life in neonates [72]. In addition, factors that have a negative influence on the use of plasma creatinine to predict renal function are renal tubule integrity issues and GFR values of less than 20 mL/

min/1.73m^2. In these individuals GFR is probably overestimated. If creatinine is measured with the Jaffé reaction ketoacids, serum bilirubin and cephalosporins interfere with the reaction and therefore the use of an enzymatic method should be advised because of less interference as compared to the Jaffé method [73]. A more direct approach to estimate the GFR is to use a marker that is freely permeable across the glomerular capillary and neither secreted nor reabsorbed by the tubulus. Markers that have been mentioned to measure the GFR are inulin, polyfructosan S, cystatin C, ^{51}Cr-EDTA, ^{125}I-iothalamate or mannitol [71, 74]. A marker to estimate the active tubular secretion in children is p-aminohippuric acid [74].

However, a comparison between serum creatinine with inulin clearance in preterm infants showed a good and clinical useful correlation and supported serum creatinine as an appropriate measure of GFR in preterm infants already on day 3 of life [73].

Collectively, the aforementioned changes in GFR dramatically alter the plasma clearance of compounds with extensive renal elimination and thus, provide a major determinant for age-appropriate dose regimen selection. Pharmacokinetic studies of drugs primarily excreted by glomerular filtration such as ceftazidime and famotidine have demonstrated significant correlations between plasma drug clearance and normal, expected maturational changes in renal function [70, 75]. For example, tobramycin is eliminated predominantly by glomerular filtration, necessitating dosing intervals of 36 to 48 h in preterm and 24 h in term newborns [76]. Failure to account for the ontogeny of renal function and adjust aminoglycoside dosing regimens accordingly can result in exposure to potentially toxic serum concentrations. Also, concomitant medications (e.g., betamethasone, indomethacin) may alter the normal pattern of renal maturation in the neonate. Thus, for drugs with extensive renal elimination, both maturational and treatment associated changes in kidney function must be considered and used to individualize treatment regimens in an age-appropriate fashion. The amount of illness especially in ELBW-infants with a hemodynamic important open ductus arteriosus should be taken into account as a contributing factor resulting in overdosing of for instance aminoglycosides.

As denoted above, development produces profound differences in processes that collectively, can influence all facets of drug disposition (i.e., absorption, distribution, metabolism and excretion). Knowledge of the impact of ontogeny on the physiologic determinants of drug disposition enables prediction of how development per se can impact pharmacokinetics and also, enables the clinician to use this information as a tool for designing age appropriate drug regimens. A recent review by van den Anker, et al. describes the implications of developmental pharmacokinetics on pediatric therapeutics [4].

6.7 Other Factors Influencing the Absorption, Distribution, Metabolism and Excretion of Drugs in Neonates and Young Infants

In addition to growth and development there are several other major variables that will influence the pharmacokinetic parameters of drugs such as inborn or acquired diseases, environmental influences such as body cooling, and pharmacogenomics. It is outside the scope of this chapter to provide extensive information on these important variables but a few will be highlighted here.

Hypoxic-ischemic events are encountered regularly in sick neonates and these events might result in a decrease in the rate and amount of drug absorption as well as impaired renal function. There are data to show that after perinatal asphyxia the GFR in neonates is 50% less as compared to neonates born without asphyxia, resulting in a decreased clearance of renally cleared drugs [77]. The persistence and/or closure of a patent ductus arteriosus has a major impact on both the volume of distribution and elimination of frequently used drugs in the newborn [78]. This has been shown for drugs such as ceftazidime where the existence of a patent ductus and or the exposure to indomethacin to close

this ductus was associated with a decreased GFR and a larger volume of distribution of ceftazidime, a solely renally cleared drug. In another study investigating ibuprofen there was a significant increase in the clearance of ibuprofen after closure of the ductus [79]. Finally, total body cooling is a new treatment modality that is being used to improve the neurological outcome of neonates who suffered from perinatal asphyxia. In a study investigating the pharmacokinetics of morphine in neonates with and without body cooling a clinically impressive decrease in morphine clearance was seen in neonates on body cooling [80].

6.8 Pharmacogenomics: Impact for Pediatric Populations

The contribution of genetic factors to explain heterogeneity of drug response in infants and children is another important issue with the ultimate goal for better treatment of children based on the individual genetic make-up. One of the major tasks is to optimally adapt the choice and amount of a drug to the individual need of a patient and for instance to prevent overdosing with the risk of adverse drug reactions. Genetic variability influences almost all ADME processes including drug absorption (e.g. via the intestinal drug transporter P-glycoprotein/ABCB1), drug metabolism (e.g. cytochrome P450 enzymes 2C9, 2C19, 2D6) and drug elimination, thereby resulting in alteration of pharmacokinetics and subsequently of pharmacodynamic processes.

There is an increasing body of evidence that genetic variants in drug metabolizing enzymes (e.g. CYP450 enzymes; http://www.cypalleles.ki.se/) as well as in drug transporters (e.g. ABCB1/P-gp, SLCO1B1/OATP1B) [80–82] are functional relevant (e.g. loss of function variants or gain of function polymorphisms) with in part dramatic changes in mRNA and/or protein expression and function. Genetic variants in drug targets such as receptor molecules or intracellular structures of signal transduction and gene regulation directly and/or indirectly may also influence drug response and tolerability in the neonate and young infant. Based on several novel and promising genomic technologies such as high-throughput genotyping (e.g. MALDI TOF mass spectrometry), genome-wide association studies and next generation sequencing, pharmacogenomic knowledge will improve our understanding of pharmacotherapy in children but will also stimulate the drug development process for innovative agents in the future [83, 84].

At present we know that age and genetic determinants of CYP2D6 expression constitute significant determinants of inter-individual variability in CYP2D6 dependent metabolism during ontogeny. Very recently it was documented that the in vivo phenotypic CYP2D6 activity was concordant with the genotype from 42 weeks postmenstrual age onwards [9, 38]. This indicates that for clinicians treating neonates, young infants, children and adolescents the genetic variation in CYP2D6 is the major player to consider if prescribing CYP2D6 substrates.

In summary, both genetic and environmental factors contribute to inter-individual variability in the PK of medications metabolized by CYP2D6 [10, 11]. In this context a recent paper using a whole body physiology-based pharmacokinetic (PBPK) modelling approach to investigate the contribution of CYP2D6 genetics on codeine administration in breastfeeding mothers and their babies supports the evidence that pediatric pharmacogenomics comprises more than a single gene, and developmental aspects of physiological processes need to be considered [85].

6.9 Developmental Pharmacodynamics

Developmental pharmacodynamics has been described as the study of age-related maturation of the structure and function of biologic systems and how this affects drug response. Relative to pharmacokinetic data there is paucity of information regarding developmental pharmacodynamics.

There is evidence that differences in receptor number, density, distribution, function, and ligand affinity differ among children of differing

ages and adults. Much of the data demonstrating these differences is acquired from studies of the central and peripheral nervous systems. A recent study in humans found that the $GABA_A$ receptor, which binds benzodiazepines and barbiturates, has significantly higher expression levels in the brain at 2 years of age as compared to older children and adults. These data suggest that the GABA receptors have a rapid increase in expression early in infancy that subsequently declines with age. In addition there is evidence in animal models that this inhibitory transmitter has excitatory functions early in development. Early in development chloride concentrations in the neuron are relatively high which leads to excitation (depolarization) of the cell upon opening of the chloride channels by GABA. With maturation, intracellular chloride concentrations decrease which result in inhibition (hyperpolarization) of the cell upon opening of the channel by GABA. These changes may explain observed differences in dosing in infants (require relatively larger doses of antiepileptic medications e.g. midazolam) and furthermore explain seizures experienced by infants upon benzodiazepine exposure. In animal studies, neonatal exposure to GABAergic agents (anticonvulsants, IV and inhaled anesthetics) during synaptogenesis accelerates apoptotic cell death in the CNS [86].

Another example in the CNS resides with the μ-opioid receptor, the numbers of which are markedly reduced (i.e., >50%) in newborn as compared to adult rats [87]. Regional opioid receptor distribution in the brain also exhibits developmental differences. In neonates receptor density is lower in the areas of the brain responsible for analgesic effect (e.g. cortex, thalamus, hippocampus) as compared to those areas of the brain where autonomic/side-effects are produced (e.g., pons, medulla, hypothalamus) as receptor density in these areas approximates that observed in adults [87]. These data suggest that differences may exist regarding the analgesic potency of opiates in neonates as compared to adults.

It is important of expanding pediatric pharmacology studies beyond descriptions of age-dependence in pharmacokinetics to include data on pharmacodynamics. A hindrance in accomplishing this goal in surgical newborns is the interaction and relative contribution of (altered physiology) and the "defective" (multi)organ function in this population. In most institutions the annual number of specific diagnoses seriously hampers clinical studies of appropriate size to reach an acceptable level of evidence. To address this disparity in pharmacodynamic data will require the development of pharmacodynamic "biomarkers" which are sufficiently robust that they can be used as surrogate endpoints to assess the relationship of drug exposure and response across the developmental continuum and specific conditions.

Creative and selective use of non-invasive surrogate endpoints and validated biomarkers can add to the current body of knowledge pertaining to the ontogeny of pharmacodynamic response.

Conclusions

The surgical newborn population shows unique differences in pharmacokinetic parameters as compared to adults and therefore requires specific dosage recommendations. While the paucity of pharmacokinetic and physiological data makes it difficult to precisely determine drug doses, knowledge of the effects of growth, maturation, environmental influences, and pharmacogenetic background on absorption, distribution, metabolism, and elimination of frequently used medicines will allow more appropriate dosing recommendations for this patient population. Clearly, much more research is needed to fully understand the impact of (abnormal) development on specific organ function and its consequences for short term (pharmacotherapy) and long term effects (neurodevelopmental outcome; pharmacovigilance).As described in this chapter, studies with substrates as markers for hepatic metabolic activity or renal function and *in vitro* data are very useful for a better understanding of this impact. Finally, there is an urgent need to better understand the metabolic activity, carrier mechanisms and drug transporters related to the gastrointestinal tract, forming a major area of interest given the pathology for pediatric surgeons taking care of these vulnerable patients.

Transfer of the Surgical Neonate

7

Christopher P. Driver

Abstract

Neonatal surgery is increasingly delivered in regional or even supra-regional centres with the specific aim of improving short and long-term outcome for complex congenital conditions. This arrangement permits the concentration of a multidisciplinary team of experts equipped with the wide range of skills required to successfully manage the specific challenges posed by the newborn surgical patient. Neonatal intensive care for these patients may need to commence immediately after delivery or may be only required following surgical intervention. It is essential therefore that nurses and clinicians in units which may potentially receive surgical neonates have the appropriate competencies required for the initial stages of management.

This chapter will discuss in utero transfer, the general principles of neonatal stabilisation prior to and during transfer, important principles of the transfer itself and condition specific considerations for common neonatal surgical conditions.

Keywords

Neonatal surgery • Neonatal transport • Guidelines

7.1 Introduction

Neonatal surgery is increasingly delivered in regional or even supra-regional centres with the specific aim of improving short and long-term outcome for complex congenital conditions. This arrangement permits the concentration of a multidisciplinary team of experts equipped with the wide range of skills required to successfully manage the specific challenges posed by the newborn surgical patient. Neonatal intensive care for these patients may need to commence immediately after delivery or may be only required following surgical intervention. It is essential therefore that nurses and clinicians in units which may potentially receive surgical neonates have the appropriate competencies required for the initial stages of management [1].

This chapter will discuss in utero transfer, the general principles of neonatal stabilisation prior to and during transfer, important principles of the transfer itself and condition specific considerations for common neonatal surgical conditions.

7.2 In Utero Transfer

With increasing antenatal diagnosis of congenital anomalies there is often the opportunity to plan the transfer arrangements in advance. Most babies born with complex surgical conditions are relatively stable and can therefore be delivered and initially managed safely in any appropriately equipped and staffed neonatal unit. There are however specific advantages of in utero transfer in certain conditions. The most significant of these is the ability to deliver a baby with a known complex condition in an environment where all potential therapeutic requirements (staff and equipment) are readily available. This enables optimal timing of appropriate specialist interventions without the need for a potentially difficult postnatal transfer in a high risk newborn. An example of this would be in a fetus with an antenatally diagnosed congenital diaphragmatic hernia who may need immediate specialist ventilatory management and rapid access to extracorporeal membrane oxygenation.

It is not without its own risks however. Transferring a mother pre-delivery can lead to a prolonged antenatal hospital stay, far from friends and family in an unfamiliar environment and with unfamiliar staff. In utero transfer should therefore only be considered if the local unit cannot provide appropriate immediate care or a postnatal transfer is considered to be high risk.

7.3 Pre-Transfer Stabilisation

Many complex surgical conditions are not diagnosed antenatally—and even pre-diagnosed babies don't always follow pre-considered plans—so any hospital offering maternity services must be fully prepared to initiate resuscitation and stabilisation prior to transfer to a specialist surgical unit for definitive repair. The general principles of management of a baby born with a surgical condition are initially little different to those applied to a medical neonate [2]. The initial aims are to ensure optimisation of blood pressure, oxygen saturation, blood glucose and blood gases to minimise the risk of secondary injury as result of poor resuscitation, ensuring a baby is in the best possible clinical condition prior to the transfer occurring [3].

The key features of stabilisation are:

- Appropriate airway and respiratory management
- Adequate monitoring of Heart Rate, Blood Pressure and Oxygen Saturation
- Appropriate lines and tubes in place, functioning and secure
- Condition specific management initiated when vital signs stabilised

A checklist for stabilisation may be a useful *aide memoire* [2] (Fig. 7.1).

7.4 General Principles of Transfer

Transfer of the surgical neonate is often provided by specialist neonatal retrieval teams based in the regional centre. These teams should comprise of an appropriately trained and experienced doctor and neonatal intensive care nurse who can guide initial resuscitation, initiate an appropriate level of neonatal intensive care and stabilise the surgical neonate prior to transfer back to the regional unit. As detailed above appropriate prior stabilisation permits a controlled and safe transfer, minimizing risk to the patient and the transfer team. Again, a Transport Checklist (Fig. 7.2) may be useful.

Airway
Is airway patent and secure?

Breathing
Is endotracheal intubation and mechanical ventilation required prior to transfer?

Circulation
Has baby been adequately fluid resuscitated to place heart rate and BP within an acceptable range? Is inotropic support required to maintain adequate perfusion?

Temperature
Ideally skin-core perfusion should be monitored to aide assessment of peripheral perfusion. The baby should be stabilised in a thermoneutral environment where possible. It should be remembered that heat loss is considerably increased with exposed viscera (e.g. gastroschisis)

Metabolic
Electrolyte, glucose and acid-base balance should be optimised prior to transfer ideally

Infection
Have appropriate antibiotics been given either for treatment or prophylaxis?
Has this been clearly documented?

Comfort
Has the need for analgesia been considered or given prior to transfer?
Has this been clearly documented?

Safety
Is all necessary equipment for transfer available and working?
Is the baby clearly identified with two name bands?

Tubes
Does the baby require a nasogastric tube to be passed for decompression aide ventilation and to reduce the risk of aspiration?
Is vascular access adequate and secured?
Is a urinary catheter required?

Parents
Are parents informed of the condition of their baby?
Has a provisional plan been discussed with them?

Condition specific treatments
Are any condition specific interventions required prior to transfer?

Fig. 7.1 Stabilisation Checklist. From: Scottish Neonatal Transfer Service Stabilisation Handbook. Greig C, Mitchell A, et al. 2007; used with permission

7.5 Mode of Transfer

The decision on the appropriate mode of transfer is dependent on a number of issues such as geography, weather, distance to travel and the condition of the infant. All have specific advantages and disadvantages. Road transfer is cheap, quick to initiate, with good patient accessibility and relatively weather immune but can be slow. Helicopters are quick, can fly at low altitude if necessary but require an appropriate landing site, have limited space, can compromise patient assessment with noise and vibration, are expensive and are weather limited. Fixed wing aircraft are quieter, quicker over long distance and can have more space but are also expensive, take longer to organise and need a land transfer to and from the airport to the hospital.

Transport incubator. The modern transport incubator should be capable of providing high

Fig. 7.2 Transfer Checklist

Medical and nursing record
Has all relevant initial resuscitation and management been documented and copied for the transport team to take?

Drugs
Have all drugs administered been documented?
Has Vitamin K been given and documented?

Results of investigations
Are all relevant results available including biochemistry, haematology, microbiology and blood gases?

Imaging
Are copies of relevant imaging available to be taken by the transport team?

Maternal Blood sample
This may be required for testing if neonatal blood transfusion is required.
Is it must be accurately and appropriately labelled with all maternal details?

Parents
Are parents informed of the condition of their baby? Has a provisional plan been discussed with them? Do they know where their baby is being transferred to and have arrangements been made for them to get there? Do parents and transport team have accurate contact phone numbers?

performance respiratory support with optimal thermoregulation during transfer. It should have facilities for continuous monitoring of heart rate, blood pressure and oxygen saturation and ideally advanced ventilatory monitoring. It requires both air and oxygen cylinders and suction equipment, battery operated pumps to administer drugs and fluids together with the ability to access external power and gases when available. It should be robust and must have the facility for secure fixation to the transport vehicle of choice during transfer. It should carry a full range of emergency equipment and drugs required for maintaining and if necessary escalating intensive care during transfer. The transport team must be familiar with all aspects of the equipment and have the ability to "trouble shoot" during the transfer if required.

7.6 Parents

In the difficult period of initial resuscitation and stabilisation it is easy to overlook the parents. They may have had an antenatal diagnosis and subsequent counselling to prepare them for what is likely to happen but with many surgical conditions the diagnosis is only made at delivery. There is often—quite appropriately—considerable anxiety and concern about their newborn child and the need for a transfer to a regional centre will only increase that. It is essential therefore that parents are informed of and involved in decision making as much as is practically possible. It is important to discuss with parents the reason for transfer, a provisional plan, the mechanism and destination of the transfer and the likely time scale. In addition parents need contact details of the receiving unit and travel directions, ideally in written form. They should get the opportunity to see their baby prior to transfer and ideally have a photograph taken. It is possible that a mother may have just undergone a surgical procedure herself and is unable to travel with her baby so the transferring team must make every effort to keep her informed.

7.7 Consent

Consent for any proposed surgical procedure may cause difficulty if a baby is transferred to specialist centre. If possible one parent (who has the legal right to consent) should accompany the baby to permit the operating surgeon to discuss the risks and benefits of surgery prior to obtaining informed consent. A consent form sent with a baby which has been signed by a parent without this discussion has limited legal standing. If a

parent cannot accompany the infant then consent can be obtained via a telephone conversation with the operating surgeon.

7.8 Condition Specific Considerations

7.8.1 Gastroschisis

This is often diagnosed antenatally allowing a postnatal management plan to be in place. The significant risks are fluid and heat loss and kinking of the mesentery leading to venous congestion of the exposed bowel. Intravenous access with careful fluid management is essential, broad spectrum antibiotics should be started, Vitamin K given and a wide bore naso/oro gastric tube passed. This must be aspirated every 15 min during transfer to ensure the risk of aspiration of gut contents is minimised. The exposed bowel can be placed in a sterile "bowel bag" for transfer or the abdomen can be carefully wrapped in clear plastic film to both reduce fluid loss and stabilise the bowel. Avoid the use of saline soaked swabs as this can accelerate heat loss. The baby should be nursed in the left lateral position to prevent kinking of the vascular pedicle. Thermoregulation is optimised by nursing and transferring in a heated incubator.

7.8.2 Oesophageal Atresia and Tracheo-Oesophageal Atresia

Unless this is a pure oesophageal atresia this condition is rarely diagnosed antenatally. The major initial risk is aspiration of unswallowed saliva. To prevent this, the baby should be nursed in the lateral or prone position and a 10 Fr Replogle tube should be placed in the upper pouch [4]. This should be placed on continuous suction at low pressure (5 kPa (35–40 mmHg)) with frequent irrigation of the air channel to prevent blockage. If a Replogle is not available a wide bore feeding tube can be used but this must be aspirated every 15 min during transfer. The volume of aspirated saliva should be recorded and replaced. Intravenous access with careful fluid management is essential, broad spectrum antibiotics should be started and Vitamin K given. The risk of associated abnormalities, including cardiac, should be considered. Thermoregulation is optimised by nursing and transferring in a heated incubator.

7.8.3 Congenital Diaphragmatic Hernia

This is increasingly diagnosed antenatally but will still often present with severe respiratory distress at birth. If antenatally diagnosed an in utero transfer to an appropriate regional facility that can provide optimal management is the preferred option. If diagnosed at birth endotracheal intubation should be performed with minimal bag/valve/mask ventilation and early passage of an oro/nasogastric tube. Pre and post ductal arterial monitoring and venous access should be initiated and a ventilation strategy of permissive hypercapnia to minimise barotrauma instituted. There is an increased risk of pneumothorax so equipment necessary to inset a chest drain should be available during transfer.

7.8.4 Myelomeningocele

This condition is also is increasingly diagnosed antenatally permitting a postnatal plan to be prepared in advance. The exposed spinal lesion should be covered with a non adherent dressing and the baby nursed in the prone position. The use of saline swabs should be avoided as this can cause significant heat loss. Latex exposure should also be avoided as these children have a high incidence of latex allergy which may be due to early repeated contact.

7.8.5 Intestinal Obstruction

The general principles of transfer of a neonate with intestinal obstruction from any cause are

similar. The major risks are aspiration of intestinal contents and fluid depletion. A wide bore naso/oro gastric tube should therefore be passed and placed on free drainage. In addition it must be aspirated regularly during stabilisation and transfer. The volume aspirated should be accurately measured, documented and replaced. Intravenous access with careful fluid management is particularly important as fluid loss may be significant. Vitamin K should be given and broad spectrum antibiotics be considered. In addition it is important copies of all X-rays are sent with the patient.

7.9 Back Transfer of the Post-Operative Neonate

This should be considered as soon as the infant's condition permits it. Early back transfer has the advantage of returning child and parent close to home, freeing up specialist surgical cots and permits maintenance of medical and nursing skills in the referring units. For this to be considered the receiving unit should have the staff and facilities to provide for the infant's predictable future needs, the remaining estimated length of in hospital stay should is balanced the costs and risks of reverse transport and the parents views should be considered. It is rarely an emergency and can therefore be carefully planned. As the post-operative patient will usually be relatively well a reduced transport team can often provide this transfer.

Fluid, Electrolyte and Nutritional Support of the Surgical Neonate

8

Simon Eaton, Paolo De Coppi, and Agostino Pierro

Abstract

The newborn infant is in a "critical epoch" of development. A healthy term infant grows at a rate of 25–30 g per day over the first 6 months of life, so that weight has doubled by the age of 5 months. This growth clearly requires adequate nutrition, but especially where medical or surgical conditions exist, must also be carefully managed together with fluid and electrolytes. Thus a significant period of inadequate nutrition, or inappropriate fluid and electrolyte administration, may not only affect short-term outcomes, but may also be a risk factor for the long-term menace of stunted mental and physical development. Amongst preterm infants, lower in-hospital growth velocity is associated with impaired neurodevelopmental outcome. Fluids and electrolytes undergo changes during the perinatal period, so an understanding of the perinatal changes in body composition is useful to understand the principles behind the fluid, electrolyte and nutritional management of surgical neonates. As well as providing the components necessary for increase in tissue mass, adequate provision of nutrients is also required to mount an appropriate immune response is extremely important, as infection and sepsis may impair growth and neurodevelopmental outcome.

8.1 Introduction

The newborn infant is in a "critical epoch" of development. A healthy term infant grows at a rate of 25–30 g per day over the first 6 months of life, so that weight has doubled by the age of 5 months. This growth clearly requires adequate

P.D. Losty et al. (eds.), *Rickham's Neonatal Surgery*, https://doi.org/10.1007/978-1-4471-4721-3_8

nutrition, but especially where medical or surgical conditions exist, must also be carefully managed together with fluid and electrolytes. Thus a significant period of inadequate nutrition, or inappropriate fluid and electrolyte administration, may not only affect short-term outcomes, but may also be a risk factor for the long-term menace of stunted mental and physical development. Amongst preterm infants, lower in-hospital growth velocity is associated with impaired neurodevelopmental outcome [1]. Fluids and electrolytes undergo changes during the perinatal period, so an understanding of the perinatal changes in body composition is useful to understand the principles behind the fluid, electrolyte and nutritional management of surgical neonates. As well as providing the components necessary for increase in tissue mass, adequate provision of nutrients is also required to mount an appropriate immune response is extremely important, as infection and sepsis may impair growth and neurodevelopmental outcome [2].

8.2 Perinatal Changes in Body Composition

Newborn infants grow very rapidly, have higher energy expenditure and lower caloric reserves than adults and therefore do not tolerate prolonged periods of starvation. The body composition of newborn infants is markedly different from that of adults. The water in body tissues includes the intracellular fluid, which represents the water contained within the cells, and extracellular fluid. Extracellular fluid is further sub- divided into: intravascular fluid (plasma); interstitial fluid (fluid surrounding tissue cells); and transcellular fluid (e.g. cerebrospinal, synovial, pleural, peritoneal fluid). Total body water (TBW) as a percentage of body weight follows an inverse relationship with fat content, as fat cells contain very little water. During the first trimester, when only 1% of body mass is fat, 90% of body mass is TBW with 65% of body mass made up of extracellular fluid [3]. As fat % increases, TBW decreases from 87% of body weight at 24–25 weeks gestation to 75% at term (Fig. 8.1) [4], eventually falling to 65–50% in adulthood. This proportion varies not only with age, but also with weight, so that among preterm infants, small for gestational age infants have a significantly higher body water content (approximately 90%) than appropriate for gestational age infants (approximately 80%) [5]. These changes in TBW are accompanied by a decrease in the extracellular compartment fluid (ECF) to intracellular compartment fluid (ICF) ratio. The ECF is 65% of total body mass at 24–25 weeks gestation declining to 40% at term whereas ICF increases from 22% at 24–25 weeks gestation to 35% of body mass at term and then to 40% at 1 month of age. Although there is a gradual decline in the extracellular compartment, there is a more abrupt loss in the early post-natal period due to decreased interstitial fluid, which largely corresponds to the physiological early post-natal weight loss. Because extracellular fluid is more easily lost from the body than intracellular fluid and infants have a

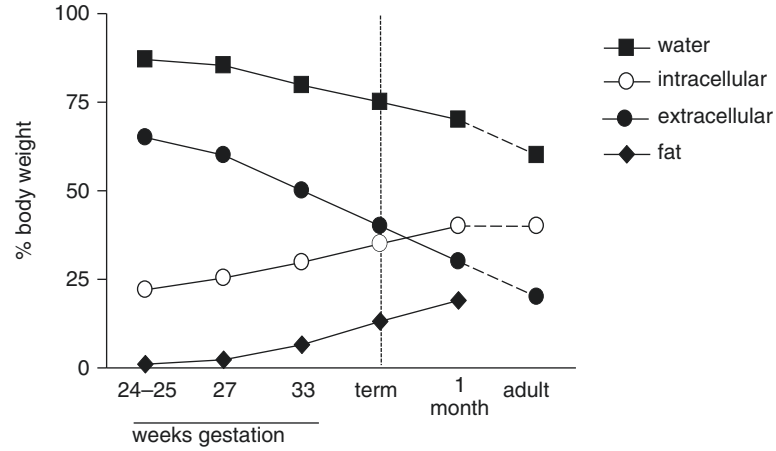

Fig. 8.1 Body composition changes with age [4–139]. Percentage body fat is not shown for adults because of the extremely wide range

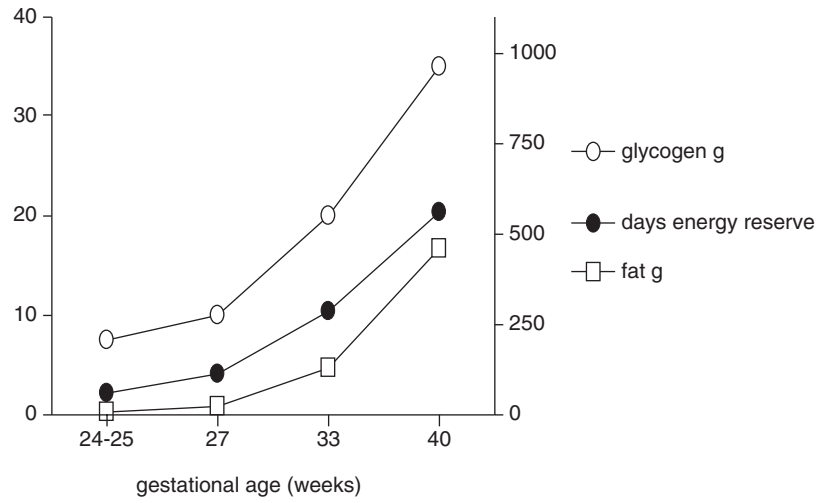

Fig. 8.2 Relationship between theoretical energy reserve and body stores of glycogen and fat [4, 140]

larger surface area to body mass ratio, they are more at risk of developing dehydration than older children and adults. This decline in body water reflects also an increase in energy content of the body. The ratio between resting energy expenditure (in kcal/kg/day) to non-protein energy reserve (in kcal/kg) gives an approximate estimate of the energy reserve of the infants. This is only ~2 days at 24–25 weeks gestation, increases to ~20 days at term as glycogen and fat stores increase (Fig. 8.2) [4] and is in excess of 50 days in the adult, hence the urgent need for adequate caloric intake in very-low-birth-weight (VLBW) and/or extremely-low-birth-weight (ELBW) infants after birth. Early PN in VLBW infants has been shown to be beneficial [6], although there is controversy on how "aggressive" nutritional intervention should be in preterm infants. Full-term neonates have higher content of endogenous fat (approximately 600 g) and therefore can tolerate a few days of undernutrition.

8.3 Energy Requirements of the Neonate

Newborn infants have a significantly higher metabolic rate and energy requirement per unit body weight than children and adults: the total energy requirement for an extremely-low birthweight (i.e. <1000 g) preterm infant fed enterally is 130–150 kcal/kg/day [7], and that of a term infant is 100–120 kcal/kg/day, compared to 60–80 kcal/kg/day for a 10-year old and 30–40 kcal/kg/day for a 20-year old individual [8–10]. Of the 100–120 kcal/kg/day required by the term infant, approximately 40–70 kcal/kg/day is needed for maintenance metabolism, 50–70 kcal/kg/day for growth (tissue synthesis and energy stored), and up to 20 kcal/kg/day to cover energy losses in excreta [11–13]. Newborn infants receiving total parenteral nutrition (TPN) require fewer calories (110–120 kcal/kg/day for a preterm infant and 90–100 kcal/kg/day for a term infant [14]), due to the absence of energy losses in excreta and to the fact that energy is not required for thermoregulation when the infant is in an incubator. These data are shown diagrammatically in Fig. 8.3, but it should be stressed that energy requirements vary greatly, depending on many variables such as ventilation, thermoregulation, physical activity, etc. Several equations have been used to estimate the resting energy expenditure, and therefore the energy requirements, of infants and children. The most frequently used are those of the World Health Organisation WHO [9] (which were revised in 2004 [10]), Schofield [15] and Harris and Benedict [16]. These are based on weight, height and/or age and are based on measurements of orally fed, healthy individuals, and thus take no account of the abnormal physiology and/or pathology of infants requiring artificial nutritional support.

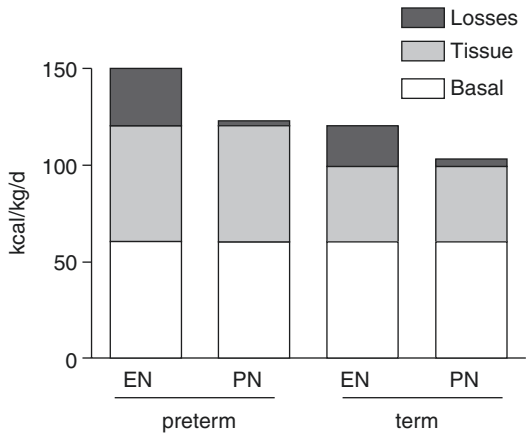

Fig. 8.3 Partition of energy metabolism in preterm and term infants receiving nutrition enterally (EN) or parenterally (PN) [7, 8, 11, 13, 14]. Energy "expended" includes basal metabolic rate, activity, the energy expended in laying down new tissue, and thermoregulation, "tissue" is the amount of energy actually stored in new tissue, "losses" include losses in stool, etc.

8.4 Energy Requirements of the Surgical and Septic Neonate

An equation has been developed to predict REE in stable surgical infants, to which the major contributing predictors are body weight, heart rate (providing an indirect measure of haemodynamic and metabolic status) and postnatal age [17]. Although adults show large increases in resting energy expenditure following trauma, surgery, burns or during severe infection [18], this does not appear to be true for infants, although there are few studies in this area. Critically-ill, post-surgical ventilated premature neonates [19], neonates with necrotizing enterocolitis [20] and surgical infants (with or without ECMO) [21] were shown to have similar REE values to healthy neonates, whereas others have suggested that REE is increased during neonatal sepsis [22] and that REE correlates with severity of illness during sepsis in neonates [23]. Another study, examining the immediate post-operative response to neonatal surgery, found that there is a peak in REE 4 h after surgery, which was short-lived, returning to baseline within 12–24 h after surgery [24]. There is no further increase in energy expenditure in the first 5–7 days following an operation [24, 25]. The timing of these changes corresponds with the postoperative changes in catecholamine levels and other biochemical and endocrine parameters [26]. It has been demonstrated that the postoperative increase in energy expenditure can, at least partially, result from severe underlying acute illness, which frequently necessitates surgery (i.e. sepsis or intense inflammation, see below) [27]. Interestingly, infants having a major operation after the second day of life have a significantly greater increase in resting energy expenditure than infants undergoing surgery within the first 48 h of life. A possible explanation for this may be greater secretion of endogenous opioids in the perinatal period blunting the endocrine and metabolic responses [26, 28, 29]. Thus, there is no clear indication that increased energy should be provided to septic or surgical neonates [14].

Resting energy expenditure is directly proportional to growth rate in healthy infants, and growth is retarded during acute metabolic stress. Studies in adult surgical patients have shown that operative stress causes marked changes in protein metabolism characterised by a postoperative increase in protein degradation, negative nitrogen balance [30, 31], and a decrease in muscle protein synthesis [32]. However, changes in whole body protein flux, protein synthesis, amino acid oxidation or protein degradation do not seem to occur in infants and young children undergoing major operations [33], which led us to speculate that infants and children divert protein and energy from growth to tissue repair, thereby avoiding the overall increase in energy expenditure and catabolism seen in the adult [20, 33, 34]. The existing knowledge on the metabolic response to sepsis in infants is limited. There are conflicting reports on whether critically-ill infants are hypermetabolic [21, 35–40]. However, most studies suggest that infants with sepsis do not become hypermetabolic [41, 42] and that septic neonates with necrotizing enterocolitis do not show any increase in whole body protein turnover, synthesis and catabolism [20]. However, the conflicting data may reflect measurements taken at different times in infants with differing degrees of sepsis [43].

8.4.1 Perinatal Changes in Fluid Balance and Renal Function

Before labour, pulmonary fluid production decreases while existing fluid is reabsorbed and efflux through the trachea increases and accelerates during labour, thereby drying out the lungs. During labour, arterial pressure increases and causes shifts in plasma from the vascular compartment and a slight rise in haematocrit. Placental transfusion can occur if there is delayed clamping of the cord and the neonate is placed at or below the level of the placenta, resulting in up to 50% increase in red blood cells and blood volume. This polycythaemia may have severe consequences such as neurological impairment, thrombus formation and tissue ischaemia [44]. Day one postpartum the neonate is oliguric. Over the following 1–2 days, dramatic shifts in fluid from the intracellular to extracellular compartment result in a diuresis and natriuresis which contributes weight loss during the first days of life. This is approximately 5–10% in the term neonate and 10–20% in the premature infant. The proportion of contributions from ECF and ICF to fluid lost is controversial and the mechanism is yet to be determined. This diuresis occurs regardless of fluid intake or insensible losses and may be related to a postnatal surge in atrial natriuretic peptide [45]. Limitations in the methodology of measuring ECF and ICF have limited our understanding of the processes. It has been demonstrated however that large increases in water and calorie intake are required to reduce the weight loss. Higher calorie intake alone reduces weight loss but the ECF still decreases. Subsequent weight gain appears to be the result of increases in tissue mass and ICF per kilogramme body weight but not ECF per kilogramme body weight. By the fifth day post-partum, urinary excretion begins to reflect the fluid status of the infant. The kidneys in neonates have small immature glomeruli and for this reason the glomerular filtration rate is reduced (about 30 mL/min/1.73 m^2 at birth to 100 mL/min/1.73m^2 at 9 months). Premature and low birth weight infants may have a lower GFR than term infants, and the initial rapid rise in GFR is absent. In neonates, the low osmolality in the renal medulla means the countercurrent system for urine concentration is less effective and urine concentration capacity is between 50 and 700 mOsm/kg compared with 1200 mOsm/kg in the adult kidney, and therefore has less tolerance for fluid imbalance.

8.4.2 Fluid and Electrolyte Requirements of the Neonate

Fluid administration varies with age as a consequence of the variation on total body water composition and the different compensatory mechanisms. In paediatric medicine, the widely used Holliday and Segar method for estimating fluid requirements allows 100 mL/kg/day for infants up to 10 kg [46]. However, newborn infants can have very wide range of maintenance requirements, depending on clinical conditions, such as ambient temperature/thermoregulation (e.g. incubator, Babytherm), phototherapy, pyrexia, patent ductus arteriosus, chronic lung disease. In addition, especially in preterm infants, fluid administration should also allow for the physiological weight loss over the first 7–10 days of life (up to a maximum of 10% of birth weight), always maintaining urine output ≥1 mL/kg/h (Table 8.1). Blood volume can be estimated as 106 mL/kg in preterm infants, 90 mL/kg in neonates, 80 mL/kg in infants and

Table 8.1 Normal maintenance fluid requirements

Premature infant	1st day of life	60–150 mL/kg/day
	2nd day of life	70–150 mL/kg/day
	3rd day of life	90–180 mL/kg/day
	>3rd day of life	Up to 200 mL/kg/day
Term infant	1st day of life	60–80 mL/kg/day
	2nd day of life	80–100 mL/kg/day
	3rd day of life	100–140 mL/kg/day
	>3rd day of life	Up to 160 mL/kg/day
Child > 4 weeks of age, up to 10 kg		100 mL/kg/day

children and about 65 mL/kg in adults [47, 48]. Adequate systemic perfusion depends (among other factors) upon adequate intravascular volume. However, infants and children can compensate for relatively large losses in circulating volume, and signs and symptoms of shock may be difficult to detect if a child has lost less than 25% of the circulating volume. The movement of fluid between the vascular space and the tissues depends on osmotic pressure, oncotic pressure, hydrostatic pressure, and changes in capillary permeability. Understanding these factors is important when trying to anticipate changes in the child's intravascular volume [49].

Not only the amount of fluids but also the type of fluid administered varies according to age. In newborn infants, 10% dextrose solution is recommended. Sodium supplementation is not usually required in the first 24 h (low urine output), and after that time can be given at 2–4 mmol/kg/day (adjusted primarily on serum sodium values and changes in weight). Potassium (1–3 mmol/kg/day) and Calcium (1 mmol/kg/day) are usually added after the first 2 days of life. In Infancy and childhood there is a variety of intravenous solution used (Table 8.2), probably the most common is 5% dextrose with ½ normal saline. Potassium is not usually necessary, except if intravenous fluid is given for a longer period of time. Fluids can be administered intravenously (IV) via peripherally or centrally placed catheters. In newborn infants, or other conditions where dextrose is administered at >10%, peripheral administration is not recommended because of complications due to hyperosmolar solutions.

8.4.3 Common Fluid and Electrolyte Disturbances and Their Treatment

8.4.3.1 Sodium

Serum sodium is the major determinant of serum osmolality and therefore extracellular fluid volume. Urinary sodium excretion is dependent on the GFR and therefore is low in neonates when compared with adults. Normal neonatal serum sodium levels are 135–140 mmol/L, controlled by moderating renal excretion. During the period of oliguria on day one of life, sodium supplementation is not normally required. Normal maintenance sodium requirement following normal diuresis is 2–4 mmol/kg/day.

Hyponatraemia

Hypo-natraemia is defined when serum sodium concentrations is less than 135 mmol/L. Treatment depends on the fluid status of the patient and in case of hypo- or hypervolaemia, fluid status should be corrected first. When normovolaemic, serum sodium should be gradually corrected with NaCl infusion, but at a rate not exceeding 0.8 mEq/kg/h. Symptoms are not reliable for clinical management since they

Table 8.2 Common intravenous fluids

Intravenous fluid	Glucose (g/100 mL)	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Osmolality (mOsm/L)
5% dextrose	5	—	—	—	252/277
10% dextrose	10	—	—	—	505/556
Normal saline (0.9% NaCl)	—	154	—	154	308
½ Normal saline (0.45% NaCl)	—	77	—	77	154
5% dextrose with ½ normal saline	5	77	—	77	406
5% dextrose with ¼ normal saline	5	34	—	34	329
Lactated Ringer's	0	130	4	109	273
Hartmann's	0	131	5	111	278

are not often apparent until serum sodium falls below 120 mmol/L and their severity is directly related to the rapidity of onset and magnitude of hyponatraemia. If not promptly recognised it may manifest as the effects of cerebral oedema: apathy, nausea, vomiting, headache, fits and coma. Urine sodium can be useful to help determine the underlying cause of hyponatraemia as the kidneys respond to a fall in serum sodium by excreting more dilute urine but the secretion of ADH in response to hypovolaemia affects this. Urine sodium concentrations <10 mmol/L indicates an appropriate renal response to euvolaemic hyponatraemia. However, if the urinary sodium is >20 mmol/L this can indicate either sodium leak from damaged renal tubules or hypervolaemia.

Hypernatraemia

Hypernatraemia (serum sodium >145 mmol/L) may be due to haemoconcentration/excessive fluid losses (e.g. diarrhoea). Symptoms and clinical signs include dry mucous membranes, loss of skin turgidity, drowsiness, irritability, hypertonicity, fits and coma. Treatment is again via correction of fluid status with appropriate electrolyte-containing solutions. Other causes of hypernatraemia are renal or respiratory insufficiency, or can be related to drug administration.

8.4.3.2 Potassium

In the 24–72 h post-partum, a large shift of potassium from intracellular to extracellular compartments occurs resulting in a rise in plasma potassium. This is followed by an increase of potassium excretion until its normal serum concentration of 3.5–5.8 mmol/L is achieved. Therefore supplementation is not required in the first day of life but after neonatal diuresis, a maintenance intake of 1–3 mmol/kg/day is required.

Hypokalaemia

Hypokalaemia is commonly iatrogenic, either due to inadequate potassium intake or use of diuretics but can also be caused by vomiting, diarrhoea, alkalosis (which drives potassium intracellularly) or polyuric renal failure. As a consequence, the normal ion gradient is disrupted and predisposes to muscle current conduction abnormalities e.g. cardiac arrhythmias, paralytic ileus, urinary retention and respiratory muscle paralysis. Treatment employs the use of KCl.

Hyperkalaemia

Hyperkalaemia can be iatrogenic or due to renal problems but can also be caused by cell lysis syndrome (e.g. trauma), adrenal insufficiency, insulin dependent diabetes mellitus or severe haemolysis or malignant hyperthermia. As in hypokalaemia, hyperkalaemia alters the electrical gradient of cell membranes and patients are vulnerable to cardiac arrhythmias, including asystole. Treatment is with insulin (plus glucose to avoid hypoglycaemia) or with salbutamol.

8.4.3.3 Calcium

Calcium plays important roles in enzyme activity, muscle contraction and relaxation, the blood coagulation cascade, bone metabolism and nerve conduction. Calcium is maintained at a total serum concentration of 1.8–2.1 mmol/L in neonates and 2–2.5 mmol/L in term infants and is divided into three fractions. Thirty to 50% is protein bound and 5–15% is complexed with citrate, lactate, bicarbonate and inorganic ions. The remaining free calcium ions are metabolically active and concentrations fluctuate with serum albumin levels. Hydrogen ions compete reversibly with calcium for albumin binding sites and therefore free calcium concentrations increase in acidosis. Calcium metabolism is under the control of many hormones but primarily 1,25-dihydroxycholecalciferol (gastrointestinal absorption of calcium, bone resorption, increased renal calcium reabsorption), parathyroid hormone (bone resorption, decreased urinary excretion) and calcitonin (bone formation and increases urinary excretion). Calcium is actively transported from maternal to fetal circulation against the concentration gradient resulting in peripartum hypercalcaemia. There is a transient fall in calcium postpartum to 1.8–2.1 mmol/L and a gradual rise to normal infant levels over 24–48 h.

Hypocalcaemia

In addition to the physiological hypocalcaemia of neonates which is usually asymptomatic, other causes of hypocalcaemia are hypoparathyroidism, including DiGeorge syndrome, and parathryoid hormone insensitivity in infants of diabetic mothers which may also be related to hypomagnesaemia. Clinical manifestations are a tremor, seizures and a prolonged QT interval on electrocardiograph.

Hypercalcaemia

This is less common than hypocalcaemia but can result from inborn errors of metabolism such as familial hypercalcaemic hypocalcuria or primary hyperparathyroidism. Iatrogenic causes are Vitamin A overdose or deficient dietary phosphate intake. Less common causes in children are tertiary hyperparathyroidism, paraneoplastic syndromes and metastatic bone disease.

8.4.3.4 Magnesium

As an important enzyme cofactor, magnesium affects ATP metabolism and glycolysis. Only 20% of total body magnesium is exchangeable with the biologically active free ion form. The remainder is bound in bone or to intracellular protein, RNA or ATP, mostly in muscle and liver. Gastrointestinal absorption of magnesium is controlled by vitamin D, parathyroid hormone and sodium reabsorption. As previously stated, hypomagnesaemia is often related to hypocalcaemia and should be considered.

8.5 Acid-Base Balance

Acidosis (pH <7.35) and alkalosis (pH >7.45) can be generated by respiratory or metabolic causes. When the cause is respiratory—$PaCO_2$ is >45 mmHg (acidosis) or <35 mmHg (alkalosis)—treatment is via appropriate respiratory support. In case of metabolic—bicarbonate <21 mmol/L (acidosis) or >26 mmol/l (alkalosis), it is useful to check the anion gap [= $Na^{+-}(Cl^- + HCO_3^-)$, which is normally 12 ± 2 mEq/L] to understand the underlying cause. Treatment should be directed towards any underlying cause e.g. metabolic acidosis caused by dehydration or sepsis. The slow infusion of buffers such as sodium bicarbonate or tris-hydroxymethylaminomethane (THAM, a sodium free buffer) should be used as therapeutic adjuncts. The amount of sodium bicarbonate required can be calculated using the following equation:

$$\mathrm{NaHCO_3\,(mmol)} = \frac{\text{base excess} \times \text{body weight (kg)}}{3}$$

Acid-base balance is maintained by a complex system achieved by intracellular and extracellular buffer systems, respiration and renal function. Intracellular systems consist of conjugate acid-base pairs in equilibrium as shown by the equation below (A = acid, H = proton).

$HA \leftrightarrow H^+ + A$—The pH can be derived from the Henderson-Hasselbach equation.

$$\mathrm{pH} = \frac{\mathrm{pK} + \log\left[\mathrm{A}^-\right]}{\left[\mathrm{HA}\right]}$$

where pK is the dissociation constant of the weak acid, $[A^-]$ is the concentration of the dissociated acid and [HA] is the concentration of the acid. The most important of these systems is the carbonic anhydrase system:

$CO_2 + H_2O \leftrightarrow H^+ + HCO_3$—Extracellular buffer systems are similar but the proton is loosely associated with proteins, haemoglobin or phosphates and take several hours to equilibrate. Respiratory compensation occurs via the carbonic anhydrase system, ridding the body of carbon dioxide thereby shifting equilibrium to the left of the reaction and reducing the number of protons. The extent of the shift is influenced by the active transport of bicarbonate across the blood-brain barrier, thereby triggering central respiratory drive. Normal extracellular pH is maintained at 7.35–7.45. Normal metabolic processes produce carbonic acid, lactic acid, ketoacids, phosphoric acid and sulphuric acid all of which are either excreted or controlled by a number of buffer systems.

In the neonate, loss of the contribution of the feto-maternal circulation and maternal respira-

tory and renal compensation mechanisms force adaptation and maturation. There is a suggestion that increased sensitivity of the respiratory centres to fluctuations in pH changes allow the neonate to control acid-base balance more. Increases in the intracellular protein mass allow greater intracellular buffering. The extracellular buffer systems are already functional.

Respiratory compensation becomes active as respiration is established. It relies on pulmonary function and lung maturity and therefore neonates with lung disease may have impaired respiratory compensation. Carbon dioxide passes freely across the blood-brain barrier allowing almost immediate response from respiratory drive centres to respiratory acidosis. The response to metabolic acidosis is delayed as interstitial bicarbonate requires a few hours to equilibrate with the cerebral bicarbonate.

Renal compensation is the most important mechanism available to the neonate for acid-base balance. Adjustments in urine acidity have been seen as soon as a few hours post-partum but takes 2–3 days to fully mature. Consequent to the changes in renal function and perfusion described previously, the ability of the neonate to handle acid-base balance is limited in the first few days of life. Proximal tubules are responsible for the reabsorption of 85–90% of filtered bicarbonate but function less efficiently in the premature neonate. It can also be affected by some drugs used in neonates. Dopamine inhibits sodium/proton pump activity in the proximal tubules and therefore decreases the amount of bicarbonate that is reabsorbed. The remaining bicarbonate reabsorption takes place in the distal tubules but they differ from the proximal tubules in their absence of carbonic anhydrase. Aldosterone is the most important hormone affecting distal tubular function and stimulates proton excretion in the distal tubules. However, the distal nephrons of the premature infant are developmentally insensitive to aldosterone. Protons are excreted in the urine as phosphate, sulphate and ammonium salts. This increases with age and gestation. However, the introduction of phosphate containing drugs increases phosphate delivery to the distal tubules and therefore can increase the capacity to excrete H^+. Dopamine decreases the reabsorption of protons in the distal tubules thereby increasing proton excretion.

8.6 Parenteral Nutrition

8.6.1 Indications

Parenteral nutrition (PN) should be utilised when enteral feeding is impossible, inadequate or hazardous for more than 4–5 days. The most frequent indications in neonatal surgery are the intestinal obstruction due to congenital anomalies. Frequently after an operation on the gastrointestinal tract, adequate enteral feeding cannot be achieved for more than 1 week and parenteral nutrition becomes necessary. This modality of therapy has improved significantly the survival rate of newborns with gastroschisis, a condition which require intravenous administration of nutrients for 2–3 weeks. Although infants with some neonatal surgical conditions, such as gastroschisis, will all receive PN, there are some other congenital anomalies where the use of PN is more controversial. An example of this is duodenal atresia, in which many surgeons would routinely initiate PN, whereas some surgeons preferentially manage patients without PN by the use of trans-anastomotic tubes [50]. In addition to congenital bowel obstruction, PN may also be used in cases of necrotizing enterocolitis, short-bowel syndrome, gastroenterological indications, and respiratory distress.

8.6.2 Route of Administration

As phlebitis may develop with the use of peripheral veins with solutions exceeding 600 mOsm, it is not possible to administer adequate calories peripherally for the growth of extremely low birthweight infants, and peripheral veins are only used for short-term, partial, nutritional supplementation. In neonates, the umbilical vessels can be used for provision of PN centrally, although the risk of complications increases if umbilical catheters are used for more than 5 days (arterial),

or 14 days (venous) [51]. Central venous catheters can either be placed percutaneously directly in a deep vein, with subcutaneous tunnelling of the extravascular part of the line, or can be a peripherally inserted central catheter (PICC). Although there has been a systematic review comparing outcomes in neonates administered PN through percutaneous central venous catheters versus peripheral cannulae, the authors concluded that there was insufficient evidence to make form recommendations [52]. For consideration of technical aspects of placement and management, the reader is directed to the ESPGHAN/ESPEN guidelines [51].

8.6.3 Components of Parenteral Nutrition

The parenteral nutrition formulation includes carbohydrate, fat, protein, electrolytes, vitamins, trace elements and water. The caloric needs for total parenteral nutrition are provided by carbohydrate and lipid. Protein is not used as a source of calories, since the catabolism of protein to produce energy is an uneconomic metabolic process compared to the oxidation of carbohydrate and fat which produces more energy at a lower metabolic cost. The ideal total parenteral nutrition regimen therefore should provide enough amino acids for protein turnover and tissue growth, and sufficient calories to minimise protein oxidation for energy. Carbohydrates and fat provide the main energy sources in the diet, and this is reflected by their importance as a source of calories in parenteral nutrition.

8.6.3.1 Fluid Requirements

As described above, the hydration and proportion of extracellular fluid change rapidly in the neonate. In a surgical infant, these changes will also be occurring simultaneously with surgical intervention and in initiation of parenteral nutrition. Fluid overload is a possibility in these infants, and careful consideration of all fluids administered (parenteral nutrition and other prescribed drugs), together with daily monitoring of weight and electrolytes is mandatory, at least until PN has been stabilised. Excessive fluid administration can result in pulmonary oedema, or failure of closure of patent ductus arteriosus. A recent report by the National Confidential Enquiry into Patient Outcome and Death highlighted the poor fluid management of many neonates receiving PN [53]. Fluid restriction, or a requirement to administer other fluids in significant volume, can result in the delivery of macronutrients being less than current recommendations.

8.6.3.2 Glucose

Glucose is a main energy source for body cells and should be the primary energy substrate in parenteral nutrition, covering 60–70% of non-protein calories [54]. The amount of glucose that can be infused safely depends on the clinical condition and maturity of the infant, as the ability of neonates to metabolise glucose may be impaired by prematurity and low birth weight. Since (1) pancreatic islet cell function is relatively unresponsive for the first 2 weeks of neonatal life; (2) glycogen stores are limited (Fig. 8.2); (3) gluconeogenesis may be impaired; and (4) liver and peripheral tissues are relatively insensitive to insulin, premature neonates are at risk from both hypoglycaemia and hyperglycaemia [55]. Glucose infusion should be at least at a rate capable of maintaining blood glucose above 2.6 mmol/L, the current consensus definition of neonatal hypoglycaemia [56]. As the rate of endogenous glucose metabolism in neonates is of the order of 5 mg/kg/min, this should be considered the lowest infusion rate likely to avoid hypoglycaemia [54]. As glucose tolerance increases, the rate of glucose infusion can be increased. However, carbohydrate conversion to fat (lipogenesis) occurs when glucose intake exceeds metabolic needs. The potential risks associated with this process are two-fold: accumulation of the newly synthesised fat in the liver, and aggravation of respiratory acidosis resulting from increased CO_2 production, although whether these are clinically relevant in PN-fed infants is uncertain. In addition, hyperglycaemia in ELBW infants is a risk factor for late onset sepsis, mortality and the risk of developing advanced NEC [57]. A rapid increase in plasma glucose concentration precedes development of NEC [58], and infants with established NEC have both a high

prevalence of hyperglycaemia, and a worse outcome if hyperglycaemic [59]. Although there has been interest in the potential of insulin therapy to decrease hyperglycaemia-related morbidity and mortality in neonates, a large RCT on insulin therapy in very-low birthweight infants was stopped early due to an increased rate of hypoglycaemia and mortality in the insulin treated arm, and a recent systematic review concluded that current evidence does not support the use of routine use of insulin in very-low birthweight infants [60, 61]. The evidence base for or against control of glucose levels in surgical infants is lacking, although a large multicentre randomised controlled trial of tight glucose control in infants and children requiring intensive care (and including surgical infants) has recently completed recruitment [62]. Hypoglycaemia usually results from sudden interruption of an infusion containing a high glucose concentration.

8.6.3.3 Lipids

Lipids provide an energy-dense (9 kcal/g of fat), isotonic alternative to glucose as an energy source for PN, which also prevent essential fatty acid deficiency and facilitate provision of fat soluble vitamins. Combined infusion of glucose and lipids confers metabolic advantages over glucose, because it lowers the metabolic rate and carbon dioxide production and increases the efficiency of energy utilisation [63, 64]. There is a close interdependence of carbohydrate and lipid infusion rates on the one hand, and net fat deposition or oxidation on the other (Fig. 8.4). When the intake of glucose calories exceeds 18 g/kg/day (equivalent to resting energy expenditure), net fat oxidation is minimal regardless of fat intake, and net fat synthesis takes place [65]. At a carbohydrate intake of 15 g/kg/day, the proportion of energy metabolism derived from fat oxidation does not exceed 20% even with a fat intake as high as 6 g/kg/day. At a carbohydrate intake of 10 g/kg/day this proportion can be as high as 50% [65]. However, lipid utilisation is often low and unpredictable in neonates, and consequently, lipids are usually introduced slowly, especially in premature neonates [66].

The most commonly used fat emulsions for parenteral nutrition of surgical infants paediatrics

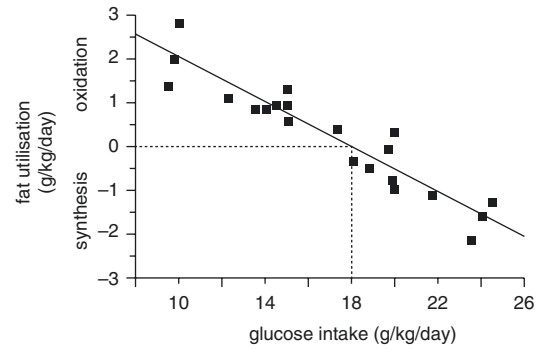

Fig. 8.4 Relationship between glucose intake and fat utilisation in surgical infants. Linear relationship between glucose intake and fat utilization ($r = -0.9$; $p < 0.0001$). Lipogenesis is significant when glucose intake exceeds 18 g/kg/day. From Pierro A, Jones MO, Hammond P, Nunn A, Lloyd DA. Utilisation of intravenous fat in the surgical newborn infant. Proceedings of the Nutrition Society 52, 237A. 1993; used with permission

are based on soybean oil, which in which the lipid is present as long-chain triglycerides (LCT). However, a frequent complication of long-term PN in surgical infants is parenteral-nutrition associated cholestasis (PNAC) and/or intestinal failure-associated liver disease (IFALD). These conditions, considered in more detail below, have been linked to the use of soybean oil, although other factors are thought to be involved. Soybean oil contains mostly Ω-6 fatty acids, which are thought to be pro-inflammatory compared with Ω-3 fatty acids. In addition, the amount of phytosterols delivered in soybean-based lipid emulsions is relatively high, and phytosterol accumulation has been postulated to cause PNAC/IFALD [67]. Hence in recent years, there has been great interest in adopting hepatoprotective lipid management strategies in PN of surgical infants. Several different approaches have been adopted:

- decreasing the amount of lipid administered [68, 69]. This can also be achieved by limiting the time on lipid, by lipid free hours or days. This could potentially result in poor growth due to inadequate calories.
- use of Omegaven®, a lipid emulsion of 10% fish oil. Fish oil is high in Ω-3 fatty acids and low in phytosterols, so has been suggested to

reverse cholestasis in surgical infants on long-term PN [70]. Use of Omegaven® as the only lipid source could, however, potentially result in essential fatty acid deficiency, due to lack of Ω-6 fatty acids, and could also result in poor growth, as the dose of Omegaven® is limited to 1.0 g/kg/day (compared with 3 g/kg/day for soybean-based lipid emulsions).

- use of lipid emulsions containing a mixture of long- (LCT) and medium-chain (MCT) triglycerides [71, 72]. This has the advantage of increasing fat utilisation [73], ability to use at up to 3 g/kg/day, and decreasing the phytosterols and Ω-6 fatty acids administered whilst ensuring adequate delivery of essential fatty acids.
- use of mixed lipid emulsions such as SMOF®, which is a mixture of **S**oybean, **M**edium-chain, **O**live and **F**ish triglycerides [71, 74, 75]. This has the advantages of lowered amounts of phytosterols and Ω-6 fatty acids, increased fat utilisation, delivery of Ω-3 fatty acids, ability to use at up to 3 g/kg/day.

Despite these different approaches, the evidence base supporting any lipid management strategy is lacking due to the paucity of RCTs in this area. It is difficult to design and implement good quality RCTs, as units already use a variety of alternate lipid management strategies [76]. It is also questionable whether maintaining an infant on a high dose of soybean-based lipid emulsion after the onset of PNAC/IFALD is ethical, so that it is difficult to decide on an appropriate comparison group.

High doses of lipid or an accidental rapid infusion of lipid may lead to fat overload syndrome, characterised by an acute febrile illness with jaundice and abnormal coagulation and respiratory problems [66, 77] and so lipids are usually advanced slowly, with close monitoring of triglyceride levels, especially in neonates with respiratory insufficiency or suspected infections [66]. Peroxidation in stored fat emulsions and the generation of free radicals during intravenous infusion of fat in premature infants have been reported [78]. However, the degree of free radical production is linked to the rate of lipid oxidation, as we have shown that a reduction in the carbohydrate to fat ratio in PN diet will result in increased oxidation of administered fat and a decrease in free radical–mediated lipid peroxide formation [79].

8.6.3.4 Amino Acids

In contrast to healthy adults who exist in a state of neutral nitrogen balance, infants need to be in positive nitrogen balance in order to achieve satisfactory growth and development. Preterm infants who are receiving glucose alone lose protein quickly (at the rate of 1–2% body protein per day), so should start to receive at least 1–1.5 g/kg/day amino acids parenterally if not receiving EN [80]. Infants are efficient at retaining nitrogen, and can retain up to 80% of the metabolizable protein intake on both oral and intravenous diets [81]. Protein metabolism, and deposition of body protein for growth, is dependent upon both protein and energy intake, so that above an energy intake of 70 kcal/kg/day, the major determinant of nitrogen retention in preterm infants is the amino acid intake [81]. The PN amino acid requirement of term newborn infants is between 2.5 and 3.0 g/kg/day, which allows for accretion of body protein [82]. Complications like azotemia, hyperammonaemia, and metabolic acidosis have been described in patients receiving high levels of intravenous amino acids [83] but rarely seen with amino acid intake of 2–3 g/kg/day [84]. In patients with severe malnutrition or with additional losses (i.e. jejunostomy, ileostomy), protein requirements are higher [85]. The nitrogen source of PN is provided as a mixture of amino acids, and mixtures specifically formulated for neonates are available. However, the ideal amino acid composition for term and preterm infants is uncertain. As well as the amino acids usually considered essential for adult humans, histidine is considered essential for infants, and the following amino acids have all been considered "conditionally essential" for neonates: arginine, cysteine, glutamine, taurine and tyrosine [86].

Cysteine is unstable in amino acid mixtures, but is central to sulphur amino acid economy and for glutathione synthesis. It is not certain whether newborn infants, especially those born prema-

turely, are capable of adequate rates of cysteine synthesis [86]. A meta-analysis of available trials in PN-fed neonates suggested that although cysteine-supplementation may improve nitrogen balance, there was insufficient data to evaluate the risks of cysteine addition, such as metabolic acidosis [87].

Like cysteine, glutamine is excluded from PN amino acid mixtures because of poor stability, although it can now be added as a dipeptide. Glutamine is important for the immune system and the intestine, as well as being essential as a nitrogen-carrier between organs [88]. It has been hypothesised that glutamine supplementation to parenterally fed neonates would decrease the incidence of infection and decrease to time to full enteral feeding. Two small studies examined the effects of PN glutamine supplementation in premature infants and found decreased duration of ventilation and decreased incidence of sepsis [89, 90]. However, a larger study in premature infants [91] found no benefit of glutamine supplementation. One randomised controlled trial [92] in surgical infants found that parenteral glutamine supplementation had no significant effect on intestinal permeability or nitrogen balance, although this study was not powered to detect differences in clinical endpoints such as incidence of sepsis or duration of PN. A large multicentre randomised controlled trial of glutamine-supplemented PN showed that although glutamine did not decrease the time to full enteral feeds, or the incidence of sepsis over the full period of PN, it did significantly decrease the incidence of sepsis during the period of exclusive parenteral feeding, i.e. before any enteral nutrition was introduced [93].

Arginine has also been considered conditionally essential to the neonate [86] and studies have shown low plasma arginine in infants with NEC [94–96]. Supplementation of PN, followed by EN, with arginine decreased the incidence of NEC in a randomised controlled trial [97], and is has been suggested that infants who have genetic polymorphisms which may alter arginine metabolism levels have an increased susceptibility to NEC [98].

Tyrosine synthesis from phenylalanine may be impaired in neonates [82, 86], and the measured tyrosine requirement for neonates is much greater than is available in current neonatal amino acid mixtures, due to poor solubility [99].

Taurine is a non-protein forming amino acid that has roles in the immune system, as an osmolyte, and in retinal and neurological function, and for bile acid conjugation [100, 101]. Neonates on PN may have poor taurine status due to poor renal reabsorption, impaired activity of synthetic enzymes, and low levels of cysteine, the immediate precursor for taurine [101]. Plasma taurine status of preterm infants has now also been suggested to affect neurodevelopmental outcome [102]. Despite the lack of strong evidence from RCT, most PN amino acid mixtures for neonates now contain taurine. This has been suggested to decrease the incidence of cholestasis in infants on PN (see below) [103].

8.6.3.5 Minerals, Vitamins and Trace Elements

Minerals, vitamins and trace elements are important structurally, as cofactors, or as components of enzymes, and provision of adequate supplies is important for the growing neonate. Fe, Ca, P and Mg should all be provided in adequate amounts for growth and development, but conversely, can cause problems if provided in excess of needs or if their metabolism is impaired. In addition, administration of adequate amounts can be problematic, because of lack of stability in solution or lack of compatibility with other components. Consequently, iron is often only supplemented in longer term PN [104] whereas calcium and phosphate supply depends on solubility in PN mixtures [104]. Vitamins and trace elements are particularly important in maintenance of the body's antioxidant defences [105]: vitamins C and E, selenium (for glutathione peroxidase), copper, zinc and manganese (all for superoxide dismutases), chromium, iodine and molybdenum can all added to parenteral nutrition. However, for many of these, the precise requirements are not known. Although there is evidence that selenium supplementation may be beneficial, selenium status varies widely geographically, so global recommendations are difficult [106]. It is suggested that if the duration of PN is less than

4 weeks, of the trace elements, only zinc needs to be added [104, 107]. There is little specific evidence for individual vitamin requirements, and the current recommendations are to continue with the available vitamin mixtures, which do not appear to cause toxicity or deficiency in the majority of neonates [107, 108]. Free radical production and lipid peroxidation will be considered in more detail below.

8.6.4 Complications of Parenteral Nutrition

8.6.4.1 Infectious Complications

In spite of significant improvement in the management of parenteral nutrition including the introduction of nutrition support teams, infection is still a major problem. More than 50% of surgical infants on PN have at least one suspected episode of sepsis, and around 30% of surgical neonates having at least one positive blood culture [93, 109]. Repeated episodes of sepsis may lead to impaired liver function [110, 111], critical illness and removal of central venous catheters. Although catheter-borne infections, which can be reduced by rigorous precautions [112], such chlorhexidine antisepsis [109], are important, microbial translocation from the intestine is also a significant source of infection in surgical infants on PN [110, 111]. Infection with enteric micro-organisms occurs significantly later than presumed catheter-related infection [113], supporting the hypothesis that a progressive impairment of host defences [114] and/or increased intestinal permeability may allow translocation of enteric organisms after an extended period of PN.

8.6.4.2 Mechanical Complications

Mechanical complications related to the intravenous infusion of nutrients are not uncommon. Extravasation of parenteral nutrition solution is a common complication of peripheral parenteral nutrition. Unfortunately, even a low osmolarity solution is detrimental for peripheral veins leading to inflammation and extravasation of the solution, which can cause tissue necrosis and infection. Extravasation injury is treated with occlusive dressings or hyaluronidase irrigation, but there is little evidence base for the best treatment in neonates [115]. Intravenous lines may become clogged from thrombus formation, calcium precipitates, or lipid deposition. There is disagreement on the ideal position of central venous lines (CVL) for parenteral nutrition in infants. Some authors advocate the atrium as the ideal position because this would give less chance of catheter dysfunction, whereas others believe that placement in the superior vena cava would reduce the risk of perforation. The current ESPGHAN/ESPEN recommendations are that the catheter tip should lie outside the atrium [51], but because complications of either approach are very rare (albeit potentially life-threatening), there is a paucity of evidence from RCTs.

8.6.4.3 Hepatic Complications

The hepatobiliary complications related to parenteral nutrition remain serious and often life threatening. The commonest hepatobiliary complication of parenteral nutrition in neonates is cholestasis. The clinical significance of this cholestasis itself is unknown, but if untreated, intestinal failure associated liver disease (IFALD) may occur, which can result in the need for liver transplantation, or can result in death. IFALD has been defined by the British Society of Paediatric Gastroenterology, Hepatology and Nutrition [116] as:

- type 1 early IFALD—persistent elevation of alkaline phosphatase (ALP) and γ-glutamyl transferase greater than 1.5 times the upper limit of reference range for at least 6 weeks;
- type 2 established IFALD, elevation of ALP γGT as above, together with elevation of total bilirubin (>50 μmol/L), with a conjugated fraction of at least 50%;
- type 3 late IFALD—elevated ALP, total bilirubin, and clinical signs of end-stage liver disease.

Type 1 is thought to be reversible, type 2 is potentially reversible if enteral feeding is increased, PN reduced and repeated episodes of

catheter-related sepsis are prevented. The incidence of PNAC/IFALD depends on the length of time on PN, and occurs in up to 50% of infants receiving long-term PN [117]. Although the frequency of this complication seems to be diminishing [118], this is probably related to the more aggressive transition to enteral feeding rather than to an improvement in the intravenous diet. Various clinical factors are thought to contribute to the development of parenteral nutrition-related cholestasis. These include prematurity, low birth weight, duration of parenteral nutrition, immature entero-hepatic circulation, intestinal microflora, septicaemia, failure to implement enteral nutrition, short-bowel syndrome due to resection, and number of laparotomies (reviewed [119]). In addition to the effects of extremely low birthweight, and length of time on PN, infants receiving PN for either gastroschisis or jejunal atresia seem to be at particular risk [120]. Parenteral nutrition-related cholestasis has a higher incidence in premature infants than in children and adults. This may be due to the immaturity of the biliary secretory system since bile salt pool size, synthesis, and intestinal concentration are low in premature infants in comparison with full term infants [121]. PNAC and IFALD are diagnoses of exclusion without any specific marker yet available. Therefore, infants with cholestasis (conjugated bilirubin >2.0 mg/dL) who are receiving or have received parenteral nutrition must have an appropriate diagnostic evaluation to exclude other causes of cholestasis, such as bacterial and viral infections, metabolic diseases (e.g. alpha-1-antitrypsin deficiency, tyrosinaemia) and congenital anomalies (e.g. Alagille syndrome, biliary atresia, choledocal cyst) [122].

The aetiology of parenteral nutrition-related cholestasis remains unclear. Possible causes include the toxicity of components of parenteral nutrition, lack of enteral feeding, continuous non-pulsatile delivery of nutrients and host factors, infection and sepsis [119]. In particular, the lipid component of PN has been particularly implicated and many units now use alternative lipid management strategies (see discussion under lipid component of PN above). In addition to lipid management, careful management of these patients under a multi-disciplinary team seems to be beneficial [71, 116, 117, 123]. Bowel lengthening procedures, such as the STEP procedure or longitudinal intestinal lengthening may help transition to enteral nutrition [124, 125], whereas in those with advanced liver disease and no prospect of enteral autonomy, transplantation may be considered. Isolated liver transplantation [126], isolated intestinal transplantation and liver plus intestinal transplant are all feasible in children, and although results are improving, overall outcomes are still poor and organ availability is, of course, a problem [127].

8.7 Enteral Nutrition

The energy requirement of an infant fed enterally is greater than the intravenous requirement because of the energetic cost of absorption from the gastrointestinal tract and energy lost in the stools (Fig. 8.3). Enteral feedings should be used in preference to parenteral nutrition. The transition from parenteral to enteral feeding should be a short as possible. Neonates undergoing abdominal surgery for congenital or acquired intestinal dysfunction often require a period of parenteral nutrition, however the authors recommend to start introducing enteral feeding as soon as the gastric aspirate is less than approximately 24 mL/day even if the aspirate is still bilious. There is evidence that during parenteral nutrition of surgical infants, the introduction of minimal enteral feeding preserves immune function [128].

8.7.1 Feeding Routes

Alternative feeding routes where neonates are unable to feeds orally include naso-gastric or oro-gastric tubes, naso-jejunal tubes, gastrostomy tubes or jejunostomy tubes. Gastric feeding is generally preferable to intestinal feeding because it allows for a more natural digestive process i.e. allows action of salivary and gastric enzymes and the antibacterial action of stomach acid. In addition gastric feeding is associated with a larger osmotic and volume tolerance and a lower fre-

quency of diarrhoea and dumping syndrome. Thus, transpyloric feeds are usually restricted to infants (1) unable to tolerate naso- or oro- gastric feeds; (2) at increased risk of aspiration; (3) with anatomical contra-indications to gastric feeds, such as microgastria. Neonates are obligatory nose breathers and therefore oro-gastric feeding may be preferable over naso-gastric feeding in preterm infants to avoid upper airway obstruction. However, naso- gastric tubes are easier to secure and may involve a lower risk of displacement. In infants requiring gastric tube feeding for extended periods (e.g. more than 6–8 weeks) it is advisable to insert a gastrostomy, to decrease the negative oral stimulation of repeated insertion of nasal or oral tubes. The tube can be inserted using an open, endoscopic or laparoscopic approach. In infants with significant gastro-oesophageal reflux, fundoplication with gastrostomy tube or enterostomy tube placement is indicated [129]. In preterm infants with gastro-oesophageal reflux, enteral feeding can be established via a naso-jejunal tube inserted under fluoroscopy. Naso-jejunal feeding usually minimise the episodes of gastro-oesophageal reflux and their consequences. However, it is common for these tubes to dislocate back in the stomach. Regular analysis of the pH in the aspirate is essential to monitor the correct position of the tube. Feeding jejunostomy tubes can be inserted through existing gastrostomy or directly into the jejunum via laparotomy or laparoscopy.

8.7.2 Selection of Enteral Feeds

Breast milk is the ideal feed for infants because it has specific anti-infectious activities, aids gastrointestinal maturation and neurological development. When breast milk is not available chemically defined formulae can be used, which are designed either for term infants or specifically for preterm infants. If malabsorption is present and persists, an appropriate specific formula should be introduced. A soy-based disaccharide-free feed is used when there is disaccharide intolerance resulting in loose stools containing disaccharides. For fat malabsorption, a formula containing medium chain triglycerides (MCT) should be used. An elemental (free amino acids) or semi-elemental (protein hydrolysate containing di- and tri- peptides) formula may be indicated when there is severe malabsorption due to short bowel syndrome or severe mucosal damage as in NEC. Semi-elemental preparations have the advantage of a lower osmolality, are well absorbed and have a more palatable taste. Infants recovering from NEC pose a particular problem, as malabsorption may be severe and prolonged. These infants may have had small bowel resected, in addition to which the remaining bowel may not have healed completely by the time feeds are begun. Feeding may provoke a relapse of the necrotising enterocolitis and feeding should therefore be introduced cautiously. However, there is no strong evidence for the time to re-introduce enteral feeds in infants who have had NEC [130]. For persistent severe malabsorption, a modular diet may be necessary. Glucose, amino acid and MCT preparations are provided separately, beginning with the amino acid solution and adding the glucose and then the fats as tolerated. Minerals, trace elements and vitamins are also added. These solutions have a high osmolality and if given too quickly may precipitate dumping syndrome, with diarrhoea, abdominal cramps and hypoglycaemia. It is important therefore to start with a dilute solution and increase slowly the concentration and volume of each component. This may take several weeks and infants will need parenteral nutritional support during this period.

8.7.3 Administration of Enteral Feeds

Enteral feeds can be administered as boluses, continuous feeds or combination of the two. Bolus feeds are more physiological and are known to stimulate intestinal motility, enterohepatic circulation of bile acids and gallbladder contraction [131]; continuous enteral feeding leads to an enlarged, non-contractile gallbladder in infants [132]. Contraction is observed immediately after resuming bolus enteral feeds and

gallbladder volume returns to baseline after 4 days. Therefore the mode of feeding has important bearings on the motility of the extrahepatic biliary tree. Bolus feeds mimic or supplement meals and are easier to administer than continuous feeds since a feeding pump is not required. Bolus feeds are usually given over 15–20 min and usually every 3 h; term infants can tolerate a period of 4 h without feeds before hypoglycaemia occurs. In preterm neonates or in neonates soon after surgery 2-hourly feeds are occasionally given. Where bolus feeds are not tolerated, for example in the presence of gastro-oesophageal reflux, continuous feeds should be administered via an infusion pump over 24 h. This modality of feeding is used in infants with gastro-oesophageal reflux, delayed gastric emptying or intestinal malabsorption. Infants with jejunal tubes should receive continuous feeds and not bolus feeds as the stomach is no longer providing a reservoir.

8.7.4 Complications of Enteral Tube Feeding

Enteral tube feeding is associated with fewer complications than parenteral feeding. The complications can be mechanical including tube blockage, tube displacement or migration and intestinal perforation. Although infection is less of a risk than with parenteral nutrition, the risk of infected enteral feeds should not be ignored [133]. Other complications involve the gastrointestinal tract. These include: gastro-oesophageal reflux with aspiration pneumonia, dumping syndrome and diarrhoea. Jejunostomy tubes inserted at laparotomy can be also associated with intestinal obstruction. The use of hyperosmolar feeds has been associated with development of necrotizing enterocolitis, dehydration and rarely, intestinal obstruction due to milk curds [134].

In surgical infants, enteral feeding often results in vomiting, interruption of feeding, inadequate calorie intake and rarely in necrotizing enterocolitis. In infants with congenital gastrointestinal anomalies, exclusive enteral feeding is commonly precluded for some time after surgery due to large gastric aspirate and intestinal dysmotility. Therefore, appropriate calorie intake is established initially by total parenteral nutrition. Supplementary enteral feeding is introduced when intestinal motility and absorption improves. The percentage of calories given enterally is gradually increased at the expense of intravenous calorie intake. This transition time from total parenteral nutrition to total enteral feeding could be quite long. The presence of significant gastric aspirate often induces clinicians and surgeons not to use the gut for nutrition. However, minimal enteral feeding can be implemented early in these patients even if its nutritional value is questionable. Minimal enteral feeding may be all that is required to enhance some immunological function. This is supported by studies in animals [135] and infants [136]. Shou et al. [135] reported that supplementation of parenteral nutrition with just 10% enteral calories as chew diet improved rat macrophage and splenocyte function. Okada et al. [136] have shown that the introduction of small volumes of enteral feed improved the impaired host bactericidal activity against coagulase negative staphylococci and the abnormal cytokine response observed during total parenteral nutrition. The increase in bactericidal activity against coagulase negative staphylococci after the addition of small enteral feeds in patients on parenteral nutrition was significantly correlated with the duration of enteral feeding. This implies that stimulation of the gastrointestinal tract may modulate immune function in neonates and prevent bacterial infection.

Neonatal Vascular Access

9

Colin T. Baillie

Abstract

Advances in the medical and surgical management of neonates are often predicated upon secure vascular access. Requirement for vascular access may be for physiological monitoring (arterial or central venous pressure), direct treatment (antibiotics, chemotherapy), supportive therapy (nutrition, transfusion, dialysis, ECMO), diagnostic radiological, and procedural purposes (drainage of CSF or chyle, minimally invasive cardiac interventions). It is important for the surgeon to have a broad working knowledge of this field, as, given the multidisciplinary nature of modern neonatal intensive care, the options for and scope of vascular access are expanding alongside the number of subspecialties with interests and relevant skills in this area.

Keywords

Vascular access • Central venous catheter • Newborn surgery

9.1 Introduction

Advances in the medical and surgical management of neonates are often predicated upon secure vascular access. Requirement for vascular access may be for physiological monitoring (arterial or central venous pressure), direct treatment (antibiotics, chemotherapy), supportive therapy (nutrition, transfusion, dialysis, ECMO), diagnostic radiological, and procedural purposes (drainage of CSF or chyle, minimally invasive cardiac interventions). It is important for the surgeon to have a broad working knowledge of this field, as, given the multidisciplinary nature of modern neonatal intensive care, the options for and scope of vascular access are expanding alongside the number of subspecialties with interests and relevant skills in this area.

Despite its obvious importance, neonatal vascular access has yet to attract a large specific evidence base in support of its related practices. Therefore, as the subject is explored, important inferences will be drawn from the paediatric and also adult literature which might reasonably be considered to have a bearing on the sub-

ject, or which might be worthy of future research to determine applicability to neonatal vascular access.

9.2 Historical Considerations

The history of intravenous access can be traced back to the seventeenth-century and the general description of the circulation by William Harvey. In the same century Sir Christopher Wren administered a potent mix of ale, opium and beer to dogs using a quill for intravenous access and a pig's bladder as a fluid reservoir. Access to the venous circulation became practical with the development of the hollow needle by Francis Rynd in 1845, and the use of these reusable steel needles continued into the 1950s. The modern IV catheter can be traced back to 1950s when the "Rochester plastic needle" was developed, rapidly to be superseded by the first generation of "over the needle" plastic catheters led by the Intracath™ (Beckton Dickinson 1957) and then in 1964, by the Angiocath™ [1].

Dr. Latta described the use of an IV solution for the treatment of cholera in a letter to the Lancet in 1832. This intravenous rehydration therapy saved thousands of lives in the Paris cholera epidemics of 1832 and 1849. Turning to intravenous nutrition, Elman and Weiner reported pioneering nutritional experiments in 1937 using intravenous infusions of carbohydrates and protein hydrolysates in adults. The major difficulties encountered were loss of peripheral access and the large volumes of fluid required to even approach provision of adequate calories. Further important advances in understanding the physiology of protein calorie malnutrition arose out of the horrors of World War II, including the appreciation of gut mucosal atrophy in starvation and the potential for reversing this process and inducing mucosal proliferation with "intravenous feeding". The modern approach to total parenteral nutrition (TPN) was developed in the Harrison Department of Surgical Research at the University of Pennsylvania initiated in the 1940s by Harry Vars, later championed by Jonathon Rhodes and finally "perfected" by Stanley Dudrick, who was the first to demonstrate in 1966 that reliable long term nutritional support could be provided using TPN in beagle puppies [2]. The same group applied this technique with spectacular success for nearly 2 years in an infant with ultra-short bowel syndrome [3]. The success of the Pennsylvania group was predicated both upon the development of a fat emulsion using cottonseed oil, and the development of polyvinyl central venous catheters which were biologically inert. (Central venous catheters in current usage are manufactured almost exclusively from silicon or polyurethane.)

The formal organization of neonatal intensive care began in the 1960s with the establishment of dedicated intensive care units and the development of technologies for neonatal ventilation, central venous access and TPN. During the subsequent half century significant advances have been made in improving the morbidity and mortality of premature infants. Much emphasis is rightly placed on evidence-based approaches to medical care, and an attempt has been made in the remainder of this chapter to emphasize these developments with respect to neonatal vascular access.

9.3 Commonplace Neonatal Vascular Access Procedures

Although the majority of the procedures outlined below are the prerogative of the neonatologist, a passing understanding is the minimum expected of the surgeon who might interfere with such access in the event of laparotomy, or who might be called upon to assist in the management of an occasional complication resulting from vascular access procedures.

9.3.1 Umbilical Venous and Arterial Cannulation

The neonatal umbilicus provides immediate reliable short term access to both arterial and venous circulations. The umbilical arteries and vein can readily be dilated to allow passage of a polyure-

thane catheter in the first 24 h of life. Measured graduations on the catheter allow for positioning which is later confirmed radiologically (Figs. 9.1 and 9.2). The catheters are secured by suture to the umbilical stump and fixed by tape to the abdominal wall.

With respect to umbilical venous catheterization (UVC), the formula for inserted catheter length (cm) is estimated by ***weight (kg) × 1.5 + 4.5 + length of cord above the skin***. The catheter tip should lie centrally at the level of or just above the diaphragm ie. within the inferior vena cava, but outwith the cardiac silhouette [4, 5]. Heparinization of the infusate is unnecessary as volume alone is usually sufficient to maintain patency. A study of 142 neonates with UVC's identified accurate central positioning in 75% and identified four life threatening complications (pericardial and pleural effusions, rupture into the liver parenchyma and rupture into the abdominal cavity causing ascites) [6]. There is now considerable experience with multi-lumen umbilical catheters suggesting that their use is associated with a significant reduction in the need for additional peripheral intravenous catheters, albeit at the price of increased catheter malfunction [7].

In the case of umbilical arterial catheterization (UAC), similar catheters are used (3Fr for babies <1500 g, 4Fr 1500–2000 g, and 5Fr >2000 g). The required insertion length (cm) is estimated by the formula ***weight (kg) × 3 + 9 + length of cord above the skin surface*** [5]. The preferred tip position is "high" (thoracic aorta T6—T9), [5, 8–10] although a "low" tip position *(abdominal aorta L3–4)* is also acceptable [10, 11]. A high position is thought to be associated with a lower incidence of ischaemic complications. Patency is ensured by continuous infusion of heparinised 0.45% saline (0.5 IU/mL). Circulation in the lower extremities should be documented hourly, and signs of significant vascular compromise should prompt rapid removal of the catheter. Damping of the arterial trace is often the first indication of an impending thrombotic problem and if persistent should prompt consideration of catheter removal.

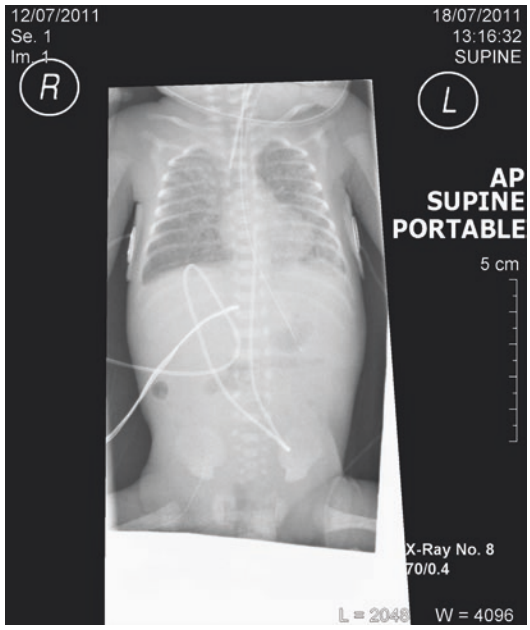

Fig. 9.1 Umbilical arterial catheter placed in ventilated neonate with tip in high position in thoracic aorta (T7–T8)

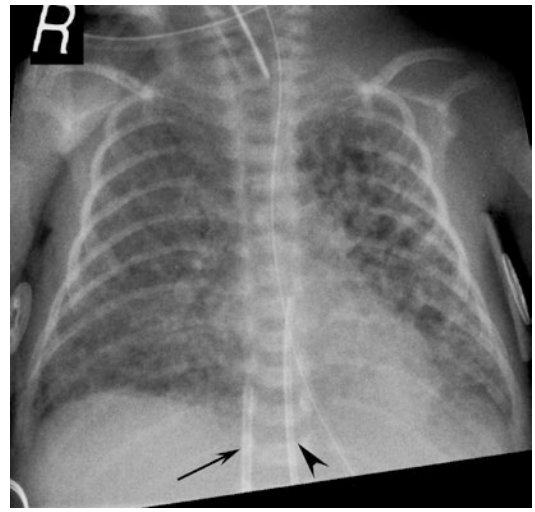

Fig. 9.2 Neonate with respiratory distress syndrome and unilateral pulmonary interstitial emphysema. The umbilical venous catheter (UVC) is positioned optimally and terminates at the diaphragmatic IVC (*arrow*). The UVC should not terminate in either the liver or the heart. The umbilical arterial catheter (arrowhead) lies to the left of the UVC and should terminate between T6 and T9 vertebral levels. *Image courtesy of Dr. Gurdeep S. Mann MRCP FRCP, Liverpool Women's Hospital*

These procedures are often used in emergency neonatal resuscitation. Infection and major vessel thrombotic complications become more common with increasing line longevity. Necrotizing enterocolitis is also associated with umbilical catheterization and when suspected, is similarly an indication for prompt line removal. Treatment of UAC-related thrombosis includes consideration of unfractionated (UFH) or low molecular weight heparin (LMWH) for 10 days. If life-, limb-, or organ-threatening symptoms result from UAC-thrombosis, thrombolysis with tissue plasminogen activator (tPA) [10], or even the option of surgical thrombectomy should be considered [12]. Currently there is no RCT evidence comparing thrombolysis with anticoagulation so firm conclusions about the relative merits of each treatment are impossible [13]. The risk of these medical interventions must be carefully weighed against the risk of haemorrhagic problems, particularly intra-ventricular haemorrhage.

9.3.2 Percutaneous Central Venous Cannulation

Peripherally inserted central lines (PICC's) are the preferred elective form of medium term vascular access in the premature neonate. The favoured routes are via the antecubital (basilic/cephalic), scalp (superficial temporal), or lower limb (saphenous) veins, although any peripheral vein can be used. Having accessed the vein, a long polyurethane catheter is "floated" into a central vein over a guidewire and the catheter tip position confirmed radiologically. There is clear guidance that the tip position of PICC lines should be outwith the cardiac silhouette to avoid the risk of tamponade [14]. The small diameter of these catheters often necessitates the use of radiological contrast to confirm tip position (Fig. 9.3).

The longevity of PICC lines is variable and is dependent on the neonate's co-morbidities in addition to prematurity. Judicious use of PICC lines includes appropriate and timely removal in the event of catheter complications, and the use of simple venous cannulae to "bridge the gap" to another PICC line insertion, when the neonate might have been compromised with respect to vascular access

Fig. 9.3 Radiograph showing PICC line inserted via left cephalic vein with tip positioned optimally in the distal SVC but outwith the cardiac silhouette

(usually as a result of sepsis). This type of management in extremely premature neonates often obviates the need for surgical venous access and is a tribute to the skill of many a neonatologist.

There is increasing experience with central venous line insertion via internal jugular [15], femoral [16] and subclavian routes. Those with particular familiarity with the Seldinger approaches in these access locations often tunnel the catheter to the site of percutaneous access, thereby adding an extra level of protection from infectious catheter complications. There is an increasing willingness amongst surgeons to abandon the traditional open techniques of central venous access in favour of the percutaneous route, as it is thought that this approach is more likely to preserve the vein for future use. NICE guidelines now dictate that real time 2D ultrasound is mandatory (a gold standard) to assist catheterization via jugular (Fig. 9.4) and femoral routes in neonates over 3 kg, and that the operator (Fig. 9.5) should be appropriately trained in using ultrasound for the procedure [17]. A meta-analyses has been published which failed to show an advantage for US-guided as opposed to landmark insertions [18], but the patient base for this study was heavily weighted towards cardiac anaesthesia and as such is probably not completely representative of the population at large. This paediatric

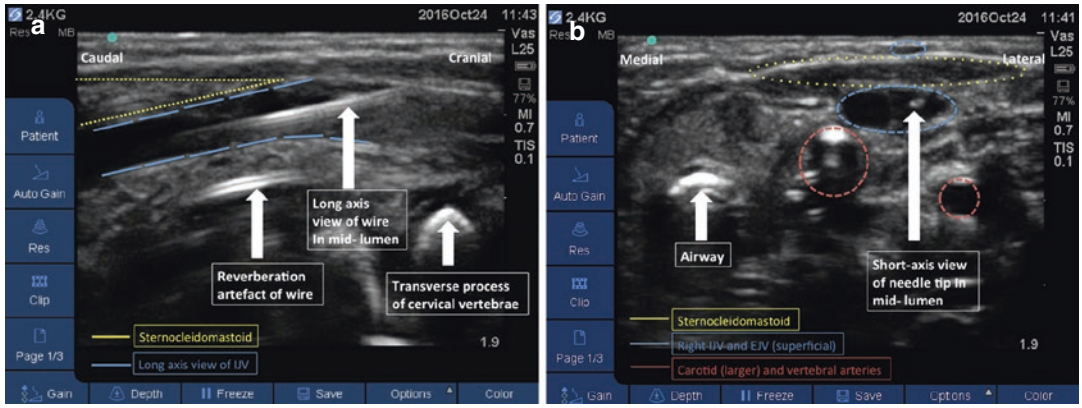

Fig. 9.4 (**a**) Ultrasound image of right side of neck in a 2.4 kg neonate. Note the proximity of significant other structures and the IJV midpoint is only 5 mm from skin. (**b**) Ultrasound image of right side of neck in a 2.4 kg neonate. Note the wire from a Seldinger CVP kit passing down the mid lumen of IJV. The wire can be followed distally into the thorax indicating correct placement. What cannot be appreciated from these static images is the significant compression of tissues that occurs during needle advancement. *Images courtesy of Dr. Peter Murphy, Consultant Anaesthetist, Royal Liverpool Children's Hospital NHS Trust*

Fig. 9.5 Shows the technique of US-assisted venepuncture of the internal jugular vein. The operator uses the US probe to locate the vein and to follow continuously the progress of the needle tip/guide wire throughout the procedure. *Images courtesy of Dr. Peter Murphy, Consultant Anaesthetist, Royal Liverpool Children's Hospital NHS Trust*

Fig. 9.6 Landmarks for percutaneous subclavian venous access. The insertion point is inferior to the clavicle at the junction of the medial two thirds with the lateral third of the clavicle (*arrow head*). The needle is advanced medially and cranially skirting just inferior to the clavicle and superior to the first rib, aiming in the direction of the suprasternal notch (*cross*)

meta-analysis and the "3 kg window" offered by NICE give some degree of flexibility to those favouring the "landmark approach" for smaller neonates (Figs. 9.6 and 9.7), but clearly a degree of familiarity with ultrasound-assisted central venous cannulation is becoming increasingly necessary.

9.3.3 Peripheral Arterial Catheterization

When arterial catheterization is required for invasive pressure monitoring outside the first 2 days of life, peripheral arterial cannulation is indicated. The radial and posterior tibial arteries are the preferred choice since catheterization of fem-

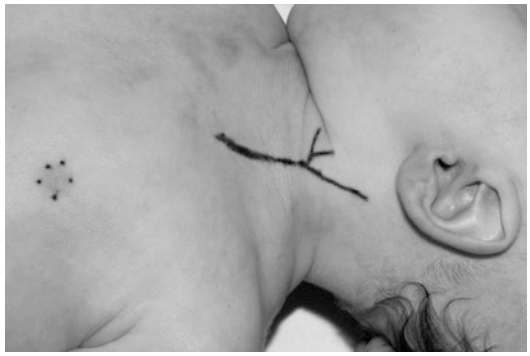

Fig. 9.7 Landmarks for percutaneous internal jugular venous access. The insertion point is over the sternomastoid muscle at the junction of its distal third with proximal two thirds (*arrow head*). The needle is advanced in the direction of the ipsilateral nipple at an angle of 30º to the skin surface whilst aspirating the syringe to confirm successful venepuncture

oral or brachial arteries carries significant risk of limb threatening consequences from distal thrombotic complications. These risks should always be carefully weighed against the potential benefits. The use of ultrasound or cold light transillumination may offer considerable assistance to arterial cannulation. As with umbilical arterial catheterization low dose heparin infusions are necessary to maintain arterial patency. In the event of distal ischaemic changes it is necessary to remove the catheter immediately. Where these changes are progressive options include passive observation, anticoagulation with UFH or LMWH, and thrombolysis usually with tPA. Not infrequently the risk of the intervention in terms of haemorrhage outweighs the potential benefit and non-viable tissues are frequently left to demarcate over time into dry gangrene before consideration of formal amputation.

9.3.4 Surgical Venous Access

As discussed earlier, technological improvements with catheters, new formulations of TPN, and the skills of both neonatologists and allied practitioners mean that surgical involvement in neonatal venous access is by no means inevitable even in the setting of extreme prematurity. However with increasing difficulty of access, requirement for "specialist" access (haemodialysis or ECMO), or when prolonged venous access is likely in a neonate undergoing surgery, surgical central venous catheterisation becomes mandatory. Additionally, when undertaking operative management of necrotising enterocolitis, complex meconium ileus or neonatal tumours (e.g. sacrococcygeal teratoma), a significant transfusion requirement may be anticipated. Under such circumstances it is advisable to insert a surgical venous catheter which allows for rapid volume expansion in the event of brisk haemorrhage.

Surgical central venous access is a routine procedure in a busy neonatal service and, although an excellent "training" operation, should not be undertaken without appropriate pre-operative planning, and meticulous attention to detail during surgery and in post-operative line management.

9.3.4.1 Pre-Operative Planning

As with any procedure undertaken under general anaesthetic, communication between neonatal, anaesthetic, surgical, laboratory, radiography and nursing personnel is vital. Clotting abnormalities should be corrected where possible and platelets should be available for peri-operative infusion should the platelet count be low ($<75 \times 10^9$/L). The size and type of line inserted, and whether single- or dual-lumen, both require careful consideration. A detailed knowledge of the vascular access history, and any requirement in the future for complex cardiac surgery will inform the choice of potential access sites. Clinical examination is mandatory as the sick neonate may have loss of epithelial integrity in neck flexural creases, or rarely a tracheostomy, which might similarly increase the risk of catheter infection at the time of surgery. Such considerations may suggest the use of (normally) second choice venous access sites.

Although urgent venous access may be required, where possible, surgery should not be undertaken without getting control of any prior catheter-related (or other) focus of sepsis, to avoid seeding microorganisms onto the newly inserted surgical line. Previous use of the intended

vascular access site is an indication for vascular imaging if the clinical situation permits. Ultrasound will determine patency of the relevant access vein but cannot provide information concerning "central run off". In practice, this is rarely a problem unless the central veins have been repeatedly accessed or there is clinical evidence of SVC or IVC thrombosis. Under such circumstances magnetic resonance venography (MRV) would be advisable to avoid predictable central access failure and consequent prolonged surgery.

9.3.4.2 Surgical Procedure: Open Technique

The internal jugular vein is most commonly the access vein of choice. The external vein is often useful but is less reliable in terms of achieving reliable access to the SVC. The procedure is performed supine under general anaesthesia, with both modest neck extension and the face turned away from the chosen side of access to expose the anterior and posterior triangles with the intervening sternomastoid muscle. A small transverse incision is made in the lower third of the neck over sternomastoid. Its two heads are split to reveal the internal jugular vein within the carotid sheath. The vein is controlled with an appropriately sized monofilament or silastic "sloop" (Fig. 9.8), taking care to handle the vein directly as little as possible as it readily undergoes venospasm. The catheter is tunnelled from the anterior chest to the cervical incision. Cutting the catheter to the appropriate length is a matter of judgement, but using the inter-nipple line as a guide, it usually needs to be trimmed a variable length above this. The venotomy can be made either with scissors or a venepuncture needle in an attempt to avoid the need for suture closure with fine prolene (Fig. 9.9). After passing the catheter, intra-operative fluoroscopic screening is required to determine the position of the catheter tip often with the aid of a bolus of radiological contrast medium should the catheter be smaller than 4.2Fr. The catheter is secured at the exit site by suture fixation and dressings. Access to the inferior vena cava is usually achieved using the saphenous vein just proximal to where it joins the femoral vein. It is important to control other tributaries of the sapheno-femoral junction to prevent the catheter from being misdirected. Other routes include the inferior epigastric vein and the external iliac vein approached extraperitoneally.

The literature concerning optimum tip position is reviewed in more detail later. In routine open surgical vascular access the "distal SVC to proximal atrium" (for upper extremity access) has been recommended [19], although this remains highly controversial [20]. When using lower extremity access the ideal tip position is in the IVC level with the base of the 12th thoracic vertebra (T12), corresponding to the diaphragmatic IVC.

Rarely surgical haemodialysis access is required in the neonate. The catheters (e.g.

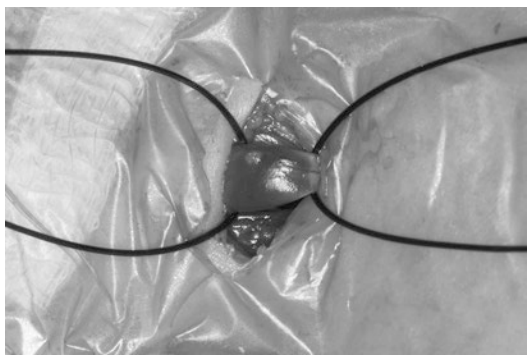

Fig. 9.8 Surgical exposure of the internal jugular vein between the heads of sternomastoid. The vein is "slooped" with silastic or monofilament suture prior to venotomy

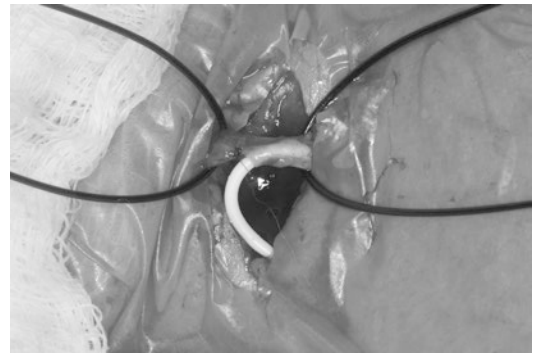

Fig. 9.9 The broviac line has been cut to length and passed via the venotomy to an estimated "junctional" position. The venotomy has been closed with fine prolene prior to confirming satisfactory tip position by fluoroscopy

Gamcath®) which are used for this purpose are of necessity quite rigid and therefore cannot exit on the chest wall when the internal jugular vein is accessed. For this reason an open procedure tunnelling the catheter is technically challenging and therefore these catheters are best inserted percutaneously. (Permcath® catheters, which are sufficiently flexible to exit the chest wall, are too large for most neonates.) To achieve and maintain long term adequate flow in the haemodialysis circuit it is advisable to use the largest internal lumen possible, preferably accessing the internal jugular vein rather than other access sites [21], and many (including the author) would argue in favour of having the catheter tip position preferentially sited within the proximal right atrium.

9.3.5 Percutaneous Versus Open Central Access

There is a developing body of opinion which believes that percutaneous access is superior to the open surgical approach [19, 22]. Given the lack of trauma to the vein associated with percutaneous access, this is an eminently reasonable proposition, especially with respect to the risk of thrombotic occlusion and potential future re-use of the vein. However there is no good supportive evidence in the literature to favour one approach over the other.

9.3.6 Complications of Venous Access

Venous access is associated with many complications. However, the three most frequent are catheter infection which may progress to septicaemia, occlusive complications such as fibrin sheath/vessel thrombosis and mechanical catheter complications such as dislodgement, migration and fracture.

9.3.6.1 Catheter Infection

The potential for the introduction of infection at the time of catheter insertion provides the rationale for consideration of the use of prophylactic antibiotics and other aseptic precautions at surgery. Although there is currently no strong evidence in relation to neonatal central line associated bloodstream infections (CLABSI's), level B evidence supports the following interventions to reduce the risk of CLABSI associated with whole population administration of TPN via central venous catheters; tunnelled/implanted catheters (confirmed only in long term use), antimicrobial coated catheters (demonstrated only in short term use), single lumen catheters, peripheral access as opposed to central access, appropriate central venous insertion site choice (internal jugular preferred to femoral vein), ultrasound guided venous access, maximal barrier precautions, and use of 2% chlorhexidene as a skin antiseptic [19]. Whether or not the benefits of these interventions will prove to be transferable to the neonatal cohort, we advocate the use of 2% alcoholic chlorhexidene pre-operative skin preparation, occlusive (opsite) draping, and a "no-touch" catheter handling discipline. At the very least, this focuses the mind of the surgeon on the danger of introducing infection. Logic also suggests that accurate fast surgery, minimal tissue handling, and the reduction of theatre "traffic" may also mitigate against primary catheter sepsis.

Cochrane reviews of systemic antibiotic prophylaxis at the time of central venous access in neonates [23] and in adult patients [19, 24] do not recommend their routine use. It has been suggested that fluconazole prophylaxis might be of value in certain high risk neonates. However a recent review of the literature has concluded that no trial has demonstrated a significant reduction in morbidity or mortality [25]. Contrary to generally received wisdom [19], and that of a prior Cochrane review in neonatal practice [26], a recent large RCT investigated the addition of 0.5 IU/mL Heparin to TPN administered through neonatal long lines (the HILLTOP trial) and demonstrated a significant reduction of culture-positive catheter-related sepsis [27]. Heparin-bonded catheters have failed to show any benefit in preventing catheter-related infection in children [28]. The use of antibiotic/heparin "locks" has also been shown to reduce the risk

of catheter-related infection in high risk groups [24, 29]. A neonatal study has recently recruited but not reported on the utility of a 15 min, 70% ethanol lock every third day. However, the benefit for neonates may be largely theoretical given that the requirement for continuous infusions effectively prevents the use of an antibiotic lock, or other form of lock for that matter.

Colonization of the exit site with microorganisms does not necessarily lead to invasive infection but provides a good rationale for tunnelling central catheters. It is advisable to monitor the skin flora at the exit site by regular swabs, thereby anticipating any invasive infection, and enabling active treatment of local cellulitis with an "informed choice" of intravenous antibiotics. There is no good evidence to suggest that any particular dressing is to be favoured in terms of preventing catheter-related infection [30]. Meticulous nursing care is essential both to keep the entry site infection free and to prevent the introduction of infection at the time of accessing the catheter. Where possible the line should not be used for routine sampling, and line interventions for treatment should be kept to the absolute minimum and performed with full aseptic technique. A Cochrane review investigating the use of in line filters has not conclusively demonstrated any benefit in terms of prevention of morbidity or mortality from introduction of secondary infection in neonates [31].

There is evidence that significant reductions in the incidence of CLABSI have been achieved in individual neonatal and paediatric intensive care units as a result of the implementation of "evidence-based catheter care bundles" [32]. This strategy postulates that CLABSI's result from lapses in technique at several levels of care [33]. Care bundles address multiple levels of intervention from insertion practice to daily line care. Level B evidence underlines the efficacy of such measures as; education and specific training, adequate hand washing policy, appropriate exit site care/dressing, hub disinfection/needle-free connectors, and regular changes of administration sets [19].

The incidence of catheter related sepsis is difficult to determine and depends critically on definition. The gold standard for line sepsis requires a positive culture from the catheter tip, once removed for presumed CLABSI. A positive blood culture, where the sample has been taken through the catheter, is a reasonable proxy, but does not exclude another potential source of blood stream infection. Exit site infection as evidenced by cellulitis or discharge of pus from the exit site may also be considered, but does not necessarily equate with colonization of the line and blood stream infection. Early diagnosis of CLABSI requires a high level of clinical suspicion and certainly should be considered in any neonate who is not "handling well". Changes in blood parameters such as C-reactive protein, liver function tests, white cell and platelet count, whilst all useful surrogate markers of infection, are frequently found to lag behind the onset of infection by 24 h or longer.

Quoted infection rates vary and are likely dependent on many variables. A recent large neonatal study of 294 peripherally inserted central catheters (PICC's) suggested a CLABSI rate of 17 per 1000 catheter days [34]. Another larger recent study of ultrasound guided percutaneous insertion of 500 Hickman® lines in children and neonates identified an infection rate of 3.2 per 1000 catheter days [22]. Local unpublished data from the author's institution of predominantly (87%) open surgical insertion of 336 central lines in children and neonates yielded an infection rate of 2.3 per 1000 catheter days. An exclusive study of 79 surgical neonates quoted a CLABSI rate of 9.9 per 1000 catheter days. A significant risk factor associated with CLABSI in this latter study was the presence of an intestinal stoma [35]. The inherent variability in the study populations, and variations in line type and mode of insertion, all conspire to make it difficult to draw firm conclusions about the factors that may be associated with neonatal CLABSI.

The commonest responsible organism is coagulase-negative *Staphylococcus* (representing 89% of blood culture isolations in a neonatal study [34]), thereby informing the choice of "best guess" antibiotic when treating suspected line sepsis. Other organisms such as coliforms are not infrequent culprits in surgical neonates. It has been

suggested that translocation of these organisms from the neonatal bowel may be the cause of such infection. Provided the neonate is not unduly compromised by the suspected line infection, an attempt to "sterilize" the line with a prolonged course of antibiotics is usually the first line of treatment. Overwhelming line sepsis demands urgent removal of the line. Where infection is due to more aggressive pathogens such as fungal species, *Pseudomonas* and *Staphylococcus aureus*, primary removal of the line is probably the best option. Failure to eradicate the organism after two attempts at sterilizing the line is another indication for line removal. However, in the setting of precarious venous access, or when venous access is likely to be prolonged (e.g. short bowel syndrome), consideration should be given to changing the line down the same track with appropriate antibiotic cover. Using this approach, the same vein can be used repeatedly over prolonged periods. Persistent low grade sepsis in the presence of a central line mandates the exclusion of bacterial endocarditis by echo-cardiography, since the consequences of missing this diagnosis may be disastrous. Timing of further central access following significant catheter-related sepsis ideally requires that the infection is appropriately treated before further surgical catheter manipulations are attempted.

9.3.6.2 Occlusive Catheter Complications

The presence of a catheter evokes the formation of a fibrin sheath around it which can usefully be employed to facilitate re-use of the catheter track for line "exchange" (see above). Sometimes, a fibrin sheath forms around the intravenous part of the catheter which, if extensive, can occlude the catheter lumen. Even in high-flow central veins the catheter can be a prothrombotic stimulus, resulting in partial or complete venous occlusion. Instillation of tissue plasminogen activator (tPA) or recombinant urokinase into a blocked catheter may be sufficient to re-establish patency. Sufficient urokinase (5000 units/mL saline) to fill the dead space of the catheter is left in situ for 30 min before attempting to aspirate the line. This procedure may be repeated once before removing the line and investigating to exclude line-related thrombosis if patency has not been restored. If successful, a contrast study through the line may reveal a fibrin sheath or local thrombosis, and give information both on tip position and adequacy of catheter "run off". The use of heparin "locks" to preserve line longevity in relation to occlusion is only of value when the line is accessed intermittently. There is grade 1B evidence to recommend against the prophylactic use of heparin in children with central venous catheters [10]. Similarly neonatal studies do not support the use of heparin in TPN as prophylaxis against catheter related thrombosis [26]. The use of heparin-bonded catheters cannot currently be recommended to prevent thrombosis or occlusive complications [28]. The general literature emphasizes (grade B) that thrombotic problems are reduced if the smallest possible catheter lumen size compatible with therapy is chosen, if an ultrasound-guided insertion technique is employed, and if the tip position is at or near the atriocaval junction [19].

When a neonatal central venous line or umbilical venous line is associated with confirmed thrombosis it should be removed. Management options include initial anticoagulation (grade 2C) with UFH or LMWH, or radiological monitoring alone (grade 2C). If thrombus propagation is demonstrated over time, anticoagulation with LMWH is recommended (grade 1B) for a minimum of 6 weeks [10].

The incidence of neonatal venous thromboembolism (VTE) is difficult to determine accurately, but data from Dutch and German national registries suggest an incidence of 0.1-0.5 cases per 10,000 births. The presence of a central line is the single most important contributory factor. It is often difficult to relate mortality directly to VTE, but certainly there is an appreciable mortality including stroke from paradoxical embolus [10].

9.3.6.3 Mechanical Complications

There is no fool-proof way of securing a central venous catheter before the Dacron cuff (if present) is firmly incorporated into the subcutaneous tissue. Reliance is usually placed on some form of exit stitch and the catheter dressing. Not infrequently incorrect application of the catheter

clamp to the non-reinforced part of the catheter results in fracture of the line. If sufficient undamaged external catheter is available distal to the fracture site, these can often be repaired with a commercially available kit. Prior to repair, the fracture site should be sealed with an adhesive clear dressing.

Extravasation of fluid into the subcutaneous tissue around the line track may similarly indicate fracture of the line or possibly occlusion due to a fibrin sheath (see above). A contrast study is indicated which usually identifies the underlying cause.

Removal of a central catheter can usually be performed under local anaesthetic at the cot side. This is not without risk and should not be left to the most junior member of the team. Usually the Dacron cuff can be dissected free via the entry site wound, but occasionally a second incision is required. Careful dissection on the fibrin sheath distal to the cuff allows the catheter to be retrieved. The major risk is cutting through the catheter beyond the cuff which might result in a catheter embolus (Fig. 9.10). Should this occur the retained catheter should be removed (size-permitting) by an interventional cardiologist using a snare inserted via the femoral vein.

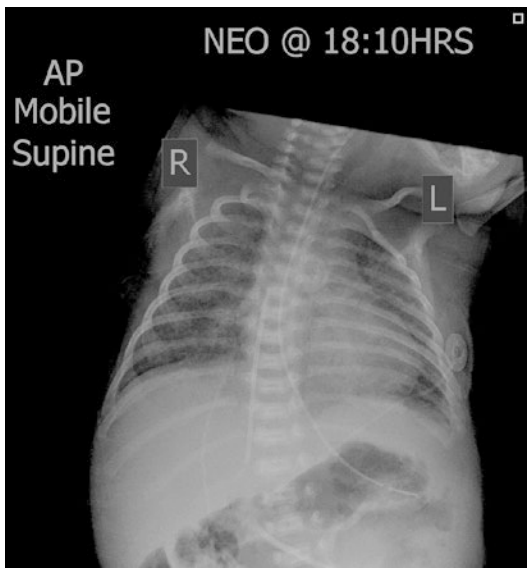

Fig. 9.10 Radiograph showing distal catheter embolus with the retained fragment free-floating in the right heart chambers following an unsuccessful attempt at removal. Such procedures should not be left to the surgical novice. This line was subsequently successfully snared and removed transfemorally in the cardiac catheter suite

9.3.6.4 Anatomical Variations

Variations in venous anatomy can trap the unwary. The most common of these is the left sided SVC. This structure drains into the coronary sinus and therefore a catheter tip lying in close relation to this structure should not be accepted. Occasionally manipulation of the catheter allows it to be directed through the innominate vein to the right SVC, but if this is not possible the attempt should be abandoned or the catheter left abnormally short as a temporizing measure.

Abnormalities of the inferior vena cava may result in dominant azygous or hemi-azygous systems. Neonates with congenital cardiac abnormalities may have significant abnormalities of venous drainage, and care needs to be taken not to encroach on the territory of the cardiac surgeon with respect to future cardiac surgical reconstruction.

9.3.6.5 Catheter Migration

There has been considerable debate about what constitutes an acceptable catheter tip position and consensus is by no means complete. The traditional approach has been to aim for a catheter tip position in the SVC. However, there is a body of expert opinion that emphasises improved performance and durability of a catheter if its tip is within the upper right atrium [20]. The European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines recommend a position in the lower third of the SVC, in a junctional position, or in the upper portion of the right atrium [19]. However, in a neonate the evidence probably supports a distal SVC tip position for PICC lines. Strictly applied this latter definition of acceptability leaves very little margin for error and probably results in many of these lines being left "short". Open insertions of central lines allow for greater control of final tip positions. Although the ideal tip position under such circumstances would be distal SVC or "junctional", many surgeons (including the author) would accept a proximal atrial position. Clearly what is "ideal" is not always possible, and for the individual

neonate a sub-optimal position may occasionally have to be accepted.

Significant migration of the catheter tip either proximally or distally has been described even when a satisfactory tip position has been documented at initial insertion. Distal migration of an upper extremity line can be the cause of arrhythmia, tricuspid valve vegetations, or pericardial effusion/tamponade. Proximal migration has been described with final line tip locations in the innominate, subclavian or internal jugular veins where occlusive/thrombotic problems are much more common.

9.3.6.6 Extravasation

Although subcutaneous extravasation is relatively common, this complication should be considered in unexplained pleural effusion or ascites. The diagnosis can readily be made by diagnostic tap of the relevant cavity, and removal of the offending catheter resolves the problem. The fatal association of cardiac tamponade with neonatal PICC lines led to the guideline that the tips of these catheters should always be left out with the cardiac silhouette [14].

9.4 Concluding Remarks

Vascular access in the neonate is a challenge to neonatologists, anaesthetists and surgeons alike. In common with other interventions in sick preterm infants, these procedures are associated with considerable morbidity and a significant mortality. The early recognition of complications related to vascular access and the subsequent assessment of management options requires considerable clinical judgement and experience. There remains ample scope for clinical research and technological advances in this field.

Radiology of Surgical Conditions in the Newborn

10

Alexandra L. Williams, Andrew Healey, and Laurence Abernethy

Abstract

When imaging the newborn baby, concerns of particular importance include temperature regulation, appropriate monitoring, minimising the radiation dose and careful use of contrast agents. Radiography and ultrasound examinations can be performed with portable equipment on the neonatal unit or intensive care unit, but more complex imaging usually requires transfer to the radiology department. It is essential that when newborn babies are transported to the Radiology Department, they are accompanied by suitably qualified personnel, capable of monitoring and managing the sick neonate. Temperature, pulse and oxygen saturation should be monitored. This involves a collaborative model of care, with close liaison between radiologist, neonatal unit and transfer team. Staff should be prepared to interrupt or abandon the procedure immediately if the baby becomes unstable. The utmost care must be taken when handling to ensure that vital lines and tubes are not disturbed or displaced.

This involves a collaborative model of care, with close liaison between radiologist, neonatal unit and transfer team. Staff should be prepared to interrupt or abandon the procedure immediately if the baby becomes unstable. The utmost care must be taken when handling to ensure that vital lines and tubes are not disturbed or displaced.

Neonates have a poor ability to maintain body temperature, and hypothermia can lead to acidosis and surfactant deficiency. Whenever possible the baby should be kept in a temperature-controlled incubator. Only the relevant body part should be exposed, and for the shortest time possible, in order to minimize heat loss. In the radiology department the rooms should be warm. To avoid heat loss in more prolonged procedures, chemical warming blankets can be placed under the baby, or the baby can be covered with a sealed clear plastic wrapping and a warming device used to blow warm air under the wrapping. Staff should check that baby is dry at frequent intervals and the core body temperature should also be monitored. Prolonged procedures without monitoring, with an uncovered baby lying in a pool of cold liquid (urine, contrast media, or skin preparation solution) must be avoided.

The skin of newborn babies is very fragile. Care should be taken to avoid pressure points and hyperextension of limbs. Adhesive drapes should be avoided, as should 2% chlorhexidine skin preparation solution, which may cause chemical burns in premature infants.

10.2 Radiation Dose

The newborn baby, like the fetus, is particularly sensitive to the effects of ionising radiation and is at greatest risk of radiation-induced disease. It is essential that when considering exposing a neonate to ionising radiation the ALARA principle is adhered i.e. that every effort is made to ensure that exposure to ionising radiation is kept "As Low As Reasonably Achievable". This relies on careful consideration by the requesting clinician, close collaboration between radiologist and clinician, and meticulous technique on the part of the radiologist and radiographer. Digital pulsed screening with low pulse rates, and removal of the anti-scatter grid, help to reduce the absorbed radiation dose. Screening times should be kept as short as possible. The most effective means of reducing radiation exposure is simple: no examination involving exposure to X-rays should be performed unless it is clinically justified. Whenever appropriate, ultrasound should be used in preference to fluoroscopy and computed tomography (CT).

Contrast may be used intravenously in computed tomography and magnetic resonance imaging, and during fluoroscopy to assess hollow organs and lines and tubes. In the past, the use of contrast media in small children was associated with high risk. Neonates are vulnerable to the smallest fluid shifts and careful consideration to fluid-balance is necessary when administering IV or intra-luminal contrast agents.

If ionic, high osmolar contrast media are used for gastrointestinal contrast studies, there is a risk of massive fluid shift into the bowel, which can rapidly deplete extracellular fluid and result in circulatory collapse. If non-ionic contrast is given by mouth, there is a risk of pulmonary oedema if aspiration occurs. The use of non-ionic low osmolar contrast agents has reduced (but not completely eradicated) the risks associated with the use of contrast.

There are some special indications for using hyperosmolar water-soluble contrast media, such as sodium meglumine amidotrizoate (Gastrografin, Bayer Schering Pharma AG, Berlin), in the gastrointestinal tract in infants, although any use of these agents is potentially hazardous and should only be attempted by experts, after careful consideration of the risks and benefits. These indications include suspected meconium ileus and meconium plug syndrome, in which enemas performed with hyperosmolar contrast can have a therapeutic effect by drawing fluid into the bowel, lubricating and emulsifying the colonic content, and stimulating colonic motility. When used for these indications, Gastrografin is usually diluted 1:2 or 1:3 with saline or water. Even when diluted, hyperosmolar contrast agents may cause rapid fluid shifts, and so must be used with great care in small infants. Dehydration should be corrected before the procedure is commenced, an intravenous fluid infusion should be running, and careful monitoring should be performed during and after the

procedure. Gastrografin may also have a beneficial effect when administered orally to older infants with cystic fibrosis and distal intestinal obstruction syndrome [1].

When iodinated contrast media are administered intravenously, for example for contrast-enhanced CT, special care must be taken because of the immature renal function of neonates. The dose should be carefully calculated on the basis of body weight and the iodine content of the contrast medium, in accordance with the manufacturer's recommendations.

MRI contrast agents containing gadolinium should be used with caution in neonates and young infants, because of immature renal function and the possible risk of nephrogenic systemic fibrosis (NSF). The most stable macrocyclic chelates are generally considered to be safest. Children at risk for renal impairment (for example, those with known medical renal disease or urinary tract structural abnormalities) should be identified and screened. Gadolinium contrast agents should be avoided in acute kidney injury or chronic kidney disease with eGFR <30 mL/min/1.73 m^2. The current recommendation for neonates and infants is that only one dose should be given during an examination, and should not be repeated within 7 days.

10.3 Imaging Modalities

A wide range of modalities are used for neonatal imaging, each of which has a role to play in the care of the surgical neonate. Close collaboration and timely discourse between clinician and radiologist ensures optimum information is obtained from the correct examination with the least radiation exposure and with minimal stress to the sick neonate.

10.3.1 Ultrasound

Ultrasound is ideally suited to the examination of neonates and young infants. Ultrasound examination is painless and non-invasive, and involves no exposure to harmful ionising radiation. With patience, diagnostic images can be obtained even with a restless child. The plane of imaging is infinitely variable and can be adapted to the anatomical location of the lesion. Colour Doppler is uniquely valuable in allowing assessment of blood flow in real time; making it immediately apparent whether a fluid-filled structure is cystic or vascular. In paediatric ultrasound it is helpful to have a range of transducers with different sizes and footprints. Ultrasound is readily accessible and portable, can be used with relative ease on a sick neonate in an incubator, and is often the initial investigation of choice. Inexpensive portable ultrasound devices are now widely available. However, ultrasound does have limitations. It is highly operator dependent. Little information is given on the function of the organ, though ultrasound of the bowel can offer information regarding peristalsis. The field of view of ultrasound is limited in some anatomical locations, as ultrasound has limited penetration of bone and cannot penetrate air. Although ultrasound equipment is relatively inexpensive, neonatal ultrasound can be resource intensive, as successful examination of a restless baby may be time-consuming and requires considerable expertise. Scrupulous attention to hygiene is necessary to minimise the risk of transmission of infection between patients, particularly when using portable ultrasound. Ultrasound transducers should be cleaned and disinfected between examinations, using an approved proprietary broad-spectrum surface disinfectant; in addition, hand washing between examinations should never be forgotten.

10.3.2 Plain Radiography

Although a range of more complex imaging modalities are available, the plain radiograph still has an important role as it is widely available, and can be performed rapidly and with portable equipment. Chest and abdominal radiographs are the first line of investigation in many neonatal surgical conditions, and can often provide the diagnosis without further imaging. Plain radiography provides anatomical information in two dimensions and gives information regarding the components of a substance, whether fat, gas, calcium and bone. Abdominal radiographs provide information

about bowel obstruction, the presence of free or intra-mural gas, and the location of masses or presence of abnormal calcification. However, plain radiography offers no dynamic or functional information and provides only a snapshot of one moment in time.

It is essential that exposure factors are optimized and the beam is well collimated to ensure a minimal dose to the neonate. Radiography in the sick neonate is usually performed in the supine position, particularly if being performed with the baby in the incubator, with decubitus films if there is concern regarding pneumoperitoneum. Care must be taken to ensure drips and lines are not disturbed.

10.3.3 Fluoroscopy

Fluoroscopy is essentially real time radiography, which often involves the use of contrast media to allow visualization of a hollow organ. Contrast can be given orally, rectally, intra-vesically, intra-arterially or intravenously, via stomata and into tubes and lines to assess patency and position. Optimum use of pulsed fluoroscopy and last image capture ensure the exposure to ionizing radiation is kept to a minimum.

10.3.4 Computed Tomography (CT)

CT offers cross sectional demonstration of anatomy, providing visualisation of anatomical details in the axial plane. These images can be reconstructed into sagittal and coronal planes and 3D reformats. Computed tomography is an accessible, rapid test but requires transfer of the sick or ventilated neonate to the radiology department. The use of contrast material may be necessary, particularly for imaging the chest and abdomen. In the neonate, with little body fat, the tissue contrast is poor, making interpretation more challenging than in the older child. Every effort should be made to keep the radiation dose as low as possible, by "right-sizing" the imaging parameters: kV, mAs, slice thickness, and area of coverage should all be individualized. There is no justification for using preset adult CT parameters, which deliver an unacceptably high radiation dose.

10.3.5 Magnetic Resonance Imaging (MRI)

The greatest benefit of MRI is that it does not involve the use of ionising radiation. Using a powerful magnetic field and radiofrequency electromagnetic impulses, MRI produces detailed anatomic or functional images in any plane, with high contrast resolution, providing information about the composition of the tissue being imaged. To date, no long-term adverse effects of MRI have been found at the field strengths routinely used in clinical practice, so long as all safety procedures are rigorously followed. Hearing protection is essential. Issues include the frequently remote location of MR scanners and the need to transport a neonate to the scanner, and poor access to the child while in the scanner. There are difficulties ensuring adequate monitoring and minimising movement during lengthy scans. In neonates the "feed and wrap" technique reduces movement and often avoids the need for sedation or general anaesthetic.

10.3.6 Radio-Isotopes

Nuclear medicine provides information on the pathophysiology of an organ with the injection or ingestion or radiopharmaceuticals. This is of limited use in the investigation of the very sick or ventilated neonate but still has a place (examples—hepatobiliary imaging with Tc^{99m} HIDA for suspected biliary atresia, renal imaging with Tc^{99m} MAG-3 for obstructive uropathy, abdominal scanning with Tc^{99m} pertechnetate for Meckel's diverticulum, thyroid scanning with Tc^{99m} pertechnetate or I^{123} in congenital hypothyroidism, I^{123} meta-iodobenzylguanidine (MIBG) in suspected neuroblastoma, fluoroDOPA PET CT in congenital hypoglycaemia of infancy). Anatomical resolution is relatively poor, but radio-isotope imaging in these situations can provide valuable functional information that is not obtained with other modalities.

10.3.7 Interventional Radiology

Interventional radiology is the application of minimally invasive diagnostic and therapeutic techniques under image guidance, often utilizing ultrasound guided modified Seldinger needle puncture technique, and fluoroscopic guided flexible preshaped wires and catheters together coaxially to perform therapy. CT and MRI can also be utilized for guidance [2]. Vascular access can be obtained by the interventional radiologist under ultrasound and fluoroscopic guidance.

Gastrostomy is often performed surgically in the neonate at the same time as a definitive surgical correction of bowel anomalies; however percutaneous gastrostomy can be performed in certain situations. If abdominal surgery is not imminently planned but gastric feeding is required a direct percutaneous puncture of the stomach using ultrasound or fluoroscopic guidance can be performed. Ultrasound guidance can be useful if a tracheo-oesophageal fistula is present not allowing endoscopic access or fluoroscopic contrast instillation via NG tube.

Percutaneous drainage of any viscus, abscess or fluid collection (ascites, pleural or pericardial effusion) can be performed under ultrasound guidance (Fig. 10.1). Percutaneous core biopsy,

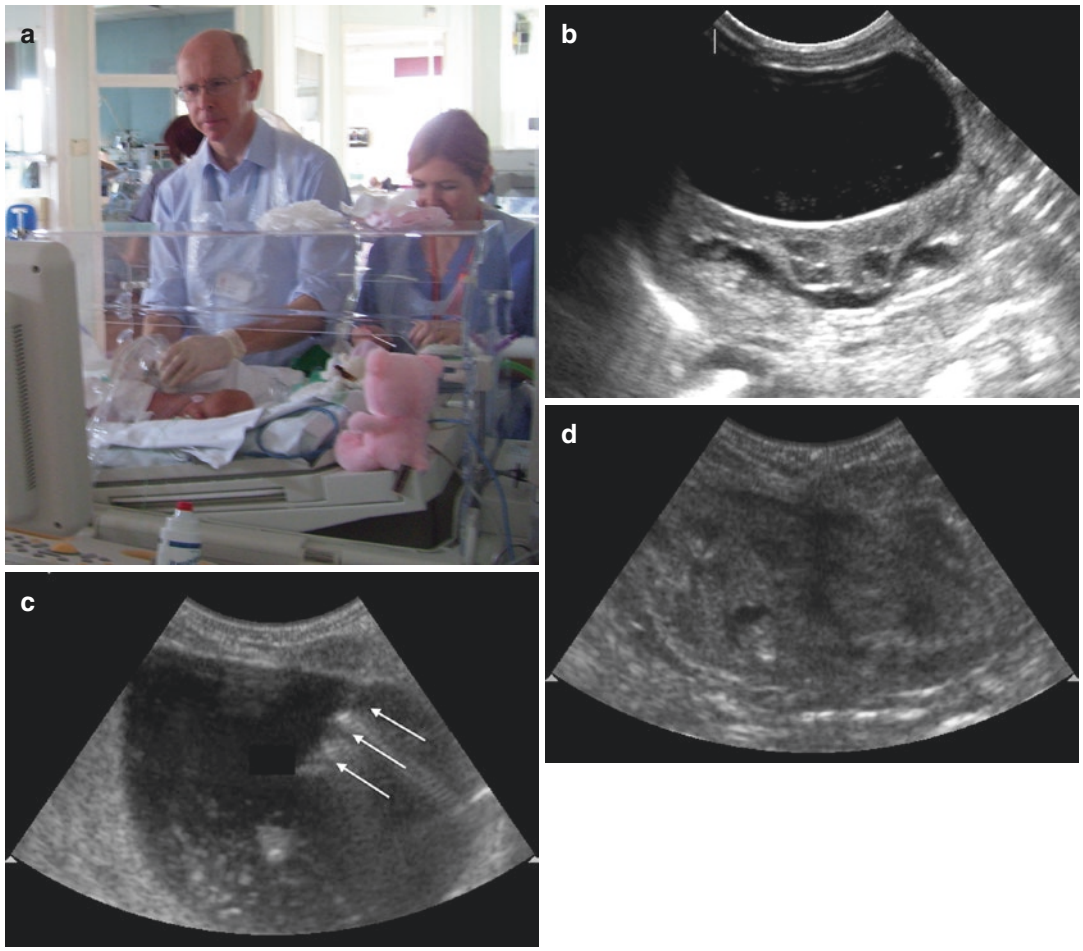

Fig. 10.1 Interventional procedures in the neonate. (**a**) Percutaneous aspiration of a perinephric collection under ultrasound guidance, performed on a premature baby on a neonatal unit. (**b**) Ultrasound image showing perinephric collection. (**c**) The needle path can be seen from the skin surface into the collection (*arrows*). (**d**) Minimal residual perinephric fluid following aspiration

usually performed under real time ultrasound guidance, is an extremely safe and effective way to obtain a tissue diagnosis allowing definitive surgical intervention. Foreign bodies can be recovered using image guidance and a snare device.

10.4 Positioning of Lines, Tubes and Catheters

Newborn babies with surgical conditions often require intensive medical care and the placement of multiple lines, tubes, and catheters. In small babies the correct placement of tubes and catheters may require considerable skill, and there is little latitude for error. Inappropriate placement may be dangerous. Plain radiographs and ultrasound are valuable for confirming the course and location of these devices, but accurate interpretation may be challenging and requires knowledge and experience of the wide range of appearances of malposition and potential complications.

In the newborn baby, the umbilical vein and artery provide an accessible route for the placement of catheters for therapy and monitoring. Correct placement may be challenging and should always be checked with radiographs of the chest and abdomen. The preferred location of the tip of an umbilical venous catheter (UVC) is at the junction between the inferior vena cava and the right atrium. If not advanced far enough, the tip of the UVC may lie in the umbilical vein or its recess, below its confluence with the left portal vein. Fluids infused via a UVC in this position will be delivered directly to the liver through the portal venous system. Oestreich (2010) [3] has demonstrated that a little air is frequently visible in the umbilical vein or portal venous system following UVC insertion; this is not in itself harmful, but may be recognised on the initial placement radiograph, and is helpful in assessing the position of the UVC.

The correctly positioned UVC should pass through the umbilical vein and its confluence with the left portal vein into the ductus venosus, which normally obliterates a few days after birth. The ductus venosus joins one of the hepatic veins to drain into the inferior vena cava just below the right atrium. It is, however, possible for the malpositioned UVC to enter the left portal vein, or to pass to the right into the right portal vein or the main portal vein, from where is possible for it to pass into the splenic vein or superior mesenteric vein. UVC placement in these positions carries a risk of inducing portal vein thrombosis. If advanced too far the UVC may pass into the right atrium, right ventricle and pulmonary artery, or through a patent foramen ovale into the left atrium. Cardiac tamponade, pulmonary embolism and lung abscess are among the possible complications. UVC malposition in a hepatic vein can cause segmental liver infarction [4] (Fig. 10.2).

The umbilical artery can be used for arterial access during the first 5–7 days of life, but it is rarely used after 7–10 days. An umbilical artery catheter (UAC) provides direct access to the arterial blood supply and allows continuous measurement of arterial blood pressure, arterial blood gas sampling, and intravascular access for fluids, medications, and exchange transfusion when other routes are not available. On radiographs, the correctly positioned UAC should be seen entering the umbilical cord and passing inferiorly to the internal iliac artery, then turning cephalad to enter the aorta and proceeding in a straight line to the left of the vertebral column. Its tip should lie above the diaphragm between levels of the T6 and T9 vertebrae. This position is above the origins of the coeliac axis (T12), the superior mesenteric artery (T12-L1), and the renal arteries (L1) (Fig. 10.2).

10.4.1 Nasogastric Tubes

The correct position should be assessed on a plain film; a position of the tip below the level of the diaphragm should be confirmed prior to use to avoid potentially catastrophic complications of feed or medications infused into the lungs. Careful evaluation of the course of tubes and lines is also required, for example an abnormal course of the NG tube can be due to mass effect from mediastinal pathology (Fig. 10.3).

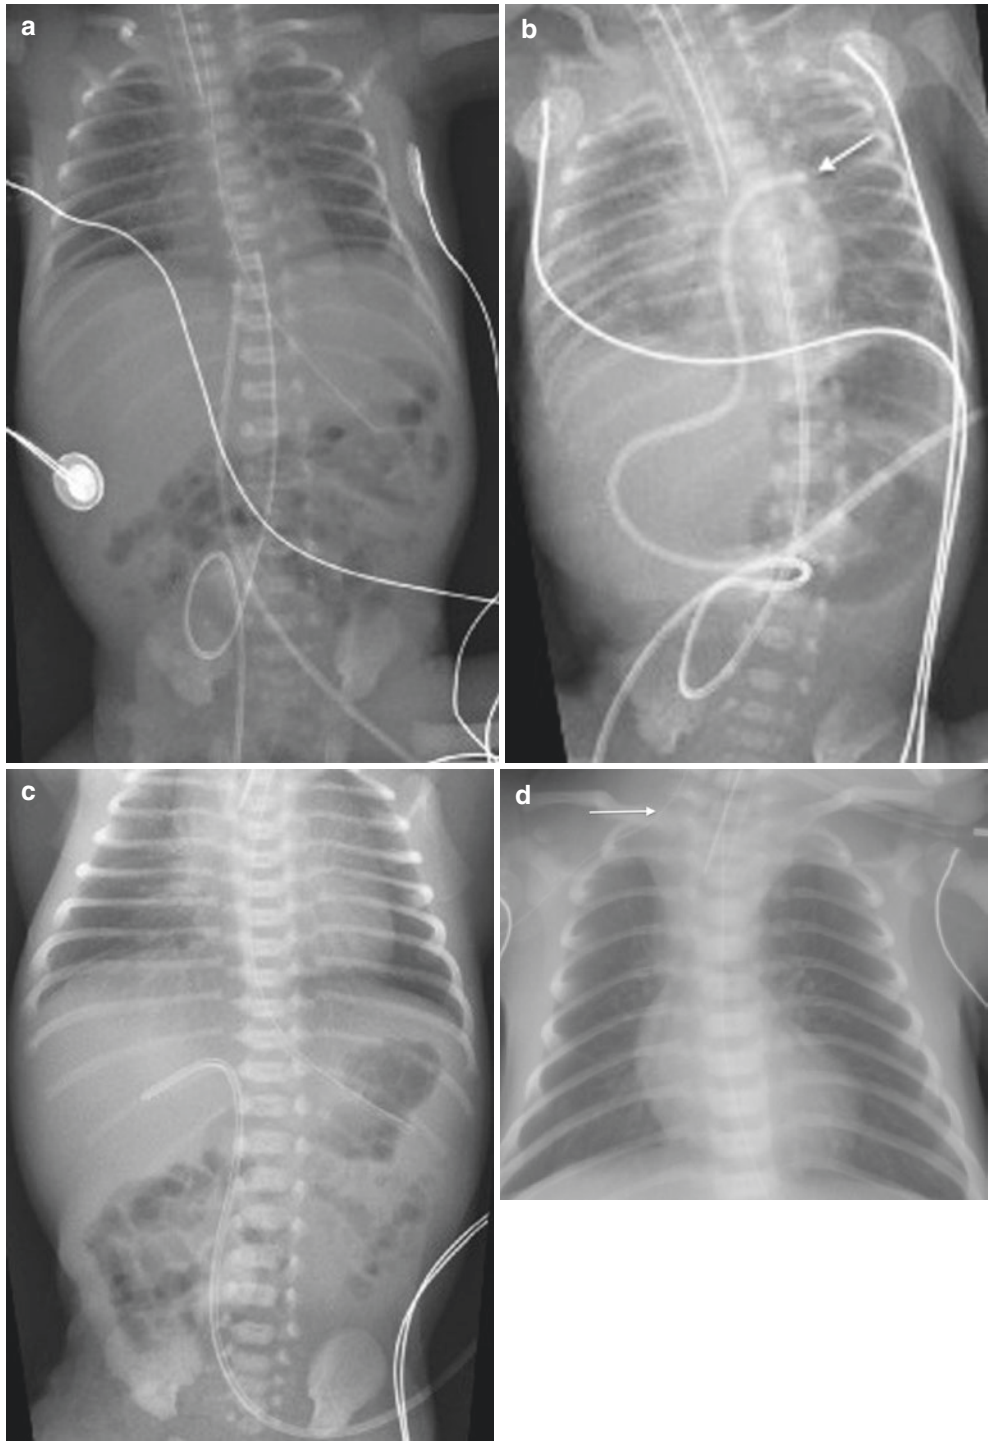

Fig. 10.2 Normal and abnormal positions of vascular access lines. (**a**) Chest and abdominal radiograph shows normal positions of umbilical arterial catheter (UAC) and umbilical venous catheter (UVC). The endotracheal tube and nasogastric tube are also in a satisfactory position. (**b**) Misplaced UVC with its tip in the pulmonary vasculature. (**c**) UVC projected over the liver and coursing to the right, which suggests that the tip lies in the right portal vein. (**d**) Malpositioned right PICC line seen passing cranially into the internal jugular vein

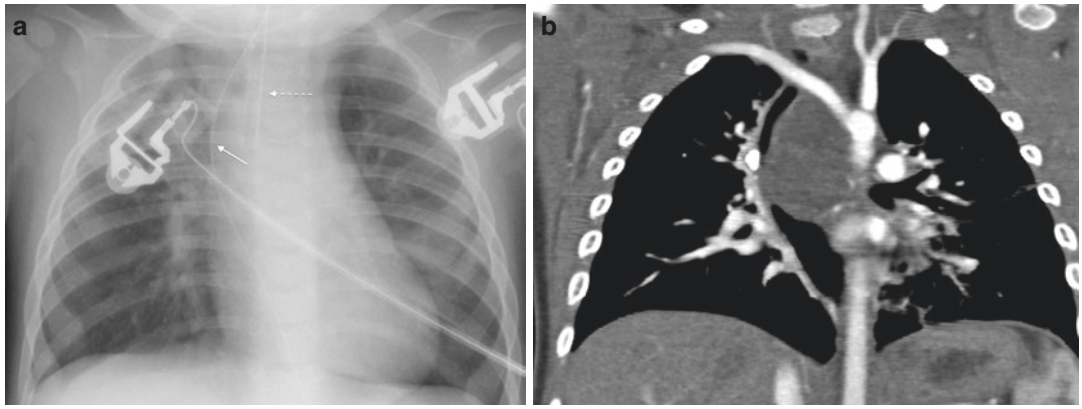

Fig. 10.3 Abnormal course of the NG tube. (**a**) Deviation of the NG tube suggesting mass effect. (**b**) CT confirms the presence of a mediastinal mass

10.4.2 Endotracheal Tubes

The correct position for the tip should be above the carina and below the thoracic inlet. An endotracheal tube, which has been advanced into a main bronchus, will cause hyperinflation of the ipsilateral lung and collapse of the contralateral lung (Fig. 10.4).

10.5 The Neonate with Jaundice

Neonatal jaundice is common, occurring in 60% of full term and 80% of preterm infants [5]. In the first 2 weeks of life this is usually due to an accumulation of unconjugated bilirubin, resulting from immaturity of the conjugating enzyme glucuronyl transferase. This is commonly known as physiological jaundice of the neonatal period and peaks at day 5–7. Persistence of jaundice beyond 2 weeks is abnormal and merits investigation.

Biochemical analysis will determine whether bilirubinaemia is unconjugated or conjugated. Prompt investigation of a conjugated hyperbilirubinaemia is required. Causes include both medical and surgical pathologies. Imaging plays an important part in differentiating intrahepatic from extrahepatic causes of persisting neonatal jaundice and can further clarify pathology in extrahepatic causes. Diagnosis of intrahepatic causes relies heavily on laboratory tests, however imaging does play a vital role in providing complementary information in neonates with complex syndromes as a cause of the jaundice, and with ultrasound guided liver biopsy which ensures a higher diagnostic yield with reduced complication rates (Fig. 10.5).

The three main causes of neonatal jaundice are biliary atresia, hepatitis and choledochal cyst.

The first line imaging investigation in a neonate with persistent conjugated hyperbilirubinaemia is ultrasound. Ultrasound is independent of liver function and can differentiate obstructive causes such as choledochal cyst, bile plug syndrome or stone disease from non-obstructive causes. Features of biliary atresia may be demonstrated and in addition, ultrasound of the abdomen may detect more unusual unsuspected causes of jaundice such as adrenal haemorrhage.

Ultrasound provides exquisite anatomical delineation of the liver, allowing an assessment of size and echotexture. The gallbladder and biliary tree can be evaluated and the whole abdomen can be imaged to look for associated findings such as ascites.

HIDA scan involves the intravenous injection of a Technetium 99 m labelled tracer, which is taken up by the normal liver, excreted in the biliary tree and accumulated in the gallbladder, eventually appearing in the bowel.

MRCP has replaced the traditional ERCP in many clinical situations. This offers detailed anatomical imaging of the biliary tree, and provides further information about the other upper

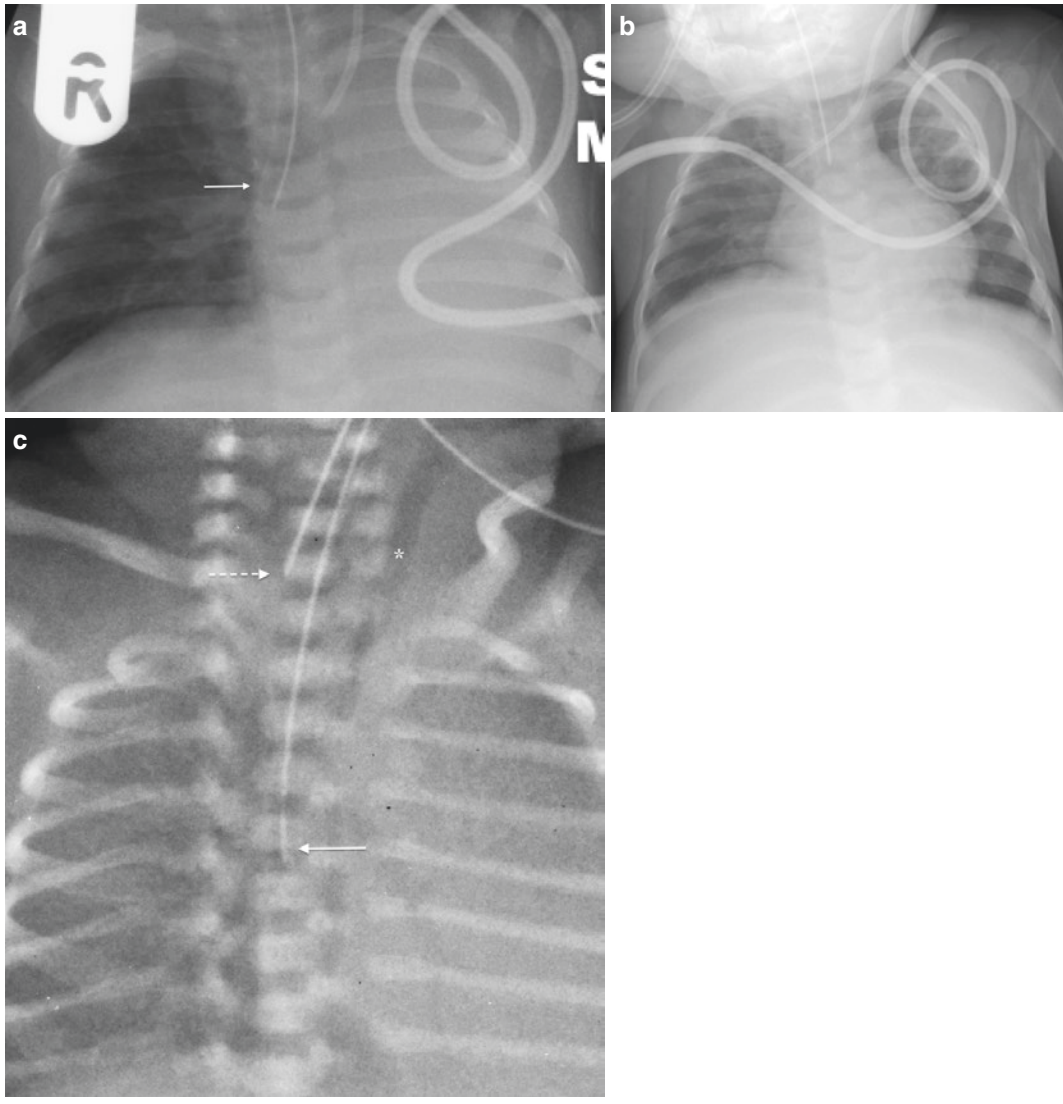

Fig. 10.4 Abnormal position of the endotracheal tube. (**a**) Chest radiograph demonstrates malpositioned ET tube with the tip in the right main bronchus. There is resulting left lung collapse with leftward mediastinal shift and complete opacification of the left hemithorax. Note also the mediastinal and intercostal drains and upper mediastinal clips. Repositioning of the tube results in re-expansion of the lung (**b**). In (**c**) a nasogastric tube is seen in the mid-oesophagus, and an ET tube is noted lying adjacent to this in the upper oesophagus. Air can be seen in the trachea (*)

abdominal organs. It does not involve ionizing radiation and is non-invasive and therefore does not harbour the risks of ERCP such as pancreatitis. ERCP still has a role where therapeutic procedures are to be performed or where the information gained from MRCP is inadequate, however this technique is used much less commonly in children, particularly in neonates, than in adult practice.

10.5.1 Biliary Atresia and Neonatal Hepatitis

Prompt diagnosis of biliary atresia permits early surgery, avoiding early irreversible cirrhosis and the need for transplantation. The main differential for biliary atresia is neonatal hepatitis. Many imaging features of these conditions overlap and there are no specific diagnostic imaging features

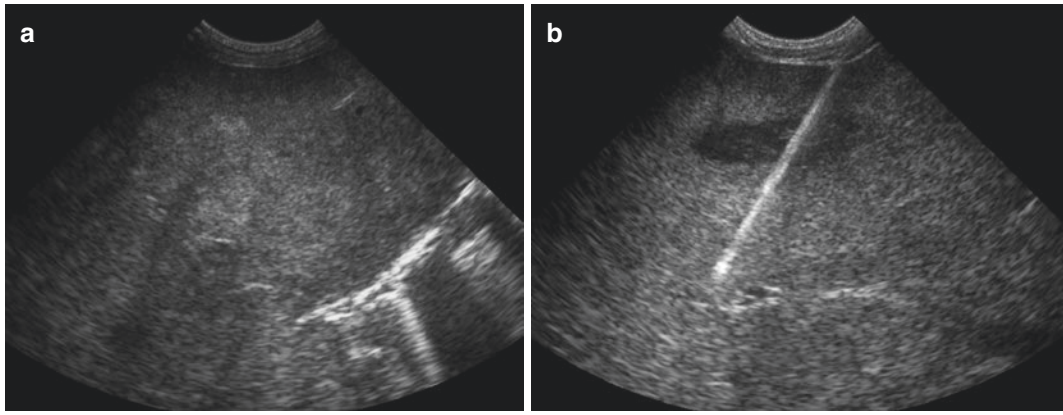

Fig. 10.5 Neuroblastoma with liver metastases. Ultrasound image (**a**) showing diffuse heterogeneity of the liver in a patient with neuroblastoma. (**b**) Percutaneous biopsy under ultrasound guidance. The needle track is visible as a hyperechoic linear focus

of neonatal hepatitis or biliary atresia. Ultrasound findings common to both conditions include enlargement of the liver with increased echogenicity and no evidence of intra-hepatic bile duct dilatation. An absent or small gallbladder occurs in 20–25% cases of atresia [6] and it has been noted that there is no variation in length following a meal in those with atretic gallbladders [6, 7]. However, a small gallbladder may also be seen in severe hepatitis due to reduced bile production and storage. A lack of visualization of the CBD with ultrasound is not diagnostic of biliary atresia.

A more specific finding in biliary atresia is the triangular cord sign, which represents the fibrous remnant of the hepatic duct junction. This is seen as an echogenic structure anterosuperior to the portal vein (Fig. 10.6). This sign is thought to be highly sensitive and specific for biliary atresia [8]. Ultrasound may also show evidence of liver failure, such as ascites, reversal of portal venous flow and splenomegaly. In addition, biliary atresia is associated with polysplenia syndrome in 10–20% [9], which may also be revealed on ultrasound. Correlation with any existing plain radiographs is necessary to identify associated vertebral and rib segmentation anomalies, typical of Alagille syndrome (arteriohepatic dysplasia), in which the ultrasound findings are similar to those of isolated biliary atresia.

Fig. 10.6 Biliary atresia. High resolution ultrasound of the liver demonstrates a triangular echogenic area (*arrow*) anterior to the portal vein at the porta hepatis. This represents the fibrous remnant of the obliterated extra-hepatic ducts and is known as the triangular cord sign

If biliary atresia is suspected or cannot be excluded on the basis of ultrasound, a HIDA scan is performed. Absence of tracer in the

gallbladder at 24 h suggests biliary atresia, however this appearance may also be seen in severe cases of neonatal jaundice due to poor hepatocellular function. Enhancing liver function with phenobarbitone may help encourage production and excretion of tracer into the small intestine in neonates with hepatitis (Fig. 10.7).

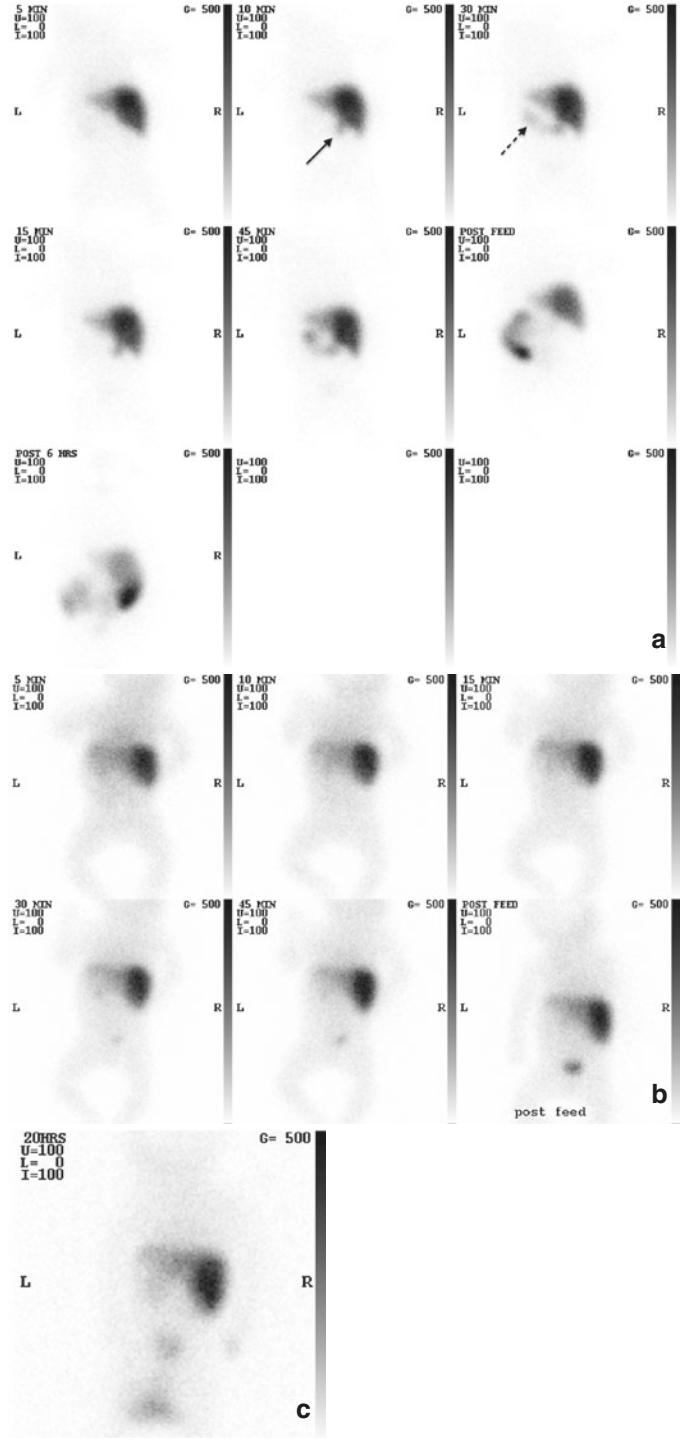

Fig. 10.7 HIDA scan. (**a**) Normal. Note initial accumulation of tracer in the liver. There is progressive passage of radioisotope into the gallbladder at 10 min (*arrow*) and thereafter into the bowel (*broken arrow*), particularly post feed. (**b**) Biliary atresia. Note the persistent tracer accumulation in the liver, lack or radioisotope in the biliary tree or gastrointestinal tract, high background activity and urinary excretion. The appearances are unchanged on the 20 h post injection acquisition (**c**)

MR cholangiography uses the signal from the fluid in the biliary tree to produce images, and is therefore useful in delineating the extrahepatic biliary tree. Identification of the extrahepatic biliary tree excludes biliary atresia. Other pathologies such as choledochal cysts can be excluded.

Rarely percutaneous cholangiography and ERCP may be required to demonstrate biliary atresia, and can also be used to demonstrate the level of the atresia. For a definitive diagnosis ultrasound guided percutaneous biopsy may be necessary.

10.5.2 Choledochal Cysts

Choledochal cysts are thought to originate from an inherent weakness in the biliary tree during development. They may be found incidentally on antenatal screening, or may present in the neonatal period with jaundice or an abdominal mass. Rarely, choledochal cysts may rupture and resulting in an acute presentation with biliary peritonitis.

Ultrasound typically shows an anechoic, thin walled, cystic lesion, in a subhepatic or periportal location, seen separate to the gallbladder and communicating with the biliary tree. No internal blood flow is seen with colour Doppler ultrasound. Secondary intrahepatic duct dilatation and complications such as cholelithiasis may be seen. There is a recognised association with biliary atresia [10]. This diagnosis is important to make in conjunction with that of choledochal cyst as the surgical management will differ.

HIDA scan may also be used to aid in the diagnosis of choledochal cysts, particularly if communication with the biliary tree cannot be established, as this helps to differentiate from a parenchymal liver cyst. On occasion, however, choledochal cysts fail to accumulate tracer and may be missed [5]. MRCP is the definitive investigation of choice to further delineate the anatomy of the biliary tree in cases of obstructive jaundice; however PTC or ERCP still play a role in the diagnosis of difficult cases and in managing the complications.

10.5.3 Inspissated Bile and Cholelithiasis

Risk factors include prematurity, sepsis, dehydration, intestinal atresia, neonates receiving total parenteral nutrition, those with cystic fibrosis and those on medications such as furosemide. An ultrasound demonstrating a dilated gallbladder and biliary tree filled with echogenic sludge in a neonate with jaundice is highly suggestive of inspissated bile syndrome. This is usually managed medically without further imaging. Persistent inspissated bile can be flushed out of the biliary tree following percutaneous transhepatic cholangiography and insertion of a drainage catheter (Fig. 10.8).

Bile pigment gallstones occur quite frequently in the neonatal period and are often an incidental finding on abdominal ultrasound scans performed for other reasons. They usually resolve spontaneously, but may rarely cause obstruction. On ultrasound, intra and extra-hepatic bile duct dilatation may be seen, with an obstructing echogenic focus causing posterior acoustic shadowing.

10.5.4 Spontaneous Perforation of the Bile Ducts

This rare cause of neonatal jaundice usually occurs at the confluence of the common hepatic and cystic duct, and is thought to be due to a congenital weakness in the wall of the ducts or due to a distal obstruction. Ultrasound may show a complex loculated subhepatic collection or ascites. On HIDA scans, tracer may be seen in the peritoneum allowing the diagnosis to be confirmed.

10.6 The Neonate with Failure to Feed/Inability to Pass NG Tube

10.6.1 Choanal Atresia

Unilateral choanal atresia will often have a delayed diagnosis, and there should be a high index of suspicion if an NG tube cannot be passed via one of the nostrils. Bilateral atresia presents

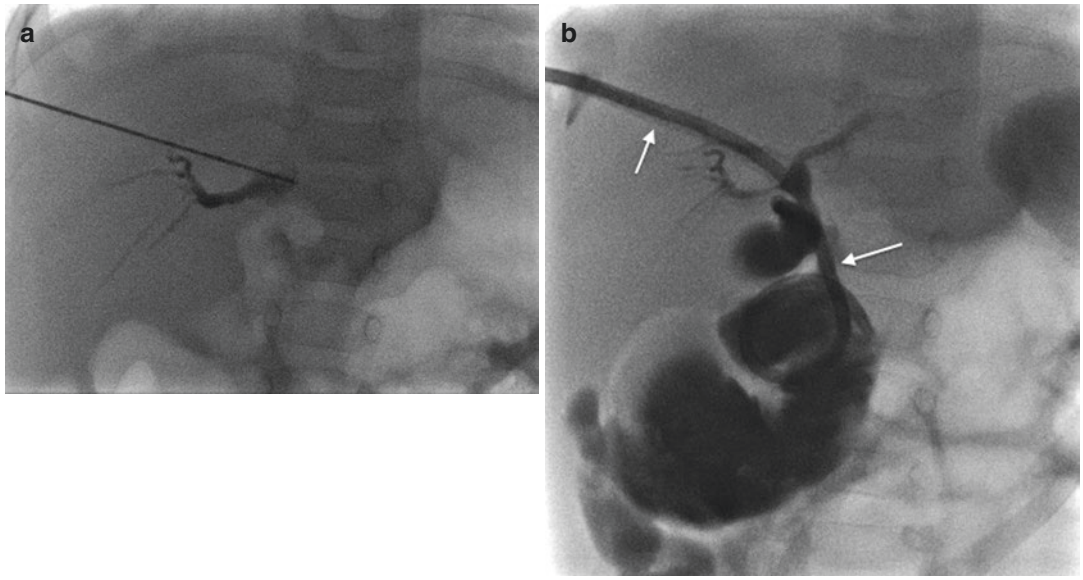

Fig. 10.8 Percutaneous transhepatic cholangiography and drainage. (**a**) contrast injected via the initial puncture needle outlines the right hepatic duct and branches, confirming position. Using Seldinger technique a guidewire is passed through the needle, and a pigtail drainage catheter (*arrows*) is then passed over the guidewire (**b**)

with gasping while feeding. Computed tomography (CT) of the paranasal sinuses will confirm unilateral or bilateral choanal atresia, and distinguish between membranous and bony atresia.

10.6.2 Oesophageal Atresia and Tracheo-Oesophageal Fistula

The neonate with oesophageal atresia (OA) usually presents in the immediate post partum period with respiratory distress, cyanosis, excessive secretions and failure to feed, although maternal polyhydramnios may raise the suspicion in utero. Failed attempts to advance an NG tube are suggestive of an oesophageal obstruction. A plain radiograph with a NG tube in situ can offer a great wealth of information (Fig. 10.9).

Often a pouch-like gas filled radiolucency can be seen in the neck, and if attempts at inserting an NG or Replogle tube have been made, the tip will be seen high in the neck or curled back on itself. In most cases of OA a co-existing trachea-oesophageal fistula (TOF) is confirmed by the presence of bowel gas, In oesophageal atresia, without distal fistula, there will be an absence of bowel gas. However, the absence of bowel gas does not completely exclude the presence of a TOF. Vertebral segmentation anomalies and cardiomegaly point to the diagnosis of the VACTER syndrome/association. Down's syndrome is associated with oesophageal atresia and tracheo-oesophageal fistula, and also with duodenal atresia, which may co-exist (Fig. 10.10).

The less common H-type tracheo-oesophageal fistula may be demonstrated on a conventional contrast swallow, but is often a difficult and elusive diagnosis, requiring a prone tube oesophagogram, sometimes supplemented by endoscopy of trachea and oesophagus. The oesophagogram is performed using non-ionic hypo-osmolar contrast agent. Using lateral imaging contrast is injected via the NG tube with the patient in the prone position and the tube is slowly withdrawn to the pharynx, in order that flow of contrast will be directed into any patent fistula (Fig. 10.11). Care must be taken to ensure that any contrast seen in the lungs or trachea is via a definite fistula and not aspiration from the pharynx. It is argued by some that a tube oesophagogram is not required following a normal contrast oesophagram [11].

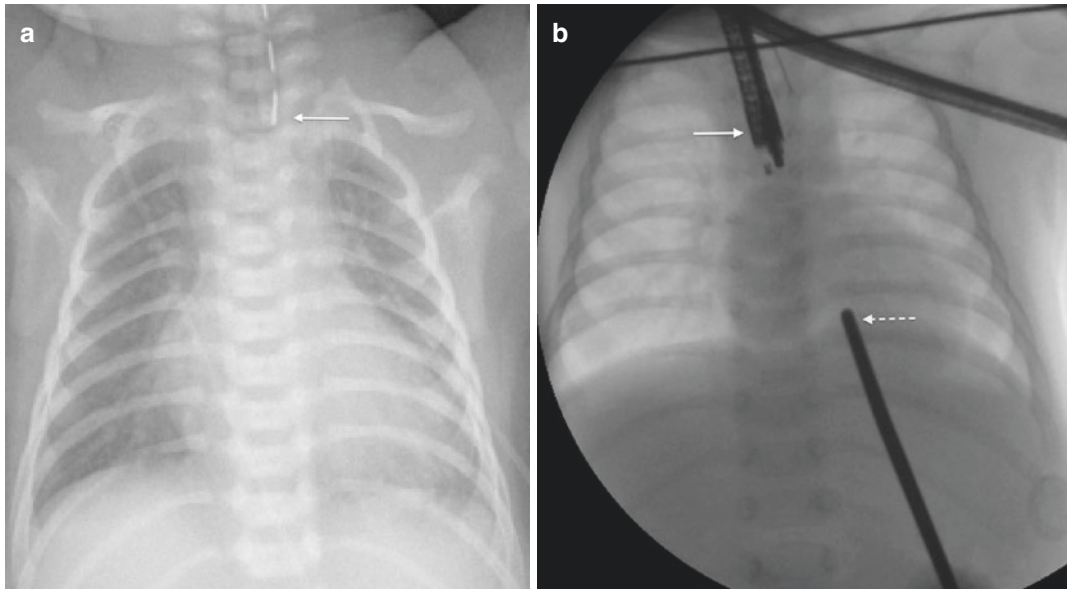

Fig. 10.9 Oesophageal atresia. (**a**) Radiograph of the chest and abdomen demonstrates a Replogle tube in the lower cervical oesophagus (*arrow*) and a paucity of abdominal bowel gas. (**b**) Selected fluoroscopy image from a gap assessment shows an endoscope in the proximal atretic oesophagus (*arrow*) and a Hagars dilator in the distal oesophagus (*broken arrow*)

Further imaging with ultrasound of the abdomen and pelvis and usually also the head and spine may be helpful to exclude further associated anomalies. Oesophageal atresia and tracheo-oesophageal fistula are often associated with tracheomalacia. CT of the thorax supplemented by bronchography and bronchoscopy can be used to assess the airways dynamically during spontaneous respiration.

Postoperative problems following repair of tracheo-oesophageal fistula may require imaging, the most common being stricturing of the oesophagus at the anastomosis site. This can be evaluated with an upper GI contrast study, and treated by balloon dilatation under fluoroscopic or endoscopic guidance [12] (Fig. 10.12).

10.7 The Neonate with Vomiting or Suspected Gastro-Oesophageal Reflux

The appropriate imaging pathway in the investigation of the neonate with vomiting depends upon the patient's age and clinical history. Vomiting in the early neonatal period is likely to be due to a congenital abnormality, whereas vomiting that develops later is likely to be due to an acquired pathology. A good clinical history regarding the nature of the vomit helps to localize the site of pathology. Non-bilious vomiting signifies gastric outflow obstruction, which early in the neonatal period could be due to a high atresia, such as pyloric or proximal duodenal atresia. A history of projectile non-bilious vomiting later in the neonatal period is suggestive of hypertrophic pyloric stenosis. Bilious vomiting indicates obstruction beyond the level of the first part of the duodenum. Faeculant vomiting in combination with abdominal distension suggests a distal obstruction or ileus, which will be dealt with later. Gastro-oesophageal reflux may present with vomiting/possiting, and may also be suspected in children with feeding difficulties, recurrent chest infection, apnoeic episodes or abnormal movement of head and neck resembling spasmodic torticollis (Sandifer syndrome).

In the vomiting neonate a plain abdominal radiograph as a first line investigation will help to direct further investigations. The characteristic

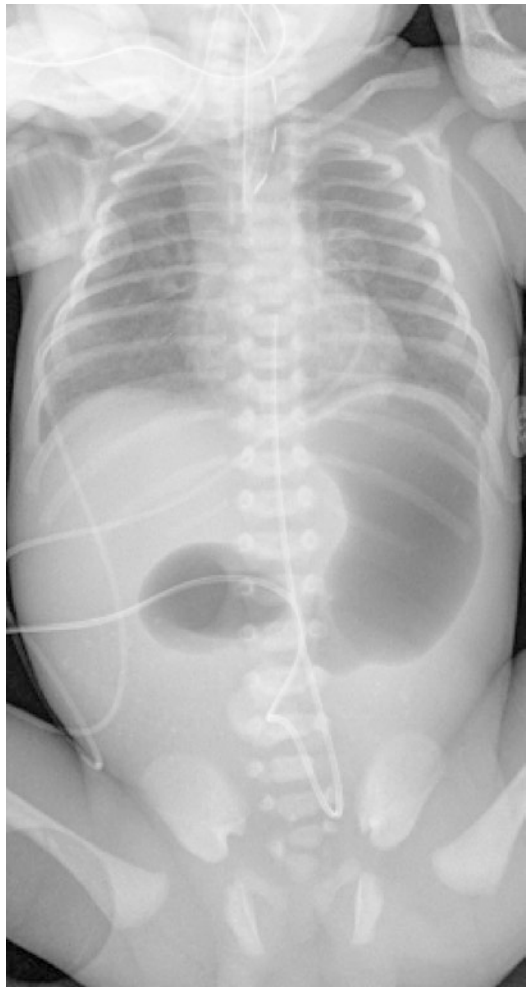

Fig. 10.10 Oesophageal and duodenal atresia. Plain supine chest and abdomen radiographs of this intubated neonate shows a Replogle tube terminating in the lower cervical oesophagus consistent with an oesophageal atresia. A "double bubble" sign in the abdomen due to dilatation of the stomach and duodenum is consistent with duodenual atresia. The presence of bowel gas with oesophageal atresia also confirms the presence of a tracheo-oesophgeal fistula. Note the sacral dysgenesis. Fine speckled calcifications can be seen in the abdomen, consistent with intra-uterine perforation and calcified meconium. An umbilical artery catheter is seen in a suitable position

appearance of some pathologies can give a definitive diagnosis without further imaging, differentiating for example duodenal atresia from jejunal atresia or a more distal obstruction.

Few loops of dilated bowel suggest a high obstruction, whereas multiple loops suggest a distal pathology. Care should be taken very early on in life, as bowel gas can take up to 24 h to reach the rectum in a normal neonate. Also frequent vomiting or the presence of a nasogastric tube with frequent aspirations may mask the typical appearances of, for example, the double bubble sign of duodenal atresia. Augmentation with the introduction of air via a gastric tube, following aspiration of the stomach, may provide the necessary contrast to reach a diagnosis.

An upper gastrointestinal (GI) contrast study is the next investigation of choice in suspected high obstruction. This is usually performed with water-soluble contrast media rather than barium, to minimise the risk of contrast impaction, and allow early surgery without the risk of peritoneal contamination with barium, iso-osmolar contrast is preferred to minimise the risk of contrast aspiration. Following a control film to demonstrate the bowel gas pattern and position of the NG tube, contrast is administered via the gastric tube into the stomach. Careful subsequent imaging allows the outflow from the stomach and caliber of the duodenum to be assessed, and the position of the duodeno-jejunal flexure to be demonstrated and documented. The lateral position shows the normal reversed C configuration to the position of the proximal duodenum, followed by its course superiorly to reach the level of the pylorus. The supine view demonstrates the duodenuo-jejunal (DJ) flexure at the level of the pylorus and to the left of the left sided pedicles of the vertebral bodies. The jejunal loops can then be seen, which normally should lie to the left of the midline (Fig. 10.13a).

10.7.1 Malrotation

Malrotation of the bowel may lead to midgut volvulus, which is a life threatening event and therefore any paediatric patient should have the position of the DJ flexure correctly documented as part of an upper GI contrast study. More than 90% of cases of malrotation and midgut volvulus occur within the first 3 months of life, with 40% occurring in the first 10 days.

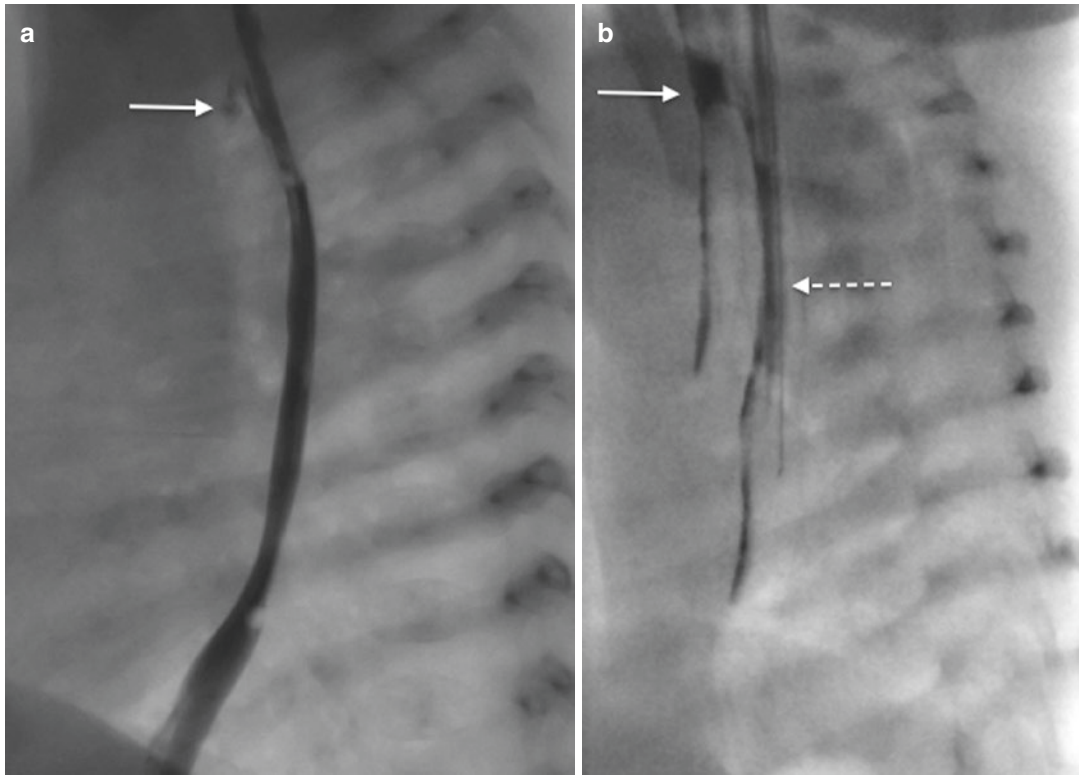

Fig. 10.11 H-type tracheo-oesophageal fistula. Prone tube oesophagogram. In (**a**) there is a tube within the oesophagus and a trace of contrast (*arrow*) is seen passing anteriorly suggesting a fistula. In (**b**) contrast is clearly seen entering the trachea (*arrow*) from the intubated oesophagus (*broken arrow*) in keeping with a fistula

Malrotation does not have any specific plain film features, however distension of the stomach and duodenum and presence of jejunal loops to the right of the midline should raise suspicion in the vomiting neonate. A normal abdominal radiograph does not exclude the diagnosis of malrotation and an upper GI contrast study is mandatory in a neonate with bilious vomiting.

The upper GI series remains the reference standard for the investigation of malrotation and volvulus [13]. The sensitivity of the upper GI series in the diagnosis of malrotation has been shown to be between 93 and 100% [14]. In malrotation, the duodenum is seen to pass anteriorly and inferolaterally to the right, and jejunal loops are seen on the right side of the abdomen (Fig. 10.13b, c). Care must be taken, as a distended gas filled stomach or proximal duodenum can displace the normal position of the DJ flexure, and the appearances of malrotation in small neonates may be subtle. Careful positioning of the patient in the supine view is required to ensure the spine is straight and the visible inferior ribs are symmetrical, and that any abnormality of the position of the DJ flexure is true. Delayed imaging in cases of uncertainty will demonstrate the position of the caecum, which in 80% of patients with malrotation lies high and near the midline, therefore helping to confirm or dismiss the diagnosis of malrotation [13, 15]. In volvulus, a dilated stomach and proximal duodenum are present, and a "corkscrew" appearance to the distal duodenum and jejunum may be seen (Fig. 10.14). Delayed imaging in cases of concern will demonstrate the position of the caecum, and help to confirm or dismiss the diagnosis of malrotation.

In the neonate with suspected malrotation, ultrasound can elegantly demonstrate the abnor-

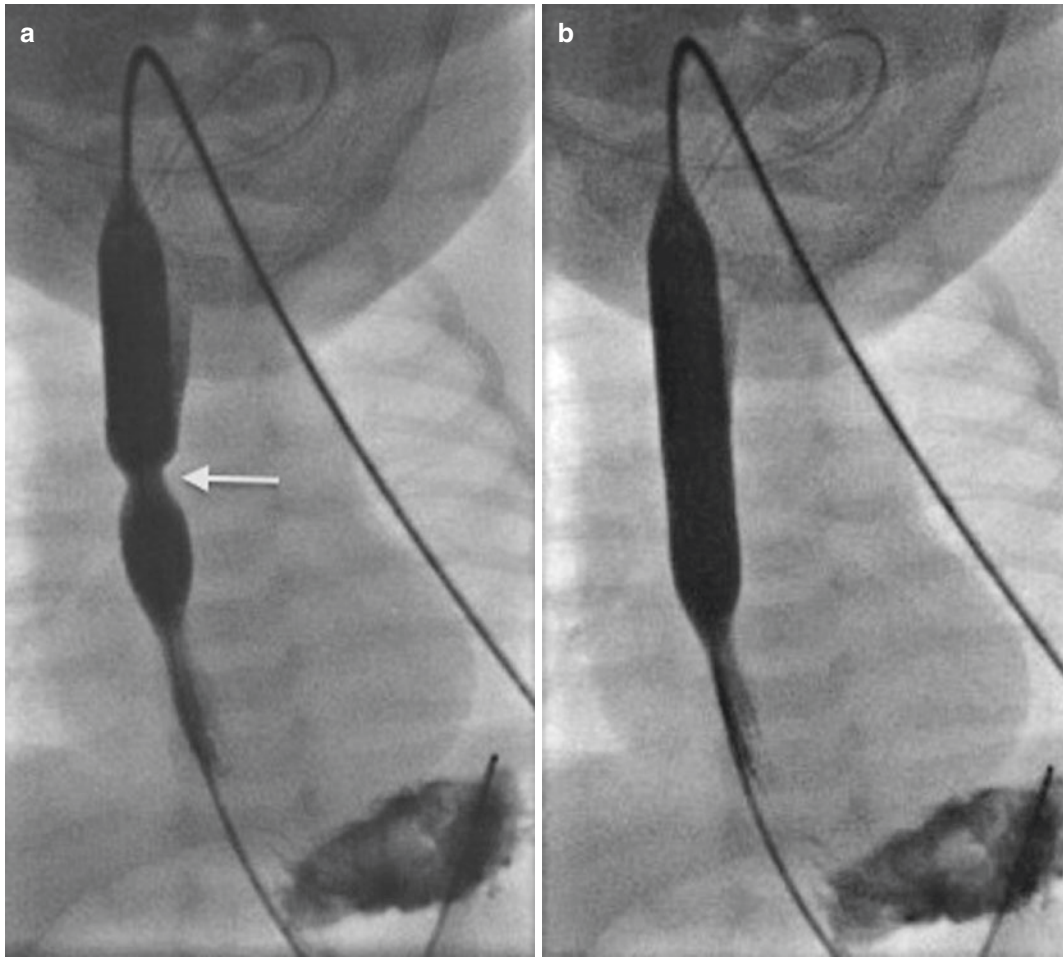

Fig. 10.12 Oesophageal stricture. AP views from fluoroscopically guided balloon dilatation of a mid-oesophageal stricture in a neonate post tracheo-oesophageal fistula repair. In (**a**) waisting of the contrast filled balloon is seen at the site of stricture (*arrow*). In (**b**) the balloon is fully inflated and no waisting is present

mal relationship of the SMA and SMV, with the vein lying to the left of the artery, and may show swirling of the SMV in a clockwise direction around the loops of volved bowel (Fig. 10.15). This investigation however has low sensitivity and specificity compared to the UGI study, as up to 29% cases of malrotation have a normal relationship of the SMA and SMV [16, 17]. In addition, such neonates are often very sick and ultrasound can be very time demanding and would need supplementing further with a contrast study, therefore upper GI contrast study remains the gold standard imaging test of choice in such cases.

10.7.2 Gastro-Oesophageal Reflux

Ultrasound can be used to diagnose gastro-oesophageal reflux. The scan is performed with the baby lying supine, turned slightly to the right side, following a feed. The gastro-oesophageal junction can usually be clearly visualised in the longitudinal plane, and reflux of fluid into the lower oesophagus can be demonstrated. However, identification of structural oesophageal abnormalities such as strictures is difficult.

Gastro-oesophageal reflux as a cause of vomiting may also be demonstrated during the upper

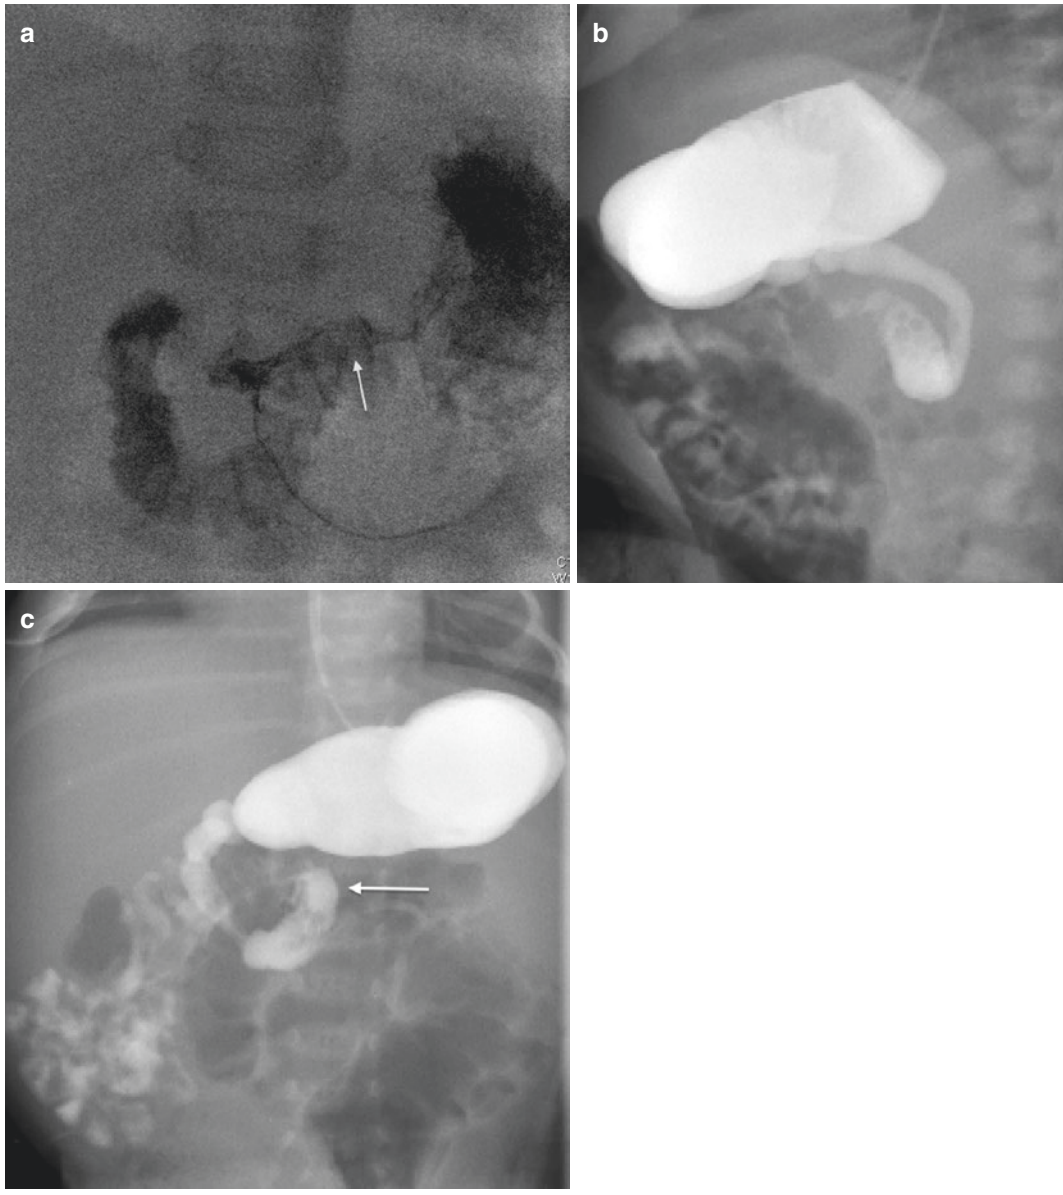

Fig. 10.13 (**a**) Normal upper GI contrast study. Note the normal anatomical position of the duodenojejunal junction at the level of the pylorus to the left of the spine (*arrow*). (**b**, **c**) Malrotation. Lateral oblique images demonstrate an apparently normal appearance, with the duodenum passing posteriorly, inferiorly and superiorly in a c-shape configuration. AP image however demonstrates failure of the third part of the duodenum to cross the midline and the duodenojejunal junction (*arrow*) is seen to the right of midline, below the level of the pylorus. Proximal jejunal loops lie in the right side of the abdomen

GI study, however the upper GI study is usually used to exclude abnormal anatomy or complications of chronic reflux, such as an oesophageal stricture.

Other diagnostic techniques are often used to identify gastro-oesophageal reflux and exclude any other pathology including endoscopy and pH monitoring. An isotope milk scan can often be

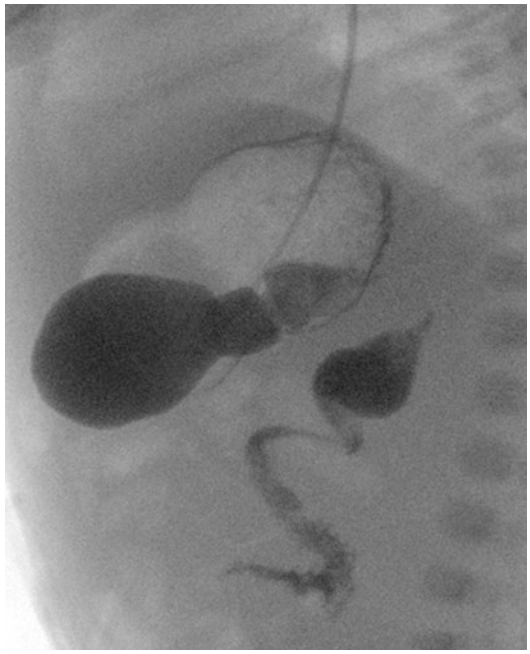

Fig. 10.14 Malrotation and volvulus. Lateral image from an upper GI contrast study demonstrates a corkscrew appearance of the duodenum and proximal jejunum, indicating a volvulus

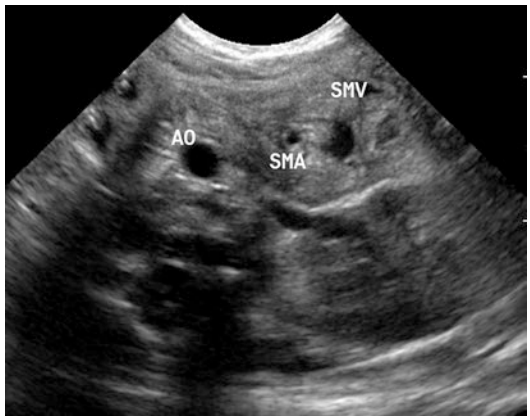

Fig. 10.15 Malrotation. Grey scale transverse ultrasound of the upper abdomen reveals abnormal relationship of the mesenteric vessels, with the SMV to the left of the SMA

useful. This involves the oral administration of Technetium 99 m labeled sulphur colloid with milk to the fasting infant. Imaging of the stomach and oesophagus with the infant supine is then performed over an hour. Images of the lungs may be acquired towards the end of the study, to look for evidence of aspiration of activity into the lungs (Fig. 10.16).

10.7.3 Atresias and Stenoses of the Foregut and Midgut

Absence of gas, on plain radiography, beyond the stomach in a neonate with antenatal polyhydramnios is consistent with a pyloric atresia. Incomplete stenosis is suggested by disproportionally large gas filled stomach relative to the distal bowel. Gastric volvulus may be diagnosed on upper GI study. Filling defects due to gastric bezoars may be seen, typically in premature infants receiving antacids or incorrectly mixed formula feeds. More rarely, a gastric teratoma may be seen on UGI contrast, again as a calcified mass on plain film/control film and as filing defect following contrast. These are often massive, calcified tumours, and are more common in male infants.

In the older neonate, particularly children between 3 and 6 weeks of life with non-bilious projectile vomiting, ultrasound is the primary investigation of choice to confirm the presence of a hypertrophic pyloric stenosis. The pylorus is visualized with a high-resolution linear probe, in longitudinal and transverse planes, and measurements of the pyloric muscle taken. A length of ≥14 mm and single wall thickness of >4 mm is diagnostic of pyloric stenosis [18] (Fig. 10.17). Ultrasound also allows real time demonstration of lack of passage of stomach contents through the pylorus into the duodenum. Pyloric stenosis is an evolving acquired condition, and in equivocal cases, where the measurements are borderline, a repeat scan within a few days is indicated.

10.7.4 Small Bowel Atresia

In duodenal atresia a characteristic “double bubble” may be seen (Fig. 10.18). These neonates usually have bilious vomiting, as the obstruction

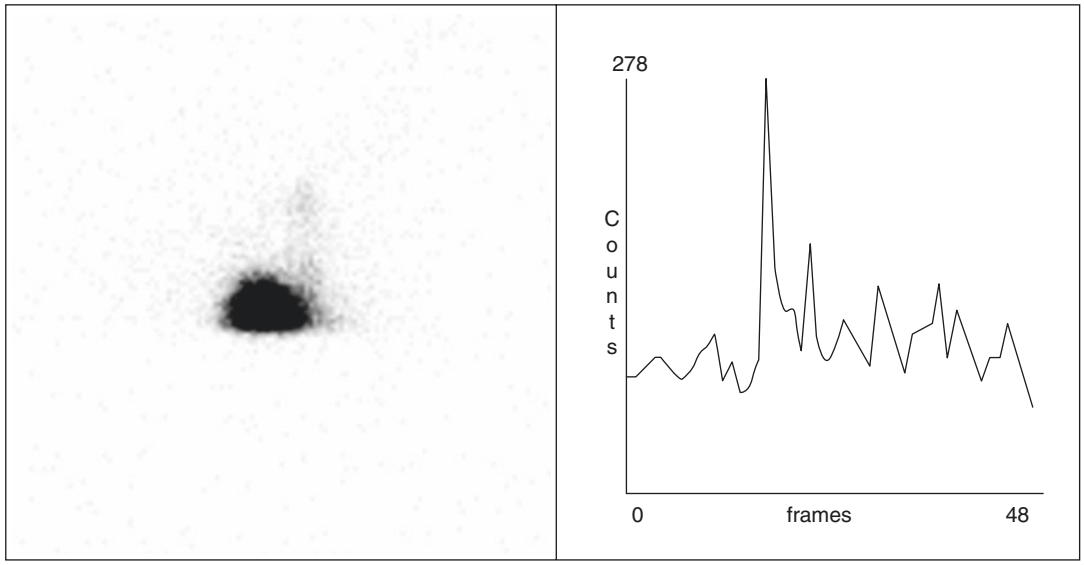

Fig. 10.16 Gastro-oesophageal reflux. Technecium 99 m labeled sulphur colloid milk study. Summation image demonstrates increased tracer extending cranially from the stomach into the oesophagus. Graph of activity against time shows a peak consistent with reflux

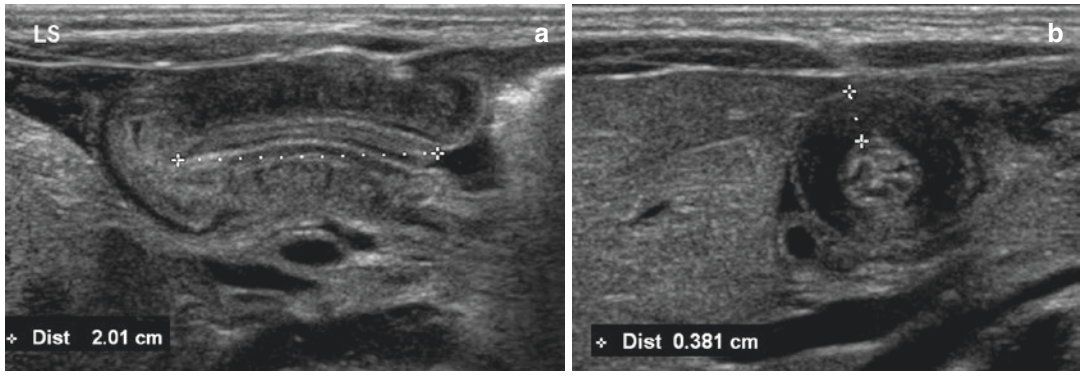

Fig. 10.17 Pyloric stenosis. (**a**) Longitudinal and (**b**) transverse ultrasound images of the pylorus show a thickened elongated pyloric muscle with channel length of 20 mm and individual muscle wall thickness measuring 4 mm, diagnostic of hypertrophic pyloric stenosis

occurs below the level of the Ampulla of Vater, but more proximal obstructions can occur resulting in non-bilious vomiting. The plain film may often clinch the diagnosis and may also provide ancillary information e.g. 11 sets of ribs may be present in the neonate with associated Down's syndrome.

Duodenal stenosis, however, may be of varying severity and distal gas may be seen. In such cases, an upper GI contrast study is required. A windsock deformity suggests the presence of a web (Fig. 10.19). Annular pancreas may mimic the plain film appearances of duodenal atresia or stenosis depending on the degree of duodenal obstruction (Fig. 10.20).

Jejunal atresia usually presents with bilious vomiting and abdominal distension, possibly with antenatal diagnosis. Plain film will show markedly distended proximal loops of small bowel, sometimes seen as the "triple-bubble sign" with an absence of distal gas. The proximal bowel may be grossly dilated.

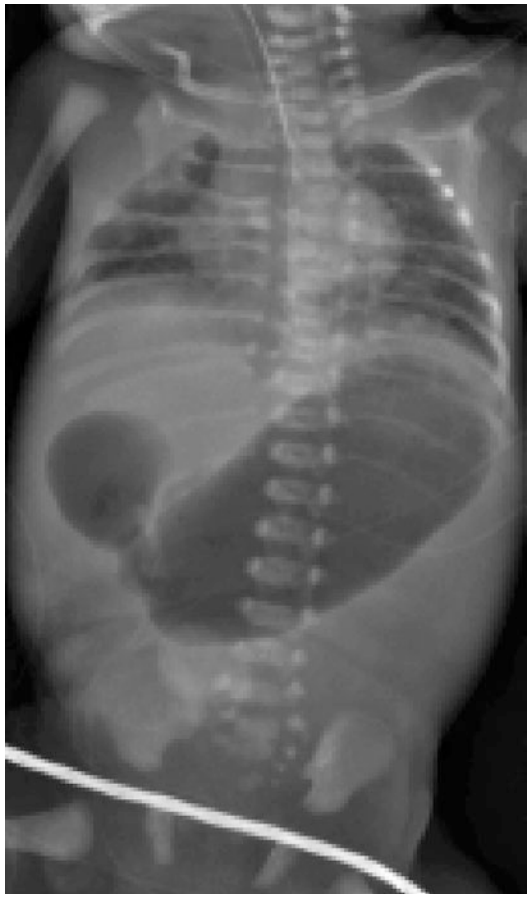

Fig. 10.18 Duodenal atresia. Supine radiograph demonstrates the classic "double bubble" sign and paucity of distal bowel gas. Note also the abnormal sacral segmentation

The plain film, particularly in the left decubitus position (left side down) may be helpful demonstrating free gas outlining the edge of the liver related to bowel perforation and there may be evidence of meconium peritonitis such as peritoneal calcification or a mass containing calcification resulting from meconium pseudocyst formation.

Other causes of high neonatal obstruction, such as duplication cysts, can be demonstrated with ultrasound, and may even have been diagnosed antenatally. Intussusception is rare in the neonatal age group; when it occurs, there is a high likelihood of a pathological lead point such as a Meckel's diverticulum, duplication cyst, polyp or tumour. Ultrasound is the imaging modality of choice to demonstrate intussusception, showing a mass with alternating linear echogenic and hypoechoic areas representing the bowel wall layers of the intussusceptum and intussuscipiens, and invaginated mesenteric fat. Transversely this is seen as alternating concentric rings with a target like appearance (Fig. 10.21). Ultrasound allows the identification of features that make successful or uncomplicated air enema reduction less likely, such as trapped fluid, and may demonstrate features to suggest the need for surgical treatment such as avascular bowel.

Obstruction or displacement of the bowel due to an extrinsic mass can also be demonstrated on a contrast study and may prompt further investigation with ultrasound.

10.8 The Neonate with Abdominal Distention/ Failure to Pass Meconium

A number of different conditions may present with abdominal distension, bilious vomiting, and failure to pass meconium, including Hirshsprung disease, ileal atresia, meconium ileus, meconium plug syndrome, anorectal anomalies, and particularly in premature infants immature left colon, inspissated milk/milk curd obstruction and necrotising enterocolisis (NEC). Radiological investigations can be helpful to differentiate between these possible diagnoses, but in many cases a rectal biopsy is necessary to exclude or make a positive diagnosis of Hirschsprung disease.

Radiological investigation begins with a plain abdominal radiograph, followed in most cases by a water-soluble contrast enema. In the neonate, air should be seen within the rectum by 24 h. In conditions resulting in low obstruction, the abdominal radiograph will normally show nonspecific signs however multiple dilated bowel loops may be evident. It is rarely possible to differentiate between dilated large and small bowel on the plain radiograph in the neonate and small infant. Complications of distal bowel obstruction, such as free gas, calcified peritoneum following meconium peritonitis may be seen. Ancillary findings such as cardiomegaly and

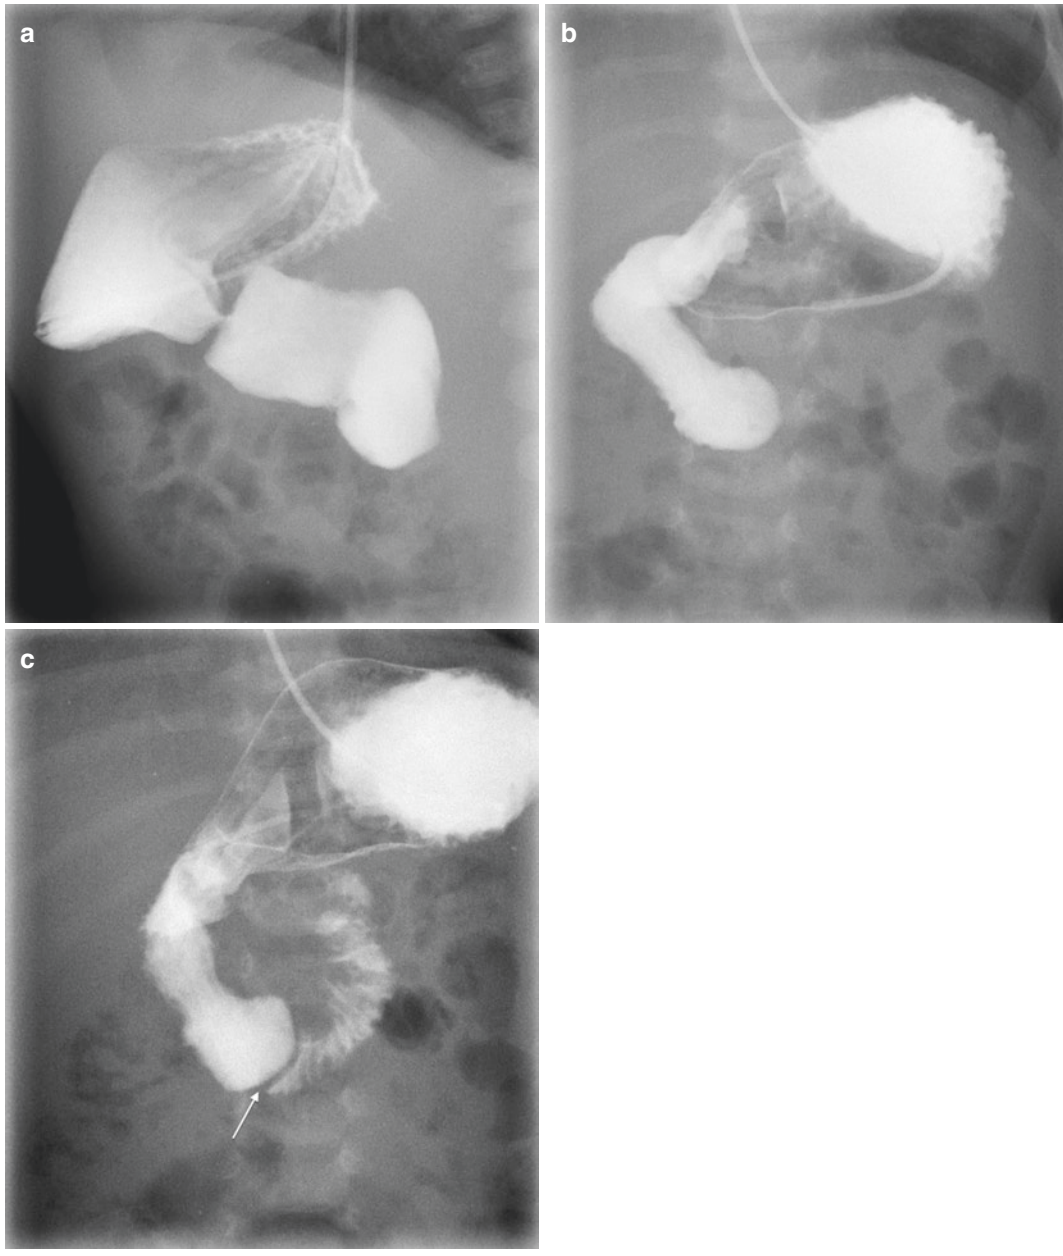

Fig. 10.19 Duodenal web. Water soluble contrast study shows a duodenal stenosis confirmed intraoperatively as being due to a web. Contrast fills the first and second parts of the duodenum which are dilated, with a sharp truncation at the junction between the second and third parts (*arrow*), which has a rounded, bulging appearance. A small amount of contrast passes distally

vertebral segmentation anomalies can also be seen suggesting VACTERL syndrome.

Pneumoperitoneum on the supine abdominal radiograph may appear as a central abdominal lucency, the "air-football sign", visualization of both sides of bowel wall (Rigler sign) or the falciform ligament or umbilical arteries, and the presence of triangular

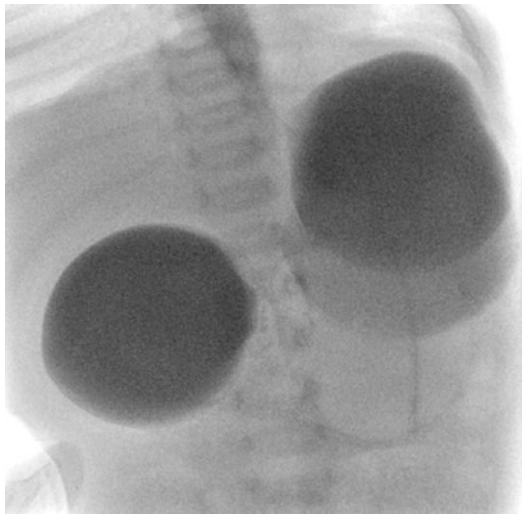

Fig. 10.20 Annular pancreas. Upper GI contrast study demonstrates a markedly distended gas and contrast filled double bubble appearance suggestive of obstruction at the level of the duodenum

shaped pockets of gas in unusual locations. Decubitus radiographs performed in the left lateral position demonstrate the free edge of the liver outlined by gas. In supine neonates too unwell to reposition, the supine horizontal beam lateral radiograph can be used to demonstrate free gas. In neonates with plain film evidence of perforation, further imaging is not usually required (Fig. 10.22).

The next step in the imaging pathway in neonates with distension/failure to pass meconium is a contrast enema, to demonstrate whether the colon is normal, dilated, or small in calibre. Contrast enema in neonates is usually performed with a low-osmolar, non-ionic, contrast medium, which is diluted to avoid significant fluid shifts in sick neonates. The rectum is screened laterally. This may show a small amount of gas in a partially collapsed spasmodic rectum indicative of Hirschsprung disease. A small caliber soft tipped catheter (a 6 French catheter is ideal) is inserted into the rectum and contrast is instilled with the patient in the left lateral position. The normal rectum has the largest diameter of the left side of the colon, and has a larger calibre than the adjacent sigmoid on contrast study.

Movement of the neonate during the procedure helps to opacify the entire colon to the caecum. Reflux into the appendix, small bowel and ideally into proximal dilated bowel is required to ensure a complete study.

Ultrasound can sometimes be used successfully to determine the level of obstruction. Dilated loops can be distinguished from collapsed loops. Dilated fluid filled small bowel proximal to an atresia can be distinguished from the meconium filled loops due to meconium ileus. It may also be possible on ultrasound to distinguish ileal loops from colon [19].

10.8.1 Hirschsprung Disease

Hirschsprung disease is failure of ganglion migration to the full extent of the bowel. Ganglion migration occurs proximal to distal so the rectum is always involved, but a variable amount of more proximal bowel may also be involved. The aganglionic segment results in a failure of relaxation of that segment and therefore a functional obstruction results.

In Hirschsprung disease non-specific signs of distal bowel obstruction may be seen on the plain abdominal radiograph, with gas-filled, dilated bowel loops throughout the abdomen and paucity of gas in the rectum. Intraluminal meconium, pneumotosis, and free intraperitoneal gas or meconium peritonitis following a perforation, usually caecal, may be seen (Fig. 10.23).

A contrast enema typically shows that the rectum has a smaller caliber than the sigmoid colon, with a zone of transition to dilated proximal colon. The rectosigmoid ratio, which is a measurement of the diameter of the rectum divided by that of the sigmoid colon, is of particular use in the diagnosis of Hirschsprung Disease. In normal individuals, where the rectum is larger than the colon, the rectosigmoid ratio is >1. A ratio of <1, i.e. a rectum that is of smaller calibre than the sigmoid, is suggestive of Hirschsprung disease. The rectum may show an irregular pattern of contraction, with a serrated or corrugated appearance. The position of

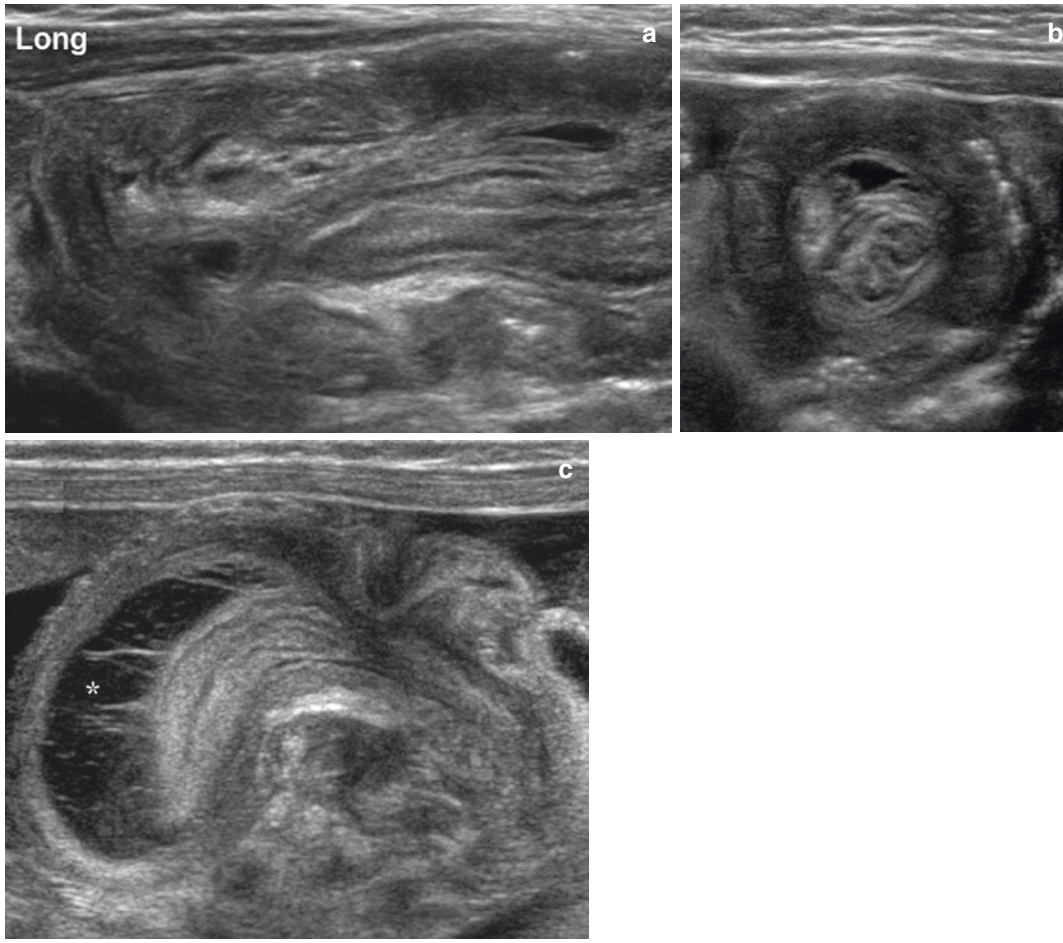

Fig. 10.21 Intussusception. Longitudinal (**a**) and transverse (**b**) ultrasound images demonstrate the typical ultrasound appearance of intususception. In transverse section, alternating rings of hypo and hyperechogencity are seen representing the intussusceptum and mesenteric fat within the intussuscipiens. (**c**) transverse ultrasound image in a neonate with intussusception. A loculated collection of fluid (*) is visible in the intussusceptum, found intraoperatively to be a duplication cyst representing a pathological lead point

the zone of transition is variable. However, in some cases the zone of transition is not easy to demonstrate, and the apparent position of the zone of transition on contrast enema is not a reliable indicator of the true extent of the aganglionic segment as determined by histopathology. Short segment aganglionosis, affecting only the distal rectum, is particularly difficult to diagnose on contrast enema and may only be excluded completely by rectal biopsy; total colonic Hirshsprung disease also presents particular diagnostic difficulties, as there may be a microcolon, or the colon may appear uniformly normal in calibre.

10.8.2 Unused Colon

The unused colon is a spectrum of abnormalities that result in a variable but continuous length of small caliber colon from rectum more proximally. This can be as a result of proximal atresia, luminal stenosis or luminal obstruction, but can also be due to immaturity, particularly in prematurity.

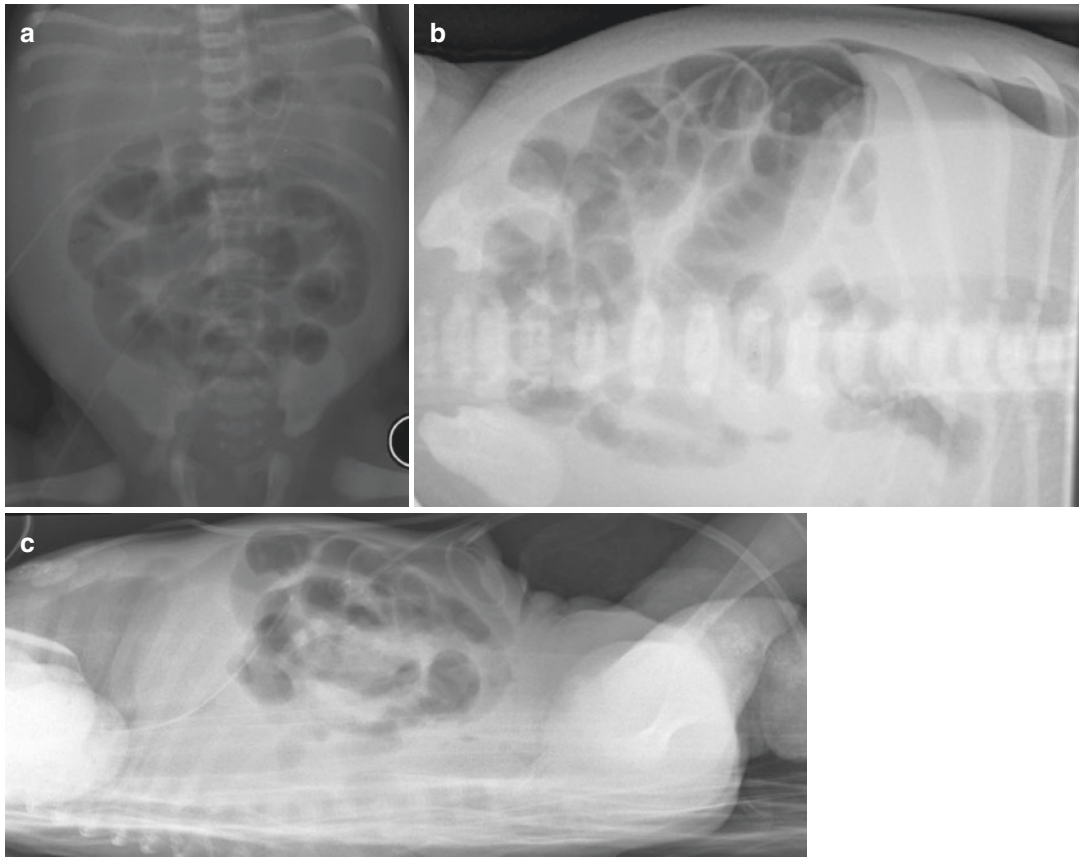

Fig. 10.22 Pneumoperitoneum secondary to perforated meconium ileus. (**a**) Supine radiograph in a neonate with abdominal distension shows central lucency consistent with the "football sign" of pneumoperitoneum, and multiple gas filled dilated loops of bowel. (**b**) Lateral decubitus film demonstrates the free gas over the liver surface. (**c**) Supine lateral shoot through film shows triangular lucency under the anterior abdominal wall consistent with pneumoperitoneum

10.8.3 Distal Small Bowel Atresia

Distal jejunal and ileal atresias may present with distension and failure to pass meconium. 15% of small bowel atresias affect the proximal ileum and 35% affect the distal ileum. Small bowel atresias can be associated with meconium ileus and Hirschsprung disease [20]. The plain abdominal radiograph may reveal evidence of bowel dilatation, pneumatosis, perforation or meconium peritonitis with peritoneal calcifications. Contrast enema typically shows a microcolon (Fig. 10.24). The more the colon is utilized the larger its calibre, therefore the more proximal the small bowel atresia (or obstruction), the less marked the reduction in caliber of the colon as the bowel distal to the atresia utilizes the colon and therefore increases its caliber [21].

10.8.4 Meconium Plug Syndrome

A small left colon, often to the level of the splenic flexure, with multiple long filling defects, is suggestive of meconium plug syndrome, also known as immature or small left colon sydrome. Long segment Hirschsprung disease is a rare but important differential in such cases. In meconium plug syndrome,

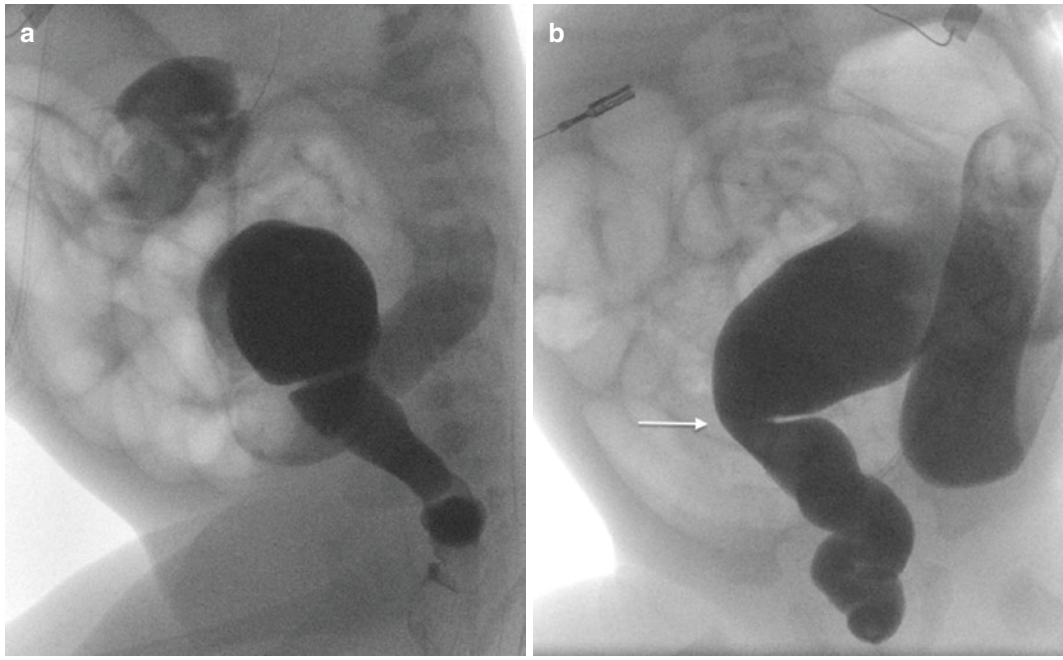

Fig. 10.23 Hirschsprung disease. Lateral and AP views from a water soluble contrast enema demonstrate a contrast filled rectum and sigmoid colon. Note the caliber change at the distal rectum and resulting reversal of the normal rectosigmoid

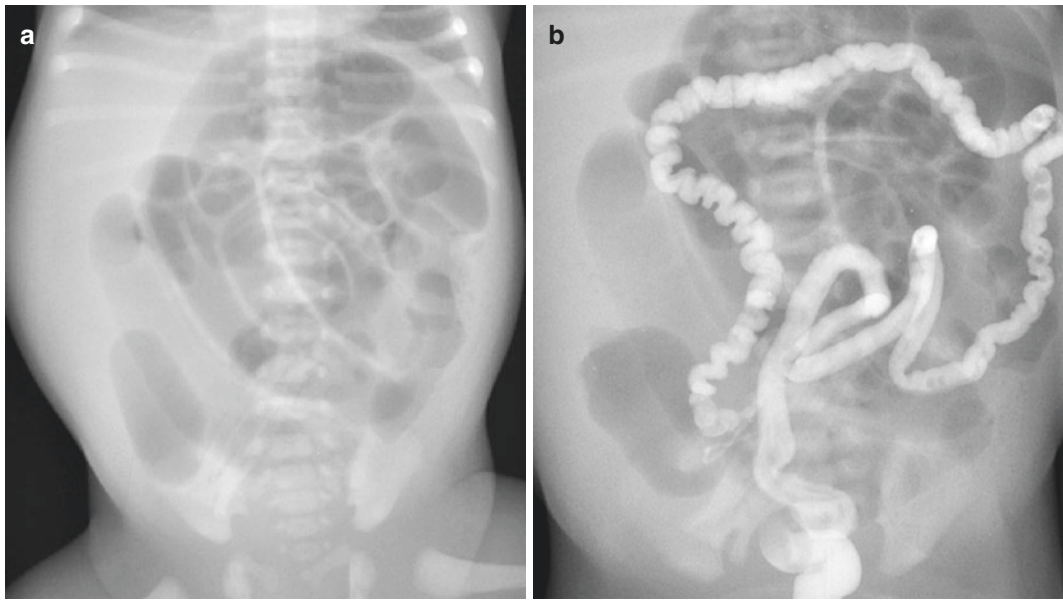

Fig. 10.24 Ileal atresia. (**a**) Plain abdominal radiograph demonstrates multiple dilated bowel loops consistent with a distal bowel obstruction. (**b**) Water soluble contrast enema demonstrates a microcolon

mechanical loosening of the meconium often occurs with therapeutic passage of the meconium plugs during or after the contrast enema with improvement in the degree of abdominal distention and a slow return to normal bowel function (Fig. 10.25).

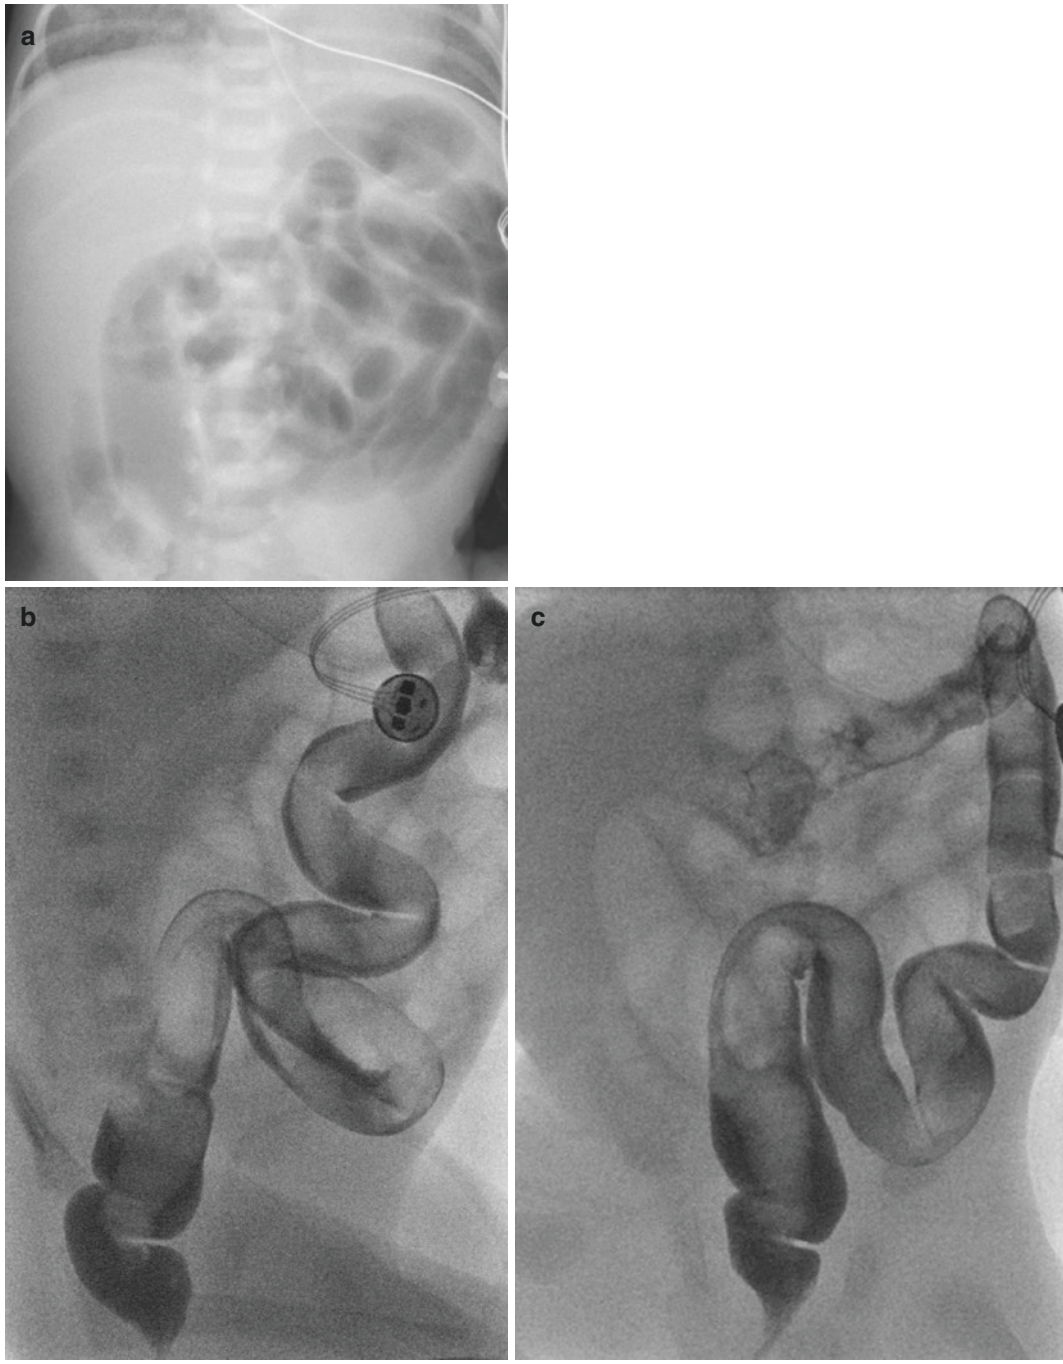

Fig. 10.25 Meconium ileus. 2 day old with known cystic fibrosis and abdominal distension and failure to pass meconium. The control film (**a**) demonstrates multiple distended air filled loops of bowel consistent with a distal bowel obstruction. Contrast enema images (**b** and **c**) demonstrate multiple filing defects consistent with meconium plugs in the left hemicolon and rectosigmoid. Note the normal rectosigmoid ratios

10.8.5 Meconium Ileus

Meconium ileus is usually a manifestation of cystic fibrosis, but it can occur in neonates with pancreatic abnormalities such as pancreatic atresia or pancreatic duct stenosis, and rarely in infants with no apparent underlying abnormality. In meconium ileus, the distal small bowel is obstructed by thick, tenacious meconium. This may be complicated by ileal atresia or stenosis,

perforation and meconium peritonitis, and volvulus. On plain film the bowel loops may vary in size and a "soap bubble" appearance may be seen in the distal bowel loops due to the presence of meconium. In male neonates with perforation and meconium peritonitis, scrotal calcification due to a patent processus vaginalis may be seen.

The contrast enema demonstrates a microcolon with meconium pellets in the collapsed distal ileum and dilated proximal small bowel loops. An enema using a hyperosmolar water-soluble contrast, sodium meglumine amidotrizoate (Gastrografin, Bayer Schering Pharma AG, Berlin) can be used therapeutically for reduction of the obstruction in meconium ileus and meconium plug syndrome; this procedure can be repeated as necessary and may help to avoid surgery in some cases [22]. Hyperosmolar contrast has a therapeutic effect by drawing fluid into the bowel, lubricating and emulsifying the colonic content, and stimulating colonic motility. When used for this purpose in a neonate, Gastrografin is usually diluted 1:2 or 1:3 with saline or water. Even when diluted, hyperosmolar contrast agents may cause rapid fluid shifts, and so should be used only by experts, after careful consideration of the balance of risks and benefits. Dehydration should be corrected before the procedure is commenced, an intravenous fluid infusion should be running, and careful monitoring should be performed during and after the procedure.

10.8.6 Colonic Atresia

Colonic atresias usually occur proximally [21]. There is a recognised association between Hirshsprung disease, particularly short segment, and colonic atresia [23]. The colon distal to the atresia will be small in calibre. In a stenosis if contrast does pass proximally this can be seen to dilute into the dilated fluid filled proximal segment, indicating the site of pathology.

A contrast enema may be indicated following upper GI contrast in patients with suspected multiple intestinal atresia syndrome. Air and contrast in the upper GI study will only pass to the proximal atresia. A contrast enema will usually show a microcolon, but may help to identify the level of the most distal atresia.

10.8.7 Anorectal Malformations

Anorectal anomalies result from the failure of descent and separation of the genitourinary system and the hindgut during the second trimester. Clinically these present with failure to pass meconium, distension and an imperforate anus. In patients with suspected anorectal malformations, plain supine radiograph demonstrates multiple dilated bowel loops suggesting a low obstruction. If there has been mixing of meconium and urine due to a fistulous connection between bowel and urinary tract, calcified intraluminal meconium may be seen. A radiopaque marker of a known length at the area of the obliterated anus is useful to assess the distance between anus and rectum in order to plan surgery. Lateral or prone radiographs are sometimes useful as air within the rectum proximal to the obstruction provides contrast.

However they may not be reliable in demonstrating the level of atresia. Air may not have reached the rectum before 24 h after birth, and the presence of impacted meconium or muscle spasm may give the incorrect impression of a high atresia (Fig. 10.26a, b).

Air may also outline the presence of a fistula. Ancillary findings such as vertebral anomalies, abnormal renal outlines and cardiomegaly would support the diagnosis of VACTERL syndrome.

Contrast studies in infants with anorectal malformations are useful to identify the presence of fistulae. In high anorectal malformations, where the rectum terminates above the levator, fistulae between the GI and GU tract are common. Low malformations in males are associated with fistulae to the prostatic urethra or bladder, whereas in females the fistula is to the proximal urethra. Low fistulae are associated with a perineal or distal vaginal fistula. A MCUG is used to help identify any fistula, particularly in those with a high atresia. Following initial diversion surgery, injection of contrast under a little pressure via a catheter in the stoma may outline the fistula (Fig. 10.26c).

Ultrasound is required in patients with anorectal malformations to exclude urogenital anomalies such as horseshoe kidney, renal agenesis or hypoplasia, and ultrasound of the brain and spine is used to exclude other developmental anomalies. Ultrasound in cases of obstruction with perforation

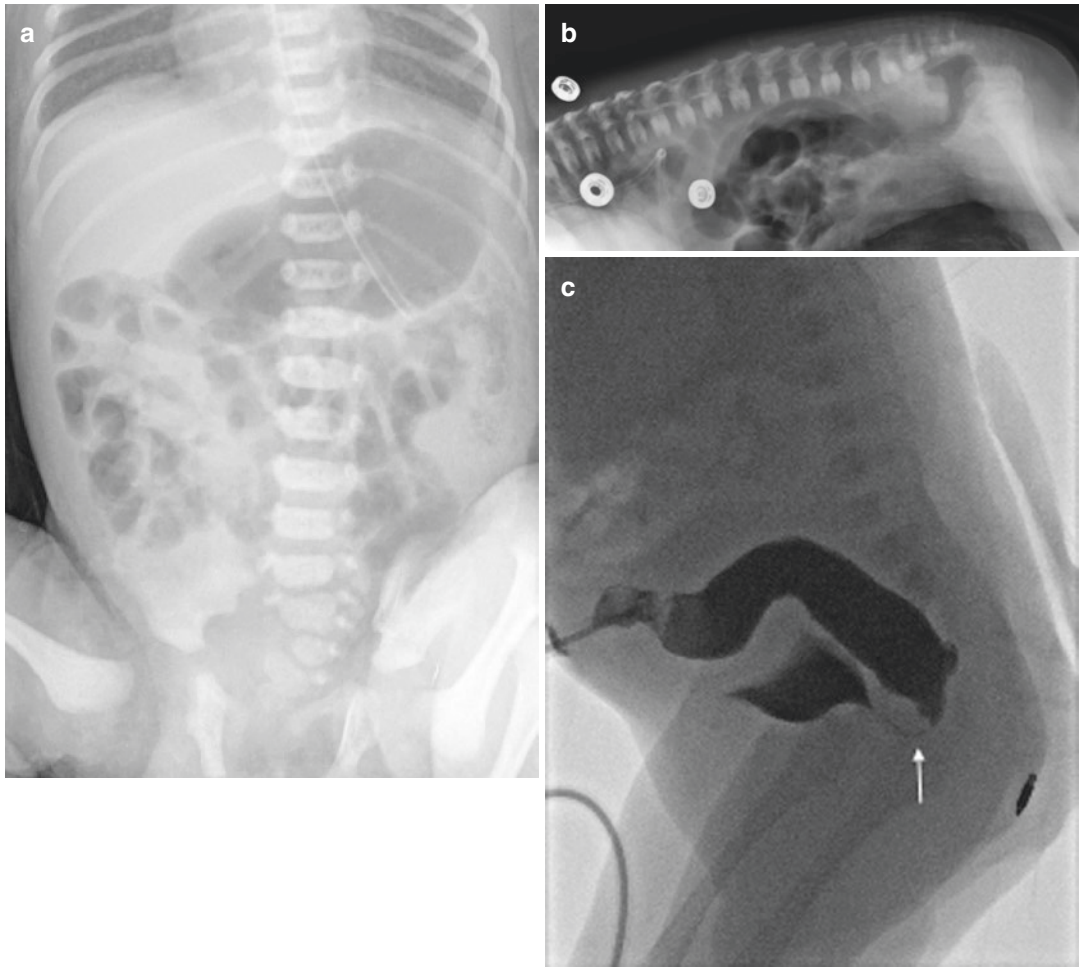

Fig. 10.26 Imperforate anus. Plain film (**a**) demonstrates gas filled bowel loops and paucity of gas in the rectum. Dysgenesis of the sacrum is noted. Prone cross table beam lateral radiograph with buttocks up (**b**) shows air in the non-dependant rectum at the level of obstruction. Selected lateral image from a post-operative water soluble distal loopogram (**c**) shows contrast filling the distal sigmoid and blind ending rectum. The radio-opaque marker placed on the skin helps to demonstrate the anal region and distance between the skin and blind end of the rectum. Contrast can be seen filling the bladder via a recto-urethral fistula (*arrow*)

and meconium peritonitis may demonstrate large peritoneal pseudocysts in neonates with meconium peritonitis.

10.8.8 Necrotising Enterocolitis (NEC)

NEC usually manifests in first 2 weeks of life and can present with vomiting, diarrhoea or more generalised features such as shock and/or sepsis. Clinical signs include distension and abdominal wall erythema. Imaging findings may precede clinical findings, therefore suggesting the diagnosis, and complications may be detected on imaging. Overall mortality of this condition is between 20 and 40%, rising to more than 60% in very low birth weight preterm infants with perforation [24]. Early detection of ischaemic or necrotic loops prior to perforation may improve outcome therefore imaging plays an important role of management [25].

During the acute stages of NEC, the main imaging modalities used are plain radiography and ultrasound. A system developed by Bell et al. (1978) [26] incorporates findings on plain radiograph with historical and clinical data to stage neonates with NEC and thus plan further management. Despite imaging advances since this time, the plain radiograph remains the imaging modality of choice in neonates with suspected NEC [27] however ultrasound is an increasingly valuable tool in NEC with the advantages of providing real time images of abdominal structures, particularly of the bowel.

The bowel gas pattern may be non-specific in neonates with NEC, and bowel distension itself is non-specific and may be seen in normal neonates, those intolerant of feeding, or neonates with ileus resulting from other pathologies. However, alteration of the normal bowel gas pattern is often the earliest, and maybe the only, imaging finding in NEC. Loss of the normal neonatal mosaic configuration of the bowel loops, and loop dilatation with rounded or elongated loops, usually due to ileus, may be seen. A persistent static dilated loop may be present on serial images, and is concerning for necrosis. In distended neonates with little bowel gas on the plain film, ultrasound is useful to determine whether there are fluid filled loops.

Intramural pneumatosis, although not specific for NEC, is most commonly seen in neonates with this condition. It is thought that in the clinical setting of NEC, the presence of intramural gas is diagnostic. The amount of gas is not thought to correlate with severity. On plain film pneumatosis is usually seen in the right iliac fossa, as it involves the distal small bowel and colon most frequently. Curvilinear lucencies may be seen, representing gas in the subserosa. This is best appreciated when seen circumferentially around en face bowel loops. Bubbly lucencies are thought to be due to gas within the submucosa. The bubbly appearance of NEC can be very similar to formed faeces, however formed faeces is not usually present until several days after normal oral intake/feeding has been established. Intramural gas on ultrasound is visible as hyperechoic foci in the bowel wall, which can result in a granular appearance. If seen in the non-dependant bowel wall this can be confused with intraluminal gas and therefore visualization of the dependant portion of the bowel wall is ideal. Differentiation from calcification may also be difficult, though there is usually more defined posterior acoustic shadowing with calcification (Fig. 10.27a, b).

Dissection of intramural gas into the lymphatics and mesenteric venous axis results in portal venous gas, which is present in up to 30% of patients with NEC. Portal venous gas is frequently seen following umbilical vein catheterization and (unlike in adults) is not a serious prognostic sign. On the plain abdominal radiograph, portal venous gas is seen as branching linear lucencies in the right upper quadrant, and is differentiated from gas in the biliary tree by its distribution, as gas in the biliary tree is more central, and by the clinical scenario, as biliary tree gas is rare in the neonate. Ultrasound elegantly demonstrates portal venous gas as multiple mobile hyperechoic foci within the vessels. This finding used to be infrequently seen and so was valuable to confirm the presence of NEC, however the excellent high resolution real time imaging obtained with modern ultrasound machines means that it is now a much more common finding, not only in NEC, but for example after insertion of umbilical venous catheters, and this has therefore diminished its usefulness (Fig. 10.27c, d).

Perforation may occur with resulting free gas. This is the only imaging finding requiring surgical intervention. Plain radiography is the modality of choice for the detection of free gas (Fig. 10.27e, f) In neonates with clinical deterioration but no evidence of perforation on the plain abdominal radiograph, lateral decubitus or horizontal beam (cross table) lateral radiographs are useful, particularly in very sick babies requiring minimal handling.

Ultrasound may detect free gas in the abdominal cavity, and unlike plain radiography clearly detects the presence of abdominal fluid, whether intraluminal, free or in a localized collection. Free fluid can be seen in cases of severe NEC, and the presence of internal septations or focal collections makes perforation more likely.

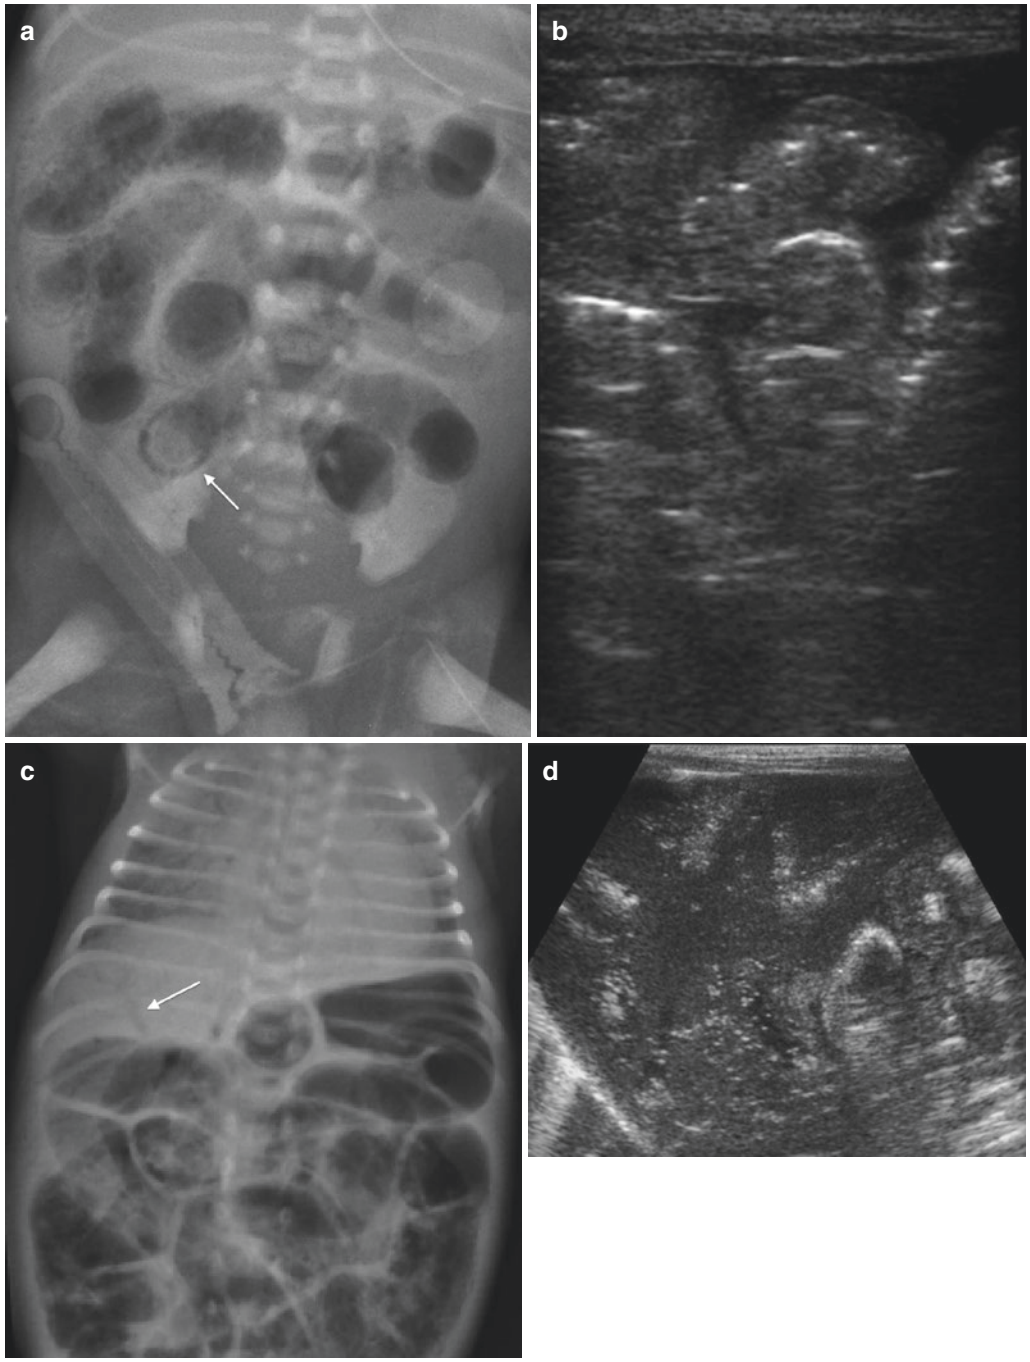

Fig. 10.27 Necrotising enterocolitis (NEC). Radiograph (**a**) in a neonate with NEC demonstrates bubbly and circumferential lucencies (*arrow*) related to the bowel wall consistent with extensive pneumotosis. US images (**b**) demonstrates circumferential hyperechoic foci in dependant and non-dependant positions within the bowel wall consistent with intramural air. Supine radiograph (**c**) in this premature neonate shows generalised asymmetrical bowel loop dilatation. Branching lucencies are seen in the right upper quadrant (*arrow*) extending to the periphery consistent with portal venous gas. Longitudinal ultrasound image of the liver (**d**) demonstrates multiple linear hyperechoic foci within the parenchyma, corresponding to air within the portal veins. On dynamic imaging these are seen as mobile foci within the vessels. Supine radiograph (**e**) shows lucency of the upper abdomen, outlining the falciform ligament (*arrow*), in a neonate with NEC. The appearances are consistent with pneumoperitoneum. Radiograph (**f**) demonstrates Rigler's sign, seen best in the left lower quadrant (*arrow*)

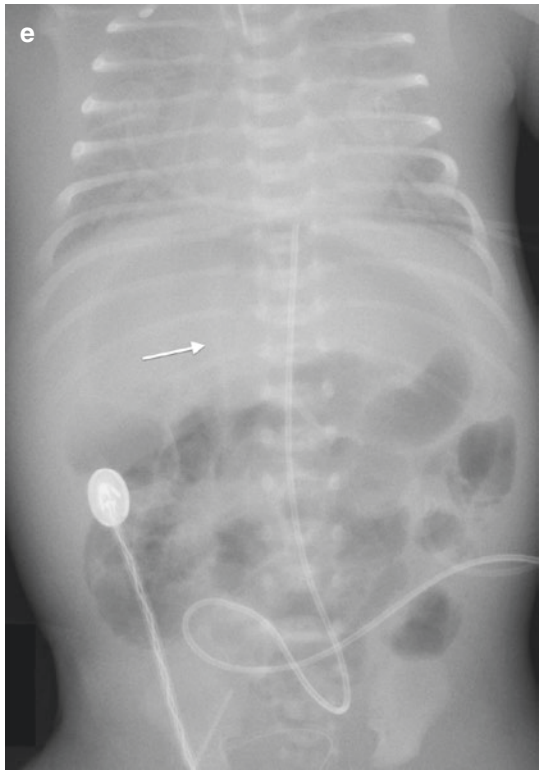

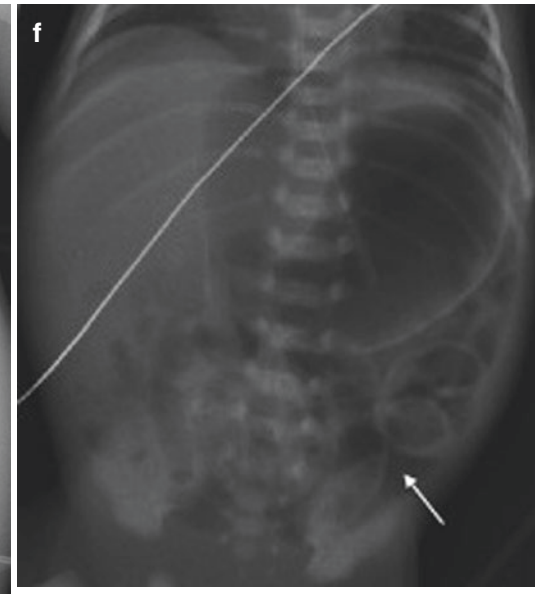

Fig. 10.27 (continued)

Ultrasound is superior to plain radiography in assessing bowel wall thickening, peristalsis and echogenicity and also in the assessment of bowel wall vascularity. Bowel wall hyperaemia is thought to result from vasodilation of mural and mesenteric vessels due to inflammation, and suggests viable inflamed bowel. Absence of flow has been found to correlate with transmural necrosis. Colour Doppler sonography of the bowel wall has been found to be more accurate than clinical examination and plain radiography in the prediction of necrosis in NEC [25]. Ultrasound may therefore be of use in patients with clinically suspected mild NEC with non-specific radiographic features, or in those clinically deteriorating but with no evidence of pneumoperitoneum on plain film.

Contrast studies are often useful in assessing the long-term complications of NEC, which include strictures of involved segments of bowel.

10.9 The Neonate with an Abdominal or Pelvic Mass

Many neonatal abdominal masses are diagnosed antenatally, and these are usually genitourinary (more than 50%) or gastrointestinal in origin. Ultrasound is the initial investigation of choice in neonates with a suspected abdominal mass, with cross sectional imaging to further determine disease site and extent and identify metastatic disease in the case of malignancy. A plain abdominal radiograph may be useful, and may show displacement of bowel loops, or calcification within a soft tissue density which is suggestive of neuroblastoma or hepatoblastoma. Sacral abnormalities may be seen in cases of sacrococcygeal teratoma or other pre-sacral mass, sometimes as part of the Currarino triad.

10.9.1 Renal Masses in the Neonate

10.9.1.1 Hydronephrosis

This is the most common cause of a neonatal mass, and with multicystic dysplastic kidney comprises 40% of all neonatal abdominal masses. The most common cause is ureteropelvic obstruction (Fig. 10.28).

In the full term neonate, a kidney with an AP diameter of the renal pelvis >1 cm on ultrasound is termed hydronephrotic. For premature infants, a useful approximation is 1 mm for each completed month of gestation. Ureteric dilatation may be seen posterior to the bladder, suggesting a distal cause of obstruction at the ureterovesical obstruction or due to posterior uretheral valves, particularly if bilateral. A cystic hypoechoic structure within the bladder at the VUJ is characteristic of a ureterocele. Ureteroceles are associated with duplex systems, which may be detected on ultrasound. A discrepancy in renal length is suggestive, as is the appearance of cortical tissue passing through the medulla. An obstructed upper moiety may be seen, and two ureters may be evident extending from the hila or retrovesically (Fig. 10.29).

A micturating cystourethrogram is performed in those with hydronephrosis to exclude reflux. In the neonate this is performed with antibiotic cover. A small urethral catheter is inserted under aseptic conditions, and water-soluble contrast is instilled into the bladder. Anteroposterior and oblique images of the bladder detect any filling defect or reflux. On voiding, the neonate is turned into the lateral position and the catheter is removed during micturition to give good contrast enhanced views of the urethra, allowing the detection of posterior urethral valves. At the end of the procedure a final image of the abdomen is acquired to ensure there is no late reflux.

Percutaneous nephrostomy is technically challenging in small infants, and requires special expertise and equipment. It is usually reserved for cases of severe bilateral obstruction with renal insufficiency, severely obstructed single kidney with elevated creatinine or for untreatable pyonephrosis (Fig. 10.30).

In the case of neonatal diagnosis of bilateral ureteric reflux, a DMSA scan to look for areas of cortical scarring and relative renal functions is the next step in the imaging pathyway. This is usually delayed until after the neonatal period, to allow maturation of renal function, with the child on prophylactic antibiotic therapy.

10.9.1.2 Multicystic Dysplastic Kidney (MCDK)

This is the second most common abdominal mass in a neonate. Multicystic dysplasia (MCD) is

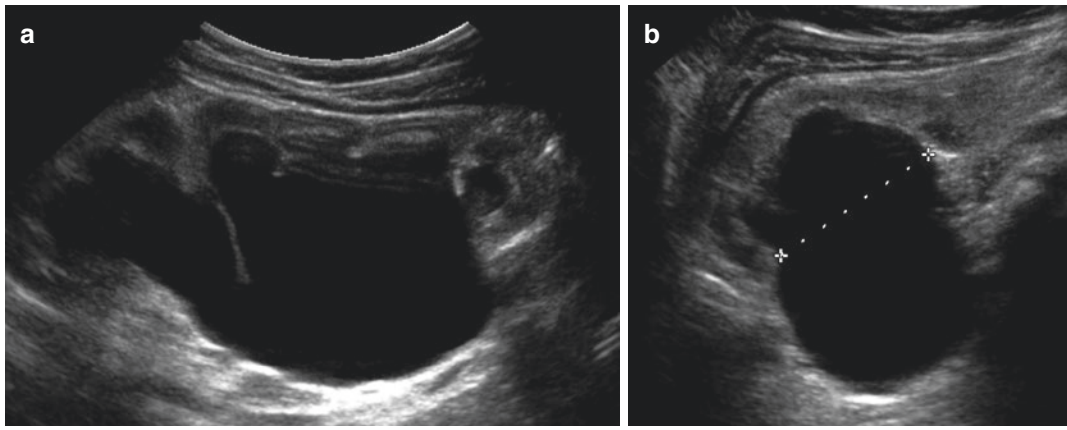

Fig. 10.28 Hydronephrosis. (**a**) Longitudinal and (**b**) transverse ultrasound images of the left kidney show a dilated collecting system with large renal pelvis and blunted calyces. The transverse view allows an accurate AP diameter of the renal pelvis to be obtained, which in this case measured 2.8 cm

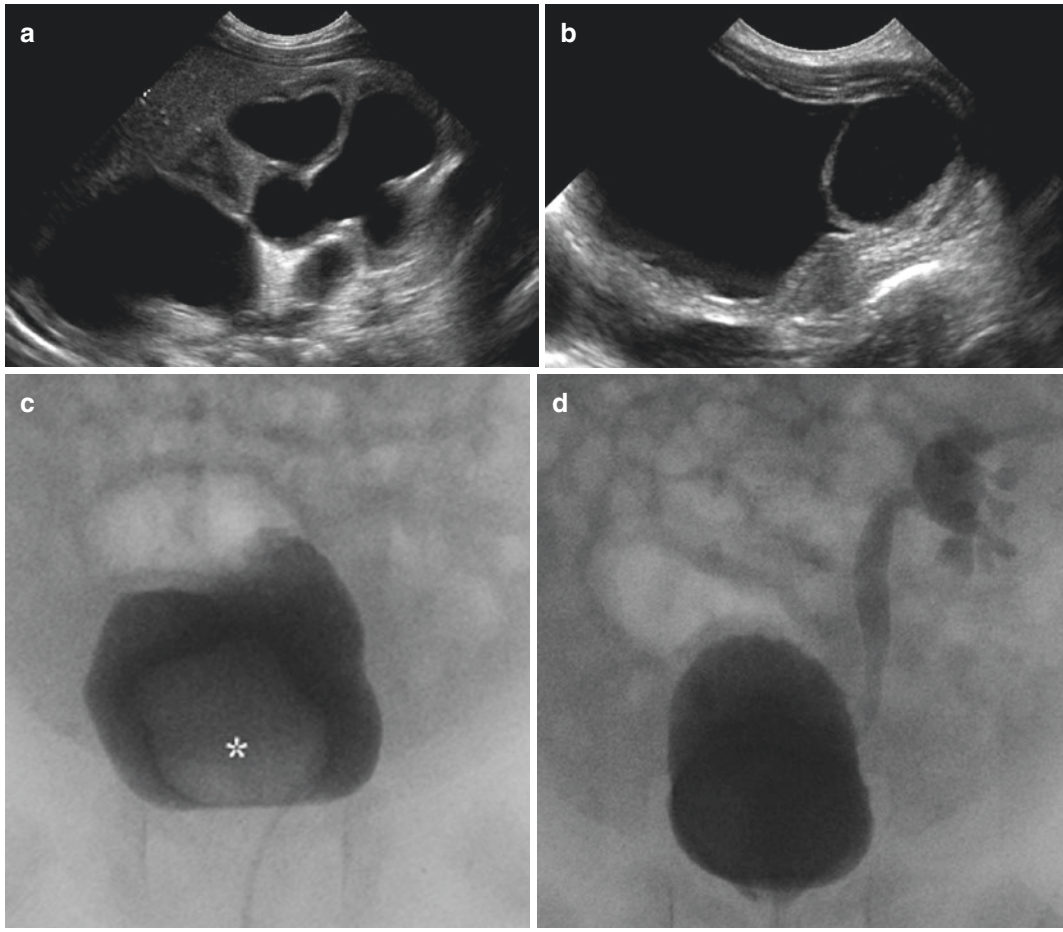

Fig. 10.29 Ultrasound image (**a**) demonstrates an enlarged hydronephrotic duplex kidney, with particular dilatation of the upper moiety. Image (**b**) demonstrates a thin walled cystic structure in the bladder (*), consistent with ureterocoele, shown on MCUG as a filling defect (**c**). Reflux into the lower moiety also demonstrated on MCUG (**d**)

defined as a non-functioning kidney replaced by multiple cysts of varying size and non-functioning dysplastic tissue. There is an abnormal contralateral kidney in up to 40%, usually due to PUJ obstruction or reflux.

On ultrasound there are multiple hypoechoic cysts of varying size which do not communicate with the collecting system, differentiating MCD from a hydronephrotic kidney. Any visible parenchyma is echogenic and the kidney may appear lobulated. The kidney may have involuted and be difficult to visualize (Fig. 10.31). MCD can occur in the upper pole of a duplex kidney. A DMSA scan will confirm absence of functioning renal tissue. Usually these children have serial scans to document growth of the contralateral kidney and ensure involution of the dysplastic kidney. MCUG will assess for contralateral vesicoureteric reflux.

10.9.1.3 Congenital Mesoblastic Nephroma (CMN)

Solid renal lesions occur much less frequently than cystic lesions. Congenital mesoblastic nephroma is the most commonly occurring renal tumour in the first few months of life, and is sometimes diagnosed antenatally. Ultrasound appearances are highly variable, ranging from uniformly solid tumours, to complex solid and cystic lesions with mixed echogenicity. Some lesions appear almost completely cystic. However, most cases presenting

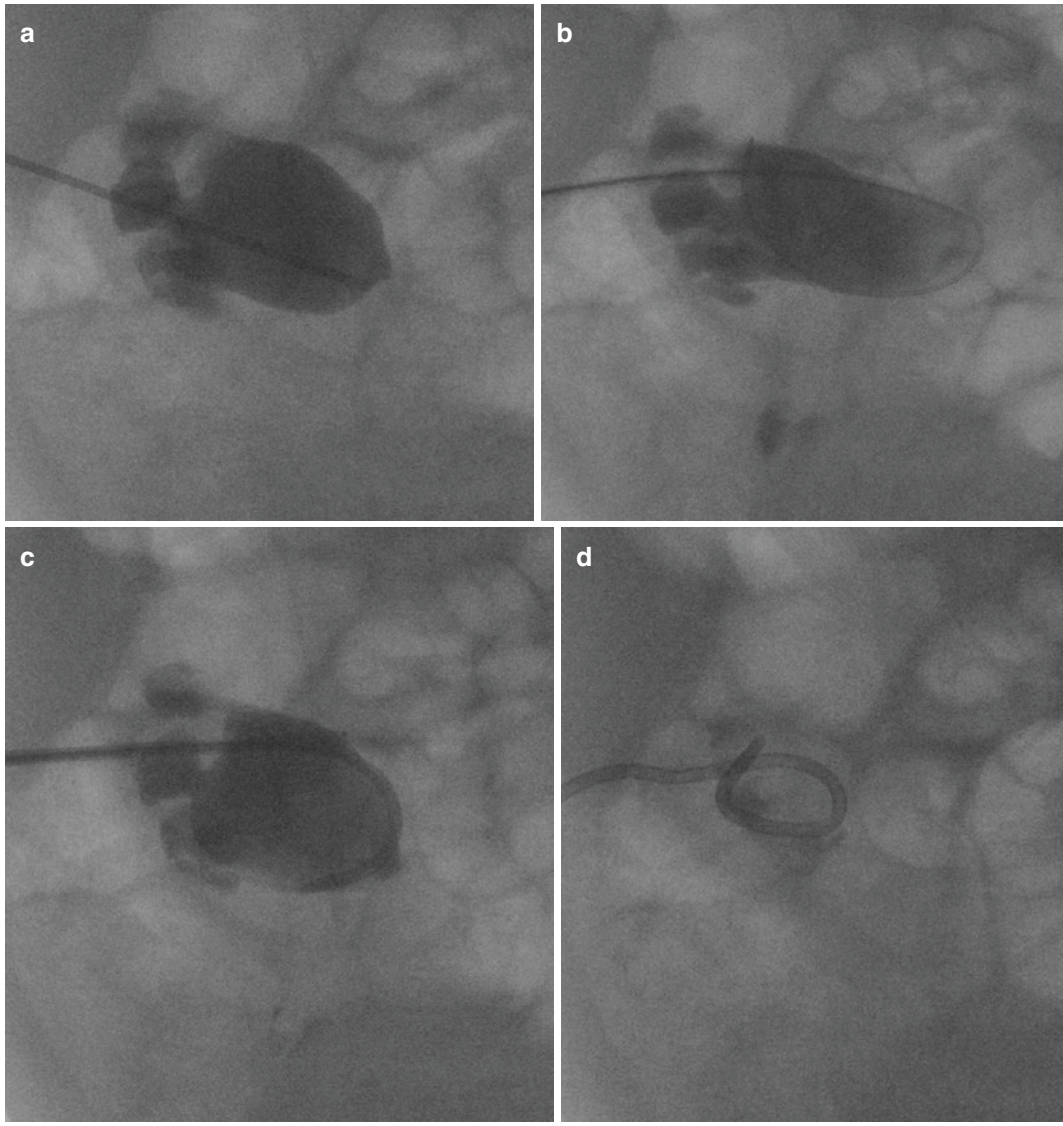

Fig. 10.30 Pyonephrosis in a lower pole moiety. Selected images from percutaneous nephrostomy in a lower moiety pyonephrosis show percutaneous needle puncture into the collecting system (**a**) followed by the introduction of guidewire (**b**) and placement of pigtail catheter (**c** and **d**)

in the neonatal period are the classic variant, which tends to present as a purely solid mass, sometimes showing a characteristic pattern of concentric rings with different echogenicity.

CT typically shows a large, uniform renal mass with minimal, predominantly peripheral enhancement. On MRI, the tumours most often show low signal intensity on T1 weighted images, though there may be areas of T1 hyperintensity if haemorrhage has occurred. T2 weighted images may show varying characteristics [28] (Fig. 10.32).

The differential diagnosis of CMN includes Wilms tumour. This is the most common renal tumour of childhood, but fewer than 2% present at less than 3 months of age. Bilateral tumours are more suggestive of CMN. Wilms tumours are often associated with congenital anomalies or syndromes (Beckwith-Wiedemann, Denys-Drash, and WAGR syndrome-Wilms tumour,

Fig. 10.31 Multicystic dysplastic kidney. Longitudinal ultrasound image demonstrates an enlarged right kidney containing multiple cysts which do not communicate with the collecting system therefore differentiating it from hydronephrosis

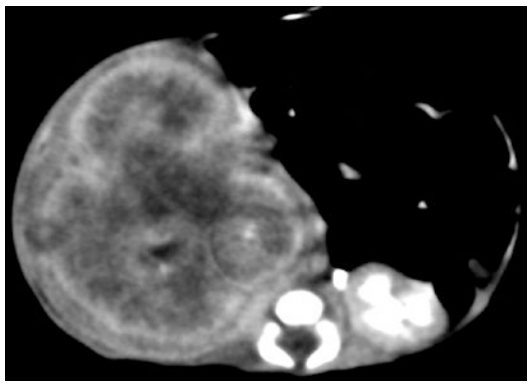

Fig. 10.32 Congenital mesoblastic nephroma. Contrast enhanced CT demonstrates large heterogeneously enhancing solid mass with smooth contours replacing the right kidney

aniridia, genitourinary abnormalities and mental retardation syndromes). Another rare differential is ossifying renal tumour of infancy. This typically presents with haematuria, and is usually at least partly ossified.

10.9.1.4 Renal Vein Thrombosis

Renal vein thrombosis is the most common non-catheter related venous thrombo-embolic event in the neonate [29]. This may present as a renal mass in a sick neonate, usually in association with haematuria or proteinuria. The ultrasound appearances vary with severity and stage of thrombosis. In the early stage, echogenic streaks are seen in the medulla representing interlobular and interlobar thrombus. Subsequently, the kidney enlarges with loss of corticomedullary differentiation. At this stage, bilateral renal vein thrombosis may produce similar appearances to infantile polycystic kidney disease. Thrombus can be hypo or hyperechogenic depending on age, and may appear to distend the vein, and to extend into the IVC. Colour Doppler allows early detection of absence of intrarenal and renal vein flow [30]. Tumour invasion of the renal vein can have a similar appearance. MRI is complementary to ultrasound in demonstrating the extent of the thombus (Fig. 10.33).

10.9.2 Ovarian Cyst

Ovarian cysts are the most common intra-abdominal cystic lesion in the female neonate [31]. Stimulation of the ovary by placental and maternal hormones results in small asymptomatic follicular cysts in up to 80% neonates [32]. Ovarian cysts in the neonate are almost invariably benign, and are only of concern if detected antenatally, if palpable or if complicated.

A simple cyst is seen as an anechoic lesion on ultrasound with thin walls. The visualization of normal adjacent ovarian tissue or a daughter cyst increases the diagnostic certainty. Serial ultrasound follow up should show a gradual reduction in size, as maternal circulating hormones begin to wane. While small ovarian lesions are seen in the adnexa on imaging, large cysts or those with long pedicles commonly extend out of the small neonatal pelvis and may be detected as an entirely intra-abdominal mass [33]. Ultrasound may confirm the cystic nature of the mass but may not be able to identify its origin. Unless a normal ovary is identifiable on one side, the side of the pathology may be difficult to determine, as lesions may appear midline on imaging or may be visible on the contralateral side of the pelvis due to the presence of a pedicle.

Complicated torted or haemorrhagic cysts can have complex ultrasound appearance, with fluid-debris levels, internal septae. A more homogenous solid looking lesion with absence of internal colour flow may be seen. MR will

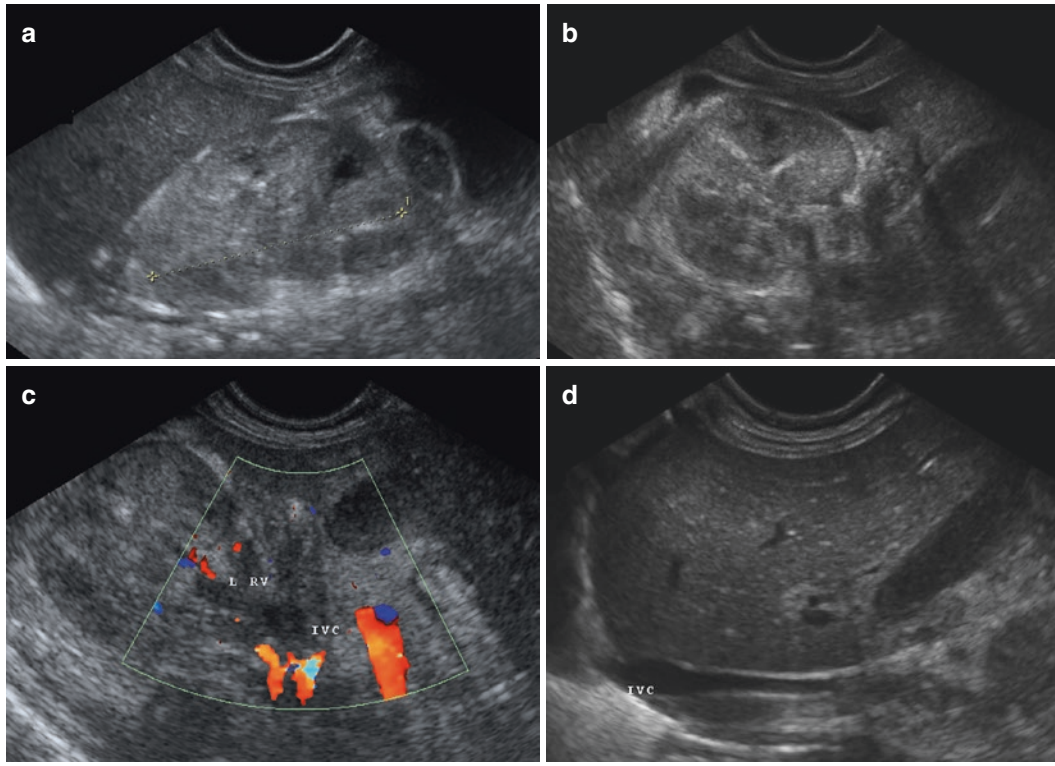

Fig. 10.33 Renal vein thrombosis. Longitudinal and transverse ultrasound images (**a** and **b**) show an enlarged hyperechoic kidney with loss of the normal corticomedullary differentiation. Colour Doppler image (**c**) shows absence of flow in the renal vein. Thrombus is also noted in the IVC (**d**)

locate the lesion and will characterize its contents whether cystic or containing mixed blood products. A haemorrhagic cyst is thought to occur due to torsion, and these are usually excised (Fig. 10.34).

Another cause of abdominoplevic masses in the female neonate is hydrocolpos, a fluid filled distended vagina or hydrometrocolpos, fluid filled distended vagina and uterus. This usually results from vaginal or cervical stenosis, hypoplasia or agenesis, contrary to those presenting in adolescents which are usually due to an imperforate hymen. This condition is usually diagnosed following clinical examination and ultrasound, and has also been diagnosed on antenatal ultrasound and MR [34]. Ultrasound of the renal tract will identify hydroureteronephrosis due to the pelvic mass, and will exclude or confirm any associated congenital renal abnormalities.

10.9.3 Duplication Cysts

GI masses are the second most common site of origin of the neonatal abdominal mass. Most gastrointestinal masses in the neonate are enteric duplication cysts, which represent part of the spectrum of mesenteric and omental cysts. These are usually diagnosed with ultrasound, and are often detected prenatally.

Duplication cysts occur anywhere along the alimentary tract but 75% are intra-abdominal, usually in the distal ileal/ileocaecal region. They are typically cystic and do not communicate with the bowel lumen, though can be tubular and communicate with the lumen therefore filling with gas. The most common mode of presentation is with obstruction, but can also present with a mass, intususception, failure to thrive or rarely haemorrhage due to ectopic gastric or pancreatic mucosa.

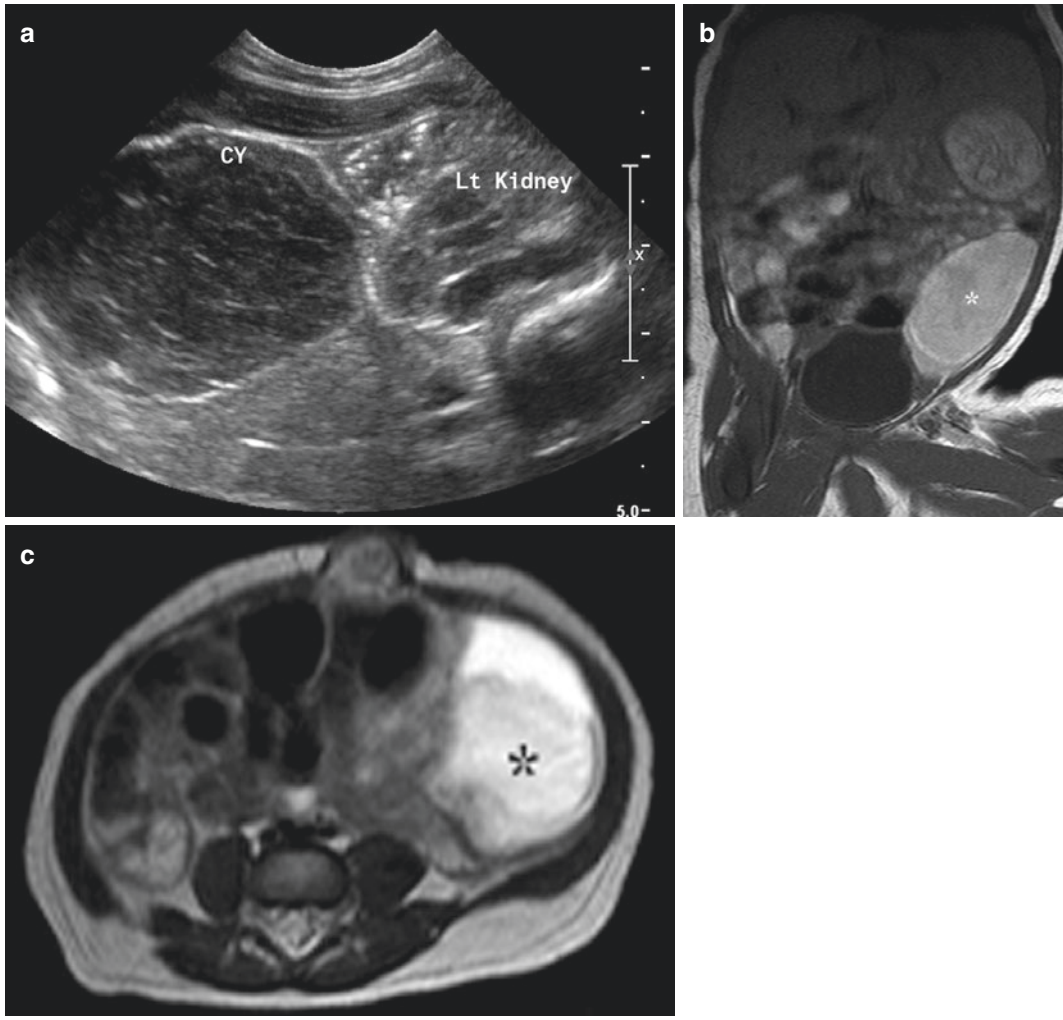

Fig. 10.34 Torsion of ovarian cyst. US image (**a**) (annotated) in a 4 day old female with an antenatal abdominal mass, shows a complex mass in the left flank (cy), inferior to the lower pole of the kidney, which has cystic and solid components. Coronal and axial MR images (**b** and **c**) show a complex lesion (*) in the left lower abdomen which is of intermediate intensity on T1, with high and intermediate intensity contents on T2 and no fat suppression, indicating haemorrhage

Ultrasound demonstrates a cystic lesion most often located in the lower abdomen that is intimately associated with the bowel. In 50% cases this has characteristic double-layered appearance or "rim sign", considered virtually diagnostic. This comprises an echogenic inner mucosal layer and hypoechoic outer muscle layer [35] (Fig. 10.35). Peristalsis of the cyst wall has also been described [36]. The cystic lumen often contains debris, either mucosal slough or old blood. Ultrasound diagnosis may not be achieved in the case of a gas-filled cyst which communicates with the bowel. These may be suspected on the plain radiograph appearances and contrast studies may show a filling defect due to an adjacent duplication cyst, or a cystic structure that fills with contrast in the case of a communicating duplication cyst. MR can be used to confirm the diagnosis if there is uncertainty and in midline lesions as it is useful to exclude any intraspinal extension in the case of possible neuroenteric cysts.

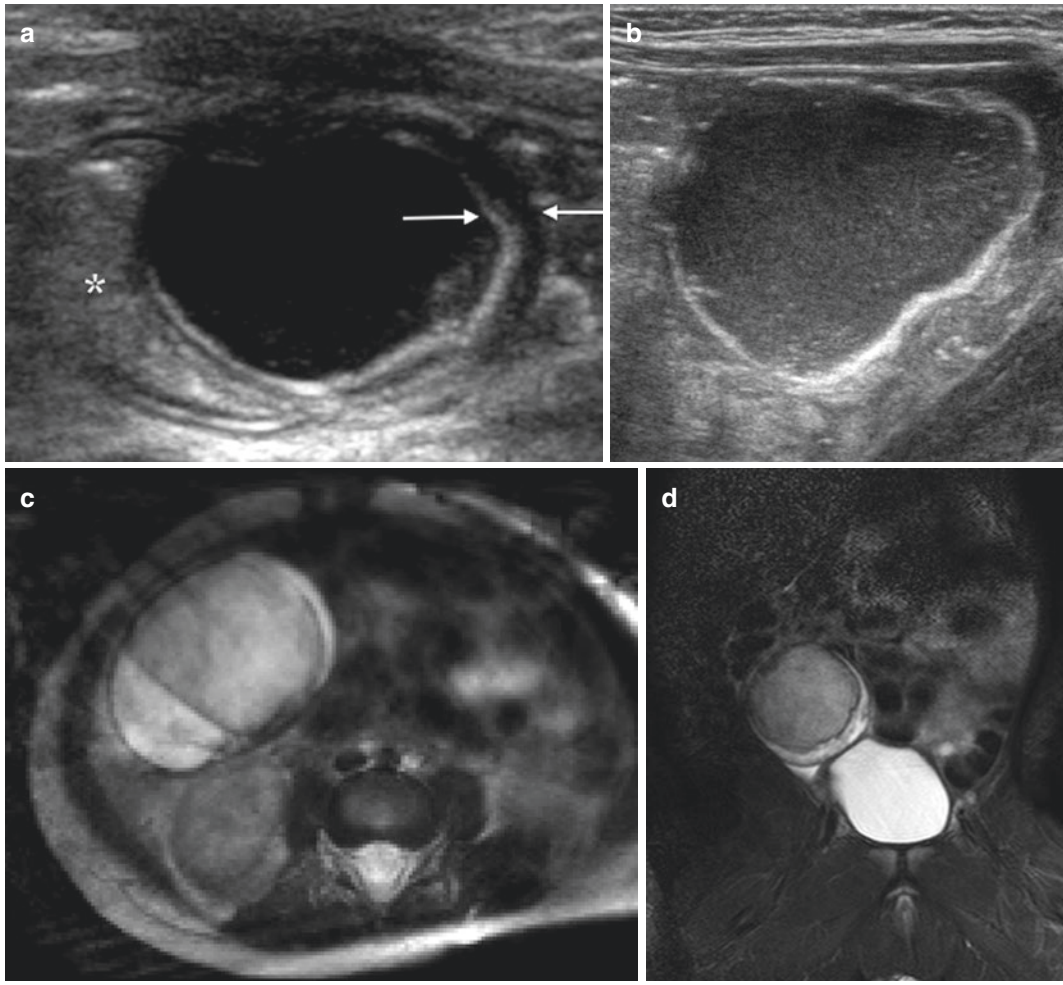

Fig. 10.35 Duplication cyst. Ultrasound image (**a**) demonstrates a cystic structure with a inner hyperechoic and outer hypoechoic wall, consistent with the characteristic "double layered" appearance (*arrows*). The intimate association with the adjacent bowel (*) is illustrated. Ultrasound and MR images (**b**–**d**) in another case show a cystic lesion on ultrasound, with a crenated appearance to the inner aspect of the wall, best seen on the STIR sequence (**d**)

In the more unusual case of haemorrhage, ectopic gastric mucosa may be detected via the use of a Technecium 99 m nuclear medicine scan.

10.9.4 Meconium Pseudocyst

Meconium psuedocyst results from intrauterine bowel perforation and resulting meconium peritonitis. Persistent communication between the perforation, usually caused by ileus, atresia or volvulus, and peritoneal cavity results in a pseudocyst. This may present with distension in the neonate, a palpable mass or may be discovered during imaging of neonates with suspected obstruction. On plain radiograph peritoneal calcification is diagnostic of meconium peritonitis in the neonate, and the pseudocyst usually contains calcifications from exuded meconium. Ultrasound reveals a cyst with thick echogenic possibly calcified walls and echogenic debris filled cyst content (Fig. 10.36).

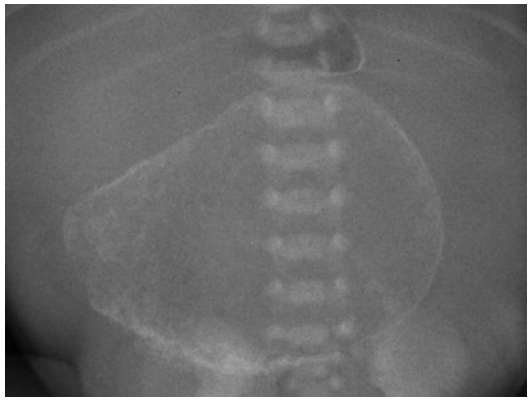

Fig. 10.36 Meconium pseudocyst. Plain abdominal radiograph demonstrates finely calcified ovoid abdominal mass

10.9.5 Adrenal Masses

The best modality for imaging the neonatal adrenal is ultrasound. The normal adrenal has a hypoechoic cortex with an echogenic medulla in a layered configuration and a varying shape, usually described as "y", "v", "z" shaped (Fig. 10.37). The normal adrenal can be up to 3 cm in length and up to 0.3 cm thick. The use of colour flow doppler helps determine internal vascularity of a mass or cystic appearing lesion. The most common reason for adrenal enlargement in the newborn is adrenal haemorrhage, and the most common adrenal mass lesion is neuroblastoma.

Adrenal haemorrhage may occur as a result of birth trauma, usually in term or large for gestational age babies. It may be suspected due to anaemia, jaundice or adrenal insufficiency. Usually this is unilateral, occurring most frequently on the right but is bilateral in 10%. Acute adrenal haemorrhage is seen on ultrasound as echogenic and mass like, but avascular on colour flow Doppler, differentiating it from the highly vascular neuroblastoma mass. Doppler can also be used to assess the renal vain and exclude thrombosis, which is a recognized associated with adrenal haemorrhage [30]. Sub-acutely, adrenal haemorrhage can have a mixed echogenicity and chronically can even be cystic. Usually adrenal haemorrhage resolves and is often found incidentally. Acutely if there is doubt over the diagnosis, or if on sequential scans the lesion is seen to enlarge, MR may be performed, which shows the classic appearance of imaging blood products. A T2 weighted gradient echo sequence produces the characteristic "blooming artefact" caused by the presence of haemosiderin (Fig. 10.38). Chronically after haemorrhage the adrenal gland may calcify. This can lead to confusion as neuroblastomas often contain calcification.

Adrenal cysts may be seen as the late sequelae of haemorrhage, or in association with Beckwith Weiderman syndrome. Bilateral adrenal gland enlargement, with a cerebriform appearance of the gland contour is suggestive of congenital adrenal hyperplasia (CAH).

10.10 Neoplasms in the Neonate

10.10.1 Neuroblastoma

Neuroblastoma is the most common extracranial solid neoplasm in children. It is rare in neonates but is still the most common malignancy in the first week of life. Fortunately there is a better prognosis in children diagnosed before the age of 2 years. It most commonly arises in the adrenal gland but can be found anywhere along the sympathetic chain. Imaging findings should be interpreted in conjunction with bone marrow aspirate and urinary catecholamines.

An abdominal radiograph may reveal stippled calcification, seen in 30% cases, within a soft tissue density. A careful search for bone metastases may reveal lucent, sclerotic or mixed density lesions. Normal structures may also be displaced by the mass.

On ultrasound the appearances are those of a heterogenous increased echogenicity mass. Shadowing echogenicities may be seen representing calcification and there may be evidence of internal low attenuation representing haemorrhage and necrosis. Careful assessment of the liver is required for evidence of metastases and of the IVC and renal veins for intravascular extension of the tumour. In neonates, neuroblastoma can present with associated skin, liver and bone marrow metastasis (Stage 4S), but has a relatively good prognosis.

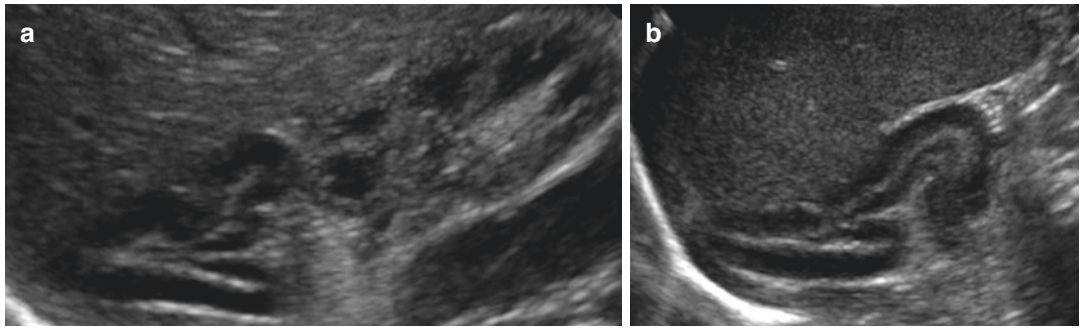

Fig. 10.37 Normal adrenals. Ultrasound appearance of (**a**) right and (**b**) left adrenal glands. Note the layering appearance due to the thick hypoechoic cortex and echogenic central medullary portion

CT further evaluates the origin of the lesion and often has characteristic findings of a large adrenal mass with low attenuation areas of necrosis and haemorhage as well as internal calcification (85%). The mass can often be seen to cross the midline and encase rather than displace vessels. Metastases may also be identified on CT. An MIBG (I^{123} metaiodobenzylguanidine) scan can assess the extent of disease and identify metastases, as tissues with high catecholamine production avidly take up MIBG. The primary tumour will also be visualized. MIBG is highly sensitive and specific for neuroblastoma, concentrating in >90% of tumours. FDG-PET may also have a role in staging high-risk neuroblastoma, but it is less sensitive than MIBG for bone metastases, and so MIBG remains the recommended modality for whole-body staging in most cases [37]. In those tumours that are not MIBG avid, a technecium 99 m MDP bone scan will be performed. MRI is used to assess the state of the involved vessels, and also to look for frequent intraspinal extension of disease via enlarged foramina (Fig. 10.39).

The major differential diagnosis is Wilms tumour. Calcification is uncommon in Wilms tumour. The tumour tends not to cross the midline and displaces vessels rather than encases them. Wilms may be bilateral and spreads along renal vein and into the IVC, unlike neuroblastoma.

Urinary chatecholamines often confirm the diagnosis. Adrenal hemorrhage may also simulate an adrenal tumour, but in haemorrhage there is absence of internal blood flow and the mass typically reduces in size and resolves over a period of a few weeks.

10.10.2 Liver Tumours

10.10.2.1 Hepatoblastoma

This malignant embryonic hepatic tumour is most common hepatic tumor in infancy. There is a strong association with birthweight; the prevalence of hepatoblastoma is inversely proportional to birth weight, [38] and the tumour is also associated with other syndromes such as Beckwith-Weidermann, Gardener syndrome and FAP. Other GU and GI abnormalities may occur in conjunction. Hepatoblastoma may be suspected antenatally, as 4% of cases are congenital [39].

Usually hepatoblastoma presents as a large, painless, palpable mass in the right upper quadrant. If a plain film has been performed a focus of soft tissue density with internal coarse calcifications may be seen in the right upper quadrant. Displacement of the adjacent bowel may also be noted. Ultrasound however should be the initial investigation of choice. The typical appearances are of a well-defined hyperechoic hypervascular solid mass with heterogenous areas of necrosis, usually in the right lobe of the liver. Internal hypoechoic fibrous septae may be present [40] and a resulting "spoke-wheel appearance" has been described [39]. Internal calcification may cause acoustic shadowing and disease may be multifocal.

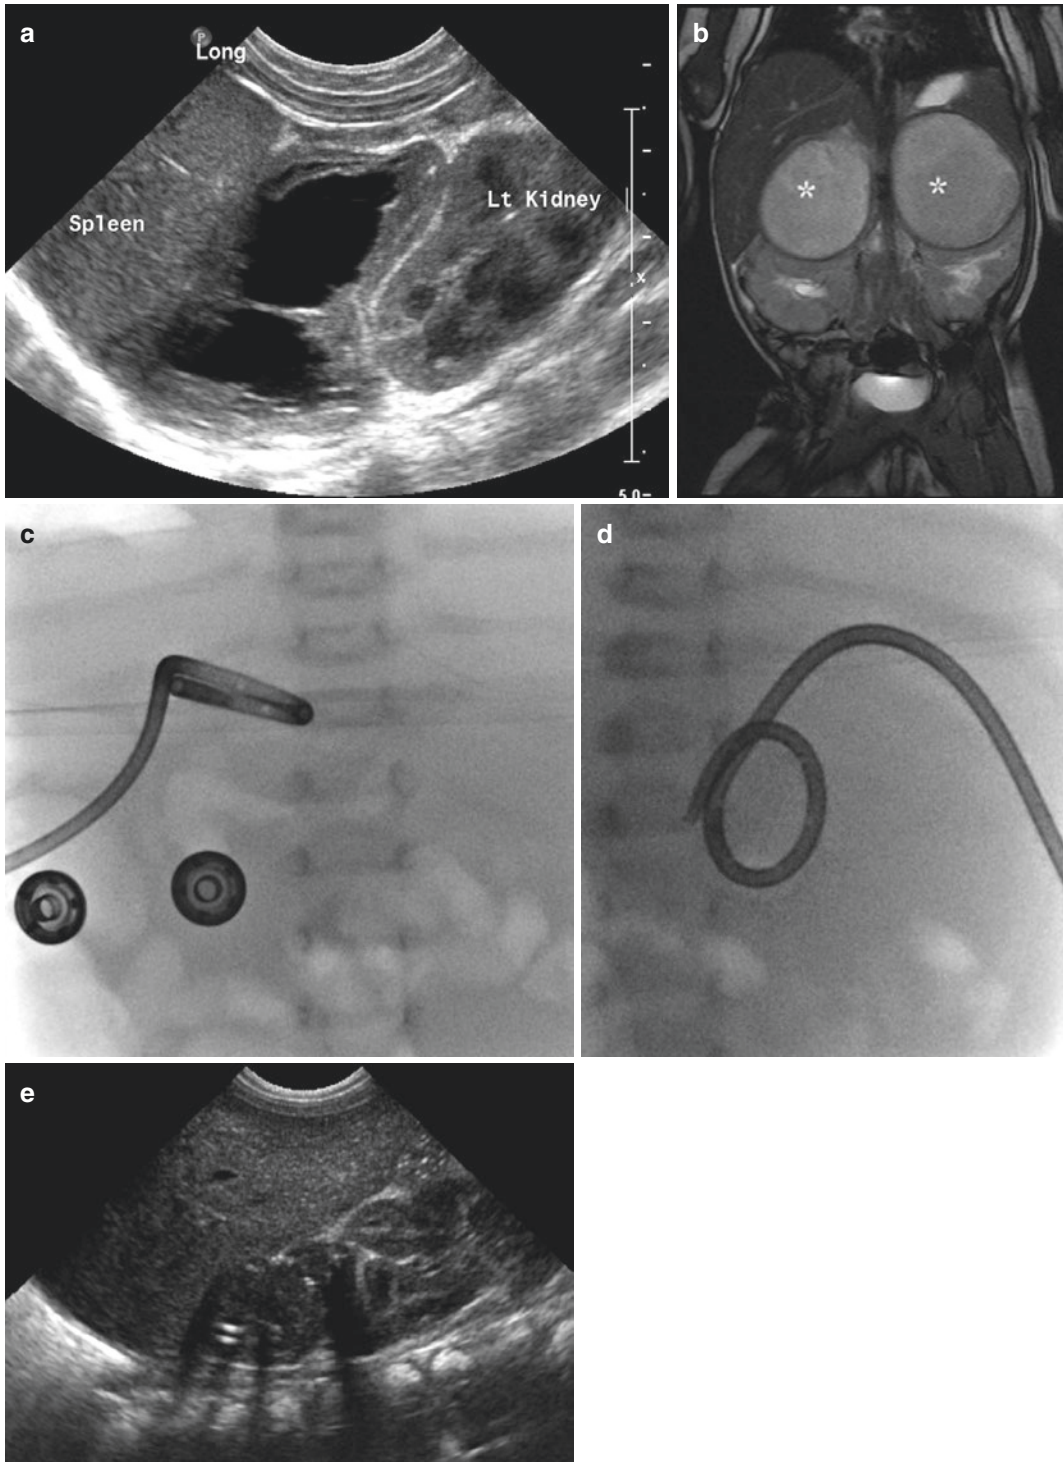

Fig. 10.38 Infected adrenal haematomas. Annotated ultrasound image (**a**) shows irregular thick walled cystic suprarenal mass. Bilateral adrenal collections (**b**–**e**). Single coronal MR image demonstrates large bilateral suprarenal collections (*). Drainage of the bilateral collections with the use of 6F pigtail drainage catheters (**c** and **d**). Ultrasound image (**e**) showing drainage catheter is the right suprarenal collection

Contrast enhanced CT aims to further define the extent of disease and the relationship of the mass to the segmental anatomy of the liver for pre-operative planning. This reveals a large sharply circumscribed mass, which shows low attenuation relative to the liver. Post contrast there is heterogeneous enhancement but the lesion remains hypoattenuating relative to the liver parenchyma. Calcifications are present in 50% [40]. Imaging also aims to identify metastasis, which are commonly to the lungs and periaortic nodes, and less commonly to the brain. If necessary for surgical planning, MR will further characterize the lesion and its extent and relationship to vessels. The mass is low signal on T1 but may have high signal related to haemorrhage, and high signal on T2, again with heterogenous areas dependant on the amount of haemorrhage and necrosis [41, 42]. MR angiography will evaluate the vasculature pre-operatively. AFP levels are

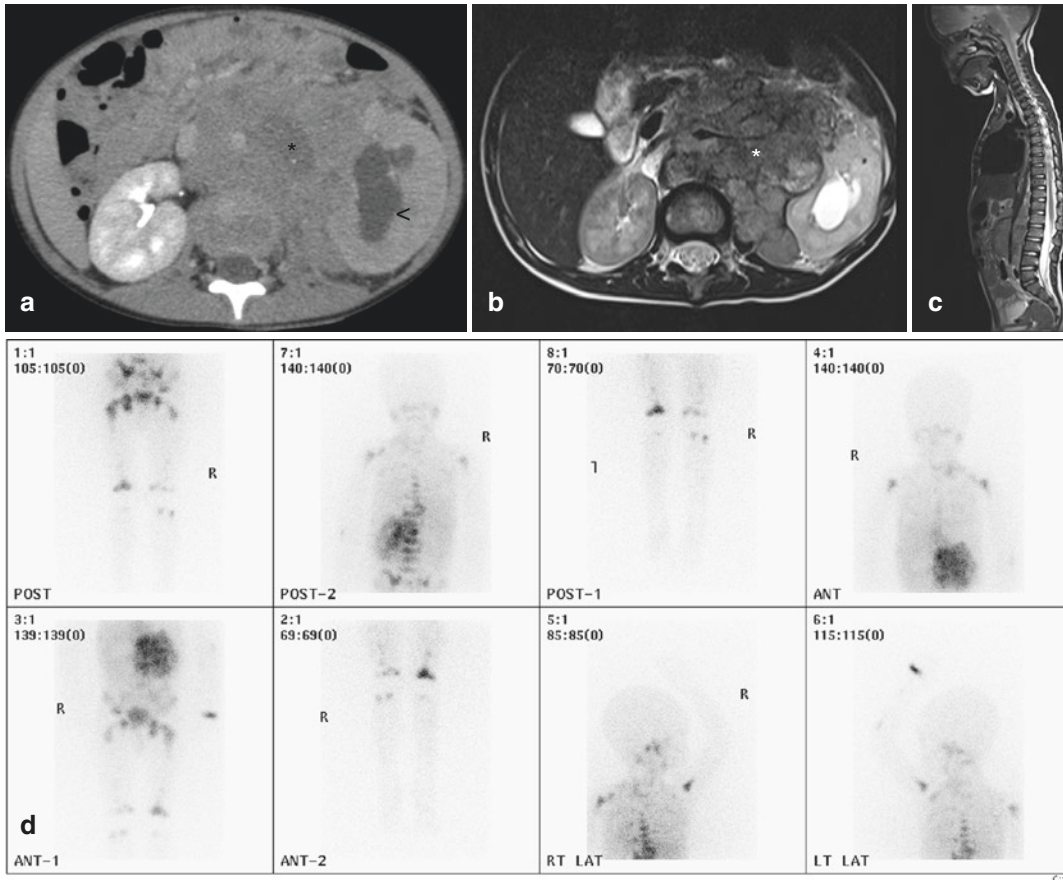

Fig. 10.39 Neuroblastoma. CT demonstrates a large heterogenous retroperitoneal mass (*) containing small calcific foci and low density areas suggestive of necrosis (**a**). Left hydronephrosis also shown (<). Axial and sagittal MR images (**b**, **c**) clealry demonstrate a heterogenous mass (*), encasing the vessels and causing a left hydronephrosis. MIBG scan confirms increased tracer uptake at the site of primary tumour, with more focal areas of uptake in the axial skeleton consistent with bone metastases. Ultrasound image of the pelvis in a more atypical case (**e**) demonstrates a heterogenous presacral mass with internal vascularity. CT (**f**) confirms the mass to be of soft tissue density, and demonstrates internal calcification. Sagittal T2 images further show the heterogeneity of the mass and demonstrate infiltration into the spinal canal via the neural foramina (**g**)

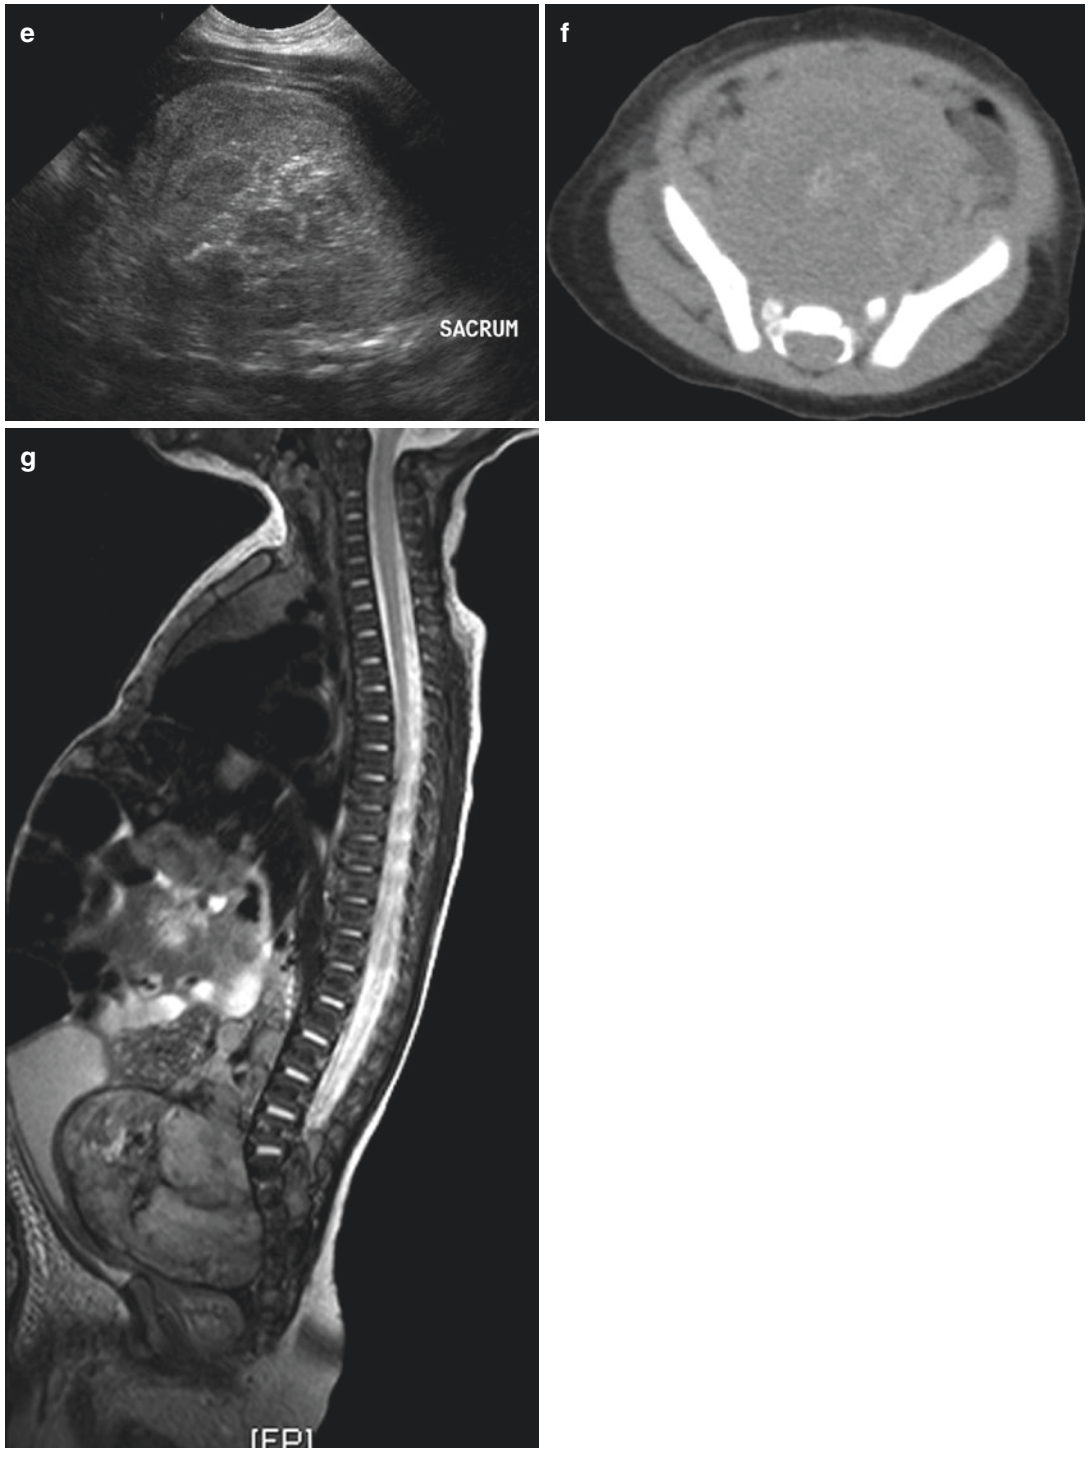

Fig. 10.39 (continued)

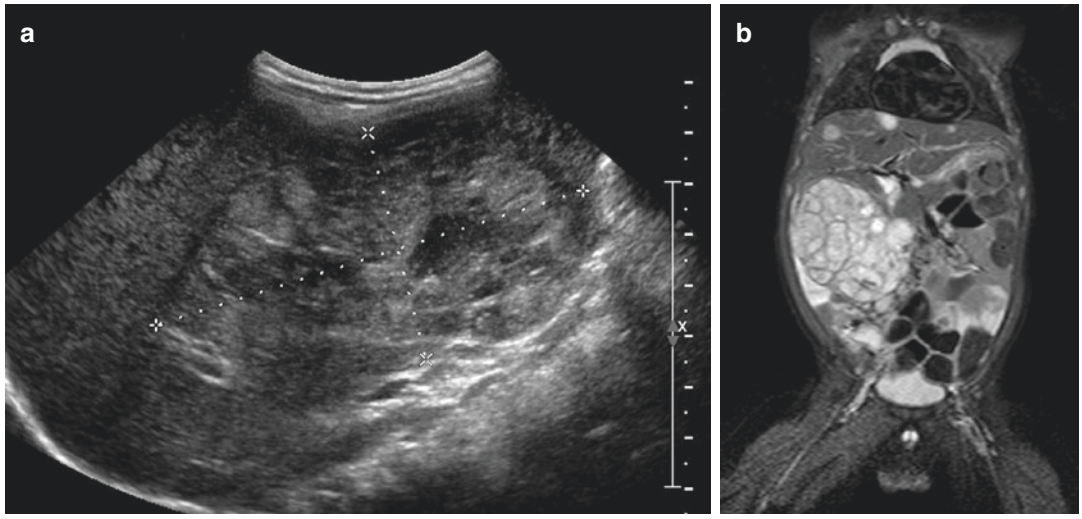

Fig. 10.40 Hepatoblastoma. (**a**) Longitudinal ultrasound image in a baby presenting with increasing lower chest upper abdominal swelling shows a large heterogenous mass involving the right lobe of the liver, marked by calipers. (**b**) Coronal STIR MR image demonstrates a large heterogenous high signal lesion in the liver with further multiple foci of signal abnormality confirming the multifocal nature of the tumour

elevated in >90% (Fig. 10.40). There are no pathognomonic features of liver tumours and correlation of imaging findings, tumour markers and clinical presentation and findings on examination is essential. Biopsy is usually required to confirm the diagnosis.

In the absence of an elevated AFP level, the differential diagnosis of a liver tumour in the neonatal period includes atypical teratoid rhabdoid tumours and benign vascular tumours, including proliferative haemangioma and haemangioendothelioma. Metastatic neuroblastoma is another differential to consider, however these lesions are usually multiple and there is usually a primary suprarenal mass. Mesenchymal hamartomas are predominantly cystic with no associated elevation in serum AFP levels. Hepatocellular carcinoma is rare in infants.

Interventional radiology has a role in chemotherapeutic tumour embolisation and subsequent imaging is directed at assessing the response to surgical/chemotherapy.

10.10.2.2 Hepatic Vascular Tumours

Infantile hepatic haemangioma is the most common benign vascular liver tumour in infancy and the third most common liver tumour in children, after hepatoblastoma and mesenchymal hamartoma. Liver haemangiomas must be distinguished from other vascular lesions such as arteriovenous malformations, and from malignant tumours such as hepatoblastoma and embryonal sarcoma.

Liver haemangiomas can be classified anatomically into three subtypes, dividing them into focal, multifocal, and diffuse lesions [43]. Focal liver haemangiomas are well-defined, solitary, spherical lesions, which are often incidental findings on ultrasound scans performed for other reasons. Multifocal lesions are also typically spherical and well-circumscribed. They sometimes co-exist with multiple cutaneous common infantile (proliferative) haemangiomas. In fact five or more cutaneous infantile haemangiomas necessitates a liver ultrasound for liver evaluation. Many are asymptomatic, but some large focal or multifocal lesions cause high-output cardiac failure because of arteriovenous or portovenous shunting. Diffuse hepatic haemangiomas present with extensive liver involvement, often with marked hepatomegaly, which may lead to abdominal distension, IVC obstruction and respiratory compromise [44]. Rarely, diffuse liver haemangiomas may present with hypothyroidism

secondary to tumour production of iodothyronine deiodinase.

More recently, liver haemangiomas have been classified according to their biological behaviour, in line with haemangiomas occurring elsewhere in the body, into proliferative (common infantile) haemangiomas and congenital haemangiomas [45]. Proliferative haemangiomas characteristically express the GLUT-1 antigen, whereas congenital haemangiomas and other vascular tumours are GLUT-1 negative. Proliferative haemangiomas develop rapidly after birth, undergoing a phase of rapid enlargement, before entering a phase of stabilisation and eventual regression. They appear highly vascular on imaging, with a characteristic pattern of centripetal enhancement on contrast-enhanced CT or MRI. Most congenital haemangiomas occurring in the liver are of the rapidly involuting type (RICH). On MRI or CT, they typically show a thin rim of peripheral enhancement. Rapid involution is typical, often leaving a small residual, sometimes calcified, lesion in a characteristic subdiaphragmatic location.

A plain radiograph may demonstrate hepatomegaly or a right upper quadrant soft tissue density mass. Fine calcification may be seen in upto 16% and in those with high output cardiac failure, cardiomegaly may be noted on a chest film [46].

Ultrasound is the primary imaging modality for diagnosis and follow-up. Focal or multifocal lesions are typically well-defined, spherical lesions with increased echogenicity in comparison with normal liver. The lesions appear highly vascular on colour Doppler (Fig. 10.41). Large feeding arteries and draining veins, collateral vascular supply, evidence of rapid arteriovenous shunting may be demonstrated. In cases with particularly marked arteriovenous shunting, there may be marked enlargement of the coeliac axis, with abrupt narrowing of the descending aorta below its origin. Diffuse liver haemangioma shows heterogeneous echogenicity throughout the liver, with marked hypervascularity on colour Doppler.

CT typically shows well-circumscribed lesions with relatively low attenuation. Following intravenous contrast the lesions show initial nodular enhancement then progressive centripetal fill-in. A central varix and enlarged draining veins may be seen. Calcification is visible in up to 50% of cases, but the calcifications are fine and granular rather than the coarse, chunky calcifications of hepatoblastoma. On MRI, the lesions typically show relatively low signal intensity on T1 weighted images and markedly high signal intensity on T2 weighted images. Flow voids may be seen within the lesion. The characteristic phases of enhancement are well demonstrated on MR without a high radiation exposure.

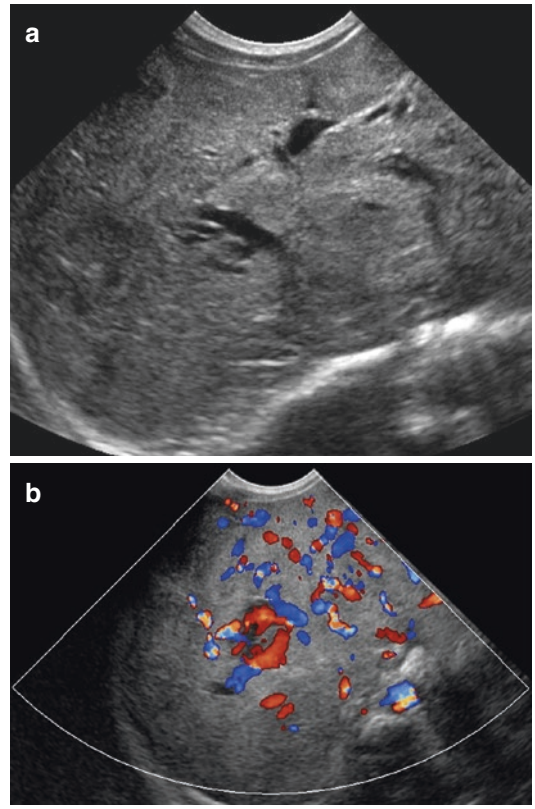

Fig. 10.41 Liver haemangioma. Grey scale and colour Doppler ultrasound images of the liver (**a** and **b**) reveal a heterogenous appearance with multiple areas of increased vascularity

Measurement of alpha-fetoprotein helps to exclude hepatoblastoma, although elevated alpha-fetoprotein must be interpreted with caution in the early neonatal period, and serial measurements may be necessary. AFP is moderately elevated in some infants with liver haemangio-

mas. In cases where the diagnosis is uncertain, percutaneous biopsy may be necessary, but this must be performed with extreme caution because of the risk of haemorrhage. Catheter angiography is generally reserved for cases requiring embolisation for rapid control of cardiac failure.

10.10.2.3 Mesenchymal Hamartoma

This is a benign developmental cystic tumour of the liver, which has a male (2:1) predominance and typically presents in children <2 years. This represents the second most common benign liver mass in children after infantile haemangioendothelioma. The imaging appearances vary from a predominantly cystic, septated mass to a largely solid mass containing few small cysts [47].

On ultrasound the cystic portions are predominantly anechoic, with solid portions and septa within the cysts appearing echogenic. The appearances are thought to be reminiscent of "Swiss cheese". The septae and solid portions are relatively hypovascular on Doppler imaging. Pedunculation of the lesion may make the site of origin difficult to determine with ultrasound. On CT a complex predominantly low attenuation cystic lesion is seen, with internal enhancing sepate/stroma. Haemorrhage and calcification are not usually a feature. The MR appearance of the cystic component is variable on T1 depending on cyst content, and the solid components may be hypointense on T1 and T2 W imaging due to fibrosis. The septae and solid components show mild enhancement post-contrast [48].

The differential diagnosis includes hepatoblastoma and focal infantile haemangioendothelioma. Hepatoblastoma has a more solid appearance on imaging with calcification and an associated marked elevation of the serum AFP. Predominantly solid hamartomas can result in diagnostic difficulty, particularly if the AFP is mildly raised, as the AFP in some hepatoblastomas can be misleadingly low. Differentiating on biopsy can also be difficult and surgery may be required. Haemangioendotheliomas demonstrate calcification in upto 50% of cases and are highly vascular tumours compared with the hypovascular solid components of mensenchymal hamartoma.

10.10.3 Intra-Abdominal Lymphatic Malformation

Lymphatic malformations are proliferations of lymphatic tissue that fail to communicate with the normal lymphatic system. These usually arise from the mesentery, related to the small bowel in 60% and the colon in 40%, but can arise from the omentum or retroperitoneum. They are usually large and present with abdominal mass in the neonate.

Ultrasound appearances are of a large well-defined anechoic cystic structure. This is usually multilocolated with thin septae but can be a single cystic structure. Haemorrhage or infection can result in complex appearances. Cross sectional imaging is useful to delineate the extent in the case of large lesions. CT shows a well-defined fluid filled mass with enhancing septae. The fluid varies in attenuation depending on its chylous or haemorrhagic constituents. MR appearances again are dependant on the nature of the fluid, varying from hypointense on T1 W-imaging and hyperintense on T2-weighted images, to hyperintense on both if the content is fatty or haemorrhagic (Fig. 10.42).

10.10.4 Presacral Masses

The usual presentation of a presacral mass is with an abdominal, pelvic or perineal mass. Pre-sacral masses are often diagnosed in utero during antenatal ultrasound, followed increasingly with fetal MR. A presacral mass may be suspected on the basis of a plain film, which may show displacement of the bowel loops. Care should be taken to assess the presacral space on the initial lateral rectal film of a lower GI study. The most common masses are teratoma and menigocoele, however duplication cyst, dermoid cyst or hamartomas, or a combination of these pathologies, can also occur in the presacral region. MR is the imaging modality of choice, possibly with a limited CT to look for the presence of calcification if the nature of the mass is uncertain.

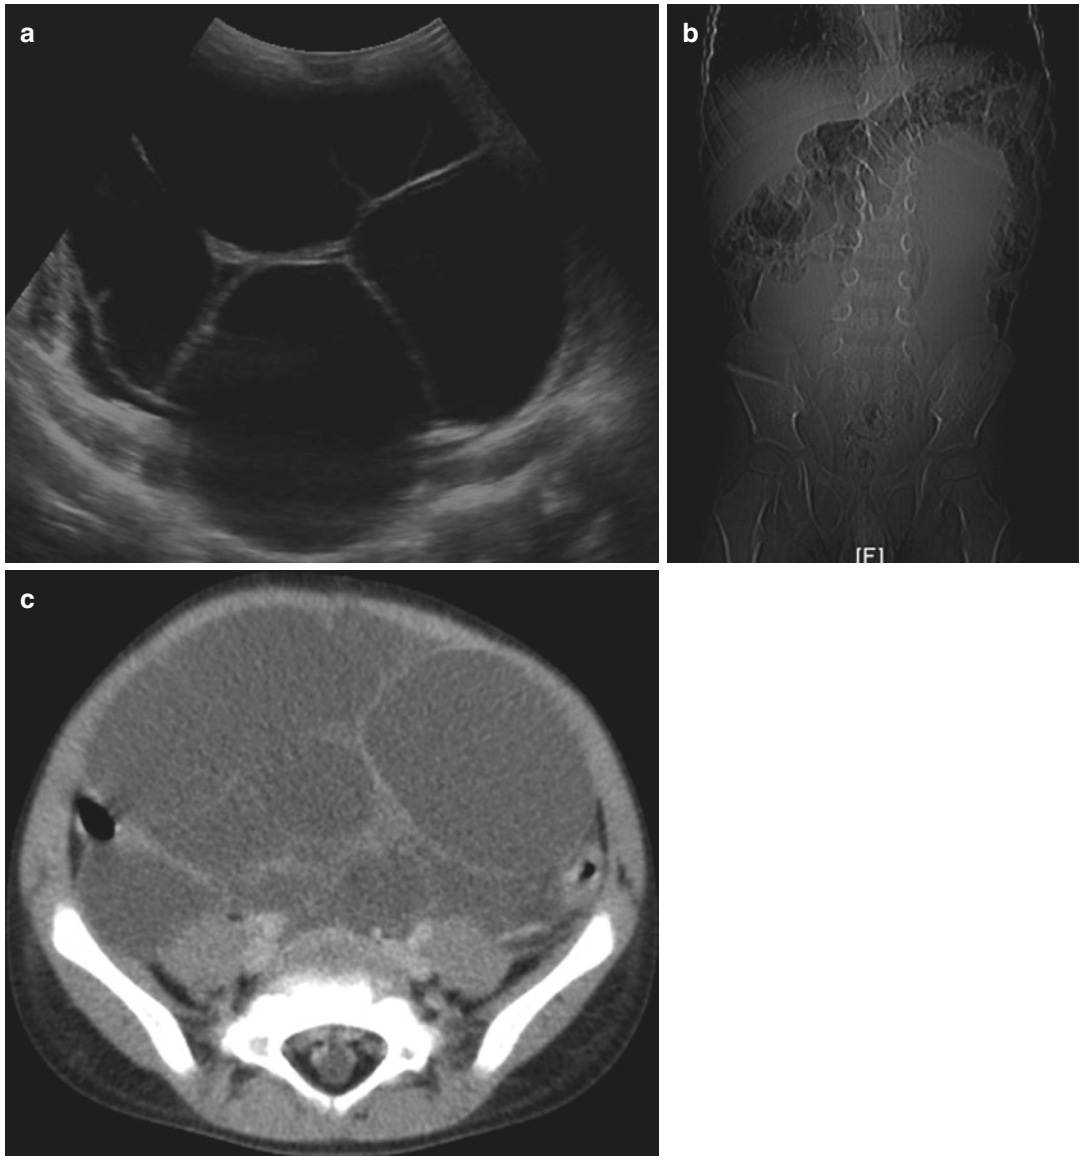

Fig. 10.42 Cystic lymphatic malformation. Ultrasound image (**a**) demonstrates a large multilocular cystic mass in the abdomen. CT scout image (**b**) illustrates the mass effect on the adjacent transverse colon and axial CT (**c**) confirms the cystic nature and the presence of thin septations

10.10.5 Sacrococcygeal Teratoma

Sacrococcygeal teratoma is the most common solid tumour in neonates. The mass may extend into the pelvis and abdomen causing some diagnostic confusion. The characteristics on imaging are determined by the tissue composition and to some extent the degree of malignancy. Benign lesions have well differentiated mature tissues and are predominantly cystic lesions with fat and calcification (in 50%). Calcification is a rare finding in malignant tumours and a predominantly soft tissue mass with haemorrhage and necrosis is more suggestive of a malignant lesion [49].

On plain radiograph, a large soft tissue density mass with internal calcification or low density suggestive of fat may be seen. On contrast studies there may be mass effect with displacement of the rectum, colon, and bladder. Ultrasound is useful in the diagnosis of the mass, showing cystic or solid components and demonstrating internal calcification, but cross sectional imaging is required for surgical planning. CT demonstrates the cystic components, internal calcification and fat and will reveal any metastatic disease or bony involvement- the coccyx is always involved in these lesions. However the exquisite anatomical detail provided by MR determines the internal content of the lesion and the relationship to and invasion of surrounding bony and soft tissue structures (Fig. 10.43).

10.10.6 Anterior Meningocoele

An anterior menigocoele, herniation of a CSF filled dural sac through a vertebral defect or foramina, may present as a presacral/abdominopelvic mass. A plain radiograph or contrast study control film showing spinal abnormalities should raise suspicion. MR is the investigation of choice in these individuals, as the hernial sac and neck are well seen, and the nerve roots and spinal defects are well demonstrated. This usually occurs at the level of the sacrum and is associated with anorectal and genitourinary abnormalities, therefore ultrasound imaging of the abdomen is recommended. In neonates with anorectal malformation and evidence of sacral abnormalities on plain film, the Currarino triad must be

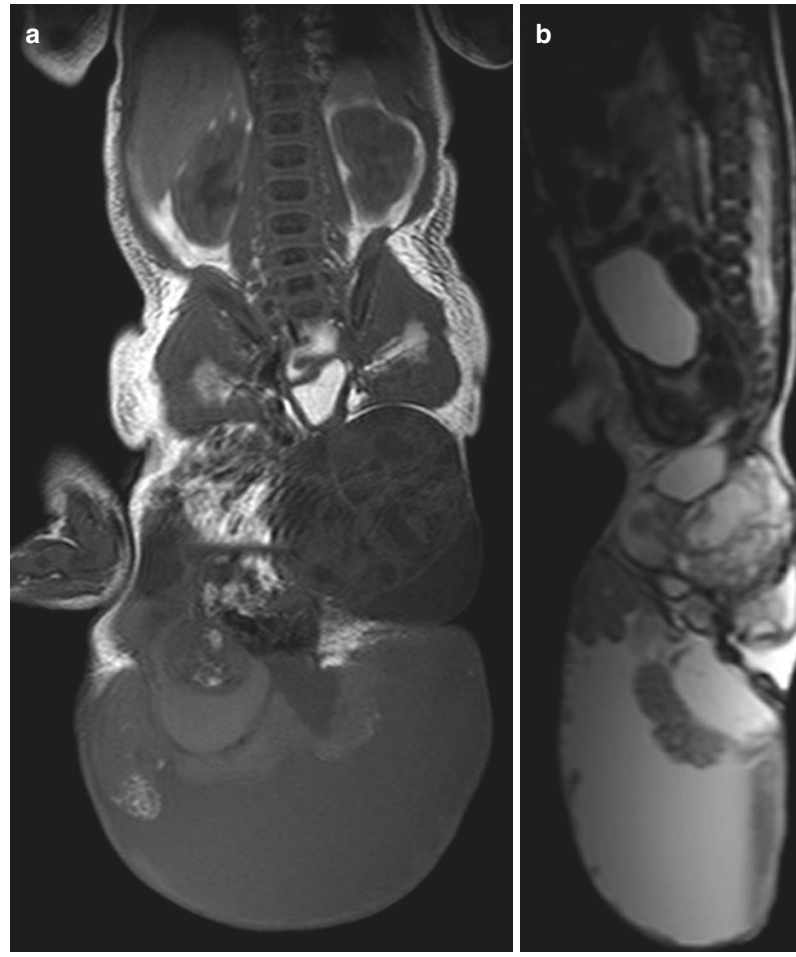

Fig. 10.43 Sacrococcygeal teratoma. (**a**) Coronal T1 W and (**b**) sagittal T2 W MR images show a large complex cystic and solid exophytic tumour arising from the tip of the coccyx

considered, also known as the ASP triad (anorectal malformation, sacrococcygeal defect and presacral mass) [50]. This is a rare syndrome that is autosomal dominant in 50% of cases.

10.10.7 Enteric Cysts

Enteric cysts from the rectum may present as presacral masses. They include duplication cysts and tailgut cysts/retrorectal cystic hamartomas. Duplication cysts of the rectum are rare, and like duplication cysts at other sites they may communicate with the true lumen of the rectum. Ultrasound of the duplication cyst may demonstrate the typical "double wall", which differentiates them from the thin-walled tailgut cyst. Cross sectional imaging further defines the mass, with the contents of the cysts appearing predominantly low on T1 (or high if high mucoid content in the case of tailgut cysts) and high on T2 unless complicated by haemorrhage. Soft tissue enhancement following gadolinium contrast agent is suggestive of malignant degeneration.

10.11 The Neonate with Difficulty in Breathing/Chest Mass

Neonates often present to radiology with a presumptive diagnosis of an intrathoracic problem following antenatal ultrasound diagnosis. Some conditions may be diagnosed antenatally. In these cases abnormalities are usually evident on the neonatal plain film.

Intrathoracic pathologies on plain radiograph that initially appear solid, may later become gas containing. The chest radiograph is used for primary diagnosis and to assess the extent of mass effect and resulting mediastinal shift. It is wise to carefully examine the position of lines and tubes in all neonates, as these may also help to support a diagnosis or raise cause for concern (Fig. 10.44).

Ultrasound can be useful, particularly in the neonate with a dense hemithorax, to differentiate lung consolidation from effusion, to further assess a peripheral intrathoracic or chest wall mass which appears apparently solid on plain radiograph or to investigate a mediastinal mass, as the sternal unfused ossification centres provide multiple acoustic windows which can be accessed in order to visualize the thymus and mediastinum in exquisite detail [51]. Further characterization can be achieved with cross sectional imaging.

10.11.1 Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernias (CDH) are increasingly diagnosed prenatally, and in the neonate imaging is used to differentiate CDH from other masses, to look for associated abnormalities and to aid in the management of complications.

CDH in the neonate can often be reliably diagnosed on plain film (Fig. 10.44). Immediately post partum, the affected hemithorax may be completely opacified, with mass effect and contralateral mediastinal shift. Once air has replaced the fluid in the GI tract, subsequent imaging shows bubbly lucencies in the hemithorax, more frequently on the left, with contralateral mediastinal shift and a paucity of gas in the abdomen. A right sided hernia often contains liver and therefore appears as a density in the thorax. The lung volumes are reduced due to resulting hypoplasia, and truncation of the development of the pulmonary vasculature leads to pulmonary hypertension.

An abnormal course of inserted tubes and lines helps to confirm the diagnosis, and a knowledge of the expected deviations of tubes and lines is required to avoid misinterpreting findings as malposition of apparatus. In a left CDH a nasogastric tube may be seen to deviate away from the side of the hernia in the oesophagus, with the tip either lodging at the GO junction or lying within the hemithorax indicating the hernia content includes the stomach. An umbilical venous catheter may demonstrate rightward deviation, apex leftward angulation or tip position in the portal venous system (Fig. 10.45). In the case of a right CDH, leftward deviation of the NG tube in the medastinum is noted. An umbilical venous catheter may be seen to deviate towards the right following

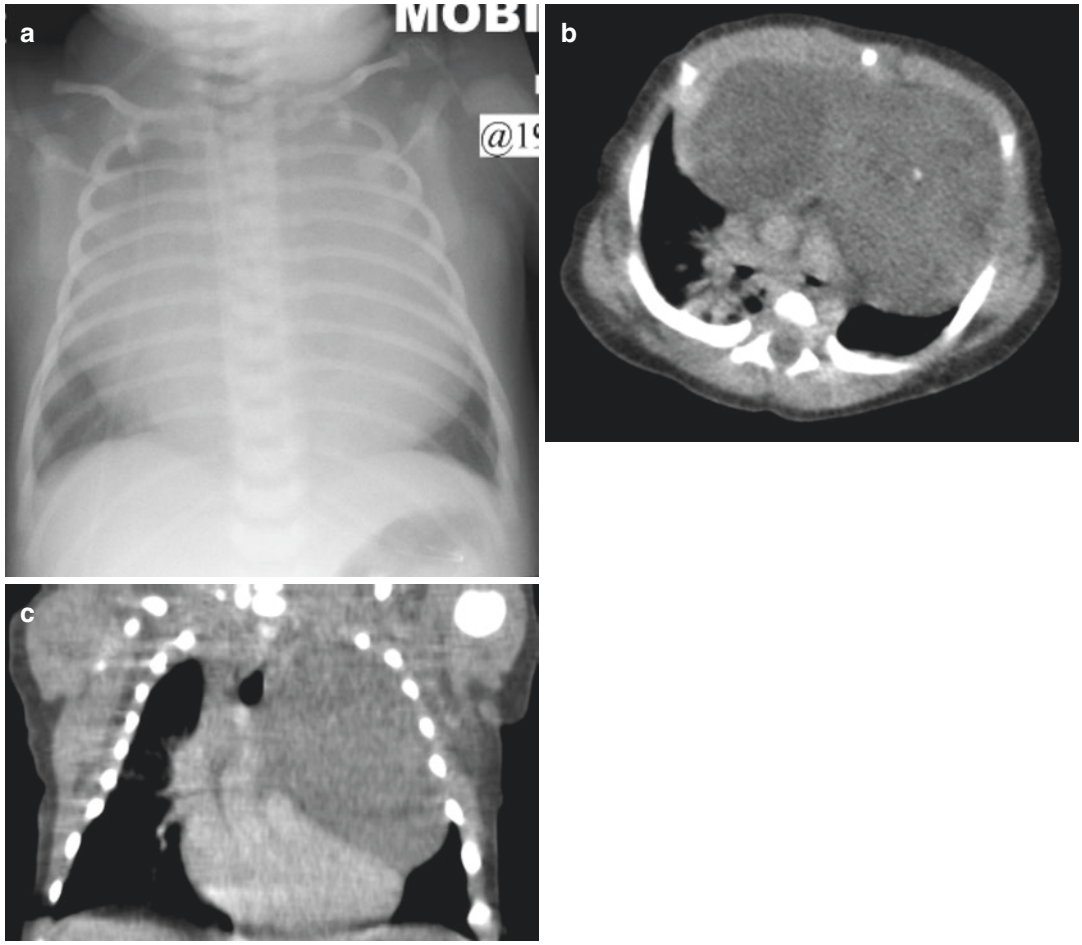

Fig. 10.44 Mediastinal teratoma. Chest radiograph (**a**) demonstrates marked mediastinal widening and a gentle deviation of the NG tube to the right. Axial (**b**) and coronal (**c**) CT demonstrate the large heterogenous anterior mediastinal mass. A small focus of calcification is present on the axial image

the abnormal position of the liver [52]. The plain film is used to confirm the diagnosis however, the amount of aeration of the lungs, the degree of mediastinal shift and the content of the hernia are not thought to predict outcome [53]. When the diagnosis is in doubt, injection of contrast through the NG under fluoroscopic guidance will outline the bowel and confirm the presence of hernia (Fig. 10.46). Cross sectional imaging can provide information about hernia contents and co-exisiting pathologies.

Associated abnormalities are present in between 25 and 50% of patients, including oesophageal atresia, cardiac malformations and GU abnormalities.

10.11.2 Congenital Airway Malformations

Congenital cystic adenomatoid malformation and congenital pulmonary adenomatoid malformations (CCAM/CPAM) are hamartomatous lesions of the lung, thought to occur due to a failure of the pulmonary mesenchyme to progress to normal bronchoalvealar development, with resultant abnormal dilatation and proliferation of the distal bronchioles. A classification system developed by Stocker is based on the size of the gross and microscopic features of the cysts and the resemblance on histology to segments of the developing bronchial tree and airspaces [54].

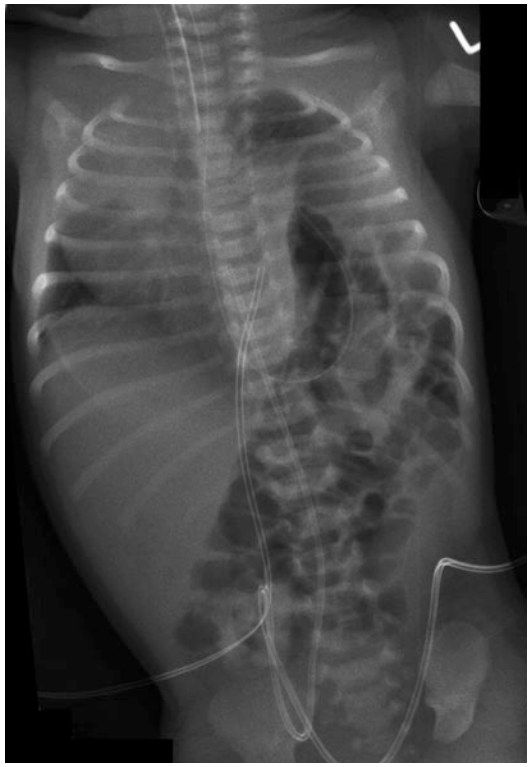

Fig. 10.45 Congenital diaphragmatic hernia. Plain chest and abdominal radiograph demonstrates large left diaphragmatic hernia. Note the course of the NG tube confirming the intrathoracic position of the stomach

Originally describing three types, this has since been extended to five [55]. On imaging, however, only three types can be distinguished: large cyst (Type I), the most common occurring and the most commonly imaged, small cyst (Type II) and microcystic or solid (Type III) [56, 57]. These lesions can have an abnormal communication with the airways and usually have pulmonary supply and drainage, though hybrid lesions can have systemic supply.

CCAMs are often suspected prenatally on ultrasound, the differentials being CHD, sequestration and foregut malformation cysts. The spectrum in utero is variable, and with time lesions may decrease in size relative to the chest. A lesion increasing in size on antenatal ultrasound with progressive mediastinal shift is cause for concern as this may lead to the development of hydrops and fetal demise in utero [58].

Plain film demonstrates variable density depending on the cyst content, number of cysts and mediastinal shift. Cross sectional imaging helps to identify and characterise CCAMs, evaluate mass effect and differentiate CCAM from sequestration.

Type I lesions have one or more large air filled cystic structures. These are often very large and exert mass effect resulting in mediastinal shift and compression of the contralateral lung. As clearance of fetal fluid from the cystic spaces is delayed, a large cyst may initially be seen as a soft tissue density mass which subsequently becomes filled with air. Air fluid levels may be seen. Type II may be seen as an air filled heterogenous multicystic mass or radio-opacity /focus of consolidation. Type III lesions appear solid at imaging due to the presence of microscopic cysts, and may be seen as a persistent area of increased homogenous density/consolidation [59].

Cystic lesions in the neonatal chest have a wide differential, including CDH, bronchogenic cyst, CLE, pulmonary sequestration. CDH can be excluded with the aid of oral contrast if required. Bronchogenic cysts are usually mediastinal (see later). Progressive lung expansion and mediastinal shift, with absence of internal opacities as in CCAM, will be seen with CLE. In the early stages where the abnormal lung is filled with fetal fluid, sequential plain films may reveal the diagnosis (Fig. 10.47).

Ultrasound may reveal echogenic parenchyma in both CCAM and sequestration but colour Doppler can be employed to identify an anomalous vessel thereby differentiating the two [51]. Cross sectional imaging helps to identify lesions seen antenatally, but not visible on plain film, perhaps due to decreasing size, and can further characterize an apparently solid plain film abnormality. Macrocystic CCAMS can have an abnormal systemic arterial supply. These lesions are known as hybrid lesions as they have features of CCAM and BPS [56].

10.11.2.1 Pulmonary Sequestration

A pulmonary sequestration has no communication with the tracheobronchial tree and has a systemic arterial supply, usually from the aorta. Intralobar sequestration is an area of lung tissue

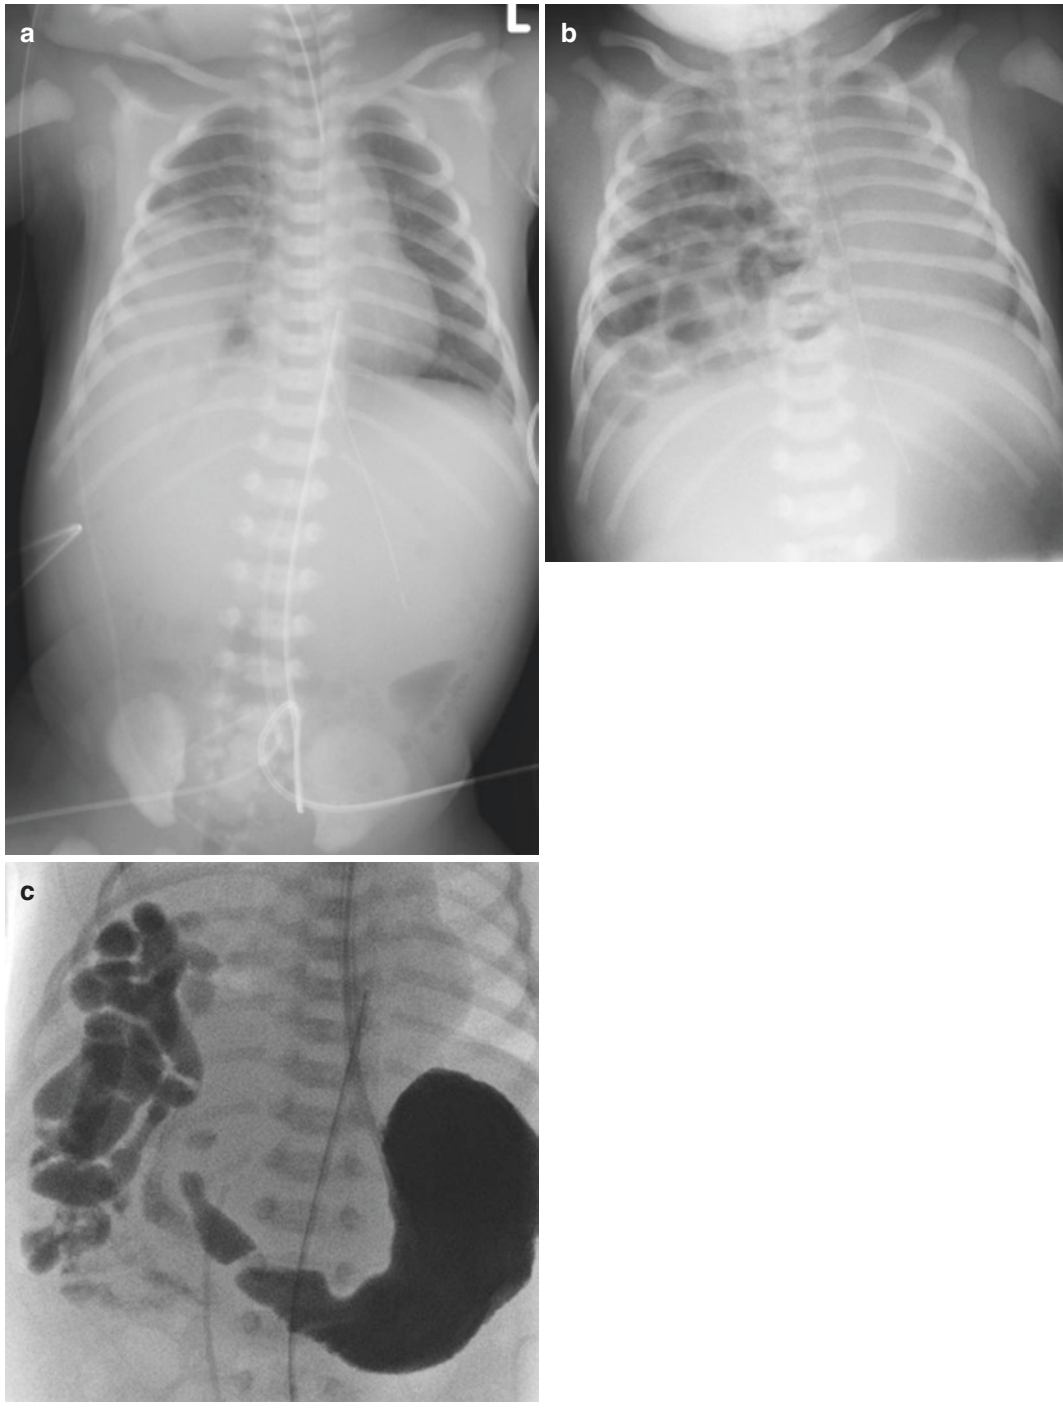

Fig. 10.46 Congenital diaphragmatic hernia. Neonate presenting with respiratory distress. Initial plain film early post delivery (**a**) demonstrates opacity in the right mid and lower zones, with absence of the normal outline of the right hemidiaphragm. The tip of the NG is well below the left hemidiaphragm. Note the low position of the umbilical venous catheter. Film 6 h later (**b**) shows marked mediastinal shift to the left and multiple air filled lucencies in the right hemithorax. The NG tube is displaced to the left in the thorax and the tip is seen to lie in the region of a distended gas filled stomach. Selected image from a water soluble upper GI contrast study (**c**) shows the normally positioned stomach to fill with contrast. The duodenum is seen to pass to the right of midline and contrast is seen in multiple loops of intrathoracic jejunum

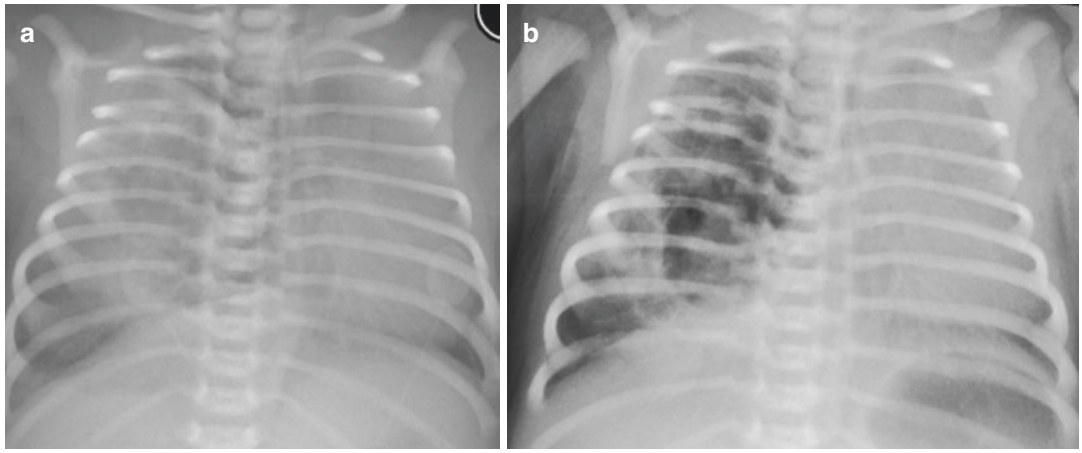

Fig. 10.47 Congenital cystic adenomatoid malformation (CCAM). (**a**) Radiograph taken shortly after birth in a neonate with respiratory distress shows ill defined slightly heterogenous density occupying a large proportion of the right hemithorax. There is evidence of contra-lateral mediastinal shift. (**b**) Radiograph taken at 12 h of life more clearly demonstrates air filled cystic lucencies within the right hemithorax. The hemidiaphragm is clearly seen and the gastric bubble is visible below the left hemidiaphragm

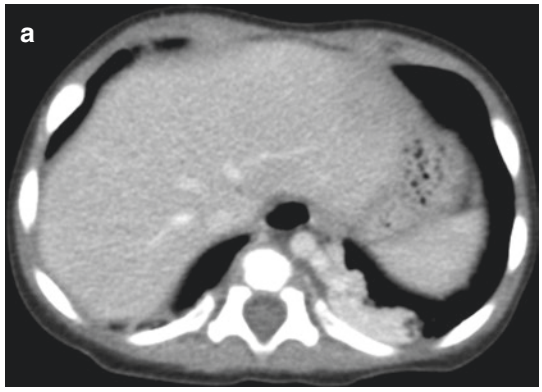
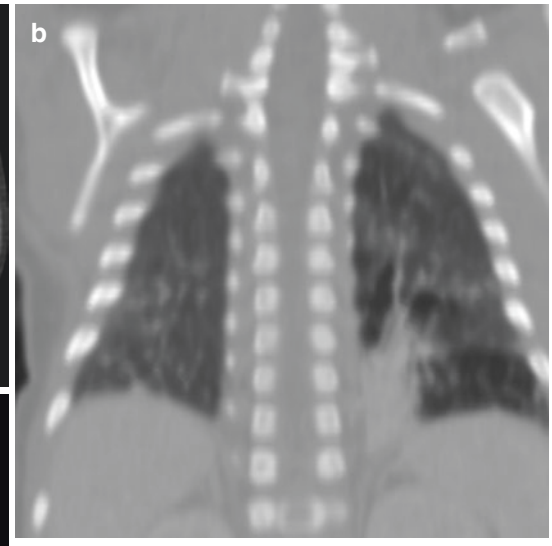
that is contained within the pleural covering of the adjacent lung but does not communicate with the tracheobronchial tree, and has systemic arterial blood supply but normal pulmonary venous drainage. They often present in adults but may be an incidental finding in children. Extralobar sequestration is an area of lung tissue that has its own pleural covering separate to that of the adjacent lung, does not communicate with the tracheobronchial tree and has systemic arterial blood supply and systemic venous drainage. They often present in infancy and may be an incidental finding in neonates. This may be associated with other congenital abnormalities, and can be situated below the diaphragm and mistaken for a neuroblastoma or adrenal haemorrhage [60].

On plain film, sequestrations appear a soft tissue density masses, usually at the lung base. The appearances on ultrasound are of a soft tissue mass, somewhat similar to CCAM, however the differentiating aberrant blood supply may be demonstrated. CT angiography with 3D reconstruction is the preferred imaging modality of choice. This allows identification of the anomalous arterial vessels, thereby differentiating this from a CCAM, and also allows the identification of anomalous veins, which differentiates intra and extra-lobar sequestration and aids surgical planning [59] (Fig. 10.48).

10.11.2.2 Congenital Lobar Emphysema (CLE)

In utero the appearances of CLE are similar to normal lung and therefore this is less frequently diagnosed antenatally relative to the other intrapleural mass lesions [61]. Diagnosis is usually made with plain radiography, performed due to respiratory distress. Usually the upper lobes are involved, most frequently the left. Early films may present some diagnostic difficulty as a dense mass/hemithorax may be seen, due to retention of fetal lung fluid. In time this clears to show the characteristic progressively hyperlucent hyperinflated lobe and its resulting mass effect including adjacent atelactasis, rib space widening, flattened ipsilateral hemidiaphragm and contralateral mediastinal shift. CT may be required to confirm the diagnosis, particularly if more than one lobe is involved, to further define mass effect or for the purpose of preoperative planning. CT demonstrates a hypoattenuated distended lobe, with a relative reduction in the pulmonary vascularity. Adjacent atelectasis may be seen and compression of the adjacent normal lung tissue, and there may be mediastinal shift [59]. On plain film and CT the presence of bronchovascular markings help to differentiate this from a pneumothorax or cyst (Fig. 10.49).





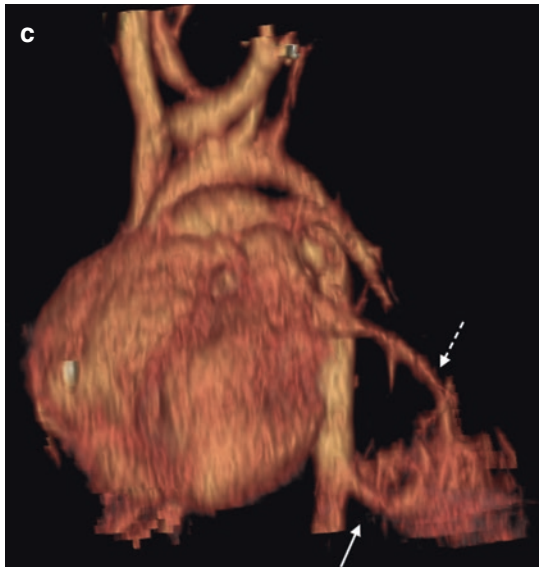


Fig. 10.48 Sequestration. (**a**) Axial and (**b**) coronal reformat CT demonstrate a focus of high attenuation in the postero-basal segment of the left lower lobe, with the impression of vascular communication with the aorta. (**c**) 3D reformat clearly demonstrates feeding artery (*solid arrow*) from the aorta and draining vein (*broken arrow*)

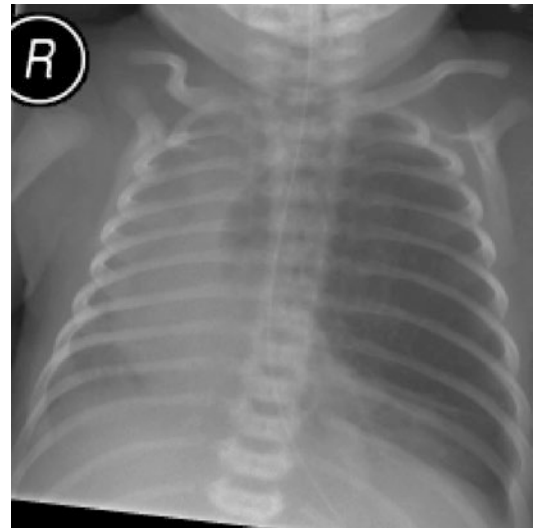

Fig. 10.49 Congenital lobar emphysema. Plain radiograph shows increased lucency and hyperexpansion of the left upper lobe with marked contralateral mediastinal shift

10.11.2.3 Bronchogenic Cysts

Bronchogenic cysts represent part of the spectrum of foregut duplication cysts. They are usually mediastinal in location, most commonly the subcarinal position or in the right paratracheal region. The usual cause for presentation results from pressure effects, though these may be discovered incidentally on the plain radiograph as a mediastinal mass (Fig. 10.3). Cross sectional imaging defines cyst content and extent, and relationship to adjacent structures, aiding surgical planning. They are usually solitary well circumscribed ovoid or spherical lesions, with uniform fluid attenuation. With IV contrast a non or minimally enhancing wall is seen. An air fluid level may be present if there has been infection, which is also suggested by an increase in size and rim enhancement, or if there is some communication with the bronchial tree or GI tract [59].

10.11.2.4 Anomalous Pulmonary Venous Drainage

This can be total, involves pulmonary arterial supply with systemic venous drainage of the lungs or partial, pulmonary arterial inflow with mixed pulmonary venous and some systemic venous drainage.

Scimitar syndrome/pulmonary venolobar syndrome/hypogenetic lung sydrome is a specific type of partial anomalous pulmonary venous return, which is characterized by ipsilateral anomalous pulmonary venous drainage of all or part of the lung into the IVC resulting in a left to right shunt. The anomalous vein usually joins the IVC below the diaphragm, though it can join the hepatic vein, portal vein, coronary sinus or right atrium. There is associated right lung hypoplasia and cardiac dextroposition. Right pulmonary artery abnormalities and systemic arterial supply, and abnormalities of the right bronchial tree may also feature. Post natal plain films may show the curvilinear density in the right lower lobe passing towards the right hemidiaphragm, The scimitar describes the characteristic shape of the draining vein from the right lower lobe to an infra diaphragmatic systemic vein. This is best depicted on contrast enhanced CT. Surgical correction is considered if there is significant left to right shunting.

10.11.2.5 Pulmonary Underdevelopment

Pulmonary agenesis and aplasia have similar imaging characteristics. Post-natally, plain film demonstrates diffuse opacification of the hemithorax and ipsilateral mediastinal shift. CT helps to confirm the absence of lung and pulmonary vasculature. In pulmonary aplasia, a blind ending bronchus will be seen.

Pulmonary hypoplasia is usually seen secondary to a pathology restricting lung growth. The most common cause is congenital diaphragmatic hernia, but other intrathoracic space occupying lesions may be a cause such as CCAM, sequestration, mediastinal mass. On cross sectional imaging, the bronchus and lung are present however the airways and vessels are decreased in number.

10.11.2.6 Pulmonary Artery Sling

This is an anomalous origin of the left pulmonary artery, which arises from the proximal right main pulmonary artery and courses between the trachea and oesophagus, forming a sling around the trachea. This diagnosis may be alluded to on upper GI studies, which reveal oesophageal compression, however multidetector CT with 3D reconstructions is the imaging of choice. Posterior compression of the trachea and anterior compression of the oesophagus are seen occurring at the same level. This anomaly can be associated with other congenital lung and cardiac anomalies.

10.11.2.7 Bronchial Atresia

This is rare and usually found incidentally in adults and it occurs due to obliteration of a segmental, subsegmental or lobar bronchus. Distal airways fill with mucous and the adjacent lung appears a little hyperinflated. The mucous filled bronchus ay be visible on plain film, but is well demonstrated on CT as a dilated tubular opacity with air trapping and decreased vascularity.

10.11.2.8 Tracheo-Bronchomalacia

Tracheal or bronchial malacia is collapse of the major airways on expiration, secondary to absence, immaturity or incompleteness of the cartilage rings of the large airways. It can be rec-

tified with positive end-expiration ventilation, and often requires prolonged ventilation until the airways fully develop. If limited to the trachea aortopexy can be curative.

10.11.3 Chest Wall Masses

Chest wall masses in neonates are rare. None of the malignant conditions of childhood such as Ewing sarcoma/PNET or metastasis from neuroblastoma, leukaemia and lymphoma frequently involve the chest wall of neonates. Benign lesions common in children including fibrous dysplasia, Langerhans cell histiocytosis and haemangioma are also rare in neonates.

Mesenchymal hamartoma of the chest wall is an uncommon benign tumour that most commonly affects infants and may present with a deforming chest wall lesions noted at birth, or as an incidental finding on plain film. These always arise in the rib and comprise of a benign proliferation of skeletal tissue with a prominent cartilaginous component and haemorrhagic cavities. The imaging features are of a large extrapleural partially calcified soft tissue mass arising from one or more ribs, with destruction and distortion of the adjacent thorax. Cross sectional imaging reveals prominent haemorrhagic cystic components, possibly with fluid-fluid levels, and mineralized elements [62] (Fig. 10.50).

Fetus in fetu, or fetiform teratomas may also be detected antenatally, requiring post-natal cross sectional imaging to define the exact nature of the mass and its relationship to adjacent structures (Fig. 10.51).

10.12 The Neonate with a Urinary Tract Infection

The management and imaging pathways of urinary tract infection (UTI) in children are controversial, but there is general consensus about the need for comprehensive investigation of UTI occurring in the neonate. In the UK, there are evidence-based guidelines for the investigation and management of UTI in children [63].

The initial imaging modality of choice is the ultrasound scan. The aim of ultrasound is to confirm underlying developmental anomalies, assess the ureters and upper tracts for hydronephrosis/hydroureteronephrosis and identify any complications such as abscess or pyonephrosis. Standard ultrasound will confirm the number of kidneys, and assess the renal length. The use of high frequency probes in neonates permits a detailed assessment of the kidney including the echogenicity of the cortex relative to the liver and spleen, the corticomedullary differentiation, the degree of dilatation of the collecting system, prominence of the proximal or distal ureters and evidence of urothelial thickening. An assessment of bladder wall thickness is made. This is difficult in the neonate who usually has an empty or partiallly filled bladder, but this should measures <5 mm when collapsed and <3 mm when full. A ureterocoele is easily identified with ultrasound. Colour Doppler is useful to assess the vascularity of the kidney.

Increased length of one or both kidneys, interruption of the central renal sinus and identification of two renal pelves or ureters is suggestive of a duplex system. When duplicated ureters insert separately into the bladder the Weigert-Meyer rule states that the upper pole ureter is the ectopic ureter and its orifice inserts inferomedially in the bladder in relationship to the lower pole normal ureter. As a result the upper pole ureter is susceptible to obstruction, seen as a dilated upper moiety on ultrasound. Careful assessment of the bladder will identify any associated ureterocoele, which is associated with an increased risk of UTI in the neonate [64]. The lower pole ureter is more likely to reflux and an MCUG is therefore performed.

In the context of UTI and reflux, detailed scanning of the cortex and medulla is useful. Debris in the collecting system and bladder may be seen, and thickening of the urothelium is well demonstrated on the high-resolution images achievable in neonates. In a patient with these features and hydronephrosis, not responding to pharmacological management, may need intervention. Focal thinning and

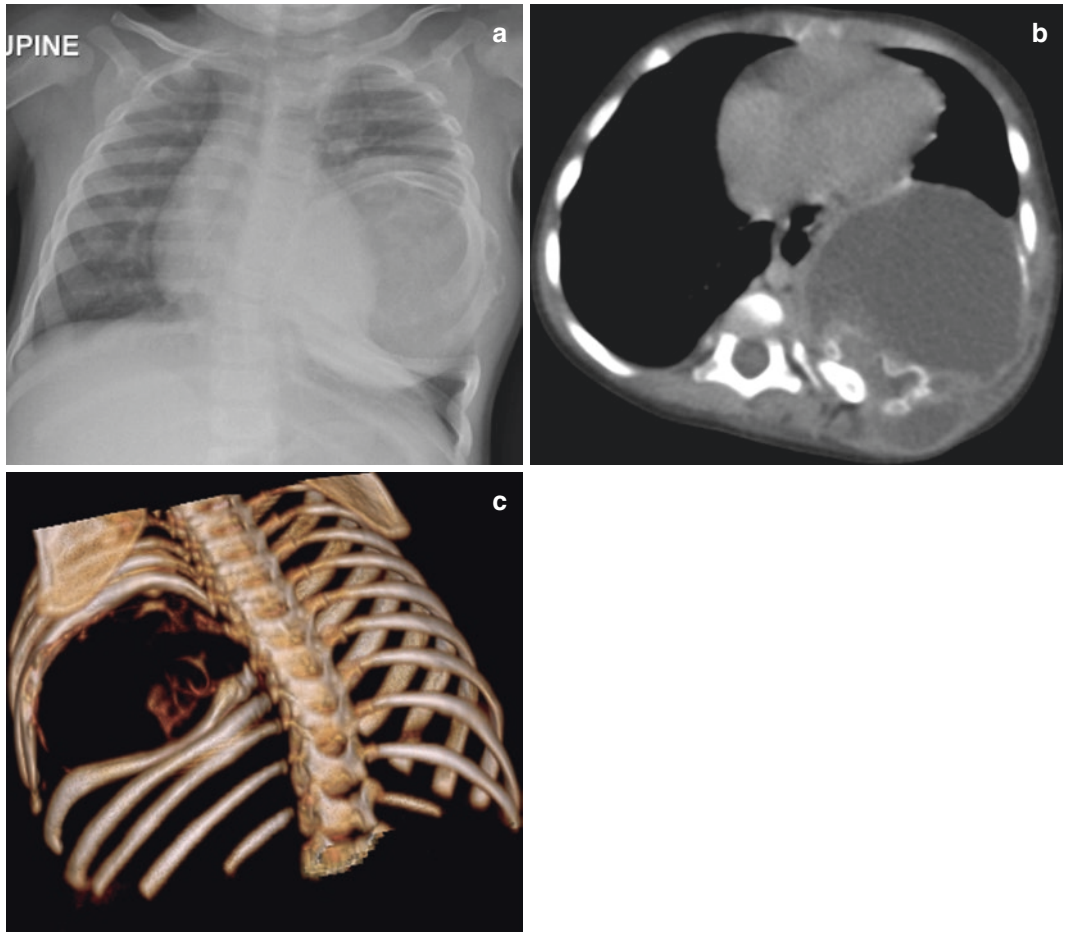

Fig. 10.50 Mesenchymal hamartoma of the chest wall. (**a**) Plain radiograph at presentation demonstrates a large soft tissue density mass involving a left posterior rib with splaying of the adjacent ribs suggesting a slow growing pathology. (**b**) Contrast enhanced axial CT shows a mass with intra and extrapleural components. (**c**) Volume rendered 3D image of the chest wall demonstrates the osseous expansion of the involved rib and splaying of adjacent ribs due to mass effect

adjacent calyceal prominence is in keeping with scarring. A DMSA scan after the neonatal period, when the kidneys have matured, will further evaluate this. In the presence of atypical infection, highly echogenic rounded foci in the collecting system are suggestive of fungal disease (Fig. 10.52).

The MCUG is used in the neonate to identify vesicoureteric reflux (Fig. 10.53), or to exclude bladder outlet obstruction as a cause of hydronephrosis. Following sterile bladder catheterization a control film is obtained to identify the position of the catheter and look for any renal tract calcification. In addition, vertebral, sacral, or other anomalies associated with syndromes such as VACTERL (Vertebral, Anorectal, Cardiac, Esophageal, Renal, Limb) may be seen. The bladder is slowly filled with warmed water-soluble contrast agent. Early bladder views allow the identification of diverticula or ureterocoeles. Oblique views of the full bladder allow a careful search for vesicoureteric reflux. In males, lateral views of the bladder and urethra during micturition are vital in order to exclude or confirm the presence of urethral valves, and a final AP view of the abdomen will identify any remaining contrast within the urinary tract.

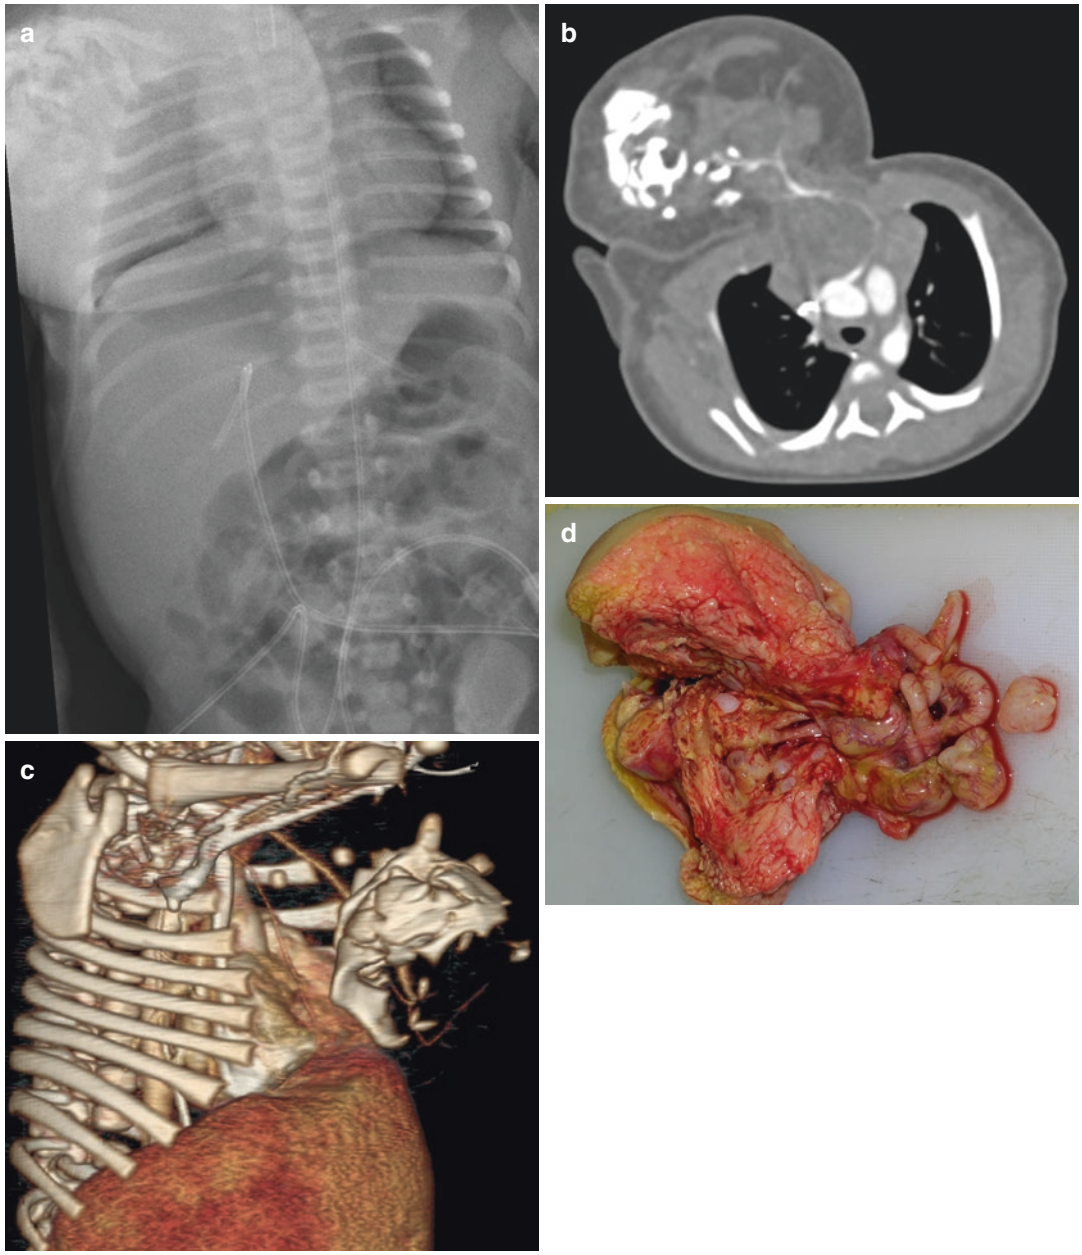

Fig. 10.51 Teratoma of the chest wall. Plain film (**a**) demonstrates a large heterogenous chest wall mass containing some areas of calcific density. Axial contrast enhanced CT (**b**) and volume rendered 3D reformat (**c**) confirms the anterior chest wall mass containing calcific density and demonstrates a feeding vessel from the mediastinum. Gross specimen image (**d**) shows the presence of a fully formed colon. Renal and uterine tissue was also present. The absence of a formed axial skeleton differentiates this fetiform teratoma from a fetus-in-fetu

In children shown to have reflux or atypical/recurrent infections a DMSA scan is performed in conjunction with an ultrasound, to identify areas of scarring. Technecium-99 m dimercaptosuccinic acid (DMSA) binds to the proximal renal tubules and produces an image of functioning renal cortex. Anterior, posterior and oblique views of the kidneys are obtained and relative

Fig. 10.52 Renal candidiasis. Oblique ultrasound image of the kidney in a neonate with sepsis demonstrates a hyperechoic spherical focus (*) in the collecting system consistent with a fungal ball

Fig. 10.53 Vesicoureteric reflux. Micturating cystourethrogram shows gross bilateral reflux, more marked on the right, with dilated tortuous ureters, dilated renal pelvises and marked calyceal blunting

renal functions are calculated. No information about the collecting system, ureters or bladder is obtained. Many abnormalities such as cysts, abscesses and non-functioning duplex moieties can have similar appearances. DMSA is usually performed after any acute infection, but is best deferred until after the neonatal period, in order to allow renal function to mature and to avoid false positive results due to recent infection (Fig. 10.54).

10.12.1 Vesico-Ureteric Reflux

Vesico-ureteric reflux is diagnosed on MCUG by the dynamic visualization of retrograde flow of contrast instilled into the bladder into the ureter/collecting system (Fig. 10.54). Reflux is graded according to the international reflux grading system, developed by the International Reflux Study Committee: I Reflux into ureter not reaching the pelvis; II Reflux reaching pelvis but no calyceal blunting; III Mild calyceal blunting; IV Progressive caliceal and ureteral dilatation; V very dilated and tortuous collecting system, intrarenal reflux [65]. The grade of reflux has been shown to have prognostic implications [66]. In the refluxing duplex system usually the ureter of the lower moeity is demonstrated, and a ureterocoele may be demonstrated relating to the site of insertion of the upper moiety. Reflux into ectopic ureters inserting low into the bladder neck will only be seen during voiding. If reflux is demonstrated in the neonate treatment dose of antibiotic followed by prophylaxis is prescribed.

Other techniques such as voiding ultrasonography with ultrasound contrast agents are in use [67]. Although there is no exposure to ionizing radiation, these methods are extremely time and resource intensive.

10.12.2 Obstructive Uropathy/Bladder Outlet Obstruction

Pelvi-ureteric junction obstruction is the most common form of urinary tract obstruction in children, and is now often detected on antenatal ultrasound. This may present as a mass in the neonate (see previous). There is an association with a contralateral MCDK [68].

Ultrasound reveals marked hydronephrosis, with a disproportionally large pelvis compared to the degree of calyceal dilatation. An abrupt caliber change is present at the renal pelvis and there

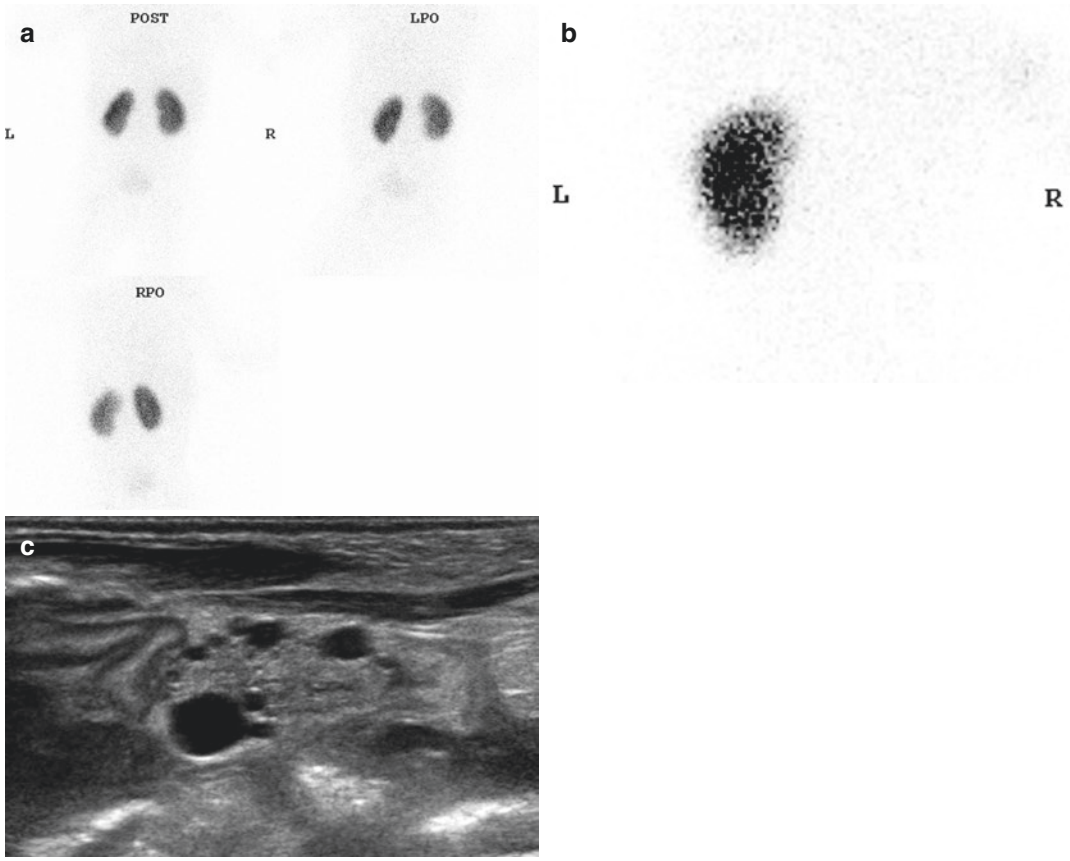

Fig. 10.54 Normal DMSA. (**a**) shows bilateral symmetrical tracer uptake with smooth cortical outline. Abnormal DMSA (**b**) shows absence of tracer uptake in the right kidney in keeping with absence of functioning renal tissue. Ultrasound image (**c**) shows a small multicystic kidney

is a normal calibre ureter downstream (Fig. 10.28). Colour Doppler may be used to identify crossing vessels causing obstruction, however in the neonate this is challenging. A nuclear medicine renal scan using Tc^{99m} MAG-3 is required to assess the degree of obstruction; however, this is usually performed after the neonatal period, to allow renal function to mature. This condition may improve with time and ultrasound is used in the serial follow up of these cases. If infected, or if the contralateral kidney is dysplastic, percutaneous nephrostomy may be required as a temporising measure prior to surgery (Fig. 10.55).

In the case of bilateral hydronephrosis in the male, or a large trabeculated bladder presenting as an abdominal mass, the MCUG is the gold standard imaging modality to exclude or confirm the presence of posterior uretheral valves. Ultrasound may suggest the diagnosis in the presence of a trabeculated thick walled bladder suggesting bladder outlet obstruction, and bilateral hydroureteronephrosis. Ascites may also be present. The condition is now frequently diagnosed antenatally on the basis of these findings and treated in utero. The classical imaging findings on MCUG are an abrupt caliber change of the urethra from the dilated posterior urethra to the small caliber more anterior bulbous urethra. Occasionally the valves themselves may be visible as a filing defect. Care must be taken as the catheter inserted for the procedure may stent the valves and obscure the caliber change, therefore withdrawal of the catheter during micturition is required (Fig. 10.56). The bladder wall may appear trabeculated, and bilateral VUR may also be seen.

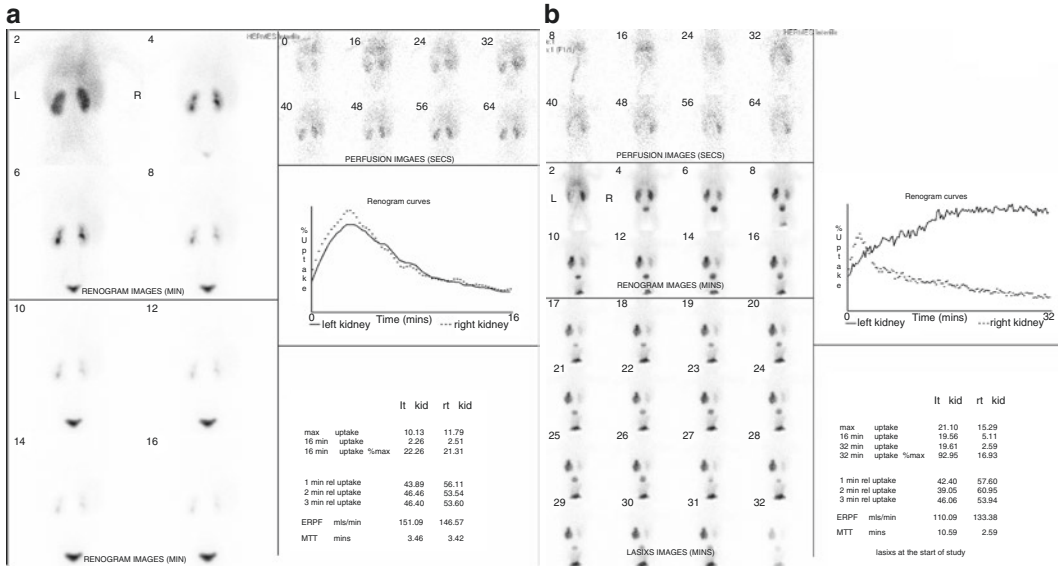

Fig. 10.55 Normal MAG 3 (**a**) shows symmetrical perfusion of the kidneys (top right), prompt bilateral tracer accumulation and excretion (left images), and smooth renogram curves. MAG 3 in PUJO (**b**) demonstrates reduced perfusion to the left kidney, delayed tracer accumulation, and delayed excretion into a dilated renal pelvis. Note the abnormal renogram curve on the left with increasing tracer uptake, compared to the smooth normal curve of the right

Fig. 10.56 Posterior urethral valves. Selected lateral image from the MCUG demonstrates an enlarged, trabeculated bladder. There is dilatation of the posterior urethra, and a linear filling defect at the point of calibre change consistent with a valve. There is resulting unilateral reflux

10.13 The Neonate with a Scrotal Swelling

Ultrasound with a high frequency linear transducer is the mainstay of imaging the swollen scrotum/inguinal region, with colour Doppler optimized to display low flow velocities in the testis. Power Doppler may also helpful in neonates, as this has higher sensitivity to low blood flow and is independent on the direction of flow, however its usefulness is limited due to increased movement artefact.

The neonate is scanned supine. Each hemiscrotum is scanned in turn in the longitudinal and transverse planes, including each testis and epididymis, and each the spermatic cord which is traced from the scrotum proximally through the inguinal canal. The normal neonatal testis is seen as a well-defined ovoid structure of intermediate echogenicity. A surrounding echogenic line represents the tunica albuginea. An internal hyperechoic line represents the mediastinum testis. The head of the epididymis is seen superiorly as a pyramidal structure of similar echogenicity to the testis, the body and tail are thin and long, extending along the longitudinal axis of the testis. The appendix testis, and the epididymal appendages may also be visible on ultrasound in the neonate. In the longitudinal plane the spermatic cord is seen as a linear hyperechoic structure, running from the inguinal canal to the scrotum.

The common neonatal scrotal pathologies include hydrocoele, hernia and torsion. Trauma, infection and neoplasm (germ cell tumour) are rare at this age. More unusual causes of neonatal scrotal swelling due to intra-abdominal pathology and a patent processus have been reported in the literature and should be considered when clinical and imaging findings are atypical. Neonatal adrenal haemorrhage presenting as a swollen scrotum is rare but well recognized [69] and a mass of calcified meconium may be present in the scrotum in association with meconium peritonitis [70], a condition which has also been described on antenatal ultrasound and in which ultrasound can avoid unnecessary surgical intervention [71]. It follows that any unusual appearances in the scrotum on ultrasound should prompt careful interrogation of the abdomen.

Abdominal radiographs taken for other clinical reasons can reveal scrotal abnormalities. The inguinal regions should be carefully examined on the neonatal plain radiograph as focal lucency over this region is suggestive of an inguinal hernia. Fine curvilinear calcification of the scrotal region can indicate meconium peritonitis. A soft tissue density mass may indicate scrotal haematoma or incarcerated hernia.

10.13.1 Hydrocoeles

In neonates, hydrocoeles are usually congenital due to a patent processus vaginalis. These are well demonstrated on ultrasound as anechoic fluid collections, surrounding the testis, which may extend upto the inguinal canal. A hydrocoele of the cord resulting from closure of the processus above the testis is seen as a fluid collection contained within the spermatic cord. More rarely an abdominoscrotal hydrocele may be encountered visualized on ultrasound as a large inguinoscrotal hydrocoele extending superiorly through the deep inguinal ring into the abdominal cavity (Fig. 10.57).

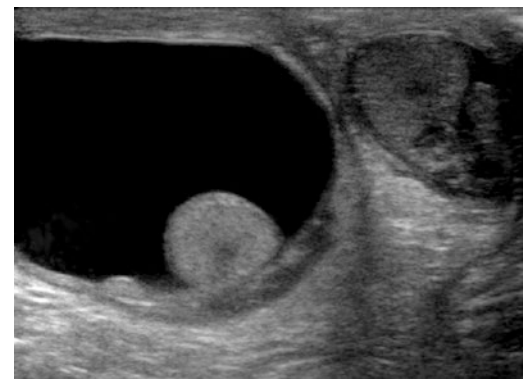

Fig. 10.57 Hydrocoele. Ultrasound demonstrates a right hemiscrotum filled with homogenous hypoechoic fluid consistent with a simple hydrocoele

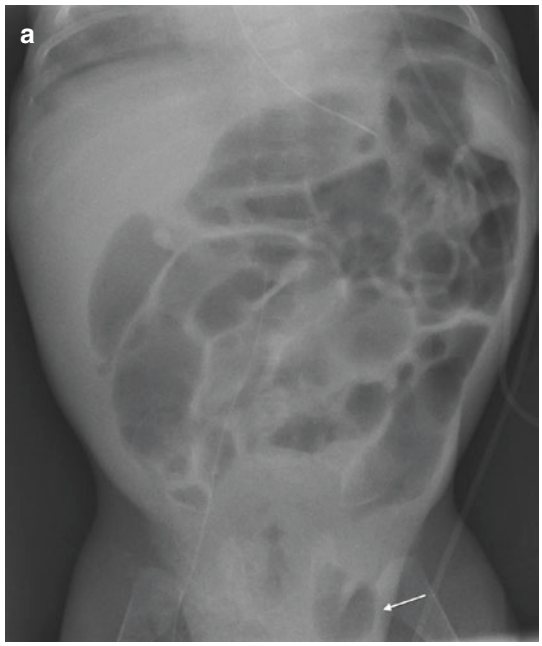
10.13.2 Hernia

Although usually this diagnosis can be made clinically, ultrasound is helpful in case of the acute scrotum, or where the clinical findings are atypical. On ultrasound, fluid or gas filled bowel loops are seen to fill the hemiscrotum. Peristalsis of the involved loops can be captured. An aperistaltic loop is suggestive of a strangulated hernia and Colour Doppler can be employed to try and assess vascularity of the involved bowel [72]. Highly echogenic omentum may be identified in the scrotum or inguinal canal. There is a high incidence of synchronous and metachronous contralateral inguinal hernias, particularly in neonates and premature infants, and the contralateral side should be interrogated to exclude synchronous inguinal hernia [73]. Careful interrogation of the inguinal regions on the plain film of a neonate with distension and multiple distended loops of bowel may reveal a knuckle of herniated bowel (Fig. 10.58).

10.13.3 Testicular Torsion

Testicular torsion in neonates is usually extravaginal. This is torsion occurring proximal to the attachment of the tunica vaginalis. This often occurs prenatally, presenting as a swollen discoloured hemiscrotum after birth and can be mistaken for haematoma due to birth trauma [74]. Appearances of the testis may be normal, particularly if scanned at the hyperacute stage. In the acute phase marked enlargement of the affected testicle with heterogeneity in echogenicity can be seen. Subtunica fluid may be present. Linear hypoechoic striations extending radially from the mediastinum testis may be present. A twist of the spermatic cord may be evident at the superficial ring, though difficult in neonates. A reactive hydrocoele may be present [75]. Absent or reduced blood flow may be demonstrated with colour Doppler ultrasound, though colour Doppler signals are sometimes difficult to obtain in the neonate and comparison of flow with the unaffected side is required [72]. Increased scrotal wall vascularity on the affected side is also an



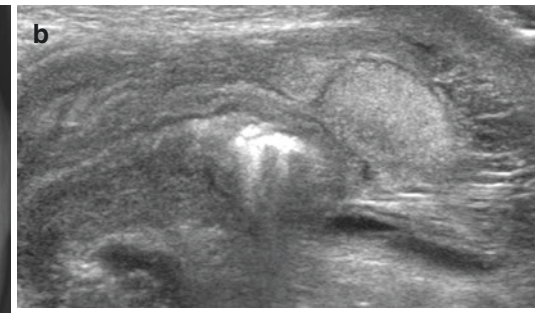


Fig. 10.58 Inguinal hernia. Plain radiograph (**a**) in a neonate with an inguinal mass demonstrates lucency in the left groin at the periphery of the image, consistent with a herniated bowel loop. Ultrasound (**b**) confirms the presence of herniated bowel along the inguinal canal into the left hemiscrotum

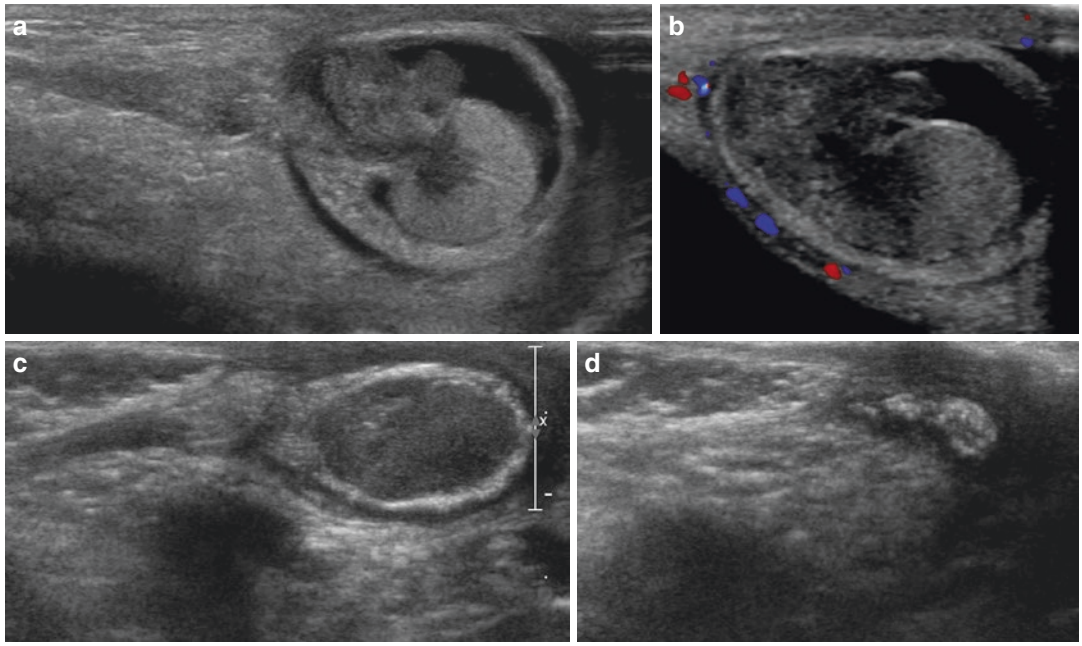

Fig. 10.59 Testicular torsion. Ultrasound images (**a** and **b**) in a neonate with an acutely swollen scrotum reveal an enlarged heterogeonous testis. The mediastinum testis is relatively hypoechoic with radiating striations, whilst the surrounding parenchyma is echogenic. Colour Doppler demonstrates peripheral flow but no flow within the parenchyma of the testis. Another case, image (**c**) shows curvilinear hyperechogenicity of the tunica, suggestive of calcification, and hypoechogenicity of the parenchyma. The appearances are suggestive of a chronic torsion. The contralateral testis in this case was atrophic and heavily calcified (**d**) in keeping with a previous torsion on the contralateral side also

indicator of infarction and necrosis. It is important to note however that some patients with early torsion will have a normal exam, and the presence of Doppler flow cannot exclude intermittent torsion-detorsion (Fig. 10.59a, b).

More chronic or prenatal torsion may be identified by a normal sized heterogeneous testis with peripheral hyperechogenicity, followed by atrophy of the testicle with further peripheral and internal hyperechogencity in keeping with calcification of the tunica albuguinia and testicular parenchyma. A complex hydrocoele is common [74, 75] (Fig. 10.59c, d). Torsion of the testicular appendages is rare in the neonate.

10.13.4 Infection

This is a rare entity in neonates, but conditions such as posterior urethral valves, and imperforate anus predispose the neonate [72]. Usually the epididymal head is involved, appearing enlarged and either hyper or hypoechoic. Similar changes in the testis suggest co-existing orchitis. Increased vascularity is noted.

10.14 Urogenital Anomalies

10.14.1 Congenital Obstruction of the Genital Tract and Cloacal Anomalies

A cloacal malformation should be suspected in a female infant with an imperforate anus, single perineal orifice and normal abdominal wall. Cloacal dysgenesis is associated with other genitourinary malformations including renal agenesis, multicystic dysplastic kidney, and renal ectopia, in addition to other manifestations of VACTERL

(Vertebral, Anorectal, Cardiac, Esophageal, Renal, Limb) syndrome. Early imaging is important to confirm the diagnosis and detect associated anomalies, and should not be delayed. Ultrasound is most useful to demonstrate renal tract obstruction, hydrocolpos and associated genitourinary anomalies. Plain radiography of the abdomen and pelvis may demonstrate bowel obstruction and calcified masses, due to admixture of urine and meconium; abnormal connection with bowel may be indicated by the presence of air within the bladder or vagina. There may also be signs of sacral agenesis and vertebral segmentation anomalies.

10.14.2 Disorders of Sexual Differentiation (DSD)/ Ambiguous Genitalia

Ultrasound imaging is of major importance in the initial assessment of a newborn infant with ambiguous genitalia, to determine the location and morphology of the gonads and whether a uterus is present. Ultrasound is most useful in the early neonatal period, when the persisting effects of maternal hormone stimulation result in relative prominence of the uterus and ovaries, and ovarian follicles may be present, helping to distinguish between ovaries and testes. High resolution ultrasound of the perineum and labial folds may be helpful in identifying the presence and nature of ectopic gonads.

Ultrasound of neonates with ambiguous genitalia requires special expertise, but is generally easier to obtain and provides superior anatomical resolution to MRI, which is limited by the very small size of the key abdominal structures and lack of well defined fat planes.

Ultrasound of the adrenals may also be helpful in the immediate postnatal period, when the adrenals are normally easily visualised. Congenital adrenal hyperplasia is an autosomal recessive disorder in which there is complete or partial deficiency of one of the enzymes involved in the synthesis of steroid hormones. Glucocorticoid deficiency stimulates secretion of adrenocorticotrophic hormone (ACTH) by the anterior pituitary, resulting in adrenal hyperplasia and excessive production of adrenal androgens. Enlargement of the adrenals may be identified on ultrasound in about 50% of cases. The adrenal cortex is enlarged relative to the medulla, and in some cases the enlarged adrenal cortex has a lobulated, convoluted, "cerebriform" appearance.

Genitography may also be used in the early postnatal period. Injection of water soluble contrast into the perineal openings under fluoroscopic control can demonstrate the configuration of the urethra and the presence of any abnormal connection between the genital tract, bladder, and bowel. This may confirm the presence of a vagina and cervix, and help to elucidate more complex malformations, for example by demonstrating the length and configuration of a common channel, such as a urogenital sinus.

10.15 Increasing Head Circumference, Suspected Hydrocephalus and Intracranial Haemorrhage

Cranial ultrasound is usually the first line modality for brain imaging in the neonatal period. The anterior fontanelle provides a window that allows high resolution imaging of the brain to be achieved with suitably designed high frequency, small footprint transducers. Image quality and field of view may be limited by the size of the anterior fontanelle, but in most neonates cranial ultrasound is sufficient to exclude hydrocephalus. Cranial ultrasound can be performed with portable scanners on preterm and unstable babies in the neonatal intensive care unit, and has become routine for monitoring babies at risk of intracranial complications, such as germinal matrix haemorrhage, hypoxic-ischaemic brain injury, and hydrocephalus. Cranial ultrasound can also diagnose major cerebral malformations and vascular abnormalities such as vein of Galen malformations (Fig. 10.60).

Small, portable ultrasound devices are now widely available and can be used successfully by practitioners from many different disciplines, but

appropriate supervised training is essential to achieve competency. A thorough knowledge of the ultrasound appearances of the normal brain in the preterm and term neonate, an understanding of normal variants, and experience of a wide range of pathology are essential for safe practice. Meticulous and careful technique and acquisition and secure storage of standard images are important. Care must be taken with the amount of pressure applied, as bradycardia may be induced by excessive pressure.

MRI provides images of the whole of the brain in multiple planes, with no limitation of the field of view. This makes MRI more sensitive that

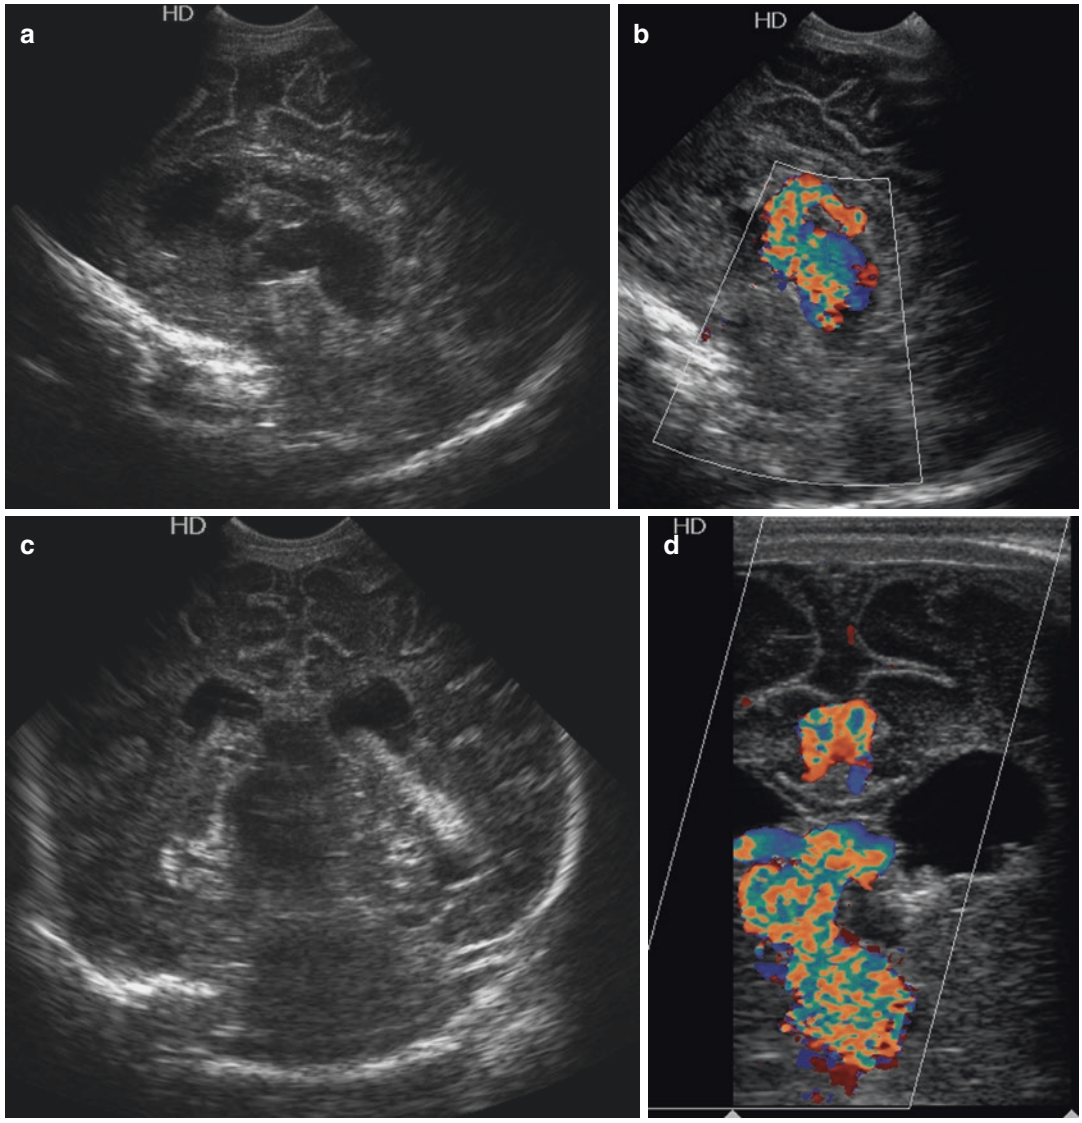

Fig. 10.60 Vein of Galen malformation. (**a**) Grey scale and (**b**) colour Doppler sagittal and coronal (**c** and **d**) ultrasound images demonstrate a hypoechoic structure in the midline which demonstrates marked colour flow. Non-contrast axial CT brain (**e**) demonstrates the highly attenuating markedly dilated vessel and prominent venous sinuses. Single sagittal image from a cerebral angiogram (**f**) demonstrates early filling of the vein of Galen which is dilated, as are the draining falciform, sagittal and straight sinuses. Post procedure radiograph (**g**) demonstrates the embolisation coils in situ

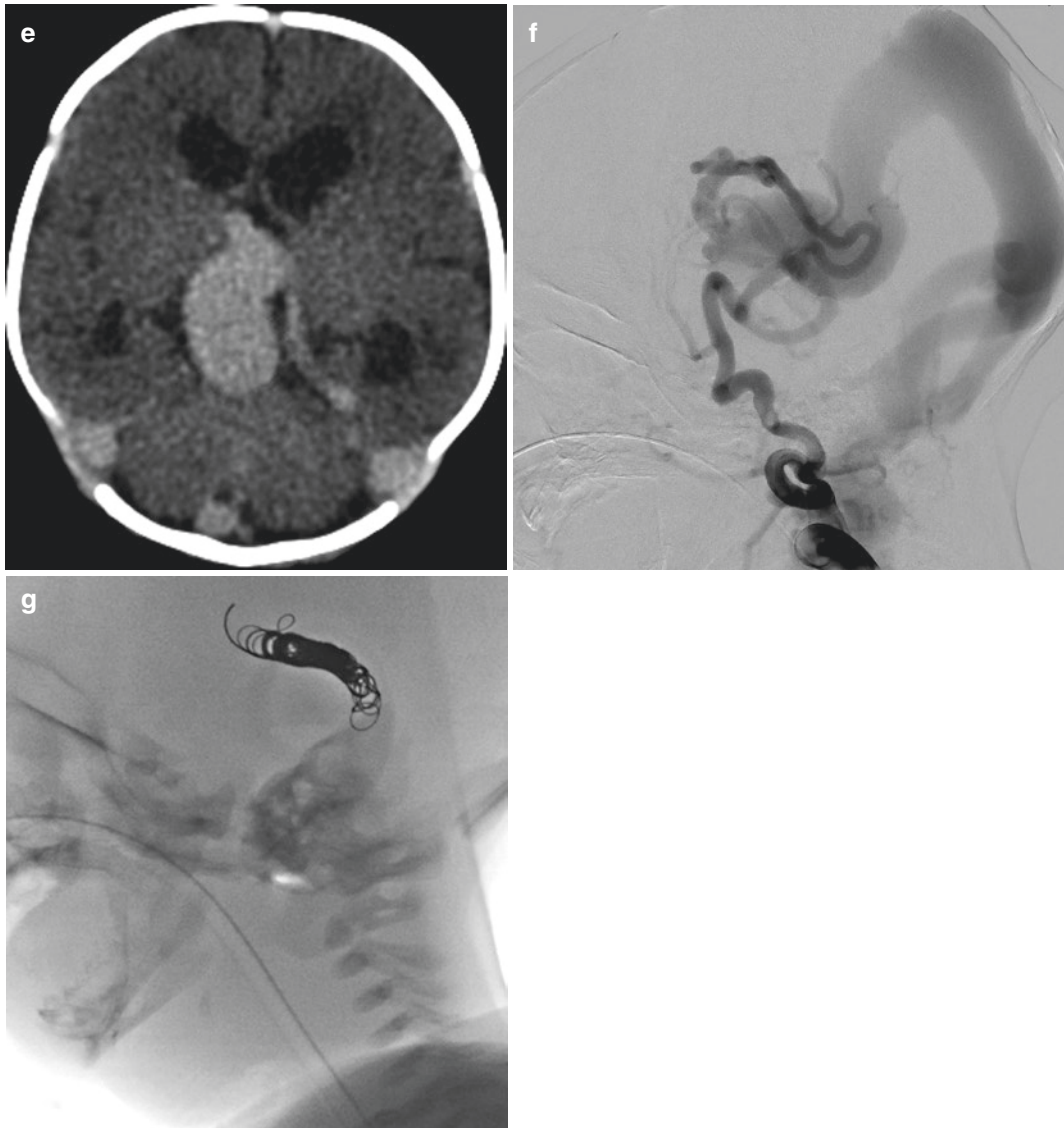

Fig. 10.60 (continued)

ultrasound for demonstrating subdural and extradural collections. High contrast resolution makes MRI more suitable for demonstrating subtle structural abnormalities and hypoxic ischaemic injury to the basal ganglia, thalami and cerebral cortex. MRI is used in preference to CT whenever possible, because of the better contrast resolution, multiplanar capability and avoidance of exposure to ionizing radiation. However, the acquisition time for a CT brain scans is much shorter (30 seconds or less with modern CT scanners), and so CT is sometimes more appropriate for urgent imaging in sick and unstable neonates. Volume CT and MRI scans can be used for image guided neurosurgery such as ventricular shunt insertion for hydrocephalus.

10.16 Suspected Spinal Dysraphism/Sacral Dimple

Isolated sacral dimples and small sacral pits are commonly found in newborn infants. Radiological investigation is usually not necessary for typical

midline sacral dimples lying in a low position, less than 25 mm from the anus [76]. Investigation is necessary for lesions that are large (more than 5 mm), away from the midline, or in a high position (more than 25 mm from the anus), lesions discharging fluid, or those associated with other markers of spinal dysraphism such as a hairy patch or vascular birthmark. Imaging of the spine is also indicated in neonates with imperforate anus and urogenital anomalies.

Ultrasound is the first investigation of choice, supplemented by MRI when ultrasound is abnormal or equivocal, when there are neurological signs, or when there is a discharging lesion. Tethering of the spinal cord can be recognised on ultrasound when the conus of the spinal cord lies below the level of the L2 vertebral body. Thickening of the filum terminale can also be recognised (> 2 mm at the L5-S1 level), and a lipoma or dermoid lesion may be identified within the lumbosacral spinal canal (Fig. 10.61).

In young infants, a high definition ultrasound scan can provide images of the spinal cord and the lumbosacral spinal canal with equal or better spatial resolution than MRI, but once spinal dysraphism or a tethered cord has been diagnosed, MRI can provide visualisation of the whole of the spinal cord, spine, sacrum and paravertebral tissues, to help exclude associated abnormalities such as syringomyelia. MRI is also valuable to evaluate the full extent and complexity of overt spinal dysraphism and dorsal dermal sinuses [77].

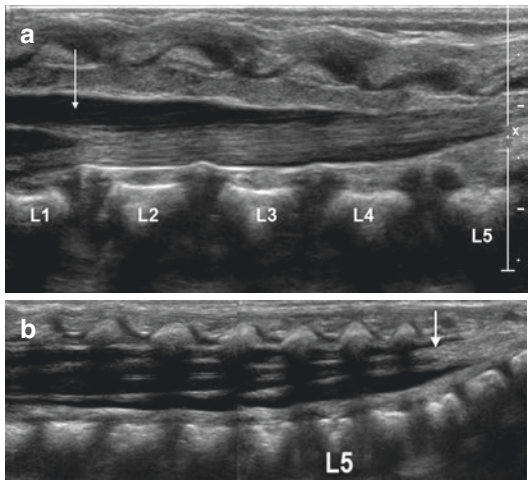

Fig. 10.61 Spinal ultrasound. (**a**) normal spinal ultrasound. Ultrasound images of the normal spine demonstrate cord terminating at a normal level (*arrow*) with a normal appearance to the conus. The nerve roots of the cauda equina are lying dependant in the canal (baby is in the prone position), with no evidence of a thickened filum. (**b**) Tethered cord. Longitudinal ultrasound images of the abnormal spine show a very low lying conus (*arrow*) and hyperechoic canal contents distal to this. The appearances of tethered cord with filar lipoma were confirmed on MR

10.17 The Neonate with a Neck Swelling

Ultrasound is ideally suited to the examination of superficial lesions of the head and neck in infants. As well as characterizing any abnormal structures ultrasound is very effective at confirming the presence of normal neck structures, particularly the thyroid and salivary glands. However, ultrasound is limited in the assessment of deep lesions and some anatomical locations are not easy to visualise. Ultrasound cannot penetrate bone and air, and so ultrasound may fail to demonstrate deep extension of lesions around the skull base, cervical spine, pharynx and trachea. MRI is often complementary to ultrasound in these situations. However, MRI does not offer the same capability for real time imaging that ultrasound can provide; imaging times are relatively long, and the images are easily degraded by movement artifact.

10.17.1 Congenital Cystic Lesions of the Neck

10.17.1.1 Thyroglossal Duct Cysts

The thyroid gland develops in the floor of the primitive pharynx, descending from the tongue through the floor of the mouth, anterior to the developing hyoid bone, to reach its final location in the neck by the seventh week of gestation. The thyroglossal duct connects the gland to the tongue during migration and normally involutes by the end of the tenth week of gestation. The foramen caecum on the tongue is the site of the original

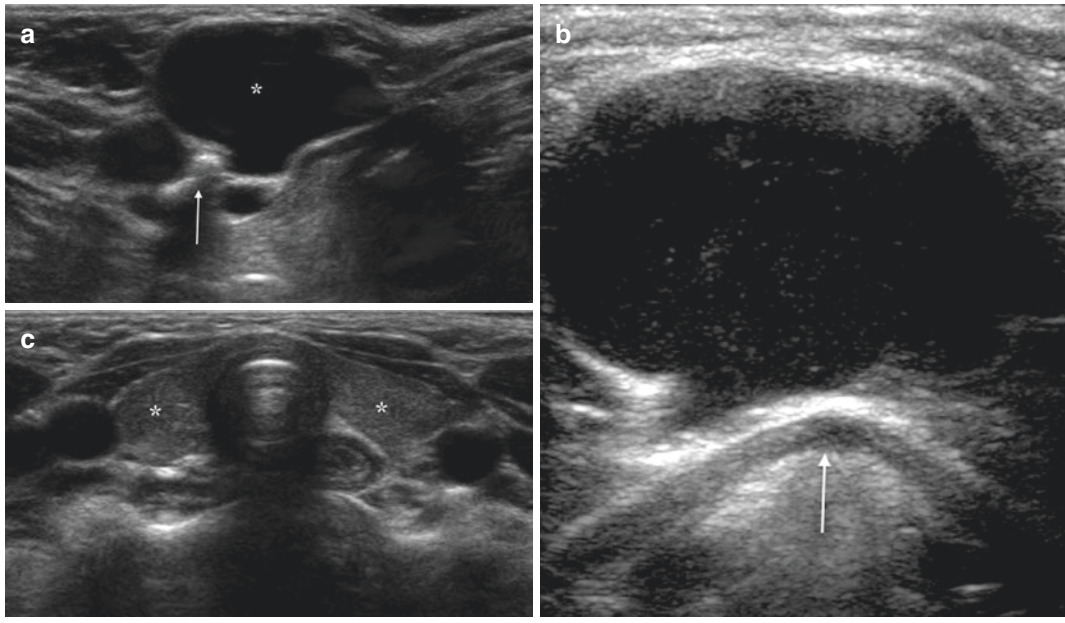

Fig. 10.62 Thyroglossal duct cyst. Longitudinal ultrasound image (**a**) reveals a midline hypoechoic cystic lesion (*), closely related to the hyoid bone (*arrow*), in keeping with a thyroglossal duct cyst. The transverse image (**b**) again confirms the relationship to the hyoid. Ultrasound image (**c**) confirms the presence of a normal thyroid (*), essential to demonstrate to avoid inadvertent excision of a lingual thyroid

opening of the duct. Persistence of any part of the thyroglossal duct may result in a cyst, but can also lead to sinus or fistula formation.

Clinically a thyroglossal duct cyst usually presents as an anterior neck mass in or near the midline. It may become infected and present with acute enlargement. On ultrasound the cyst may appear anechoic, hyperechoic or heterogeneous due to the presence of proteinaceous material (Fig. 10.62). The cyst may be complex, containing septations, and can be very mobile.

10.17.1.2 Lymphatic Malformations

Lymphatic malformations consist of fluid-filled cystic structures, formed from lymphatic vessels which fail to connect with normal drainage pathways. The lesions may be unilocular or multilocular, and there is a wide variation in the size of the individual cysts. Lymphatic malformations may be macrocystic or microcystic. Microcystic lymphatic malformations (previously known as lymphangiomas) consist of multiple tiny cysts within a solid matrix; macrocystic lymphatic malformations (cystic hygromas) may be very large and exert significant mass effect on adjacent structures. Both types may undergo rapid enlargement as a result of haemorrhage or infection.

Lymphatic malformations may occur at any anatomical location except in the central nervous system, but the neck, axilla and mediastinum are the commonest sites. Cervical lymphatic malformations are associated with trisomy syndromes, Turner syndrome, Noonan syndrome, and fetal alcohol syndrome. Soft tissue lymphatic malformations may be associated with overgrowth of adjacent skeletal structures, particularly in the craniofacial region.

Ultrasound in macrocystic lymphatic malformations characteristically reveals large, thin walled, fluid-filled cystic spaces, which may contain internal septations. If there has been recent haemorrhage or infection, mobile echogenic debris may be visible. The cysts may be mobile but are usually not compressible. Colour Doppler typically shows only sparse blood vessels around the walls of the cysts (Fig. 10.63a–c). Microcystic lymphatic malformations are shown to consist of multiple tiny cysts, sometimes at the limit of ultrasound resolution, within a densely echogenic solid

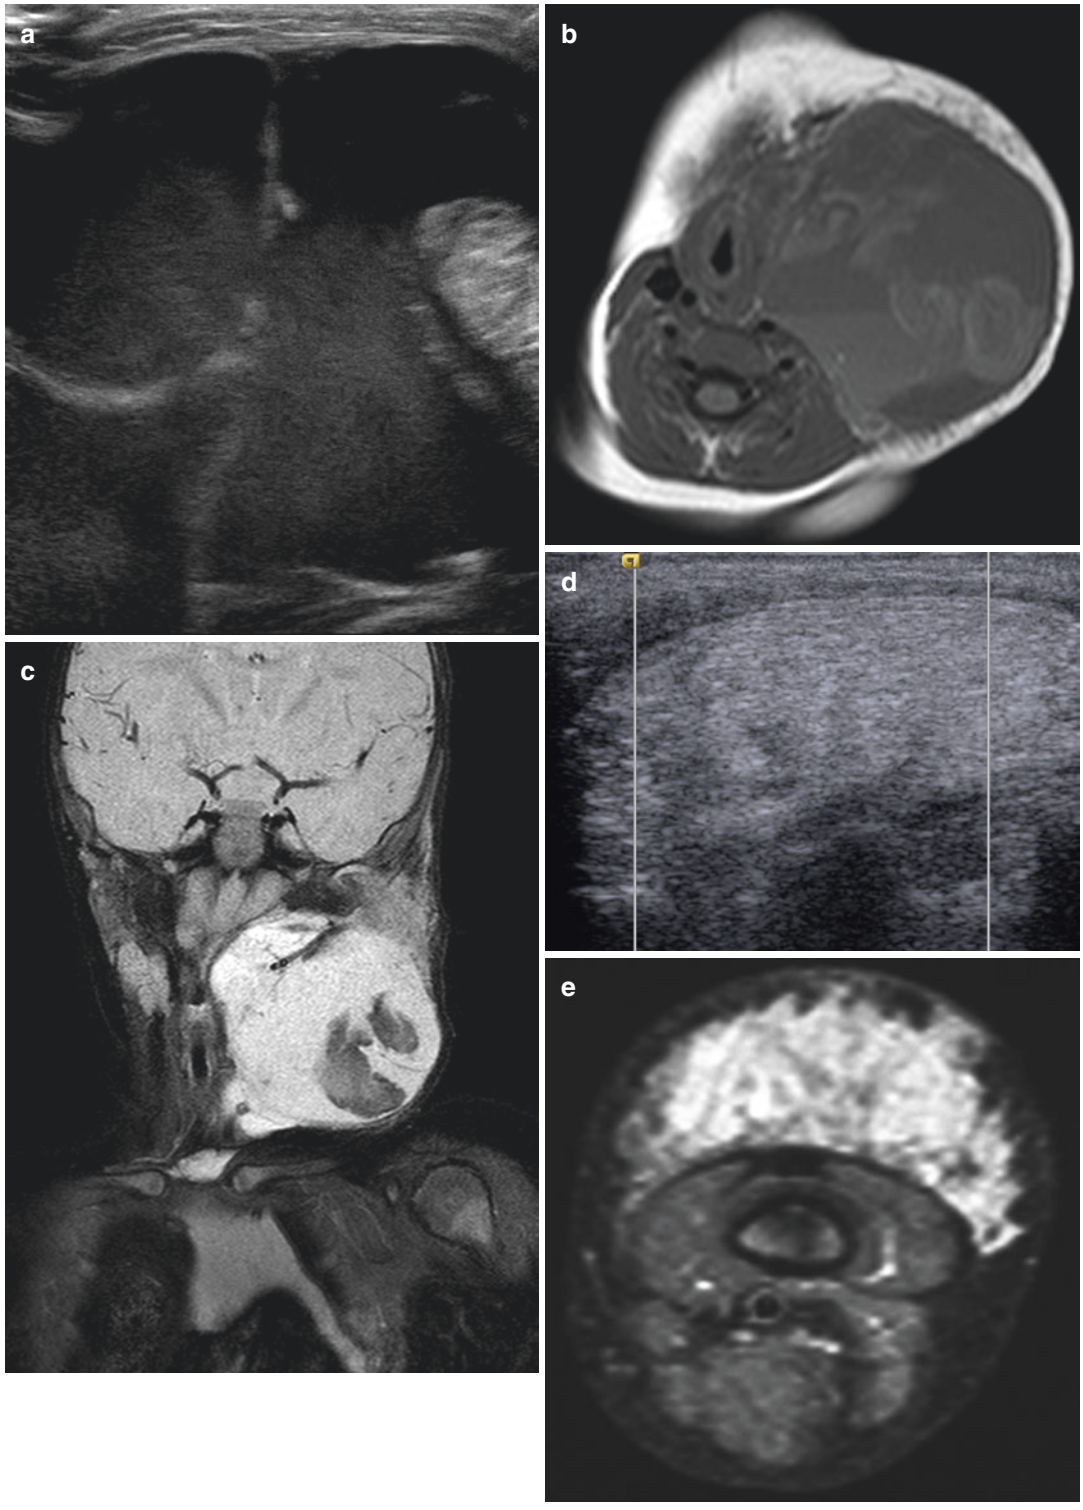

Fig. 10.63 Lymphatic malformations. Macrocystic lesion (**a**–**c**) demonstrates large avascular cystic spaces on ultrasound, with fluid-fluid levels and internal debris noted on the axial T1 and coronal T2 weighted MR images. Microcystic lesion (**d** and **e**) is depicted by a hyperechoic lesion on ultrasound, due to the presence of multiple small echogenic cystic walls, and high signal abnormality on the T2 STIR sequence

matrix. Grey scale ultrasound appearances may be similar to those of a proliferative haemangioma, but colour Doppler shows that a microcystic lymphatic malformation is much less vascular and lacks the high density of small vessels typically seen in a proliferative haemangioma (Fig. 10.63d, e).

MRI is the optimal modality for assessing the deep extension of lymphatic malformations in areas which are not accessible to ultrasound; for example, deep to the carotid and jugular vessels, into the retropharyngeal region and upper mediastinum.

Macrocystic lymphatic malformations can be surgically resected but they can also be effectively treated with sclerotherapy. A sclerosant agent such as doxycycline or sodium tetradecyl sulphate can be injected into the cystic spaces after percutaneous aspiration. Sclerotherapy is not usually performed in the neonatal period, unless the lesion is very large, symptomatic, or causing potentially dangerous compression of vital structures.

10.17.1.3 Branchial Cysts

Branchial cleft anomalies may take the form of cysts, sinuses with an external opening to the skin surface, or fistulae which have both cutaneous and internal openings. Cysts tend to present in older children or young adults, whereas sinuses and fistulae are often noticed in the neonatal period. The abnormalities are bilateral in 2–3% of cases and can be familial.

First branchial cleft abnormalities occur in the region between the external auditory meatus, the parotid gland and the submandibular triangle. They may present clinically with recurrent inflammation in the region of the ear or angle of the mandible. The cyst may be superficial or deep to the parotid gland.

Second branchial cleft anomalies are the commonest, accounting for 90% of all branchial abnormalities. 75% of these are cysts, which are usually located in the anterior triangle of the neck, along the line of the anterior border of the sternomastoid muscle, anterolateral to the internal jugular vein and carotid artery, and lateral to the thyroid. A fistula passes from the tonsillar fossa to the supraclavicular region of the neck, with the ostium lying just above the clavicle. On imaging, a second branchial cleft cyst typically displaces the sternomastoid posteriorly, and its contents may be anechoic, or contain debris (Fig. 10.64).

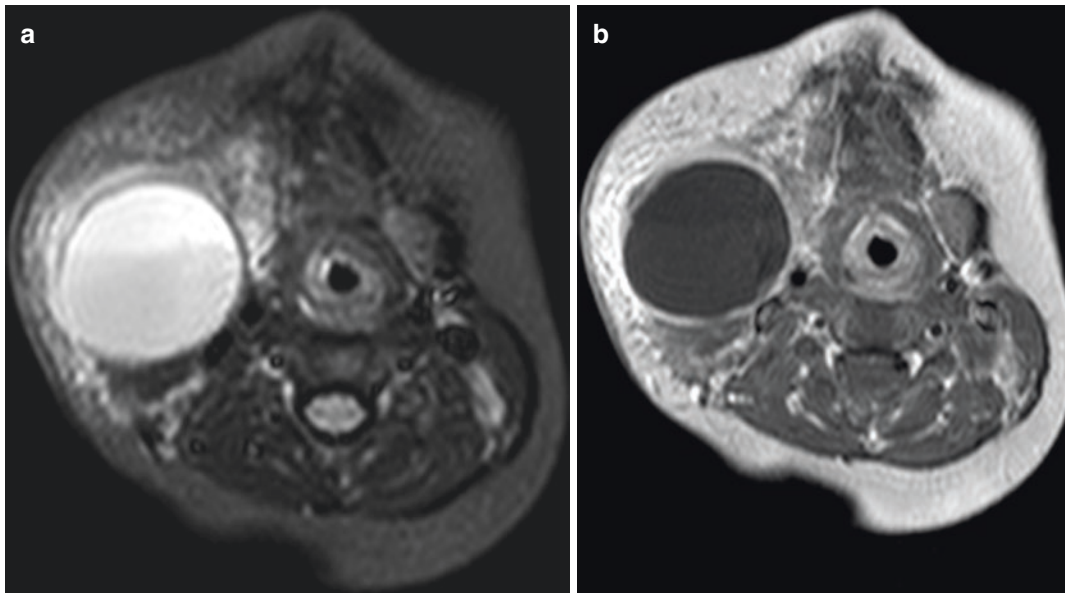

Fig. 10.64 Branchial cleft cyst. Axial T1 post gad and T2 weighted imaging demonstrates a well defined cystic mass with rim enhancement, containing fluid-fluid layers, in the right carotid space, closely related to the sternomastoid muscle

Third and fourth branchial cleft abnormalities are rare. They may present in childhood or adult life and mainly occur on the left side. Third branchial cleft cysts lie posterior to the carotid artery and sternomastoid muscle. In fourth branchial cleft anomalies, only sinuses have been reported; they run a very long course into the mediastinum and are associated with ectopic parathyroid glands and parathyroid adenomas.

10.17.1.4 Dermoid Cysts

Dermoid cysts, which are composed of ectoderm and mesoderm, can be found in the head and neck. Ultrasound of dermoid cysts typically shows a hypoechoic structure with well-defined walls, containing echogenic elements due to the presence of fat or calcification. Cranial lesions often related to cranial sutures (Fig. 10.65). Lateral and medial margins of the orbit are also common sites. Midline cranial lesions in particular require careful investigation to exclude intracranial extension. Ultrasound is valuable in initial assessment but further imaging with CT or MRI is often necessary.

Dermoid cysts also occur in the neck, typically in the midline above the hyoid, but sometimes between the hyoid and the isthmus of the thyroid. Lesions in this location may be difficult to differentiate from thyroglossal cysts, but dermoid cysts tend not to show movement with the tongue. Dermoid cysts can also occur adjacent to or within the thyroid.

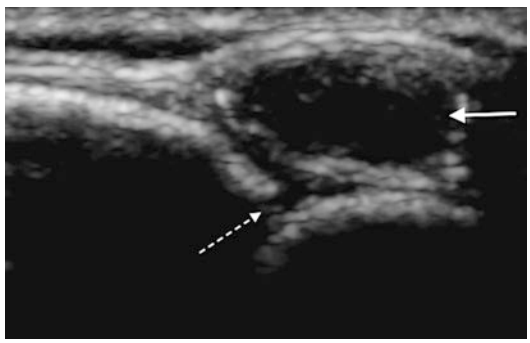

Fig. 10.65 Dermoid cyst. Ultrasound demonstrates a well demarcated focal cystic lesion (*solid arrow*) closely associated with the underlying cranial suture (*broken arrow*)

10.17.1.5 Thymic Cysts

The thymus descends from the third pharyngeal pouch, following which the thymo-pharyngeal duct that normally involutes completely. Remnants of the duct or possibly cystic degeneration may result in the presence of a thymic cyst. Two thirds of these present in the first decade and they usually present as a swelling in the lower third of the neck laterally. Although the cysts are usually unilocular and hypoechoic, they may be mulitilocular and if they bleed can contain echogenic fluid. In 50% of cases there is mediastinal extension and it may be possible to demonstrate continuity with the thymus on ultrasound.

10.17.2 Jugular Varix

Jugular varix (jugular vein ectasia) is a common venous malformation, which presents as a bluish neck swelling in infants due to dilatation of the external or internal jugular vein. It may enlarge alarmingly when the child cries or strains, but is usually of no clinical significance, and becomes less prominent with age. Ultrasound examination is often reassuring, revealing simple dilatation of the jugular vein with turbulent flow, but no evidence of venous obstruction or thrombosis and no other significant vascular abnormality (Fig. 10.66).

10.17.3 Benign Sternomastoid Tumour of Infancy (Fibromatosis Colli)

Benign sternomastoid tumour of infancy is characterised by diffuse or focal enlargement of the sternomastoid muscle, typically first recognised at 2–8 weeks after birth. It is often associated with a history of birth trauma, suggesting that it may be caused by haematoma formation followed by healing with fibrosis. However, associations with hip dysplasia and tibial torsion suggest that some cases may be caused by abnormal fetal position in utero. Shortening of the muscle may cause torticollis. Spontaneous resolution usually occurs over a period of

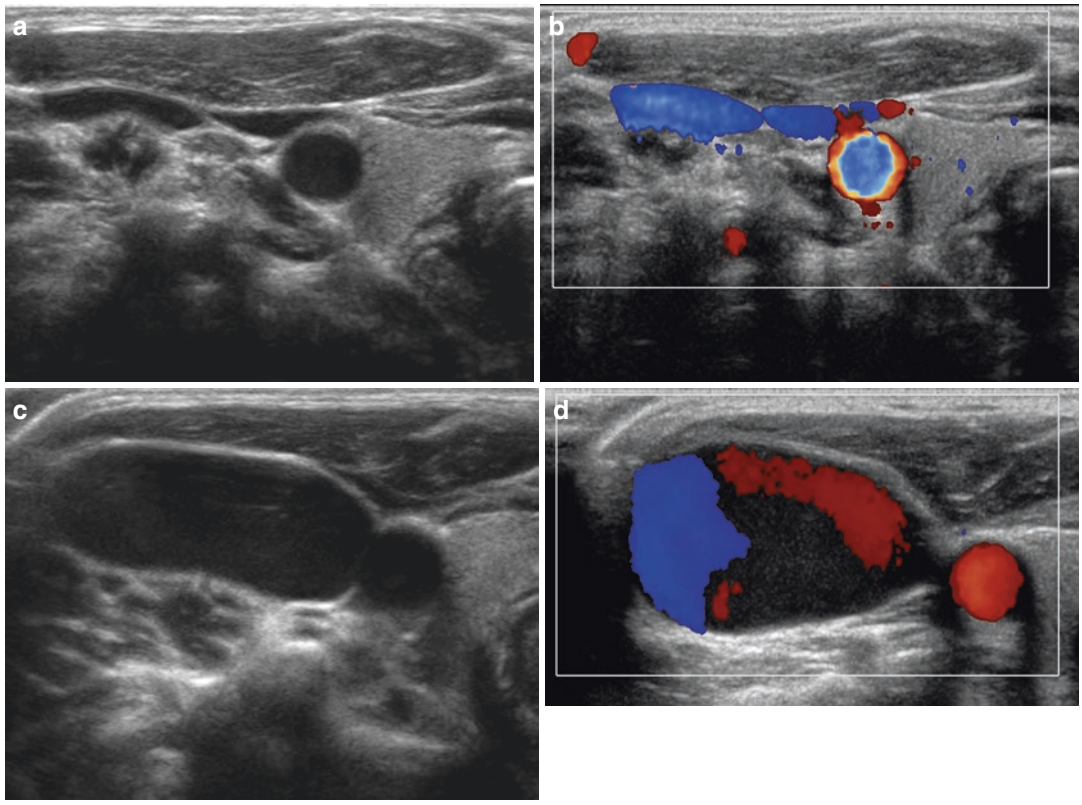

Fig. 10.66 Jugular varix. Grey scale and colour Doppler ultrasound images of the jugular vein (**a**–**d**) demonstrates marked dilatation with Valsalva consistent with varix/ectasia in a child presenting with a neck mass on crying

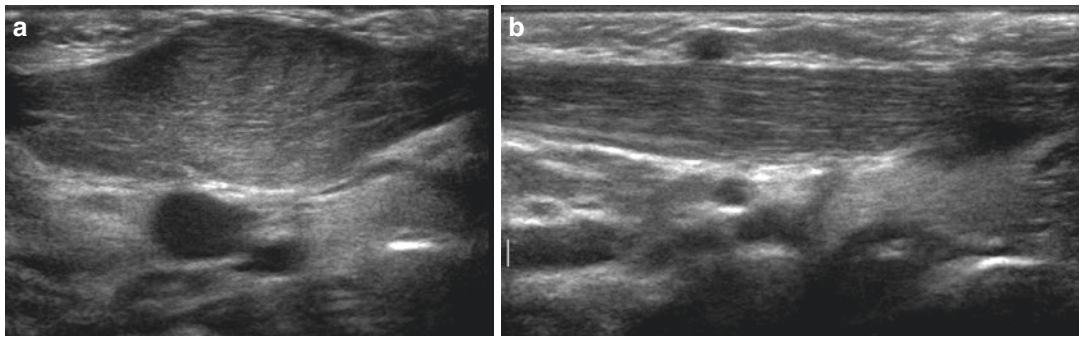

Fig. 10.67 Fibromatosis colli (benign sternomastoid tumour of infancy). Longitudinal grey scale ultrasound image of the sternomastoid shows a smooth fusiform swelling of the muscle belly (**a**), compared with the normal contralateral side (**b**)

4–8 months, and may be helped by physiotherapy, but some cases require surgery for persisting torticollis. Severe, untreated cases may result in strabismus, facial asymmetry and plagiocephaly.

Ultrasound shows a well-defined mass within the belly of the muscle, which is usually isoechoic or slightly hypoechoic in comparison with normal muscle, but may be hyperechoic (Fig. 10.67). Calcification may be visible.

Sometimes there is diffuse enlargement of the whole of the muscle [78].

10.18 The Neonate with a Superficial Vascular Birthmark or Soft Tissue Swelling

10.18.1 Proliferative Haemangiomas (Common Infantile Haemangiomas)

These benign vascular tumours may occur at any site but seem to have a particular predilection for the parotid region. Superficial cutaneous lesions are easily recognised as typical "strawberry naevi", but deeper lesions may cause diagnostic difficulty. Proliferative haemangiomas usually appear shortly after birth, although some cutaneous manifestation may be visible at birth in up to 40% of affected children. These lesions undergo a proliferative phase of rapid growth, becoming raised, bulky but soft, compressible lesions with a characteristic strawberry-red colour. Following a few weeks of proliferation and growth, they typically enter a phase of stabilisition lasting for several months, followed by a phase of involution. The rate of regression is variable; 50% enter the phase of involution by 5 years of age, and 90% by the age of 9 years. The prognosis for cosmetic outcome is not universally favourable; even after involution, some residual abnormality is present in 20–40% of cases, including telangiectasia, increased or decreased pigmentation, thinning of overlying skin and persisting fibrofatty masses.

Proliferative haemangiomas occur more frequently in girls than in boys, and there is a significant association with prematurity. Systemic haemangiomatosis is a condition in which multiple cutaneous and visceral haemangiomas occur; although this condition is rare, it is usually recommended that infants with five or more cutaneous lesions should have an abdominal ultrasound scan to exclude hepatic or splenic lesions.

Haemangiomas usually only require treatment if they cause secondary problems such as airway or vision obstruction or difficulty with feeding. Although eventual stabilisation and regression can be expected, proliferative haemangiomas may cause significant symptoms. Ulceration, bleeding and secondary infection may occur, particularly in peri-oral lesions. Large lesions close to the eye and airway may have disastrous consequences. In the young infant, permanent visual impairment may occur if the eye is occluded for more than 1 week; a large proliferative haemangioma on the eyelid therefore requires urgent investigation and treatment. Similarly, lesions involving the oropharynx, larynx or trachea may rapidly progress to cause airway obstruction, and require prompt intervention. Intra-lesional steroids, systemic steroids or propranolol are effective methods of inducing involution. Surgery is rarely required.

Imaging is not usually necessary for typical cutaneous proliferative haemangiomas, but it can be very valuable in determining the extent of particularly large lesions and those at dangerous sites. If the nature of the lesion is not certain on the basis of its clinical features, ultrasound and colour flow imaging may be helpful in showing a typical appearance of a well defined, solid, echogenic mass which is intensely vascular, containing a high density of small vessels with high blood flow velocity (Fig. 10.68). However, appearances change as the lesion undergoes stabilisation and regression. The lesions become relatively less vascular, and the residual vascular spaces enlarge as the solid components regress. In the past, lesions with these appearances were sometimes described as "cavernous haemangiomas".

Some haemangiomas are present at birth and show differing patterns of biological behaviour; the rapidly involuting congenital haemangioma (RICH) regresses spontaneously, whereas the non-involuting congenital haemangioma (NICH) does not.

Rarer vascular tumours, such as Kaposiform haemangioendotheliomas and tufted haemangiomas are much more serious and may cause a severe coagulation disorder due to platelet consumption (Kasabach-Merritt syndrome). The characteristic clinical features of Kasabach-Merritt Syndrome are an enlarging soft tissue mass associated with a severe systemic bleeding

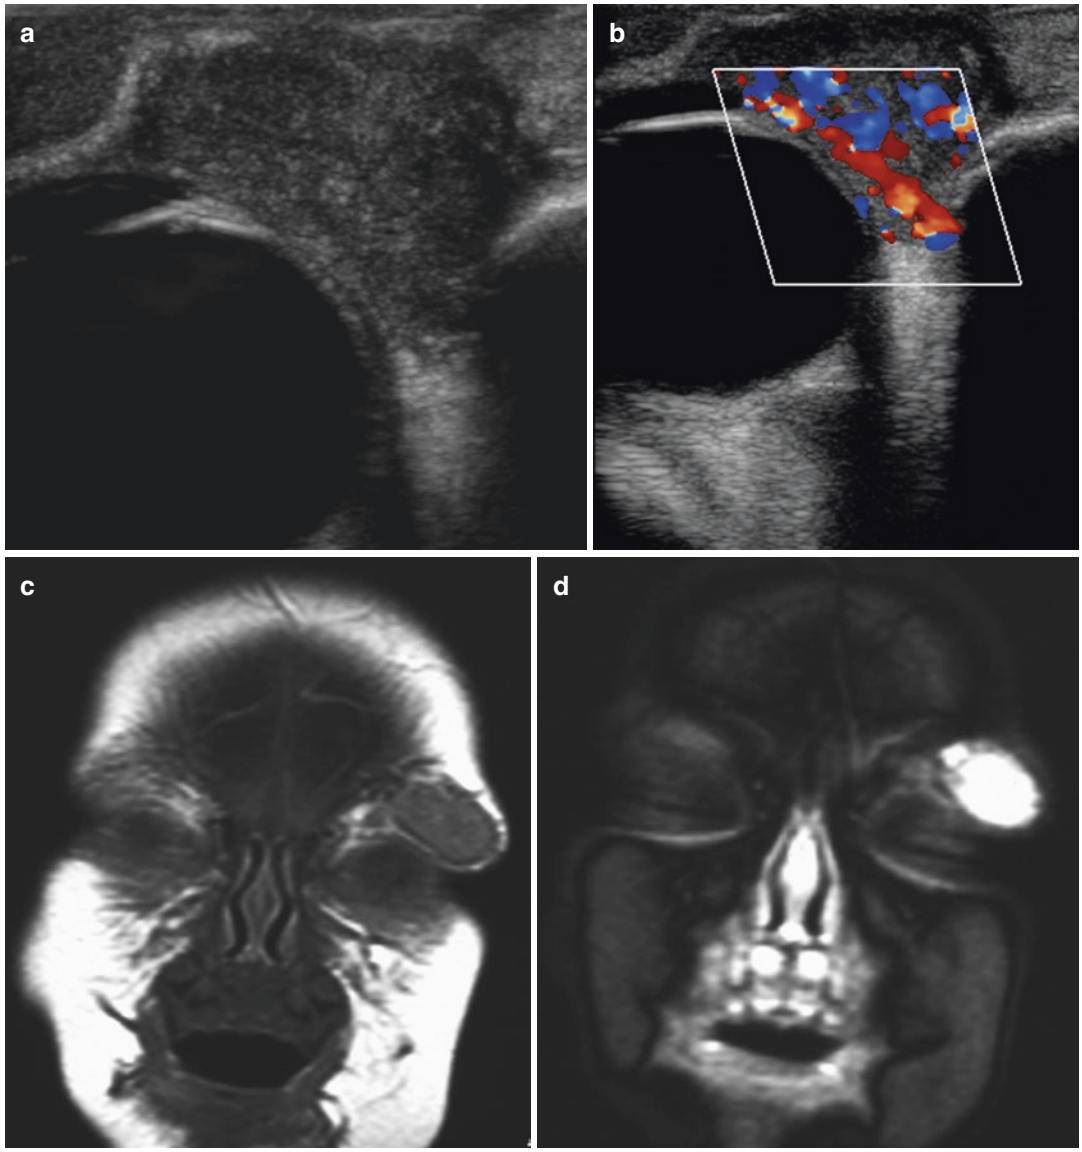

Fig. 10.68 Proliferative haemangioma. Grey scale (**a**) and colour Doppler (**b**) ultrasound demonstrates a highly vascular mass at the lateral aspect of the eyelid extending posteriorly into the orbit. On MR this is of intermediate T1 (**c**) and high signal on the T2 STIR (**d**)

disorder and marked reduction in platelet count, which may be impossible to correct by platelet transfusion (Fig. 10.69). On ultrasound they are seen as ill defined soft tissue masses with variable echogenicity. Calcifications may be present which are never present in infantile/proliferative haemangiomas. MR imaging shows a heterogenous lesion with mainly intermediate or low signal on T1-weighted sequences and high signal on T2-weighted sequences, with subcutaneous stranding. Gradient echo sequences may show signal voids due to the presence of haemosiderin.

These lesions are initially managed medically with platelet transfusion and systemic treatment with steroids or vincristine, but in critical cases with life-threatening platelet consumption, interventional radiology may be life-saving. Embolisation of the tumour can control

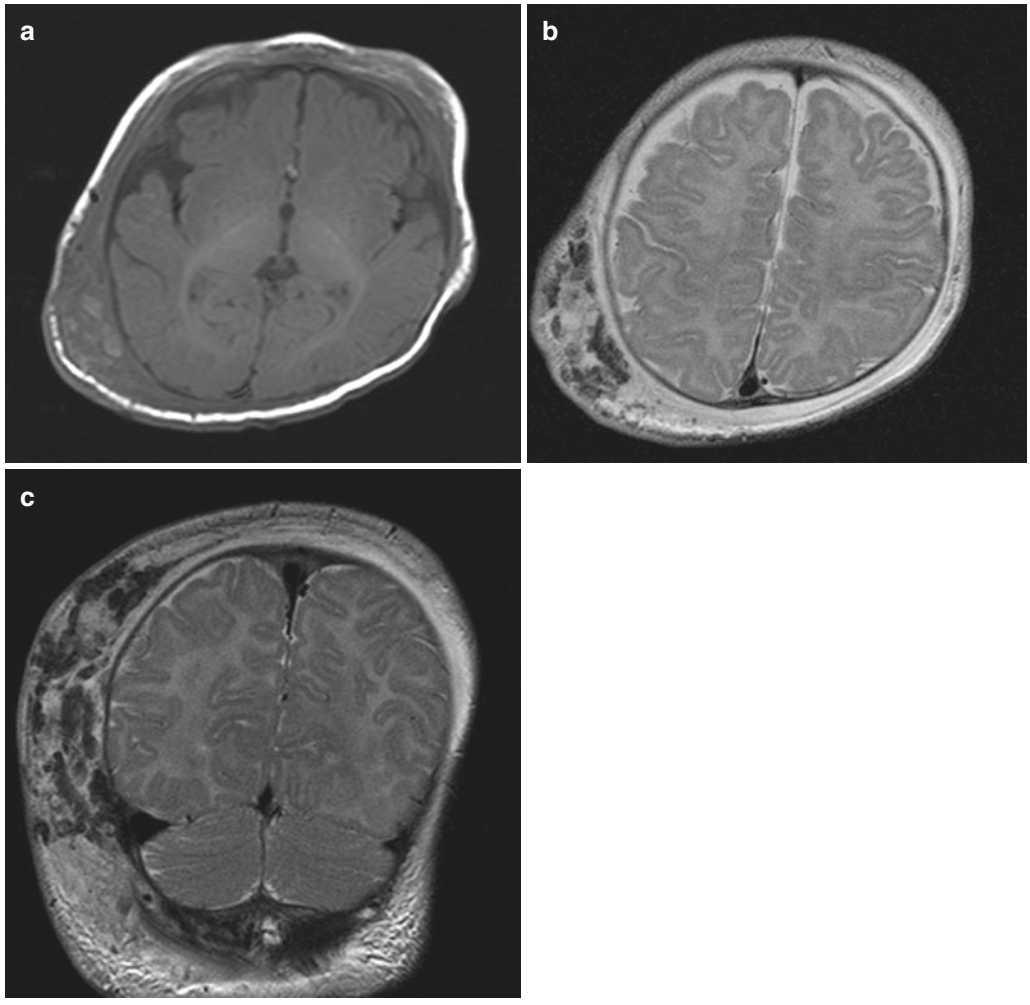

Fig. 10.69 Kaposiform haemangioendothelioma presenting with Kasabach-Merrit syndrome. Axial T1 (**a**) and axial (**b**) and coronal (**c**) T2 weighted images demonstrate extensive heterogenous soft tissue abnormality in the right parieto-occipital area with internal flow voids

platelet consumption acutely and allow time for chemotherapy to take effect.

10.18.2 Vascular Malformations

Venous malformations are congenital hamartomatous lesions, which do not grow by cellular proliferation in the same way as haemangiomas, and do not spontaneously regress. The lesions may become more or less apparent with body habitus, particularly becoming more apparent initially with neonatal weight loss prior to full feeds and then apparent regression with eventual weight gain. Venous malformations are varied and complex; some patients have diffuse malformations involving both deep and superficial systems, whereas others have localised or segmental abnormalities. Localised, superficial lesions have characteristic clinical features; they are bluish in colour, and there is no local increase in skin temperature. They are easily compressible and typically increase in size on Valsalva manoeuvre. However, deeper lesions are impossible to assess fully on clinical criteria alone, and are often much more extensive than initially expected.

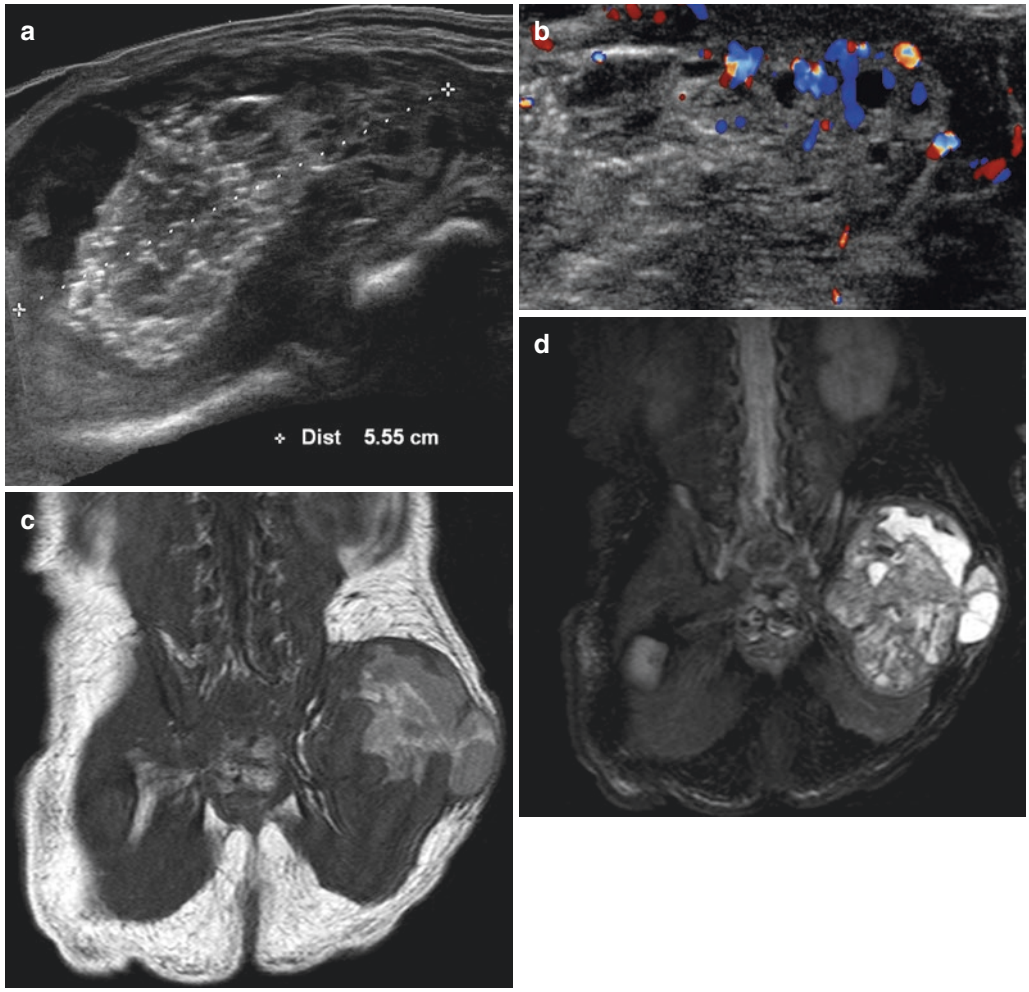

Fig. 10.70 Venolymphatic malformation. Neonate presenting with buttock swelling increasing in size. Panoramic grey scale (**a**) and colour Doppler ultrasound images (**b**) show heterogenous mass within the soft tissues, marked with calipers, with cystic spaces and vascular elements. T1 (**c**) and T2 fat suppressed (**d**) coronal MR images demonstrate a heterogenous partly solid partly cystic soft tissue mass

Grey scale ultrasound reveals the vascular spaces as hypoechoic structures. Varicosities, stenoses, complex interconnecting channels and venous lakes are typical. Colour flow imaging shows slow, turbulent flow within dilated, compressible vascular spaces (Fig. 10.70). Colour Doppler US shows that these lesions consist mainly of dilated vascular spaces and the spectral waveform is consistent with a low flow, low pressure lesion. Phleboliths may be seen on plain film or on ultrasound, and are typical of venous malformations.

Arteriovenous malformations are also hamartomatous, consisting of a network of abnormal vascular channels comprising both feeding arteries and draining veins. Clinically, high flow vascular malformations present as a soft tissue mass with cutaneous discolouration, locally increased temperature and palpable arterial pulsation. Arteriovenous malformations tend to be present at birth, and to grow in parallel with the growth of the child, although some lesions manifest unpredictable, aggressive growth. However, arteriovenous malformations may progressively enlarge as a result of increasing blood flow and arteriovenous shunting. Skin ulceration and uncontrollable haemorrhage may occur, and large lesions may result in high-output cardiac failure.

Ultrasound is helpful in confirming the vascular nature of the lesion and demonstrating high velocity blood flow.

Vascular malformations rarely require treatment in the neonatal period, unless control of serious complications is necessary. Venous malformations can be treated with percutaneous sclerotherapy, under imaging guidance. Sclerotherapy is often effective in controlling symptoms, and can be performed as frequently as is required. Arteriovenous malformations can be extremely difficult to treat effectively. Trans-arterial embolisation may be necessary to control haemorrhage or cardiac failure.

Anaesthesia for Neonatal Surgery

11

Richard E. Sarginson and Sanaulla K. Syed

Abstract

Neonatal anaesthesia has evolved considerably over the last two decades. New agents and techniques have been widely adopted by paediatric anaesthetists, allowing a renewed emphasis on minimizing, or avoiding, periods of post-operative ventilation and sedation.

The newer drugs include remifentanil, an "ultra-short" acting opioid, the local anaesthetic agent levo-bupivacaine, the volatile anaesthetic agent, desflurane, and sugammadex, a relaxant reversal agent. There is also a better understanding of the pharmacology of the more established drugs.

Techniques include a variety of local and regional blocks, often aided by better needles and ultrasound imaging. Ultrasound guidance has also enabled more accurate and rapid vascular access. A number of devices and instruments have enlarged the repertoire of airway management techniques available to paediatric anaesthetists, including the laryngeal mask airway, micro-cuff endotracheal tubes and small fibre-optic bronchoscopes. Forced air warming devices have proved effective in preventing hypothermia.

desflurane, and sugammadex, a relaxant reversal agent. There is also a better understanding of the pharmacology of the more established drugs [3].

Techniques include a variety of local and regional blocks, often aided by better needles and ultrasound imaging. Ultrasound guidance has also enabled more accurate and rapid vascular access. A number of devices and instruments have enlarged the repertoire of airway management techniques available to paediatric anaesthetists, including the laryngeal mask airway, micro-cuff endotracheal tubes and small fibre-optic bronchoscopes. Forced air warming devices have proved effective in preventing hypothermia [2].

Overall, the survival rates of surgical neonates have continued to improve. However, there are also some clouds on the horizon. Concerns have been raised about the possible occurrence of neural toxicity induced by anaesthesic agents in human neonates. Larger cohorts of paediatric anaesthetists and intensivists are now employed in most institutions, following changes in medical working practices. Individual clinicians may face difficulty in acquiring and maintaining sufficient exposure to rare conditions and technical procedures. Continuity of care is affected by shift working patterns, particularly amongst trainees.

The dramatic improvements in neonatal care of recent decades have also resulted in difficult ethical dilemmas, particularly the wisdom of the treatment of severely malformed or damaged babies. There can also be crises in the availability of neonatal surgical beds in any particular regional centre during conditions of peak demand.

We aim to provide a current perspective of neonatal anesthesia for a largely surgical readership in this chapter. Neonatal anatomy and physiology are covered in detail elsewhere in this volume. We start by reviewing the available drugs and techniques for general and regional anaesthesia. We look at some general aspects of perioperative management of neonates, including vascular access. The anaesthetic management of number of specific conditions is then considered, particularly those situations where close cooperation is needed between the surgeon and anaesthetist. We focus our attention mainly on conditions in the domain of "general" paediatric surgery. However, we also consider the impact of co-existing congenital heart disease or airway abnormalities found in a proportion of babies with congenital defects such as diaphragmatic hernia, oesophageal atresia, exompahalos or craniofacial syndromes. Finally, we discuss some current controversies and ethical questions in our field.

11.2 History

Specialist neonatal anaesthesia evolved in the post war period in large regional paediatric centers with neonatal surgical units. The local configurations varied, depending on the location of maternity and neonatal paediatric units. In Liverpool, by the late 1960s, Stead and Nightingale could report institutional figures for 3000 neonatal operations over a 20-year period, during which only ten *intra-operative* deaths had occurred [4]. These results were based on a technique originally described by Jackson Rees [5, 6], incorporating intubation, muscle relaxation with D-tubocurarine, controlled ventilation by hand using a T-piece and the use of nitrous oxide ± halothane and morphine. Emphasis was also placed on maintenance of temperature, careful fluid management and close clinical monitoring, using an amplified oesphageal stethoscope, brachial blood pressure and clinical assessment of the quality of the pulse, heart sounds and perfusion. Regional techniques and analgesia regimens received rather less attention until the 1980s. Babies capable of resuming spontaneous respiration were subsequently managed on the neonatal surgical unit and babies requiring ventilation either went to the Paediatric Intensive Care Unit (PICU) or were returned to Neonatal Intensive Care Unit (NICU) in a Womens Hospital 3 miles away. Remarkable progress was made with a limited repertoire of drugs and monitoring equipment and a high level of clinical observation and experience.

The majority of neonates still require general anaesthesia for surgical procedures, including intubation, muscle relaxation and artificial ventilation. Some lower limb and groin operations can

be performed under spinal or caudal block. The need for pre or post-operative ventilation remains a consideration in the choice of technique. The timing of some procedures needs careful thought and discussion. In the following section we survey of the pharmacology of the common anaesthetic drugs now used in neonates.

11.3 Pharmacology in the Neonate

The population defined as "neonates" encompasses babies varying in weight from 500 g to 5 kg and 24–44 weeks post conceptual age (PCA). Postnatal age (PNA) varies from a few hours to 20 weeks. The "ex premie" infant of greater than 44 weeks PCA, with various persisting morbidities, is often included in "neonatal" pharmacological studies, trials and discussions.

Consequently, anaesthetists are faced with a heterogeneous "neonatal" group, with considerable variation in body habitus, organ function maturation, congenital malformation and disease processes, all of which may affect the pharmacodynamics and pharmacokinetics of anaesthetic drugs.

11.4 General and Developmental Pharmacology

Pharmacodynamics (PD) is the science of the dose response relationship in the body [3, 7]. This is often described in terms of the blood concentration required to achieve a target effect. Although this relationship is reasonably well established for some drugs, such as muscle relaxants, it remains poorly understood for many other anaesthetic agents. In part, this is due to the problem of understanding and measuring the desired theraputic effects of particular anaesthetic agents. For example, general anaesthetics, such as propofol or volatile agents, are used to induce "unconsciousness", a state that is difficult to define or measure in neonates. Many general anaesthetic agents are less effective for other desirable effects, such as providing analgesia or obtunding the stress response. Other agents, such as opioids or regional blocks, are used in combination with general anaesthetic agents to achieve these aims. This is often referred to as balanced anaesthesia. Anaesthetic drugs and combinations also have side effects, such as inducing hypotension, which also have PD aspects [3].

Pharmacokinetic (PK) theory is used to describe and predict the effects of processes, such as plasma protein binding, metabolism and renal elimination, on the time course of the blood concentration of a drug in the body. Typically, this involves the use of somewhat abstract compartment models. The aim is to determine the various components of the model in particular patient populations. These include the volume of distribution, clearance and various rate constants. For neonates, adjustment of PK models is needed in relation to size and the maturation of physiological functions, such as glomerular filtration rate (GFR). Fat free mass may be a better measure of size than total body weight for predicting GFR and drug clearance [3]. The relationship between postmenstrual age (PMA) and GFR has been well described [8]. The maturation of the clearance of drugs such as morphine and paracetamol can be estimated with reasonable accuracy from the PMA [7].

11.5 Allometric Scaling

Several theorists have attempted to interpret the available data relating size to metabolic rate, typically measured by oxygen consumption [9]. Rubner (1883) found that the metabolic rate depended on the surface to volume ratio, $M^{2/3}$, where M is the body mass. Kleiber (1932) reported that basal metabolic rate scaled with $M^{3/4}$ in mammals over a wide range of size. West and colleagues sought to explain a universal ¾ "power" scaling law on the basis of a model where the energy costs of vascular transport are minimized. However, doubt has recently been cast on the concept of such a

universal scaling law [10, 11]. It appears that the exponent value for M ranges between 2/3 and >3/4, depending on the species and the size range under study and the metabolic conditions. Many drug-dosing calculations are currently based on surface area calculations. Allometric scaling theory may be useful in predicting variables such as oxygen consumption and GFR. It remains to be seen which scaling model will best explain specific drug PD and PK data in relation to size.

11.6 Pharmacogenetics and Pharmacogenomics

Pharmacogenetics is defined as the study of genetic variations which give rise to different responses to drugs between individuals. Examples from anaesthesia include the rare variant of pseudocholinesterase that results in the prolonged action of suxamethonium and the variant in ryanodine receptors associated with malignant hyperthermia. Although some patients will have a family history of the relevant condition, few neonates will have undergone tests, an exception being the long QT syndromes.

Pharmacogenomics is wider in scope, incorporating genome-wide studies to identify pathophysiological processes invoving many genes. Most work in this field has been concerned with the profiling and detection of disease. Developmental pharmacogenomic studies explain some of the inter-individual variation in many drugs metabolized by Cytochrome P450 enzymes [7, 12].

11.7 Inhalational Agents

Volatile inhalational agents continue to have a prominent place in neonatal anaesthesia [13]. The use of nitrous oxide has waned over the last 20 years. Sevoflurane has replaced Halothane as the main inhalational induction agent. It has more of the desirable characteristics of an ideal agent, being relatively non-irritant in the airway, potent due to a high lipid-gas solubility, and rapidly absorbed and eliminated due to the low blood gas solubility (Table 11.1). The other commonly used volatile agents, at least for maintenance of anaesthesia, are Isoflurane and Desflurane [14, 15].

Neonates have a higher alveolar ventilation and lower functional residual capacity than older children and adults. They also have a higher cardiac output and greater perfusion of vessel rich tissues, all factors leading to a more rapid wash in of inhalational anaesthetics in early life. The minimal anaesthetic concentration (MAC) is used to describe anaesthetic vapour potency. This is the concentration at which half of the subjects will move in response to a surgical stimulus. The MAC for Halothane, Isoflurane and Desflurane is low in premature neonates, peaks at 1–6 months and then gradually falls as age increases. A different pattern has been found for Sevoflurane, with neonates having MAC values more similar to infants. During the maintenance phase of anaesthesia, inhalational agents will commonly be used in combination with either an opioid or regional block, which both reduce the MAC value. In

Table 11.1 Physicochemical properties of Inhalational anaesthetics

	Halothane	Isoflurane	Sevoflurane	Desflurane	Xenon
BP (°C)	50.2	48.5	58.5	23.5	−108
MAC (%) in O_2	0.89	1.52	3.3	9.16	71
MAC (%) in N_2O	0.36	0.92	2.5	7.33	NA
B-G	2.4	1.4	0.75	0.45	0.14
O-G	224	98	80	29	1.9
Odour	Non irritant	Irritant	Non irritant	Pungent	0dourless
% Metabolised	20	0.2	3.5	0.02	<0.01

BP boiling point, °C; *MAC* minimum alveolar anaesthetic concentration; *B-G* blood-gas partition coefficient; *O-G* oil-gas partition coefficient

practice, there is considerable variation in the response to volatile agents and a degree of dose titration is necessary at various stages of surgery.

11.8 Nitrous Oxide

Nitrous oxide (N_2O) has analgesic properties but is insufficient by itself to guarantee lack of awareness during anaesthesia, particularly where muscle relaxation removes motor responses from the patient. N_2O also displaces nitrogen from enclosed airspaces, which can result in gas volume expansion of trapped air in the gut, peritoneum, emphasematous lobes or venous air emboli. It also inhibits vitamin B_{12} synthesis, which can result in anaemia and possibly polyneuropathy if it is administered repeatedly or for long time periods. It is still used by some anaesthetists as a carrier gas, which reduces the MAC values of volatile agents. It is also has a role, typically in the form of "Entonox" (a 50:50 O_2-N_2O mixture), for procedural analgesia, for example during chest drain removal.

Although nitrous oxide had a major role during the development of neonatal anaesthesia, the short acting potent opioid, remifentanil, has largely replaced it for major neonatal surgery. In common with many developments in the evolution of anaesthetic practice, no large scale randomized controlled trial (RCT), with appropriate outcome measures, has been done to test the claimed advantages of remifentanil over nitrous oxide. N_2O is implicated in the occurrence of neuro-toxicity in neonatal experimental rats and monkeys. It is likely that its use may drop further, although it probably will continue to have a niche for smoothing gas induction and procedural sedation.

Xenon has low blood gas solubility and can be used for anaesthesia with minimal cardiovascular side effects, albeit with a MAC value of 70% in adult volunteers. It is expensive and is under investigation for neuroprotection in asphyxiated infants.

11.9 Intravenous Agents

A number of drugs are used for the induction and maintenance of anaesthesia, sedation during mechanical ventilation on PICU and "procedural" sedation [16]. From a historical perspective, thiopentone has been largely replaced by propofol. Ketamine has undergone a recent re-evaluation and renaissance, particularly as an analgesic agent in subanaesthetic doses. Intravenous agents, for example propofol, midazolam, ketamine or dexmedetomidine can be used for maintenance of anaesthesia as an altenative to volatile agents, although this is not a common approach in neonates.

11.9.1 Thiopentone

Thiopentone is a highly lipid soluble barbiturate derivative, with a rapid onset of action. The initial offset and recovery after a bolus dose is largely governed by redistribution. Metabolism in the liver is capacity limited and the relevant enzymes become saturated during thiopentone infusions, resulting in very slow elimination. The effective induction dose in neonates (ED50) is in the region of 3 mg/kg, less than in older infants (Table 11.2). Thiopentone has anticonvulsive properties and is effective in reducing intracranial pressure and cerebral oxygen consumption. Thiopentone use in babies has waned relative to propofol or sevoflurane induction, probably due to the better recovery profiles for the latter agents. However, there are circumstances where it should still be considered, particularly in babies with neurological conditions resulting in seizures or raised intracranial pressure.

Table 11.2 Effective dose definitions

• ED_{50}: dose at which 50% of the population or sample manifests a given effect
• ED_{90}: dose at which 90% of the population or sample manifests a given effect
• ED_{max}: dose at which maximal response to a given drug is reached

11.9.2 Propofol

Propofol is an alkylated phenol, which is soluble in lipid but not water. It has a large volume of distribution, rapid redistribution and rapid elimination. The prompt offset and recovery, together with a low incidence of nausea and vomiting, have made propofol the main agent for intravenous induction and total intravenous anaesthesia in paediatric outpatient surgery. It is formulated in an oil-water emulsion. It can induce significant degrees of hypotension, mainly due to vasodilation, and a period of apnoea after a standard induction dose. The volume of distribution and clearance of propofol are both reduced in neonates, where postmenstrual and postnatal ages are predictors of clearance maturation [17]. It should be used with caution or avoided in hypovolaemic or septic babies, patients with ventricular dysfunction and patients with raised intracranial pressure. In the neonatal ICU setting, there is a recent report of significant hypotension, poorly responsive to fluids, associated with a low dose of propofol (1 mg/kg) used to facilitate endotracheal intubation for surfactant administration in preterm infants of 30 weeks PCA [18]. This has been contested by another group who used 2 mg/kg after atropine administration in a similar group of premature babies [19].

11.9.3 The Propofol Infusion Syndrome

Propofol infusions in children have been associated with a severe illness characterized by lactic acidosis, lipaemic serum, cardiac arrhythmias and failure, multi-organ dysfunction and rhabdomyolysis. Some cases have been fatal, particularly where the problem was not recognized and treated early by stopping the drug and starting haemofiltration. The aetiology is poorly understood but appears to involve impaired fatty acid oxidation [20]. A number of case reports were collated by Bray [21] and subsequently propofol was withdrawn as a sedative agent in neonatal and paediatric intensive care. Most cases occurred where doses of ≥4 mg/kg/h were used for >24 h, although there are sporadic reports of an earlier onset [22]. The use of propofol is largely confined to induction of anaesthesia in neonates, although a case could be made for low dose infusions in combination with remifentanil for limited periods. Further research is needed.

11.9.4 Ketamine

Ketamine is a very lipid soluble N-methyl-D-aspartate glutamate (NMDA) receptor antagonist. The role of ketamine in paediatric anaesthesia and analgesia is still under active investigation [23]. The standard formulation is a racemic mixture of the S+ and R− enantiomers. There is also a S+ ketamine formulation, which has twice the analgesic potency of the mixture and is shorter acting. Ketamine produces a state of "dissociative" anaesthesia and, in contrast to other intravenous anaesthetic agents, analgesia. Ketamine is metabolized in the liver to produce norketamine, which has about a third of the potency of ketamine. Further metabolism results in water-soluble substances excreted by the kidney. Elimination is prolonged in neonates due to immature liver metabolism and renal function.

Ketamine has sympathomimetic and bronchodilator activity. Induction doses of 1–2 mg/kg do not result in hypotension in otherwise healthy patients, although it does have a dose dependent negative inotropic effect on the myocardium.

It can be given intramuscularly (IM) at 4–5 times the intravenous dose. The IM onset of action is within 5 min, in contrast to 1 min IV. The status of ketamine in neonates is a little uncertain. It can be used for induction in cardiovascularly unstable patients and is also used by infusion for analgesia, ICU sedation and as a component of intravenous anaesthesia. It has been used in combination with propofol or dexmedetomidine. The preservative free formulation has also been used as an adjunct to local anaesthetics in the epidural space, typically in "single shot" caudal blocks. However, concerns about potential spinal cord and brain neural toxicity may limit its use in the neonatal population.

11.9.5 Midazolam

Midazolam is a relatively short acting benzodiazepine compared with diazepam and lorazepam. It has dose dependent hypnotic, amnesic and anticonvulsant properties. Midazolam is not used alone as an "anaesthetic" agent but may be used to supplement an opioid during intravenous anaesthesia and is used for intensive care sedation. It is also extensively used in PICU as part of sedation regimens for children and infants undergoing mechanical ventilation. The maturation of midazolam clearance lags somewhat behind the maturation of glomerular filtration rate in the first few months of life [24]. There are a number of concerns about midazolam in neonates, particularly preterm infants [25]. It has been associated with lack of sedation and even seizures, together with poorer neurological outcomes in sedation trials in neonatal intensive care units [26]. This seems to be related to the functional maturation of γ-aminobutyric acid type A ($GABA_A$) receptors, the site of action of benzodiazepines, in early life. The use of midazolam should probably be restricted to the short term or avoided in neonates pending further research.

11.9.6 Alpha-2-Adrenergic Agonists

Clonidine and dexmedetomidine are α-2 agonists with a spectrum of useful sedative and analgesic properties, together with limited cardiovascular and respiratory side effects. Dexmedetomidine is pure α-2 agonist with a shorter adult elimination half-life (2–3 h) than clonidine (12–24 h). However, clearance in neonates is approximately one third of that in adults, which implies that infusion rates to maintain a target effect site concentration should be reduced in the newborn population [27]. Dexmedatomidine is only approved by the FDA for ICU sedation of adults for less than 24 h and is not licenced in the UK. There has been a recent proliferation of "off label" paediatric studies but neonatal data is limited to phase 2/3 studies. It has been used as a sole drug for sedation or in combination with a variety of agents, including ketamine and opioids, as a component of intravenous anaesthesia. Other potential indications include premedication, sedation for procedures such as radiology scans and treatment of sedation withdrawal phenomena [28, 29]. Clonidine has been used as an analgesic adjunct to local anaesthetics in epidural or caudal "single shot" injections or infusions. It has also been used as a PICU sedative agent and to treat opioid withdrawal symptoms. Data on both drugs for various possible neonatal indications is limited and further research is necessary.

11.9.7 Muscle Relaxants

Muscle relaxants are used to enable endotracheal intubation, to maintain muscle relaxation during major surgery in body cavities and occasionally to control severe laryngospasm. Their use has been a major enabling factor in the development of many surgical techniques.

Knowledge of neonatal responses to muscle relaxants is necessary for their effective use in this age group [30]. Acetylcholine receptors (AChRs) cluster to form primitive motor-end plates on muscle fibres from 9 to16 weeks post conceptual age (PCA). The number of nerve terminals is reduced during the second trimester. The neuromuscular junction (NMJ) then matures and continues to grow for the first year of life. The high extracellular fluid (ECF) volume in neonates increases in the volume of distribution for muscle relaxants.

Succinylcholine (suxamethonium) is the only depolarizing neuromuscular blocking agent in clinical use. The rapid onset and short duration of action are unique and desirable features, particularly for emergency cases. Elimination depends on hydrolysis by plasma cholinesterase. Infants require 2–3 mg/kg of succinylcholine to produce reliable conditions for intubation [31]. The increased dose requirement of succinylcholine in younger patients is mainly due to its rapid distribution in the ECF. A deficiency in plasma cholinesterase may result in prolonged neuromuscular block ("sux apnoea") but this is a relatively rare occurrence. Although infants aged less than 6 months have only half the plasma cholinesterase

activity of adults, this does not prolong the effect of succinylcholine.

There is an ongoing debate about the use of succinylcholine. The recent development of sugammadex provides an alternative means of limiting the duration of aminosteroidal nondepolarizing block, albeit currently an expensive one [32].

The clinically available non-depolarizing neuromuscular blocking relaxants (NDR) can be classified into benzylquinolinium or aminosteroidal compounds. Although neonates and infants are more sensitive to NDRs than adults, in terms of requiring a lower plasma concentration to produce a given effect, this is offset by an increased volume of distribution and dose does not vary significantly with age. The increased sensitivity of the neuromuscular junction of the human neonate and infant to NDRs is the result of reduced acetylcholine release from immature motor nerves. Fewer neonatal NMJ receptors need to be occupied to produce block. The effect site compartment concentration of muscle relaxants is less in neonates than older age groups. Different muscle groups have different response curves. The diaphragm requires a greater dose of relaxant to attain a similar degree of relaxation as the adductor pollicis, which is commonly used for monitoring.

11.9.8 Atracurium

Atracurium is a bisquaternary benzylquinolinium diester with an intermediate duration of action. Atracurium is eliminated mainly by Hofmann elimination, a spontaneous fragmentation of the molecule at normal body pH and temperature, which is independent of renal or hepatic function. The ED95 of atracurium was found to be significantly lower in neonates and infants than in children. After 0.5 mg/kg atracurium, 95% depression of twitch occurs more rapidly in neonates than in children (0.9 min vs. 1.4 min), while recovery to 10% of the control twitch height is also more rapid (22.7 vs. 28.6 min). The predictable recovery and lack of accumulation with repeat doses or an infusion of atracurium has made this drug the standard NDR in our neonatal practice over the last two decades.

11.9.9 Vecuronium and Rocuronium

These drugs are popular in situations of cardiovascular instability, due to their virtual absence of side effects. There is also likely to be renewed interest in these agents because their neuromuscular block effects can be rapidly reversed by Sugammadex, even from profound levels of block.

Vecuronium is a monoquaternary aminosteroid relaxant. The ED95 of vecuronium is significantly lower, and the duration of action considerably longer, in neonates than in children aged 3–10 years.

Rocuronium is an analogue of vecuronium with a more rapid onset of action. The ED95 of rocuronium is also lower, and the duration of action longer, in infants than in children. Clinically relevant doses of rocuronium produce a negligible increase in heart rate, with no change in arterial blood pressure.

Other NDMRs have been used in infants, including mivacurium and rapacuronium, but we have no experience of these drugs in our hospital.

11.10 Reversal Agents

Spontaneous recovery from neuromuscular block (NMB) is gradual and shows considerable variation between individuals. The exact time course for onset, duration and recovery in an individual patient is unpredictable and can only be measured by monitoring the clinical response. Residual degrees of block, despite apparent clinical recovery in diaphragm function, can be associated with morbidity, for example upper airway obstruction or aspiration pneumonitis. Atracurium has the most predictable offset of the available NDRs in neonates.

11.10.1 Neostigmine

Neostigmine has been the standard “reversal” agent for non-depolarizing muscle relaxants

for decades. It acts by inhibiting acetylcholinesterase at two binding sites. Acetylcholine levels remain elevated until neostigmine is hydrolysed. However, it has side effects at muscarinic ACh receptors, including bradycardia, hypotension, bronchospasm, increased salivation and gastrointestinal smooth muscle contraction. An anti-muscurinic drug, either atropine or glycopyrrolate, is given with neostigmine to counteract the muscarinic side effects. These drugs also have side effects, such as tachycardia and dry mouth, and "balancing" the muscarinic and anti-muscurinic effects can prove difficult.

Infants show a more rapid recovery from NMB than older children and adolescents when given standard neostigmine doses and there is evidence that lower doses in mg/kg terms are needed to reverse similar degrees of block [33].

11.10.2 Sugammadex

Sugammadex is a relatively new drug, with a "doughnut" shaped molecular structure. It encapsulates molecules of the aminosteroid relaxants, rocuronium and vecuronium, inactivating them. Sugammadex, 2 mg/kg, was sufficient to inactivate a moderate degree of rocuronium induced NMJ block in children [34]. Furthermore, the rate of recovery was rapid, with a narrow range of variation (1.2 ± 0.3 min). This is considerably faster than neostigmine and without any significant side effects. Higher doses of sugammadex (up to 16 mg/kg) can be used to reverse more profound degrees of block. One implication of this is that a rapidly induced neuromuscular block with a large dose of rocuronium can be reversed within a similar time period to the offset of suxamethonium in emergency situations. However, there are a few caveats restricting the current use of sugammadex. There is limited reported clinical experience in the neonatal age group. It is expensive and only inactivates rocuronium and vecuronium. However, the advantages of this drug are such that it is likely to become widely used for aminosteroid NMR reversal unless some unsuspected adverse effect is discovered.

11.11 Opioids and Other Analgesics

The control of pain is a crucial aspect of neonatal anaesthesia and post-operative care [35]. The studies of Anand and colleagues in the late 1980s emphasized the role of effective analgesia on the outcome of major neonatal surgery [36–39]. Opioids have been studied in a number of neonatal settings, ranging from analgesia in post-operative babies breathing spontaneously to procedural pain relief in babies with varying levels of respiratory support in neonatal intensive care units. There is still no consensus on optimal "multimodal" analgesic & sedation regimens, particularly in the neonatal ICU [40].

The main opioids used in our practice are fentanyl, morphine and remifentanil. In recent years, the unique properties of remifentanil have had a major impact on the intraoperative analgesic management of the neonatal surgical population.

11.11.1 Morphine

Morphine is widely used for post-operative analgesia and intensive care sedation. The onset of action in the central nervous system is approximately 5 min, with peak effect at 15 min. The clearance of morphine and its metabolites is prolonged in neonates, the half-life being longest in the preterm infants (9.0 ± 3.4 h) reducing to 6.5 ± 2.8 h at term and 2.0 ± 1.8 h beyond 11 days PNA [37]. The volume of distribution appears to be reasonably constant over early life. Morphine is frequently delivered by a loading dose, followed by an infusion and boluses in a nurse controlled analgesia (NCA) regimen (Table 11.3).

Table 11.3 Intravenous morphine infusion in neonates for postoperative pain relief

Programme	Background	Bolus	Lockout
NCA	0.5 mL/h	0.5 mL	60 min

Dose and programme information
Weight (kg) × 0.2 mg morphine made up to 20 mL in normal saline 10 μg/kg/mL
NCA nurse controlled analgesia
From Acute Pain management guidelines, Alder Hey Children's Hospital

There is considerable inter-individual and intra-individual variation over time in dose requirements during the neonatal period. Consequently, morphine dose guidelines need to be adjusted to account for post conceptual and postnatal age. The pharmacodynamic study of the effects and side effects of morphine and other opioids is difficult in neonates. There seems to be wide range of blood concentrations associated with therapeutic effect, particularly in ventilated pre-term neonates. The effectiveness of morphine in controlling the response to invasive procedures such as endotracheal tube suctioning in ventilated neonates has been questioned [38].

11.11.2 Fentanyl

Fentanyl is a very potent synthetic μ-opioid with high lipid solubility and a more rapid onset of action than morphine. It became popular for the intra-operative management of infants undergoing major surgery, including cardiac surgery, in the 1980s [41, 42]. It is associated with cardiovascular stability and enables the co-administration of lower concentrations of intra-operative volatile or intravenous agent. Fentanyl has also been used for analgesia and sedation in ventilated neonates [43, 44]. Tolerance and withdrawal phenomena both seem to occur within a week, in common with other opioids. However, the dose of fentanyl required for stable intraoperative haemodynamics, control of pulmonary hypertension and blunting of the stress response (≥10 μg/kg) causes profound respiratory depression and will commit the infant to period of post-operative ventilation. In some cases, ventilation is required for non-pharmacological reasons but in other cases can be avoided by the use of alternatives such as remifentanil.

11.11.3 Remifentanil

Remifentanil is a very potent ultra-short acting μ-opioid. It was introduced into clinical practice in 1996, although it only became available in most paediatric institutions somewhat later. It is hydrolysed by non-specific plasma and tissue esterases and its elimination is effectively independent of hepatic and renal function. Esterase function appears to be mature at birth and allometry alone is sufficient to model remifentanil PKs across the paediatric age range [45]. Although remifentanil is not licenced for neonates, many anaesthetists have adopted it as the opioid of choice for intra-operative use in this group [46]. Neonates, including premature babies, tolerate a bolus dose of 1 μg/kg, followed by an infusion in the range 0.1—0.25 μg/kg/min. Higher infusion rates have also been reported. To some extent, the dose rate depends on the doses of other anaesthetic agents used simultaneously, for example sevoflurane, nitrous oxide or propofol [47, 48]. We use a dilution of 10 μg/mL attached to a dedicated line to give remifentanil. The line must be flushed prior to extubation to avoid subsequent inadvertent administration.

Remifentanil has had a major impact on our approach to neonatal anaesthesia in recent years, allowing greater flexibility in timing of regional block procedures and more babies to be extubated at the end of surgery or earlier in intensive care. However, no large scale randomized controlled trials comparing remifentanil-based anaesthetic techniques with other opioid regimens have been done in the neonatal surgical population. There are some smaller trials in babies undergoing procedures in neonatal intensive care, where the rapid dose adjustment and recovery characteristics of remifentanil are very attractive [49, 50].

Other opioids such as sufentanil and alfentanil are also available in some hospitals.

11.11.4 Codeine and Tramadol

Codeine and tramadol are used for mild to moderate pain in children. Codeine is an opioid with a lower affinity for μ-receptors than morphine. It is partially metabolized to morphine by the CYP2D6 enzyme, which is subject to polymorphisms [51]. The maturation of this enzyme is important to the analgesic effect of codeine [52].

In older patients, the analgesic effectiveness of codeine is enhanced by co-administration of paracetamol. The very limited data on neonatal codeine pharmacodynamics and kinetics, together with the unpredictable metabolism of codeine to morphine, suggests that it has little place in neonates.

Tramadol is a synthetic phenyl-piperidine analog of codeine and is a racemic mixture of two enantiomers. The M1 metabolite has a higher affinity for opioid receptors and a longer duration of action. The developmental pharmacology of this drug is complex. M1 formation develops more rapidly with age due to liver enzyme maturation than does GFR dependent elimination in the kidney [53]. A recent trial of tramadol versus fentanyl for near term neonates undergoing gastro-intestinal surgery showed similar postoperative efficacy for both drugs with no specific advantage for tramadol over fentanyl in terms of time to extubation or establishment of feeds [54]. Further research is needed to establish the analgesic role of tramadol in the neonatal population.

11.11.5 Paracetamol

Paracetamol is a mainstay for treatment of mild to moderate pain and has been extensively studied in neonates. Most studies have focused on the pharmacokinetic, rather than pharmacodynamic aspects of paracetamol treatment. An intravenous preparation is now available which enables more extensive peri-operative use. It is currently not recommended for babies with a postconceptual age (PCA) of <32 weeks [55]. The recommended dose is 10 mg/kg 6 hourly between 32 and 44 weeks PCA [56]. An alternative 'Stockholm protocol' is 7.5 mg/kg 6 hourly between 33 and 36 weeks and 7.5 mg/kg 8 hourly between 28 and 32 weeks PCA [57]. Pain services in most institutions have published guidelines based on these studies. It is crucially important to avoid dosing errors with intravenous paracetamol because of the risk of liver damage from overdose. The main risks are double dosing (between wards and theatres) and ten times errors.

11.11.6 Non-Steroidal Anti-Inflammatory Agents (NSAIDS)

These drugs are widely used in paediatric surgery as part of multi-modal analgesic regimens, particularly for "day case" ambulatory patients. The commonly used agents are Ibuprofen and Diclofenac, the latter being available as a suppository as well as an oral preparation. Currently, NSAIDS are not recommended for babies under 3 months of age, not least due to a potential impact on glomerular filtration rate [35].

11.11.7 Local Anaesthetics

The local anaesthetics (LAs) currently in use are all amino amides. These agents are extensively bound to plasma proteins, including alpha-1 acid glycoprotein (AAG) and albumin. Neonatal AAG levels are low, reaching adult levels by 1 year [58]. Clearance of LAs is lower in neonates, maturing between 3 and 8 months [59]. The potential for local anaesthetic toxicity is higher in neonates than older children. Great care is needed in the handling of these drugs around small babies. We recommend drawing up the correct dose of the local anaesthetic just prior to use and immediately discarding any surplus.

The longer acting local anaesthetics, bupivacaine, levobupivacaine and ropivacaine, are used for most regional and neuraxial blocks in children. Bupivacaine is a racemic mixture. The S-enantiomer, levobupivacaine, is mainly used now because it is less toxic to the heart. However, the maximum recommended dose is 2 mg/kg, the same as bupivacaine, with a maximum infusion rate of 0.2 mg/kg/h. The onset of action of these agents is slower than lidocaine. The optimum concentration depends on the indication and site. Most "single shot" injections are given as 0.25% and infusions as 0.1–0.125% solutions. 0.5% bupivacaine, levobupivacaine or rocuronium is used for spinal anaesthesia, in a dose of 1 mg/kg [60]. There is scope for further investigation of the volume and concentration the local anaesthetic for various neonatal blocks in relation to

the effectiveness and duration of analgesia [61]. Infusions are usually stopped by 48 h to avoid excessive accumulation. A number of adjunct agents have been combined with local anaesthetics to either reduce absorption or augment and prolong the effect. These include adrenaline, clonidine, ketamine and opioids. However, there is concern about the potential neurotoxocity of such mixtures and these adjunct drugs are not licenced for spinal or epidural use in the neonatal population.

11.11.8 Topical Local Analgesia

Various topical preparations of local anaesthetics are available for application to skin. The most extensively studied are the "eutectic mixture" cream of lidocaine and prilocaine (EMLA) and tetracaine (Ametop) [62]. Their status in neonates is uncertain due to absence of a licence in this age group and a limited number of studies. However, the balance of risk favours their use, providing care is taken with dose. For example, a small dose application to the area over the sacrococcygeal membrane is useful for "awake" caudal blocks. There is a risk of methaemoglobinaemia if excessive prilocaine is absorbed in small prematures. Oral sucrose (25%) also has an impact on pain responses and has been compared with topical local anaesthetic creams [63].

Lidocaine can be applied to mucosal surfaces in spray or nebulized format for airway endoscopies and is safe provided accurate doses are applied. Local infiltration of either lidocaine or longer acting agents is somewhat under-utilised for other "minor" procedures, such as line, drain or catheter insertion.

11.12 Regional Analgesia Techniques

Several studies have shown that regional anaesthetic techniques provide good intra-operative conditions and post-operative pain relief in neonatal patients but other outcomes, such as PICU and hospital stays, morbidity or resumption of bowel function have been less studied [64]. Epidural analgesia attenuates the neuroendocrine stress response after major abdominal surgery in infants to a greater degree than systemic morphine [65].

Two national prospective audits in French speaking countries [66, 67] and one in the UK [68] show that regional anaesthetic techniques have a reasonably good safety record in neonatal patients.

Some adverse incidents in the original French study were associated with suboptimal equipment. Suitable regional anaesthesia equipment for infants is now widely available. The recent French study [67] shows a sixfold higher complication rate for central blocks, compared with peripheral blocks, in the whole paediatric population. In the neonatal subgroups, the majority of the blocks were caudals, lumbar epidurals, infraorbital, ilioinguinal and rectus sheath blocks. Other blocks, such as thoracic epidurals, sciatic or brachial plexus were rarely performed. When reporting complication rates or estimating risks, the denominator for individual blocks is important. The "risk-benefit" profile for paravertebral or transabdominis plane blocks remains to be established.

Ultrasound (US) is an important aid in regional anaesthesia. Improvements in technology have enabled high-resolution US images of nerves and surrounding structures which can be helpful in performing neuraxial blocks in neonates, whose spines are still ossifying (Fig. 11.1).

The anatomy of the spinal column and epidural space can be viewed prior to performing an epidural. Needles can be inserted in to the epidural space under real time imaging or using a trajectory estimated from imaging. The insertion of catheters and the distribution of fluid injectate can also be visualized by ultrasound during general anaesthesia (Fig. 11.2). However, such techniques require considerable resources and expertise. There is a recent pro-con debate about the place of regional vs systemic analgesia for neonatal surgery published in the journal, Pediatric Anesthesia [69]. The choice of technique currently depends as much on the available facilities, the expertise of the individual anaesthetist and the institutional culture as on clear-cut evidence of the major outcome benefits of any particular technique. Furthermore, the advent of

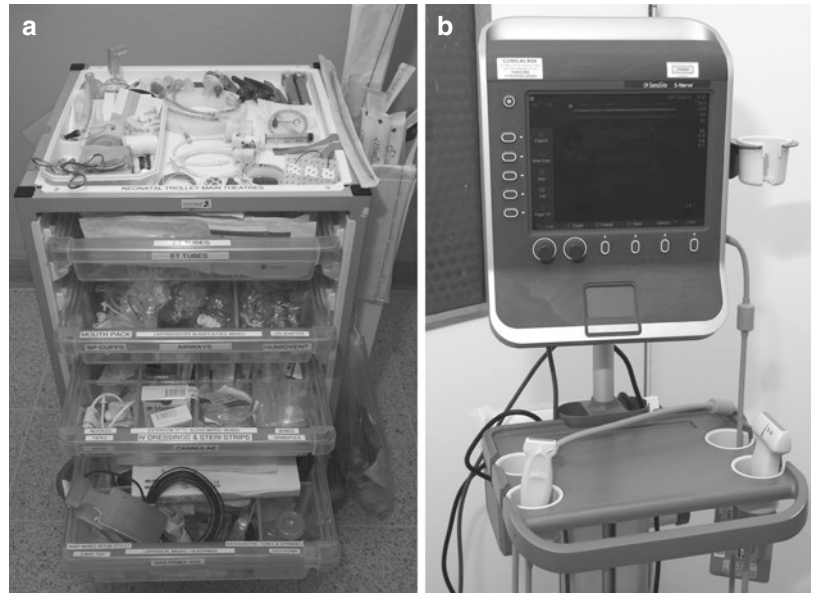

Fig. 11.1 *Left*—neonatal anaesthetic equipment cart which can be wheeled to the operating table at the time of induction. *Right*—the Sonosite "S Nerve" ultrasound device

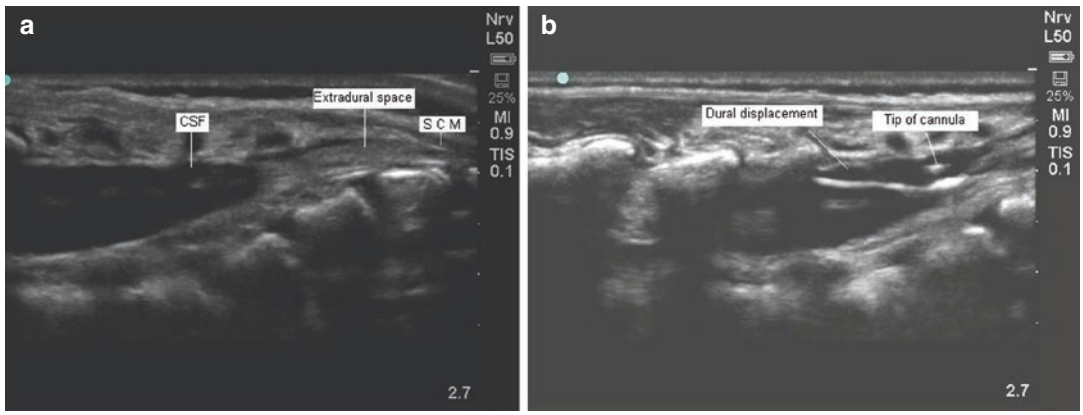

Fig. 11.2 Caudal space ultrasound images in a term neonate. Top image (**a**) shows the dural sac terminating at L4. *CSF* cerebrospinal fluid; *SCM* sacro-coccygeal membrane. Bottom image (**b**) shows the tip of a cannula inserted into the caudal extradural space through the SCM. The start of a bolus injection of local anaesthetic displaces the dura anteriorly. Images obtained from the Sonosite S-Nerve machine. Depth of field = 2.7 cm

remifentanil and ultrasound guided blocks such as the paravertebral and transabdominis plane (TAP) blocks has increased the range of options for both intra-operative and post-operative management.

11.12.1 Caudal Blockade

The long established "single shot" caudal block is well suited to the neonate [70]. It is now possible to visualise the injection and spread of local anaesthetics in the caudal space with ultrasound imaging (Fig. 11.2) [71]. The block can be used for almost all surgical interventions below the level of the umbilicus, most commonly inguinal hernia repair. The "awake" caudal technique is a useful alternative to general or spinal anaesthesia in premature infants [72]. A recent comparison between spinal and caudal anaesthesia was reported in 575 preterm amd ex-preterm infants undergoing herniotomy. There was a higher overall success rate in

the caudal group, with fewer babies needing additional sedation or conversion to general anaesthesia and fewer attempts at caudal compared with spinal puncture [73].

11.12.2 Epidural Catheters Inserted Via the Caudal Route

Epidural catheters can be threaded to the appropriate segmental level via a caudal cannula inserted through the sacral hiatus, a technique described in a large case series by Busoni [70]. However, the position of the catheter had to be either estimated or identified by X-ray, with contrast. The use of ultrasound to visualize the catheter position was first reported by Chawathe [74], where a radiologist scanned the study patients during first 24 h. The use of portable ultrasound by the anaesthetist to assess the catheter position in the operating theatre has since been described [75].

11.12.3 Epidural Blockade

Bösenberg and colleagues originally showed a reduction in the post-operative ventilation rate for babies undergoing tracheo-oesophageal fistula repair by using epidural analgesia [76]. Similar results are achievable for major abdominal surgery. Epidural analgesia may also be associated with earlier resumption of peristalsis in small babies, although the evidence for this is limited at present [77]. The tip of the epidural catheter needs to lie at the appropriate dermatomal level for the surgery. This can be achieved by direct epidural puncture or threading the catheter up from the caudal or lumbar regions.

The neonatal subgroup in a large prospective safety of 10,000 epidural blocks [68] had 6 complications in 529 epidural blocks, significantly higher than in the older age groups. However, most complications were due to drug errors or systemic toxicity and none were due to catheter insertion. There are sporadic reports of serious complications elsewhere, leading to continuing debate about safety of the technique [69].

Recently, Willschke et al. have described an ultrasound-guided approach to epidural blockade in neonates and infants [78].

11.12.4 Transversus Abdominis Plane Block

The transversus abdominis plane (TAP) block has been recently described and offers an alternative to epidural block, at least in the early post–operative period [79]. There are small case series of TAP blocks for lower abdominal operations and stoma formation in neonates [80, 81]. A single injection can provide effective blockade of the thoracolumbar spinal nerves innervating the abdominal wall. The needle-tip position and injection should be monitored by real time ultrasound in neonates because of the proximity of intra-abdominal organs to the injection site (Fig. 11.3). The duration of action of the TAP block is an open question and more studies are needed to establish its place in neonatal anaesthesia. There is some preliminary evidence that this block in neonates may considerably reduce post-operative analgesia doses [82].

11.12.5 Rectus Sheath Block

Rectus sheath block (RSB) is a simple procedure that can be performed using either a landmark technique or under ultrasound guidance [83]. 25 G styletted neonatal spinal needles are useful for this block because the resistance of the anterior and posterior rectus fascia is easily felt. Bilateral blocks can be used for peri-umbilical incisions, such as those used for laparoscopy, pyloric stenosis or primary closure of gastroschisis. Unilateral RSB can also be used for other procedures where the rectus muscle is incised, such as ventriculo-peritoneal shunt insertion or gastrostomy.

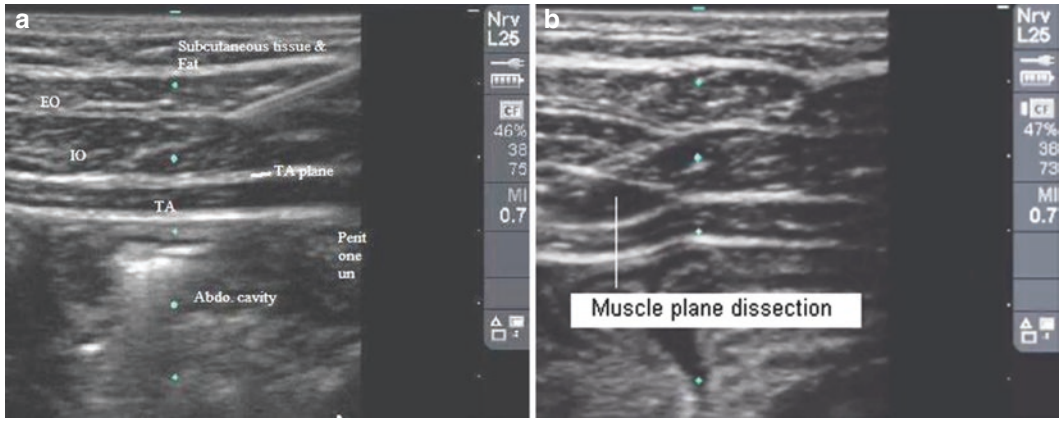

Fig. 11.3 Transversus abdominis (TA) plane anatomy and block in a term neonate. Top image (**a**) shows the layers of the left lateral abdominal wall at umbilical level. Left side of the image is lateral. Needle seen approaching the TA plane. *EO* external oblique; *IO* internal oblique; *TA* transversus abdominis. Bottom image (**b**) shows local anaesthetic being injected into the TA plane, causing plane "dissection"

11.12.6 Ilio-Inguinal Block

This technique is widely used to provide analgesia for pediatric inguinal hernia repair under general anaesthesia. The accuracy of needle placement is improved by ultrasound (US) guidance [84], particularly in the thin abdominal wall muscle layers of the neonatal population. The ilio-inguinal and ilio-hypogastric nerves are usually easily visualized between internal oblique and tansversus abdominis near the iliac crest, where the muscles thicken. A medial to lateral "in plane" needle direction, using US guidance, reduces the risk of peritoneal puncture.

11.12.7 Spinals

Premature infants are at risk of postoperative apnoeic and desaturation episodes up to 60 weeks PCA [85]. Recent concerns about the potential for general anaesthetic neurotoxicity in neonatal animals and the increasing survival rates in extremely premature babies with bronchopulmonary dysplasia have provoked a renewed interest in unsupplemented ("awake") spinal anaesthesia. Although spinal anaesthesia for inguinal hernia repair reduces the risk of post-operative apnoea in comparison with general anaesthesia, there is debate over the magnitude and significance of this effect. A Cochrane meta-analysis of the 4 available RCTs in 2003 [86] did not demonstrate a major advantage but some patients had additional sedation in the spinal group and the numbers were relatively small (108 infants). This report and the evidence that newer volatile anaesthetic agents, sevoflurane and desflurane, are associated with a lower rate of post-operative apnoea than that previously reported for halothane [87, 88] influenced many anaesthetists to continue with general anaesthesia for this group.

The success rate of spinal block was 97.4% in 1554 infants treated over three decades in the Vermont Infant Spinal registry [89]. However, failure rates are higher in less experienced hands and this technique has a significant "learning curve", with higher failure rates described in smaller series [90, 91]. An alternative approach is to use "awake" caudal blocks.

Spinal blocks have shorter durations of action in neonates in comparison to older children and adults. This is due to a larger cerebrospinal fluid volume and turnover rate. Using a variety of spinal local anaesthetic agent formulations, various studies have reported durations of action between 46 and 128 min. The most comprehensive information comes from Frawley and colleagues, who

report durations between 85 and 87.5 min for 1 mg/kg of Ropivacaine and Levobupivacaine respectively [60, 85].

Complications during infant spinal anaesthesia are rare. Intravascular injection was the only reported complication in the 506 spinal anaesthetics considered in the French language study of paediatric regional anaesthesia [66]. Spinal anaesthesia has a sedative effect on most infants. This seems to be related to the reduction in afferent signals to the reticular activating system [92].

The dermatomal spread of hyperbaric local anaesthetics depends on the position of infants. Inadvertently high blocks have been reported but not epidural haematoma formation. Easley and Tobias reported aseptic meningitis in an infant after spinal anaesthesia [93].

11.12.8 Paravertebral Block (PVB)

The paravertebral space (PVS) is situated in the angle between the transverse process and the vertebral body and runs craniocaudally alongside the entire length of the vertebral column. In the thoracic region, adjacent levels of the PVS communicate with each other, but at the lumbar level, individual segments are separated by the origins of the psoas muscle [94].

PVB has been used in children since 1992, when two different techniques were described. Lönnqvist used a percutaneous catheter technique [95] and Sabanathan placed a catheter surgically during thoracotomy [96]. In children, the main indication for PVB is unilateral thoracic and abdominal surgery. However, placement of two paravertebral catheters during bilateral thoracotomy or sternotomy has also been described.

Ultrasound can used to locate the transverse process and the parietal pleura. Neonates need accurate placement of the needle into the smaller paravertebral space. Experience with this block continues to grow [97].

Most paediatric studies are extended case series, limiting formal comparison with other analgesic techniques [98, 99]. In children, it has been shown that PVB can produce extended postoperative analgesia lasting >12 h, exceeding the expected duration of the local anaesthetic. PVB may also produce pre-emptive analgesia [100].

Paravertebral block should be avoided in sepsis and empyema and used with caution in babies with coagulopathy.

11.13 Vascular Access

Peripheral venous access is the mainstay for the delivery of fluids and drugs to babies [101]. The saphenous veins at the ankle and scalp veins are particularly reliable for volume transfusion. “Long lines” (peripherally inserted central venous catheters) can be inserted into the SVC from forearm, antecubital or scalp veins, taking care to position the tip above the pericardial reflection [102]. The Vygon 22 G 20 cm lines are particularly useful because the guidewire can be passed through a 24 G cannula. In chubby infants, veins can be visualized with a small ultrasound probe.

Central venous access is important in many infants undergoing major surgery. The need for this depends on a number of factors, including the adequacy of peripheral access, the anticipated need for parenteral nutrition, the urgency of surgery and the estimated risks and benefits. For example we would place a central line in a baby with gastroschisis for TPN. SVC pressure and oxygen saturation measurements help to judge if the baby will tolerate primary closure. However, we rarely place a central line during tracheo-oesophageal fistula repair, provided adequate peripheral access has been obtained.

The options for central lines include percutaneous insertion in the internal jugular (IJV), subclavian or femoral vein, tunnelled surgical placement of a “Broviac” type line or a percutaneous PICC line. Ultrasound imaging is invaluable for vein location and needle guidance during percutaneous techniques. There are a large number of potential complications associated with central lines, some of which can be fatal.

Arterial access is valuable for continuous blood pressure monitoring and blood gas sampling. Continuous blood gas electrodes are also available but are not in widespread use. However, there are risks attached to the use of arterial lines, including limb ischaemia, flush emboli, inadvertent arterial drug administration and insertion time. Cold light transillumination devices and small ultrasound probes help the accurate location of neonatal arteries.

11.13.1 Pre-Operative Assessment and Preparation

Neonatal anaesthesia is often required under circumstances of considerable urgency. Furthermore, babies with acute conditions are often transferred from district hospitals or specialist neonatal units to the neonatal surgical centre. Many regional neonatal surgical centres are not co-located with maternity units or their associated neonatal ICUs. Good communication between teams is vital.

Surgery is rarely so urgent to preclude the adequate anaesthetic assessment of a baby. The maternal and perinatal history should be reviewed and the baby examined. Relevant maternal information includes the drug history, any pregnancy related illnesses such as pre-eclampsia or diabetes and chronic maternal illness. The birth history should include the mode of delivery, APGAR scores, any resuscitation or birth trauma, medications, feeds and fluids administered. The baby's vital signs, hydration state and breathing pattern should be observed. The airway and cardiorespiratory system should be assessed. Radiographs, echocardiograms, fluid therapy and current medication should be reviewed. Many babies will come from another hospital with a detailed referral letter but sometimes a telephone conversation with the relevant neonatologist will also be required.

The surgeon and anaesthetist should discuss the proposed surgery, any further consultations, investigations, and the availability of blood products. A cardiac assessment will be needed in neonatal conditions associated with congenital heart disease or babies showing signs of cardiac failure, unexplained hypoxaemia, murmurs, abnormal pulses or chest X-ray abnormalities. A plan for post-operative care should be discussed and the parents interviewed and given the opportunity to ask questions and discuss concerns. In many instances, discussions with family members will occur on several occasions, taking into account factors such as instrumental delivery, transfer between hospitals, tiredness and emotional turmoil.

11.13.2 Intra-Operative Management

11.13.2.1 Induction of Anaesthesia

Anaesthesia is generally induced in the operating theatre. It is important to assemble and check the appropriate equipment, drugs and fluids for an individual baby before inducing anaesthesia (Table 11.4) (Fig. 11.4). Some babies will be transferred to the theatre from an intensive care unit, already intubated and ventilated.

Induction of anaesthesia can be done by inhalation of a volatile agent, typically sevofurane, or intravenous injection. The intravenous options are

Table 11.4 Checks before anaesthetising a neonate

• Pre-operative huddle with surgeon and theatre team (WHO guidelines)
• Warm theatre environment and elimination of distractions
• Anaesthetic equipment checked and appropriate for the particular patient
• Labelled drugs drawn at required dosage for the particular patient
• Meticulous care during preparation of IV infusion drips, avoiding air entrainment
• Blood and blood products in close proximity if required for the given surgery
• Non-invasive monitoring in place before induction of the patient
• Spatial awareness about the position of monitors and venous access on the patient
• Provision of anaesthetic care by single team if possible
• Post-operative care plan discussed, including ICU bed if necessary

Fig. 11.4 Top surface of a neonatal cart—equipment prepared for a term baby

propofol, thiopentone, ketamine or midazolam, sometimes in combination with an opioid.

11.13.2.2 Intubation

Experienced neonatal anaesthetists typically undertake intubation after the induction of anaesthesia and the administration of a muscle relaxant [103]. Neonatologists typically use a variety of sedative agents, without relaxants, or awake intubation. In the vast majority of cases, a standard neonatal laryngoscope and careful head positioning are used for intubation.

The size, type and fixation of the endotracheal tube are critical. A variety of tubes are available. They are labeled by the internal diameter in mm but the external diameter can vary, depending on the material and manufacturer. The size range of tubes manufactured is illogical because the increments are in the diameter rather than the cross sectional area. However, if departments keep a range of tubes from different manufacturers, small increments in external diameter are possible.

Although formulae exist for the size and length of tube for different ages, there are significant variations in the diameter and length of the trachea. Experienced anaesthetists "custom" fit a tube with a small leak at 12–15 cm lung inflation pressure.

Recently, paediatric tubes with microcuffs have become available, which allow control of the leak in situations of changing compliance. The jury is still out on the pros and cons of cuffed versus uncuffed tubes [104]. Glottic and subglottic damage still occurs from endotracheal tube placement in neonates. The placement of an excessively large tube, which causes ischaemic damage of the laryngeal and subglottic mucosa, is usually responsible. This may result in post-extubation glottic and suglottic oedema, granulations, cyst formation and fibrosis. The subsequent onset of inspiratory stridor and intercostal recession typically occurs when half of more of the subglottic orifice has been lost. Holzki and colleagues recently published a unique long-term study of this problem [105]. Dexamethasone is a valuable treatment for early extubation stridor and can be considered prophylactically for patients who have been intubated long term, for example preterm infants.

A different approach may be necessary in some circumstances. "Difficult intubation" refers to the situation where the laryngeal inlet cannot be visualized using a traditional laryngoscope [106]. Most of these cases are predictable from the pre-operative assessment, for example babies with micrognathic syndromes such as Treacher-Collins, Goldenhar, or the Pierre Robin sequence. Other rare conditions include congenital fusion of the jaws, laryngeal atresia and various masses that impinge on the airway, e.g. cystic hygromas.

There are also situations where the larynx is easily visualized by conventional laryngoscopy but anatomical abnormalities below the larynx can impede the passage of a tube, for example congenital or acquired subglottic stenosis and long segment distal tracheal stenosis (funnel trachea).

Various techniques are available. It is wise to preserve the baby's spontaneous respiration, where possible, until the airway has been visualized and secured. A nasopharyngeal airway can be valuable during the gaseous induction of a micrognathic infant with a volatile agent, typically Sevoflurane. A size 1 Laryngeal mask airway (LMA) can be placed in most cases and is a useful conduit for a fibre-optic bronchoscope (FOB). Gas exchange and anaesthesia can be maintained through the LMA during attempts to intubate, which can either be done by loading a tube over a 2.2 mm FOB or by passing a guidewire into the trachea through a larger FOB with a suction channel placed just above the laryngeal

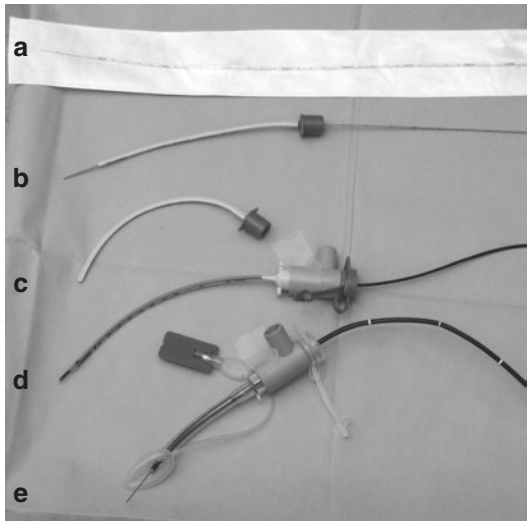

Fig. 11.5 Difficult intubation equipment. (**a**) Tube exchange catheter; (**b**) 2.0 mm internal diameter ETT and bougie; (**c**) 3.0 mm internal diameter endotracheal tube (ETT); (**d**) 2.2 Fiber-optic bronchoscope with connector port and ETT; (**e**) 3.6 Fiber-optic bronchoscope with guide-wire through suction channel and size 1 laryngeal mask airway

inlet. A tube exchange catheter is then threaded over the guidewire after withdrawing the FOB. A tube can then be inserted over the exchange catheter following removal of the LMA. Figure 11.5 shows some of the available equipment. Other devices are available for difficult intubation in some institutions, such the Bonfils and Brambrink video laryngoscopes.

11.13.2.3 The Role of Rapid Sequence Induction

Rapid sequence induction (RSI) is used in older children and adults to reduce the risk of aspiration of gastric contents into the lungs in the emergency situation, with a potentially full stomach. The main elements of this technique are pre-oxygenation using 100% oxygen via a facemask prior to intravenous induction, the use of a rapid onset muscle relaxant, cricoid pressure delivered by an assistant and intubation without mask ventilation of the lungs.

This technique is less practical in small infants and neonates. Pre-oxygenation is less effective due to their high metabolic rate and low functional residual lung volume. Babies may also struggle and it can be difficult to apply effective cricoid pressure without distorting the trachea, which can lead to difficulties in intubation. An alternative is to empty the stomach via a nasogastric tube, careful gaseous induction with sevoflurane and 100% oxygen and gentle mask ventilation after administration of a non depolarizing relaxant, with or without carefully applied cricoid pressure [107].

11.13.2.4 Maintenance of Anaesthesia and Analgesia

This is usually achieved by a combination of a volatile agent and either an opioid or regional block technique. The availability of the short-acting agents desflurane and remifentanil have enabled rapidly titrated anaesthesia and the prospect of rapid recovery after intense intra-operative analgesia. The intra-operative use of remifentanil also allows the option of performing blocks at the end of surgery, rather than at the beginning. This approach may be useful when the extent of surgery is unpredictable or needs to be expedited when the bowel is compromised or there is stomach or airspace distension.

If a baby is very small or has poor lung compliance and a neonatal ventilator is used intra-operatively, some form of total intravenous anaesthesia may be required. Otherwise, maintenance is usually continued with a volatile agent, combined with an opioid or regional blockade.

11.13.2.5 Ventilation

There are a number of options for ventilating the lungs of neonates during surgery [108, 109]. The traditional method is hand ventilation using a T piece [5], which is generally still used during induction and intubation. There are also advantages to hand ventilation during thoracic surgery, where changes in compliance or kinking of large airways during lung retraction can be rapidly appreciated. There may be more subtle advantages to hand ventilation, including maintaining close contact with the patient and inevitably providing “biologically variable ventilation”, which may have a role in preventing atelectasis [110, 111]. This fascinating topic awaits further investigation in the neonatal population.

Fig. 11.6 Surgery on 720 g preterm baby ventilated with Dräger Babylog 800 neonatal ventilator

Mechanical ventilation, using a neonatal ventilator or an oscillator, can offer advantages to the patient in some conditions. The lungs are particularly susceptible to overdistension and ventilator induced lung injury during CDH repair or surgery on premature babies with RDS or other forms of acute lung injury (Fig. 11.6). Lung protective ventilation methods, with limited tidal volumes and permissive hypercapnia may be beneficial to such babies.

The third option is ventilation using a modern circle system and anaesthetic ventilator but this option is questionable in small prematures or infants with poor compliance. It is wise to have a T piece available at all stages of neonatal anaesthesia, irrespective of the form of ventilation selected.

11.13.2.6 Temperature

Neonates are vulnerable to hypothermia, which is associated with diverse adverse peri-operative outcomes, including delayed recovery, increased infection risk, increased blood loss and impaired peripheral perfusion [112]. In most circumstances, active measures are necessary to maintain near normothermia. General measures to minimize heat losses include raising the air temperature while a baby is exposed, minimizing the time out of an incubator, warming fluids and humidifying inspired gases. The availability of infant forced air-warming devices has had a major impact on our practice [113]. Temperature monitoring is mandatory, usually by an oesphageal probe, which is carefully placed into the mid-oesophagus. Rapid changes of temperature can occur when body cavities are closed and vigilance is necessary to avoid overheating.

Occasionally, babies who are being treated with theraputic hypothermia for a brain injury after asphyxia or a cardiorespiratory arrest appear for surgery.

11.13.2.7 Humidification

Humidification of inspired gases is achieved either by using a heated water bath humidifier in the inspiratory limb of the breathing circuit or the use of a heat and moisture exchange humidifier (HME) attached to the endotracheal tube. The latter can be combined with a bacterial filter but the issue of excessive dead space can become a problem in small babies. The efficiency of various HMEs in the neonatal population is not well evaluated.

11.13.2.8 Fluids and Electrolytes

Fluid and electrolyte therapy has to be judged in the individual surgical neonate, depending on the clinical circumstances [114]. Well infants, undergoing elective surgery, are very different to sick babies with large fluid deficits, capillary leak and ongoing losses. Starvation times for elective cases are 2 h after clear fluids and 4 h after milk.

During surgery, fluid administration can be divided into “maintenance” and “theraputic” infusions. Maintenance fluid refers to sufficient water, electrolytes and glucose to maintain normal intravascular tonicity and glycaemia, whilst avoiding hyper- or hypo- natraemia and glycaemia. This can generally be achieved by an infusion of a dextrose-electrolyte solution from a syringe pump. On occasions, parenteral nutrition will be in progress and the infusion rate may need to be adjusted to avoid hyperglycaemia (see below). The exact composition of the fluid depends on the age and size of the baby. A small, premature newborn undergoing major surgery will often need 10% dextrose in a balanced salt solution given at 3–4 mL/kg/h. Older infants, born near term and undergoing minor

surgery will need less or no glucose. Rather than placing over-reliance on protocol driven fluid regimens, it is important to assess the clinical response to fluid administration and measure electrolytes and glucose values at appropriate intervals.

Theraputic fluid refers to those fluids administered to replace fluid losses, blood loss and to achieve goal directed therapy. The goals may be to compensate for hypotension due to anaesthetic drugs, capillary leak in sepsis and ongoing gastrointestinal losses. The goals may include superior vena caval oxygen saturation $\geq$ 70% in addition to maintaining blood pressure, tissue perfusion and urine flow, although this approach has not been extensively evaluated in infants. A variety of isotonic crystalloids and colloids are used for this purpose. There is little evidence to support any particular crystalloid, colloid or combination. Boluyt [115] recommended normal saline in an evidence-based guideline. However, large volumes of this fluid produce a dose dependent hyperchloraemic acidosis and many anaesthetists believe that there is sufficient evidence from studies in older age groups to use balanced solutions such as Hartmann's solution or Plasmalyte [116]. Colloids include gelatin solutions or 4.5% albumin. More clinical trials are needed in this field.

The authors administer intravascular volume therapy manually by using a burrette, syringe and three-way tap distal to a fluid warmer. This has the advantage that precise fluid volumes can be given at variable rates, in contast to maintenance fluid, where a volumetric pump can be used.

11.13.2.9 Blood Products

A significant proportion of surgical neonates will need peri-operative transfusion of one or more blood products—red cells, platelets, fresh frozen plasma (FFP) and cryoprecipitate [117]. Occasionally, massive transfusion is required during extensive surgery for necrotizing enterocolitis (NEC) or the excision of large tumours, such as sacro-coccygeal teratoma. However, in many other procedures, blood loss is minimal. Blood volume estimates are 80–90 mL/kg in term and 90–100 mL/kg in preterm infants. The haemoglobin (Hb) value of neonates varies considerably, partly depending on local placental transfusion practice. The anaesthetist should consider a transfusion threshold and an allowable blood loss. Guidelines in this area are largely based on expert opinion. Haemoglobin thresholds range from 12 g/dL for acute blood loss in the first 24 hrs postnatally to 7 g/dL for older stable babies who have adapted to lower levels of haemoglobin. Fresh frozen plasma and cryoprecipitate may be required to treat coagulopathy and low fibrinogen levels associated with sepsis or large volume transfusion.

11.13.2.10 Glucose and Nutrition

Good nutrition is vital in the neonatal period [118]. Neonates have high metabolic rates, grow rapidly and have limited nonprotein energy reserves, particularly low birth weight preterm infants. Whenever possible, enteral feeding is preferable and should be interrupted for no more than 4 h prior to surgery and be re-established as soon as possible. Where enteral feeding is delayed or disrupted by abdominal pathology or acute illness, parenteral nutrition, and the means to deliver it, should be established early. During anaesthesia, energy requirements are at the resting energy expenditure (REE) level, in the range of 40–70 kcal/kg/day. Considerable variations have been reported in the REE of term and preterm infants. Allowing for growth in addition to REE, values of 100–120 kcal/kg/day in term surgical babies and 110–160 kcal/kg/day in preterms are described. The stress response of surgical trauma or critical illness appears to have little effect on energy requirements with only a modest increase in the first 24 h after surgery. Pierro and colleagues [118] recommend not exceeding 18g/kg/day glucose in TPN to avoid net fat synthesis and increased CO_2 production. Where babies already established on TPN come to theatre, the infusion rate may need to be reduced to avoid hyperglycaemia or hyponatraemia.

The majority of babies will not be on TPN. A reasonable estimate of the intra-operative glucose requirement is 120–150 mg/kg/h for a term baby. This value is likely to be higher in preterm

and growth retarded infants, infants of diabetic mothers and babies with Beckwith-Wiedemann syndrome. If a neonate requires a higher than expected glucose concentration to maintain normoglycaemia, the possibility of an insulinoma should be considered [119].

11.13.2.11 Monitoring

Basic monitoring should be attached to infants before the induction of anaesthesia. This includes ECG, oxygen saturation and non-invasive blood pressure. Depending on the surgical condition and pathophysiological state of the baby, more invasive minitoring may be established after induction. This might include the insertion of an arterial line or a central venous line, which enable continuous pressure monitoring and sampling of arterial or central venous blood gases. End tidal carbon dioxide (ET-CO_2) monitoring is established at the time of intubation. The difference between the arterial and ET-CO_2 tensions depends on the siting of the ET monitoring tube, which should be as close as possible to the endotracheal tube.

Suitable alarm limits should be set on the anaesthetic machine and monitor screens.

11.13.2.12 Unexpected Events

A large number of untoward intra-operative events are possible and experienced surgical and anaesthetic teams will aim to minimize the risk of their occurrence. This is is promoted by a culture of mutual respect, dialogue, regular audit and critical incident reviews. Clinically, there are common patterns of presentation of intra-operative problems, such as a fall in oxygen saturation, acute changes in lung compliance or airway resistance, hypotension, hypertension, tachycardia or bradycardia. The differential diagnosis is extensive for many of these signs. Relatively common problems are summarized in (Table 11.5). For example, hypotension during a laparotomy may be due to hypovolaemia, haemorrhage, sepsis or anaesthetic drug induced vasodilatation. During a thoracotomy, distortion of the great veins due to retraction is another possible cause for hypotension. Hypertension could be due to inadequate anaesthesia or occasionally an undiagnosed coarctation of the aorta or a renal problem.

Table 11.5 Some possible intra-operative complications in an anaesthetized neonate

A. Respiratory complications
1. Dislodgment or disconnection of the endotracheal tube
2. Endotracheal tube obstruction or kinking
3. Endo-bronchial intubation
4. Pneumothorax or mediastinal air-leak
5. Pulmonary haemorrhage
6. Pulmonary or lobar collapse and atelectasis
7. Restriction of chest by pressure from drapes, retractors or hands
B. Circulatory complications
1. Hypotension
2. Tachycardia or bradycardia
3. Systemic or pulmonary hypertension
4. Venous air embolism
C. Miscellaneous
1. Hypothermia or hyperthermia
2. Low urine output
3. Coagulopathy
4. Failure of anaesthetic or monitoring equipment

11.13.3 Post-Operative Care

Before committing a baby to surgery, the surgical, anaesthetic and neonatal staff should discuss a post-operative care plan. In most instances, the post-operative care location and the timing of extubation will depend on the anaesthetic techniques chosen. Babies will generally be kept intubated and ventilated if they are admitted to a PICU or NICU. The transfer arrangements depend on the local circumstances. Transport is a potentially hazardous process, requiring care and adequate monitoring. The team responsible for the subsequent care of the baby should receive a detailed handover.

Babies deemed suitable for early extubation will usually be cared for in a theatre recovery room. They should be placed in a suitable thermal environment and the have ECG, blood pressure, pulse oximetry and apnoea monitoring

established. Transfer to a neonatal surgical unit should only occur when the anaesthetist and recovery nurse are satisfied that the vital signs are stable, respiration is adequate, and analgesia is satisfactory. Post-operative orders for observation, fluid management, feeding, analgesia, antiemetic drugs and antibiotics should be agreed and completed. It is unwise to prescribe fluids for more than 12–24 h because losses may be unpredictable and the fluid status of infants needs frequent review.

Skilled care by experienced neonatal surgical nurses is very important for a successful outcome [120]. Most institutions also have a specialist pain service to advise upon, audit and troubleshoot regional block and opioid infusions, together with the wider aspects of pain management. However, we would encourage anaesthetists to follow up babies in the post-operative period.

11.14 Specific Conditions

11.14.1 Congenital Diaphragmatic Hernia (CDH)

The majority of CDH cases are now diagnosed antenatally. There is a spectrum of severity, particularly in the degree of lung hypoplasia and the presence or absence of associated cardiac lesions. It is generally accepted that surgery is rarely urgent and steps should be taken to stabilize and optimize the baby's condition on an intensive care unit before undertaking operation. These infants are very susceptible to ventilator induced lung injury. Improvements in survival rates have been related to "gentle" ventilation regimens that limit tidal volumes and peak distending pressures with an acceptance of a degree of permissive hypercapnia [121–123]. High frequency oscillatory ventilation (HFOV) has been used both as a "rescue" technique for infants failing on conventional mechanical ventilation (CMV) and as a primary mode of ventilation [124] (Fig. 11.7). There is a place for ECMO in a small group of infants who have shown evidence of sufficient lung capacity after initial

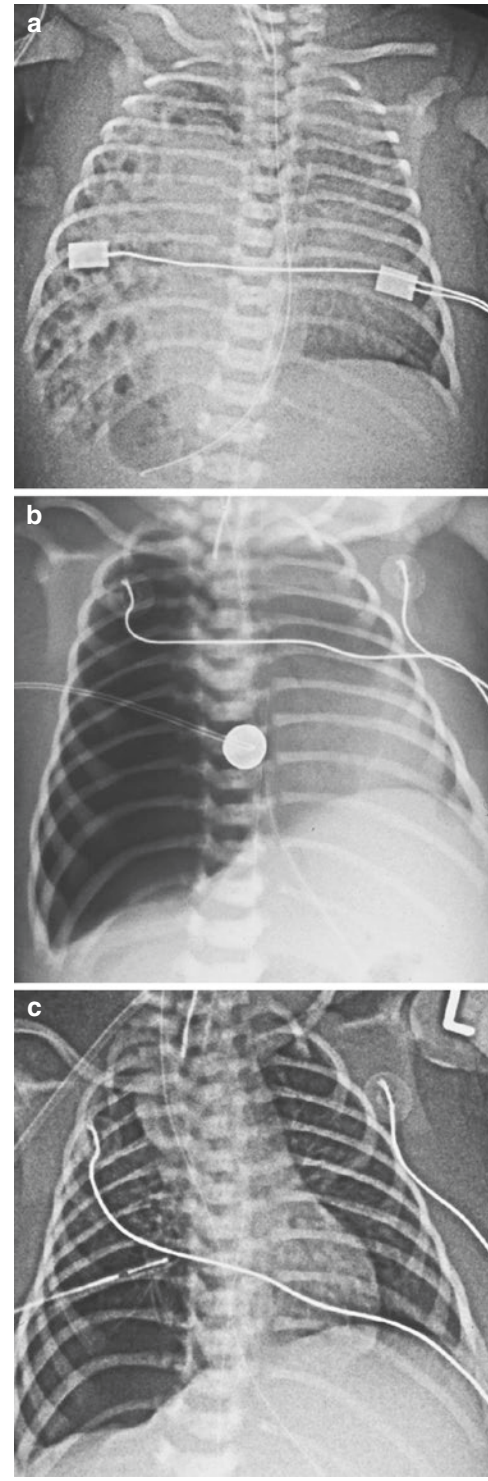

Fig. 11.7 Right sided CDH (**a**). The patient developed a tension pneumothorax postoperatively on conventional ventilation (**b**) and was successfully managed with high frequency oscillatory ventilation (**c**)

resuscitation but subsequently deteriorate. Diaphragm repairs can be carried out during HFOV or ECMO.

Whether repairs are undertaken in theatre or on the ICU depends on the local circumstances. If a baby is stable on either CMV or HFOV and meets the criteria for repair, it is advisable to continue the ventilation mode during repair and use an opioid-muscle relaxant technique of anaesthesia. The lung mechanics may deteriorate to varying degrees with the return of herniated viscera to the abdomen, due to elevation of the unaffected diaphragm. On occasions, patch closure of either the abdomen or diaphragm may be required. Some babies with CDH can be considered for epidural of paravertebral blocks if their lung mechanics are good enough for a trial of early weaning.

CDH babies who have undergone foetal endoscopic tracheal occlusion (FETO) are beginning to appear in some units [125]. This procedure can result in tracheo-malacia, which may be severe enough to require stenting.

11.14.2 Oesophageal Atresia and Tracheo-Oesophageal Fistula (OA/TOF)

Infants with OA/TOF are often born with other features in the VACTERL cluster of abnormalities and need a detailed pre-operative clinical evaluation, looking for evidence of congenital heart disease, chromosomal abnormality, other gastro-intestinal atresias and renal and bony malformations. It is particularly important to establish whether a duct dependent cardiac lesion is present.

There are a number of classifications of variants of OA/TOF [126, 127]. In oesophageal atresia with distal tracheo-oesphageal fistula, the fistula site on the posterior tracheal wall ranges from the mid-trachea to carina and is occasionally in a bronchus [128]. Most OA/TOF babies present breathing spontaneously and the diagnosis is based on the coiling of a nasogastric tube in the upper pouch, together with distal bowel gas, in a baby who chokes with feeding attempts (Fig. 11.8).

A small number of infants require resuscitation and are transferred after intubation and ventilation. This can be a difficult situation, with gaseous distension of the bowel, compromised ventilation and the risk of aspiration. The priority is to control the fistula. A 2 or 3F Fogarty catheter can be placed in the fistula as a temporizing measure but surgical ligation is urgent, even if oesphageal repair has to be delayed due to poor intra-operative tolerance of lung retraction.

Various approaches to the induction of anaesthesia of OA/TOF infants have been described. In our institution, babies usually undergo a gaseous induction with sevoflurane, followed either by muscle relaxation and intubation or placement of a size 1 laryngeal mask airway (LMA) after gaseous induction if the baby has adequate spontaneous respiration. The trachea is then examined with an Olympus 2.2 fibre-optic bronchoscope (FOB) through the endotracheal tube or LMA. The identification of the rare upper pouch fistula may be easier with the LMA method [Atz 06] (Fig. 11.9).

The tube is carefully positioned in relation to the fistula. We believe direct vision of the fistula site is important for subsequent surgical and anaesthetic management (Fig. 11.9). It is particularly important to avoid displacement of the ETT into a carinal fistula orifice [129]. The endotracheal tube should be initially sited above a carinal fistula, with the option of advancing it into the left main bronchus if abdominal distension is a problem. Alternatively, a Fogarty catheter can be placed under direct vision to control a carinal fistula prior to ligation [130], although this has not been necessary in most cases in our experience.

A group in Zurich reported 47 cases of fibre-optic assisted TOF repair, without any major problems due to gastric hyperinflation despite intermittent advancement of the thin FOB via the ETT into the fistulae [131]. The passage of a FOB or guidewire can be useful to aid the surgical identification of and the approach to a lower tracheal or high H fistula. However, there is a risk

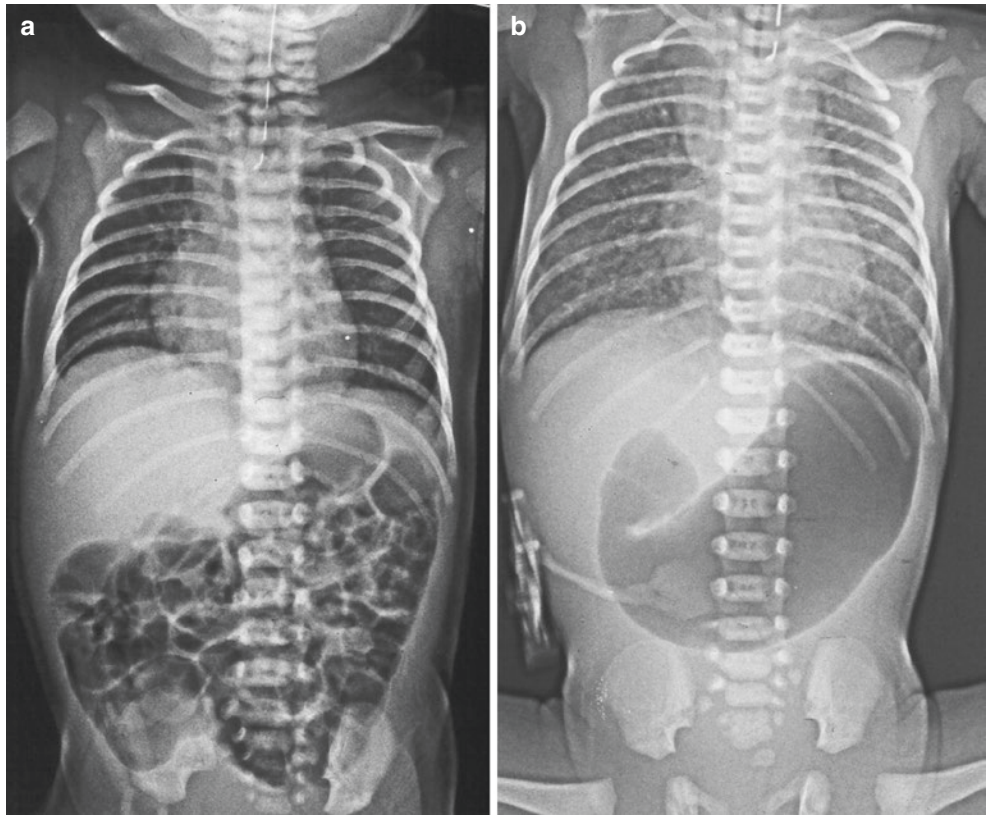

Fig. 11.8 Pre-operative radiographs in babies with oesophageal atresia and tracheo-oesophageal fistula. The case on the right also had duodenal and ano-rectal atresias

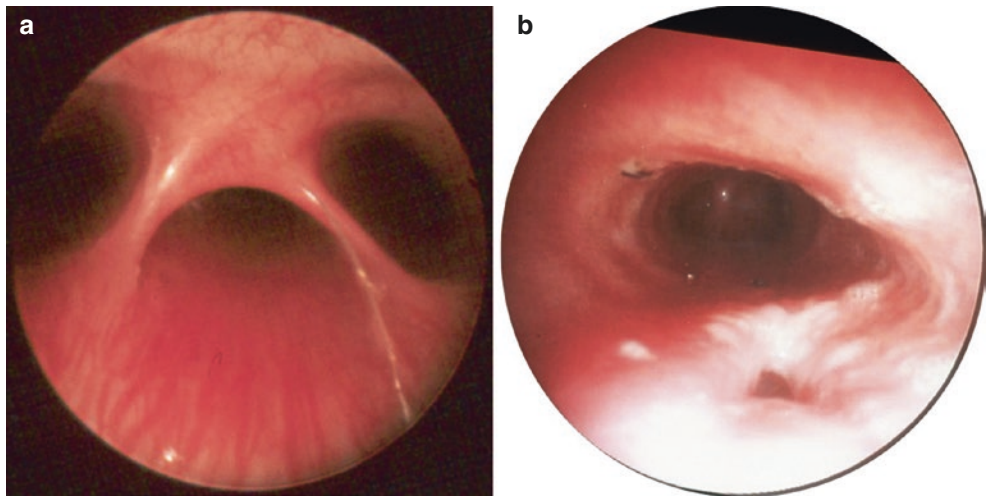

Fig. 11.9 Bronchoscopic images of a carinal fistula (*left*) and an "H" fistula (*right*). The "H" fistula is high on the posterior tracheal wall and is easily missed

that gastric fluid may reflux through a fistula into the trachea during FOB manipulations.

The tube can sometimes be advanced beyond a midtracheal fistula and it may help to orientate the bevel orifice away from the fistula. Another option is to use a microcuff tube to occlude a midtracheal of high fistula.

Once the baby is positioned for thoracotomy, we arrange the drapes so that we can rapidly access the tube, which is cut long and can be repositioned with the aid of the FOB if necessary. Suctioning may also be required intra-operatively.

A few babies may be too small or ill to allow these manoevres. The anaesthetist and surgeon have to agree on a feasible plan of action in the individual case.

In some institutions, tracheo-oesophageal fistulae are repaired using thoracoscopic techniques, in which case the endotracheal tube may need to be advanced into the left main bronchus to allow endoscopic instrumentation and single lung ventilation. This can be accomplished either by direct vision using a FOB or by using fluoroscopic control [132]. The alternative is to site a bronchial blocker in the right main bronchus (see below—thoracic problems).

We advocate hand ventilation using a T piece during dissection and repair of the oesophagus to detect changes in compliance and resistance during lung retraction. Good communication between the anaesthetist and surgeon is vital.

Analgesic options for oesophageal atresia repair are either systemic opioids (e.g. remifentanil intra-operatively followed by morphine) or an epidural or paravertebral block. These techniques enable early extubation. If a baby is to be ventilated in the early post-operative period, intra-operative fentanyl (10–20 μgm/kg) is well tolerated.

11.14.3 Airway, Thoracic and Respiratory Problems

A number of relatively rare disorders affecting the tracheo-bronchial tree and the lungs require surgery in the neonatal period [133]. Many of these babies will present with obvious symptoms and a reasonably certain pre-operative diagnosis. However, in some babies, the onset of symptoms can be more subtle and insidious and in some cases the problem may co-exist with a more obvious congenital disorder, typically congenital heart disease. Cases of congenital subglottic stenosis, long segment lower tracheal stenosis (funnel trachea) and "H" tracheo-oesophageal fistula can present in this way. Stenoses of the trachea can be quite narrow before obvious symptoms become apparent. Difficulties in passing a normal sized tube through the stenosed segment during anaesthesia may trigger the diagnosis, which is made by a combination of airway endoscopy, bronchography and CT imaging. Urgent referral to a centre specializing in slide tracheoplasty is required for severe long segment tracheal stenosis.

Space-occupying congenital lesions of the lung include cystic pulmonary adenoid malformation (CPAM), congenital lobar emphysema (CLE) and sequestered lobes. These conditions may present with obvious respiratory distress or be asymptomatic at birth. The surgical approach to these lesions may be by open thoracotomy or thoracoscopy [134]. Although many thoracic operations can be accomplished using two lung anaesthesia and lung retraction or delivery of a lesion through the incision, some situations are better managed with single lung ventilation. This is much more difficult in neonates than adults or older children and requires the accurate placement of a tube into the mainstem bronchus on the opposite side to surgery or the use of a blocking device in the main bronchus of the operative side. There are problems associated with both approaches. Placement of a tube into either of the bronchi can be accomplished with a small 2.2 FOB, which will pass through a 3.0 mm ETT. A blocker is placed outside the ETT to allow FOB visualization. 2 or 3F Fogarty catheters, pulmonary artery catheters or Cook 5F Arndt catheters (in larger infants) have all been described for this purpose, although none are ideal. A detailed discussion of this subject can be found in Tobias [133]. When possible, the use of a combination intra-operative remifentanil, a low concentration of volatile agent and a regional technique such as epidural or paravertebral block will enable early extubation [135].

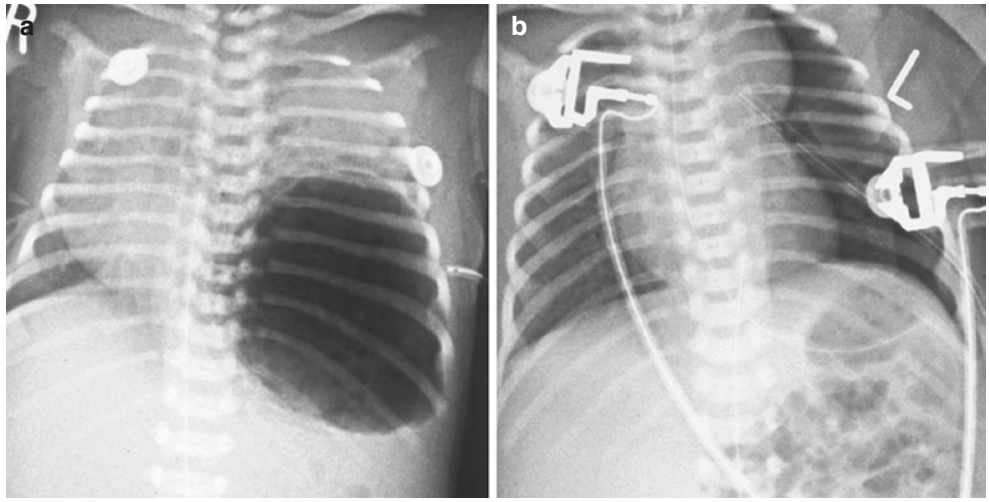

Fig. 11.10 Pre-operative radiograph of left sided cystic pulmonary adenoid malformation (**a**). An attempt to place a chest drain at the referring hospital was unsuccessful! Post operative film (**b**) with the baby established on high frequency oscillatory ventilation

In principle, there is an argument for preserving spontaneous respiration during the early phases of anaesthesia until isolation of a hyper-inflated lobe or segment has been achieved. However, in practice some babies are already in respiratory failure and ventilated when they present for surgery. In this situation, high frequency oscillatory ventilation can be effective when gas exchange is inadequate on conventional ventilation (Fig. 11.10).

11.14.4 Abdominal Wall Defects

The major defects are gastroschisis and exomphalos, with the incidence of gastroschisis increasing in recent decades. Many cases are diagnosed antenatally.

Gastroschisis is generally an isolated problem, without other major congenital malformations other than small bowel atresias, although the authors have encountered occasional exceptions. Babies with this condition tend to be small for dates and are susceptible to hypothermia and fluid depletion. Although there are a number of strategies for surgical treatment, the aim in our institution currently is to achieve a primary closure as soon as is reasonably possible. This can be achieved in 70–80% of cases. Close co-operation between surgeon and anaesthetist is necessary during attempts at primary closure. Various approaches to judging the impact of primary closure on lung mechanics, the circulation and abdominal pressure have been described, including measuring bladder pressure and changes in CVP and SVC oxygen saturation. Although placement of an arterial line, central line and blocks is desirable, the state of the bowel should be closely observed during any anaesthetic interventions.

Many of these babies are admitted to an ICU postoperatively for ventilation. Selected cases can be rapidly weaned and extubated if a sequence of remifentanil and regional blockade is used, for example caudal catheter epidural, rectus sheath or TAP blocks. Some can be extubated in theatre but will need to be closely observed for signs of respiratory compromise [136].

Exomphalos presents similar problems to gastroschisis, although fluid losses are not as severe if the sac is intact. They may also have concomitant congenital heart disease. Very large defects are likely to need staged closure, which can be often deferred in the neonatal period.

11.14.5 Bowel Obstructions

Neonates can present with a wide spectrum of congenital and acquired gut obstructions in the neonatal period [137]. The more common condi-

tions include intestinal atresias (which may be multiple), malrotation, meconium ileus and pyloric stenosis. Meconium ileus can be a presenting feature of cystic fibrosis. Duodenal atresia can be associated with Down's syndrome. The anaesthetic management of this group has been transformed in recent years by the use of intra-opreative remifentanil and the post-operative use of caudal epidural catheters or transabdominis plane (TAP) blocks, supplemented by low dose opioid regimens and intravenous paracetamol. This is a field of ongoing study in our department.

Most infants in this group can be extubated in theatre and returned to the neonatal surgical unit breathing spontaneously, unless they have perforated bowel and extensive peritonitis with signs of sepsis,. Sicker babies with signs of septic shock generally need more invasive monitoring and intensive care, including a period of ventilatory support.

11.14.6 Coexistent Congenital Heart Defects

A small group of babies may need abdominal or thoracic operations prior to correction of heart defects, such as hypolastic left heart syndrome (HLHS), transposition of the great arteries, truncus arteriosus, tetralogy of Fallot or atrio-ventricular septal defect (AVSD). Examples would include repair of oesophageal atresia and laparotomy for NEC, duodenal atresia, imperforate anus or Hirschprung's disease. A proportion of these babies will be ventilated in an ICU prior to surgery. An anaesthetic technique based on opioids, supplemented by low concentrations of isoflurane or midazolam is well tolerated [138]. Arterial and central venous monitoring is advisable. There is a strong argument for these cases to be transferred to a hospital with a cardiac service, with the involvement of a specialist paediatric cardiac anaesthetist if time allows.

Duct dependent lesions are managed with prostoglandin E1. The adequacy of the duct should be assessed prior to transfer to theatre and the continuity of the infusion assured during the operative period.

11.14.7 Persistent Pulmonary Hypertension of the Newborn (PPHN)

During birth, the circulation undergoes a transition from the fetal to the neonatal circulation. The key events are a dramatic fall in the pulmonary vascular resistance (PVR) with a simultaneous increase in pulmonary blood flow as the lungs expand, a rise in the systemic vascular resistance and closure of the fetal shunts at the foramen ovale and ductus arteriosus [139]. A major part of this process occurs over a few minutes during birth. However, after an initially rapid fall in PVR, there is a slower decline over days and the closure of the duct may take hours or days. Various physiological and pathological processes can delay or reverse the decline of PVR, including hypoxia, hypercarbia, acidosis, asphyxia, meconium aspiration, pulmonary hyoplasia, congenital heart disease and acute abdominal episodes. PPHN can present in the neonatal peri-operatve period. If right atrial, ventricular or pulmonary artery pressures rise to systemic levels or higher, right to left shunting may occur at the foramen ovale or ductus arteriosus, which does not close fully for 2–3 weeks.

Treatment includes measures to improve oxygenation, control hypercarbia and acidosis, good analgesia and the use of inhaled nitric oxide (iNO), high frequency oscillatory ventilation (HFOV) and inotropic support in the more severe cases [140, 141]. Occasionally extracorporeal membrane oxygenation (ECMO) is required in cases refractory to conventional treatment. Expert echocardiography is needed to establish the diagnosis and assess the response to treatment.

11.14.8 Prematurity and the NICU Graduate

Premature babies present a number of challenges, depending on the degree of prematurity and low weight [142, 143]. Some operations are required urgently (e.g. for perforated NEC), whereas other procedures can often be deferred until the infant grows to a reasonable size, when surgery and anaesthesia carry lower risks and morbidity (e.g.

repair of most inguinal hernias or V-P shunt insertion).

Premature infants are at increased risk of developing a wide range of conditions, including intraventricular haemorrage, periventricular leukomalacia, hydrocephalus, necrotising enterocolitis (NEC), respiratory distress syndrome (RDS) and chronic lung disease, patent ductus arteriosus (PDA), retinopathy, metabolic bone disease, inguinal hernia and episodes of infection and sepsis. Great care is needed in the anaesthetic management of these infants. Avoidance of hyperoxia, overdistension of the lungs, and excessive deadspace are important considerations during anaesthesia. We recommend the use of a neonatal ventilator and humidification system in theatre is for the smaller babies (<2 kg). A T piece circuit should also be available. Other important considerations are the provision of adequate venous access, fluid, electrolyte and glucose administration and temperature control.

11.14.9 Necrotising Enterocolitis (NEC)

NEC remains a difficult problem, which still carries a high morbidity and mortality. Babies with this condition are often very small, with compromised ventilation and unstable haemodynamics. NEC is also associated with severe congenital heart defects, such as hypoplastic left heart syndrome (HLHS), where splanchnic perfusion may be precarious. The optimal surgical management is still a subject of debate and trial [144, 145]. During surgery, large volumes of fluid and blood products may be needed. It is particularly difficult to assess volume status intra-operatively. Most babies will require periods of TPN post-operatively. Although a long line into a central vein can be used for inotropes and glucose administration, they are not suitable for sampling or rapid fluid administration. A Broviac line placed into the superior vena cava (SVC) is particularly valuable prior to laparotomy and enables intermittent monitoring of SVC oxygen saturation ($S_{vc}O_2$) and reliable delivery of blood products. Aiming for $S_{vc}O_2$ value of ≥70% been shown to improve outcome in the early goal directed resuscitation of adults and children with sepsis. Trials of this approach or the use of cerebral near infrared spectroscopy to guide resuscitation are anticipated in premature neonates with NEC. An arterial line is desirable but may be difficult to place.

At the completion of surgery, it is wise to admit small preterm babies who have undergone extensive surgery for NEC to the PICU for a period of observation and cardiorespiratory support, prior to transfer, if the neonatal ICU is in a separate hospital.

11.15 Minimally Invasive Surgery

Laparoscopic and thorascopic approaches have emerged in recent years for a number of neonatal conditions, although currently this approach is more common in older infants and children outside a few pioneering centres. Ponsky and Rothenberg recently described 649 cases in babies under 5 kg undergoing 43 different laparoscopic or thoracoscopic procedures [146]. The commoner procedures were fundoplication, pyloromyotomy, PDA ligation, oesphageal atresia/tracheo-oesphageal fistula repair and colonic pull through. Low complication and conversion to open surgery rates were reported, together with impressive operating times. Most publications in this field do not describe anaesthetic management in detail and most case series are not confined to neonates. Kalfa et al. [147] described eight anaesthetic incidents in 49 neonates undergoing 50 laparoscopic or thoracoscopic procedues over a 10-year period. Three required temporary or definitive interruption of CO_2 insufflation due to the 02 saturation dropping below 70%. Risk factors for anaesthetic incidents included low preoperative temperature, high variation of end tidal CO_2, thoracic insufflation, a high oxygen or a vascular expansion requirement at the start of insufflation and surgical time > 100 min. A further multicentre report [148] described similar findings. It appears that these procedures are successful if experienced teams use instruments and

insufflation equipment designed for small infants, with low open conversion rates. When single lung ventilation is used for thoracic cases, a degree of permissive hypercapnia is well tolerated [149]. However, much larger series are needed to assess the risk of potentially catastrophic events such as gas embolism.

11.16 Controversies and Ethics

11.16.1 Neonatal Anaesthetic Neurotoxocity

This is currently a difficult and controversial issue, with a rapidly expanding literature. Several anaesthetic agents have been shown to cause abnormal neural apoptosis in neonatal rodents and some primate species, including volatile agents, barbiturates, benzodiazepines and ketamine. The peak vulnerability is around 1 week of postnatal age and also involves suppression of neurogenesis and synaptogenesis. The effects are related to the dose and duration of exposure to the drug. The degree of damage is more pronounced with combinations of agents.

The occurrence of this problem in humans is unknown. No large-scale prospective studies of children exposed to neonatal anaesthesia or ICU sedation have been completed, with detailed assessments of long-term neuro-developmental outcomes. Many premature and term infants undergoing surgery and anaesthesia also have conditions which may influence neurological outcome. Readers are referred to recent editorials and reviews on the subject [150–152]. Various clinical studies are underway to investigate this issue but it is likely to be several years before good data is available. A large Danish epidemiological study did not demonstrate any deficit in academic performance at 15–16 years in 2689 adolescents who had undergone hernia repair as babies [153]. However, anaesthetic exposure for hernia repair is relatively short lived in contrast to major surgery and ICU sedation.

Until this issue is better understood, we believe surgical, anaesthetic and intensive care departments can adopt some precautionary principles. Some operations can reasonably be delayed to a later age on risk—benefit grounds, for example cultural circumcision. Anaesthetists can adjust their practice to minimize the dose exposure of babies to the agents or combinations of agents currently associated with neurotoxicity in experimental animals. For example, the use of remifentanil and regional techniques can reduce the cumulative dose exposure to volatile anaesthetics intra-operatively and to sedative drugs on ICU. Benzodiazepines can largely be avoided if post-operative ventilation periods are shortened or eliminated. Individual doctors and departments have to weigh up the available evidence and make decisions under conditions of considerable uncertainty.

11.16.2 Evidence

In recent years, a large number of evidence-based medicine (EBM) guidelines have appeared, based on the grading of the quality and quantity of evidence [154, 155]. Recommendations or guidelines for treatment should take into account the importance of the outcomes under consideration and the quality of the evidence supporting interventions aimed at various outcomes. Relevant outcomes can range from mortality, quality of survival and organ function to costs such as operation times, equipment investments, intensive care and neonatal unit stays.

Well-executed, registered, randomized controlled trials (RCTs) are seen as the best form of evidence. In the fields of neonatal surgery, anaesthesia and intensive care, such evidence is often scanty and much current practice is based on case series, personal or institutional experience and expert opinion. There are a large number of reasons for this, some of which are understated by the more assertive advocates of the EBM approach.

Many neonatal conditions are rare and exhibit considerable variation in phenotype. Anaesthetic drugs, fluids and ventilation are generally titrated

to the condition of the individual patient, generating several problems in trial design if inflexible treatment regimens are investigated [156]. Many drugs are being used "off label" in this population, with a consequent lack of basic pharmacological data [157]. If the current best treatment is used for the control arm of an RCT and the treatment is reasonably effective, a large, costly trial of patients will be needed to determine the advantages or otherwise for a new treatment. Furthermore, important outcomes, such as long-term neurological function, are more difficult to measure than short-term physiological or pharmaco-kinetic data. There may be rare but potentially devastating outcomes or side effects that will only be picked up in large studies. Examples include the propofol infusion syndrome and the debate over the value of epidural versus systemic opioid analgesia in the neonatal surgical population [69]. The skill and experience of anaesthetists undertaking procedures such as spinal, epidural or paravertebral blocks, inevitably varies. Consequently, the risk of devastating complications, such as paraplegia, is difficult to quantify. The effectiveness and risk of regional procedures in a large multicentre study may vary more between centres and individual practitioners than a comparative intravenous analgesia method, such as titrated opioid therapy.

11.16.3 Treatment of Multiple Congenital Defects

A small number of babies present with multiple major congenital defects, typically congenital heart disease and either oesphageal atresia or diaphragmatic hernia. Some combinations of defects may present only once or twice in an individual surgeon's or anaesthetist's career. An early multidisciplinary case conference is important in such cases. Decisions need to be made about the sequence of treatment, whether treatment can be reasonably be undertaken locally and in some instances whether prolonged complex treatment in the face of a poor overall prognosis is justified.

There are also difficult decisions to be made over the management of extremely premature babies of borderline survivability [158]. These decisions are generally in the domain of the neonatologist and surgeon, with anaesthetists being asked to perform a more technical role. However, experienced neonatal anaesthetists are aware of clinical situations where aggressive treatment is very unlikely to result in a favourable outcome. The ethical dilemmas involved should not be avoided, despite the potential for differing opinions, debate and conflict.

Intensive Care and the Surgical Neonate

12

Francis A. Potter

Abstract

This chapter examines the role of the Intensive Care Unit in the management of the surgical neonate. It discusses some of the techniques that are used and looks at the requirements of some specific neonatal conditions.

Keywords

Intensive care and the Surgical Neonate • Ventilation • Newborn surgery

In the context of the surgical neonate, Intensive Care is concerned with the support of potentially failing or failed systems so as to allow treatment of the acute problem–usually by some form of operation. It may be needed pre-operatively to prepare the infant for surgery but it is more commonly required after the surgical insult.

The hallmark of intensive care has been mechanical ventilation of the lungs and this remains the case today. Other modalities of system support: inotropes and vasoactive drugs for the cardiovascular system, acute renal replacement with haemofiltration or peritoneal dialysis are also generally available in paediatric intensive care, but some technologies such as extracorporeal membrane oxygenation (ECMO) remain confined to a few centres.

e-mail: frank.potter@alderhey.nhs.uk

The organization of delivery of this care varies both within and between countries. Within the UK there are broadly two models of care: patients being cared for as part of a unit looking after (surgical) neonates only–usually with a small number of ventilator cots; or with surgical neonates receiving care alongside other, older, paediatric intensive care patients.

The overall pattern of surgical treatment will also both influence and be influenced by the availability of intensive care—for example using regional anaesthesia to try to avoid post-operative ventilation, timing of surgery for diaphragmatic hernia repair, use of silos for staged repair of abdominal wall defects.

Intensive Care for the surgical neonate contains elements of medical neonatal care of the premature infant: support for the immature respiratory system, obtaining good enough nutrition to allow satisfactory early growth and development, and elements of paediatric intensive care-which itself derives much of its technique and technology from its adult counterpart.

P.D. Losty et al. (eds.), *Rickham's Neonatal Surgery*, https://doi.org/10.1007/978-1-4471-4721-3_12

Most of what is done is done on the basis of extension or extrapolation from other practice. Faced with a particular problem in an individual infant, evidence from large multicentre trials, performed on cohorts of similar patients (both similar to each other and similar to the patient in question) is, generally speaking, absent. But despite a relatively weak evidence base, there have been many areas of success and there is, in consequence, pressure to apply apparently successful techniques and treatments to ever younger, smaller and sicker infants [1].

Support for the Respiratory System—Mechanical Ventilation of the Lungs.

Spontaneous ventilation contains many subtleties. If one uses the frequency and tidal volumes of an infant (or adult) breathing spontaneously as the settings for mechanical ventilation, then this tends to produce a hypercarbic, hypoxic patient with atelectatic lungs. In order to replicate the gas exchange produced by spontaneous breathing, mechanical ventilation requires fewer breaths of greater tidal volume, with an overall increase in the minute volume. In mechanical ventilation, for any one breath, there is a decision as to which of two variables, the volume of the breath or the positive pressure with which it is given, is to be the controlled variable, with the other being the dependent variable.

Within paediatric practice, pressure controlled ventilation (PCV) has generally been the default mode of ventilation. Originally this was because infants and small children were always ventilated using uncuffed endotracheal tubes. With each breath, some variable volume of gas would be lost to the breathing system through the leak around the tube, and it was easier to compensate for this leak by inflating the lungs to a particular pressure rather than a particular volume. Volume controlled ventilation was reserved for circumstances in which it was important to guarantee a particular minute ventilation, such as in attempting to control intracranial pressure by controlling the arterial partial pressure of carbon dioxide.

However, variants of pressure controlled ventilation have become the predominant form of ventilation across the spectrum of intensive care medicine. This has come about because of the recognition that, at least in sick patients, all mechanical ventilation damages the lung and that it is high peak pressure, high tidal volume ventilation which does this most effectively, probably because it maximises the shearing forces involved in opening and closing lung units.

It is easy to demonstrate this lung damage in experimental animals and clinical experience confirms this notion. The past half century has seen a search for the best (more correctly, the least harmful) mode of ventilation. Outcome trials in adults [2, 3], culminating in the ARDS network study [4] have produced the present consensus on ventilation strategy, often referred to as the ‘open lung’ approach:

Mechanical ventilation should be done with a low tidal volume (6 mL/kg) between a relatively high end expiratory pressure (and volume) and a relatively low peak inspiratory pressure (and volume) that is between the two ‘inflexion points’ of the compliance loop of the lung. In theory, any group of ventilated alveoli should never contain so little gas that their walls come together so that the alveoli collapse, or so much gas that their walls are overly stretched.

In circumstances where an infant needs mechanical ventilation, the starting position is that the lungs will contain at least some groups of alveoli that have collapsed and need to be reinflated (regions of atelectasis). However, such lungs are both prone to atelectasis and are, inevitably, inhomogeneous: thus airway pressures sufficient to open up one atelectatic lung region are likely to be overdistending (and so damaging) other, more normal, lung regions, while airway pressures low enough not to overdistend any lung region will almost certainly both leave other regions of alveoli atelectatic, and allow more alveoli to collapse.

The gas used for ventilation should have the lowest concentration of oxygen as is compatible with delivery of sufficient oxygen to the tissues so as to minimise oxygen toxicity. The gas should, if at all possible, contain some nitrogen thus avoiding collapse of alveoli from diffusion atelectasis if all the oxygen within an alveolus is absorbed .

Above some threshold of respiratory acidosis, (usually taken that the arterial pH should be greater than 7.2) the ventilatory minute volume is dictated by its 'cost' in terms by the ventilatory pressures and volumes produced rather than pursuit of a particular arterial carbon dioxide reading (permissive hypercapnoea) [5].

At least some spontaneous respiratory effort should be maintained in an effort to prevent disuse atrophy of the respiratory muscles [6], but spontaneous respiration should be synchronized with the ventilator.

An absolute feature of this strategy, perhaps unspoken, is that mechanical ventilation should always be for as short a time as necessary.

This strategy has been extrapolated to the intensive care of the surgical neonate. The ventilatory mode that is used most commonly in our paediatric intensive care unit is that of biphasic positive airways pressure (BIPAP).

In BIPAP mode, the ventilator provides two levels of continuous airways pressure and cycles between the two at a chosen frequency. Thus if the upper pressure chosen was 15 cmH_2O, the lower 5 cmH_2O, the upper: lower ratio 1:3 and the frequency 30 times each minute then, if the infant made no spontaneous effort, the ventilator would effectively deliver 30 pressure controlled breaths each minute, each breath consisting of a 2 s cycle with one half second of inspiration and one and a half seconds of expiration.

If, however the infant were breathing spontaneously, say 50 times each minute, then these spontaneous breaths could occur during a lower (5 cmH_2O) or upper (15 cmH_2O) pressure phase no matter how these breaths happened to be distributed. The response times of the inspiratory and expiratory valves are very short; hence, in BIPAP mode, the valves can open and close so as to allow spontaneous breaths to occur at any time in the respiratory cycle without losing or adding significantly to the pressure in the child's airways and ventilator tubing.

In addition, an extra variation on BIPAP—additional supported breath mode (ASB)—allows a spontaneous breath occurring during the lower pressure phase of the BIPAP cycle, to trigger a supported ventilator breath (Fig. 12.1).

This mode of ventilation allows provision of a varying degree of support of breathing through the course of the infant's illness. Immediately post-operation or when the infant is most sick, it provides full pressure controlled ventilation operating between the lower and upper BIPAP pressures at the chosen frequency.(In practice, BPAP is often set up for neonates with settings that effectively provide simply pressure controlled ventilation at a rate of 35–40 breaths a minute and an inspiratory time of 0.4–0.5 s.) As the infants condition improves, it allows spontaneous breathing to occur without producing airway pressure surges (when breathing out at the upper pressure level) or losing airway pressure (when breathing in). At this stage, the infant will be receiving some combination of mandatory pressure controlled breaths, spontaneously triggered, supported, breaths and will also be able to take spontaneous breaths at any time. The infant is guaranteed a background minute volume of breaths from the machine, while additional spontaneous respiratory efforts are readily accommodated.

Other modes of ventilation, synchronised intermittent mandatory ventilation (SIMV), assisted control-mode ventilation (ACMV), may be used in intensive care for the surgical neonate. Some small premature infants appear much more comfortable if they are ventilated using synchronized intermittent positive pressure ventilation (SIPPV) mode in which any spontaneous inspiratory effort on the infant's part triggers a pressure controlled breath from the ventilator (using this mode of ventilation outwith of premature infants tends to result in gross hyperventilation) It remains the case that since no one form of conventional mechanical ventilation has been conclusively shown to be intrinsically superior to any other it is important to fit the mode of ventilation to the infant rather than the other way about.

An obvious difference between the short-term (hours) mechanical ventilation associated with surgical anaesthesia and the long-term (days) mechanical ventilation of intensive care comes at the end of the process. After an operation, the patient returns to full spontaneous ventilation within a matter of a few minutes of reversal of

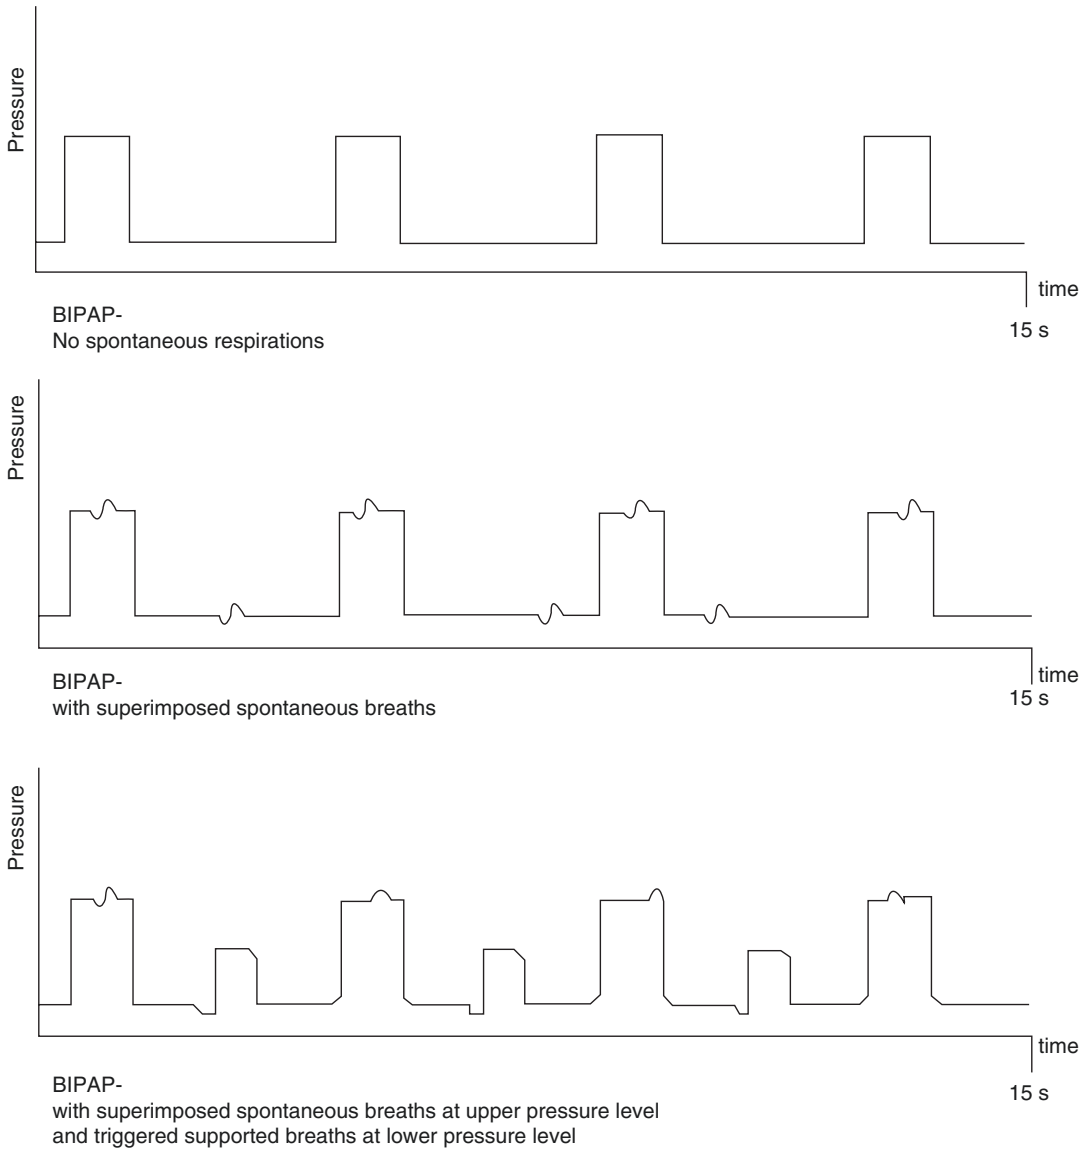

Fig. 12.1 Patterns of ventilation with BIPAP

neuromuscular blockade. After days of mechanical ventilation, a sick infant is gradually accustomed to breathing spontaneously once more in a process termed 'weaning'. Originally, the technique involved taking the infant off mechanical ventilation for a short period (5–10 min) and then returning her (doubtless tired) to mechanical ventilation for the rest of the hour, repeating the process with progressive prolongation of the period of spontaneous respiration until adequate continuous spontaneous respiration was re-established.

Today the process involves using the sophistication of a modern intensive care ventilator to achieve the same aim in a less labour intensive manner. The ventilator provides progressively less of the work of breathing while the infant takes on more of the burden. In BIPAP mode weaning is achieved by decreasing the magnitude of the upper pressure level, decreasing the proportion of time spent at the upper pressure in each minute and decreasing the amount of sup-

port pressure (ASB) given to spontaneous breaths.

Among the subtleties of spontaneous respiration that have been lost with mechanical ventilation to date are the intrinsic variability of tidal volume and respiratory frequency. There is now a body of animal work [7] and mathematical explanation [8] that might well result in the introduction of biologically variable ventilation (BVV) in the next few years. If, for example, the upper pressure that a ventilator delivers is varied breath-by-breath in a normal distribution about a mean pressure instead of invariably delivering the same mean pressure, then the mean inspiratory volume that is produced is increased (see Fig. 12.2). This concept may offer a significant further improvement of infant care.

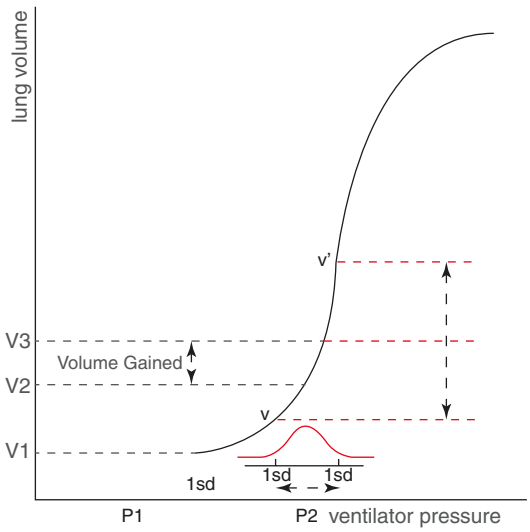

Fig. 12.2 The Effect of 'Noise' on Mechanical Ventilation. In the example of a ventilator operating constantly between pressures P1 and P2, the volume change imposed on the lung is (V2−V1). Now, if the ventilator upper pressure were to be a Gaussian distribution with the mean pressure P2, then, because of the shape of the lung compliance curve, the 'loss' of volume for a pressure of 1sd below mean P2, (v−V1) is more than compensated by the 'gain' of volume for a pressure of 1sd above mean P2, (v′−V1), so that overall, for the same mean pressure change, an additional lung volume (V3−V2) is gained. Based on a figure reprinted with permission from Macmillan Publishers Ltd.: by Suki B et al. published in Nature, 393:128, copyright 1998

12.1 High Frequency Oscillatory Ventilation (HFOV)

HFOV differs from conventional mechanical ventilation in three respects. The tidal volume of each breath is very small (usually less than the anatomical dead space), inspiration and expiration are both active, rather than expiration being passive, and the respiratory frequency is some 8–30 times greater—such that it is measured in cycles per second (Hz) rather than breaths per minute. Gas is moved in and out of the airway by movement of what is, in essence, a loudspeaker diaphragm and gas exchange occurs by facilitated diffusion rather than bulk flow. Proponents of HFOV argue that it is a logical way of achieving the aims of the present consensus for good ventilation.

First, the lung is opened to a relatively high mean volume by the distending pressure (mean airway pressure MAP). Then, the lung is oscillated about this point by the small tidal volume so that the peak lung volume is smaller and the minimum lung volume greater than would be the case with conventional mechanical ventilation- thus minimising the lung damage produced by high peak pressures and the shearing forces of opening and closing broncho-alveolar units.

To use an emotive shorthand, HFOV may be thought of as a 'gentler' means of ventilation than conventional mechanical ventilation—a lovely concept- but there is currently little first class evidence that HFOV leads to superior outcomes.

Some have argued that HFOV has seemingly fallen at the hurdle of randomised trials because, at the time that the trials were conducted, insufficient attention was given to the initial use of a high mean airway pressure to recruit collapsed alveoli- something that has been emphasised with increasing experience of the technique [9].

Alternatively, it has been suggested that, as the strategic aims ('opening' of alveoli and maintaining 'open' alveoli with minimal overdistention) of both conventional ventilation and HFOV are the same, in the majority of cases it matters little which ventilatory method is used. The superior-

ity of HFOV, say its champions, is best discerned in the very sick, but not moribund, patient [10]. There is a good deal of small-study evidence and much clinical experience that HFOV can produce marked improvement in oxygenation in certain patients, and so its present position is that it is usually used as a rescue therapy when conventional mechanical ventilation in the supine position appears to be failing.

Prone positioning [11] and inhaled nitric oxide (iNO) [12] are two other therapies that often give physiological improvement but have yet to definitively demonstrate that they improve outcome for infants. Both prone positioning and inhaled nitric oxide (iNO) are thought to improve oxygenation by improving ventilation:perfusion matching within the lungs.

With prone positioning, the alteration of chest and lung mechanics and the effect of gravity have several effects including increasing the functional residual capacity and redistributing perfusion towards better ventilated regions of the lung and redistributing ventilation towards better perfused lung regions.

In the case of inhaled nitric oxide, the gas acts as a vasodilator. Because nitric oxide is inhaled and very rapidly inactivated by the haem moiety within red blood cells, then its greatest effect is on the pulmonary vessels associated with ventilated alveoli; improving ventilation-perfusion matching without producing generalised vasodilatation and systemic hypotension [13].

12.2 Extra-Corporeal Membrane Oxygenation (ECMO)

This is the most invasive therapy yet devised in the treatment of acute respiratory failure.

The idea is to produce a state of complete lung rest during which specific therapy (e.g. antibiotics for bacterial infection, steroids for asthma) or the patient's own defences (e.g. viral infection) produce resolution of the lung problem. Meantime a sufficient part of the patient's blood is directed via the extra-corporeal circuit to a membrane oxygenator and then returned (oxygenated), to the patient's circulation. For 'Respiratory' ECMO, when the infant has good cardiac function, this is usually done by means of a double-lumen cannula inserted into the internal jugular vein (veno-venous ECMO). 'Cardiac' ECMO, when the main problem is poor cardiac function, more closely resembles prolonged cardio-pulmonary by-pass, with blood being led to the oxygenator from right atrial or bi-caval cannulation and then returned to the patient via an aortic cannula, all being achieved via a sternotomy.

There is a risk of mortality or morbidity from mechanical failure of any part of the circuit and since the extra-corporeal circuit requires that the patient's blood is fully anticoagulated there is also the risk of bleeding (particularly within the Central Nervous System). In the United Kingdom, there has been a conscious decision to offer this therapy only within a small number of specialized units, with the idea that the relatively high throughput of such cases through these units helps to maintain skills and minimises iatrogenic problems.

There is good quality data on the outcome of using ECMO in different situations. The results in the neonatal period for 'medical' respiratory failure- particularly that caused by meconium aspiration syndrome are very good [14]. The use of this treatment for neonatal surgical conditions has produced more equivocal results [15]. In particular it has been suggested that an obvious application for ECMO therapy is in the treatment of diaphragmatic hernia. In this context, ECMO has been used as a rescue therapy when infants have developed respiratory failure following their surgical correction. More radically, ECMO has been used as a primary therapy for infants with actual or incipient respiratory failure pre-operatively [16]. These infants have then undergone surgical repair while receiving ECMO. Both of these approaches have produced instances of individual success, but neither approach has been demonstrated to be unequivocally better than 'conventional' treatment of diaphragmatic hernia.

12.3 Control of the Airway

Infants requiring surgical intensive care nearly always require an endotracheal tube to facilitate mechanical ventilation of their lungs. There has always been concern over the effects of long-term endotracheal intubation. Nasal intubation (championed by its supporters as facilitating secure fixation) can produce loss of alar cartilage from pressure necrosis, oral intubation may similarly produce cosmetic damage to the tongue and lips and, more importantly, the presence of a snugly fitting or too big endotracheal tube can damage the larynx and, in particular, produce sub-glottic stenosis.

The reported incidence of subglottic stenosis has declined over the past 40 years, even in very-low birthweight infants who are intubated for substantial lengths of time [17]. The common presumption is that this decrease has come about because of more widespread awareness of the problem and a tendency to undersize tracheal tubes so as to ensure that a leak is present at all times at a low inflation pressure (often quoted in studies as being about 10 cmH_2O). The leak, it was argued, meant that radial pressure exerted on the subglottis from the tube must be small, certainly below the pressure at which subglottic mucosal perfusion would be compromised (the purported mechanism of sub-glottic injury). This approach carries its own problems- too great a leak producing inadequate ventilation, poor performance of in-line capnography, greater potential for aspiration—and so may necessitate multiple changes of endotracheal tubes to obtain a near-perfect 'cricoid fit' [18].

Over the past decade, this approach has been challenged. Within anaesthesia, there has been a move towards using cuffed tubes for all but the very smallest of infants. Better designed, high-volume, low-pressure (HVLP) cuffs may, provided due attention is paid to cuff pressures, produce as little damage as uncuffed tubes but allow better monitoring and fewer tube changes [19]. The use of cuffed tubes in small children and infants has become more widespread in anaesthetic practice and is entering the PICU–literally *in situ* in post-operative patients.

12.4 Support for the Cardiovascular System

The mainstays of support for the cardiovascular system in patients treated in intensive therapy units are sufficient fluids as to provide adequate filling of the circulation and the use of drugs to either increase cardiac contractility (positive inotropes), or alter the tone of blood vessels (vasoconstrictors or vasodilators) in an effort to optimise tissue perfusion and oxygen delivery (Table 12.1).

Here again, the emphasis is very much on clinical experience and reliance on extrapolation from knowledge gained from work on healthy volunteers, laboratory animals, and sick adults. The lack of class one evidence has not prevented an overall improvement in clinical outcome, but the paucity of randomised controlled trials does need to be borne in mind .

The main cardiovascular derangement affecting the surgical neonate is shock. Recognition is easier than definition. The adult literature continues, for the moment, to use clinical hypotension for this purpose, and in neonatal practice, even allowing for gestational age adjustment, there is no absolute agreement as to exact cut-off points. Good practice for the sick infant would have shock recognised and acted upon from clinical signs—heart rate (<90 bpm or >160 bpm), peripheral pulse palpability, skin perfusion, altered consciousness, hypo- or hyperthermia-before actual hypotension had arisen.

Shock is evaluated and treatment is directed by haemodynamic variables. In everyday clinical practice, the variables that are used and the way that they are measured often differ, in both trivial and important ways, from those used in older children and adults. Invasive arterial monitoring is often done using femoral or umbilical lines rather than using more peripheral arteries (difficulty of access and fear of vascular compromise). Cardiac output, despite usually being the variable of greatest concern, is seldom the subject of continuous invasive measurement in infants, although it is possible that this situation may change in the near future if newer methods

Table 12.1 Drugs for the cardiovascular system

Drug	Receptor	Actions	Caveats and comments
Dopamine (low dose)	DA_1	↑ blood pressure ↑ diuresis	
Dopamine	DA1, DA2, α_1	↑ blood pressure ↑ cardiac inotropy	
Dopamine (high dose)	DA1, DA2, α_1, β_1	↑ blood pressure ↑ cardiac output	↑ bp may be at expense of ↑ SVR →↔ or↓ cardiac output
Low dose adrenaline	β_2 β_1	↑ cardiac inotropy ↑ chronotropy ↑ cardiac output ↓ SVR	↓ SVR primarily because of vasodilatation in skeletal muscle- may divert blood Flow from viscera ↑ [lactate] in serum- multifactorial- makes [lactate] less useful as a marker of adequate tissue perfusion
High dose adrenaline	β_2 β_1	↑ inotropy ↑ chronotropy ↑ cardiac output ↑ SVR	Danger of arrhythmias
Noradrenaline	α_1	↑ blood pressure CO↑ or ↔ or ↓	↑ SVR may → ↓ cardiac output Cardiac output may be ↑ because ↑ aortic diastolic pressure may ↑ coronary perfusion and so ↑ cardiac contractility
Vasopressin	V_1 V_2 V_3	↑ blood pressure ?↑ cardiac output	Cardiac output may be ↑ because ↑ aortic diastolic pressure may ↑ coronary perfusion and so ↑ cardiac contractility May restore depleted blood [vasopressin]

such as pulse index contour analysis [20] or lithium dilution monitoring [21] enter everyday practice. On the other hand, it is probably technically easier to obtain intermittent echocardiographic evidence of cardiac performance in small infants than is the case for adults in intensive care.

The American College of Critical Care Medicine (ACCM) issued guidelines, based on literature and best practice review, covering the treatment of septic shock in infants and children in 2002. Application of these guidelines (which were updated in 2007) has been associated with improved outcomes in many centres [22].

In terms of which fluid to use to achieve adequate filling of the circulation, there are still many areas of reasonable doubt. Rather than being prescriptive as to particular fluids, the emphasis of the guidelines was more on early rapid infusion of isotonic fluid with the aim of restoring normal perfusion and blood pressure. Failure to achieve these end points should prompt establishment of invasive monitoring so as to allow determination of perfusion pressure—the difference between mean arterial pressure and central venous pressure (MAP-CVP)—to help guide further fluid therapy. Put simply, if a fluid bolus produces no appreciable rise in CVP the patient needs more fluid; if more fluid produces a rise in CVP and a fall in (MAP-CVP) value, then this suggests that too much fluid has been given. Present preferences as to which fluid to use include the idea of using blood to maintain haemoglobin concentration above 10 g/dL [23] and an inclination to the idea that near-isotonic crystalloids may be as good as colloid in most circumstances [24].

Several features of crystalloid fluid management need further consideration. An infant's daily water and electrolyte requirements may be met by infusing dilute saline (one-fifth 'normal' saline −0.18%NaCl) at about 4 mL/kg/h. It has long been appreciated that starved infants are at risk of hypoglycaemia which could produce dev-

astating neurological damage. Since dilute saline could be made iso-osmolar with plasma (and thus painless to infuse) by the addition of dextrose—guarding against hypoglycaemia- it came about that dextrose 4% with sodium chloride 0.18% ('four and a fifth') became the near-universal standard infant, and indeed, paediatric intravenous fluid. However, this is an inefficient and dangerous fluid to give for the purpose of volume expansion. The dextrose is metabolised, rendering once iso-osmolar fluid very hypotonic, so very large volumes of this hypotonic fluid are required to achieve any appreciable expansion of vascular volume, producing potentially catastrophic hyponatraemia [25].

The crystalloid solutions needed for adequate volume expansion are those nearer to isotonic solutions; 0.9% saline, Hartmann's solution or Polyionique solution. No solution is perfect: polyionique is not readily available outside France, Hartmann's is less than isotonic and 0.9% saline tends to produce a marked hyperchloraemic acidosis which may have important clinical consequences [26]. None of these solutions alone provides any dextrose, although this problem has been addressed by commercial manufacturers who have produced preparations such as 1% dextrose in Hartmann's solution. The lesser quantities of dextrose in modern solutions reflect both the idea that less glucose is required to maintain normoglycaemia in most circumstances and an increasing concern that hyperglycaemia may have adverse effects on outcome in critically ill children—although a multicentre randomised trial showed no overall benefit from tight glycaemic control [27].

After the question of adequate fluid loading of the circulation, the picture with inotropic and vasoactive drugs is hardly any more clear. The main group of drugs used here is the catecholamine family. These drugs act via a variety of adrenergic receptors (α,β_1,β_2) (alpha, beta one, beta two) and dopamine (DA_1, DA_2) receptors to produce degrees of alteration in vascular resistance (vasodilatation and vasoconstriction), contractility (inotropy), and heart rate (chronotropy). The specificity of action of these drugs varies with their dose and their pharmacokinetics and pharmacodynamics are often altered by the patient's illness. Add in developmental differences between neonates (premature or term), infants, children and adults and it is clear that the effect of any particular drug on an individual patient in a particular circumstance is more amenable to close observation than it is to accurate prediction.

Bearing these caveats in mind, where does one start? In the context of surgical neonates requiring cardiovascular support, this will usually be because of either hypovolaemia or 'septic' shock (whether or not an infective organism is ever isolated) The ACCM recommend dopamine (5 μg/kg/min) or adrenaline (0.05–0.3 μg/kg/min) as the first line inotropic drug as it is thought that most infants with septic shock have diminished cardiac output with normal or raised systemic vascular resistance (SVR). Both drugs have been demonstrated to counteract hypotension in the smallest of infants; adrenaline produces more of a chronotropic effect (which points to it having a greater effect on actual increase in cardiac output) [28]. The ACCM specifically recommends early intervention with inotropic drugs- giving these drugs either into a peripheral vein or intraosseous needle pending the insertion of a central line, notwithstanding the risk of tissue damage from exravasation of the inotrope.

If dopamine fails to bring about satisfactory improvement, adrenaline is started as the second inotrope. In distinction with adult practice, where noradrenaline is commonly used as a vasoconstrictor, noradrenaline is used in surgical neonates only as rescue therapy when the dopamine/adrenaline combination is manifestly failing or where there is clear clinical suspicion of low systemic vascular resistance (very low diastolic pressure).

Particular features of septic shock in neonates are that catecholamine therapy is sometimes less effective than expected and that such therapy demonstrates tachyphylaxis. Proposed reasons for these observations include the idea that the vasoconstrictive effects of the catecholamines are opposed by the vasodilatory effects of endogenous nitric oxide, production of which is increased in sepsis [29], and that there is down-

regulation of catecholamine receptors with continued exposure to catecholamines [30]. Endocrine status is thought to be important in this downregulation. Treatment of sub-clinical hypothyroidism (with tri-iodothyronine T3) has been demonstrated to restore catecholamine effectiveness in children following cardiac surgery [31, 32], while there has been much greater debate over the role of cortisol and the significance of any degree of impairment of the hypothalamic-pituitary-adrenal axis in paediatric critical illness. Low dose hydrocortisone has been demonstrated to improve refractory hypotension in low birthweight infants receiving dopamine [33] though this has yet to be demonstrated as having a proven effect of improved outcome [34].

Vasopressin (Anti-Diuretic Hormone) acts via its own receptors (V_{1a}) in vascular smooth muscle to increase blood pressure, systemic vascular resistance and urine output in catecholamine-resistant shock. Vasopressin is almost always used in combination with catecholamines as rescue therapy for refractory hypotension and while it has several theoretical advantages in this regard [35], favourable outcome trials are lacking, even in adults [36].

Another approach to the treatment of shock has been the use of phospherodiesterase inhibitors. Intracellularly, catecholamines act via 'second messenger' mechanisms to increase intracellular concentrations of cyclic adenosine monophosphate (cAMP). Phospherodiesterase type III inhibitor drugs (inamarinone, milrinone, enoximone) inhibit the breakdown of cAMP and so should act synergistically with catecholamines. This group of drugs has become widely used-particularly in the post-operative phase of infants who have undergone cardiac surgery-despite the relative paucity of outcome evidence for their use [37].

Levosimenden re-sensitises the actin-myosin-tropomyosin complex within the cardiac muscle cell to calcium ions–thereby increasing contractility. It also has vasodilating properties through its action on potassium channels in vascular smooth muscle cells. It has active metabolites and so a loading dose and 24 h infusion produce clinical effects for several days. Up to the present, its reported use in children has been pretty well confined to instances of severe heart failure [38].

12.5 Renal Support

Providing support for the neonatal surgical patient who has suffered an acute kidney injury is one of the most difficult areas of neonatal intensive care. There are three main reasons why an infant might require renal replacement therapy: fluid overload, metabolic derangement (acidosis, uraemia) and acute hyperkalaemia; severe fluid overload producing generalized systemic and pulmonary oedema is the commonest problem in the surgical infant. Commonly, options for renal replacement therapy are intermittent haemodialysis, peritoneal dialysis and continuous haemofiltration; each has particular problems associated with its use in the context of the surgical neonate.

Intermittent haemodialysis gives the best overall metabolic control of kidney failure, but generally speaking the volume of the circuitry and the potential cardiovascular disturbance of the osmotic fluid shifts caused by dialysis make the technique unsuitable for a sick surgical infant [39].

12.5.1 Peritoneal Dialysis

In this technique, dextrose-containing dialysate fluid is run into the peritoneal cavity by way of a dedicated catheter (which can be inserted either at open operation or percutaneously). The peritoneum acts as a semi-permeable membrane across which solutes move down their concentration gradients and tissue fluid moves down its osmotic gradient, expanding the volume of the peritoneal fluid during it's 'dwell time'. This fluid is then run out of the infant and the cycle is repeated. The technique is usually well tolerated, particularly in infants who are on mechanical ventilation (the increased work of breathing from limitation of movement of the diaphragm is less of a problem than when the infant is breathing spontaneously) and the technique has proved useful in infants who have undergone cardiac surgery [40].

Recent abdominal surgery is a strong relative contra-indication to peritoneal dialysis, and so the technique has a very limited applicability in surgical infants.

12.5.2 Haemofiltration

In this technique, part of the infant's cardiac output is directed through an extra-corporeal circuit where the blood undergoes ultrafiltration through a synthetic semi-permeable membrane, the ultrafiltrated plasma being partly or wholly replaced with crystalloid solution. Originally, blood was taken from the arterial side of the circulation and returned to a large vein, but nowadays blood is usually taken and returned to the circulation via a double-lumen intravenous line and is pumped around the circuit by a roller-pump. As with dialysis, the technique involves a degree of anticoagulation and the relative size of the circuitry (150–300 mL) compared to the blood volume of the patient (150–400 mL) necessitates both that the circuit is primed with autologous blood and that nursing management of the circuit is impeccable. Haemofiltration provides the best management of the fluid overloaded patient, and is usually the technique used for surgical infants, but the technical challenges of line insertion and maintenance can be very exacting in infants of less than 2 kg [41].

For smaller infants, renal support usually consists of maintaining renal perfusion as best as one can (inotropic and vasodilatory support,) avoidance of further renal insult (aminoglycosides, NSAIDs, X-ray contrast media) and managing the problems of fluid overload with a judicious combination of mechanical ventilation, limitation of input and diuretics while waiting for spontaneous recovery of kidney function.

12.6 Nutritional Support

Babies have less in the way of nutritional reserves than do older children and adults. Premature infants have even less reserve and so infants, and especially premature infants, need nutritional support early. A newborn infant has an energy requirement of 100–120 kcal/kg/day (compared to a young adult's 30–40 kcal/kg/day). Two fifths of this energy is required for maintenance metabolism and the same amount again is required for growth. One fifth of the energy intake is accounted for by the cost of enteral absorption and excreted losses. Thus a parenterally-fed, incubated infant needs only 80–100 kcal/kg/day.

Unlike adults, infants show an immediate (within hours), brief (return to baseline after 24 h) and modest (20–30%) increase in energy requirements following quite major surgery [42].

Critically ill infants suffer fewer infective and immunological problems and generally do better if they are enterally fed rather than receiving their nutrition intravenously. However, it is often difficult, or even impossible, to achieve this seemingly straightforward goal in clinical practice. Enteral nutrition may be precluded by intestinal obstruction from a congenital lesion. There is often a degree of malabsorption. This may be relatively modest—gut dysmotility commonly accompanies both surgery and critical illness—or it may be very severe as when the bowel is very slowly recovering from necrotizing enterocolitis or when extensive bowel resection has reduced the absorptive surface area to a critical minimum.

There has been an increasing appreciation of the immunological and anti-infective benefits of maintaining some enteral nutrition—such as will maintain small bowel villous integrity—in virtually all circumstances even when it is of no effective nutritional value [43]. Thus some 'trophic feeding' should be maintained, even when 'large gastric aspirates' and vomiting are real practical problems. Because infants have limited nutritional reserves, parenteral nutrition is required when enteral feeding is likely to be significantly compromised for 48 h or more, but the default position should be to have some enteral feeding whenever possible and to make the transition from parenteral to enteral nutrition as quickly as possible as gut function returns.

It is generally accepted that expressed breast milk is the best enteral feed for infants. On occasion, (e.g. disaccharide intolerance, fat malab-

sorption) then specific formula feeds are required (soy-based disaccharide free, medium chain triglyceride (MCT) formulae). Very severe malabsorption sometimes requires elemental (amino acid, glucose, MCT) or near-elemental (containing dipeptides rather than individual amino acids) feeds [44]. These solutions have a high osmolarity and frequently produce diarrhoea and a form of dumping syndrome. They usually have to be given as slow, continuous, pump feeds.

The way that feeds are given is important. Bolus feeding is more physiological and appears to maintain gut motility, the enterohepatic circulation of bile acids and gall bladder activity [45]. However continuous pump feeds guard against hypoglycaemia, and are often required because of poor absorption or gastro-oesophageal reflux.

When intravenous feeding is required, the tailored formula contains carbohydrate, fats, electrolytes, protein, micronutrients and water. Sufficient amino acids are provided to allow for protein turnover and growth but caloric requirements are met by the lipid and carbohydrate components. If more glucose is given that the infant can utilise, then this is converted to fat. Such lipogenesis has two undesirable features; it increases carbon dioxide production and so increases the work of breathing, and newly synthesized fat may be deposited in the liver.

If, however the amount of glucose given is less than the daily caloric requirement and the caloric deficit is made up with intravenous lipid, then the lipid is oxidised rather than being stored. Giving some of the caloric requirement as fat provides essential fatty acids and increases the efficiency of energy use. It also reduces protein breakdown.

Infants require about 3 g of protein per day. In parenteral nutrition solutions, this protein requirement is given as a mixture of essential amino acids. The exact composition varies; there have been vogues for increasing the content of one or other amino acids to optimise growth or to obtain other benefits. Presently, glutamine supplementation is under investigation. Glutamine is not very soluble and so was not used in many commercial parenteral nutrition solutions. There are studies in animals and adult patients which suggest that glutamine supplementation may help gastro-intestinal function, but large-scale trials are lacking [46].

12.7 Sedation

Adults and older children are able to report their distress at receiving intensive care and there is no good reason to suppose that neonates would enjoy the experience any more than their older brethren. This notion that neonates should be provided with sedation and analgesia has come to be accepted over the last 40 years or so. The primary purpose of giving sedation to neonates undergoing mechanical ventilation and other unpleasant procedures on an intensive care unit is humane consideration, though other benefits may accrue. Good sedation is not physiologically 'cost-free' either in terms of obvious depression of the cardiovascular or respiratory systems or less obvious alterations of the endocrine and immune systems. Sedation for an appreciable length of time often gives rise to a withdrawal syndrome characterised by agitation and autonomic features.

A distinction should be made between analgesia and sedation. Sedation is always given systemically–usually with intravenous drugs, but analgesia may well be best provided using regional techniques such as an epidural or paravertebral block. At other times systemic analgesia (intravenous opioids) may provide sufficient sedation as to allow good toleration of tracheal intubation and mechanical ventilation.

For most infants, induction of sedation (more accurately, induction of anaesthesia) is a prerequisite for intubation of the trachea and establishment of access and cardiovascular monitoring lines. There is a clear role for muscle relaxant (paralysing) drugs at this stage, but thereafter it usually the case that relaxants can be allowed to wear off and sedative drugs alone are given in sufficient quantity as to allow compliance with ventilation. Very occasionally, usually when faced with profound hypoxic respiratory failure, complete muscle paralysis is necessary, but it

should only be done after doing everything possible to ensure lack of awareness.

As with much else in paediatric intensive care, the adequate clinical trial base for sedation practice is small and clinical experience has to be relied on more than is readily comfortable.

'Standard sedation' for paediatric intensive care units in the UK has been a combination of an opiate (typically morphine or fentanyl) and a benzodiazepine—usually midazolam [47] and this combination is often used for surgical neonates.

Midazolam (a water-soluble, short-acting benzodiazepine) in doses of 50–100 μg/kg/h is an effective sedative and has the great advantage of having little depressant effect on the cardiovascular system when given by infusion. It is so widely used that it is disconcerting that a recent Cochrane review felt that it could not be recommended for use in premature infants, because the few small trials that have examined the use of midazolam in such infants have identified higher instances of complications in the midazolam group [48].

Clonidine (an α-adrenoceptor agonist) has come to be seen as an alternative to midazolam in paediatric intensive care practise. A recent attempt to compare midazolam and clonidine in a randomised controlled trial was unable to give a definitive answer [49].

Opiates are the most commonly used agents given to facilitate mechanical ventilation in premature infants. Morphine is the most commonly used drug. It is metabolised, in the liver and elsewhere, by two forms of glucuronidation. Morphine-6-glucuronide is active and its excretion is reduced in renal impairment, potentiating the action of the drug. Newborn infants tend to form morphine-3-glucuronide which is pharmacologically inactive. Metabolism of morphine shifts towards the adult pattern (predominantly morphine-6-glucuronide)within a few months of life [50]. Advocates of fentanyl see its lack of histamine release as an advantage in avoiding cardiovascular depression. In theory, constantly infused remifentanil, which is rapidly metabolised by non-specific esterases in blood and so does not rely on unpredictable hepatic or renal metabolism for its elimination, should be a good drug to use in neonates, as its effects dissipate quickly even after prolonged infusion. At present, routine use of remifentil would be expensive. Infants develop tolerance to opiates, and many authorities think that this happens quickly with fentanyl and remifentanil.

A variety of other enterally given sedative agents are commonly used (either alone or more usually in combination with intravenous analgesics). These enteral drugs include promethazine, trimeprazine, triclofos and chloral hydrate. As gut absorption is often poor during critical illness, the effects of these drugs may be variable.

Over the past decade there has been increasing awareness of the problem of withdrawal syndromes (agitation, seizures, sweating, vomiting) following discontinuation of opiates and other sedative drugs, particularly midazolam. Various strategies have been tried to reduce the incidence and severity of such withdrawal effects, including tapering of dosages of drugs, prospective cycling of combinations of sedatives and analgesics and substitution of sedative drugs (particularly with drugs such as clonidine which can be given both intravenously and enterally). Overall, the question of sedation continues to pose problems, and it appears to be particularly resistant to disentanglement by randomized clinical trial. The views of physicians, nurses and parents on sedation may be varied, but they seem, invariably, to be firmly held.

12.8 Some Aspects of Intensive Care for Particular Conditions in Neonatal Surgery

With virtually all lesions, the greatest challenges and ethical dilemmas are thrown up by the occurrence of the lesion in an infant who has been born very prematurely or who has other co-existing problems. There are few, if any, hard and fast rules left to guide one as to what is possible, still less as to what is right, and the importance of honest communication between all those involved in the care of a particular infant cannot be over-emphasised.

12.8.1 Necrotizing Enterocolitis (NEC)

This disease is strongly associated with prematurity, thus the main practical problems usually relate to the size of the infant. Infants with severe necrotising enterocolitis are likely to present for intensive care because of a degree of septic shock. Increased vascular permeability means that fluid therapy that is sufficient to maintain the circulation almost invariably produces a degree of pulmonary and systemic oedema which exacerbates the cardio-respiratory failure that is already present. Treatment of this fluid overload is usually at the limits of what can be achieved from mechanical ventilation, adjustment of fluid intake and diuretic therapy but haemofiltration is often fraught with concerns about lines being too large to allow adequate limb perfusion or the infant's circulation being able to cope with the whole process. Most intensivists have little doubt that the placement of percutaneous lines in such infants for monitoring, giving parenteral nutrition and intravenous drugs has been facilitated by the increasing availability and use of ultrasound control for vascular access procedures.

12.8.2 Congenital Diaphragmatic Hernia (CDH)

There has been increasing appreciation that the main problem for an infant with CDH is the degree of lung hypoplasia present. The task for the intensivist is to add as little as possible to the burden of problems for the infant's lungs. The aims are to avoid injurious effects of mechanical ventilation, attenuate the problem of pulmonary hypertension as much as possible and to minimise problems of infection.

Most infants with CDH are intubated and started on mechanical ventilation at birth. The principles of low tidal volume, high end-expiratory and low peak airway pressure ventilation with permissive hypercapnoea are followed. Common targets are to obtain a pre-ductal oxygen saturation of greater than 85% with an arterial pH of greater than 7.35, but with a peak inspiratory pressure of less than 25 cmH_2O High frequency oscillatory ventilation is often used if these targets cannot be met with conventional ventilation. Centres reporting good results with HFOV for diaphragmatic hernia stress the importance of keeping mean airway pressure as low as possible (<20 cmH_2O).

HFOV is a means of avoiding injurious ventilation in these infants rather than rescue therapy for hypoxia and hypercapnoea [51].

All infants see a decrease in their pulmonary vascular pressures over the first hours and days of their extra-uterine life, but characteristically this fall in pulmonary vascular resistance can be interrupted or reversed if the infant is subjected to a significant physiological insult. Pulmonary hypertensive crises may manifest as episodes of arterial oxygen desaturation. Other than very rare instances of direct pulmonary arterial pressure measurement, quantification of pulmonary hypertension is usually by means of signs of tricuspid regurgitation seen on Doppler echocardiography.

In infants with CDH, the fall in pulmonary vascular resistance is delayed and the infant is prone to pulmonary hypertension.. Surgery for repair of the hernia often exacerbates the respiratory failure seen in this condition. It has become accepted practice to delay surgical repair until there is evidence both of satisfactory ventilation (low inspiratory pressures and oxygen requirements) and of lowered pulmonary vascular pressures (no right-to-left shunt on echocardiographic assessment).

In the past, treatment of pulmonary hypertension in these babies was principally by manipulation of mechanical ventilation so as to try to maintain a near-normal arterial carbon dioxide to avoid respiratory acidosis. Now, with the primacy of avoiding injurious ventilation, pulmonary vasoconstriction is opposed by the use of inhaled nitric oxide as a specific pulmonary vasodilator. Prostacyclin is sometimes used as second-line therapy for this purpose. Inhaled nitric oxide therapy for CDH infants is widely practiced but the results of randomised trials of iNO in such infants show no marked effect on outcome [52]. However, the widespread adoption of the combi-

nation of 'gentler' ventilation and nitric oxide therapy as standard therapy has coincided with improved survival figures [53].

12.8.3 Oesophageal Atresia/Tracheo-Oesophageal Fistula (OA/TOF)

There have been reports of successful management of infants with OA/TOF using regional anaesthetic techniques to obviate post–operative mechanical ventilation [54], but in most cases infants are ventilated immediately following surgery when pain is likely to be at its worst and analgesic requirements greatest. A particular problem in infants with these conditions is tracheobronchomalacia.

Tracheobronchomalacia commonly presents as either difficulty in reducing the level of respiratory support as mechanical ventilation is reduced or as a 'failure of extubation'. As the index of suspicion for this condition has risen in the past decades, so its incidence has increased. It is also recognised as occurring in association with congenital cardiovascular anomalies and an acquired form of the disease may arise after severe tracheobronchial inflammation or after formation of a tracheostomy.

The diagnosis is usually made by a combination of bronchoscopy and bronchography. Flexible fibreoptic bronchoscopy via the endotracheal tube may be performed at the bedside on PICU and bronchography is best performed using a biplanar fluoroscopy unit. In both cases it is important to maintain spontaneous ventilation of the infant to demonstrate dynamic collapse of the trachea. The stenting effect of the endotracheal tube is minimised by carefully withdrawing the tube to the immediate subglottic region. The two investigations are complementary [55].

There is controversy as to how tracheobronchomalacia is best treated. The traditional view has been that tracheobronchomalacia tends to improve spontaneously over a time course of months/years and so there has been a school of thought that infants with severe tracheobronchomalacia should undergo a tracheostomy followed by whatever degree of 'pneumatic stent' is required (varying from nothing, through a continuous positive airways pressure circuit (CPAP) to actual long-term ventilation of the lungs pending resolution of the condition.) This approach involves a very protracted hospital stay, (many, many months if long-term ventilation is required) is labour intensive, and carries all the risks inherent in managing a infant with a tracheostomy.

Thus there are many advocates of taking a different course in an effort to avoid tracheostomy. This usually entails the operation of aortopexy-securing the anterior surface of the ascending aorta to the posterior surface of the sternum, with the effect of pulling the anterior wall of the trachea forwards, helping to maintain tracheal patency throughout the respiratory cycle. Various techniques of aortopexy have been described, including thoracoscopic procedures; usually in short case series, and usually with very good results. A recent single-centre retrospective study, looking at infants and children who had undergone aortopexy, suggested that the procedure was effective in over 80% of cases [56]. Nonetheless, a diagnosis of severe tracheobronchomalacia in infancy, particularly if there are significant co-morbidities, is still associated with a heavy burden of treatment and significant mortality.

12.8.4 Abdominal Wall Defects (Gastroschisis and Exomphalos)

The majority of infants undergoing primary repair of abdominal wall defects will receive a short period of post operative mechanical ventilation and cardiovascular monitoring. This may be extended as appropriate for infants undergoing staged repair with a silo. The challenge for intensive care comes with infants with giant (liver-out) defects with severe viscero-abdominal disproportion. Having the resources to be able to offer days of mechanical ventilation allows consideration of traction-compression-closure as a technique for treating such infants [57]. Infants with giant exomphalos point up many of the challenges and dilemmas of paediatric surgical intensive care:

consideration of multiple co-morbidities, each individually treatable, but possibly insurmountable in their totality, the necessity for prolonged, meticulous, system support in the face of the threat of sepsis, and the flexibility to improvise or extend techniques to the treatment of the smallest patients.

Infections and Antibiotic Therapy in Surgical Newborn Infants

13

Hendrik K.F. van Saene, Nia Taylor, Shijie Cai, Nicola Reilly, Andy Petros, and Stephen C. Donnell

Abstract

Colonisation of the gastro-intestinal tract of newborn infants starts immediately after birth and occurs within a few days. Initially, the type of delivery (passage through the birth canal versus caesarean section) and the type of diet (breast versus formula feeding) might affect the colonisation pattern. Nearly all full-term, formula-fed, vaginally delivered infants were colonised with anaerobic bacteria within 4–6 days. 61% harboured *Bacteroides fragilis*. In contrast, anaerobes were present in 59% and *B. fragilis* in only 9% of infants delivered by caesarean section, suggesting that significant contamination occurred during passage through the birth canal. Both prematurity and breast feeding reduced the likelihood of isolating anaerobic species. Enterococci were isolated from all neonates, *Escherichia coli* from 82.6%, anaerobic cocci from 52.2% and both streptococci and staphylococci from 34.8%. Colonisation of the small bowel occurs perorally. In newborn infants with congenital small bowel obstruction, a faecal-type flora is found immediately proximal to the site of obstruction, and the distal bowel remains sterile.

13.1 Pathogenesis of Infections: Gut Overgrowth

13.1.1 Introduction: Flora Development in the Neonate

Colonisation of the gastro-intestinal tract of newborn infants starts immediately after birth and occurs within a few days. Initially, the type of delivery (passage through the birth canal versus caesarean section) and the type of diet (breast versus formula feeding) might affect the colonisation pattern. Nearly all full-term, formula-fed, vaginally delivered infants were colonised with anaerobic bacteria within 4–6 days. 61% harboured *Bacteroides fragilis*. In contrast, anaerobes were present in 59% and *B. fragilis* in only 9% of infants delivered by caesarean section, suggesting that significant contamination occurred during passage through the birth canal. Both prematurity and breast feeding reduced the likelihood of isolating anaerobic species. Enterococci were isolated from all neonates, *Escherichia coli* from 82.6%, anaerobic cocci from 52.2% and both streptococci and staphylococci from 34.8% [1]. Colonisation of the small bowel occurs perorally. In newborn infants with congenital small bowel obstruction, a faecal-type flora is found immediately proximal to the site of obstruction, and the distal bowel remains sterile [2].

Other environmental factors also have a major role since differences exist between infants from different hospital wards. Critical illness predisposes surgical neonates to acquisition and subsequent carriage of abnormal aerobic Gram-negative bacilli (AGNB) and methicillin-resistant *Staphylococcus aureus* (MRSA). These abnormal bacteria are most often transmitted amongst neonates via the hands of health care workers (HCW) [3].

13.1.2 Definition

The fundamental pathophysiological event in the surgical neonate is gut overgrowth. Gut overgrowth can be conveniently defined as abnormal bacteria in abnormal concentrations at an abnormal site. More scientifically, gut overgrowth is defined as $\geq 10^5$ AGNB and/or MRSA per ml of digestive tract (small intestine) secretion [4].

13.1.3 Four Harmful Side-Effects

Gut overgrowth harms the surgical neonate in four main ways:

1. Immunosuppression—overgrowth of abnormal AGNB (and associated endotoxin) has been shown to impair systemic immunity due to generalised inflammation following absorption of AGNB and/or endotoxin [5];
2. Inflammation—overgrowth of abnormal AGNB and/or endotoxin has been shown to lead to cytokinaemia and inflammation of major organ systems [6];
3. Infection—there is a quantitative relationship between surveillance and diagnostic samples. As soon as there is overgrowth in surveillance samples the diagnostic samples become positive which is the first stage in the development of infection [7];
4. Resistance—the abnormal carrier state in overgrowth concentrations guarantees increased spontaneous mutation leading to polyclonality and antibiotic resistance [8].

Selective decontamination of the digestive tract (SDD) is a prophylactic measure using selected antimicrobials to control gut overgrowth thereby reducing the four harmful side effects of it. Immunosuppression was reverted to normality in patients who were successfully decontaminated [9]. Patients free from AGNB overgrowth were able to control generalised inflammation [10]. SDD has been shown to control severe infections of lower airways and blood, to reduce mortality without resistance emerging [11].

13.1.4 Risk Factors

1. Critical illness related carriage in overgrowth concentrations (CIRCO) is common on admission [12]
2. CIRCO often develops during treatment on ICU [13]
   Drugs including opiate analogues [14], H_2 antagonists [15, 16] and antibiotics [17] promote gut overgrowth of potential pathogens following the impairment of gut motility, the

increase in gastric pH of ≥4, and the suppression of the indigenous anaerobic flora required for colonisation resistance, respectively.

13.1.4.1 Diagnosis

The traditional microbiological approach of obtaining and culturing diagnostic samples such as tracheal aspirate, blood and urine can never detect gut overgrowth, as these samples only confirm the clinical diagnosis of infection. Surveillance samples of throat and gut are the only samples that allow the detection of overgrowth [18].

13.2 Prevention

13.2.1 Surgical Prophylaxis

All neonates undergoing operations classified as potentially contaminated, contaminated or 'dirty' were given 48 h of antibiotic prophylaxis in the form of cefotaxime and metronidazole [19]. Infants with suspected central venous line-related blood stream infections were prescribed teicoplanin and gentamicin initially, pending blood culture results [20]. The standards of hygiene recommended by the Centres of Disease Control (CDC) were used [21].

13.2.2 Early Enteral Feeding

A period of starvation ('nil by mouth') is common practice after gastro-intestinal surgery during which an intestinal anastomosis has been formed [22]. The stomach is decompressed with a nasogastric tube and parenteral nutrition is given, with oral feeding being introduced as gastric dysmotility resolves. The rationale of 'nil by mouth' is to prevent post-operative nausea and vomiting and to protect the anastomosis, allowing it time to heal before being stressed by food. It is, however, unclear whether deferral of enteral feeding is beneficial.

Contrary to widespread opinion, evidence from clinical studies directly comparing strategies of early feeding with 'nil by mouth' after elective gastro-intestinal surgery, suggests that initiating feeding early is advantageous. Eleven studies with 837 patients who met the inclusion criteria have been meta-analysed [22]. Early feeding reduced the risk of any type of infection (relative risk 0.72, 95% confidence interval 0.54–0.98, p = 0.036) and the mean length of stay in hospital (number of days reduced by 0.84, 0.36–1.33, p = 0.001). Risk reductions were also seen for anastomotic dehiscence (0.53, 0.26–1.08, p = 0.080), wound infection, pneumonia, intra-abdominal abscess, and mortality, but these failed to reach significance. The risk of vomiting was increased among patients fed early (1.27, 1.01–1.61, p = 0.046). There seems to be no clear advantage to keeping patients nil by mouth after elective gastro-intestinal surgery. Early feeding may be of benefit. The significantly reduced risk of infection following early feeding may be due to the control of overgrowth achieved in patients who received early enteral feeding.

13.2.3 Enteral Antimicrobials: SDD

Recently, four studies with 355 children who met the inclusion criteria for randomisation have been meta-analysed [23]. Pneumonia was diagnosed in 5 of 170 children (2.9%) for SDD and 16 of 165 patients (9.7%) for controls (odds ratio, 0.31; 95% confidence interval, 0.11–0.87; p = 0.027). There was no difference in overall mortality. The significant reduction in infectious morbidity is highly likely due to overgrowth control, and the sample size was too small to impact survival for a paediatric mortality varying between 5 and 10%. A recent French Consensus Conference recommends SDD as pneumonia prophylaxis in critically ill children [24].

13.3 Treatment

Shankar was the first to classify infections in surgical new born infants, using the carrier state [25]. Out of a total of 167 infants, 21 infants (15%) had 33 episodes of infection. The predominant infecting micro-organism was *Staphylococcus aureus* (n = 11), others were enterococci, coagulase negative staphylococcus, *Candida* spp., AGNB and

anaerobes. A total of 27 out of 33 infective episodes (82%) were caused by micro-organisms carried by the infants on admission (primary endogenous). Only six (18%) infections were caused by micro-organisms acquired in the unit: three secondary endogenous infections (micro-organisms not present in the admission flora, but acquired and carried later on during treatment on the unit) and three exogenous infections (not preceded by previous carriage). The micro-organisms causing infections were mostly low level pathogens such as coagulase-negative staphylococci, enterococci and anaerobes. 'Normal' potential pathogens included *S.aureus* and *Candida* spp. Only two infections were caused by 'abnormal' flora, and the responsible micro-organisms were *Klebsiella* and MRSA causing one secondary and one exogenous infection each. Bloodstream and wound infections were the two main infection types in the surgical newborn infants. Lower airway infections were not diagnosed, highly likely because none of them were mechanically ventilated.

The pathogenesis of practically all infections is endogenous in surgical new born infants [26–29]. The same pathogenesis applies to all types of micro-organisms whether they are low level or potential pathogens both normal and abnormal. If the surgical new born infant was admitted immediately after delivery the pathogens are low level and 'normal' such as *Escherichia coli*, *S.aureus* and *Candida* species. If the patient is admitted from another hospital, or has been treated on the surgical neonatal unit, the abnormal pathogens such as AGNB and MRSA may be carried by the new born infant apart from low level and normal pathogens.

13.4 Septicaemia

Septicaemia [11] is defined as sepsis (i.e. clinical picture caused by generalised inflammation due to micro-organisms and/or their toxic products) combined with a positive blood culture. Once the diagnosis of sepsis has been made and blood cultures taken, immediate antibiotic combination therapy should be started in order to provide an adequate spectrum of antimicrobial therapy. This is a combination of an aminoglycoside with cefotaxime. If an intra-abdominal focus is suspected, metronidazole and amphotericin B are added to this treatment. Initial empirical therapy is adjusted according to diagnostic culture results. The source of sepsis should be identified and eliminated as soon as possible. SDD using enteral polymyxin/tobramycin/amphotericin B should be commenced immediately to eradicate the internal source [11].

13.5 Wound Infection

Clinical signs of wound infection [11] are purulent discharge, redness, swelling, tenderness, and local warmth. The clinical diagnosis is microbiologically confirmed by isolating $\geq$3+ or $\geq 10^5$ micro-organisms from the purulent discharge in which $\geq$2+ leukocytes can be seen. Systemic antimicrobial therapy is seldom indicated, unless symptoms of sepsis occur. Local treatment, drainage, debridement, and removal of plastic devices are essential and generally sufficient. Following treatment, the wounds are rinsed twice daily with a disinfectant, 2% taurolin, for 3 days. Aquaform gel mixed with 2% polymyxin/tobramycin/amphotericin B and/or vancomycin can be applied to colonised/infected wounds [11].

13.6 Control of Antibiotic Resistance

The two potential pathogens that display antimicrobial resistance are AGNB producing extended spectrum beta-lactamase (ESBL) and MRSA.

Available parenteral antimicrobials with good activity against many resistant potential pathogens include the carbapenems and cefepime [30]. The enteral antimicrobials polymyxin/tobramycin need to be added to the parenteral antimicrobials, to eradicate gut overgrowth that promotes polyclonality and resistance [31]. Compounds directed against resistant Gram-positive bacteria include streptogramin combinations such as quinupristin/dalfopristin and linezolid. Similarly, enteral vancomycin needs to be added to the parenteral anti-

microbials active against Gram-positive bacteria to control gut overgrowth.

Fetal Surgery

14

Alan W. Flake and N. Scott Adzick

Abstract

Maternal fetal surgery for correction of an anatomic defect was first performed 30 years ago by Michael Harrison. At that time, the concept of the fetus as a patient was the subject of philosophical and ethical debate and the rationale and pre-requisites for prenatal surgical treatment were in evolution. Over the past three decades, the concept of the fetus as a patient has become commonly accepted and the ethical framework for maternal fetal intervention is now well developed. Improvements in prenatal diagnosis now provide certainty for the primary diagnosis and, in competent hands, can identify or exclude virtually all significant associated anomalies. Clinical experience with prenatally diagnosed fetuses has provided insight into the natural history of specific anomalies, improved our ability to predict the outcome for an individual fetus, and allowed more accurate selection of fetuses that will benefit from prenatal surgery. While application of open fetal surgery has remained limited to only a few anomalies, it is important to appreciate that the development of this field has accelerated

Fetal surgery • Birth defects • Fetus • Outcomes

Maternal fetal surgery for correction of an anatomic defect was first performed 30 years ago by Michael Harrison [1]. At that time, the concept of the fetus as a patient was the subject of philosophical and ethical debate [2] and the rationale and pre-requisites for prenatal surgical treatment were in evolution. Over the past three decades, the concept of the fetus as a patient has become commonly accepted and the ethical framework for maternal fetal intervention is now well developed [3]. Improvements in prenatal diagnosis now provide certainty for the primary diagnosis and, in competent hands, can identify or exclude virtually all significant associated anomalies. Clinical experience with prenatally diagnosed fetuses has provided insight into the natural history of specific anomalies, improved our ability to predict the outcome for an individual fetus, and allowed more accurate selection of fetuses that will benefit from prenatal surgery. While application of open fetal surgery has remained limited to only a few anomalies, it is important to appreciate that the development of this field has accelerated technological progress in prenatal diagnosis and intervention, led to improved understanding of the pathophysiology and natural history of candidate disorders, allowed comprehensive counseling of prospective parents in centers with focused expertise in fetal anomalies, and driven the evolution of less invasive therapeutic approaches. In this chapter we will discuss the rationale and current indications for open fetal surgery, the evidence supporting its efficacy, and basic physiologic and technical considerations common to all fetal surgical interventions.

14.1 Rationale and Foundation for Fetal Surgery

Observations by clinicians of neonates with specific anatomic defects born with secondary irreversible organ damage led to the conclusion that the damage occurred before birth and the compelling rationale that the only way to prevent that damage, was to correct the defect by fetal intervention. This led to experimental validation of the pathophysiology of specific fetal defects in the lamb model and to the development of techniques for their prenatal surgical correction [4–6]. Finally, pre-clinical studies in the primate model defined the anesthetic, tocolytic, and technical methods and devices [7] that proved essential for clinical translation [8–10]. Ultimately, these efforts supported the first systematic clinical application of fetal surgery in the early 1980's.

The pre-requisites for fetal surgery were developed during this formative period and, with slight modification, still apply today (Table 14.1). However, with advances in prenatal diagnosis, increased prenatal experience, and technical progress in fetal surgery, our ability to meet these

Table 14.1 Prerequisites for fetal surgery

• Accurate Prenatal Diagnosis
• No Associated Anomalies
• Defined Natural History
• Correctable Lesion Leading to Fetal Death or Organ Destruction
• Technical Feasibility

criteria for specific anomalies has improved dramatically. For instance, the requirement for an accurate prenatal diagnosis and the exclusion of associated anomalies is now practically taken for granted. The armamentarium for examining the fetus in the womb, including high resolution ultrasound (2D, 3D and 4D), haste MRI, and fetal echocardiography, when expertly applied, are capable of detecting essentially any significant fetal structural anomaly. When combined with maternal serum screening, karyotype analysis, and molecular diagnostic techniques, the likelihood of missing an associated anomaly or performing an intervention on an unrecognized syndromic fetus has been dramatically reduced. In addition, with accumulated experience and normograms for many fetal parameters, the limits of normality and abnormality have been clarified, allowing appropriate interpretation of normal variation (for instance, minimal renal pelviectasis). The presumed pathophysiology of specific anatomic defects has been confirmed either in animal models when possible, or by clinical observation, and the ability to reverse the pathophysiology by fetal surgical correction has been validated. Finally, significant progress in our ability to safely operate on the mother and her fetus has been made. Advances in the technical aspects of fetal intervention, maternal anesthesia, tocolysis and the accumulation of clinical experience have evolved to the point where open fetal surgery can be performed in experienced centers with a minimum of maternal morbidity, and to this date no maternal mortality [11]. Nevertheless, fetal surgical interventions have until recently been limited to fetal anomalies perceived to be lethal because of the potential risk of this major surgical procedure to the usually young, healthy mother. The fetal surgical treatment of myelomeningocele (MMC), a non-lethal disorder, has extended the original pre-requisites for fetal surgery to disorders causing irreversible organ damage with associated quality of life impacting morbidities prior to birth.

Despite this progress, fetal surgery remains controversial. The controversies primarily relate to our understanding of the "natural history" of specific anomalies, and whether we can accurately select fetuses that will benefit from fetal intervention. Our knowledge of the natural history of many disorders without fetal treatment has improved allowing accurate selection of fetuses that might benefit from fetal intervention. The natural history of Congenital Pulmonary Airway Malformation (CPAM), fetal Sacrococcygeal Teratoma (SCT), and Lower Urinary Tract Obstruction (LUTO) for instance, are relatively well understood. However, the natural history remains controversial for Congenital Diaphragmatic Hernia (CDH) and cardiac outflow tract anomalies making interpretation of the results of fetal therapy more difficult. The importance of randomized controlled trials (RCT) to resolve these controversies cannot be overemphasized and the design and implementation of such trials is a current focus for fetal treatment centers [12, 13]. Challenges in performing RCTs include the rarity of appropriate subjects, ethical challenges, and the resources required for organization, financing, and impartial evaluation of results obtained. The future of fetal intervention depends upon developing evidence based support for fetal interventional procedures which will be a major focus in coming years.

Currently, there is a relatively limited list of fetal anomalies for which a compelling rationale exists for fetal intervention. Anatomic anomalies that are currently treated by fetal intervention and their associated pathophysiology are shown in Table 14.2. However, there are basic considerations common to all fetal surgery that will be discussed as a basis for discussion of specific anomalies.

Table 14.2 Anatomic anomalies treated by fetal intervention

Anomaly	Pathophysiologic consequences	Fetal treatment
Cystic adenomatoid malformation	Hydrops; Lung hypoplasia	Open surgery or Thoracoamniotic shunt
Sacrococcygeal teratoma	High output cardiac failure	Open surgery; Tumor debulking
Myelomeningocele	Spinal chord damage; Brain stem compression; Hydrocephalus	Open Surgery; Defect closure

14.2 Basic Considerations that are Common to all Open Fetal Surgery

14.2.1 Ethical Considerations and Preoperative Management

Fetal surgery is unique in its involvement of a healthy patient who undertakes considerable surgical risk without expectation of direct benefit, creating a unique subset of ethical concerns. Such concerns have been explored and an ethical framework has been well established [14]. In general, the fetus achieves independent moral status as a patient once he/she reaches the point of viability. The pre-viable fetus, then, is a patient only when the pregnant woman chooses to continue her pregnancy and presents for treatment on behalf of her fetus. For the eligible fetus, the risks of such a procedure are clearly offset by the considerable benefit of salvage, but the fetus cannot be considered to be an independent or autonomous decision-maker, and the beneficence-based obligation to the fetus must be balanced with both beneficence-based and autonomy-based obligations to the mother. Thus, the fetus is not a separate patient, and maternal safety is a primary concern in considering fetal intervention.

Furthermore, the mother is under no obligation to present her fetus for treatment, and she must be provided all necessary information for truly informed consent. The treatment team has a responsibility to consider the risks to the mother in the context of the likelihood of fetal loss or severe, reversible disability. For this reason, both fetal and maternal factors can be contraindications to open fetal surgery, including chromosomal abnormalities, significant anatomic abnormalities, maternal obesity, heavy smoking history or other medical conditions. Patient selection should take place through multidisciplinary evaluation following a screening process including detailed ultrasonographic examination for characterization of the defect and any other abnormalities, ultra-fast fetal MRI for anatomic definition, fetal echocardiogram to assess heart function and detect any cardiac abnormality, and karyotyping and/or more high resolution genetic analysis. Following this evaluation, cases should be reviewed by a multidisciplinary team of fetal surgeons, obstetricians, anesthesiologists, radiologists, a nurse coordinator, geneticist, and social workers.

Eligible families must undergo extensive counseling to discuss the proposed surgical procedure, postoperative and postnatal care. A team meeting provides an appropriate forum for the family to learn about the procedure and its risks, benefits and alternatives. Depending upon gestational age, all appropriate options should be discussed in a non-directive manner, including termination, expectant management with palliative or best available postnatal treatment, and prenatal therapy. Parents must understand the likely outcomes of all possibilities, as well as the risks involved. For any fetal surgery, complications may include preterm labor, premature rupture of membranes, chorioamnionitis, uterine rupture, medication side effects, risk of fetal demise, as well as surgical complications and future reproductive issues. The mother must be counseled regarding the need for caesarean section in this and all future pregnancies, and care must be taken to “allow” families to opt for non-surgical management.

14.2.2 General Principles of Open Fetal Surgery

14.2.2.1 Personnel and Equipment

Care of the fetal surgery patient requires a multidisciplinary team with clearly defined roles, as well as highly specialized equipment. Because the mother and fetus have separate, though co-dependent anesthetic concerns, both an obstetric anesthesiologist and a pediatric anesthesiologist are necessary. A sonographer and an echocardiographer should be an integral part of the surgery team, and a high-resolution ultrasound machine with color Doppler should be used to identify fetal and placental anatomy and to assess for potential hazards such as velamentous cord insertion. Ultrasound images before and after maternal incision are used to select the optimal site for hysterotomy. During the procedure, continuous echocardiography should be used in combination with pulse oximetry, when possible, to monitor fetal heart rate, cardiac function, and volume status. An OR nursing team trained in fetal surgical procedures and familiar with the specialized instrumentation is of critical importance. The surgical team should be led by a pediatric surgeon or a perinatologist with specific training in fetal surgical techniques. In our institution, two pediatric surgeons with experience in all aspects of fetal therapy are scrubbed on all fetal surgical procedures, to assure maximal expertise with these uncommon procedures.

14.2.2.2 Anesthesia

Patients should be admitted prior to the planned procedure for monitoring and initiation of tocolysis with Indomethecin. Antibiotics should also be administered preoperatively to decrease the risk of maternal complications and chorioamnionitis. At the time of the procedure, anesthetic management should be initiated with placement of an epidural catheter to assist in both intra-operative and post-operative pain management. Typically, a Fentanyl/Bupivicaine mixture provides optimal pain control and reduces uterine irritability. General anesthesia is induced with inhalational agents, generally at a MAC of 2–2.5, sufficient to provide uterine relaxation. Maternal monitoring should include a radial arterial line, frequent cuff pressures, multiple large bore IV catheters, a foley catheter, pulse oximetry, and continuous EKG. Fluid management strategies should be aimed at euvolemia, given the predilection to postoperative non-cardiac pulmonary edema in the pregnant patient.

14.2.2.3 Positioning and Draping

Patients should be positioned supine with a left lateral tilt provided by a roll under the right side, in order to maximize venous return by preventing inferior vena caval compression by the uterus. Skin prep should include mid-abdomen to mid-thigh, and the operative field can be squared with sterile towels and covered with a fenestrated and pocketed drape.

14.2.2.4 Incision and Exposure

In general, the uterus is exposed through a low transverse abdominal incision. Placental position may guide the fascial incision. In general, subcutaneous flaps can be raised and the fascia may be divided in the midline from the umbilicus to the symphysis pubis. For posterior placentas, a ring retractor can then be positioned for retraction of the abdominal wall. A late gestational uterus with an anterior placenta may dictate that the fascia be divided transversely to allow anterior rotation of the uterus and a posterior hysterotomy.

14.2.2.5 Opening the Gravid Uterus

Prior to hysterotomy, the uterus is palpated to determine whether sufficient relaxation has been achieved. Transuterine ultrasound is used to confirm fetal and placental position prior to hysterotomy. Under ultrasound guidance, electrocautery is used to map the placental margins on the surface of the uterus and a safe site for hysterotomy (>6 cm from the placenta) is determined, avoiding uterine vasculature. Unlike a standard caesarean section, the lower segment of the uterus is avoided due to increased risk of amniotic fluid leak, chorioamnionitis and preterm labor.

Once a site is chosen, opposing 0 PDS traction sutures are placed through the uterine wall and fetal membranes under ultrasound guidance. Using electrocautery, a 2 cm incision is made in the myometrium between the sutures and the membranes are visualized and opened in a controlled fashion. A specialized uterine stapler is then placed through the fetal membranes and the stapler is fired once in either direction. It is important to use a uterine stapler intended for fetal surgery, as it compresses the myometrium and controls the membranes to minimize blood loss during hysterotomy while maintaining membrane integrity for closure. Absorbable staples are used to avoid subsequent fertility issues. Using a Level I rapid infuser, warmed Lactated Ringer's solution is infused into the amniotic space via a catheter to maintain amniotic fluid volumes and fetal temperature, while preventing cord compression. When an extremity is available (CPAM, SCT) a fetal peripheral intravenous line is then placed for infusion of fluids, blood, or medications.

14.2.2.6 Closure of the Gravid Uterus

Proper uterine closure is critically important, as the fetus must be returned to the amniotic space in such a way as to allow gestation to continue as normally as possible. The closure must have adequate strength to prevent uterine rupture, must be watertight to prevent amniotic fluid leaks, and must not contribute to preterm labor or future infertility. A two-layer closure should be performed, using double-armed full thickness 0 PDS stay sutures approximately 2 cm apart and 2 cm back from the staple line and a running 2–0 PDS suture through myometrium and membranes. Prior to completing the running layer, approximately 400 cc of warmed Lactated Ringer's solution containing 500 mg of Oxacillin should be instilled into the amniotic cavity and adequate amniotic fluid volumes should be confirmed by ultrasound. An omental flap should be used to buttress the uterine closure, and the maternal laparotomy should be closed in layers. Skin closure should be performed with an absorbable subcuticular layer, and dressings should consist only of a transparent Tegaderm, in order to allow continued fetal monitoring by ultrasound postoperatively.

14.2.2.7 Tocolysis and Postoperative Care

Preterm labor can compromise even the most carefully conducted intervention, and adequate tocolysis is of paramount importance to the success of any open fetal surgical procedure. Preoperative placement of an epidural catheter provides analgesia once the uterine relaxing effects of inhaled anesthesia have worn off, preventing a maternal stress response and uterine irritability. Placement of an Indomethacin suppository preoperatively begins the process, and a loading dose of 6 g IV magnesium sulfate is administered during hysterotomy closure. A maintenance infusion of magnesium sulfate is continued at 2–4 g/h for 18–24 h postoperatively, and Indomethacin suppositories are placed every 6 h postoperatively through 24 h. Patients must be closely monitored for signs of magnesium toxicity and serum magnesium levels should be checked frequently during this period. In addition, daily fetal echocardiography is required to detect any signs of Indomethacin toxicity, which can manifest as ductal constriction, oligohydramnios or tricuspid regurgitation. Uterine activity is monitored by tocodynamometer, and fetal heart rate is followed for any signs of distress. Daily ultrasound performed during the inpatient hospitalization assesses for fetal movement, amniotic fluid and membrane status, and serial anatomic evaluation.

During the postoperative period, fluid status must be carefully managed. Both the physiology of pregnancy and the magnesium sulfate regimen predispose the patient to noncardiogenic pulmonary edema, one of the most serious complications observed in otherwise healthy mothers. Empiric furosemide diuresis can be added if signs of pulmonary edema develop. After 48 h, patients begin a tocolytic regimen of 10–20 mg oral Nifedipine every 6 h, which is continued through delivery. Patients can usually be discharged by postoperative day 4, but should be required to remain on modified bedrest for the first 2 weeks after discharge. In the absence of uterine irritability, patients can then be allowed moderate activity, though they should remain nearby and return for twice-weekly ultrasounds

with obstetrical assessment. Once the fetus reaches 36 weeks' gestation, lung maturity is assessed by amniocentesis, and caesarean section is performed once the lungs are mature.

14.3 Anatomic Anomalies Currently Treated by Open Fetal Surgery

14.3.1 Fetal Lung Lesions

Fetal lung lesions represent a spectrum of pulmonary maldevelopment and for the purpose of discussion can be divided into four classifications: Congenital Pulmonary Airway Malformations (CPAM); Extralobar Bronchopulmonary Sequestration (BPS); Intralobar BPS; and Hybrid Lesions. It is important to realize that CPAMs may have features suggestive of BPS, such as systemic blood supply (hybrid lesions) or BPS may contain CPAM histology often suggested by a cyst within an extralobar BPS. In addition, lobar or segmental bronchial stenosis or atresia may be present suggesting an etiologic link with obstruction. CPAM is a hamartomatous tumor that is thought to arise from aberrant events during lung branching morphogenesis [15]. Grossly CPAMs appear as a discrete intraparenchymal masses that derive their blood supply from the pulmonary circulation and can contain cysts of any size ranging from the visually imperceptible (microcystic CCAM) to the predominantly cystic (macrocystic CCAM). Histologically CCAM is characterized by an overgrowth of one or several components of lung tissue with typically bronchial and epithelial elements. Bronchopulmonary Sequestration (BPS) consists of a mass of nonfunctional lung tissue that arises as an aberrant outpouching from the developing foregut. Characteristic features include the absence of a communicating bronchus and aberrant systemic blood supply. Intralobar sequestration shares a visceral pleural lining with usually a lower pulmonary lobe and may be aerated by intra-alveolar communications. The combination of systemic vascular inflow with pulmonary venous outflow in these lesions often results in a high-flow, low-resistance circuit leading to cardiac failure in childhood.

The differential diagnosis of fetal lung lesions also includes bronchogenic cysts, congenital lobar emphysema, segmental bronchial stenosis, bronchial atresia, unilateral lung agenesis, congenital diaphragmatic hernia (particularly right sided), mediastinal tumors, and congenital high airway obstruction (CHAOS). Detailed ultrasonographic features including lesion volume, consistency, location, arterial blood supply, and venous drainage will usually provide a definitive diagnosis.

14.3.1.1 Pathophysiology and Natural History

The natural history of postnatally recognized CCAM includes recurrent pulmonary infection that is resistant to antibiotic treatment, pneumothorax, and ultimately a propensity for malignant degeneration [16–18]. For these reasons we recommend resection of all CCAMs even when asymptomatic. The postnatal natural history of BPS is dependent upon whether they are intralobar or extralobar. Intralobar BPS should always be resected due to likely events of infection or high output cardiac failure. Extralobar BPS should be resected if there appears to be risk for cardiac failure, there is significant mass effect, or lymphatic congestion results in associated pleural effusion. In contrast to postnatally diagnosed lesions, the natural history of prenatal cystic lung lesions is relatively unpredictable. Approximately 15–20% of fetal CPAM lesions will decrease in size and 2/3rds of BPS lesions shrink considerably prior to birth [19, 20]. Despite a relative or absolute decrease in size and a tendency to become iso-echogenic with lung tissue by ultrasound examination in the third trimester, few if any of these lesions truly disappear and postnatal CT scan will confirm the persistence of the lesion after birth. Other CPAMs will grow dramatically during gestation with secondary compression of the surrounding lung and mediastinal structures. This may result in heart failure (hydrops) in the fetus or the presence of a large mass preventing ventilation at term. In addition, there is a low incidence of significant pulmonary hypoplasia

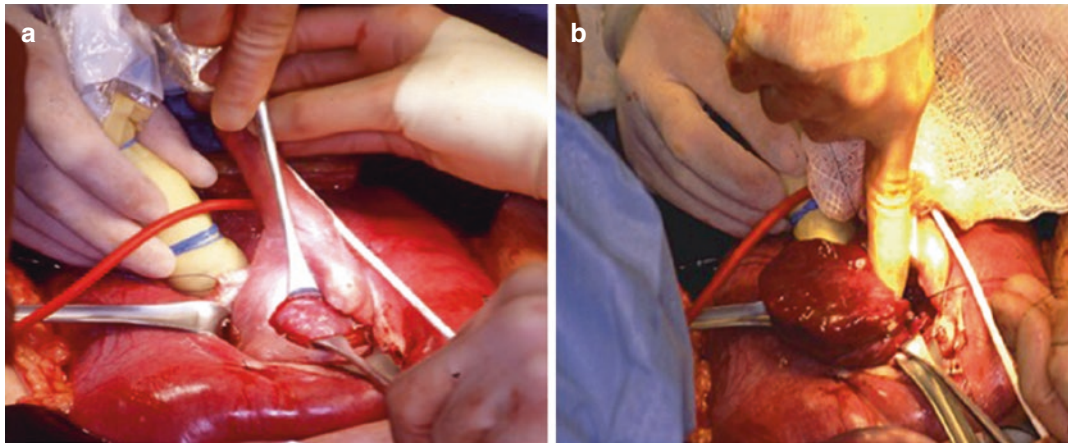

Fig. 14.1 (**a**) Resection of a fetal CPAM. The picture illustrates the fetal position with the arm and chest wall exposed and the head within the uterus. Continuous echocardiographic monitoring is performed during the procedure and an IC and pulse oximeter are placed on the exposed hand. A thoracotomy has been performed and the tumor can be seen bulging out of the incision. (**b**) A hilar dissection is performed. Here the pulmonary artery and bronchus have already been divided and the pulmonary vein is being ligated prior to removal of the tumor

that may impact survival after birth. The evolution of hydrops associated with CPAM is nearly uniformly fatal without intervention and is the sole indication for fetal surgery [19]. Given the uncertain natural history of these lesions, and the requirement for early intervention when hydrops develops, it was important to develop predictive parameters for the development of hydrops. One such parameter is the CPAM volume (using the formula for a prolate ellipse—length × height × width × 0.52) divided by the head circumference (to control for gestational age) ratio, called the CVR [21]. By serial measurement of the CVR, we have determined that most CPAMs follow a predictable growth profile, increasing in size until they plateau at around 28 weeks gestation. A CVR on presentation of ≥1.6 in a microcystic CPAM predicts an 80% likelihood of the development of hydrops, and these fetuses require very close sonographic surveillance (2–3 times per week) to monitor for signs of hydrops. A CVR of <1.6 portends a low likelihood of hydrops and we recommend initial weekly surveillance with decreasing frequency after 28 weeks. CPAMs with a predominant macrocystic component must be observed frequently throughout pregnancy as their growth is less predictable than microcystic CPAMs and we have observed rapid growth after 28 weeks in a few cases.

14.3.1.2 Fetal Intervention for Lung Lesions

Fetal intervention for CPAM is one of the unequivocal success stories of fetal surgery. The majority of lung lesions require no fetal intervention and can be managed postnatally as described above with excellent outcomes [22]. CPAMs that present with CVRs of ≥1.6 are a high risk category and require close surveillance. We [23] and others [24, 25] have observed growth arrest of microcystic CPAMs with steroid therapy reducing the need for fetal surgical resection. At the present time, we empirically treat CPAMs at risk for evolution of hydrops, or in early stages of hydrops, with steroids prior to fetal intervention. If signs of hydrops persist or progress in the fetus less than 32 weeks gestation, fetal surgery is indicated, either open resection for microcystic lesions (Fig. 14.1), or thoracoamniotic shunt placement for macrocystic lesions with a single dominant cyst or multiple communicating cysts. If hydrops develops in a fetus after 32 weeks gestation, or if there is persistence of major mediastinal shift closer to term, we recommend delivery and resection by the Ex Utero Intrapartum Treatment (EXIT) procedure [26]. The results of fetal therapy for hydrops induced by fetal lung lesions have significantly improved upon the natural history. Of 24 fetuses undergoing open fetal

surgery at the Children's Hospital of Philadelphia between 21 and 31 weeks gestation, there are 13 healthy survivors with 1–16 years of follow up. Resections involved a single lobectomy in 18 cases, right middle and lower lobectomies in 4 cases, extralobar BPS resection in 1 case, and 1 left pneumonectomy for CCAM. In survivors resection resulted in resolution of hydrops within 1–2 weeks after resection and impressive compensatory lung growth prior to delivery. Follow up developmental testing has been normal in all survivors. The results of thoracoamniotic shunt placement for hydrops due to CCAMs with a predominant cyst are even better with good quality of life survival of approximately 75% of shunted patients.

14.3.2 Sacrococcygeal Teratoma

A particularly challenging fetal anomaly requiring expertise in its pre and perinatal management is Sacrococcygeal Teratoma (SCT) [27, 28]. SCT is a teratoma arising from the presacral area that occurs in 1/30,000–1/40,000 live births. SCTs have malignant potential but are predominantly benign at birth. By definition they are comprised of elements from all three germ layers on microscopic examination and usually contain cystic and solid elements. Fetal karyotype is usually normal and there are usually no associated anomalies. SCTs have been classified (AAP Surgical Section Classification) based on the anatomic distribution of the tumor [29]. Type I SCT is predominantly external with a minimal presacral component. Type IV SCT is predominantly presacral with extension into the pelvis and abdomen and Types II and III are intermediate between these extremes. The majority of SCTs are Types I or II. Type IV is of significance because it can be missed after birth if not detected prenatally with subsequent presentation with pelvic outlet obstruction or malignancy.

14.3.2.1 Pathophysiology and Natural History

The natural history of prenatally diagnosed SCT is considerably worse than that after delivery [30]. After birth, the majority of patients with SCT do well after early surgical resection, which must include the coccyx to prevent recurrence of the tumor. In contrast, the mortality associated with prenatally diagnosed SCT ranges from 30% to 50%. The high mortality rate of fetal SCT can be attributed to a variety of mechanisms all of which relate to the size or blood flow of the tumor. Mass effect can result in preterm labor and/or dystocia and these were common mechanisms of fetal demise prior to the advent of prenatal diagnosis. SCTs can hemorrhage internally resulting in rapid enlargement of the tumor and fetal anemia, or rupture and bleed into the amniotic fluid resulting in fetal anemia or sudden death. Finally, predominantly solid SCT have high associated blood flow with arteriovenous shunting. This represents a low resistance vascular steal from the fetus and placenta and can ultimately result in high output cardiac failure [31]. Serial echocardiographic assessment can document the evolution of high output failure with increasing combined cardiac outputs and descending aortic blood flow, increasing left and right ventricular end diastolic diameters, increasing inferior vena caval diameter, and increasing placental thickness [32]. Fetal hydrops and placentomegaly may subsequently occur with the end result being fetal demise and often the maternal mirror syndrome. The evolution of hydrops secondary to high output cardiac failure in the immature fetus with SCT is associated with near 100% mortality and is the sole indication for fetal resection of these tumors.

14.3.2.2 Fetal Intervention for SCT

The fetus presenting with a large predominantly solid SCT is at high risk for progression to hydrops [33]. We recommend frequent surveillance by sonography and echocardiography with measurement of the cardiovascular parameters noted above. This may be as often as 3 times per week in the fetus verging on hydrops as they can decompensate rapidly and success of fetal treatment is dependent upon intervention before progression of hydrops. Fetal debulking of the tumor to remove the vascular steal is recommended when the evolution of high output cardiac failure

is recognized at prior to 28 weeks gestation in a fetus with Type I SCT. Timing of intervention is critical and should be recommended when the first overt evidence of hydrops occurs. The presence of advanced hydrops and/or the presence of placentomegaly are contraindications for fetal intervention. A significant number of pregnancies complicated by high-risk SCT will manifest signs of fetal or maternal decompensation, or both, between 27 and 32 weeks of gestation. In this grey zone between fetal intervention and adequate maturation for delivery, we have moved toward pre-emptive delivery by the EXIT procedure with debulking of the tumor on placental support [28]. Once the cardiac failure has resolved and the infant has been stabilized after birth, a formal resection of the residual tumor and coccyx can be performed. After fetal resection of the SCT, hydrops will generally resolve within 2–3 weeks. Since 1995, we have operated on 7 anatomically appropriate fetuses with SCT and associated high output failure with 5 survivors. One survivor has required postnatal treatment of pulmonary metastases of germ cell tumor but at 11 years of age has no evidence of disease. Another survivor had significant morbidity likely related to emboli at the time of tumor resection. The other three survivors remain healthy. These cases demonstrate that fetal resection of a large tumor can reverse the pathophysiology of high output cardiac failure in carefully selected cases and that early intervention offers the best hope of survival once high output failure is documented. However, SCT remains one of the most difficult and challenging fetal anomalies to manage and parents should be counseled appropriately. Our algorithm for pre and perinatal management of high risk fetal SCT is shown in Fig. 14.2.

14.3.3 Fetal Myelomeningocele

Myelomeningocele (MMC) or open spina bifida is a common and devastating congenital anomaly for which there is no satisfactory postnatal treatment. It is the first non-fatal anomaly considered for fetal surgical intervention necessitating a careful analysis of risks and benefit. It is

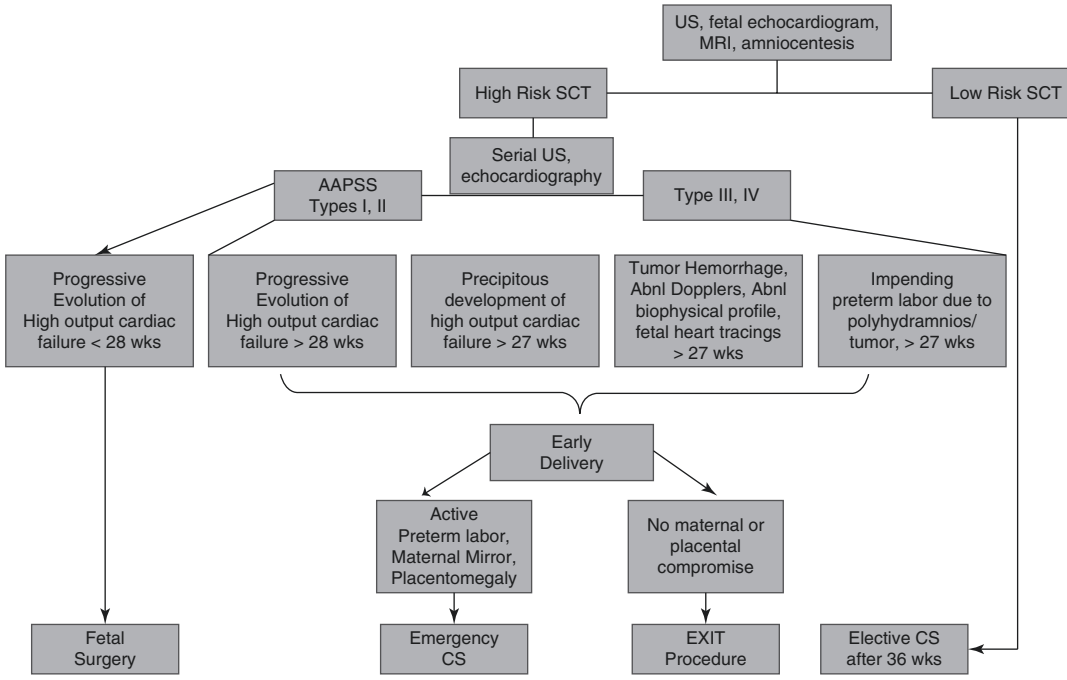

Fig. 14.2 CHOP Algorithm for pre and perinatal management of fetal SCT. (Reprinted with permission from Ref. [28])

characterized by protrusion of meninges and neural elements through a defect in the vertebral arches with secondary complications of lifelong paralysis and varying degrees of mental retardation, bowel and bladder dysfunction, and orthopedic disabilities [34]. MMC has been determined to have both genetic and micronutrient causes. While substantial progress could be made in preventing this disorder through folic acid supplementation, MMC still effects approximately 1/2000 live births and this figure does not include the 23% of MMC pregnancies in which the fetus is aborted [35–38].

14.3.3.1 Pathophysiology and Natural History

There is experimental and clinical evidence implicating the "two hit hypothesis" in the pathophysiology of MMC recently reviewed by Adzick [13]. The first "hit" is failure of neurulation resulting in an open spinal defect. Interestingly, there is minimal evidence for primary neural injury during this phase of the pathogenesis. The second "hit" results from exposure of the neural elements to the amniotic fluid and mechanical effects within the intrauterine environment. This is where evidence suggests the neural damage occurs and this evidence constitutes the rationale for fetal coverage of the MMC defect. A secondary result of the open spinal defect is the Arnold-Chiari malformation which is responsible for a significant component of the morbidity and mortality of MMC. Loss of cerebral spinal fluid through the defect results in a sump effect that causes descent of the hindbrain into the posterior fossa with secondary brainstem compression. With current postnatal treatment nearly 14% of all MMC neonates do not survive past 5 years of age, with the mortality rising to 35% of those with symptoms of brainstem compression from the Arnold-Chiari malformation. Whereas 70% of patients have an IQ >80, only half are able to live independently as adults, even with adapted accommodations [39, 40]. In addition to the motor and sensory deficits due to the spinal cord lesion, MMC patients have significant complications from hydrocephalus, the Arnold-Chiari II malformation, and tethering of the cord at the site of surgical repair. Hydrocephalus occurs in more than 85% of patients with MMC and at least 80% require placement of shunts to prevent neurologic and intellectual compromise associated with hydrocephalus. The rate of shunt related complications and morbidity is high contributing significantly to the overall morbidity of MMC. Thus it is clear that improvements in treatment are desperately needed.

14.3.3.2 Fetal Intervention for MMC

The rationale for open fetal MMC repair is based upon the prevention of neurologic deficits and associated morbidities. With evidence from animal models supporting the likelihood of improved functional outcomes, the first attempts at human MMC repair were reported in the late 1990s. The first endoscopic attempts at MMC repair were reported in 1997 with no apparent improvement in clinical outcome [41]. A subsequent report comparing outcomes between endoscopic and open repair demonstrated superior results with the open approach [42], and thus far attempts at endoscopic repair have not been proven effective in a well designed study. The first successful open fetal surgery for MMC demonstrating improved neurologic function was performed at CHOP in 1998 [43], and was followed by two studies of open MMC repairs reported in 1999 ($n = 10$) [44] and 2003 ($n = 50$) [45] at CHOP. The technique consists of excision of the MMC sac with preservation of the neural placode, closure of mobilized paravertebral myofascial flaps which are lined by Dura, and direct closure of the skin if possible with the use of an alloderm patch in larger defects. In these series overall survival was 90 and 94% respectively, with partial or complete reversal of hindbrain herniation in 100% of fetuses within 3 weeks of operation (Fig. 14.3), and VP shunt rates were significantly lower than expected based on historical controls.

Based on these promising initial results for open MMC repair, a group of three centers in the United States undertook a randomized clinical trial comparing prenatal open MMC surgery with postnatal surgery, the Management of Myelomeningocele Study (MOMS), in 2003. The study was carried out at CHOP, Vanderbilt University and UCSF, with an independent Data

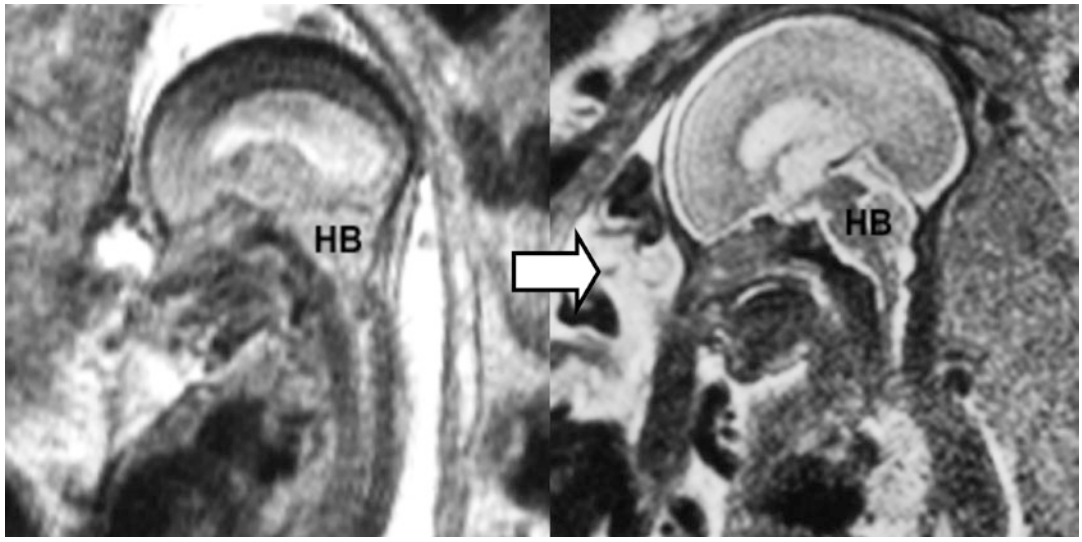

Fig. 14.3 (**a**) MRI appearance of hindbrain herniation in Arnold-Chiari II malformation. (**b**) Reversal of hindbrain herniation 3 weeks after fetal repair of MMC. Fluid spaces in the cisterna magna are uniformly restored after fetal repair. (**c**) Algorithm for management of fetal MMC

and Study Coordinating Center at George Washington University Biostatistics Center. While the trial was being conducted, a moratorium on open fetal MMC repair outside the trial was agreed upon by other fetal centers in the US. The study was powered to recruit 200 patients but was halted in December 2010 when a planned interim analysis demonstrated clear benefit for prenatal surgery after randomization of 183 patients. The results were reported in 2011 [46] and included 158 women randomized prior to July 1, 2009, with 78 in the prenatal group and 90 in the postnatal repair group. The inclusion criteria required that the fetus be 19–25.9 weeks of gestation, with MMC located between T1-S1, with evidence of hindbrain herniation, and normal karyotype without evidence of other abnormalities. The first primary endpoint of the study was a composite of fetal or neonatal death and the need for a CSF shunt at 12 months of age. Sixty-eight percent of the prenatal surgery group versus 98% of the postnatal group fulfilled the primary endpoint, with actual shunt rates of 40% versus 82% respectively. At 12 months of age, rates of moderate or severe hindbrain herniation were significantly lower in the prenatal group (25%) compared the postnatal group (67%). The secondary outcome was a score derived from the Bayley Mental Development Index and the difference between the functional and anatomic level of the lesion at 30 months of age, and was significantly better in the prenatal group versus postnatal repair. Children in the prenatal group were significantly more likely to walk without the use of orthotics or devices (42% vs. 21%), and scored significantly higher in parent-reported self-care and mobility scores. Importantly, prenatal surgery was associated with higher rates of prematurity and maternal morbidity, though infant mortality rates were equal and no maternal mortalities occurred.

Long-term follow-up on neurodevelopmental outcomes at age 5 through 9 of the MOMS cohort (MOMS II) will be a fundamental component of evaluation of the overall efficacy of prenatal therapy for MMC. Results of 5-year follow-up on the cohort of patients treated at CHOP prior to the MOMS trial were recently reported [47]. The majority of children achieved complete independence in cognitive (84%) and mobility (68%) scores, but continued to require significant assistance in self-care. Improved understanding of long-term functional limitations will allow for more effective interventions to maximize clinical outcomes following MMC repair.

14.3.4 Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) occurs in 1 in 3000 to 1 in 5000 live births and is associated with high rates of morbidity and mortality due to pulmonary underdevelopment resulting from the anatomic defect. CDH was one of the first anomalies considered for fetal intervention, however the early experiences with open fetal surgery and tracheal occlusion have produced mixed results and raised controversies regarding the natural history of the anomaly and identification of patients likely to benefit from prenatal therapy.

14.3.4.1 Pathophysiology and Natural History

CDH results from failure of closure of the foramen of Bochdalek between 8 and 10 weeks of gestation. The cause of that failure is the subject of active investigation, with strong evidence implicating genetic factors including disruption of retinoid signaling [48]. Herniation of abdominal contents into the thoracic space results in pulmonary hypoplasia (PH) due to interference with branching morphogenesis during lung development, resulting in a reduction in the number of airways, alveolar, and vascular structures, in turn leading to decreased surface area for gas exchange and fixed increased vascular resistance [49]. Pulmonary vasculature in CDH is also grossly abnormal, with hypermuscular peripheral pulmonary arteries resulting in increased pulmonary vasoreactivity and persistent pulmonary hypertension (PPH). As hypoxemia and acidosis stimulate further pulmonary vasospasm, patients may decompensate rapidly and prove refractory to ventilation by conventional modalities [50]. Improvements in neonatal management, including immediate intubation and ventilation with low peak pressures, blood pressure support, delayed surgery, and extracorporeal membrane oxygenation (ECMO), have resulted in improved outcomes [51]. However, CDH resulting in severe pulmonary insufficiency remains a clinical problem with no adequate postnatal treatment option. The frustration of physicians and surgeons observing the effects of this prenatal insult has prompted considerable exploration of fetal interventions to prevent or reverse pulmonary hypoplasia and restore sufficient lung mass for neonatal survival.

14.3.4.2 Fetal Intervention for CDH

To meet the fundamental criteria for consideration of fetal intervention, the natural history of the condition must be well-described. While advances in prenatal imaging have led to detailed analysis of the anatomic abnormalities encountered in CDH, controversy exists regarding their prognostic power. The most significant prognostic factor for poor outcome is a finding of herniation of the liver into the thorax ('liver-up'), which is associated with a 55% mortality rate compared to mortality of 26% in 'liver-down' cases [52]. Measurements of lung volume, whether by direct measurement or lung-to-head ratio (LHR), calculated using the contralateral lung at the level of the four-chamber view of the heart [53, 54], or "observed to expected" LHR or lung volume determined by US or MRI, do not provide additional independent predictive value for mortality over liver herniation, but do provide additional evidence of severity. With improving survival and no validated prenatal prognostic indicator of morbidity, selection of a group with a defined expected mortality or quality-of-life-impacting morbidity for fetal intervention poses a significant challenge to trial design and analysis.

Initial trials of prenatal treatment employed open fetal surgery and a patch repair of the diaphragmatic defect, however fetuses with liver herniation could not be salvaged by this approach due to kinking of the umbilical vein resulting in intrauterine demise [55]. While no differences in survival were found in 'liver-down' CDH repaired in utero compared to postnatal repair, these patients were later determined to have favorable outcomes with postnatal therapy, and the open approach was ultimately abandoned. More recently, tracheal occlusion (TO) has been studied as a potential treatment for CDH-induced pulmonary hypoplasia. The lungs are net producers of amniotic fluid, and lung fluid volumes are normally regulated by fetal laryngeal tone. In

animal models, pulmonary hypoplasia may be induced by shunting of fluid from the lungs to the amniotic space, while obstruction of tracheal outflow generates large fetal lungs [56]. Fetal lamb models of TO in CDH demonstrated accelerated lung growth and improved pulmonary function [57, 58], although these studies raised concerns regarding lung maturity as measured by surfactant production and type II pneumocyte levels [59]. Based on the experimental data in animals, clinical trials were initiated at UCSF in the late 1990s, with an uncontrolled case series suggesting benefit for TO by a fetoscopic approach in CDH [60]. A subsequent RCT at UCSF demonstrated no benefit in the TO group [61], and an interim prospective trial at CHOP observed that even in cases when lung growth occurred, many of the neonates had severe respiratory compromise raising doubts about the biology of TO in severe CDH [62]. These results led to diminished interest in pursuing TO in North America. However, Jan Deprest and the Eurofetus study group have developed a minimally-invasive approach to TO utilizing a deployable balloon through a single small trocar, and have reported promising initial results [63]. However, there are serious flaws in this data including a 28% rate of primary repair of the diaphragm, suggesting the patients were not as severe as the selection criteria would suggest, no concurrent controls, and a simultaneous improvement in CDH survival in Europe due to adoption of permissive hypercapnia techniques during the decade of these reports [64]. Recently a multi-center RCT, the Tracheal Occlusion to Accelerate Lung Growth (TOTAL) Trial was initiated by Eurofetus and the results of this trial are anticipated with interest. A US consortium to investigate FETO is currently being organized to augment the European trial.

14.4 Other Invasive Maternal/ Fetal Procedures

While the most common fetal anomalies treated by open fetal surgery are emphasized above, the spectrum of fetal intervention includes not only open fetal surgery, but also minimally invasive fetal surgeries such as shunting or fetoscopic procedures, as well as the Ex Utero Intrapartum Treatment (EXIT) procedure.

Fetoscopy first became available in the 1970's, and was initially used primarily as a diagnostic tool. With the development of more sophisticated camera equipment and specialized endoscopic tools, minimally invasive interventions have become not only feasible, but widely applied. Procedures performed in this manner range from laser coagulation of placental anastomoses in TTTS to balloon tracheal occlusion for CDH. Complications of these procedures may include bleeding, separation or rupture of fetal membranes, chorioamnionitis or preterm delivery. Most fetoscopic procedures can be performed entirely percutaneously, minimizing maternal and fetal risks. Such cases usually require only local anesthesia, while procedures which could cause fetal pain generally involve intraumbilical or usually intramuscular administration of opioid and/or muscle relaxant. Similarly, the lack of a hysterotomy obviates the need for extensive tocolysis, and most procedures are performed with only a single dose of indomethacin or nifedipine, if any tocolysis is required. Randomized controlled trials have demonstrated benefit for fetoscopic laser ablation in TTTS [65] and are currently being conducted for fetoscopic tracheal occlusion for CDH.

The EXIT procedure was originally used to deal with surgically applied clips in the early experience with TO for treatment of CDH [66] and was subsequently applied to the difficult airway in cases of large anterior neck mass. The indications for the procedure have now expanded [67], and it is used in any case in which difficulty obtaining an airway after birth is expected or in some circumstances where instability immediately after seperation from the placenta is anticipated (massive SCT with hydrops). Some such indications include not only giant anterior neck masses, but congenital high airway obstruction syndrome (CHAOS), hypoplastic craniofacial syndrome, thoracic masses, mediastinal tumors, pleural effusions, large CCAM's, premature infants with large SCTs, or as a bridge to extracorporeal membrane oxygenation (ECMO) for

severe CDH with a combined cardiac defect or other cyanotic lesion, minimizing any time during which the fetus might be hypoxic or acidotic.

During an EXIT procedure, the mother is positioned supine with a left lateral tilt to maximize venous return and maximize blood supply to the uterus and placenta. A deep general anesthetic is maintained with halogenated agents to achieve uterine relaxation. Although inhaled agents cross the placenta and may provide sufficient fetal anesthesia, fetal anesthesia is supplemented by an intramuscular dose of narcotic and a paralytic agent to prevent fetal discomfort and breathing during the procedure. Careful mapping by ultrasound of the placental edges is performed and the uterus is opened with the same absorbable stapler used in open fetal surgery to control blood loss during the procedure. A peripheral intravenous line is always established for fluid resuscitation, blood transfusion, and drug administration if necessary. A pulse oximeter should be applied to the exposed fetal hand in order to monitor oxygenation during the procedure, and continuous transthoracic fetal echocardiography provides constant assessment of fetal cardiac function and volume status. Infusion of warmed Lactated Ringer's solution is used to maintain uterine volume and to prevent spasm of the cord vessels, and the fetus is maintained on placental circulation while an airway is established. In cases of giant fetal neck masses, tracheal anatomy may be significantly distorted or compressed, and the carina may be displaced superiorly, yielding a small window through which to establish an airway. Rigid bronchoscopy and/or operative tracheostomy may be sufficient, but in some cases decompression of a cystic mass or partial tumor resection may be required.

Success of this procedure rests upon adequate uterine relaxation to maintain utero-placental blood flow and prevent placental separation. This relaxation can cause bleeding complications postoperatively, and Oxytocin is routinely administered immediately following division of the fetal cord. Maternal risks inherent to this procedure include hemorrhage, scar dehiscence or uterine rupture in a subsequent pregnancy (due often to classical cesarean incision required to avoid the placenta or atraumatically deliver a large tumor), and wound infection. Generally, the fetus is felt to be able to be maintained on placental circulation for around 60 min, though procedures as long as 2.5 h have been performed successfully [68]. Fetal risks of this procedure include bradycardia, hypoxic/anoxic brain injury, hemorrhage and death. These complications may occur due to cord compression, placental abruption, or loss of myometrial relaxation all of which result in inadequate uteroplacental gas exchange. Nevertheless, in competent hands the EXIT procedure has been applied with excellent results and minimal maternal or fetal morbity and is an essential component of the Fetal Treatment Center armamentarium.

14.5 Efficacy and Future of Fetal Surgery

The anomalies discussed in this chapter represent the full spectrum of efficacy in fetal surgery. In some cases, fetal surgery has clearly altered the natural history of the disease and improved outcomes (CPAM, TTTS, MMC). For some lesions there is too limited an experience for definitive statements to be made (SCT). For CDH, fetal intervention remains controversial as interventions have not yet shown benefit and selection of a cohort appropriate for fetal therapy has become increasingly difficult as improvements in postnatal management have increased survival rates even in severely affected fetuses.

Dramatic progress has been made in imaging and diagnosis of fetal anomalies, and technical development continues to allow more minimally invasive forms of therapy. As imaging modalities become more sophisticated, our capabilities for image-guided intervention will move to ever earlier gestational time points. In doing so, preterm labor and premature delivery can likely be decreased, though improvements in tocolysis should be a priority to optimize patient outcomes. In the future, randomized controlled trials must be conducted where appropriate to establish clear benefit to patients, allowing fetal surgery to transition from experimental therapy to standard of care.

Minimal Access Neonatal Surgery

15

Gordon Alexander MacKinlay

Abstract

Minimal access techniques—Laparoscopy, thoracoscopy and retroperitoneoscopy—have gradually been adopted in many centres undertaking paediatric surgery. In some units the approach has become commonplace but in others the skills required are developing more slowly or the necessary equipment is unavailable. Hopefully this will change as more and more paediatric surgeons learn to appreciate the benefits that endoscopic surgery provides to the young patients in their care.

Keywords

Minimally invasive surgery • Newborn surgery • Outcomes

In the twenty-first century it is unacceptable to perform any surgical procedure on a child by the open route if it can be safely and easily be carried out through minimally invasive surgery.

Minimal access techniques—laparoscopy, thoracoscopy, and retroperitoneoscopy—have gradually been adopted in many centres undertaking paediatric surgery. In some units the approach has become commonplace but in others the skills required are developing more slowly or the necessary equipment is unavailable. Hopefully this will change as more and more paediatric surgeons learn to appreciate the benefits that endoscopic surgery provides to the young patients in their care.

Endoscopic surgery involves minimal access wounds in the abdominal or thoracic wall and leads to reduced handling, drying and retraction of viscera. This results in less post-operative ileus and therefore earlier feeding is possible. There is less adhesion formation which is not only beneficial should further surgery be required but also prevents long-term complications. As the degree of the surgical insult is reduced there appears to be less immunosuppression and this may also lead to faster recovery. There are fewer respiratory complications and fewer wound infections. For the surgeon there is improved visualisation in 'difficult' areas of the abdomen such as the pelvis or the oesophageal hiatus. As far as the parents and child are concerned the minimal scarring is

P.D. Losty et al. (eds.), *Rickham's Neonatal Surgery*, https://doi.org/10.1007/978-1-4471-4721-3_15

the most obvious benefit. It has been said that 'each scar on a child is a scar on the soul of the parents' [1].

The application of minimal access techniques to the neonate requiring surgery is dependent on the experience of the individual surgeon and an advanced degree of expertise and confidence in minimal access techniques on older children. Many neonatal surgical conditions are amenable to minimal access techniques. These are encompassed in this chapter although individual disease entities are covered in greater detail throughout this book.

15.1 Physiological Considerations in Neonates Undergoing Minimal Access Surgery

It is important for both the surgeon and the anaesthetist to be aware of the likely physiological effects of endoscopic surgery on the neonate.

The metabolic response to surgery differs in neonates to that seen in older children and adults [2]. There is a small increase in oxygen consumption and resting energy expenditure immediately after surgery with a return to normal levels by 12–24 h. The increase in resting energy expenditure is significantly greater in infants undergoing a major operation than in those subjected to a minor procedure. The limited increase in energy expenditure may be due to diversion of energy from growth to tissue repair. There are limited data available on older children, but they appear to have a different pattern of postoperative resting energy expenditure. There is a fall in the early postoperative period, similar to data collected in adults, but no late hypermetabolism. Protein metabolism mirrors energy expenditure and contributes to the overall changes observed. Various factors affect the magnitude of the response. It seems that in children intraoperative thermoregulation and metabolism are significant drivers of many of the postoperative changes. Minimally invasive surgery may maintain preoperative metabolic processes by altering the postoperative processes on a physiological level or by maintaining thermoregulation in children.

The carbon dioxide gas used in insufflation of the body cavity, thorax or abdomen will have a more significant effect in small infants. In thoracoscopy the impaired respiratory capacity imposed by lung collapse has significant implications for oxygenation and CO_2 excretion [3]. Further, the absorption of CO_2 insufflated into the chest, coupled with the impaired ventilation, can lead to a marked increase in arterial CO_2 concentration. The ability to increase CO_2 excretion, in the face of the increased load created by its absorption, is crucial to safe thoracoscopy in children.

The CO_2 is absorbed and excreted via the lungs. There is an increase in end-tidal CO_2 as a result of absorption from the pleura or peritoneum. In thoracoscopy there is the additional factor of ipsilateral lung collapse further increasing the $EtCO_2$ [4]. Single lung ventilation has a significant effect on $EtCO_2$.

There are also haemodynamic changes due to right to left shunting, a phenomenon that is very important in the early stages of thoracoscopy for oesophageal atresia during which the anaesthetist may find it easiest to control the situation by a period of hand 'bagging' the infant.

The insufflation of cold CO_2 into the thorax does not appear to cool the infant. In our study [4] we found that thoracoscopy was associated with an increase in core temperature in the intraoperative period. This may be due to maintained thermoregulation due to the absence of an open surgical wound. This finding is in keeping with the increase in core temperature noted in children undergoing laparoscopy [5] and during thoracoscopy in another study [6]. Thoracoscopy may, therefore, alter intraoperative core-temperature regulation.

15.2 Thoracic Procedures

15.2.1 Diaphragmatic Hernia

It is recommended that thoracoscopic repair of congenital diaphragmatic hernia should only be carried out by surgeons with specific training and experience in laparoscopic and thoracoscopic surgery in neonates and children [7].

The first laparoscopic repair of a posterolateral Bochdalek diaphragmatic hernia was by van der Zee and Bax in 1995 [8]. The first reported congenital diaphragmatic hernia surgically corrected by a thoracoscopic approach was by Becmeur et al. [9] in 2001 although these were in older infants of 8 and 19 months.

The baby should be in a stable cardiovascular and respiratory condition and under general anaesthesia. Endo-tracheal intubation is sufficient without single lung intubation and the patient is placed in a lateral decubitus position on the operating table. The surgeon stands at the head of the table with the assistant to his left and the scrub nurse on the opposite side of the table.

The telescope port (usually 5 mm) is placed below the tip of the scapula and two working ports (3 mm) are placed, one in the anterior axillary line in the 4th intercostal space and the other half way between the telescope port and the spine in the 4th or 5th space.

The first port is inserted after injecting 0.25% Marcaine and adrenaline and is inserted using an open technique, gently opening the space first with an artery forceps and then the port is introduced with a blunt trocar. CO_2 is insufflated at a flow rate of 0.5 L/min at a pressure of 6 mmHg to begin with (it may be increased to 8 mmHg later if necessary and with the agreement of the anaesthetist. A 30° telescope is introduced and gradually the bowel will reduce through the defect sufficiently to allow the two working ports to be introduced under direct vision. Reduction is best achieved using blunt atraumatic instruments such as 3 mm Johan forceps that are fenestrated and handle bowel safely.

The bowel is gradually reduced through the defect. Pushing the stomach down carries the spleen safely into the abdomen without potential trauma from handling the spleen directly.

Once the abdominal contents are reduced the defect is best repaired with non-absorbable sutures. Care should especially be taken at careful repair of the lateral corner of the defect as recurrence can occur here. If necessary a suture passed from outside the chest wall at this point and tied subcutaneously will secure this area safely. It may be necessary to use a patch such as a GORE-TEX® soft tissue patch. This needs to be cut to size externally, rolled and passed through a port. It can then be sutured into position with non-absorbable sutures tied intra-corporeally.

A chest drain is not necessary allowing the hypoplastic lung to expand slowly.

15.2.2 Oesophageal Atresia

Tovar [10] observed—'Only a handful of cases of this particularly rare condition are treated every year in most large centers and it is obviously difficult to acquire the necessary skills for this particular operation in small babies with tiny thoracic spaces. How to achieve this goal when not so many consultants operate upon more than one or two cases per year?'

Thoracoscopic repair of oesophageal atresia was first successfully achieved by Lobe and Rothenberg at the International Pediatric Endosurgery Group (IPEG) meeting in Berlin in 1999 [11]. This was in a 2-month-old infant with isolated oesophageal atresia. In 2000 Rothenberg [12] reported the first thoracoscopic division of a tracheoesophageal fistula and repair of oesophageal atresia in an infant. The first in the UK was in Edinburgh in 2001 [13].

The baby is anaesthetised with endotracheal intubation and placed semi-prone on the operating table (Fig. 15.1). Some use a bronchial blocker to achieve single lung ventilation but this

Fig. 15.1 Semi-prone position on table

adds to the anaesthetic time and has little advantage over endotracheal intubation. When the first port is inserted, CO_2 is insufflated at a flow rate of 0.5 L per minute to a pressure of 6 mmHg. Initially there is usually a period of desaturation and a rise in pCO_2, requiring ventilation to be adjusted accordingly. Within a few minutes however the baby stabilises and the other two ports can be inserted.

The first port (5 mm) is inserted below the tip of the scapula. As CO_2 is insufflated the lung gradually collapses. A short 4.5 mm 30° telescope is used. Two further ports are inserted, both 3.5 mm, one up in the axilla and the other more posteriorly in a line with the other two (Fig. 15.2). It is important that valved ports are used with good seals round the instruments to maintain the tension pneumothorax. The pressure on the insufflator may read 6 mmHg but with a leaky seal the lung will not collapse.

The assistant stands (or sits) to the right of the surgeon to hold the camera and the table height is adjusted to give a comfortable ergonomic position for the surgeon (Fig. 15.2).

With the lung collapsed a good view of the posterior mediastinum is obtained. The distal pouch is seen to distend and collapse with respiration. The azygos vein may be divided if necessary using a 3 mm monopolar hook diathermy. Lifting the vein gently with the hook, it empties, and is easily divided. Dissection commences around the distal pouch to free it circumferentially. A right-angled forceps such as a 3 mm Mixter forceps facilitates this. The fistula is then transfixed and ligated, close to its junction with the trachea, with a 5/0 non-absorbable suture such as braided polyester. The fistula is then divided.

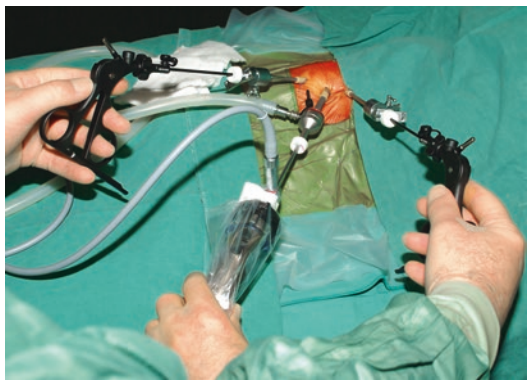

Fig. 15.2 Comfortable ergonomic position of instruments

The upper pouch is then identified; asking the anaesthetist to gently jiggle the Replogle tube will help in its location. Little dissection of the upper pouch is usually necessary unless there is a long gap. With pressure on the Replogle tube an opening in the distal end of the upper pouch is made with scissors. Cutting across three-quarters of the diameter in the first instance creates a flap (later excised) that can be used for traction to facilitate initial suture placement. Care must be taken to ensure that the mucosa is opened. The anastomosis is achieved with interrupted 5/0 braided polyglycolic acid sutures. Some prefer monofilament sutures but the braided suture ensures secure knot tying without slipping. If there is any tension, by using the tumbled square knot technique, the ends can be approximated safely. In cases of tension it is also helpful to paralyse and ventilate the infant for a few days to prevent disruption of the anastomosis [14]. Once the first few sutures are placed, a fine (5 Fr) silastic nasogastric tube is passed by the anaesthetist and advanced into the stomach with surgical guidance. This tube facilitates suture placement (ensure that sutures include the mucosa) and can be used to commence nasogastric feeds within 24 h.

Once the anastomosis is complete then a small chest drain may be passed through the lowest port site, if desired, and the lung is seen to expand as the other ports are removed. The port sites are closed with absorbable sutures to deeper layers and tissue glue to skin. An excellent cosmetic result is achieved without the potential sequelae of a thoracotomy incision. A contrast swallow at 5 days may be performed, prior to commencing oral feeds.

15.2.3 Aortopexy

If tracheomalacia is present and related to the oesophageal atresia it is usually due to an intrinsic

localized anomaly of the trachea at the site of the distal fistula. Aortopexy is appropriate in such cases and may be performed thoracoscopically [15].

The patient is placed supine on the operating table with a pad of Gamgee under the left side of the chest to elevate it 15–20°. The surgeon stands to the left of the operating table with the assistant seated to his left. The monitor is at the opposite side of the table. A 5 mm cannula is inserted in the mid axillary line by an open technique after infiltrating the skin and subcutaneous tissue with 0.25% Marcaine with adrenaline. CO_2 is insufflated at a pressure of 5 mmHg and a flow rate of 0.5 L/min. A 30° telescope is introduced and then two 3.5 mm ports are inserted above and below the first. The anterior mediastinum is visualized and the thymus swept away to the right from the aortic root, taking care of the phrenic nerve. The ascending aorta is identified and if required the pericardial reflection over the aorta can be opened. A hollow needle is passed through the sternum to check the appropriate position for the sutures and a tiny skin incision is made alongside it. A 3/0 prolene suture on a round-bodied needle is inserted through this incision and through the sternum, which is soft at this age, and then carefully a superficial bite of the aortic wall is taken with the needle ensuring that it does not enter the lumen! The suture is then cut so that the needle can be passed through the chest wall for extraction leaving sufficient length of suture intra-thoracically to be passed back out through the previously positioned hollow needle. This suture is then held externally in an artery forceps whilst two or three other sutures are positioned in a similar manner, above and below the first.

Under bronchoscopic control the 3–4 sutures are then pulled upwards and tied subcutaneously as the tracheal lumen is observed to open up. The lung is then allowed to re-expand, the port holes are closed and no drain is required.

15.2.4 Lung Resection

Thoracoscopic resection of lung lesions in the neonatal period is seldom necessary as many conditions can be left until the child is older. It requires advanced paediatric endoscopic skills, as the working space is limited. Congenital lung cysts, congenital cystic adenomatoid malformations, pulmonary sequestrations and congenital lobar emphysema can all be treated thoracoscopically. There is no difference in measurable outcomes between early and delayed resection of congenital lung lesions [16]. It is appropriate to use a management strategy of observation, with delayed resection, for asymptomatic patients [17].

Congenital lobar emphysema can often be treated conservatively [18]. Congenital cystic adenomatoid malformation (CCAM) is often diagnosed antenatally. Whilst some surgeons perform lobectomy for CCAM in the neonatal period, most will wait until the infant is older but it is wise to undertake surgery before infection arises as this can make lobectomy more difficult [19]. In my practice we choose to perform a thoracoscopic lobectomy before the infant's first winter.

Pulmonary sequestration may be intra or extra-lobar and surgery can be postponed until the infant is a few months of age.

Congenital lung cysts usually present beyond the neonatal period and elective surgery can be planned appropriately.

Thoracoscopy for all these conditions is feasible and best performed in a lateral decubitus position. Anaesthesia is best administered via a right or left mainstem intubation of the contralateral side or by introducing a bronchial blocker (a Fogarty catheter is usually used). The baby is supported on a bean bag with a cotton wool roll under the chest to allow the rib spaces to open up and taped to the table which can then be tilted toward or away from the surgeon as necessary to allow gravity to displace the collapsed lung appropriately during the procedure. The surgeon and assistant stand on the same side of the operating table with the baby facing them. The monitor is positioned on the opposite side of the table.

Each port site in turn is infiltrated with 0.25% Marcaine with adrenaline prior to incision. The first port is inserted by an open technique, a 5 mm incision is made in the mid axillary line in the 5th

or 6th space and blunt dissection is used to find a way through the intercostal muscles into the pleural cavity. A 5 mm cannula is then inserted using a blunt trocar and then a short 4.5 or 5 mm 30° telescope is introduced. If desired a smaller port and 'scope may be used but a larger telescope gives a better view. Once it is confirmed that the port is intra-pleural, CO_2 is insufflated at a pressure of 5 mmHg at a low flow rate (0.5 L/min). The port at this level should be looking directly into the oblique fissure. Appropriate positioning of two further 3 mm ports is under direct vision. These are usually in the anterior axillary line above and below the level of the optic port. For a lobectomy a pulsed bipolar sealing device is desirable for dividing the branches of the pulmonary artery to the affected lobe. This may be a 3 mm or 5 mm instrument depending on the manufacturer. If a 3 mm instrument is not available then a 5 mm port will be required, or ligation and division of the vessels may be performed but this is more time consuming. Dissection is performed from anterior to posterior [20].

For a lower lobectomy first the inferior pulmonary ligament is mobilized and the inferior pulmonary vein is identified but not mobilized at this point. In the case of a sequestration a systemic vessel (sometimes more than one) is usually identified coming directly from the aorta below the diaphragm (or sometimes above). This vessel is ligated (or clipped) and divided first in sequestration. After division of all the vessels the bronchus to the lobe is divided and oversewn with non-absorbable sutures. A stapling device is too large for neonates or small infants.

The lobe is then extracted through the lowest port site and a chest drain inserted and connected to an underwater seal.

15.2.5 Cyst Excision

Bronchogenic or other cysts are dissected out as appropriate and by keeping close to the cyst wall during mobilization most can be excised safely and relatively easily.

Foregut duplication cysts such as oesophageal duplication are best approached with the baby semi-prone as for oesophageal atresia repair. The pleura overlying the cyst is incised and the duplication is carefully mobilized from the oesophageal wall. The oesophageal mucosa is exposed but should be left intact and the defect in the oesophageal muscle is then repaired.

15.2.6 Chylothorax

Thoracoscopic ligation of the thoracic duct may be performed in cases of chylothorax. The magnification obtained in thoracoscopy can make the identification of a chyle leak easier. The approach is similar to that for oesophageal atresia repair and the port sites described for that (above) allow excellent visualization of the posterior mediastinum. The duct may either be ligated or clipped.

15.2.7 Mediastinal Masses

Mediastinal masses are uncommon in the neonate and usually arise from the sympathetic chain as a neuroblastoma, ganglioneuroblastoma or ganglioneuroma. Rarely is it necessary to undertake surgery for these in the newborn and it is important to evaluate the case in conjunction with the oncological multi-disciplinary team. Thoracoscopic excision and extraction of the tumour in a bag is required.

15.3 Abdominal Procedures

Neonatal laparoscopic surgical procedures have become widely accepted over recent years. Laparoscopy is well tolerated in the neonate and many congenital abdominal conditions can be approached in this way with the benefits of minimal access surgery.

For the majority of laparoscopic procedures the primary (optic) port is best placed at the umbilicus. This not only gives access to all quadrants of the abdomen but is also the most cosmetic. I always use the inferior umbilical fold for the umbilical

port site. The incision should, if possible, be within the fold, which can be everted to achieve optimal placement. Some surgeons choose the upper fold for example in the approach for pyloric stenosis but this is illogical as it places the optic closer to the operative field and thus achieves a more restricted view. In the neonate, in particular, the lower fold is best as often the umbilical vein is still patent and can bleed whereas the arteries in the inferior fold are rapidly occluded.

Others choose the centre of the umbilicus for their incision as the most direct approach but this distorts the appearance of the normal umbilicus. An incision within the inferior umbilical fold can be widened if necessary to allow exteriorization of bowel for extra-corporeal surgery. Simply stretching the skin incision with an artery forceps will extend the incision along Langer's lines, which are circumferential at the umbilicus. Extending it with a scalpel may cross the lines and create a cosmetically inferior scar.

15.3.1 Pyloromyotomy

Pyloromyotomy can easily be performed laparoscopically and this is the preferred approach. A double-blind multicenter randomized controlled trial of open versus laparoscopic pyloromyotomy was halted at the recommendation of the data monitoring and ethics committee because of significant treatment benefit in the laparoscopic group [21]. My own unit chose not to participate in that trial as we already considered laparoscopy was the best approach and this study proved it.

The baby is placed either at the foot of a shortened operating table or, if preferred, across the table. The surgeon stands at the baby's feet and the assistant to the left. The monitor is best placed across the table if a flat screen is available otherwise at the head of the table.

A 5 mm port is inserted in the inferior umbilical fold under direct vision having infiltrated the skin and subcutaneous tissue with 0.25% Marcaine with adrenaline. Only a very short length of port should be inside the abdomen so it is best sheathed with a short length of catheter to limit its excursion into the abdomen. The catheter may be sutured to the skin and fascia to prevent dislodgement. The instruments are introduced directly into the abdomen through 3 mm access wounds, one in the right hypochondrium, the other just to the left of the midline in the epigastrium (Fig. 15.3). A 3 mm fenestrated forceps of the Johan type is passed through the right hypochondrial site and used to grasp the duodenum gently, just beyond the pylorus. A laparoscopic retractable pyloromyotomy knife or a suitably narrow blade such as an ophthalmic 69 Beaver, on a handle, is carefully introduced through the epigastric site and an incision is made along the length of the pylorus from the pyloro-duodenal junction onto the antrum of the stomach. It is important that this incision is down into the muscle of the pylorus. The blade is removed and replaced with a 3 mm laparoscopic spreader that is introduced into the split in the pyloric tumour (Fig. 15.4). As the

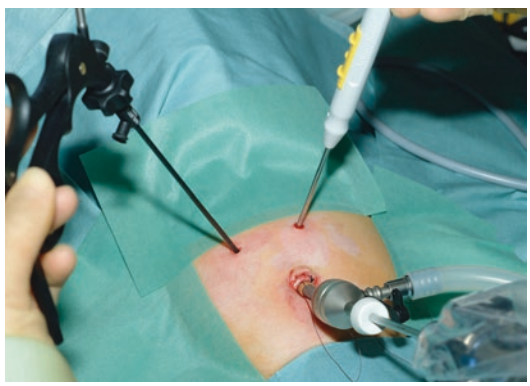

Fig. 15.3 Instrument sites in pyloromyotomy

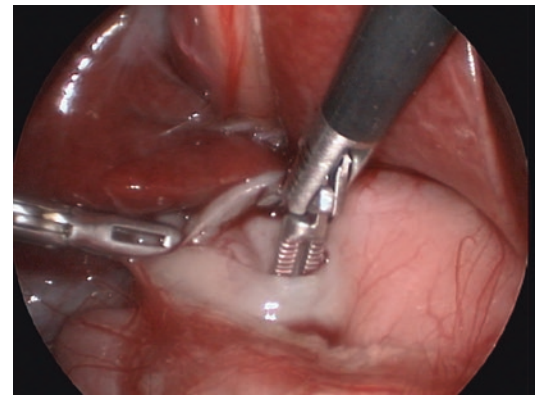

Fig. 15.4 Spreading the pyloromyotomy

Fig. 15.5 Barely perceptible wounds post pyloromyotomy

spreader is opened to its full extent the muscle is widely separated to show the intact mucosa bulging. Changing the graspers to either side of the split allows further separation and moving the instruments in opposite directions parallel to the pylorus confirms that an adequate length pyloromyotomy has been achieved.

The instruments are carefully removed, taking care not to draw the flimsy omentum out behind them. The wounds are closed with a deep 4/0 polyglycolic acid suture and tissue glue to skin (Fig. 15.5). The operation takes only a few minutes. Feeding can commence as soon as the baby returns to the ward as the gastric paresis that occurs in some open techniques is seldom seen.

15.3.2 Fundoplication

Occasionally pre-term infants with severe gastro-oesophageal reflux may have difficulty weaning from ventilation or suffer recurrent severe respiratory symptoms due to aspiration until an anti-reflux operation is performed. Laparoscopic fundoplication is well tolerated [22] and significantly improves the outcome. The baby is placed on the operating table in a position similar to that for pyloromyotomy.

A 5 mm port is inserted by the open technique through a 5 mm incision in the inferior umbilical fold having infiltrated the skin and subcutaneous tissue with 0.25% Marcaine with adrenaline. Pneumoperitoneum is established with CO_2 at a pressure of 8–10 mmHg at a flow rate of 0.5–1 L/min depending on the size of the baby. Two further 'working' ports each 3.5 mm are inserted, one in the right, the other in the left hypochondrium. The exact position is dependent on the size of the baby. If the baby is too small for a Nathanson liver retractor an instrument is passed through a 3 mm stab wound in the right side of the abdomen just below the edge of the liver and the left lobe of the liver is elevated by this instrument which if ratcheted can be fixed to the peritoneum in the left flank. A further 3 mm stab incision in the left flank is used for an instrument to retract the gastric fundus (Fig. 15.6). The short gastric vessels rarely need to be divided in these cases. The oesophagus is gently mobilized at the hiatus with minimal dissection and a window developed behind the oesophagus where the two limbs of the right crus of the diaphragm will be visualized. Care is taken to leave the posterior vagus attached to the oesophagus. The two limbs of the right crus are approximated with one suture of braided polyester to narrow the hiatus, taking care to leave room for normal swallowing. A wide bore nasogastric tube in situ at this stage can prevent too tight a closure. It is removed at the end of the procedure or replaced with an appropriate sized tube for post-operative feeding if required. The fundus is then grasped by an instrument passed from right to left behind the oesophagus and gently drawn

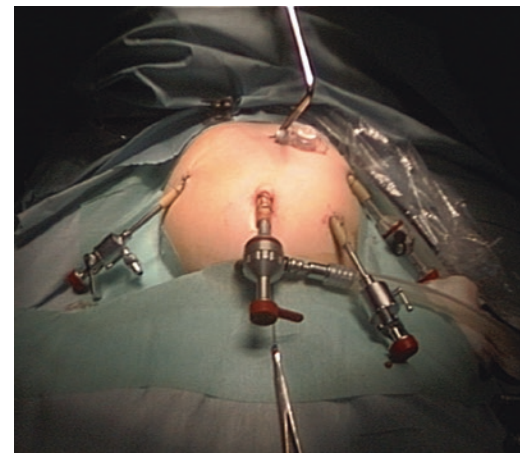

Fig. 15.6 Port sites for laparoscopic fundoplication (note gastrostomy button)

through to allow a loose wrap of fundus around the intra-abdominal portion of the oesophagus. This is approximated using three sutures of 3/0 braided polyester. The first suture brings the two parts of fundus together. The second suture, above the first, approximates the two sides and is also attached to the diaphragm at the hiatus. The third suture approximates the two sides also taking a bite of the anterior wall of the oesophagus. The latter two sutures help to prevent wrap migration into the thorax.

The ports are removed and closed with absorbable sutures to fascia and tissue glue to skin.

15.3.3 Gastrostomy

If a gastrostomy is required in the neonatal period it is safest to place it under laparoscopic guidance. In a small baby a telescope port is placed at the umbilicus and a further 3 mm 'stab' wound made in the right hypochondrium through which an atraumatic grasper is passed. The site of the proposed gastrostomy is chosen and the stomach held close to the abdominal wall as a 2/0 polyglycolic acid suture on a curved, round bodied needle is passed though the abdominal wall picking up the anterior gastric wall and back out through the abdominal wall a few mm away from the entry site. A further suture about 1 cm from the first is passed in similar fashion such that traction on the two 'U' sutures will bring the stomach up to the anterior abdominal wall. Suitable reduction in insufflation pressure facilitates this manoeuvre.

Using a Seldinger technique a cannula is passed percutaneously into the stomach between the two sutures followed by a guide wire. Graduated dilators are then passed though the abdominal wall into the stomach dilating up to 14Fr for a 12Fr button gastrostomy tube (of measured length) that is finally passed over the guide wire, into the stomach. Using one of the smaller size dilators to stiffen and guide the tube into the stomach facilitates this. The two sutures are then tied over the wings of the button device to retain it in place (Fig. 15.6). These sutures are removed in 7 days.

15.3.4 Duodenal Atresia

Laparoscopic repair of duodenal atresia has developed since 2001. The baby is placed at the end of the operating table as described for pyloric stenosis. The surgeon stands at the foot of the table with the assistant to the left. The first (5 mm) port is inserted in the inferior umbilical fold and once pneumoperitoneum is established two further 3.5 mm ports are placed, one in the right lower quadrant, the other in the left hypochondrium. An instrument for a liver retractor may be introduced through a stab wound in the epigastric region or the liver may be hitched up with a percutaneous suture through the falciform ligament. Alternatively the apical stitch in the anastomosis can be brought out through the abdominal wall to stabilize the enterostomies for the anastomosis [23, 24]. The duodenum is Kocherised, the proximal dilated and collapsed distal segments are identified and a diamond shaped anastomosis is made after incising the proximal bowel transversely and the distal bowel longitudinally. This is achieved with interrupted polyglycolic acid sutures. Others have used nitinol u-clips with good results [25].

Laparoscopic repair of duodenal atresia remains one of the most demanding paediatric laparoscopic surgical procedures [26].

15.3.5 Malrotation

Laparoscopic correction of malrotation in the neonate was first described in 1998 [27]. At first many considered it should only be considered for cases without volvulus but it is feasible even with volvulus and signs of ischaemia [28].

The baby is placed supine at the end of the table as for pyloromyotomy.

A 5 mm port is inserted in the inferior umbilical fold and the abdomen insufflated with CO_2 at a pressure of 8–10 mmHg with a flow rate of 0.5 L/min. A 5 mm 30° telescope is inserted and the bowel inspected. In the case of volvulus there may be evidence of chylous fluid in the peritoneal cavity. The bowel is collapsed and shows a dusky appearance with only the stomach and duodenum

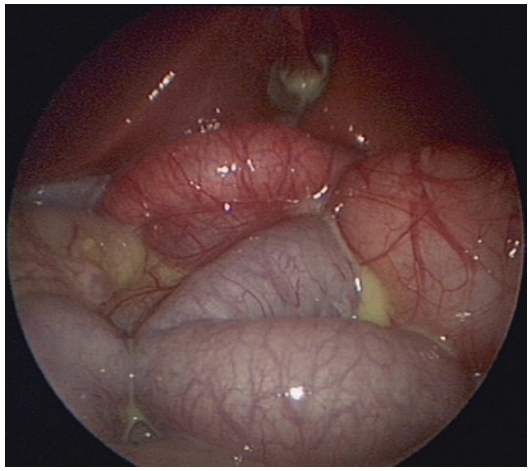

Fig. 15.7 Ischaemic bowel and chylous fluid in volvulus neonatorum

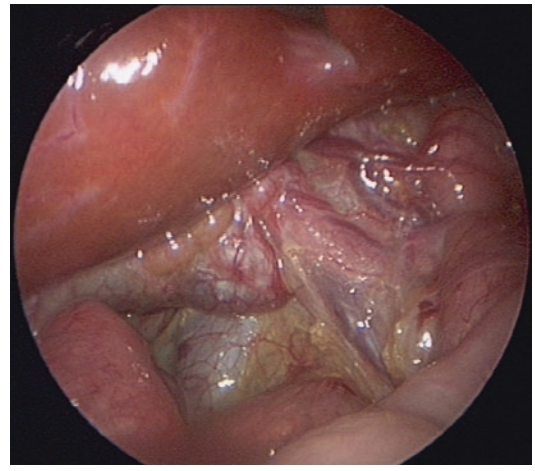

Fig. 15.8 Wide separation of root of mesentery, having corrected the volvulus

appearing pink (Fig. 15.7). Two 3.5 mm ports are placed on either side of the abdomen slightly below the level of the umbilicus and using two atraumatic bowel graspers such as fenestrated Johan forceps the bowel is gently inspected. As the bowel always rotates in a clockwise direction (north and south of the equator unlike water emptying down a plug hole) the bowel is gently rotated en masse in an anticlockwise direction. As the bowel is derotated the colour improves and returns to normal. Once this has been achieved Ladd's bands are visualised and divided with a 3 mm monopolar hook diathermy. The root of the mesentery is widely separated by carefully dividing the peritoneum with the hook diathermy. Once wide separation has been achieved the operative procedure is complete (Fig. 15.8). The ports are removed and the wounds closed (Fig. 15.9). Feeding can recommence within 24 h.

15.3.6 Small Bowel Atresias and Duplications

Small bowel atresias can be dealt with using a laparoscopically assisted approach, identifying the atresia laparoscopically and exteriorizing the loop of bowel via the umbilical port site and performing the resection, tapering (if necessary) and anastomosis externally [29, 30].

Fig. 15.9 Post operative wounds following correction of volvulus neonatorum

Duplication cysts can also be treated using this technique, aspirating the fluid from the cyst before exteriorizing the affected loop of bowel.

15.3.7 Hirschsprung Disease

In the early 1990s Georgeson [31] described the laparoscopic approach to endo-rectal pull-through for Hirschsprung disease. This can be performed in the neonatal period or delayed for a

period during which the bowel is decompressed by regular irrigations every 6–8 h.

The advantage of the laparoscopic approach is the ability to obtain biopsies to determine the exact level of the disease. Others prefer a purely transanal approach [32] but occasionally one may encounter a total colonic Hirschsprung's or a higher than expected transition zone so the laparoscopic biopsy technique is safer.

For the laparoscopic endo-rectal pull through the baby is placed in a supine position across the end of the operating table with the right side towards the foot of the table. The surgeon stands at the head of the baby and the assistant is best seated at the end of the table to hold the camera. The first port (5 mm) is inserted either in the inferior umbilical fold or as suggested by Georgeson it may be placed in the right hypochondrium to provide a wider view of the abdomen. Either way it is placed using an open technique having first infiltrated the skin and subcutaneous tissue with 0.25% Marcaine with adrenaline.

The abdomen is insufflated with CO_2 at a flow rate of 0.5 L/min to a pressure of 8 mmHg. Two further 3.5 mm ports are inserted, one to the right side of the abdomen at umbilical level and the other a little higher on the left.

The baby is placed in a Trendelenburg position and prepped front and back from the lower chest downwards including the legs that are encased in sterile stockinette or similar. The baby's bottom should be close to the edge of the table to facilitate the rectal dissection. Some padding is used to support the legs comfortably at the edge of the table.

First seromuscular biopsies are taken using a fine grasper and curved laparoscopic Metzenbaum scissors. These are sent for frozen section to confirm the level of disease prior to commencing dissection. With an atraumatic instrument lifting the colon towards the anterior abdominal wall, a window is developed in the mesocolon using a 3 mm hook diathermy. This is continued, staying close to the bowel wall, down to the peritoneal reflection and circumferential dissection at this level for a further 1–2 cm is performed. Staying close to the bowel wall prevents damage to the nervi erigentes and the vas in the male. The bowel is thus mobilized from the transition zone down to below the peritoneal reflection.

The ports are left in position and the CO_2 insufflation discontinued allowing the abdomen to deflate. The surgeon and assistant move to the opposite side of the table. The baby's feet are elevated using the stockinette, which can be fixed to the drapes over the baby's torso giving access to the anus. The rectal mucosa is accessed by placing 6–8 traction sutures through the perianal skin and the muco-cutaneous junction to radially retract the anal margin. Alternatively a retractor ring and hooks provides excellent exposure. Care must be taken not to overstretch the anal sphincters at this stage and during the dissection.

The mucosa is marked with cautery 5–10 mm above the dentate line circumferentially and then using a fine cautery needle the mucosa is incised at this level attaching multiple 5/0 silk sutures to the edge of the mucosa to provide traction. It is imperative that only the mucosa is dissected free from the underlying internal sphincter. Once a good submucosal plane is developed the dissection becomes easier and is continued until the rectal sleeve prolapses down. The advantage of the previous laparoscopic dissection is that there is little bleeding at this stage. Once the sleeve has prolapsed easily it is incised circumferentially and the mobilized bowel is pulled through it until the highest (ganglionic) biopsy site is seen. It is preferable to pull down a further 5–10 cm to ensure that the affected disease is fully resected. The muscle cuff is split posteriorly and pushed back into the pelvis. The affected bowel is sent to pathology for confirmation of the level of disease and the pulled through bowel is anastomosed carefully to the distal mucosal cuff using multiple 5/0 absorbable sutures to ensure that there is no leak.

On completion of the anastomosis the retraction sutures/ hooks are removed and the anus retracts. The surgeon, after a change of gloves, moves back to the other side of the table to check with the 'scope that there is no twist on the bowel. The ports are removed and the sites closed. Feeds can recommence the following morning.

15.3.8 High Ano-Rectal Malformations

Georgeson described a similar approach to high ano-rectal malformations [33]. In the neonatal period these cases are usually treated with a colostomy initially and the rectal pull through procedure is usually performed when the baby is a few weeks of age. It can be successfully treated with a primary single stage procedure within a day or two of birth [34].

The aim is to correct the high anorectal anomaly without the mid sagittal division of the muscles in the widely accepted approach described by Peña. The dissection is similar to the dissection for Hirshsprung's disease beginning at the peritoneal reflection continuing deeply close to the rectal wall until it tapers into the fistula distally. When the rectourinary or high rectovaginal fistula is reached the bowel is divided and the fistula usually sutured or clipped.

The legs are then elevated and the perineal dissection commenced after defining the perineal anal site using a muscle stimulator. A vertical 1 cm incision is made and the initial dissection is commenced with an artery forceps followed by a Veress needle with a radially expanding sheath, which is advanced in the midline with laparoscopic guidance from above entering the pelvis in the midline immediately posterior to the urethra in the male. The magnified view of the pelvic floor afforded by the laparoscope enables accurate placement in the 'v' of the puborectalis sling. The sheath is left in situ and the needle removed prior to gently dilating the tract in a gradual manner to 5 mm and then 10 or 12 mm. The rectum is then grasped from below and drawn down through the tract to be anastomosed to the skin at the neo-anus. A recent study has compared the anorectal angle and continence using this technique with that in the posterior sagittal approach [35]. This confirmed that a similar anorectal angle is achieved in both operations and that the laparoscopic approach has less detrimental functional impact.

15.3.9 Necrotising Enterocolitis

Laparoscopy in the initial evaluation of NEC is invaluable and can help to avoid potentially un-necessary surgery in an already extremely unwell infant [36]. In tiny preterm infants it is best to insert a 3.5 mm port at the umbilicus by the open technique and then the abdomen is insufflated with CO_2 at a flow rate of 0.2 L/min to a pressure of 5 mmHg. A 3 mm 30° telescope is used. In some cases free intestinal content may appear at the umbilicus whilst performing open access for the first port in which case there is obvious perforation and little visibility on inserting the telescope may indicate the need for laparotomy. On the other hand if there is no sign of free fluid on gentle inspection at laparoscopy then conservative management can be continued and the morbidity of a laparotomy in an extremely sick premature infant is avoided. Pneumatosis may be clearly visible (Fig. 15.10). This correlates with the preoperative radiological appearance (Fig. 15.11).

If necessary the laparoscopy can be performed in the neonatal unit. After an appropriate period of conservative management contrast studies of the bowel are advised prior to re-introducing feeds. If an isolated stricture is identified then further laparoscopy allows the area to be mobilized and exteriorized at the umbilical port site for resection and anastomosis. Even a tiny premature infant with severe necrotizing entero-

Fig. 15.10 Visualisation of pneumatosis intestinalis in NEC

Fig. 15.11 Pre-operative x-ray showing pneumatosis

colitis can grow up with an abdomen with imperceptible scars.

15.3.10 Biliary Tract

The laparoscopic Kasai procedure was first described in 2002 [37] and subsequently a few cases were published but the results seemed not as good as the conventional open repair. At a meeting of the International Pediatric Endosurgery Group in 2007 it was concluded that the results were inferior and the procedure was not recommended [38]. A prospective study was stopped after inclusion of 12 laparoscopically operated infants due to a lower survival with the native liver after laparoscopic versus conventional Kasai operation [39].

In Japan and elsewhere in the East where the condition is more common they aim to make the laparoscopic dissection of the porta hepatis as close as possible to Kasai's original description and the longer term results are awaited [40, 41].

Certainly the laparoscopic approach for correctable biliary atresia is well suited to the laparoscopic approach as is choledochal cyst excision. Whilst I have successfully performed a number of these resections laparoscopically we cannot compete with the large numbers in the Far East [42].

For choledochal cyst excision a 5 mm port is placed in the inferior umbilical fold by an open technique. CO_2 pneumoperitoneum is established at 10 mmHg with a flow rate of 1 L/min. Two further 3.5 mm working ports are positioned in the left and right upper quadrants. A Nathanson Liver retractor is inserted in the epigastrium to give good exposure of the gallbladder, choledochal cyst and porta hepatis (Fig. 15.12). An intraoperative cholangiogram is performed via a flexible needle passed through the abdominal wall into the gallbladder.

It is sometimes helpful to mobilise the gallbladder from its bed early in the dissection and it can be used to provide traction during dissection of the cyst. Dissection is largely performed using a 3 mm monopolar diathermy hook. The cyst is dissected carefully keeping close to the

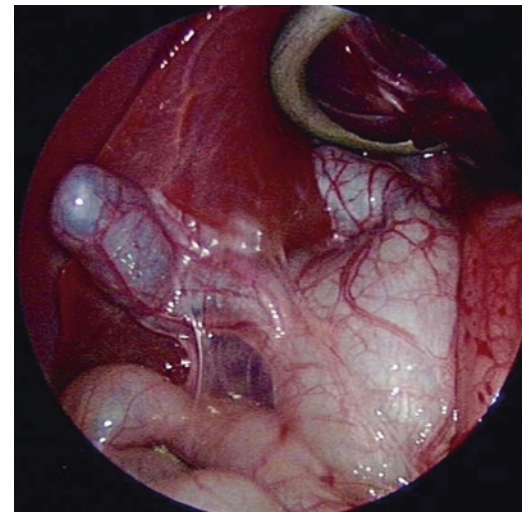

Fig. 15.12 Laparoscopic view of gall bladder and dilated cystic duct leading into choledochal cyst

cyst wall and separating it from the pancreas, duodenum, portal vein and hepatic artery. Occasionally I find that the communication with the duodenum is barely perceptible but if identified it is closed with an absorbable suture. Once the cyst is freed right up to the common hepatic duct it is left in situ whilst a Roux-en-Y jejunal loop is constructed. The jejunum is traced down from the duodeno-jejunal junction and the chosen loop exteriorized at the umbilical port site for the Roux-en Y construction prior to returning it taking it retro-colically up to the porta. The cyst content is aspirated percutaneously and the common hepatic duct transected. The cyst can be extracted via the umbilical port site (Fig. 15.13). An end to side hepato-jejunostomy is performed using interrupted 5/0 absorbable sutures. A suction drain is positioned below the anastomosis and the ports removed and the wounds closed.

If preferred it is simpler and quicker to perform a hepato-duodenostomy and Liem [42] claims that the incidence of ascending cholangitis is not significantly greater than hepato-jejunostomy. (I have used this technique in one case with an operative time of around 2 h, less than half the time taken for hepato-jejunostomy).

Fig. 15.13 Excised choledochal cyst with gallbladder attached

15.3.11 Pancreas

For hyperinsulinism in the neonatal period, refractory to medical management, the laparoscopic approach to the pancreas is easier than open surgery in view of the great magnification of the anatomy, which is beautifully displayed. Laparoscopic pancreatectomy for persistent hyperinsulinemic hypoglycemia of infancy was first described in 2001 [43]. The approach is with a 5 mm port at the inferior umbilical fold and two further 3.5 mm ports in the right and left upper quadrants. Exposure is facilitated with two stay sutures through the abdominal wall picking up the antrum and body of the stomach [44]. Dissection is performed using a monopolar 3 mm diathermy hook carefully dissecting the pancreas from surrounding structures. If a focal nodule is identified this can be excised otherwise, as in open surgery, dissection is continued up to the common bile duct and the pancreas transected at this level and suture ligated.

15.3.12 Ovarian Cyst

Laparoscopy is excellent in establishing the diagnosis in a neonatal intra-abdominal cyst distinguishing ovarian cysts from duplication and other intra-abdominal cysts. Percutaneous aspiration under ultrasound guidance is potentially dangerous [45].

A 5 mm port is placed in the inferior umbilical fold by open technique after infiltrating with 0.25% Marcaine with adrenaline. The abdomen is insufflated to 8 mmHg at a flow rate of 0.5 L/min. A 30° telescope is introduced and the cyst is visualized. The cyst may be punctured under direct vision inside the abdomen and then the deflated cyst can be exteriorized via the umbilical port site and treated as appropriate depending on how necrotic it is. Occasionally on inspection a cyst may be auto-amputated with no attachment and the ovary may be absent on one side confirming the diagnosis [46].

15.3.13 Intersex

Laparoscopy can be useful as part of the multidisciplinary work up of a neonate with ambiguous genitalia. Laparoscopic biopsies of gonads may be taken if required.

15.4 Tumour Surgery

15.4.1 Renal Tumours

Laparoscopic nephrectomy may be performed in the neonate for conditions such as mesoblastic nephroma in which case the tumour is mobilized laparoscopically and extracted via a Pfannenstiel incision in a bag.

15.4.2 Hepatic Tumours

As part of the diagnostic work up of a newborn with a hepatic lesion it is safe to perform trucut biopsy under laparoscopic guidance. As bleeding may be quite significant this is safer than percutaneous ultrasound guided biopsy. It is very important to position an additional 5 mm port prior to the biopsy to enable the introduction of an endopledget. This is held close to the biopsy site as the needle is withdrawn to be able to apply local pressure and control any potential haemorrhage.

15.4.3 Sacrococcygeal Teratoma

In cases of large sacrococcygeal teratoma in a haemodynamically unstable infant it is helpful to use a laparoscopic approach to interrupt the median sacral artery. It is also helpful in dissection of the intrapelvic component [47].

15.5 Inguinal Hernia

Whether or not inguinal herniae in children should be routinely performed laparoscopically is a matter for debate. The numbers of cases are large and the majority, in most centres, are performed by open surgery.

In the neonate and premature baby however the hernia sac is easily torn during open surgery and it can become a frustrating and tedious operation particularly for surgeons in training. The laparoscopic approach, providing that the surgeon has acquired the necessary skills, may be simpler and also may reduce the likelihood of injury to the vas in males, as the magnification is so great. It also enables the evaluation of the contralateral side.

The baby is placed supine on the operating table and the bladder emptied by a Credé manoeuvre a 5 mm port, or smaller, is inserted in the inferior umbilical fold. The abdomen is insufflated with CO_2 to a pressure of 8 mmHg at a flow rate of 0.5 L/min. A 30° telescope is used. Two further 3.5 mm ports are inserted at a slightly lower level in either flank. If desired the instruments can be passed through tiny stab wounds, avoiding the use of ports and affording greater cosmetic benefit. Putting the baby in a Trendelenberg position gives good exposure of the internal inguinal rings as the bowel is displaced by gravity. A 3/0 absorbable suture on a round-bodied needle is inserted through the abdominal wall and grasped with a laparoscopic needle holder. The internal inguinal ring can be closed with a purse string suture or an N or Z type closure is achieved [48]. Some prefer to incise at least part of the peritoneum at the internal ring prior to the suturing in the hope of reducing recurrence.

Others use a laparoscopic assisted extraperitoneal technique [49] in which a special 'herniotomy hook needle' (similar to an aneurysm needle) is used. The hook is prepared with a monofilament absorbable suture and passed through a 2 mm stab incision made over the internal inguinal ring and the hook is passed retroperitoneally from lateral to medial lifting the peritoneum forward from the vas and vessels and once beyond them is brought into the peritoneal cavity where a grasper holds the suture as the needle is withdrawn to a subcutaneous position prior to advancing it round the

remainder of the circumference of the internal ring back to the suture. This is threaded through the needle, which is withdrawn, thus completely encircling the hernial sac. It is then ligated externally closing the internal ring and burying the knot subcutaneously. The recurrence rate with this method is said to be minimal.

Conclusion

Many senior paediatric surgeons argue that evidence is lacking for changing from open surgery to minimal access surgery. It is true that there have been very few randomised controlled trials to support the approach. Small incisions for laparoscopic ports are just a different approach to the abdomen. I doubt that when surgeons determined that they could open the abdomen via a midline, paramedian, subcostal, Pfannenstiel incision etc. that randomised trials were demanded. The time has come to accept the laparoscopic approach that has been proving its success in paediatric surgery over more than two decades. Although we as paediatric surgeons pride ourselves in making small neat wounds which are closed with subcuticular sutures or even skin glue the scars grow with them and underlying them is a potential for adhesive problems which are not as common with endoscopic surgery. Children deserve to grow up without scar even if they require major surgery. I am sure that the next generation of surgeons will be surprised to learn that surgeons used to open up body cavities through big incisions. Our adult surgical colleagues have adopted the endoscopic approach in many areas. We are fortunate that paediatric surgery covers an age range rather than an organ system and these techniques are applicable for most of the surgery that we perform. The neonate especially can benefit with less long-term morbidity.

The Genetics of Neonatal Surgical Conditions

16

Ian Ellis

Abstract

It is noteworthy that in 1953, the same year that Peter Paul Rickham was establishing the first neonatal surgical unit at Alder Hey Children's Hospital in Liverpool, just 200 miles away in Cambridge, Francis Crick and James Watson were unraveling the structure of DNA, the fundamental genetic material. Crick and Watson's Nobel Prize winning work describing the double helix structure of DNA also described a mechanism for its replication. The two parent DNA strands each acting as the framework for copying into the two daughter strands. The usual accuracy of the copying of billions of base-pairs into gametes at meiosis and daughter cells during mitosis is itself a marvel. Changes in the usually faithful copying of DNA strands (mutations) can be the basis of positive genetic change that encourages our evolution over generations. Or the sudden deleterious change in a DNA sequence may be the pathogenic mutation that underlies a congenital malformation that presents to a neonatal surgeon. Here lies the origin of many neonatal surgical conditions and ultimately important clues to their improved management and ultimately their reduction or even prevention.

16.1 Introduction

It is noteworthy that in 1953, the same year that Peter Paul Rickham was establishing the first neonatal surgical unit at Alder Hey Children's Hospital in Liverpool, just 200 miles away in Cambridge, Francis Crick and James Watson were unraveling the structure of DNA, the fundamental genetic material. Crick and Watson's Nobel Prize winning work describing the double helix structure of DNA also described a mechanism for its replication [1]. The two parent DNA strands each acting as the framework for copying into the two daughter strands. The usual accuracy of the copying of billions of base-pairs into gametes at meiosis and daughter cells during mitosis is itself a marvel. Changes in the usually faithful copying of DNA strands (mutations) can be the basis of positive genetic change that encourages our evolution over generations. Or the sudden deleterious change in a DNA sequence may be the pathogenic mutation that underlies a congenital malformation that presents to a neonatal surgeon. Here lies the origin of many neonatal surgical conditions and ultimately important clues to their improved management and ultimately their reduction or even prevention.

16.2 DNA Structure and Genetic Function

The human genome contains approximately 3200×10^6 base-pairs of which approximately 2000×10^6 is non-coding, intervening DNA sequences. This has been referred to as '*junk DNA*', but it is now realized that this term undervalues its evolutionary legacy in the creation of new genes, its repository of old pseudogenes and its rich patterning with variable sequence DNA and single-nucleotide polymorphisms (SNPs) that allow the tracking of DNA within the individual genome, between family members and across population groups. Only about 48×10^6 bases of DNA is actually devoted to coding genes, about 1.5% of the entire human genome. In 1993 the first physical map of the human genome was achieved locating the major chromosome fragments and their marker probes. The Human Genome Project was completed in 2003 and is available in the public domain [2]. It has 20,000 genes of which more than 4000 are now known to be associated with genetic disorders.

DNA, (Deoxyribonucleic Acid) is the chemical chain composed of a specific sequence of four chemical bases (nucleotides); adenine (A), guanine (G), cytosine (C), and thymine (T) held together with a sugar and phosphate backbone. The two DNA strands are themselves held together by hydrogen bonds between mutual base-pairs of purine and pyrimidine bases, adenine pairing with thymine (A:T) and guanine pairing with cytosine (G:C). The linking of these nucleotide bases A to T and G with C, form the cross-bridging rungs of the DNA helix ladder, with the sugar-phosphate backbones forming the vertical sides of the ladder. The two DNA chains twist together in the double helix, one reading in the 5′–3′ direction, referred to as the sense chain. The opposite strand with its complementary nucleotide sequence running 3′–5′ is referred to as the anti-sense chain. As noted by Crick and

Watson the double stranded, double helix structure of DNA allows copying, either of itself (DNA replication) or as a template (DNA transcription) to direct gene expression via messenger RNA (mRNA) in protein synthesis. Apart from gamete egg and sperm cells all other body cells regardless of the degree of differentiation or tissue specialization of that cell carries the same DNA within the nucleus for that person. A small amount of DNA is also present in the mitochondria of the cell cytoplasm. Mitochondrial DNA is maternally transmitted via the cytoplasm of the ovum cell and is associated with disorders related to mitochondrial function and high energy ATP tissue activity; MELAS and MERFF, Leigh's syndrome, (myopathy, encephalopathy epilepsy, multiple strokes, lactic acidosis, ptosis and eye muscle disorders). When the nuclear DNA strands unwind each strand forms the template, for its replication by DNA polymerase. This is referred to as semi-conservative replication into daughter strands, in either DNA repair or when the entire DNA genome is copied prior to cell division. The process whereby specific regions of DNA are transcribed into messenger RNA is under strict control. DNA expression is regulated by sequence specific transcription factors that can open or close the reading grooves of DNA, allowing or denying access to RNA polymerase. Similarly the methylation of DNA can modify that region of the DNA preventing RNA polymerase binding and hence suppress the expression of gene sequences (see below). The process of DNA modification may occur during gametogenesis whereby paternally derived (from the sperm) DNA or maternally derived (from the ovum) gene sequence(s) can be turned on or off. This process of DNA methylation is known as imprinting and along with other changes in the DNA (for example the expansion of DNA triplet repeats in specific genes) are referred to as epigenetic effects. More detailed texts describe the molecular structure and function of the DNA and genes [3–5].

DNA is expressed by RNA polymerase copying specific gene sequence(s) into messenger RNA (mRNA). This passes out of the nuclear envelope into the cytoplasm where the mRNA is translated on the ribosome into a specified sequence of amino-acids forming the peptide chain of a synthesized protein. The sequence of mRNA bases is read in groups of three;

A-G-C- T-G-C- A-G-G- etc.,

the permutations of the four bases forming triplets in the messenger RNA (mRNA) with 4^3 ($4 \times 4 \times 4 = 64$) permutations that creates the genetic code. Each triplet in the genetic code is referred to as a codon. One codon AUG (as uracil substitutes for thymine in mRNA) is the initiation codon that begins protein synthesis (translation), whilst the codons UAA, UGA and UAG are stop codons signaling the termination of protein synthesis. With 61 remaining codons, there is overlap (referred to as degeneracy) in the ability of several codons to code for the same amino acid. In this way, some changes in the sequence of bases in the DNA may not lead to a change in the amino-acid sequence of a synthesized protein. Mutations that do not change the sequence of amino-acids are referred to as silent mutations and are part of the complex picture whereby not all DNA mutations may be pathogenic. DNA mutations that occur at key promoter binding sites where RNA polymerase binds to initiate mRNA synthesis and DNA sequence changes at intron/exon boundaries may be tolerated or they may lead to significant failure of DNA expression, gene function and hence adverse clinical consequences.

16.3 The Objectives of Clinical Genetics

It is fitting that the two specialties of neonatal surgery and clinical genetics that have made tremendous advances in the last 50 years should come together in this volume. Each now contributes significantly to the shared understanding of the cause of malformations and to offering strategies for more specific treatment and prevention of these conditions. Working co-operatively an international European network *EUROCAT*, of local and national congenital malformation registries for the epidemiologic surveillance of congenital anomalies was established in 1979 [6].

The combined registries now survey more than 1.7 million births per annum, (nearly 30% of all European births) drawn from 43 registries in 23 countries and collaborates with the World Health Organization (WHO) Collaborating Centre for the Surveillance of Congenital Anomalies [7]. A number of information toolkits related to congenital disorders and birth defects, particularly for developing countries are now available on the Internet [8].

The terms medical and clinical genetics are used interchangeably. Medical genetics is usually used as an overarching term to include the clinical and laboratory research, and resulting genetic counselling of a birth defect. Clinical genetics is a term reserved for the more direct patient and family based contact involved in this, particularly associated with the process of diagnosis and genetic counselling. Most specialist tertiary (teaching) hospital centres that perform neonatal surgery might also provide a clinical genetics service with access to medical genetics laboratories providing chromosome and molecular genetic (DNA) analysis. Human genetics is a broader term to describe the study of all human traits, those normally occurring and those that are disease (medical/clinically) associated. Medical (clinical) genetics including genetic counselling is best delivered as a co-ordinated package delivered by a multi-disciplinary team of medical geneticists, genetic counsellors, clinical psychologists and social support workers. The services offered by clinical genetics in the context of a neonatal surgical referral may include some or all of the following:

1. Examining the child, interpreting prenatal and other genetic test results. Advising on further specialised examinations and assessments for the child and relevant family members. Gathering relevant medical, pregnancy and 3-generation family history and interpreting this. Where appropriate examining parents, affected or at-risk family members.
2. Identifying the syndrome or differential genetic diagnosis. Communicating this to the family and the multi-disciplinary team caring for the neonate. Working in liaison with the neonatal surgical team to arrange referral to other clinicians for on-going care and assessment, or where the child does not survive involving agencies for bereavement counselling etc.,
3. With an appropriate diagnosis, discussing recurrence risks and who else in the family may be at risk. Offering discussion or a further genetics referral for members of the extended family, for appropriate screening, reproductive and pre-natal diagnosis options.
4. Offering support to the parents over the acute period and longer term, addressing their information and psychosocial needs. Putting families in touch with support groups and where requested and appropriate, with similarly affected families
5. Participation in data collection and malformation registers for incidence, outcome and research and teaching.

One chapter on Medical Genetics alone cannot do justice, nor can it remain up to date in such a rapidly expanding field. Rather this chapter presents an outline of approaches and describes what is the state of the science and art of medical genetics at this time (2016). The principles upon which medical genetics has been built will be described, its' approaches and what it can offer to neonatal surgery, to the child at the time of neonatal surgery, as they grow and to their parents and to the extended family.

Practice will vary between neonatal surgical units and their available medical genetic diagnostic services and access to clinical genetics expertise. Many will be placed in tertiary teaching and research hospitals where clinical and laboratory genetic services may be highly developed. It may be routine practise for all neonates with one and particularly more than one malformation, or a complex series of birth anomalies to be reviewed by a general paediatrician or a specialist clinical geneticist or dysmorphologist with an interest in birth defects. Much will depend upon the experience and expertise locally, what level of genetics service has been developed alongside the neonatal surgical unit. Standard chromosome analysis may be available to all infants or a genetics

opinion might only be sought for more highly selected cases. I have tried to indicate those 'red flag conditions' that should be recognised and those babies who would more likely benefit from seeking a clinical genetics opinion prior to expensive genetic investigation. It is for example now easy to E mail clinical photographs for a clinical genetics opinion. Even if genetic testing facilities are not available locally, samples for the newer techniques of DNA analysis are small, stable and can be sent internationally at low cost. However, the cost of laboratory analysis may be prohibitively high for some countries and their families. With prior arrangements, there may be a collaborating or research centre pleased to receive such samples from neonatal surgical centres especially in the developing, emerging world.

16.4 Syndromes, Sequences and Malformations

As genetics has dissected into the human genome and identified critical developmental genes, there has been a significant contribution to understanding the embryology and patho-physiology process of many paediatric surgical conditions. The emphasis must be on closer liaison between specialties, particularly between the paediatric surgeon and the clinical geneticist for diagnosis, management and in research. A syndrome (from the Greek, meaning *'running together'*), is a group of features that occur together without necessarily stating or knowing what that cause is. A malformation is an observed morphologic abnormality that arises from an abnormal developmental process that might be genetic (inherited or sporadic, (de novo, acquired) or may be secondary to a teratogen, vascular or disruptive event, e.g. cleft lip or neural tube defect (spina bifida) with associated anencephaly, hydrocephalus, talipes. A deformation sequence—is a pattern of (sometimes multiple) anomalies that result from physical force acting on an otherwise normal structure e.g. abnormal uterine or twin compression or the Potter sequence that follows oligohydramnios. A disruption process—is the loss of a tissue that was previously normal e.g. the effect of constricting amniotic bands. Some malformations may occur together in an associated group, for example the VACTERL Association (that includes *V* vertebral anomalies, *A* anal atresia, *C* cardiac abnormalities, *T* tracheo-oesophageal fistula, *R* renal /or radial, *L* limb abnormalities) or as the CHARGE Association, (the variable combination of congenital malformations including: *C* coloboma, *H* heart disease, *A* atresia choanae, *R* retarded growth and retarded development and/or CNS anomalies, *G* genital hypoplasia, and *E* ear anomalies and/or deafness). Dysplasia is the abnormal organisation of cells that results in a structural change of that tissue e.g. the altered cartilage and bone that occurs in skeletal dysplasia conditions.

Multifactorial / polygenic inheritance—are those common disorders with a significant genetic component and environmental influences, for example cleft lip and /or palate and congenital heart disease. Apart from genetic causes, vascular disruptions, physical deformations, amniotic bands and teratogens can affect the development of the fetus. Notable amongst teratogens are the viruses, rubella (German measles) CMV (cytomegalovirus) and perhaps the Coxsackie viruses. Prescribed drugs such as phenytoin and sodium valproate given for epilepsy, retinoids used for acne and psoriasis treatment and their effects on Vitamin A, or the fetal malformations seen with maternal exposure to warfarin, lithium therapy and thalidomide treatment. These may affect embryonic development in a recognised teratogenic syndrome, non-specifically or produce a syndrome that mimics a genetic disorder (known as a phenocopy) and may lead to the mistaken belief of a higher recurrence risk than actually applies if that drug is subsequently avoided. Other teratogenic effects may be due to cytotoxic drugs given for cancer treatment, effects upon the developing genitalia in children whose mothers' have taken sex hormones during the pregnancy, the increased risk of neural tube defects and facial clefts in children whose mothers' smoked before and during early pregnancy, the consequences of maternal alcohol ingestion, and the effects of low maternal folate levels for those women who have taken anti-folate drugs, for example methotrexate.

16.5 Developmental Genes and Malformations

Only a brief summary is presented here of the structure and function of the 22 pairs of autosomes and 2 sex chromosomes, XX in the female and XY in the male that make up the human complement in the nucleus of every diploid cell. The reader is directed to a number of general and specialist texts for more background and detailed explanation. The 23 pairs of human chromosomes consist of extremely tightly coiled DNA bearing the 20,000 genes that encode human heredity and function. Far from being merely an inert information store with genes dispersed at intervals, the human genome is highly organised and regulated. Genetic information flows in a dynamic and highly controlled process, with key genes switched on and off at critical points of embryogenesis, organ and limb formation, cell differentiation and tissue repair. Chromosomal DNA is intimately wound around histone protein clusters and regions of DNA can be methylated (imprinted) to restrict DNA copying (transcription) into active mRNA prior to translation into the amino-acid chains during ribosomal protein synthesis. Furthermore key proteins (see below) can bind DNA at specific sites to act as gene repressors controlling the switching on and off of genes in what can best be described as a carefully conducted orchestra of developmental regulation and careful control of the day to day function of a mature neonatal or adult cell [9, 10].

An increasing number of the genes associated with surgical malformations have now been identified. They are either DNA transcription factors acting directly on the regulatory genes or they code for proteins associated with them. Genes coding for DNA transcription factors produce proteins that are highly sequence specific and are therefore able to recognise and hence to regulate key segments of the genomic DNA. The ability of these proteins to bind and control DNA expression is mediated via DNA binding domains (DBD) configured as a zinc finger, basic helix-loop helix, fork-head or with a basic-leucine zipper structure. Transcription factors are gene specific proteins able to locate the enhancer or promoter region within the spiral groove of double stranded DNA and control the expression of developmental genes, promoting RNA polymerase binding or repressing gene transcription and hence expression. Together with other genes and their expressed protein products; co-activators, chromatin and histone acetylases, kinases and especially methylases they can selectively turn gene expression on and off in a usually co-ordinated orchestra of organised development. An example of such a genes is CHD7 a helicase DNA-binding protein where loss-of-function mutations cause the CHARGE syndrome [11]. Mutation analysis of CHD7 identifies a mutation in about 60% of cases with CHARGE syndrome. Information on the effects of CHD7 mutations is available from a dedicated website [12], that is updated with genotype and phenotype information [13, 14].

16.6 *Hox* Homeobox Genes

Hox (Homeobox) genes are involved in body pattern formation and orientation, acting as regulators of embryonic development. They were first identified as the genes controlling segmentation, antenna, leg and wing formation in the fruit fly, *Drosophila melangomaster* and have been found in plants, fungi and unicellular organisms and to be very highly conserved across species over 700 million years of evolution. The 39 human *Hox* genes are located in four clusters (A–D), (see Table 16.1). They are believed to have developed from the duplication and divergence from a primordial homeobox gene.

Each *Hox* gene is small composed of two coding exons with an intervening intron. The DNA sequence (180 base-pairs long homeobox) contains a highly conserved region that codes for a protein of 60 amino-acids creating three helical regions. These helical regions (helix-turn-helix) are able to bind to the DNA structure; helix 3 lying within the major grove and helices 1 and 2 lie above the DNA. The ordering A–D of these transcription factor genes in their chromosome clusters is important as it controls rostral (head) to caudal (tail) development in the human

Table 16.1 The chromosome location of the four human *Hox* gene clusters

Cluster	Chromosome	*Hox* Genes
HOXA	Chrom. 7p14–15	HOXD1, HOXD3, HOXD4, HOXD8, HOXD9, HOXD10, HOXD11, HOXD12, HOXD13
HOXB	Chrom. 17q21–22	HOXB1, HOXB2, HOXB3, HOXB4, HOXB5, HOXB6, HOXB7, HOXB8, HOXB9, HOXB13
HOXC	Chrom. 12q12–13	HOXC4, HOXC5, HOXC6, HOXC8, HOXC9, HOXC10, HOXC11, HOXC12, HOXC13
HOXD	Chrom. 2q31-q37	HOXD1, HOXD3, HOXD4, HOXD8, HOXD9, HOXD10, HOXD11, HOXD12, HOXD13

embryo. The 3′ genes in the clusters are expressed earlier and more anteriorly than the 5′ genes. The *Hox* genes control the differentiation of uncommitted cells in the embryo as they form limbs and organs in the segmentation process. The *Hox* genes relate positional information along the AP axis of the developing embryo creating functional domains for groups of cells. *Hox* gene expression occurs during early gastrulation when the embryo is generating its body axis. Segmentation involves processes of programmed cell death and the migration of cells, with the target genes of *Hox* genes acting to promote cell division, cell adhesion, apoptosis, and cell migration. In the fruit fly, mutations in the Antennapedia gene cause legs instead of the antenna to develop on the head of a fly.

Human *Hox* gene mutations are particularly associated with limb and digit abnormalities, including polydactyly, hypodactyly and syndactyly and genital anomalies. HOXB5 expression affects lung development and mutations are associated with congenital cystic adenomatoid malformation. HOXA5, HOXB4 and HOXB6 are also associated with pulmonary development [15–19]. HOXA10 and HAOXA11 mutations are found in congenital malformations of the female genital tract, especially with uterine malformations. HOXA11 and HOXA13 and HOXD10 and HOXD13 are active in the developing limb, and mutations in HOXA13 lead to hand-foot-genital syndrome, whilst HOXD13 mutations are associated with synpolydactyly and the HOXD13 allele, 180A > G (A60A) has been identified as a risk factor for cryptorchidism [20–24].

16.7 SOX Genes

A super-family series of 20 SOX genes play a critical role during embryonic development and in the differentiation of precursor multi-potential stem cells. The SOX genes are highly conserved across eukaryotic cells and mammalian development. These genes produce proteins that are transcription factors, able to recognise and bind to specific sequences of DNA. By binding to the minor groove of DNA their carefully formed protein shapes can enable or prevent RNA polymerase access and hence regulate transcription of specific target genes. Mutations in these genes lead to disorders that involve the abnormal development of tissues in which a particular SOX gene is active (expressed). As a result, the genetic disorders caused by SOX mutations typically have a wide variety of signs and symptoms. The 20 human SOX genes mostly share >50% amino acid homology with each other and with the HMG (high mobility group) in the Sry gene on the Y chromosome that plays a major signalling role in determining testis differentiation and hence male development. Mutations in SOX2 (chrom. 3q276.3-q27) are associated with microphthalmia and its pathway interacts with PAX6. The SOX9 (chrom. 17q23) gene product regulates chondrocyte differentiation and also acts to regulate transcription of the anti-Müllerian hormone, AMH. Mutations in SOX9 are associated with campomelic dysplasia, a skeletal malformation syndrome with bowed tibiae and often sex-reversal. The SOX-10 protein is important for the development of the neural crest and the peripheral nervous system development. SOX10 (chrom. 22q13.1) is active in the development of the neural crest. It interacts with PAX3

and may be regulated by another transcription factor, MIcrophthalmia-associated Transcription Factor (MITF). SOX10 mutations are seen in Waardenburg-Hirschprung disease. Mutations in SOX14 (chrom3q22–23) are associated with limb defects seen in the blepharophimosis, ptosis, epicanthus inversus syndrome (BPES) and in the Mobius syndrome. The SOX17 gene and particularly the c.775 T > A (p.Y259N) mutation has been found to be a recurrent mutation in human kidney and urinary tract malformations including vesicoureteric reflux [25].

16.8 PAX Genes

The PAX family of 9 genes (PAired Box) are transcription factors that contain a paired domain and a partial or complete homeodomain. They are active in the early embryonic development of specific tissues, and are organised into four groups, (see Table 16.2).

PAX gene activity tends to be inactivated after birth, except in tissues that can regrow for healing or regeneration. The following tissue activities for PAX genes have been proposed or confirmed. PAX1 is involved in vertebral development and segmentation of the embryo. PAX2 is active in the kidney and optic nerve development and PAX2 mutations cause renal-coloboma syndrome. PAX3 is involved in ear, eye and facial development and mutations occur in Waardenburg syndrome, PAX4 with pancreatic islet beta cells and PAX5 are involved with neural and spermatogenesis development and b-cell differentiation, PAX6 appears as a master controller gene for the development of the eyes and sensory organs, neural and epidermal tissues as well as other ectodermal derived structures. PAX6 is the gene associated with aniridia. PAX7 associated with myogenesis, PAX8 with thyroid development and PAX9 has wide expression in organ, skeletal and teeth development. There are nine genes in the PAX gene family. These genes are divided into subgroups based on various aspects of similarity. Subgroup I includes PAX1 and PAX9; subgroup II includes PAX2, PAX5, and PAX8; subgroup III includes PAX3 and PAX7; and subgroup IV includes PAX4 and PAX6. Mutations in PAX genes lead to disorders that involve the incomplete development of tissues in which a particular PAX gene is expressed. Additionally, the over-expression of PAX genes has been noted in a variety of cancers. It is thought that the cell protection function of PAX genes prevents cell death and permits tumour growth (proliferation).

Table 16.2 Pax group organisation

Pax group	Pax genes
1	Pax 1 and Pax 9
2	Pax 2, Pax 5 and Pax 8
3	Pax 3 and Pax 7
4	Pax 4 and Pax 6

The gene TBX5 from the family of T-box transcription factors [26], encodes a protein transcription factor, T-box 5 that controls DNA expression. It is related to the T-box 3 gene implicated in ulnar mammary syndrome. TBX5 mutations are associated with pre-axial radial ray abnormalities of the upper limb and cardiac development abnormalities of Holt-Oram syndrome. Mutations in TBX5 are found in more than 70% of Holt-Oram patients [27–29].

16.9 Multi-factorial Conditions and Polygenic Inheritance

These are a wide group of conditions and malformations in which inheritance and environment contribute. Literally *'nature and nurture'*, it is the contribution of variable numbers of genes, (polygenic inheritance) together with an environmental influences that can include diet, drug and teratogen effects bacterial or virus infection, occupation and lifestyle including smoking and alcohol exposure that determines whether a condition will or will not develop. This is the accepted background for continuous traits such as height, blood pressure, intelligence. The heritability of any trait or condition is the degree to which its occurrence is due to inherited genetic factors. It is recognised that some common malformations, for example cleft

lip and/or palate, congenital heart disease and neural tube defects (spina bifida) cluster in some families and that after the first or second case has occurred in one family, the recurrence risk for close family members is increased over the population (prior) risk. This was studied by the statistician Fisher [30] who suggested the additive effects of multiple pairs of genes each contributing to (or diminishing) the relative risk of that condition occurring. Falconer [31] developed a model that a threshold exists, beyond which the condition or malformation would be expressed. Families who had already experienced that malformation are in a higher risk group shifted further towards the threshold than the general population who are at lower risk. It is suggested that affected families carry a higher genetic predisposition and/or indeed share an adverse environment accounting for their higher risk of recurrence. Where the genetics are complex and still poorly understood, empiric recurrence risks are quoted. For example the risk of cleft palate in the general population is about 1%. If parents have had a child with an otherwise isolated cleft, their empiric risk of recurrence is increased to around a 2–3% risk. After their second affected child, their risk increases to around a 10% risk with adjusted risks for relatives of the parents and for the affected child and their sibs when they in turn seek genetic advice. Heritability is the degree to which inherited / genetics factors as opposed to other factors (diet, lifestyle, environment) contribute to the aetiology for any condition. This may be based upon observation that all gene carriers manifest (for example all children who have the FGFR3 achondroplasia gene mutation show disproportionate short limb short stature). In this condition the gene penetrance is said to be complete as all gene carriers manifest the condition. In contrast many other dominant genes characteristically show very variable expression ranging from complete expression of that gene's full spectrum of effects in some family members, through to mildly relatives. There may also be carriers of that gene mutation who show no clinical signs, but can yet pass the gene mutation on and have a fully affected child. The later is referred to as non-penetrance.

The heritability of congenital malformation can vary for congenital heart disease or cleft lip and palate. There may be a sex difference for congenital pyloric stenosis or congenital dislocation of the hip. Careful assessment is needed not to miss a syndrome that might have a chromosomal or single gene cause. Twin and adoption studies may be needed to demonstrate the variable inheritance of complex multi-factorial, polygenic traits. Surveys of congenital malformations and the introduction of more formal systematic Malformation Registers indicate that 2–3% of children are born with some congenital anomaly of varying severity. Depending on definitions and how the data is acquired, these malformations may range from those lethal conditions that may be detected antenatally through to those conditions referred to the neonatal surgeon. Observation, delayed or staged treatment may be suggested and clinical genetics may be involved in parallel to this.

16.10 The Genetics of Hirschprung Disease

Hirschprung disease (HSCR) causes intestinal immotility in 1 in 5000 live births. It is an example of a congenital disorder with a complex polygenic aetiology. HSCR results from the congenital absence of intestinal ganglions. In 80% of children with HSCR this may affect the rectosigmoid junction (short segment), but in 15–20% the aganglionosis may extend proximal to the sigmoid colon (long segment). In about 5% there may be total colonic aganglionosis or rarely the entire bowel may be involved in total intestinal aganglionosis. Hirschprung disease may be an isolated condition in a child or occur as part of a complex syndrome [32] or it may be an isolated finding [33]. HSCR and its associated multisystem disorders are referred to as the neurocristopathies.

First analysed by Cedric Carter [34], the recurrence risk and severity of HSCR depends on the family history, the proximity of affected relative(s) to the person seeking advice, the severity (higher recurrence risk for long and especially

total colonic aganglionosis versus short segment diseases) and a higher recurrence risk when the affected member(s) have been in the less frequently affected sex. An empiric recurrence risk of about 4% is quoted in short segment HSCR where there is no other family history and no other syndromic features are present. The receptor tyrosine kinase (RET) gene has been identified as the major gene, with RET mutations accounting for than 80% of cases where a gene mutation has been found [35]. The research technique of genome-wide association studies (GWAS) has been used to find multiple regions of the genome that predispose individuals to a disease using commonly occurring markers known as single-nucleotide polymorphisms (SNPs). GWAS studies collect hundreds of DNA samples from subjects with the condition (cases) and from people from the same population who do not show the conditions (controls). The DNA samples are then tested against the millions of SNP variants that are widely distributed across the genome as random genetic markers using SNP arrays. If there is a SNP pattern (one allele) that is more frequent amongst the cases than the controls, then the map location of that SNP suggests that there may be a closely linked region of the DNA or indeed a gene that is *'associated'* with that disease or trait. The power of GWAS is that no candidate region or gene needs to be suggested in advance of the study, single cases of the disease can be used and samples can be pooled across multiple study groups and populations, provided that the diagnostic criteria for the disease are robust and reliable and that adequate controls can be found from amongst the multiple study populations [36].

So far another ten genes (GDNF, NRTN, SOX10, EDNRB, EDN3, ECE1, ZFHX1B, PHOX2B, TCF4, and KIAA1279) [37] have also been identified in the aetiology of HSCR. Other genes acting as modifiers and enhancers (SOX10) affecting the expression of Hirschprung disease have been found, making this a truly complex disorder. A gene mutation is found in about 50% of familial cases of Hirschsprung's and in up to 20% of isolated cases. Despite these advances the ability of genetic testing to reliably predict an affected pregnancy, estimate the likely severity and explain the heritability versus non-genetic factors in the aetiology of HSCR remains limited to about 2% of cases.

16.11 Investigation of Malformations and Syndrome Recognition

Syndrome diagnosis is arguably one of the greatest clinical arts practised. It requires consummate knowledge of the growing list of genetic and malformation syndromes, and their variable presentation. There may be age specific facial features that are present for perhaps only the first months or year of life and then fade into a general coarsening or non-specific facial dysmorphism. Conversely the facial appearance may not appear until older or the diagnosis may remain elusive until other physical or behavioural features appear. Observation and return visits over a number of years may be needed before the careful eye of the dysmorphologist can make a diagnosis. Syndrome diagnosis may be an 'all or none effect'. Recognising a facial appearance, (the gestält, *"I have seen this before—I know what this is"*), or it can be a long process of watching and re-evaluating [38]. One needs to allow for the often variable expression of syndromes or malformation sequences, or it may be a painstaking process of identifying facial and malformation features, known as '*handles*' that occur sufficiently often with that syndrome / condition to be diagnostically useful. These diagnostic '*handles*' need to be clues that are specific enough to be useful without generating too wide a diagnostic differential. For example agenesis of the corpus callosum is more diagnostically useful and a better handle for syndrome diagnosis than the non-specific mild ventricular dilatation. Similarly pre-axial polydactyly, (duplication of the thumb) is more closely associated with specific syndromes than post-axial polydactyly (duplication of the little finger or ulnar placed finger digit(s)). Post-axial duplication occurs in the general population, and it may be coincidental and not an associated feature of the child's syndrome.

Referral to a paediatrician with an interest in neonatal malformations, dysmorphologist or clinical geneticist is suggested, if any of the following are present:

- more than one malformation present
- more severe or a more symmetric pattern than might usually be expected
- microcephaly or growth retardation (less than the third centile)
- a family history of this, or other congenital abnormalities
- 3 or more parental miscarriages
- parental consanguinity (cousin) partnership

Depending on local practice, complete assessment may be undertaken by a geneticist/dysmorphologist or they may provide initial telephone advice. The following information, gathered for the discussion is most helpful:

- a complete description of the neonate
- facial appearance and relevant photographs
- birth weight and head circumference
- pregnancy history including growth charts, ante-natal scans and any pre-natal tests, particularly chromosome analysis
- record of maternal drugs (both prescribed and non-prescribed), smoking and detailed alcohol history
- parental medical history and exposure to potential teratogens
- a three generation family history, including the child and any siblings (brothers and sisters) from either parent, the child's aunts and uncles through both parents and details of their children, the child's four-grandparents and their siblings
- specific questioning of the parents for any other children in the family who have had a similar condition, a malformation, surgical problem, learning difficulty or who have died young
- any family history of consanguinity or of parents being related or distant cousins

Depending on circumstances the geneticist may request any of the following:

- further clinical photographs
- specific X-rays or a skeletal survey
- chromosome analysis
- DNA for storage
- specific samples for metabolite or enzyme studies
- a skin biopsy to establish a fibroblast cell line, liver or muscle biopsy (these may be post-mortem)
- a cardiac echo, a renal ultrasound and either a brain ultrasound or a brain MRI scan due to the increased risk of finding an associated malformation

Syndrome diagnosis can be certainly aided, but not itself made by using dysmorphology databases and their associated searching tools. They require the clinical assessment of the child with a malformation or series/sequence of congenital anomalies. Carefully selected features (*handles*) can then be entered into such search databases to generate a syndrome diagnosis differential to aid further investigation and hopefully diagnosis. Widely used and easy to navigate databases include the series of London Dysmorphology Databases; 1990, (Baraitser and Winter), http://www.lmdatabases.com/about_lmd.html#lddb that include specific dysmorphology, neurogenetics and eye malformation databases. The dysmorphology database contains information on nearly 5000 dysmorphic and multiple congenital anomaly syndromes with over 20,000 images of facial and malformation features and relevant radiographs. The dysmorphology database currently (2012) costs UK £600 and a subscription for three updates currently cost UK £200. A similar internet based subscription limited access application developed in Australia is POSSUM, http://www.possum.net.au/index.html. Online Mendelian Inheritance in Man [39] is an open access internet based resource catalogue that is continuously updated with comprehensive clinical, research and genetic testing information on over 12,000 single gene (Mendelian) conditions. It is a rich source of diagnostic information and its multiple links allow clinicians ready access to management and support group information [40], published literature and where applicable genetic

testing resources [41]. A number of dedicated textbooks for dysmorphology can also be used [42–45].

Making a diagnosis allows the geneticist to explain to the parents' what has happened and if known why this has occurred. Information can be shared with the child's surgical team and with the often multiple members of the multidisciplinary team caring for the child with congenital anomalies. For the parents' a specific diagnosis allows access to genetic counselling with a more accurate recurrence risk and discussion of the options available for pre-natal diagnosis. A diagnosis may only be a label for a very rare combination of malformations, but it allows forms and statements to be completed, and thereby facilitates access to special educational needs, financial welfare and social care benefits. Parents can achieve a degree of closure in their search for a cause, sometimes their need for something or someone to blame and to begin the process of coming to terms with what has happened and begin to deal with the understandable, but incorrect feelings of guilt over what has happened to their child. Support for families is available from support groups that are specific for that condition/malformation or from these umbrella organisations:

Without a syndrome diagnosis, follow-up visits to the genetics clinic for careful review, access to syndrome diagnosis databases, relevant books and publications with targeted investigation and referral for other opinion(s) may occur over several years. In challenging cases the clinical history and photographs will be shared with dysmorphology colleagues at national or international meetings and may result in publication. Families may spend years searching for a more specific diagnosis with their clinicians. If a confident diagnosis cannot be made, that child's condition may be regarded as a SWAN (Syndrome Without A Name) for which more general support groups exist, http://www.undiagnosed-usa.org/ in the United States and http://www.undiagnosed.org.uk/ in the United Kingdom.

16.12 Methods of Genetic Investigation

In 1956, Tijo and Levan correctly identified the number of human chromosomes in the cell as 46 and in 1959 Lejeune identified the first human chromosome karyotype abnormality in Down syndrome. Non-disjunction is the failure of chromosomes to separate in cell division into daughter cells and is the commonest cause of trisomy, for example age related trisomy 21, Down syndrome. A chromosome might be lost, resulting in monosomy which apart from those affecting the sex chromosomes (45,X—Turner's syndrome) are rare. They can occur in mosaic form where there is a mixed population of body cells with the normal complement 46 chromosomes and abnormal cells with 45 chromosomes. Careful karyotype analysis of 100 blood cells or examination of another tissue; buccal scrape or a cultured skin biopsy might be required to reveal mosaicism especially if it is only present at a low level or confined to one tissue or body region. Deletions, duplications, and more complex re-arrangements including translocations that can be 2-way or even 3-way, inversions can all affect a child's chromosome pattern and produce varying congenital malformation depending on the increase or decrease of chromosome material that results [46].

For many years, light microscopy analysis of banded (chemically stained), cultured cell metaphase chromosomes had to suffice. This can be enhanced by the development of techniques for the preparation of longer chromosomes for higher resolution chromosome analysis. Chromosomes have a shorter (p for petit) and a longer (q) arm separated by the centromere. Chromosomes with a centrally placed centromere are known as meta-

centric chromosomes, the centromere displaced from the centre produces a sub-metacentric chromosome and the acrocentric chromosomes has their centromere at one end, with a very small p arm composed of DNA coding for rRNA. The human centromeric chromosomes 13, 14, 15, 21 and 22 are prone to form translocations with another acrocentric chromosome. These fusion products are known as Robertsonian translocations and when unbalanced can lead to trisomy 13 (Patau's syndrome) and trisomy 21 (Down's syndrome). Chromosome analysis should be offered to the parents of these children as one might be the unknowing carrier of a balanced (45 chromosome karyotype) and at high risk of having further affected children [47].

The resolution of light microscopy is approximately 4 Mb (4 million base-pairs of DNA), but a chromosome loss smaller than this cannot be seen even by high resolution chromosome banding without more specific identification techniques. The early 1990s saw the introduction of an increasing range of specific chromosome analysis probes. The technique of Fluorescent In Situ Hybridisation (FISH), exploits the property of single stranded DNA to bind to its specific complementary sequence. By making fluorescently labelled unique sequence probes, specific DNA regions (for the common chromosome trisomies 13, 18 and 21 and now all of the human chromosomes) can be identified. This technique allows the identification of a chromosome microdeletion (for example the chromosome 22q11 region that is deleted in the contiguous gene of the Di George / Velo-Cardio-Facial/ CATCH-22 syndrome associated with cleft palate, hypocalcaemia and congenital heart disease) or submicroscopic duplications. With an increasing range of chromosome probes, complex translocation re-arrangements and inversions, and the formation of derived chromosome rings can be identified as well as the tips (telomeres) of chromosomes screened for deletions where 2–3% of children with multiple congenital anomalies may be found to have a telomeric chromosome abnormality. A checklist has been developed for identifying patients with suspected sub-microscopic sub-telomeric rearrangements [48–50]. Criteria for genetic investigation / referral are: multiple congenital anomalies (two or more major anomalies) or a single major anomaly together with abnormal neurology, dysmorphic features or an abnormal growth (length, weight, OFC) pattern with 2 or more growth parameters +/− >3SD or a single growth parameter +/− >4SD.

In the technique known as 'chromosome painting' the origin and possible functional significance of unknown chromosome fragments, sometimes appearing as small chromosome rings can be discerned using a range of chromosome specific FISH probes ('*paints*'). The limitation of FISH analysis has been that it only answers a specific question, what is this chromosome fragment?—is it for example derived from chromosome 21 and therefore does this child have a form of Down's syndrome? Or FISH testing can be used to address the clinical enquiry does this fetus / child with congenital heart disease or a cleft palate have Down syndrome or Di George syndrome?, In each case only a limited number of questions can be asked and answered by using a selected number of available chromosome FISH probes.

16.13 Microarray Analysis

It is in the molecular investigation (molecular cytogenetics) of genetic syndromes and malformations that the most rapid progress is occurring. The limited resolution of chromosome studies by light microscopy analysis, even when supplemented by the increased diagnostic yield of telomere analysis and targeted FISH probe analysis has led to the development of the technique of genomic micro-array chromosome analysis. This semi-automated technique introduced in the year 2000, allows for the more sensitive analysis of the whole genome than previous chromosome analysis. The diagnostic yield, finding genomic imbalances (duplications, trisomy or deletions, monosomy) for children with previously undiagnosed congenital anomalies, facial dysmorphism, developmental delay or growth retardation has been highly significant. The wider availability and falling cost (current cost per case analysed

around US$ 1200) of micro-array analysis has led to this becoming increasingly adopted as the first line investigation, in preference to the conventional analysis of stained and banded chromosome metaphase preparations. The cost is likely to fall quickly, as the technique becomes more widely available and DNA chips become commercially mass produced [51, 52].

Microarray analysis depends upon using many thousands of DNA probes already immobilised on a chip to interrogate the patient's DNA by a process of comparative genomic hybridisation (CGH). Also known as array CGH, the technique depends on immobilizing fluorescently labelled probe DNA to the solid surface of the chip surface. Affymetrix uses a glass or silicon chip surface whereas the Illumina chip uses microscopic beads. The target (patient sample) DNA for investigation is rendered single stranded and fluorescently labelled prior to being applied to the chip that might have anything from 2000 to 30,000 or even up to 300,000 oligonucleotide probes from which the non-hybridised patient DNA is washed off. Where the patient DNA (for example fluorescently labelled red) has covalently bonded (bases G to C; bases A to T) to the immobilised probe DNA of the chip, (for example fluorescently labelled green, there will be a 1:1 ratio of the complementary fluorescent signals, and in this example, the red to green ratio will thus be 1. But where a region of the patient's DNA is deleted there will be an excess of unhybridized green target probe and the red to green ratio will be less than 1. If the patient's DNA has a region of duplication, there will be relatively more red signal (patient DNA) retained at that point (spot) on the array and the red to green ratio will be greater than 1. This technique can identify deletions or duplications down to a resolution that varies with the size (60-mer probes produced by Agilent or shorter 25-mer probes produced by Affymetrix) and the genome density of the probes and their cost. Microarray analysis will identify an abnormality in between 3% and 5% and in more carefully selected series up to 10% of previously undiagnosed children. Array CGH will not identify balanced (reciprocal translocations) chromosomal rearrangements in which no genetic material is gained or lost. It will not identify sequence changes at the base-pair or rearrangements at the gene level below the resolution of the probe set used. The limitation of microarray testing (sensitivity) is down to a resolution of 5–10 Mb or using the more expensive high-density arrays, deletions and duplications as small as $\approx$ 1–3 Mb changes can be identified. Microarray chip designs vary between manufacturers and should be chosen for their intended use, as much as for cost. One chip design may for example have a 180 kB backbone spanning the human genome, but have enhancement of 15 kB in approximately 1500 regions that are particularly associated with major diseases.

A current, but significant drawback of CGH micro-array is the frequent identification of variants in the genome of tested patients that are of no clinical significance. It is increasingly recognised that about 0.5% of human genomic DNA has regional variation with regions of DNA varying in length from 1 kb (1000 base-pairs) up to several megabases in length that are repeated / duplicated or deleted. These regions of variation are known as copy number variants (CNVs) and vary across different chromosomal regions. They are part of the normal variation in the structure of genomic DNA that are usually stably inherited from parent to child and are not believed to be associated with any disease phenotype. These variants in segments of the DNA are in addition to the variation in single base-pairs (nucleotide) polymorphisms (SNPs) that are widely scattered through the human genome and that act as prolific markers to track variation and inheritance. Current research studies such as the Deciphering Developmental Disorders (DDD) study [53], is gathering information on their frequency and if there is any malformation/disease association. The finding of an apparent micro-array variant in a child needs careful interpretation, asking the following questions:

1. Is this a region of the genome known to be associated with copy number variants (CNV)?
2. Requesting parental samples for testing. If the micro-array finding is de novo then it is circumstantially, but not definitely proven to be

causal for the child's condition. It remains possible that the apparent stable inheritance of a chromosomal region anomaly does cause a malformation/disease by an epigenetic imprinting effect.
3. Have other people been reported with this micro-array abnormality and do they have a similar malformation/disease phenotype?

Despite these cautions, the introduction of microarray analysis and their falling costs has opened an exciting window for the investigation of children with malformations. Specific treatment my still elude us, but for the clinicians involved and particularly parents, there is at last some explanation for what has happened [54, 55]. Stem cell research and forms of gene therapy using anti-sense oligonucleotides (ASOs) and RNA interference (RNAi) sequences to target the suppression of mutant genes are under development.

16.14 Molecular Genetic (DNA) Testing

Nowhere has growth been more explosive than in the range of DNA analysis techniques and the exponential expansion in the number of genes that can now be screened. The current and still moving horizon of DNA sequencing has moved from slow and laborious chemical and pyrosequencing methods introduced in 1977 by Maxam and Gilbert and refined by Fred Sanger as Sanger sequencing, sharing the 1980 Nobel Prize for chemistry [56]. The technique of MLPA (multiplex ligation-dependent probe amplification) developed from multiplex polymerase chain reaction (PCR) allows multiple DNA targets to be amplified and analysed. Provided the gene sequence of the wild-type DNA sequence is known, designed oligonucleotide primers can be used to amplify specific DNA regions (referred to as amplicons) for capillary sequencing or further analysis [57]. In the 1980s Applied Biosystems developed the first automated sequencing machine the ABI 370, and in the 1990s came high-throughput sequencing in what is now termed, Next Generation Sequencing (NGS) or massively parallel sequencing using robotics [58]. It is now possible to sequence a person's exome (the approximately 180,000 expressed exons, about 30 megabases of DNA that constitutes about 1% of the total genome), in a few days at a cost rapidly approaching USD $1000. Perhaps the only limitation of microarray analysis and of sequencing the genome—is the vast amount of data generated. Deciding whether a sequence change or a small deletion/duplication is clinically significant in a neonate with an undiagnosed multiple malformation condition is complex. If the sequence change or microarray finding has been reported before, it may be possible to say that it is causally or even functionally associated with that pattern of malformation(s). Changes in the DNA sequence may not be disease causing if the alteration occurs in a non-coding or non-regulatory of the genome; if the change of a single nucleotide does not lead to an amino acid change, known as a silent mutation because the genetic code is degenerate with multiple combinations of the 3 base codons accounting for any of the 20 amino acids. DNA sequence changes may affect RNA splicing if the recognition sequence of an intron-exon boundary is disrupted. The DNA mutation may be a missense mutation that changes the amino acid sequence, but the consequence of this will depend on the amino acids substituted. If an amino acid is changed for one of similar size, acidity/base, hydrophilic/hydrophobic character or this occurs in a non-critical region of the protein the change may be neutral and not clinically evident. However, the amino acid change may for example, involve cysteine that can form disulphide bridges and significantly change the 3D conformation of protein folding and hence its function.

Mutations may create a stop codon (nonsense mutation) that leads to premature termination of mRNA translation. Protein synthesis will stop at that point and the closer this is to the start of polypeptide synthesis at the 5′ end, the greater will be the functional loss of the intended protein. Likewise mutations at promoter end of genes will led to the failure of gene transcription and function. The deletion of 1 or 2 nucleotides in the

DNA will lead to frame-shift mutation disrupting the ordered reading of triplet codons and produce a complete change of the consequent protein sequence and the likely downstream appearance of a stop codon. It is now realised that genes are far more dynamic than its mere nucleotide sequence would suggest. Epigenetic effects occur where key areas of the genome can be methylated that leads to the non-expression of that gene (gene silencing) in future cell divisions. The imprint occurs in meiosis and differentially affects the expression of maternally and paternally inherited copies of the same gene in all subsequent somatic cell divisions. It is thus important not only what DNA sequence you inherit, but also whether this was inherited from the mother or the father. Imprinting particularly affects the Prader-Wiili and Angelman syndrome region (15q11–13) of the human genome and the Beckwith-Wiedemann syndrome region (11p15).

DNA changes are referred to as a mutation if they are believed to be causally related to the disease/ condition. A sequence change that is not believed to be pathogenic, but occurs in more than 1% of the population is termed a polymorphism. A private polymorphism is a neutral change that is rarer than this, (less than 1% of the population). If a DNA sequence change has not been previously reported, its presence may be coincidental. If the variant is found in an unaffected parent, it is probably a polymorphic variant that is unlikely to contribute to the malformation seen in the affected child. If the DNA sequence change is not present in either parent (therefore occurring de novo) then it is likely to be associated with the aetiology of the malformation(s) in that child. Internet based databases such as the DECIPHER database at the Sanger Centre [59] have been established to collect information on these new findings and to collate updates on their functional and clinical significance. The new science of bioinformatics has been born out of the need to collect, collate and ultimately interpret the literally billions of nucleotide sequence changes that have been generated from sequencing individual genomes. With the increasing availability and decreasing cost of next generation / whole genome sequencing the challenge is the interpretation of so much sequence data and the likely finding of numerous sequence variants of unknown clinical significance. Known as unclassified variants (UCVs), or copy number variants (CNVs) or single nucleotide variants (SNVs) they be disregarded if they are known to occur in regions of known DNA variation. If present in a parent they may be innocent polymorphisms; but it is possible that they contribute to the pathogenesis of a multifactorial or polygenic condition as genetic modifiers or that sequence change itself is susceptible to imprinting by methylation and hence variation in expression. If a sequence change has been found to be de novo, (not present in the parents and non-paternity can be excluded), then that apparent DNA mutation can be circumstantially associated with the aetiology of a malformation or syndrome. Further evidence of causation would come from its finding this mutation in multiple other cases and being able to implicate its role in the embryology and pathogenesis of that condition. Microarray reports and extensive sequencing data must therefore be interpreted with caution. The reporting laboratory and reference to the literature may help to classify whether this mutation has clinical validity and ranges from Class 5: definitely pathogenic (>99% probability) and can be used for prenatal testing, Class 4b: probably pathogenic (95–99% probability) that requires additional confirmatory evidence, Class 4a: possibly pathogenic (80–95% probability) that may help with clinical diagnosis, but cannot be reliably used for prenatal testing; Class 3: uncertain where there is no clear evidence of whether the finding is causal or benign through to Class 2 and Class 1: likely benign (1–5% probability) or benign (<1% probability) respectively that the variant found is pathogenic. This requires careful explanation of this to the clinical team and counselling of the family to avoid a genetic change being over interpreted and wrongly accepted as the genetic cause of a child's condition. The consequences may be failure to pursue other investigations, the risk of giving incorrect information to the parents and hence inaccurate recurrence risks to them and

close family members. Ultimately this can lead to false reassurance in a future pregnancy or a missed recurrence. Non-specialists are cautioned to seek advice and to tread carefully.

16.15 Non-genetic Investigation of Malformations

Emphasising that not all malformations are genetic, let alone inherited, other causes may need to be sought. These may include teratogens either ingested as prescribed or non-prescribed or abused drugs, exposure to environmental toxins and chemicals and maternal alcohol ingestion and smoking during the pregnancy. The effect of teratogenic infections such as rubella virus for which careful examination of the neonate, taking a maternal and pregnancy history and confirmatory viral antibody titres may be diagnostic. Clinical photographs are an essential record of the child, their malformation(s) and to include views of their face (full face, with frontal and lateral views, full body standing to show proportions and any distinguishing features) that may be shown to dysmorphologists to allow them to search amongst hundreds of possible syndromes for specific malformation(s) and distinguishing features. Building up a picture of the key malformations and those supporting features whilst ignoring common or co-incidental features, a likelihood of perhaps 4–6 syndromes in the differential diagnosis can be derived for further exploration.

The investigation of other malformation conditions may require a skeletal survey, targeted biochemical analysis, enzyme assays or the screening for either excessive or insufficient levels of key metabolites. For example measurement of the 17-OH steroid profile in congenital adrenal hyperplasia (CAH) or of the 7-dehydrocholesterol level to diagnose Smith-Lemli-Opitz (SLO) syndrome. Both of these conditions are associated with ambiguous genitalia and need to be considered amongst the many other chromosomal, single gene and mosaic genetic causes of disorders of sexual development (DSD) [60, 61]. If a metabolic syndrome is suspected, it may be prudent to ask the parents, particularly when a child is moribund or has died for consent to store plasma, urine, CSF, liver and often to take a skin biopsy sample to establish a skin fibroblast cell line. If an EDTA blood sample has not already been taken, spleen or liver tissue even many hours post-mortem provides a highly cellular sample for DNA extraction.

16.16 Approaches to Genetic Counselling

The process of genetic counselling is intended to inform and support patients and their families about their condition and help them make informed decisions. The American National Society of Genetic Counselors' (NSGC) developed a revised definition of genetic counseling: 'Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates the following:

- interpretation of family and medical histories to assess the chance of disease occurrence or recurrence
- Education about inheritance, testing, management, prevention, resources and research.
- Counseling to promote informed choices and adaptation to the risk or condition.' [62]

Some genetic counselling sessions may be straight-forward, informing the family of the diagnosis, sources of information, perhaps just a low recurrence risk and will require only one visit. Other referrals might require several sessions to collect additional information, to update the family or to deal with ongoing medical and/or psychosocial problems.

A detailed history (pedigree) should be taken to at least three generations to include the patient's brothers and sisters and any children they have, the grandparents and their siblings and

families. A shorthand notation for drawing the family tree uses square symbols for male family members, circles for females and a diamond symbol where the sex is unknown, those of the same genetic generation are kept on the same line, their children drawn below and so on [63].

The parents should be asked about their other children, any miscarriages, stillbirths or neonatal deaths. Questions should include the parents' medical history, history of the pregnancy and asking about all drugs and potential teratogen exposure information is important. It may be necessary to seek old medical records if something relevant is mentioned by the family. It is important to particularly ask whether the parents' or their families are related as consanguinity (inbreeding) makes autosomal recessive conditions with a high, (25% or 1 in 4) recurrence risk to further children likely, but not necessarily the cause. Autosomal recessive conditions may be the underlying cause even if no previous family history is yet known. With autosomal recessive conditions, parents are healthy, and more often unknowing carriers of one copy of the mutant gene. Consanguinity is a particularly common practice in some Middle Eastern, south Asian and Muslim ethnic communities and also with within geographically and socially isolated communities. A pedigree is useful in the assessment and diagnosis of a genetic disease and to determine a person's risk of developing a genetic disease or to determine the risk of having a child with a genetic disease. The family tree may help particularly if there have been other affected family members that helps to identify the pattern of inheritance. Typically autosomal dominant inheritance shows transmission from an affected parent to half the children (50% risk, a 1 in 2 chance) independent of their sex. There is often very variable expression (varying from mild to severely affected). With small families the dominant pattern may not be obvious and incomplete penetrance of a malformation gene, may lead to the apparent 'skipping of generations', only for the condition to re-appear in a grandchild or niece/nephew. It may sometimes be difficult to determine if a condition represents a new dominant gene mutation, a multi-factorial condition or result from the transmission of a non-penetrant gene from one parent, or be the result of a '*rogue gene*' appearing from non-paternity! Sex-linked recessive (X-chromosome) conditions are carried by women, who are usually healthy, and may be the unknowing carriers of a mutated gene that will be passed onto affect half their boys. Sometimes a woman carrying an X-linked trait may be a manifesting carrier, expressing mild features of the condition. This may be due to unequal X-inactivation (Lyonisation) between the two X-chromosomes with preferential expression of the mutant X over the normal (wild-type) X chromosome. Further information on genetics and inheritance patterns is available from a selection of books and internet sources [64–66].

More complex family trees may underlie a chromosome re-arrangement that is balanced (no chromosome material gained or lost) in the unaffected family members, but leads to unbalanced chromosomal rearrangements in the affected children where there is a duplication (trisomy) or loss (deletion) of some chromosome segment(s). Malformation may be due to the teratogenic effects of prescribed, non-prescribed or illicit drug exposure or alcohol that may be undeclared and /or taken without clear knowledge of the pregnant mother. Viral teratogens should also be borne in mind. Besides depicting familial relationships, a pedigree should also contain medical information with birth date, age of death, cause of death, health problems, and results of genetic tests. Obtaining medical records on affected relatives with their consent will ensure the medical information is as complete and accurate as possible. Increasingly the collection of family tree information and genetic counselling for malformations with an established syndrome / genetic diagnosis is undertaken by genetic counsellors / genetic nurse specialists working alongside medical geneticists. They would have an appropriate professional background and have attained a Masters degree in Medical Genetics / Genetic Counselling. With the rapid expansion of genetic testing and the increasing finding of positive results from detailed chromosome (micro-array)

and high-throughput DNA sequencing and that soon expected form whole genome sequencing (WGS), there has been a rapidly rising demand for the delivery of genetic information by non-specialists. In the UK this has led to the listing of genetic competencies by nurses and health visitors [67]. These include:

1. identifying those who might benefit from genetic information & services
2. providing genetic information appropriate to family's culture, knowledge & language
3. ensure clients have informed decision making and voluntary action
4. knowledge of genetic & other factors in the manifestation of the condition
5. understanding of the utility & limitations of genetic testing
6. recognize limitation of one's own genetic expertise
7. communicate this information effectively to family and other clinicians

During a clinical genetics / genetic counseling visit which may be held jointly with the neonatal surgical team, the parents may ask questions, depending on many factors—the type of malformation(s) the child has and its surgical prognosis. The family will also often ask about the following:

The Condition

1. what is this condition, what happened?, why?, what caused it?, what else might affect the child, what will happen now?

The Prognosis

2. is it treatable / fully correctable?, will it get better, is there a treatment?, can their child lead a normal, pain free life?, is it life threatening, could more problems appear?, could there be learning difficulties?, what about mobility, limb function?

The Cause

3. whose fault was it?, what can I / we do?, what are the chances of this condition occurring again?

Recurrence Risk and Options

4. if this condition does recur, could it be milder or more severe? what are our options, are there any tests?, who else is at risk? can they be tested?, what can I do?, who can help us?

16.17 Methods of Ante-natal Diagnosis

Antenatal ultrasound was first used in 1964 and 2 years later the first prenatal chromosome analysis by amniocentesis was performed. Chorionic villus sampling (CVS) performed around 11 weeks gestation followed and DNA from the sample was first used for the prenatal diagnosis of sickle cell disease by Kan and Dozy [68] in the 1970s, and subsequently for an increasing range of single gene disorders. After the success of 'in vitro' fertilisation (IVF) by Edwards and Steptoe, the technique has been used alongside molecular genetic testing of single cells to achieve pre-implantation genetic diagnosis (PGD) by Handyside and Winston in 1990. In this way families at risk of already identified single gene disorders, or known chromosome rearrangements can have fertilised embryos screened. Molecular analysis of single cells using modified techniques of the polymerase chain reaction (PCR) allows the amplification of targeted genomic regions and only those unaffected conceptions implanted into the mother's uterus. Couples at high risk are thus able to continue with a pregnancy from an early stage reassured that they have escaped the *'genetic lottery'* and should be able to have unaffected children without needing to resort to selective termination of pregnancy. At present techniques of early and non-invasive prenatal diagnosis (NIPD) and even population screening are being developed based on the identification of cell-free fetal DNA (cffDNA) in the maternal blood. This is DNA derived from the pregnancy that can be found from as early as 4 to 6 weeks gestation in the maternal circulation, but is completely cleared within a few hours of birth or the end of the pregnancy. Initially used to determine the Rhesus status and then for fetal sexing in sex-linked conditions, the

use of cffDNA is currently being explored for a range of single-gene and chromosomal conditions. The advantages of requiring only a maternal blood sample is easier, less skilled and less costly sampling than current CVS under ultrasound guidance, it can be offered to many more women or indeed become population based with no risk of unintended pregnancy loss. With appropriate laboratory testing facilities, cffDNA testing can provide results well before a CVS or an amniocentesis could be performed. The sensitivity and specificity of cffDNA analysis remains to be determined for an increasing range of conditions, but when coupled with the increasing speed and falling cost of high-throughput DNA analysis will provide an important option to be developed [69]. The challenge will be its acceptability and the potential use / abuse in, for example Internet based requests for pre-natal sex selection for family / social planning outside of the context of serious genetic disorders [70, 71].

16.18 Approaches to and the Ethics of Pre-natal Diagnosis

Faced with the finding of anomalies in their child from ante-natal testing or more often and unexpectedly from an ultrasound scan; parents will want to ask many of the questions listed above. The recurrence risk may range from a low risk for a sporadic condition (<1%), through the empiric recurrence risk after the first occurrence of a multi-factorial condition (say 2–3% risk) through to the 25% recurrence of an autosomal or X (sex)-linked condition and up to 50% risk with variable expression (severity) of a dominant disorder. The surgical options and outcomes will vary depending on the condition, from a single and fully corrective procedure with no expected adverse sequelae; through the multi-stage repair of a complex bilateral cleft lip and palate to the uncertain outcome for a child with a complex ano-rectal or urogenital malformation in terms of control over continence, sexual function and the psycho-social and sexual consequences for the child and their family. Discussing the neonatal surgical option(s) and likely outcomes will often be led by the neonatal surgical team, but in depth discussion will require a multi-disciplinary approach from the many specialties and therapists (speech, educational, dietetic, psychologist etc.,) that may be involved in the repair, recovery and adjustment of the growing child. Parents will vary in their response to this information; what may be seen as a minor anomaly, easily repaired by the surgical team with an apparently good cosmetic appearance, may because of the shock of its initial diagnosis, uncertainly over its long-term outcome and the perceived social stigmatisation of the condition lead to requests for pre-natal testing in a subsequent pregnancy and even consideration of termination for a similarly affected pregnancy. Advances in surgical techniques for that condition, the family's access to that surgical expertise (its cost, geographical access, other children) will all influence the parents' decision making.

Parents may decline the offer of pre-natal testing if they have had a very positive experience of their child's condition, if they have strong personal religious views, "*that it is God's will*", or a moral view that they would not intervene to terminate an affected pregnancy. There are many factors in an intensely personal discussion that cannot be predicted and should not be predicated. Parents will weigh up the severity of the condition, their experience of the condition, if they feel they can cope with that condition or a second affected child, the gestation at which the diagnosis can be made and if a termination can be performed in the first or second trimester. Attitudes and the legal position on therapeutic termination of pregnancy will vary from country to country and from culture to culture. What is legal, what is acceptable and what defines disability and handicap as well as the availability of surgical excellence and its support teams as well as the cost to the family or if state funded care is available, all contribute to the complexity of decision making. Denial of the diagnosis or of a progressive or lethal outcome is most difficult in the context of a newborn child, and when many health professionals are involved in giving information

about the prognosis. The challenge is to identify the needs of the family and to carefully share the information at the rate and in the depth that the family needs. The role of genetic counselling in a European / North American setting, based on Judaeo-Christian ethics is to equip the parents to make these incredibly emotive and long lasting decisions themselves. These discussions are often in very difficult and time-pressured circumstances giving the family as much unbiased information as they need and can understand. Parents should be supported, perhaps guided, but never led [72, 73]. The most difficult questions to respond to are, "What should I do, or what would you do if this was your child or pregnancy?" The response should be to sensitively explain that this is not our child, the long term care will not fall to us, the consequences of the parents' decision will be theirs and they will have to live with this. They should have our support, whatever decision they make, whether to continue an affected pregnancy and seek pre-natal or post natal treatment or to terminate the pregnancy. We have to be non-directive and non-judgemental in our approach and support whatever the parents' decide, even if we might have made a different decision ourselves [74–76]. A consequence of the greatly improved survival rates for children operated on for neonatal surgical conditions, is discussing with them now as young adults, their attitude to their own condition, the risks of recurrence and what their feelings might be of having an affected child themselves. Sources of information and support for families are available from multiple sources included with this chapter [77].

Birth Trauma

17

Mark Tattersall, Devender Roberts,
and Leanne Bricker

Abstract

Birth trauma refers to the variety of injuries that can be sustained by the infant during the process of labour and delivery. It is a significant cause of neonatal morbidity and mortality. The process of birth involves a combination of mechanical forces acting upon the fetus that can produce tissue haemorrhage and disruption of physiological integrity. These factors may result from the method of delivery, route of delivery or fetal position and size. In addition, obstetric intervention may amplify the effects of these forces and cause or exacerbate birth trauma. Whilst one aim of the obstetrician is to prevent birth trauma by identifying fetuses at risk and making appropriate plans for delivery, most birth injuries are unavoidable and occur despite skilled obstetric and neonatal care. In any discussion of birth trauma it is important to realise that whilst caesarean delivery may be protective of some types of birth trauma, fetal injuries can be seen with caesarean section, even when this is performed as an elective procedure.

Birth trauma refers to the variety of injuries that can be sustained by the infant during the process of labour and delivery. It is a significant cause of neonatal morbidity and mortality. The process of birth involves a combination of mechanical forces acting upon the fetus that can produce tissue haemorrhage and disruption of physiological integrity. These factors may result from the method of delivery, route of delivery or fetal position and size [1]. In addition, obstetric intervention may amplify the effects of these forces and cause or exacerbate birth trauma. Whilst one aim of the obstetrician is to prevent birth trauma by identifying fetuses at risk and making appropriate plans for delivery, most birth injuries are unavoidable and occur despite skilled obstetric and neonatal care. In any discussion of birth trauma it is important to realise that whilst caesarean delivery may be protective of some types of birth trauma, fetal injuries can be seen with caesarean section, even when this is performed as an elective procedure [2].

Birth trauma has been estimated to occur in 3% of all live births and accounts for 2% of all neonatal mortality and 10% of all neonatal deaths in infants delivered at term [3]. Whilst the cause of much birth trauma is difficult to define and it can sometimes prove impossible to explain, a large number of risk factors have been identified for birth trauma and these can be divided into those pertaining to the mother and those relevant to the fetus, as shown in Table 17.1.

There are a wide variety of types of injury that can occur during the process of labour and birth and which will be discussed in this chapter. For ease, injuries have been broken down into the following types:

- Injuries to the Head
- Fractures
- Nerve injuries
- Anoxic injuries

Table 17.1 Risk factors for birth trauma [72]

Maternal	Fetal
Diabetes	Macrosomia
Obesity	Pregnancy prolonged beyond Term +18 days
Small pelvis	Abnormal presentation
Large pregnancy weight gain	Instrumental delivery
Short maternal stature	Perinatal depression
Induction of labour	Shoulder dystocia
Epidural usage	
History of macrosomic infant	

17.1 Head Injuries

The head is the most common part of the body injured during labour and delivery, which is due to the fact that this is usually the presenting part.

17.1.1 Superficial Injuries

Superficial head injuries can occur at all types of delivery and are relatively common. Bruising, abrasions and lacerations can occur at the time of spontaneous vaginal and instrumental deliveries. Rates of 0.1% of all deliveries [4], around 10% with ventouse deliveries and approximately 35% with forceps deliveries [5] have been quoted. Lacerations to the scalp, face, cheek or ear can occur at Caesarean section and it is good practice to specifically counsel mothers regarding this risk. It is estimated that the risk of such lacerations is approximately 1%, with the risk not necessarily being associated with any particular type of Caesarean section, the presentation, dilatation, presence of intact membranes or the experience of the surgeon [6–8]. If a full-thickness laceration is present, suturing is often required and consultation with a plastic surgeon is recommended to achieve a cosmetically satisfactory result, particularly for injuries to the face. The two most common types of injuries to the head are caput succedaneum and cephalohaematoma. Other head injuries include subgaleal haemorrhages, intracranial haemorrhages, nasal injuries and eye injuries. Figure 17.1 illustrates the location of the fluid collections in the major types of scalp injuries.

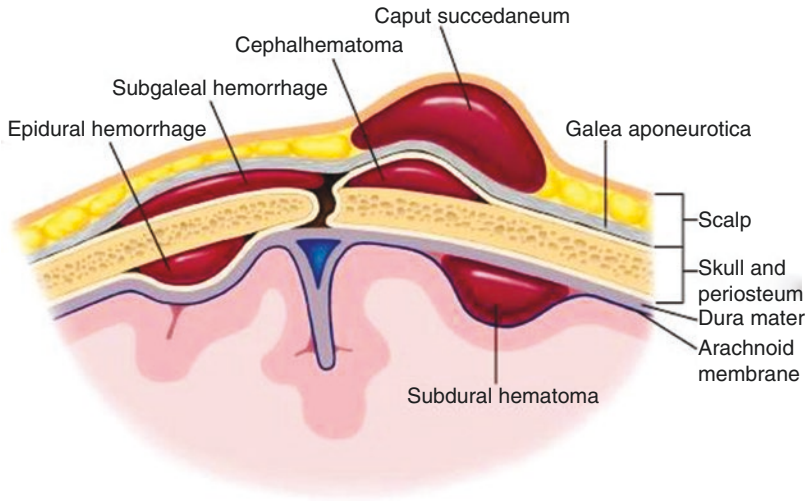

Fig. 17.1 Schematic diagram illustrating anatomical regions of the newborn skull and site(s) for potential birth injury(s)

17.1.2 Caput Succedaneum

A caput succedaneum is a subcutaneous, extra-periosteal collection of serosanguinous fluid which is associated with head moulding. This common lesion at birth is usually seen on the presenting portion of an infant's skull during vaginal birth and is often accompanied by bruising and petechiae. It is caused by the high pressure exerted on the fetal head during labour by the uterus and vaginal walls as the head passes through the birth canal. This prolonged pressure causes leakage of serosanguinous fluid from the subcutaneous tissues into the area between the scalp and the lining of the periosteum, causing oedema and bruising. Caput succedaneum is easily differentiated from a cephalohaematoma by the fact that the fluid accumulation crosses over the cranial sutures due to the collection being above the periosteum. Again in contrast to cephalohaematoma, a caput succedaneum is evident immediately after delivery and will subsequently decrease in size over time. A caput succedaneum has a soft, boggy feel and may display petechiae, purpura or ecchymosis. The swelling is generally 1–2 cm in depth and is most commonly seen in the midline with the circumference being highly variable in size and the margins usually being irregular in shape. In caput succedaneum, the collection of serous fluid characteristically shifts from side to side as the infant's head position is changed.

Risk factors for caput succedaneum include nulliparity, a prolonged second stage of labour, premature rupture of membranes and ventouse delivery, with the latter being a particular risk where the vacuum is applied for over 10 min, there is inappropriate cup placement or repetitive cup detachments. In the case of ventouse delivery, the 'artificial' caput succedaneum (commonly known as a 'chignon') is caused by a collection of interstitial fluid and microhaemorrhages occurring under the cup site and is helpful in keeping the vacuum cup more attached to the fetal scalp [9]. In rare cases of ventouse delivery, caput succedaneum can be associated with breakage of the skin of the scalp if the cup "pops off" the head and abrades the underlying skin. Although it is thought that pressure exerted on the fetal head during labour and delivery is the causative factor in the development of caput succedaneum, it is important to note that there are several cases reported in the literature where this injury has been described as being identified by ultrasound in the third trimester, suggesting that this injury does not always occur during labour and delivery. Caput succedaneum does not usually require any treatment, resolving spontaneously within the first few days after birth [10, 11].

Alopecia can occur in conjunction with caput succedaneum. This is usually in the form of a halo scalp ring, where hair loss develops as a result of tissue necrosis from prolonged pressure of the

scalp against the ring of the cervical os during the birth process. In most cases, the hair grows back over time, but scarring and permanent hair loss have been reported in association with caput succedaneum [12]. An important final point to note is that caput succedaneum can be confused with a subgaleal haemorrhage (discussed below), as this also crosses the suture lines. It is important that such a misdiagnosis is not made as this can have potentially catastrophic results due to the more serious nature of the latter diagnosis.

17.1.3 Cephalohaematoma

A cephalohaematoma is a collection of blood below the periosteum of the skull. This extracranial haemorrhage occurs when friction during the birth process causes the emissary and diploic veins between the periosteum and the skull to rupture. As the haematoma is subperiosteal, it does not extend across suture lines as the ligaments which attach the periosteum to the skull at the cranial suture lines contain the blood. A cephalohaematoma can thus usually be easily distinguished from a caput succedaneum or a subgaleeal haemorrhage, although where there is a caput succedaneum or scalp swelling overlying a cephalohaematoma, this can obscure its boundaries and make diagnosis more difficult. Figure 17.2 shows a MRI where the differences between a caput succedaneum and a cephalohaematoma can be clearly seen. A cephalohaematoma is not usually present at birth unless there is a history of prolonged head engagement and usually develops during the first 24 h of life due to the slow nature of subperiosteal bleeding. In contrast to caput succedaneum, there is not usually any discolouration of the overlying skin due to the accumulation being in a deeper, more vascular tissue plane. This also accounts for the increased blood content of cephalohaematomas, which continue to increase in size until pressure in the space builds and acts as a tamponade to stop further bleeding. Cephalohaematomas present as firm masses that may be either unilateral or bilateral covering one or more bones of the scalp. The lesion cannot usually be transillumi-

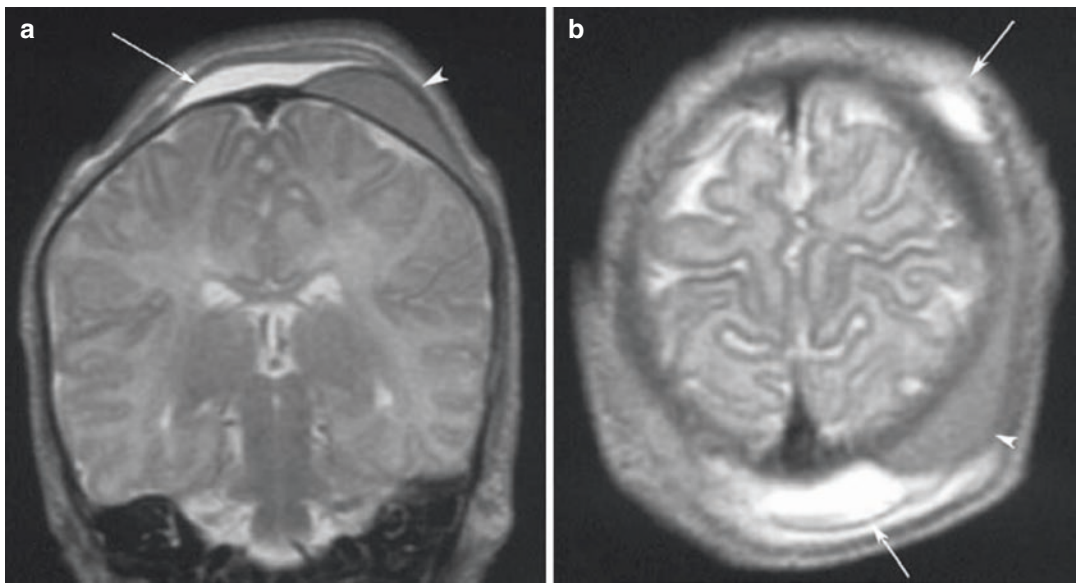

Fig. 17.2 Brain MRI. Coronal (**a**) and axial (**b**) images reveal the caput succedaneum (*arrow*) with crossing the suture line and the cephalhaematoma (*arrowhead*) without crossing the suture line. The low signal intensity of the cephalhaematoma suggests the subacute haematoma. From: Choi JW, Lee CH, Suh SI. Scalp swelling crossing the suture line on skull radiograph: is it always a sign of caput succedaneum? Pediatr Radiol (2006) 36: 364. doi:10.1007/s00247-006-0113-6

nated and are most commonly found in the parietal region, although it may occur over any of the bones of the skull. The right parietal bone is involved twice as commonly as the left and unilateral lesions are five-times more common than bilateral ones.

The incidence of cephalohaematomas has been estimated to be up to 2.5% of all live births [13–15]. The rate of cephalohaematoma is significantly increased with ventouse delivery (compared with normal vaginal delivery) [16, 17] and is also increased to a smaller extent by forceps delivery [18]. Other risk factors for cephalohaematomas include primiparity, macrosomic infants, prolonged labours and abnormal fetal positions such as occipito-transverse or occipito-posterior. Cephalohaematoma is twice as common in males than in females for reasons that are unknown. Although cephalohaematomas may be potentially more serious than caput succedaneum, they are usually benign if there is no underlying coagulation disorder and treatment is rarely indicated. The haematoma generally resolves spontaneously and completely by 3 months of age.

There are a number of important complications which may be associated with a cephalohaematoma. Linear skull fractures occur in approximately 5% of unilateral and 18% of bilateral cephalohaematomas. Routine radiography is not recommended, but should be undertaken if the cephalohaematoma is excessively large, there are neurological signs present or when a particularly difficult delivery has taken place. Such linear skull fractures rarely require treatment. Cephalohaematomas can become infected and when signs of sepsis are present and the focus of the infection cannot otherwise be explained, the cephalohaematoma should be suspected as the site of infection. There is an increased risk of infection if a scalp electrode has been used during labour, if a needle aspiration of the cephalohaematoma has previously been attempted or if there is already systemic infection existing in the infant. The most common organisms include E. coli and S. aureus. Needle aspiration is used to diagnose infection of a cephalohaematoma, but is only performed when other possible sources of infection have been excluded, as it may introduce organisms into a previously sterile area. Treatment of infected cephalohaematoma is usually with intravenous antibiotics for up to 2 weeks, with initial antibiotic selection made to cover both E. coli and S. aureus. When infection has been diagnosed following needle aspiration, antibiotics are usually adjusted according to sensitivity results and CT can be used to reveal any evidence of osteomyelitis, epidural abscess or subdural empyema, which may necessitate a longer course of intravenous antibiotics. In cases where there is no clinical improvement despite antibiotic treatment, surgical incision, drainage and evacuation may also be considered.

Anaemia may be a complication associated with larger cephalohaematomas and can occasionally require transfusion. Hyperbilirubinaemia is a common side effect of cephalohaematoma, which occurs when the red blood cells in a cephalohaematoma are destroyed, with an end metabolic product being bilirubin. Bilirubin levels should therefore be monitored whilst a significant cephalohaematoma resolves and phototherapy is effective is returning unconjugated bilirubin levels to normal.

Calcification can rarely be a complication of cephalohaematoma, which usually occurs when the lesion persists beyond 4 weeks of age. It can cause a misshapen head and such skull deformities can require treatment. Figure 17.3 shows a CT scan of a calcified haematoma. A persistent

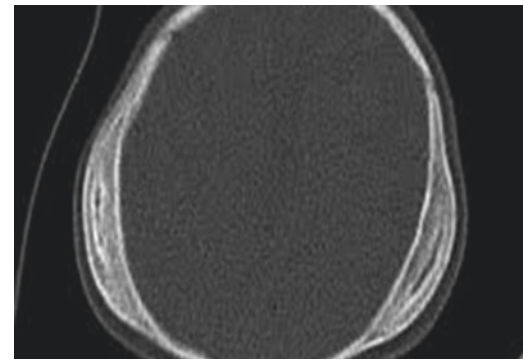

Fig. 17.3 Computed tomography scan showing calcified cephalohematoma. From: Kestle JRW. Tumors of the cranial vault in children. In Tonn J-C, Westphal M, Rutka, JT, eds. Oncology of CNS Tumors. Springer-Verlag: Berlin Heidelberg; 2010: 629–635

disfiguring calcified cephalohaematoma can require surgical treatment. The bony cap of a calcified cephalohaematoma is removed and the underlying material is debrided. A contouring surgical burr is used to reshape the skull and reform the correct anatomical form, with bony shavings used to fill in any depression left. Passive cranial moulding helmet therapy has also been used as an effective non-surgical treatment for calcified cephalohaematomas. It relies upon the malleability of the infant's head prior to 12 months of age and involves placing a moulded helmet on the infant's head for 18–20 h per day until the desired cranial shape is achieved. This non-surgical treatment is usually only successful in the case of partially calcified cephalohaematomas, as fully calcified cephalohaematomas do not usually respond as well.

17.1.4 Subgaleal Haemorrhage

Subgaleal haemorrhage is a potentially fatal lesion, which results from bleeding into the subaponeurotic space, a potential space between the epicranial aponeurosis of the scalp and the periosteum of bone. The epicranial aponeurosis is a sheet of fibrous tissue which covers the entire cranial vault from the orbital ridges anteriorly to the nuchal ridge posteriorly. Its lateral margins blend with the temporal fascia. The space formed is potentially a large one, estimated to be able to accommodate up to 360 ml of blood. The fact that such extensive blood loss is possible means that mortality rates from subgaleal haemorrhage have been estimated to be up to 22%. Diagnosis of subgaleal haemorrhage is generally made clinically, with a boggy swelling over the scalp generally being noted between 12 and 72 h after delivery, although in severe cases signs may be present at delivery. The swelling may be associated with bruising and periorbital or periauricular oedema. The infant usually has an irritable cry and signs of pain, especially when the head or scalp is manipulated. Severe cases are associated with cardiovascular collapse. Subgaleal haemaorrhage can be distinguished from cephalohaematoma in that the swelling crosses the suture lines. The presentation can often be insidious, which can cause delay in diagnosis and treatment, which contributes significantly to the high mortality. Subgaleal haemarrhage is most common after ventouse delivery [19, 20]. It is thought that use of a ventouse produces a shearing force to the scalp that tears the emissary veins and produces the haemorrhage, but it is important to note that subgaleal haemorrhage has also been observed in association with Caesarean section delivery. Subgaleal haemorrhage has been estimated to occur in less than 0.1% of all deliveries, but in up to 1% of ventouse deliveries [21].

The diagnosis of subgaleal haemorrhage is usually made by careful physical examination demonstrating a ballotable lesion which crosses the suture lines. It is important that treatment is not delayed whilst waiting for CT or MRI confirmation of the diagnosis. The priority is to stabilise the infant and radiologic examination can be safely deferred useless there are focal neurological signs indicating the potential for a subdural lesion. Serial head measurements can be used to monitor the evolution of a subgaleal haemorrhage, with it having been estimated that approximately 38 ml of blood have accumulated for each centimetre increase in head circumference. Signs that indicate increasing severity include severe anaemia, hypotension, weak pulses and tachycardia and once hypovolaemic shock has developed the infant's chances of survival are poor, due to decreased organ perfusion, myocardial damage and widespread cellular death. It is thus critical that a subgaleal haemorrhage is recognised early and treated with aggressive volume resuscitation in order to provide the best chances of full recovery. Treatment also requires careful monitoring of the infant's condition, regularly assessing vital signs, neurological status and clotting variables. If blood products are transfused, it is essential to monitor the haematocrit, coagulation studies and the platelet count until haemostasis is achieved.

17.1.5 Intracranial Haemorrhage

Intracranial haemorrhage, including subarachnoid haemorrhage and subdural haemorrhage should be considered after any difficult delivery

to prevent life-threatening complications. However, it is important to realise that the presence of such lesions in newborns is not always subsequent to birth trauma. For example, a series of six cases have been reported where intracranial haemorrhage occurred in the absence of birth trauma [22]. In three of these cases, there was a clotting factor deficiency, highlighting the role that such abnormalities play in intracranial haemorrhage. Intracranial haemorrhage is regarded as the most serious complication of neonatal alloimmune thrombocytopenia, a condition estimated to occur in 1 in 2000–5000 neonates [23].

Subarachnoid haemorrhage is the most common intracranial lesion detected after birth. Where it is secondary to birth trauma, it commonly occurs in conjunction with another cranial lesion, such as caput succedaneum, cephalohaematoma or a skull fracture. A subarachnoid haemorrhage occurs when bridging veins tear or vessels rupture and bleed into the subarchnoid space. It is a relatively benign lesion and rarely has complications, being often discovered as an incidental finding on CT scan. When symptomatic, the most common presentation is with transient seizure activity on day 2 or 3 of life in an otherwise healthy infant. If signs of apnoea, lethargy or abnormal neurology are present, imaging should be undertaken to confirm the diagnosis and exclude other pathology. In rare cases, massive haemorrhage can develop leading to progressive hypovolaemic shock and death. Severe cases can require craniotomy and haematoma evacuation and aggressive management of coagulopathies. Hydrocephalus is a rare complication, which develops due to adhesions or meningeal inflammation blocking the flow of cerebrospinal fluid.

A subdural haemorrhage occurs when tears in the falx, tentorium or bridging cortical veins bleed between the dura and arachnoid. It is thought that excessive vertical moulding of the cranium in a difficult delivery provides excessive stretch on these vessels. Subdural haemorrhages can vary in severity from small asymptomatic lesions which may present as an incidental finding on imaging to a massive haemorrhage associated with deteriorating neurological function and signs of brain stem compression. Severe haemorrhages tend to present between 12 and 72 h after birth with abnormal neurological signs that may include seizures, apnoea, hypotonia, cyanotic episodes, hemiparesis, decreased movements and unequal or sluggish pupils. A full fontanelle or a rapidly increasing head circumference can be indicative of raised intracranial pressure and should therefore prompt urgent review of management. The majority of subdural haemorrhages occur over the cerebral hemispheres or within the posterior fossa. Haemorrhages in the posterior fossa are clinically important as they can cause brainstem compression, which may present with symptoms of abnormal pupil reactivity, changes in vital signs, severe, progressive neurological deterioration or even coma. Subdural haemorrhage associated with tentorial tears can cause particularly severe haemorrhage and are generally seen in situations where there is rapid forcing of the head through the birth canal, for example in precipitate labour or vaginal breech delivery.

Subdural haemorrhages are best diagnosed by the use of CT or MRI, although cranial ultrasound may detect a very large bleed. The treatment of subdural haemorrhages depends upon the location and extent of the haemorrhage, as well as its progression. Small haemorrhages may be successfully managed conservatively with careful continuing assessment of vital signs, haematocrit, platelet count and perfusion status [24]. Transfusion of packed red cells, platelets and clotting factors should take place as indicated. Anticonvulsant treatment should be added if seizure activity is present. If there is seizure activity of abnormal or focal neurological findings, consultation should taken place with a neurologist and neurosurgeon. Surgery is needed the minority of cases [24–26] and is considered if there are signs of brainstem compression or deterioration in neurological status. Smaller lesions may be treated using Burr holes or subdural drains in order to decrease brain compression from accumulated blood, but severe lesions may require craniotomy and haematoma removal. The prognosis for subdural haemorrhage depends upon the extent and severity of the bleeding. The prognosis is generally good if only a small haemorrhage is present and the infant experiences only transient seizure activity. However, developmental delay

or cerebral palsy have been described in severe cases. Although short-term outcome appears favourable in the majority of cases, long-term outcome remains unclear and careful follow-up is required [26].

17.1.6 Nasal Injuries

Nasal injuries of some form are estimated to occur in between 0.5% and 1% of live births [4]. The injury usually involves dislocation of the cartilaginous portion of the septum from the vomerine groove and columella and present with deviation of the tip of the nose to one side with leaning of the columella and flattening of the nasal aperture and frequently bruising. These injuries are usually benign and rarely result in long-term complications, but as newborn infants are obligate nose breathers, severe septal deviation can compromise breathing. Ideally, nasal injuries should be detected and treated early, ideally within the first 3 days of life. Manual manipulation of the nose into proper alignment is usually performed by an Ear Nose and Throat specialist and involves, steadying the head, grasping the dorsum of the nose and lifting a nasal elevator to push the anterior end of the septum into the septal groove and columella.

17.1.7 Eye Injuries

Birth trauma to the eye is relatively common. The commonest type of injury are benign conjunctival haemorrhages, which are frequently observed after normal vaginal delivery [10]. These appear as a bright red patch or crescentic band located on one side of the iris or completely surrounding it and are due to the rupture of small capillaries in the conjunctivae. These dilated blood vessels are thought to be damaged due to increased venous pressure in the head and neck produced by compression of the fetal thorax and/or abdomen by uterine contractions during labour and delivery. The presence of a nuchal cord may also contribute [27]. These conjunctival haemorrhages require no treatment and resolve within 7–10 days with no risk of permanent damage [28].

More serious eye damage is rare, but damage to the cornea and haemorrhage into the orbit of the eye have been described [29]. Corneal damage can occur due to an inappropriately placed forceps blade slipping over the orbital wall and exerting pressure on the cornea. Such an injury may permanently impair vision. Orbital haemorrhage can occur during difficult delivery and presents as either unilateral or bilateral proptosis. Treatment with antibiotic ointment is essential to prevent infection and patching usually results in complete recovery.

17.2 Fractures

17.2.1 Skull Fractures

Skull fracture should be suspected in any case of cephalohaematoma or subarachnoid haemorrhage. Between 10 and 25% of cephalohaematomas are associated with a skull fracture. Skull X-ray is indicated when physical assessment suggests a fracture or there are abnormal neurological signs [11]. Skull fractures can occur with any type of delivery, including Caesarean section, but are most commonly associated with instrumental delivery [30]. Neurosurgical consultation is highly recommended in the case of any fracture. Skull fractures can be linear or depressed. Linear skull fractures are usually asymptomatic and heal without intervention, although a repeat X-ray should be performed at 6 weeks of age to exclude a leptomeningeal cyst, an uncommon complication that results from extrusion of the leptomeninges into the fracture site and can interfere with the normal healing process. A depressed skull fracture is seen as either an indentation of the skull or a “ping-pong” type defect. Surgical intervention is usually needed to elevate the skull and prevent brain compression, as when such fractures are treated early they have an excellent prognosis in the absence of underlying brain injury.

17.2.2 Clavicular Fracture

Clavicular fractures are the most common type of fracture that may occur as a result of birth trauma.

In some studies, they have been reported to be the most common type of birth trauma. Rates of between 0.2% and 5% have been reported [3, 31–37]. This large variability in observed incidence probably results from differences in the way in which infants were screened for clavicular fracture as many fractures are asymptomatic or present late and also whether the study was prospective or retrospective. Although a displaced fractured clavicle may be easy to diagnose clinically, a non-displaced fracture may often only be apparent if the neonate is subjected to X-rays or multiple physical examinations as some fractures may not be apparent until 1 week after birth.

Although some clavicular fractures may occur either intentionally or non-intentionally during attempts to relieve shoulder dystocia, the majority occur following vaginal deliveries not reported as being complicated by difficulty delivering the shoulders [33, 35]. Although clavicular fractures are also associated with higher birth weights [3, 33], nearly 80% of newborns with clavicular fractures weigh less than 4000 grams [36]. This means that in the majority of cases, the risk of clavicular fracture cannot be appreciated prior to delivery. Isolated clavicular fractures usually heal without sequelae, although they can be associated with brachial plexus, phrenic and right recurrent laryngeal nerve injuries and so these must be excluded if a clavicular fracture is diagnosed in a newborn.

17.2.3 Long Bone Fractures

Fractures of the long bones due to birth trauma are uncommon, since the force required to break such bones is much higher [38]. For example, femoral fractures have been estimated to occur once in every 10,000 deliveries [38, 39].

17.3 Nerve Injuries

17.3.1 Brachial Plexus Injury

Brachial plexus injuries at birth are frequently attributed to the use of excessive lateral traction on the neck during a difficult delivery of the shoulders in a vertex presentation or the delivery of the aftercoming head in a vaginal breech delivery and it is also thought that direct compression of the plexus may occur with the use of forceps. Early studies implicated vaginal breech deliveries as the cause of the majority of brachial plexus injuries. For example, in 1973, 72% of neonates with this type of injury were estimated to have been delivered in this way [40] and the risk of brachial plexus injury in vaginal breech delivery has been estimated to be 17 times that of a vertex presentation [32]. However, with changes in the management of breech presentation the association of brachial plexus injury with shoulder dystocia has become more important. Other risk factors for brachial plexus injury include primiparity, prolonged labour, heavier birth weight and forceps delivery [3, 16, 41, 42]. The incidence of brachial plexus injury has been estimated by a variety of studies to be between 0.4 and 0.9 per 1000 live births [40, 41, 43–47], although a single study suggested a rate as high as 2.6 per 1000 live births [3].

Upper brachial plexus injuries are the most common type seen following delivery. These palsies were first described clinically by Smellie in 1764 in his midwifery text and in 1874 Erb localised the lesion to the junction of 5th and 6th cervical roots (now known as Erb's point) and also credited Duchenne with the original clinical dissection 2 years previously. It is noteworthy that Erb recognised that the cause of the palsy was excessive lateral traction of the neck during delivery and condemned the use of the 'Prague manoeuvre' common at the time, in which strong traction was placed on the shoulder to deliver the aftercoming head in breech presentations. Erb-Duchenne palsies comprise 90% of all brachial plexus injuries and cause paralysis of the deltoid, infrascapular and flexor muscles of the forearm. The presentation is thus with a flaccid upper arm, internal shoulder rotation, elbow extension, forearm pronation, wrist and finger flexion (the "waiter's tip" deformity) and an asymetric Moro reflex. The arm falls limply to the side, but the grasp remains intact. Figure 17.4 shows the characteristic appearance of a child with an Erb-Duchenne palsy. The Moro reflex is present in cases of shoulder girdle fracture and so can differentiate such pseudopalsies from brachial

Fig. 17.4 An 8-month-old boy with Erb's palsy at birth had no shoulder abduction or elbow flexion against gravity. From: Shigematsu K, Yajima H, Kobata Y, Kawamura K, Maegawa N, Takakura Y. Oberlin partial ulnar nerve transfer for restoration in obstetric brachial plexus palsy of a newborn: case report. J Brachial Plex Peripher Nerve Inj. 2006 Sep 29;1:3

plexus palsy. The Klumpke paralysis, described in 1885, involves the 5th, 6th and 7th cervical roots. Clincially, this differs from the Erb-Duchenne paralysis in that the grasp reflex is also absent. Horner's syndrome (ptosis, miosis and anhidrosis) can also be present if sympathetic fibres from the 1st thoracic root are also involved.

Before 1970, the literature suggested a poor prognosis for brachial plexus injuries with full recovery only occurring in the minority of patients [43, 48]. However, more recent reports have suggested full recovery occurs spontaneously in 80–95% of cases [40, 45, 46, 49]. It is now generally accepted that initial management of brachial plexus injuries should be with physiotherapy and dynamic splints and surgery should be delayed for at least 3 months and reserved to cases resistant to conservative measures [50].

It has been proposed that performing elective Caesarean section for fetuses estimated to be relatively macrosomic might be effective in reducing the incidence of shoulder dystocia and hence brachial plexus injuries. However such an approach is limited by the fact that ultrasound estimation of fetal weight is relatively inaccurate and that about half of brachial plexus injuries occur in the absence of shoulder dystocia [51–53] and calculations have suggested that more than 1000 Caesarean sections and their associated expense and morbidity would be required to prevent a single permanent brachial plexus injury, using any possible threshold to perform Caesarean section [54, 55].

17.3.2 Phrenic Nerve Injury

When a phrenic nerve injury occurs as a result of birth trauma, the majority occur in conjunction with a brachial plexus injury [4]. Given that the phrenic nerve innervates the diaphragm and this is the major effector of spontaneous respiration in the newborn, the injury should be suspected when there is evidence of respiratory distress following a difficult labour or delivery, particularly if there is evidence of a brachial plexus injury. Although respiratory distress usually presents on the first day of life, this may be delayed until up to 1 month of age [4]. The infant's breathing is usually laboured and thoracic, and auscultation reveals decreased breath sounds on the affected side. The diagnosis is confirmed by chest X-ray, which will show elevation of the affected hemidiaphragm, and fluoroscopy which reveals paradoxical "see-saw" movement of the affected side. It is important to realise that radiography can sometimes provide a false negative result, particularly if the patient is receiving ventilatory support. Recovery is usually spontaneous, but pulmonary infection can be a serious complication and so prophylactic antibiotics may be helpful. An affected infant should be placed on the affected side and respiratory support provided as necessary. Feeding by nasogastric tube may be utilised to save the infant energy to utilise for breathing. Diaphragmatic pacing can be used and surgical plication of the diaphragm is occasionally necessary.

17.3.3 Facial Nerve Injury

Facial nerve palsy acquired due to birth trauma needs to be distinguished from developmental facial paralysis and is estimated to occur in less than 1% of live births [4, 56]. Factors predictive of the injury include forceps delivery, a prolonged second stage of labour, increased birth weight and primiparity [3], although over 90% of facial nerve palsies due to birth trauma occur in infants delivered with the use of forceps [32, 56]. In a forceps

delivery, the injury is thought to be caused by pressure from the forceps blade on the stylomastoid foramen or compression of the bone overlying the vertical segment of the facial canal. When an injury occurs following normal delivery, it is believed that the pressure is caused by the sacral promontory. The prognosis for these injuries is good, with spontaneous recovery usual in a timeframe ranging from hours to weeks. Electromyography (EMG) is recommended, together with recording of the auditory brainstem response to exclude auditory nerve involvement. Although some experts recommend surgical intervention as early as 1–3 months of age, most reports favour observation for up to 1 year or up to 2 years if there have been improved EMG findings.

17.3.4 Laryngeal Nerve Injury

The major problem caused by injury to the laryngeal nerve is vocal cord paralysis, due to dysfunction of the motor supply to the larynx. However, it has been estimated that only 19% of vocal cord paralysis in newborns is attributable to birth trauma [4]. The injury occurs when the laryngeal nerves are overstretched during delivery and presentation is usually immediately after delivery. The presenting signs depend upon whether the vocal cord paralysis is unilateral or bilateral. 60% of cases involve bilateral paralysis and these cases tend to present with a high-pitched cry, inspiratory stridor and potentially a compromised airway. The remaining cases involve unilateral paralysis and tend to have more mild stridor and a hoarse or breathy cry. In either group, there may also be dysphonia, dysphagia or aspiration. Laryngeal nerve injury has been reported in all types of delivery.

Direct laryngoscopy allows the otolaryngologist to directly observe paralysis of the vocal cords. Investigation usually also involves a modified barium swallow and the early involvement of a speech therapist may help optimise feeding [4]. Management of unilateral vocal cord paralysis is usually conservative with monitoring for any possible aspiration and treatment of any gastro-esophageal reflux. Bilateral vocal cord paralysis more commonly requires treatment with tracheostomy, with the mean time before decannulation being over 4 years. Further surgical management is usually reserved for cases where permanent paralysis seems likely. Arytenopexy has been used to lateralise the laryngeal structures and increase the tracheal opening, with the aim of allowing for decannulation. Alternatively, a muscle-pedicle reinnervation procedure has been described with 50% of patients successfully decannulated with no further loss of voice. Unfortunately, it has been reported that this procedure can result in a further loss of voice and so it has been suggested that procedures such as this should be delayed until the child is old enough to take part in the decision process [4].

17.4 Anoxic Injuries

Cerebral palsy is a term used to describe a group of motor impairment syndromes through to occur secondary to disorders of early brain development. Encephalopathy is the precursor of cerebral palsy and has clinical signs which include altered states of arousal (i.e. hyperalterness with or without seizures or unresponsiveness), abnormalities of muscle tone and strength, focal neurological deficits or delayed developmental milestones). Although encephalophathy is often described as ‘hypoxic-ischaemic encephalopathy (HIE)’, such clinical signs can reflect multiple mechanisms of brain injury over any time course with the underlying pathological processes including genetic, developmental, metabolic-toxic, infectious, traumatic and neoplastic-infiltrative processes [57]. Maternal infection and chorioamnionitis are associated with an increased risk of subsequent cerebral palsy [58, 59], which together with the findings of raised inflammatory cytokines in infants with HIE [60] and in those who subsequently develop cerebral palsy [61], provides evidence that inflammation also plays a significant role in the development of these brain injuries. There are a number of different mechanisms by which hypoxia and subsequent ischaemia can lead to neuronal or glial cell loss and brain damage. Brain ischaemia is associated with a fall in both extracellular and intracellular pH. Whilst mild acidosis is protective, severe aci-

dosis promotes free radical production and cytotoxic oedema. The brain is particularly vulnerable to oxidative stress injury due to its high metabolic rate and the fact that it has minimal antioxidant activity. In addition changes in pH and ionic flux induced by hypoxia lead to depolarisation of the cellular membrane and increased intracellular calcium levels, which activate multiple enyzymatic pathways that release further oxygen free radicals [57].

Despite obstetric and neonatal interventions in developed countries being successful in detecting and reducing intrapartum morbidity, particularly from intrapartum hypoxia, a number of longitudinal studies have shown that despite a decrease in perinatal mortality, the incidence of cerebral palsy has remained relatively unchanged [62, 63]. Such data suggested that the proportion of cases of cerebral palsy which are due to birth asphyxia, and which therefore could potentially be prevented due to improved intrapartum care, is much less than previously thought. Such a view has been confirmed by studies which have examined cases of cerebral palsy and come to the conclusion than intrapartum asphyxia is unlikely to be a cause in any more than 10% of all cases of cerebral palsy [64, 65]. All of this evidence points to events in the antepartum period as be causative of the majority of cases of cerebral palsy, a finding which is most important not only in relation to litigation, but also with respect to the possible causes and prevention of cerebral palsy.

Neuroimaging can be helpful to assess both severity and the timing of causation in encephalopathic infants. Cranial ultrasound can be used to detect abnormalities within the thalami and basal ganglia, as well as in the periventricular parenchymal or intraventricular regions. Cystic lesions have been shown to develop over 14 days [66] and so their detection within days after birth suggests an antenatal timing of causation. However, magnetic resonance imaging (MRI) is the most sensitive technique for imaging the neonatal brain. The gestational age at birth is predictive of the pattern of hypoxic-ischaemic injury with hypoperfusion resulting in a periventricular border zone of white matter injury in the premature, but injury to the subcortical white matter and parasagittal cortex in term neonates [67]. It has been determined that diffusion based-MRI values are usually normal on the first day after injury, decrease between 2 and 4-days after injury and return to normal after approximately 7 days [66]. Such knowledge can be useful in timing the causation of an encephalopathy. Together with electroencephalography, MRI can also be useful to predict prognosis in neonatal encephalopathy, with the presence of cortical and basal ganglia abnormalities being predictive of a poor outcome [68, 69]. Traditional care for neonatal encephalopathy has been supportive, but recent trials have shown benefits from the use of selective brain cooling to improve outcomes and it is likely that there is a short therapeutic window of up to 6 h during which interventions such as this may be effective, so early identification of the neonate with such brain injuries may become increasingly important in the future [70, 71].

Conclusion

It is clear that there are a wide variety of different injuries that can be sustained during the birth process. The majority of these will be minor and of no long-term consequence to the infant or their family, but there some of these injuries will result in long-term impairment or disability. Although some infants can be highlighted to be at increased risk of specific injuries due to factors relating to the mother, the fetus or the mechanism of delivery, it is clear that the majority of birth trauma is difficult to predict and thus avoid, despite skilled obstetric and neonatal care. Although caesarean delivery is often portrayed as the means by which all birth trauma could be avoided, it is important that medical staff remind patients that such a means of delivery is not free from risk and indeed can be associated with significant fetal trauma, as well as maternal morbidity.

Pierre Robin Sequence

18

Rona Slator

Abstract

Pierre Robin Sequence (PRS) is a rare condition described in the early twentieth century as the triad of micrognathia, glossoptosis and upper airway obstruction occurring in infants. Up to 90% of infants affected will have a cleft palate. The severity of the condition varies widely. The airway obstruction may be immediately life threatening, or associated with difficulties with feeding and faltering growth which can also be severe. More commonly the airway obstruction is more mild, and can often be managed by conservative intervention such as positioning of the child.

Investigation and management regimes vary widely, but the specific definitions of PRS used in published literature are numerous making comparison between treatments difficult. Recently a consensus document has been published, the aim of which is to improve consistency in definition of PRS and thus improve the evidence base for intervention. This chapter describes the condition, and outlines management options and outcomes.

Keywords

Pierre Robin Sequence • Orofacial clefts • Airway • Glossoptosis

18.1 What is Pierre Robin Sequence?

Pierre Robin Sequence (PRS) is a well recognised entity made up of the triad of micrognathia (small mandible), glossoptosis (tongue falling back) and airway obstruction. In addition, up to 90% of neonates with these features will also have a cleft palate [1, 2]. This group of problems was initially recognised and described by a number of authors in the nineteenth and twentieth centuries. Subsequently Dr Pierre Robin, a French stomatologist, wrote extensively on the severity of the difficulties these infants had in maintaining their airway and feeding [3–5], and as a result the condition bears his name.

The triad of features has previously been known as Pierre Robin Syndrome and the Robin anomalad. It is now largely known as Pierre

Robin Sequence or Robin Sequence. It is described this way as it is currently generally believed that a small mandible is the starting point of a sequence of events that give rise to the clinical problems recognised as this condition, namely breathing and feeding difficulties. The clinical manifestations of PRS are very variable, however, and there has been no consensus as to the specific inclusion criteria that should be used to diagnose the condition [6, 7]. A survey published in 2010 found 14 different definitions of PRS [8]. PRS is also relatively rare [9, 10]. There has been a lack of systematic evaluation of treatment protocols and outcomes, and management of the condition remains variable and controversial. As a result and following a 2 day meeting in 2014, an international multidisciplinary consensus group came together recently to try to overcome these problems. A consensus report has been generated which provides agreed recommendations for the initial evaluation and clinical descriptors [11]. Ideally researchers and clinicians will increasingly use uniform definitions and comparable assessments so that an evidence base can be built to guide standards of care for infants and children with this condition.

18.2 Aetiology

The cause or causes of PRS are not known. It is hypothesised that mandibular hypoplasia leads to the PRS phenotype. The cause of mandibular hypoplasia may be intrinsic or extrinsic but hypoplasia starts during embryonic development and is thought to result in the tongue being displaced upwards and backwards preventing closure of the palatine shelves [6]. A classic cleft palate in PRS is described as being U shaped (see Fig. 18.1), the suggestion being that this reflects the separation of the palatine shelves by the tongue during development. Data from the West Midlands Cleft Centre, UK, suggest that the extent of the cleft palate is not directly related to the degree of airway obstruction (see Fig. 18.2) but most infants with PRS have extensive clefts of the palate [9, 12, 13].

It has been hypothesised that extrinsic events such as oligohydramnios or multiple births may induce growth restriction of the mandible. Other congenital anomalies such as cervical hemivertebrae may also result in mandibular growth restriction by preventing the extension of the neck during embryonic growth. Intrinsic causes may be part of a wider craniofacial syndrome or isolated to the mandible. These are likely to be due to genetic causes.

Fig. 18.1 Intra oral photograph showing the typical U shaped cleft palate of an infant with PRS

It has also been suggested that the anomalies of breathing and feeding may not be entirely due to anatomical features, but may also be related to brainstem dysfunction. Abadie and colleagues have described anomalies in oesophageal motility and pharyngolaryngeal tone which occurred more frequently in infants diagnosed with PRS who had more severe feeding and breathing problems [14].

18.3 Genetics

Retrospective studies of large series of children with PRS suggest that approximately half of the children affected will have other anomalies and/or a recognised syndrome [15–17]. The most commonly diagnosed syndromes in children with PRS are Stickler's syndrome and 22q11 deletion syndrome, but >100 syndromes include micrognathia as part of the condition and >40 syndromes have been identified in children with PRS [18]. 14–18% children with PRS will have Stickler's syndrome [16, 19, 20]. Infants with Stickler's syndrome may have severe short sight and this can in turn lead to retinal detachment. Early symptoms of retinal detachment in small children may be missed by family members as the children may not understand or be able to

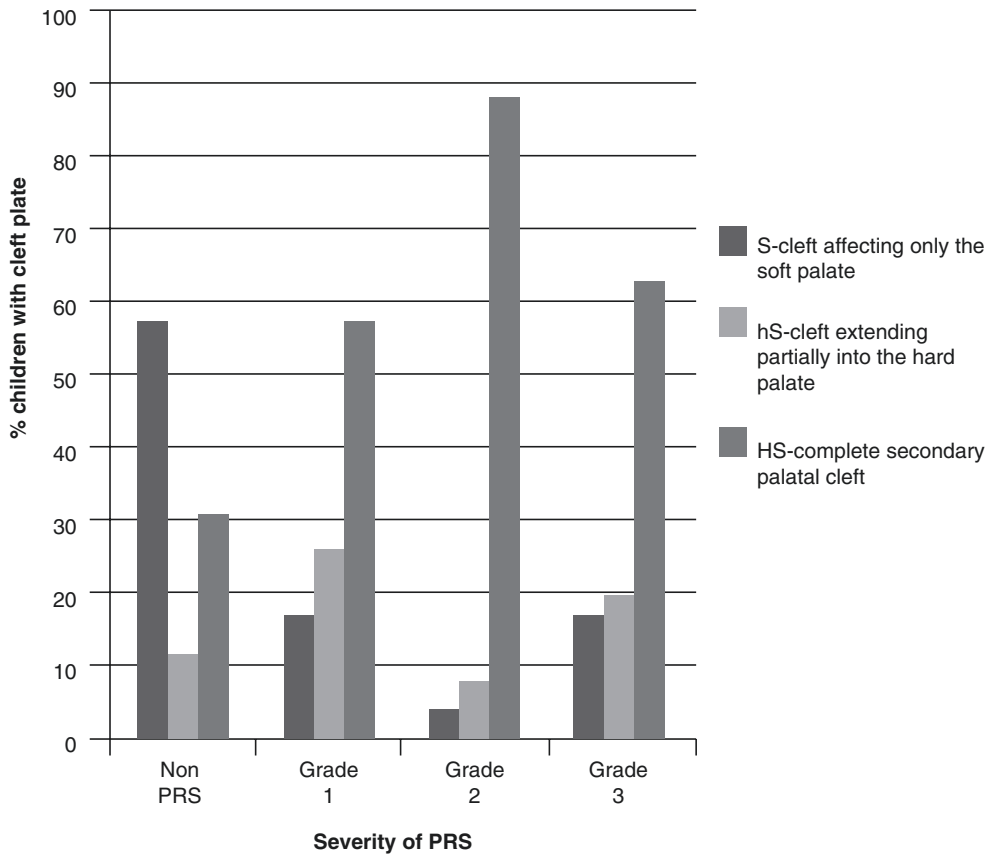

Fig. 18.2 Data from the West Midlands Cleft Centre, UK, showing the severity of PRS related to the extent of the cleft palate in all children with isolated cleft palate over a period of 5 years. Grade 1 PRS—managed by positioning alone. Grade 2 PRS—managed with positioning and nasogastric tube feeding. Grade 3 PRS—managed with NPA and nasogastric tube feeding

describe what is happening to them. Treatment to reduce the risk of retinal detachment can however be carried out if the diagnosis of Stickler's is known. A genetics review and ophthalmology opinion are important parts of the clinical management of these children.

In so called 'isolated PRS' where there is no other anomaly found a proportion of children will have a family history of PRS [15, 19, 21, 22] suggesting an hereditary cause. A number of studies have looked for chromosomal anomalies in 'isolated PRS' [23, 24] and comparison of these studies shows that no particular candidate gene has been identified for certain. However, some consistencies have been found and GAD67 on 2q31, PVRL1 on 11q23-q24 and SOX9 on 17q24.3-q25.1 are suggested to be important [25].

18.4 Incidence

The incidence of PRS in published studies varies from 1 in 5,600 [13] to 1 in 14,000 [9] births, and PRS is stated to affect from 6% to up to a third of the cleft palate population [9, 12, 13]. The variable results published probably reflect the variability in diagnostic inclusion criteria used. Personal experience indicates that the higher frequency is likely to be the more accurate one if all severities of airway obstruction are included.

18.5 Antenatal Diagnosis

Antenatal diagnosis of PRS is currently rare. It relies on the identification of a small mandible on

the profile view of the face on ultrasound scan. This is difficult to do before the 3rd trimester as the mandible is small in the early trimesters. Later scans may not be routinely carried out and this feature is not regularly looked for, making it unlikely to be diagnosed. Although oligohydramnios has been suggested as a cause for a small mandible, polyhydramnios has also been identified as being associated with PRS in several studies [26–28]. It is thought that this is the result of poor swallowing by the infant. It is recommended that examination of the facial profile is undertaken where there is a finding of polyhydramnios. Measurement of the fronto-naso-mental angle may provide an objective way to diagnose retrognathia antenatally [29].

18.6 Clinical Presentation

The Clinical Consensus Report agrees that micrognathia, glossoptosis and upper airway obstruction are required to make a diagnosis of PRS [11]. The airway obstruction is typically a high oro-pharyngeal obstruction due to the tongue falling against the pharynx and causes an inspiratory stertor sound rather than the lower stridor type sound typical of a glottic obstruction. Very many infants with PRS will also have a problem with feeding. The severity of both these problems is very variable. Some infants will have rapidly life threatening airway obstruction at or shortly after birth requiring immediate airway intervention. Others will have clearly increased respiratory effort, episodes of cyanosis and reduced oxygen saturation which can be easily identified. In these cases oral feeding is unlikely to be successful. More commonly however, the airway obstruction is quite mild initially and may only be noticeable when the baby is asleep or feeding. A mild tracheal tug and/or slightly noisy breathing when sleeping supine may be the only indicators of a problem.

It is therefore mandatory that all babies with an isolated cleft palate are assessed for the possibility of PRS. Assessment should include examination of the size of the mandible (Fig. 18.3) and of the intraoral position of the tongue as well as looking for signs of airway obstruction. It should also include a feeding assessment. In some infants with PRS the airway problem will initially only be manifest when the baby is trying to feed. It is also important to establish whether or not the infant has additional feeding problems, such as an unsafe swallow, that are independent of the cleft palate and airway obstruction. Cole and colleagues describe a protocol for such an assessment to identify neonates at risk and to classify them according to severity of symptoms and signs [30]. Infants with mild symptoms and signs are classified as Grade 1 and are managed with side to side lying. Infants in Grade 2 have slightly greater symptoms and are nursed on their side and are initially fed by nasogastric tube. Grade 3 infants are monitored in a specialist centre and have 24 h oxygen saturation assessment. These infants need more active airway intervention and are usually managed with a nasopharyngeal airway. This protocol facilitates the early identification of infants at risk, management plans, and communication with other members of the cleft/craniofacial team.

18.7 Investigations

Some centres recommend thorough investigation of all infants identified as being at risk of PRS [31]. In other centres the nature and extent of investigation will depend on the severity of the obstruction and response to treatment. Infants who have clinical signs of upper airway obstruction should have as a minimum continuous pulse oximetry to monitor whether or not oxygen desaturations occur. This is especially important at night and during deep REM sleep when the child's voluntary neck muscles are relaxed and airway obstruction may be exacerbated. Many clinicians recommend further investigation of the airway obstruction which may include CO_2 monitoring and polysomnography.

Determining the site or sites of the airway obstruction may be crucial to planning effective management [32] and some centres recommend this before any airway intervention. Endoscopic examination such as bedside laryngoscopy can be carried out to visualise the upper airway and

Fig. 18.3 Two infants with PRS showing differing degrees of micrognathia

vocal cord mobility. Direct laryngoscopy and bronchoscopy are required to visualise the subglottic structures including the trachea and bronchi. Severe micrognathia may make this extremely difficult however.

18.8 Management

Infants who have PRS need to have both their airway secured and feeding established so that weight gain occurs satisfactorily. Those identified with a mild degree of PRS may only require a change in position for their airway to be controlled and for them to be able to adequately feed orally and gain weight. The infants may be positioned prone or on their side to relieve the obstruction. In the UK it is not advised for babies to be nursed prone [33] and side to side lying is therefore encouraged. If this is not sufficient, further measures are introduced. It is estimated that positioning alone and positioning with feeding management is successful for about half or more of all children identified with PRS [34–36] (see Fig. 18.4).

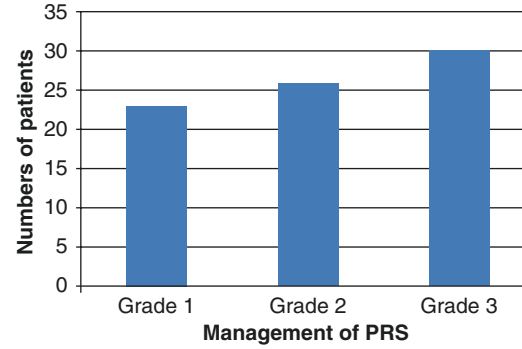

Fig. 18.4 Numbers of patients with PRS referred to the West Midlands Cleft Centre, UK, over a period of 5 years and their management regimes. Grade 1—managed by positioning alone. Grade 2—managed with positioning and nasogastric tube feeding. Grade 3—managed with NPA and nasogastric tube feeding

Babies managed by positioning alone need to be monitored carefully particularly with regard to their weight gain. If respiratory effort is not adequately relieved weight gain will falter as the

child grows. This may be due to requiring additional calories to counter the increased respiratory effort and an increased effort during feeding. If feeding is not efficient enough, calorific intake may not be sufficient and the baby may then become tired making maintenance of the airway and feeding more difficult. A downward spiral may then be encountered and weight gain falls off. Similarly, if the child develops an upper respiratory infection airway obstruction and effort may increase sufficiently for the child to not manage their airway and/or adequate feeding.

If positioning alone is not sufficient to relieve the airway and allow adequate oral feeding, nasogastric feeding may provide a solution [1, 30]. Nasogastric feeding provides the infant with nutrition and reduces/eliminates the effort of coordinating breathing and swallowing. Where the infant is stable with side lying but develops airway problems during feeding or has poor weight gain, nasogastric feeding may prevent the need for more invasive intervention while the infant grows. Weight gain must be carefully monitored in this situation, and if not sufficient further investigation of the upper airway obstruction is required.

If nasogastric feeding and side lying do not relieve the airway obstruction more invasive intervention will be needed. A nasopharyngeal airway (NPA) can be placed intranasally extending into the pharynx far enough to bypass the obstruction caused by the base of the tongue. The baby then breathes through the NPA (see Fig. 18.5). Successful use of this technique has been described in several publications [31, 37, 38]. Placement of the NPA allows the baby to be nursed supine and to be fed orally. It is extremely important to introduce oral feeding to the neonate as early as possible, and use of the NPA allows the introduction of early oral feeding. This is usually only for short periods of time and once or twice a day initially. However, as the baby grows oral feeding can be increased as tolerated by the infant.

With appropriate training and support for parents, infants can also be discharged home with the NPA in place [38–40]. As the infant grows s/he can be weaned from the NPA during the day, and the NPA removed completely

Fig. 18.5 Infant with nasopharyngeal airway and nasogastric tube

usually at the age of about 4 months [39]. Centres vary in how long they leave the NPA in place [40]. Removal of the NPA through the night is only carried out following sleep studies in hospital to demonstrate that there are no continuing airway problems.

In circumstances where it is felt that home management of a NPA is unsafe and a prolonged hospital stay is to be avoided alternative surgical options may be considered.

Other methods of conservative treatment have also been described but have not been adopted by the majority of centres regularly treating infants with PRS. A palatal plate with an extension posteriorly to push the tongue forward [12, 41] to relieve airway obstruction has been described. In a small study of 7 patients another centre has described successful use of continuous positive airway pressure as a method of overcoming the airway obstruction while the infants grow and their airway problems resolve [42]. The role for such therapies is as yet unclear.

18.9 Surgical Therapies

Surgical intervention may be required if positioning, nasogastric feeding and a NPA do not relieve the airway obstruction. In these circumstances further evaluation of the airway and consideration of a central respiratory problem is necessary. Central apnoea, hypotonia, laryngomalacia, tracheomalacia and bronchial stenosis have all been described in PRS and need to be excluded. Multiple levels of airway obstruction may also be present. Surgical treatment described for PRS is aimed at relieving the upper airway obstruction caused by the base of the tongue falling against the posterior pharyngeal wall. If other levels or causes of airway obstruction are present these need to be identified and addressed or treatment will not be successful.

Surgical treatments used regularly for PRS include tongue-lip adhesion (TLA), subperiosteal release of the floor of the mouth (SRFM), mandibular distraction osteogenesis (MDO) and tracheostomy. Different institutions have differing levels of experience with and indications for each of these interventions.

18.9.1 Tongue Lip Adhesion

Tongue lip adhesion was first descibed by Douglas in 1946 [43] and has been modified by a number of authors since [44, 45]. The ventral surface of the tongue is sutured to the inner aspect of the lower lip pulling the tongue forward and preventing it falling back into the pharynx. To prevent dehiscence suturing of tongue muscle to lip muscle is advised. The posterior tongue can also be anchored to the mandible. In some institutions where NPA placement is not used regularly TLA is the first line of intervention if positioning alone fails.

Complications described for this procedure include scarring, the need for a second procedure, and the possibility of the procedure interfering with oral feeding. It is also not always successful in relieving airway obstruction [46, 47]. Efforts are now being made to describe more accurately which patients will benefit from this procedure [48].

18.9.2 Subperiosteal Release of the Floor of the Mouth

Subperiosteal release of the floor of the mouth was first described by Delorme in 1989 [49]. This technique is predicated on the theory that the tongue is rotated backwards by an anterior insertion into the small mandible. An incision is made under the chin to the inner aspect of the mandible. Dissection proceeds subperiosteally releasing the attachments to the mandible from angle to angle of the mandible. The base of the tongue can then move posteriorly allowing the tip of the tongue to rotate into the mouth and out of the pharynx [2, 50, 51]. Patients have to remain intubated for several days until swelling has settled and the tongue has settled into its new position. This procedure is not always successful in relieving the airway problems [51].

18.9.3 Mandibular Distraction Osteogenesis

Distraction osteogenesis is a well known technique for moving and lengthening bone. Mandibular distraction has been described for the treatment of PRS [52, 53] where the level of airway obstruction is at the base of the tongue and where other treatment modalities have failed. The aim is to distract the mandible forward with its attachments to the floor of the mouth thus moving the tongue forward and increasing the size of the airway. The technique involves an osteotomy through each side of the mandible and insertion of either internal or external distractors. External devices are easier to use, adjust and remove but can also be knocked, and they result in external scars. Internal devices require further surgery to remove. Recently absorbable distractors have been used successfully [54, 55].

MDO occurs in 4 stages: osteotomies and application of distractors, a latent phase, and then a period of distraction followed by a period of consolidation. Patients remain intubated until the advancement has occurred. It is not always successful in relieving the airway obstruction and algorithms are being developed to improve patient selection [56, 57].

Authors advocating this treatment acknowledge that such treatment will not remove the possible need for further orthognathic surgery and the long term effects of distraction are not well established. Complications include loss of teeth, scarring, and marginal mandibular branch nerve palsy [53]. A recent study of longer term follow up of infants treated with mandibular distraction showed increased dental anomalies and a shorter mandible than a comparison group of children with PRS as an infant who had not been treated with mandibular distraction [55]. One child in this study required repeat distraction at the age of 5 years. MDO is reported in some studies as having a high rate of success in avoiding tracheostomy in the series published [53, 58]. Where it is successful advocates describe the rapid resolution of both airway and feeding problems in infants with PRS with reduced need for prolonged hospital stay, nasogastric tube feeding or nasopharyngeal airway. Mandibular distraction osteogenesis for PRS is only indicated for a small number of patients where other interventions have failed. Further information is required to fully evaluate the short and long term effects of this treatment as compared to other management regimes for PRS.

18.9.4 Tracheostomy

In some infants with PRS, the cause or causes of the infant's problems are not clear even after extensive investigation. In these cases management can be extremely difficult. These infants nearly always have multiple problems—'syndromic PRS'. A multidisciplinary approach to the problem is required for these complex patients. This should include input from respiratory paediatricians, ENT surgeons, dieticians, specialists in dysphagia, and gastroenterologists, as well as the cleft/craniofacial team. Where all other treatment options fail and if there is subglottic airway obstruction, tracheostomy is the only remaining option. Tracheostomy at such a young age is associated with complications and even death.

18.10 Feeding and Growth

Upper airway obstruction makes coordinating feeding and breathing difficult. Respiratory rate may be raised and the extra effort of respiration results in the infants becoming tired and using more calories for breathing than usual. Feeding and weight gain need to be carefully monitored and managed [59]. Infants who fail to gain weight may need increased calories in their feed and particularly those treated with positioning only may need to have their airway assessed further. Many infants with PRS need nasogastric feeding in the early months [1, 30]. Most infants can be weaned from nasogastric feeding by the age of one and often before palate repair surgery [37].

Upper airway obstruction results in increased negative pressure in the thorax and abdomen produced by the extra effort of respiration against the obstruction. This seems to exacerbate gastro oesophageal reflux (GOR) which is extremely common in these infants and can be very severe [60]. GOR may also exacerbate the airway obstruction if oedema is caused by the refluxing acidic stomach contents into the airway. Thickening of feeds and medical treatment of GOR are regularly needed in these infants. Some will need further investigation and may require fundoplication.

18.11 Natural History of PRS

Most infants with PRS and obstruction at the tongue base level will grow out of the problem within a few months of birth. As the infants grow the airway obstruction improves and intervention to maintain the airway can be withdrawn. It is not clear if the clinical improvement is due to an increase in airway size alone, or due to increased muscular control of the tongue and pharynx, or both. However, it does occur for most children with PRS, particularly those with no other problems. Where children have multiple problems, so called 'syndromic PRS', problems with airway and/or oral feeding may persist.

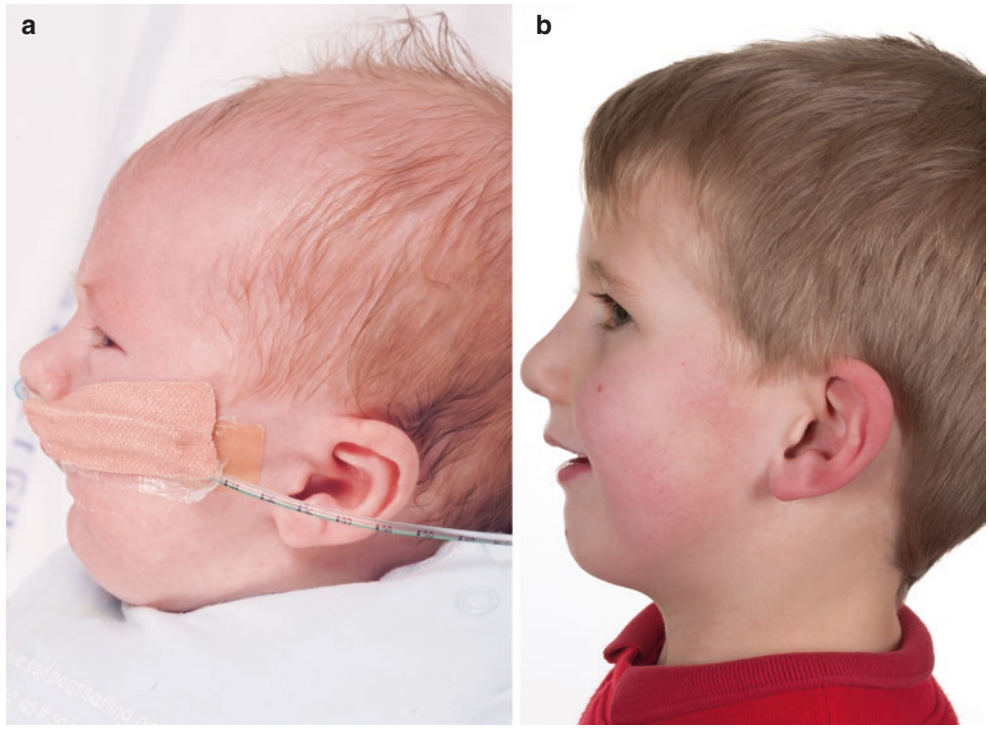

Fig. 18.6 Mandibular growth (**a**) Infant with PRS (**b**) Same child aged 5 years

Most infants will have mandibular growth that appears to catch up with the rest of the face (see Fig. 18.6). It is thought that this occurs in children where mandibular hypoplasia has been due to extrinsic factors. In other children, even though the mandible grows and the clinical problems resolve, the mandible continues to appear small in proportion to the maxilla. It is assumed that these children have an intrinsic problem with mandibular growth. There is little longitudinal data on mandibular growth in this condition [61] and at present there is no way to predict which children will have 'catch up' growth and which will not. There is indeed controversy as to whether catch up growth occurs at all.

Children who have had PRS appear to be at risk of a recurrence of upper airway obstruction during their early years. At the time of palate repair recurrence of upper airway obstruction may complicate the immediate post operative period. This can be relieved with a NPA usually placed at the end of the surgical procedure. Removal of the NPA 24–48 h after surgery is usually then uneventful. Some surgeons who undertake early palate repair (for example, at age 6 months) will plan to repair the palate a little later than their usual protocol (for example, at age 9–12 months) to avoid such complications. This also seems to be effective.

Similarly, upper respiratory tract infections may precipitate a short period of upper airway obstruction usually only manifest when the child is sleeping deeply. The episodes can often be managed by conservative supportive methods until the infective episode settles. In the longer term these children seem to grow out of these obstructive problems.

Knowledge of the long term effects of PRS is scanty. A population based study of Swedish students suggested that individuals with PRS had less favourable educational outcomes than their peers without PRS [62]. A study in Holland suggested that intellectual disability was not

present in isolated PRS but was found in approximately 40% of children with PRS and other anomalies or syndromes [20]. A recent study from the West Midlands Cleft Centre suggests that the speech outcomes of children with PRS Grade 3 are worse than those of children with similar sized clefts but without PRS or other syndrome [63]. This difference was particularly marked with articulation problems but also occurred to a lesser extent with structural speech difficulties.

Conclusions

PRS is a well recognised triad consisting of small mandible, glossptosis and airway obstruction. Most infants with this triad will also have a cleft palate and all babies with isolated cleft palate should be examined with this condition in mind in order to identify and address problems early. Up to a third of infants with cleft palate only may have a degree of upper airway obstruction. Where not identified and treated infants will fail to thrive and their airway obstruction can rapidly deteriorate.

It is imperative that infants identified as having PRS are managed by a specialist team with experience of the condition. With appropriate assessment and monitoring, many infants with this condition can be managed relatively easily and successfully, often in the home environment. These infants usually have no other problems. However, infants with 'syndromic PRS' who have anomalies in addition to the PRS triad often have extremely complex medical problems and can be extremely difficult to manage. These infants require careful and full multidisciplinary care in a unit that has regular experience of managing such problems.

Despite the fact that specific inclusion criteria for this condition vary, knowledge is increasing. Treatment protocols vary [31, 52, 53] but the aim must be in all cases to use the least invasive method of intervention that allows the infant to breathe normally and to feed and grow. Most infants will grow out of the immediate problems of airway obstruction and feeding within the first year of life, and many within the first 6 months. Further information about the long term outcomes for this condition following different treatment regimes is needed before there will be enough evidence for consistency of treatment methods. It is hoped that the Clinical Consensus Report [11] will help clinicians move in this direction. This is an exciting area of increasing knowledge.

Conjoined Twins

19

Lewis Spitz, Edward Kiely, and Agostino Pierro

Abstract

Conjoined twins can be subdivided into (a) symmetrical conjoined twins, and (b) heteropagus or parasitic twins. This chapter presents a brief summary of the history of conjoined twins followed by a classification of the various types according to the site of attachment, the investigations required, and the operative procedure. The experience of the team at Great Ormond Street Hospital is presented.

Keywords

Siamese twins • Conjoined twins • Conjoined twin classification • Separation techniques

Conjoined twins can be subdivided into (a) symmetrical conjoined twins, and (b) heteropagus or parasitic twins.

19.1 Symmetrical Conjoined Twins

19.1.1 History

One of the earliest depictions of conjoined twins is a stone carving of pygopagus twins dating back to 80 BC, discovered in Fiesole and kept in the San Marco Museum in Florence, Italy (Fig. 19.1).

An attempt at separation of conjoined twins took place in Kappadokia, Armenia, in around AD 945. When one of the male ischiopagus twins died at the age of 30 years, the surviving twin was separated from his dead brother, but he died 3 days later [1].

The first well-documented case is that of the Biddenden maids born in Kent in AD 1100 and "joined at the hips and the shoulders" (Fig. 19.2). They lived together for 34 years. When Mary fell ill and died, Eliza was advised to be separated from her deceased twin but absolutely refused saying, "as we came together we will also go together". She died 6 hours later. It is unlikely that they were joined at the hips and shoulders as depicted in numerous illustrations. A more plausible explanation was that they were ischiopagus twins [2].

Fig. 19.1 Stone carving of pygopagus conjoined twins dating back to 80 BC

Fig. 19.2 Monument to the Biddenden maids born in Kent in AD 1100

The Scottish Brothers were born near Glasgow in 1490. They were "two complete individuals above the waist but the lower half of their bodies was fused—one set of genitalia and two legs". They were taken to the court of King James IV who ordered that they be carefully brought up and educated at court. They learned to sing, played various musical instruments and became fluent in several languages. They had different personalities, often differing in opinions and sometimes quarrelling. They died in 1518, aged 28 years [3].

In the Sixteenth Century, Ambroise Paré collected examples of six sets of conjoined twins and was one of the first to classify the different varieties of conjoined twins [4].

The Isle-Brewer xiphopagus twins, Priscilla and Aquila, were born in 1680 joined "from the navel up to a point just below the nipples". The vicar at their christening believed that the monstrous birth was a sign of impending evil. They were abducted and displayed but died in 1683 [5].

The first successful separation of conjoined twins took place in 1689. The surgeon, Johannes Fatio, separated omphalopagus twins in Basel, Switzerland, by "tracing the umbilical vessels to the navel where he tied them separately. He then transfixed and tied the bridge between the two infants with a silken cord and cut the isthmus". The ligature fell off on the ninth postoperative day and both children survived. Koenig, an observer at the procedure, published the case as his own and to him is credited the first successful separation [6, 7].

The most celebrated pair of conjoined twins was Chang and Eng Bunker, born on a river boat in Siam (Thailand) in 1811. They were joined at the xiphisternum by a short band that stretched so that they were eventually able to stand side-by-side (Fig. 19.3). They became proficient swimmers and their peculiar movement attracted the attention of Robert Hunter, a travelling Scottish merchant, who eventually persuaded their mother to permit him to take them to the United States where they were exhibited by the showman, Phineas Barnum. They married sisters, lived in separate houses in North Carolina spending 3 days in each house alternately, and had 21 children between them. Physiologically and psychologically they were different—Chang was smaller and more feeble; Eng was good-natured, Chang cross and irritable; Chang drank heavily, but Eng appeared unaffected by the alcohol. They wished to be separated but could not persuade surgeons to carry out the operation which was considered to be too hazardous at the time. They lived together for 63 years and died in 1874 [8, 9].

Fig. 19.3 Portrait of Chang and Eng from Royal College of Surgeons of England, London, UK

The Tocci Brothers, born in 1877, were extensively united parapagus conjoined twins. They also wished to be separated but the extent of their union dictated that surgery at the time was clearly not feasible. They lived together for 63 years and died in 1940 [10]. Other conjoined twins have declined any suggestion of separation. Lori and Reba Schappell, craniopagus twins, born in 1961, never wanted to be separated stating "God made us this way and He had a purpose for us and you do not ruin what God has made".

Hoyle in 1990 [11] reviewed all attempts at surgical separation of conjoined twins, performed successfully and unsuccessfully, through to 1987. Of a total of over 600 publications, separation was attempted in 167 cases. The survival rate increased dramatically in the most recent decade prior to 1987. He concluded that "the current excellent outcomes (for separation) suggest that separation should always be considered with rare exceptions". Since 1990, there have been an increasing number of publications reporting successful separation.

19.1.2 Etiology and Embryology

In the absence of an experimental model, the exact etiology of conjoined twins is unknown. The uncertainty between fission and fusion theories remains. As it seems likely that fission of a single fertilised ovum occurs in the same manner each time, the wide variety of types of conjoined twinning make fusion the more likely mechanism.

Conjoined twins often have remarkably different personalities. This difference in personality is clear from the early months of life and remains unexplained. Regardless of the mechanism, twins are always joined homologously—chest to chest, pelvis to pelvis etc.—and are always the same sex. Spencer [12, 13] has proposed that union occurs at sites where ectoderm is absent or programmed to disrupt or fuse.

The fusion theory suggests that two separate embryonic discs from a monovular pregnancy, lie on the surface of a single yolk sac. At around the third week of pregnancy, fusion occurs at sites where the ectoderm is not present or where it is disrupted. Ectoderm is absent over the precursors of the septum transversum and heart. Fusion at this level results in thoracopagus and omphalopagus twins. Ectoderm disrupts at the sites of the oro-pharyngeal and cloacal membranes and fuses at the edge of the embryonic disc. Union at these sites results in cephalopagus, ischiopagus and parapagus twins. Dorsal union—craniopagus, rachipagus, pygopagus—results in each twin having its own umbilicus and separate abdomen.

The other types of union are considered ventral and usually share a single cord and peritoneal cavity. These cords will frequently have more than three vessels. Associated anomalies are common and predominantly affect the structures which are joined. The patterns of abnormality encountered depend on the type of union and each of the eight types of twinning has a range of associated anatomical defects [14].

These abnormalities may preclude extrauterine survival and may render separation impossible. According to Spencer, thoracopagus twins always have a single heart with multiple chambers and separation is rarely an option. Others have been less rigid in their definition of thoracopagus and there have been well documented cases where separation of thoracopagus with separate hearts has been successful.

19.1.3 Incidence

The frequency of conjoined twins has been estimated at 1:50,000 pregnancies but as up to 60% of these twins succumb in utero the true incidence is 1:250,000 live births. With the advent of routine prenatal ultrasound, the anatomy is seen early in gestation and elective termination will be an option.

Female twins predominate in the ratio of 3:1.

19.1.4 Classification

Conjoined twins are classified on the basis of the site of union, with the suffix -pagus meaning fixed or fastened. The twins can have four (tetrapus), three (tripus), or two (bipus) legs. The classification of conjoined twins, limited to eight types with approximate percentages of frequency, is summarized in Table 19.1

1. Thoracopagus: (Fig. 19.4) The twins lie face to face and are joined at the sternum, diaphragm, upper abdomen wall and liver and have an exomphalos. In the majority of the cases they share the pericardium (90%) and heart (85%). They may have a common small intestine (50%) which joins at the duodenum and separates at ileum; the biliary tree can be joined in 25% of patients. There may be associated cardiac anomalies such as ventricular septal defect, atrial septal defect, tetralogy of Fallot.
2. Omphalopagus: The heart is never fused; the liver is joined in 80% of cases and there is an exomphalos. The stomach and proximal small bowel are usually separate, and each twin has a rectum. In up to one-third of omphalopagus twins, the intestines usually join at Meckel's diverticulum, the terminal ileum and colon are shared, and may also have a dual blood supply. There is usually no union of the genitourinary tract.
3. Pygopagus: (Fig. 19.5) The twins are joined dorsally, sharing the sacrococcygeal and perineal regions. They face away from each other—share the sacrum, coccyx and part of the pelvic bones. The spinal cords are usually separate [15]. Twenty-five percent share the lower GI tract and have a single anus and one or two rectums. In 15% of cases there is a single bladder. There is an increased incidence of vertebral anomalies, including hemivertebrae, hemisacral

Table 19.1 Characteristic features of different conjoined twins

Type of fusion	Incidence	Extent of union	Shared structures
Ventral (87%)			
Cephalopagus	11%	Top of head to umbilicus	
Thoracopagus	19%	Thorax, upper abdomen, conjoined hearts 85%	Liver 100% Pericardium 90% Cardiac defects 75% Upper intestine 60% Biliary tree 17%
Omphalopagus	18%	Upper abdomen; Separate hearts	Liver 90% Upper foregut 16% Cardiac 25%
Ischiopagus	11%	Cloacal membrane	Pelvis bone 100% Lower GI tract 70% Genitourinary 50%
Parapagus	28%	Cloacal membrane	Cardiac 75% Intestine 100% Liver 100% Genitourinary 100%
Dorsal (13%)			
Craniopagus	5%	Cranial neuropore	Skull, venous sinus, and meninges 100% Cerebral cortex 37%
Rachipagus	2%	Neural tube	Vertebral column
Pygopagus	6%	Caudal neuropore	Sacrum and coccyx 100% Lower GI tract 25% Genitourinary tract 15%

Fig. 19.4 Thoracopagus conjoined twins sharing a heart

Fig. 19.5 Pygopagus

agenesis and thoracic anomalies [16]. Although the pelvic conjunction is fundamentally different than in ischiopagus twinning, the types are similar insofar as numerous other associated orthopaedic anomalies have been reported in association with pelvic conjunction, such as hip subluxation or dislocation, congenital vertical talus, talipes equinovarus, Sprengel shoulder and scoliosis. There can also be a variable degree of spinal and cord fusion. Although there may be only one anus and rectum, the remainder of the intestines are usually separate. The upper bodies are not fused and there are four arms and four legs.

4. Ischiopagus: (Fig. 19.6) The twins may lie face to face or end to end. They have two sacra or two symphysis pubis. They may share the lower gastrointestinal tract (70%) and/or the genitourinary tract (50%) and may have crossing ureters. The twins can be tetrapus, tripus, or bipus although the most common arrangement is the presence of four legs. Pelvic conjunction leads to complex urogenital and orthopaedic anatomy. The kidneys usually function normally, but are often malrotated or ectopic in location. When two bladders are present they lie side by side in a collateral position or they may lie in a sagittal midline location with one bladder draining into the other. The ureters frequently cross over and insert into a contralateral bladder such that they will need to be re-routed during separation. Partial urethral duplication is possible but a single urethral orifice is typical. The distal gastrointestinal tract is often shared, with anorectal agenesis and rectovesical fistula. Contrast studies are necessary to delineate distal bowel anatomy. Urogenital sinus or cloaca may be present. In boys there is an increased incidence of undescended testes.
5. Craniopagus: The conjoined twins share the skull, meninges and the venous sinuses. The brains are usually separate although some cortical fusion can occur in 33% of cases.
6. Cephalopagus: The twins often have a fused thorax in addition to a fused head. The single fused head may have two faces (janiceps) facing away from each other; one face may be rudimentary. These twins are terminated or die in utero. They are nonviable.
7. Rachipagus: The twins have generally vertebral anomalies and neural tube defects.
8. Parapagus: (Fig. 19.7) This is a relatively new term denoting extensive side-to-side fusion. The twins share the umbilicus, lower abdomen, pelvis (single symphysis pubis) and the GU tract. They can have anorectal anomaly and colovesical fistula and may be at risk of anencephaly.

Fig. 19.7 Parapagus

19.1.5 Diagnosis

19.1.5.1 Antenatal Diagnosis and Imaging

Fetal ultrasound can detect the presence of conjoined twins in almost all cases. Accurate antenatal assessment allows the parents to be counselled as to the probable outcome of the pregnancy and the likelihood of successful postnatal separation. Prenatal diagnosis of conjoined twins is important for optimum obstetric management, including decisions regarding termination of pregnancy, timing and method of delivery to minimize maternal and fetal mortality.

19.1.5.2 Fetal Ultrasound

Prenatal ultrasonography (US) is capable of diagnosing conjoined twin pregnancies as early as 12 weeks' gestation [17–19]. Transvaginal US may also aid early diagnosis [20]. Diagnosis of conjoined twins may be straightforward when fusion of fetal parts is obvious. The possibility of conjoined twins should be suspected in a twin pregnancy with a single placenta and no visible separating amniotic membrane. The sonographic findings in conjoined twins include inseparable fetal bodies and skin contours, an unchanged relative position of the fetuses, both fetal heads persistently at the same level, bibreech or bicephalic presentations, fewer limbs than expected, and a single umbilical cord with more than three vessels [21]. Polyhydramnios occurs in as many as 50% of conjoined twin pregnancies compared with 10% of normal twins and 2% of singleton pregnancies. Detailed US assessment at around 20 weeks gestation should be able to define the site and extent of the conjoined area and provide a reasonable evaluation of which viscera are shared.

Fetal echocardiographic (ECHO) assessment of the heart needs to be detailed and accurate. A shared heart is incompatible with postnatal survival and is usually an indication for termination of the pregnancy. Hearts can be confirmed as separate when they are seen to be anatomically separate or when the heart rates are different. It has been the experience of many authors that fetal ECHO underestimates the severity of cardiac anomalies [22].

Prenatal ECHO is facilitated by amniotic fluid, particularly polyhydramnios in later pregnancy, acting as an acoustic window. Recently 3D US imaging has been advocated as a new tool to demonstrate the extent of fusion in conjoined twins.

19.1.5.3 Magnetic Resonance Imaging (MRI)

MRI, with its ability to differentiate soft tissues, provides an excellent alternative technique [23] for overall fetal assessment. Ultrafast T2-weighted (T2-W) sequences of short duration, such as the single-shot fast spin-echo sequence, allow minimal image degradation by fetal motion and high-quality images of fetal organs without the need for fetal or maternal sedation.

19.1.6 Postnatal Imaging

The choice of imaging study will depend to some degree on the site of fusion. All conjoined twins should have chest and abdominal radiography for an overall general assessment, and partly to help health professionals understand the extent of the conjoined area. Unexpected diaphragmatic hernia or vertebral anomalies can thus be detected early.

19.1.6.1 Ultrasound

All neonates should have routine cerebral US, and when indicated a spinal US, as baseline investigations. In addition, abdominal US to assess the liver, to document the presence of two spleens, gallbladders, biliary systems, and kidneys bladders, is necessary. Detailed Doppler studies to evaluate the great vessels in the abdomen and hepatic venous drainage should also be performed, but midline abdominal conjunction may make accurate Doppler assessment unreliable. Meticulous labelling of the images, ensuring the correct twin is consistently noted to be on the same side.

19.1.6.2 Echocardiography (ECHO)

ECHO is mandatory for every twin due to the high frequency of congenital heart disease. 3D ECHO has been advocated postnatally as it may

facilitate understanding of the cardiac connections, and can be helpful to plan treatment [24]. Andrews et al analysed 23 sets of conjoined twins and classified twins according to the degree of cardiac fusion as follows: separate hearts and pericardium (group A, $n = 5$), separate hearts and common pericardium (group B, $n = 7$), fused atria and separate ventricles (group C, $n = 2$), and fused atria and ventricles (group D, $n = 9$)35. None of the twins from groups C or D survived demonstrating that the outcome in twins with fused hearts remains dismal.

19.1.6.3 Computed Tomography (CT)

Due to its high spatial resolution and speed multidetector CT (MDCT), ~~is~~ the best overall modality for evaluating conjoined twins in the postnatal setting (Fig. 19.8).

Contrast enhancement is mandatory to assess the vascular anatomy. It can demonstrate the shared liver and vascular connections. Delayed images give very useful information on excretion by both twins' kidneys, the ureteric anatomy, and the location and number of bladders. Separate studies examining each twin's vascular anatomy on different days are recommended.

19.1.6.4 MRI

MRI has an increasing role in the postnatal evaluation of conjoined twins, particularly those joined at the head or thorax. MR has the capability of producing 3D reconstructed images in any direction with much improved resolution and tissue characterization and is of value in preoperative planning e.g. pygopagus (Fig 19.9). MR is the optimum examination to assess for any cortical fusion in craniopagus twins. Intracardiac and great vessel anatomy and blood flow, and ventricular wall motion can all be accurately assessed in thoracopagus cases. MR cholangiopancreatography (MRCP) is likely to offer the best hope of assessing the biliary anatomy. Liver anatomy can be best appreciated after intravenous contrast enhancement, either at CT or MRI. Demonstration of separate hepatic venous drainage into the inferior vena cava and right atrium of each twin is essential to plan separation as absent or severely anomalous hepatic venous drainage in one twin is incompatible with survival after surgery.

It is not unusual to find large calibre vessels crossing the area of fusion. It is important to visualise these vessels by CT or MRI before separation to minimise blood loss and mortality during separation.

Fig. 19.8 CT scan of omphalopagus conjoined twins showing shared liver

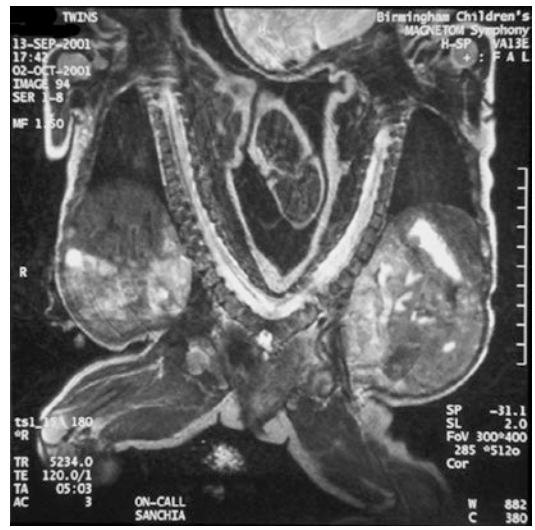

Fig. 19.9 MRI scan of pygopagus twins showing spinal cord and vertebral anatomy

19.1.6.5 Contrast Studies of the Gastrointestinal and Genitourinary Tracts

Abdominal conjunction often involves fusion of parts of the intestine. Even in the absence of fused bowel, when contrast medium is given to one twin the bowel loops may be freely mobile across the 'midline' and be seen to project into the peritoneal cavity of the other twin during fluoroscopy [25]. Pelvic conjunction leads to complex fusion and anomalies in the anorectal region. These require an individual approach with contrast studies (enemas, loopograms and cystograms) of the distal bowel and bladder. Contrast studies provide limited information and often, particularly due to overlapping bowel loops, the anatomy can only be revealed at the time of separation.

Urological abnormalities are confined to those in whom the pelvis is joined: ischiopagus, parapagus or pygopagus twins. Most twins share four kidneys and two bladders, occasionally with one ureter crossing from the contralateral twin to the other. The bladders are usually side by side but they may be sagittally placed [26]. CT scanning usually provides sufficient information regarding the upper renal tracts and bladders. Detailed urethral anatomy and possible fistulas require retrograde contrast medium examinations.

19.1.6.6 Nuclear Medicine

The kidneys, albeit ectopic or too few in number, usually function normally in conjoined twins [25]. Cross-sectional imaging can usually clarify the genitourinary anatomy without the need for isotope renography studies. There is an increased frequency of pelviureteric or ureterovesical obstruction in these twins, but this is seldom of major importance prior to separation.

19.1.7 Obstetric Management

Delivery should take place at, or close to, the surgical unit where separation will be performed. Delivery must always be by classical Caesarian section at 36–38 weeks' gestation.

19.1.8 Anaesthetic Management

Anaesthesia involves two separate anaesthetic teams with all members being clearly aware for which child is their responsibility [27]. Endotracheal intubation should be via the nose for added security. Because of repositioning and movement once separation has been performed there is a risk of accidental extubation and the nasal route is more secure.

Full arterial and central venous pressure monitoring is essential, together with ECG, pulse oximetry and capnography. Adequate wide bore venous access is essential as brisk haemorrhage may be encountered necessitating rapid large volume transfusion. All drugs and intravenous fluids administered are calculated on a total weight basis with half being delivered to each twin. Because of the cross-circulation, drugs given intravenously may have an unpredictable effect and particular care must be taken to administer such drugs incrementally. Urine output is carefully monitored.

All lines and monitoring cables are best colour coded for each twin to avoid confusion during repositioning.

19.1.9 Separation Procedure

The key to a successful outcome is thorough preoperative planning.

From the imaging, the extent of major organ union will be apparent and the details of each major system separation is planned in advance. The order in which these phases of separation will be performed is best decided during the operation itself. Many anatomical variants exist for each of the different types of union. For instance, although the liver is joined in 100% of thoracopagus twins, in 50% there is intestinal union in addition. The surgeon will need to have planned for each possibility—such as what to do if there is a single duodenum, or a single common bile duct.

In the more extensive forms of ischiopagus or parapagus union, the terminal ileum and the large bowel are single. Allocation of these structures

cannot be planned in detail as the mesenteric blood supply is abnormal and unpredictable. As a general rule, these children have two bladders which may lie side by side or may lie anteriorly and posteriorly. Plans must be in place to deal with either eventuality, together with plans for dealing with crossed or uncrossed ureters.

Most importantly, with extensive union, there will be a substantial body wall defect after separation. This is invariably more extensive than anticipated. The management of this problem also needs to be planned in advance. We have used tissue expanders in the past and found them to be troublesome and unhelpful in providing substantial extra tissue. With the sole exception of craniopagus union, where the expanders sit on bone, we would not recommend their use. We use polypropylene mesh over a plastic liner to close the defect and plicate this as tolerated. Even with the largest of defects, the body wall can be closed within 2 weeks.

Initially, one surgical team comprising both lead surgeons is sufficient to commence the procedure. Our preference is to start the operation from posteriorly. The skin and soft tissue are divided down to muscle and fascia. The wound is then sutured closed and the babies turned around. We have done this with the more extensive unions, as otherwise, it is difficult to allocate body wall equally and one may easily leave one with significantly less. Once this incision has been made, it is easy to complete the separation at the final stage of the operation.

If a vestigial limb is present posteriorly, it may be bivalved and divided and the bones filleted out. This provides vascularlised healthy tissue to assist in closure. Allocation of this extra tissue is decided at the time of surgery.

On opening the chest and abdomen anteriorly, it is usually best to divide the conjoined sternum to improve access. The lobar anatomy of conjoined livers is not readily discerned and in any case precision is unnecessary in this regard. A point is chosen, midway between the gall bladders and the porta hepatis on either side and the liver is divided in the usual manner. The use of an ultrasound dissector combined with one of the high energy sealing devices results in virtually bloodless conditions.

Once the liver is divided, the remainder of the gastrointestinal anatomy is easier to manage.

The urological aspects are dealt with before the decision about allocating the rectum [26]. Usually each twin has a bladder and at least a posterior urethra. Occasionally, two bladders lying fore and after are divided and the two halves united on either side. If the bladders are side by side, then the division takes place between them. In ischiopagus and parapagus twins the ureters may cross into the opposite twin's bladder.

Our experience suggests that in almost all cases, it is possible to preserve at least one corpus of the penis for each twin. Occasionally, there are three or more corpora cavernosa in which case a more normal penis will result.

Once the urological procedure has been completed, a decision is made on allocation of the rectum and anus. This will depend on the blood supply which is available. It has been our practice to leave the terminal ileum and colon with one twin whilst leaving the rectum with the other when conditions permit.

Once the pelvic viscera have been allocated, the posterior part of the pelvic ring is divided. Preoperative imaging will have revealed if there are substantial vessels crossing at this level. Finally, the previously sutured skin wound is opened and separation is complete.

Closure of a large body wall defect is straightforward. If the sternum is short and the heart or pericardium are exposed, a polypropylene patch is sutured to the chest wall skeleton laterally and superiorly and to the diaphragm inferiorly. This patch is left permanently in situ. The abdomen is closed by suturing two flaps of polypropylene mesh to the muscle on either side and covering the viscera with a plastic liner, such as an intestinal bag.

With wide undermining, there is usually sufficient skin to cover the chest wall defect. The skin over the abdomen is tacked to the mesh to cover the area where the mesh is sutured to muscle. This allows tissue to grow from the fascia through the mesh to the overlying subcutaneous fat and ensures a strong attachment of mesh to muscle [28–32].

19.1.10 Postoperative Management

Almost all these patients are electively ventilated after surgery with the usual monitoring which is employed after major surgery. There are, however, two problems which are not common in other children—fluid loss and cardiac performance.

If the abdomen has been closed with a mesh, there will be substantial fluid losses through the mesh for the first few days.

We estimate the losses by use of absorbent gauze dressings, weighed on an hourly basis. The fluid is then replaced ml for ml with human albumin solution. The mesh is tightened, commencing on the day after operation. Limited tension is applied for the first few days. However, after the first 4 days, increasing tension can be applied to the mesh. The abdominal wall stretches and grows rapidly, especially in young infants. It is usual to achieve abdominal wall closure within 2 weeks.

The other aspect in which conjoined twins differ is in cardiac performance. It is a feature of those who have extensive union, that one circulation supports the other. In general, the thinner and more active twin has a heart which is more robust and which supports the other twin's circulation. This difference in cardiac performance is not evident on pre-operative testing.

Once the circulations are separated, the more dependent twin may be significantly compromised. It is of critical importance that the lowest filling pressure possible is used and that the after load is also reduced. We try to maintain as low a central venous pressure as possible, together with as low a blood pressure as possible, commensurate with an adequate urine output. This phase of compromised cardiac performance lasts a number of days but is usually resolved by 7 days after operation.

The timing of enteral feeding is variable but does not await body wall closure.

In the majority, complete removal of the mesh is achieved when the abdomen is closed. On occasion, it is necessary to leave some mesh and this has not been a particular problem over the following years.

The *outcome* in our series [33] could be divided into one of three courses.

1. *Non-operative management*: Table 19.2 is indicated when there is complex cardiac union without the possibility of reconstructing even a single functioning heart or where there is extensive cerebral fusion. Parents faced with the prospect of a surviving twin having severe deformities may refuse consent for separation. In eight of nine cases in our series there was cardiac fusion while in one with extensive parapagus fusion (a normal triplet survived) parents refused surgery. All nine sets died within a short period.

2. *Emergency separation*: Table 19.3 is required when one twin is dead or dying and threatening the survival of its sibling, where there is a correctable congenital anomaly incompatible with survival if left untreated such as

Table 19.2 Separation not attempted outcomes

Classification	Sex	Shared organ(s)	Associated anomalies	Outcome
Thoracopagus	F	Cardiac fusion	Pulmonary atresia, esophageal atresia, omphalocele	Died
Thoracopagus	F	Cardiac fusion	Omphalocele	Died
Thoracopagus	F	Cardiac fusion	?	Died
Parapagus	F	Extensive union	Surviving triplet	Died
Thoracopagus	F	Cardiac fusion	?	Died
Thoracopagus	F	Cardiac fusion	?	Died
Thoracopagus	F	Cardiac fusion	?	Died
Thoracopagus	F	Cardiac fusion	?	Died
Thoracopagus	F	Cardiac fusion	?	Died

Table 19.3 Emergency separation outcomes

Classification	Sex	Shared organ(s)	Associated Anomalies	Age at operation	Outcome
Thoracopagus	F	Pericardium, diaphragm, Liver, CBD, small bowel	Pulmonary atresia	3 days	1 A&W, 1 died cardiac failure
Omphalopagus	F	Liver, small bowel	Omphalocele and liver ruptured at birth; Cloacal exstrophy	1 day	1 died before arrival, 1 dies intraop
Thoracopagus	M	Cardiac-atrial communication, liver	Unilocular heart Absent hepatic veins	8 days	1 died intraop; 1 died at 6 weeks/ SIDS
Thoracopagus	F	Liver	Unilocular heart, CDH	1 day	both died
Omphalopagus	F	Liver, jejunal atresia	Omphalocele, volvulus	2 days	Both A&W
Omphalopagus	M	Distal colon, bladder	Hypoplastic lung, Anorectal anomaly	1 day	1 died in transit, 1 A&W
Omphalopagus	F	Liver	Cardiac (DORV)	1 week	1 A&W, 1 died 3rd day
Parapagus	F	Lungs, diaphragm, aorta, liver, intestine	AV canal, PPH	1 day	Both died
Thoracopagus	F	Pericardium, cardiac defect, liver	Porencephalic cyst	5 days	1 died postop-PPH; 1 died at 2 weeks
Omphalopagus	F	Liver, small bowel	Intestinal obstruction	1 week	Both A&W
Omphalopagus	F	Ileum, 1 colon, bladders	Both ARAs	2 days	Both A&W

oesophageal or intestinal atresia, or where serious damage has occurred during birth to the connecting bridge or area of fusion (ruptured omphalocele).

Emergency separation was necessary in 11 of our cases. One had a rupture of the shared omphalocele resulting in tearing of the united liver with exsanguinating haemorrhage resulting in the death of one twin. Emergency separation was undertaken in an attempt to salvage the surviving twin who died at the end of the procedure.

In three sets of thoracopagus twins, cardiac instability prompted emergency separation. Only one of these infants survived. Prenatal volvulus with necrosis and perforation occurred in a set of omphalopagus twins necessitating emergency separation. Both twins had intestinal atresia which was repaired but developed short bowel syndrome which required many months for adaptation to occur. Both survived and eventually thrived.

Another set of omphalopagus twins were transferred soon after birth as one had severe pulmonary hypoplasia requiring mechanical ventilation. This twin died during transfer. The transport team were was instructed to digitally compress the area of union to prevent exsanguination into the surviving twin while avoiding applying a clamp as prior experience showed that much of the surviving twin's intestine may reside in the peritoneal cavity of its sibling. This twin did survive.

The survival rate for emergency separation was nine out of a possible 22 infants—40%. In retrospect survival was not possible in six of these cases.

Table 19.4 Planned separation outcomes

Classification	Sex	Shared organ(s)	Associated anomalies	Age at operation	Closure	Outcome (to discharge from hospital)
Craniopagus	F	Sagittal sinus	Nil	2 months	Skin grafts	Both A&W[a]
Ischiopagus	M	Liver, ileocolon, rectourethral fistula, penis	ARA, Crossed ureters, TRIPUS	8 months	Primary	Both A&W
Parapagus	F	Pericardiu, diaphragm, liver, ileocolon, ARA, genito-urinary	Renal agenesis	3 years	Prolene mesh	1 A&W, 1 died at 3 days
Parapagus	M	Pericardium, liver, ileocolon, genito-urinary	ARA	10 months	Prolene mesh	1 A&W[b]
Thoracopagus	F	Pericardium, liver, CBD, jejunum	Omphalocele	3 months	Prolene mesh	Both A&W
Omphalopagus	F	Liver, CBD	Nil	3 months	Prolene mesh	Both A&W
Omphalopagus	F	Liver	Nil	6 weeks	Prolene mesh	Both A&W
Pygopagus	F	Sacrum, spinal cord, vagina, ARA	Nil	3 months	Primary closure	Both A&W
Omphalopagus	M	Liver	HIV	8 months	Prolene Permacol	Both A&W[c]
Pygopagus	M	Sacrum, spinal cord, urethra, penis, anus		19 months	Primary	Both A&W
Ischiopagus	M	Urethra, penis	TRIPUS, ARA	4 months	Mesh	Both A&W (scoliosis)
Pygopagus	F	Sacrum, spinal cord		4 months	Primary	Both A&W
Ischiopagus	M	Anus, bladder extrophy, ileo-colon, Bipus		7 months	Primary	Both A&W
Ischiopagus	M	Liver, colon	TRIPUS	2 years	Primary	Both A&W

[a]One died at 6 months S.I.D.S
[b]One vomited, aspirated and died at 6 months
[c]? One died after return to Nigeria? D&V

3. *Planned separation*: Table 19.4 if the twins are stable and healthy at birth, they should be allowed to feed normally and thrive with the intention to separate at around 2–3 months. This allows time to carry out investigations to define as accurately as possible the nature and extent of shared organs. The operative procedure can then be planned with involvement of all the relevant staff.

Eighteen sets underwent planned separation, of whom three died, (two at home 6 months after successful separation), and 33 survived (91%).

Table 19.5 Outcome of management of conjoined twins in the major series

Authors	Year	Number	No operation	Emergency separation Survivors (%)	Planned separation Survived (%)
O'Neill (USA) [20]	1988	18	5	5 sets 1 (10%)	8 sets 13 (81%)
Cywes/Rode (S. Africa) [25, 34]	2006	33	16	None	17 sets 22 (65%)
Al Rabeeah (Saudi Arabia) [35]	2006	29	19 (1 abandoned operation)	None	10 sets 19 (95%)
Saguil (Philippines) [36]	2009	22	6	6 sets 1 (8%)	9 sets 15 (83%)
Spitz/Kiely/Pierro (UK)	2010	40	9	11 sets 9 (40%)	18 sets 33 (91%)

The outcome for the management of conjoined twins in the literature is given in Table 19.5.

19.1.11 Follow-Up

The extent of the union will determine whether the infant/s will have minor or major residual problems. One or both twins may have congenital cardiac abnormalities which may require surgical correction. Residual scars or contractures may require plastic surgical correction. Short bowel syndrome occurs when each twin is allocated 50% of the shared intestine. There will be a need for parenteral nutrition and meticulous dietary support for a period of time pending intestinal adaptation. Intestinal stomas may be temporary or permanent and will require the input of a stoma therapist. Imperforate anus when present will need reconstruction.

Prolonged urological follow- up is essential, particularly in the cases of ischio- and pygopagus twins. Shared bladder, cross ureters, vesicoureteric reflux and renal abnormalities will require regular monitoring to prevent further damage and to diagnose early and treat urinary calculi. Lifelong orthopaedic follow- up will be needed for limb deformities, deletion of lower limb/s and for scoliosis and chest wall deformities.

Psychological support should commence preoperatively when separation is undertaken at a later age and is essential following separation especially were there is the loss of one of the twins. Where the separation has involved prolonged periods of hospitalisation (some of our twins have been discharged within 2 weeks of separation) there may been developmental and behavioural problems which will require attention.

19.2 Ethics

If separation is possible with the expected survival of both twins, we would strongly recommend that the surgical procedure should be performed. If there is complex cardiac fusion, the chances of survival of one or both twins is so remote that surgery should be declined and nature allowed to take its course.

If one twin has a lethal abnormality and cannot survive independently from its "normal" twin and if separation does not take place both twins would die, then separation should proceed even though at the expense of the abnormal twin who has survived only by being supported by its sibling.

Yet, twins can survive joined together for many years. Alice D. Dreger [37] contends that "when it comes to cases in which one twin must be 'sacrificed', it is ethically wrong to take one life so another may live". She further states that "not in a single case has the twin chosen to survive ever actually survived to go home". This is clearly incorrect as borne out in our and other series.

19.3 Heteropagus (Parasitic) Twins

19.3.1 Definition

Heteropagus or parasitic twin is a grossly defective fetus, or fetal parts, attached externally, with or without internal connections, to a relatively normal twin (the autosite) in one of the same eight areas in which symmetrical twins are united. They are usually comprised of externally attached supernumerary limbs but may also contain viscera or visceral parts but only rarely a beating heart or intact brain.

Fetus in Fetu is a fetiform mass enclosed within the body of the autosite, usually the abdominal cavity, rarely within the brain, with grossly recognisable fetal parts including an axial skeleton, attached to the autosite by a pedicle containing a few large blood vessels. Its growth rate is similar to the host within which it is discovered.

19.3.2 Incidence

The estimated incidence of heteropagus twins less than for symmetrical twins, < 1 per million births. The female preponderance seen in symmetrical twins is not evident in heteropagus twins where there is an equal distribution of the sexes.

19.3.3 Embryological Considerations

The most plausible theory for the occurrence of heteropagus twins was proposed by Dönitz in 1866 [38]. He postulated that heteropagus twins originated from symmetrical twins one of which suffered secondary damage as a consequence of vascular compromise. The affected "twin" would then have to rely on collateral blood supply from the autosite while ischemic damage occurred in various parts of the affected "twin". In support of this theory, hypoplastic umbilical vessels have been found in the heteropagus twin and vascular connections from the autosite to the heteropagus twin may be found during surgical separation. Others have disputed this theory as it cannot account for all the abnormalities found in these twins and particularly cannot explain the acephalic occurrence. It is generally accepted that the heteropagus twin is genetically identical to the autosite and this has been substantiated by DNA analyses.

19.3.4 Anatomical Types

196 reports of heteropagus twins have appeared in the literature up to 2010 [39].

The breakdown of these cases are as follows:

Thoracopagus	1
Cephalopagus	6
Parapagus	3
Omphalopagus	71
Ischiopagus	32
Pygopagus	46
Craniopagus	11
Rachipagus	28

Dipygus or caudal duplication (Fig. 19.10) is a rare abnormality comprising two sets of accessory lower limbs sited between the autosite's limbs and including accessory external genitalia.

Omphalopagus (Fig. 19.11) or epigastric heteropagus accounts for the majority of cases—more prevalent in recent series where almost 60% of cases were in this region.

Fetus in fetu [40, 41] occurs most commonly within the abdominal cavity with 57 reported cases with only 9 having a brain and 6 a heart, both always small and rudimentary. In most cases a pedicle of vessels arise from the retroperitoneal region and attaches to the umbilical area of the parasite. In the cranial region the majority of fetus in feto are epignathi attaching to the posterior pharynx near the location of Rathke's pouch. Only 7 cases of intracranial fetuses in fetu have been reported.

Sacral parasite is a rare variety of heteropagus twin and needs to be differentiated from sacrococcygeal teratoma. Some authors consider fetus in fetu and fetiform teratomas within the spectrum of teratomas, but this remains controversial.

Fig. 19.10 Dipygus with prolapsed intestine

Fig. 19.11 Parasitic omphalopagus twins

19.3.5 Diagnosis

Prenatal identification of heteropagus twins has been documented on at least 7 occasions at gestational ages ranging from 9 to 28 weeks [42]. The importance of recognition of the nature of the abnormality is evident in that the condition is entirely benign and compatible with normal development. The diagnosis in utero should not be considered an indication for termination of the pregnancy provided that it is not causing gross deformity of adjacent structures.

19.3.6 Obstetric Care

Depending on the size and extent of the parasitic twin, delivery can be by normal vaginal route. If an obstructive delivery is anticipated, Caesarian section at around 38 weeks of gestation would be indicated.

19.3.7 Investigation

Sharing of organs and vascular connections are infrequent in heteropagus twins. As a result, preoperative imaging has usually been restricted to C.T., ultrasound and MRI scans which will reveal bony and soft tissue structures. Occasionally angiography has been undertaken to show vascular communications. More recently MRA (magnetic resonance angiography), has replaced invasive conventional angiography. Echocardiography of the autosite is mandatory in thoracopagus parasitic twins as over 25% have congenital cardiac defects.

19.3.8 Surgery

Separation of the parasite from the autosite is generally undertaken in early infancy. As sharing of organs and major vascular connections is

unusual, the surgical procedure is generally straightforward and uncomplicated. The initial skin incision should be carefully planned to take sufficient skin and subcutaneous tissue from the parasite to ensure tension free closure of the wound following separation. This will avoid wound breakdown or infection, the most commonly encountered complications. A thorough search of the autosite at the site of attachment must be carried out to exclude any retained abnormal or extraneous tissue and to correct possible anomalies in the autosite such as associated congenital intestinal abnormalities.

19.3.9 Outcome

The prognosis for the autosite is generally excellent with little or no consequences for the host.

Congenital Malformations of the Airway and Chest Wall

20

Emma L. Sidebotham and David C.G. Crabbe

Abstract

Malformations of the neonatal airway and chest wall are uncommon but invariably serious. As a generalisation, the earlier a congenital anomaly of the airway presents the more ominous it is likely to be. Many infants will have other major congenital malformations. Management is complex and successful treatment requires careful consideration by a multidisciplinary team that must include a sympathetic paediatric intensive care unit. The first part of this chapter deals with these conditions.

The majority of chest wall deformities in children are acquired rather than congenital. The second part of the chapter deals with true congenital deformities, many of which are due to skeletal dysplasias.

Keywords

Chest wall deformities • Pectus • Airway lesions • Airway malformations

20.1 Introduction

Malformations of the neonatal airway and chest wall are uncommon but invariably serious. As a generalisation, the earlier a congenital anomaly of the airway presents the more ominous it is likely to be. Many infants will have other major congenital malformations. Management is complex and successful treatment requires careful consideration by a multidisciplinary team that must include a sympathetic paediatric intensive care unit. The first part of this chapter deals with these conditions.

The majority of chest wall deformities in children are acquired rather than congenital. The second part of the chapter deals with true congenital deformities, many of which are due to skeletal dysplasias. Severe deformities in the neonatal period carry a poor prognosis with respiratory failure in infancy. Although not strictly congenital, chest wall deformity arising from thoracotomy in the neonatal period is discussed because of the importance of surgical technique to avoid late morbidity.

20.2 Congenital Malformations of the Airway

20.2.1 History

Anatomical descriptions of congenital airway malformations appear in the literature from the eighteenth and nineteenth centuries. Sporadic reports of infants with tracheal stenosis appeared during the early twentieth century but these remained of academic importance until 1958 when Cantrell and Guild successfully resected a segmental stenosis in a 7 year old girl [1]. The subsequent history of paediatric tracheal surgery has been recorded in detail by Backer and Holinger [2]. The first reports of tracheomalacia date from North America in the late 1930s when the condition was recognised in association with vascular rings. In 1948 Gross and Neuhauser reported correction of tracheal compression by pexing an aberrant innominate artery to the sternum [3].

20.2.2 Airway Embryology

Development of the airway begins on day 22 of embryogenesis when the respiratory diverticulum forms as a bud from the ventral aspect of the pharynx at the laryngotracheal groove. As this endodermal bud grows in a caudal direction the mesoderm of the primitive mesentery, destined to become the mediastinum, proliferates and invests the bud. The endoderm gives rise to the epithelium of the trachea, bronchi and alveoli, whilst the mesoderm forms the cartilage, muscle and connective tissue of the respiratory tract. As the respiratory diverticulum elongates from day 28, lateral invaginations of mesoderm form the tracheo-oesophageal septum which separates the future airway from the foregut. This process of separation is complete by day 35.

Between day 26 and 28 the tip of the respiratory diverticulum bifurcates to form the left and right primary bronchial buds. These buds are the rudiments of the left and right main bronchi and the lungs. Around this time the blood supply switches from the splenic plexus to the definitive pulmonary vasculature. From weeks 5 to 28 of development the bronchial buds will undergo a further 16 rounds of bifurcation, together with the investing layer of mesoderm, to form the respiratory tree.

20.2.3 Nomenclature

There is no universally accepted classification of congenital malformations of the airway. Atresia refers to an orifice or passage that is absent or abnormally closed. Agenesis refers to the failure of an organ to develop during embryonic life. In the context of airway malformations these terms have entered common usage with a certain amount of interchangability—for example, tracheal atresia is commonly, but incorrectly, referred to as tracheal agenesis.

20.2.4 Congenital High Airway Obstruction Syndrome

Congenital high airway obstruction syndrome (CHAOS) is associated with intrinsic or extrinsic obstruction to the fetal airway [4]. Obstruction of the trachea or larynx results in distension of the large airways which is readily visible on fetal ultrasound (Fig. 20.1). The lungs hyperexpand and invert the diaphragms [5]. The fetus becomes hydropic. Causes include laryngeal atresia and

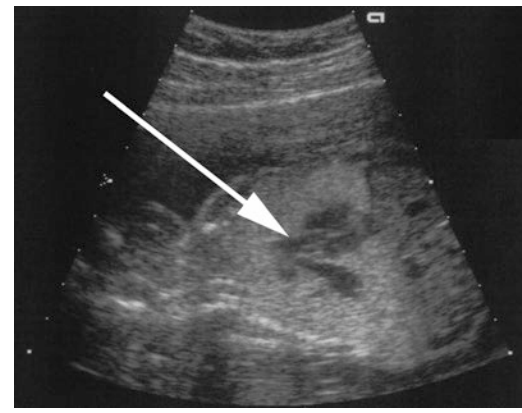

Fig. 20.1 CHAOS. The dilated trachea and main bronchi can be seen on this fetal ultrasound image

extrinsic compression of the upper airway from cervical tumours, including teratomas and lymphangiomas.

20.2.5 Laryngeal Clefts

Laryngeal clefts result from failure of caudal progression of the tracheo-oesophageal septum. They affect around 1 in 2000 births. The male to female ratio is approximately 2:1. Laryngeal clefts typically present with a combination of stridor, choking on feeds and recurrent aspiration pneumonia [6]. Stridor and a hoarse cry should alert the surgeon to the diagnosis as these symptoms are distinctly unusual in an infant with an H-type tracheo-oesophageal fistula. Stridor occurs because the posterior wall of the larynx is abnormally mobile and the redundant mucosa prolapses into the airway causing intermittent airway obstruction. Early severe symptoms are associated with extensive clefts. Minor clefts may escape detection.

20.2.5.1 Associated Malformations

Laryngeal clefts are seen in association with the Opitz–Frias and Pallister–Hall syndromes. The Opitz-Frias (G/BBB) syndrome affects midline structures [7]. The most common features of this condition are hypertelorism, defects of the larynx, trachea, and oesophagus and hypospadias. Cleft lip with or without a cleft palate, cardiac defects, anorectal malformations and agenesis of the corpus callosum affect approximately 50% cases. Opitz G/BBB syndrome may be X-linked or inherited in an autosomal dominant manner. The X-linked form is associated with a mutation in the MID1 gene on chromosome X. The autosomal dominant form is associated with a chromosome 22 mutation.

The Pallister-Hall syndrome is characterized by a spectrum of anomalies including central or postaxial polydactyly, hypothalamic hamartomata, which may be associated with pituitary insufficiency, a bifid epiglottis and a laryngotracheal cleft [8]. The condition is associated with mutations of the GLI3 gene on chromosome 7p13 and is inherited in an autosomal dominant manner.

20.2.5.2 Classification

In 1989 Benjamin and Inglis proposed a classification system for laryngeal clefts based on the extent of the cleft [9] (Table 20.1). Diagnosis of a laryngeal cleft requires careful endoscopic examination of the airway under general anaesthesia. The cleft may be obscured by redundant laryngeal or oesophageal mucosa and the only way to confirm or exclude the diagnosis with certainty is to attempt to part the inter-arytenoid notch with a right-angled probe (Fig. 20.2).

20.2.5.3 Management

Type 1 clefts can be managed conservatively in most cases [10]. If the infant remains unable to feed without aspiration endoscopic suture repair of the cleft may be necessary. Optimum management of type 2 and 3 clefts is less clear cut. The conventional approach involves open repair through an anterior laryngofissure with a covering tracheostomy. However, there is an increasing trend towards endoscopic repair without

Table 20.1 Benjamin and Inglis classification of laryngeal clefts

I above the true cords, limited to the interarytenoid region
II extension below true cords, partial involvement of the cricoid lamina
III total cricoid cleft ± extension into the cervical trachea
IV cleft involves the thoracic trachea and may extend to the carina

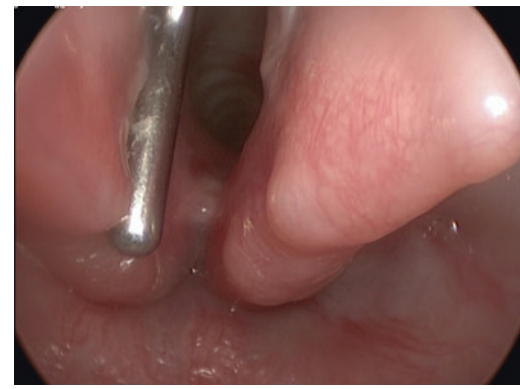

Fig. 20.2 The inter-arytenoid fissure is probed to look for a laryngeal cleft

tracheostomy. Complete larnygotracheal clefts are exceedingly difficult to repair and the complication rate is high [11]. Repair of the upper part of the cleft is performed using the anterior approach or via a lateral pharyngotomy. Repair of the lower part of the cleft is usually performed via a right thoracotomy. Tracheostomy is best avoided because of the risk of erosion and dehiscence of the repair. Careful consideration should be given to palliative care for infants with extensive clefts because associated malformations are common and the prognosis is poor.

20.2.6 Laryngeal Atresia

Laryngeal atresia is a rare, complex anomaly. In 1954 Holinger classified the condition into membranous and cartilaginous types [12]. In 1965 Smith and Bain proposed a more complex classification based on the site of the obstruction [13]. The diagnosis may be suspected antenatally if ultrasonographic features of the CHAOS are present. After birth the affected infant will make respiratory effort to no avail and expire quickly. Laryngeal atresia is frequently associated with tracheal agenesis and a tracheo-esophageal fistula. Endotracheal intubation is impossible but the lungs may be inflated with bag and mask ventilation or by esophageal intubation.

20.2.7 Tracheal Agenesis

Congenital absence of the trachea is a rare cause of severe neonatal respiratory distress. Less than 100 cases have been reported following the first description by Payne in 1900. Floyd et al. classified tracheal agenesis into three variants [14] (Table 20.2). In 90% of cases other congenital malformations are present, most frequently involving cardiovascular, gastro-intestinal and genito-urinary systems [15]. Tracheal atresia may be suspected antenatally if the CHAOS develops.

Tracheal agenesis presents at birth with severe respiratory obstruction in a baby who is unable to cry. Oxygenation can usually be improved temporarily by bag and mask ventilation by retrograde insufflation of the lungs through the tracheo-oesophageal fistula. Although the glottis can be visualised with a laryngoscope endotracheal intubation is impossible because the trachea is atretic [16].

Heroic attempts have been made to treat affected children with minimal success and considerable morbidity. Fuchimoto et al. recently reported the oldest survivor who has reached the age of five with a tracheostomy and overnight mechanical ventilation [17].

20.2.8 Pulmonary Agenesis

By longstanding convention anomalies of lung development are considered in three categories [18] (Table 20.3). The aetiology of these conditions is unknown. They are all associated with an increased incidence of cardiac, spinal and limb anomalies [19]. Pulmonary agenesis and aplasia are commonly associated with tracheal stenosis.

All three conditions may be asymptomatic. Pulmonary agenesis is well reported as an incidental finding at autopsy in the elderly [20]. More often these conditions are associated with

Table 20.2 Floyd's classification of tracheal agenesis [6]

• Type I—a short segment of trachea connects to the anterior esophagus (13%)
• Type II—the airway and esophagus are fused at the level of the carina, with no tracheal remnant (65%)
• Type III—right and left mainstem bronchi join the esophagus directly (22%)

Table 20.3 Anomalies of lung development

• Pulmonary agenesis: unilateral absence of bronchus, pulmonary vessels and lung parenchyma beyond the tracheal bifurcation
• Pulmonary aplasia: a rudimentary bronchus is present which forms a blind-end pouch without lung tissue
• Pulmonary hypoplasia: a variable reduction of lung parenchyma that may or may not be associated with a smaller than normal bronchus and pulmonary vessels

tachypnoea and frequent lower respiratory tract infection in infancy because of the reduced respiratory reserve [21]. Early presentation may signal the presence of tracheal stenosis. During childhood, particularly adolescence, asymmetrical growth of the rib cage may become obvious but scoliosis is uncommon in the absence of vertebral anomalies.

Pulmonary agenesis may be detected on prenatal ultrasound [22]. In postnatal life the diagnosis is usually made on a chest X-ray which shows displacement of the mediastinum (Fig. 20.3). The solitary lung herniates across the midline. Bronchoscopy is wise to exclude tracheal stenosis and a bronchial obstruction. Contrast enhanced CT may be necessary to excluded a vascular ring.

The prognosis depends on the presence of other anomalies [23, 24]. Tracheal stenosis associated with a solitary lung carries a poor prognosis. In the absence of other congenital anomalies symptoms improve with age although some infants succumb to recurrent infection. Pulmonary hypertension is uncommon providing the heart is structurally normal.

20.2.9 Abnormalities of Bronchial Branching

Variations of lobar or segmental bronchial anatomy are rare [25]. Major bronchial abnormalities include tracheal bronchus and accessory cardiac bronchus (ACB) (Fig. 20.4). The term *tracheal*

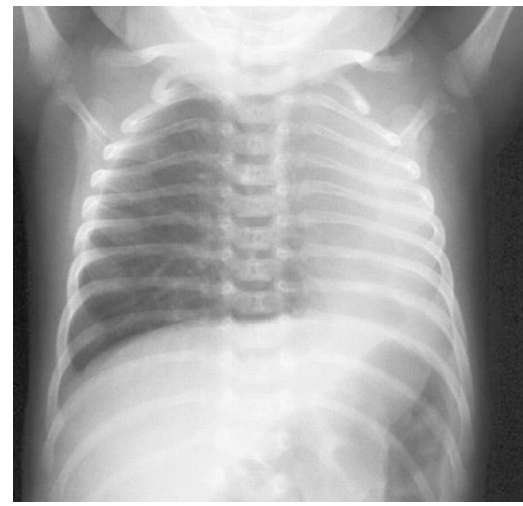

Fig. 20.3 Chest X-ray showing pulmonary agenesis

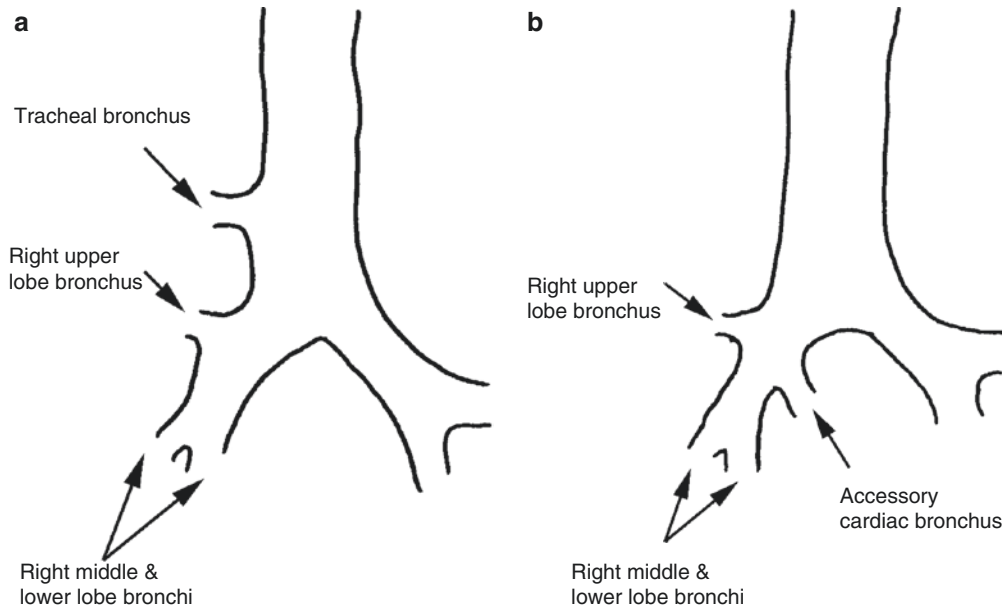

Fig. 20.4 (**a**) Tracheal bronchus (**b**) accessory cardiac bronchus

bronchus includes a variety of bronchial anomalies supplying the upper lobes (usually the right) originating from the trachea. A tracheal bronchus to the right upper lobe is seen in 0.1–2% population and a tracheal bronchus to the left upper lobe in 0.3–1% population, based on bronchographic and bronchoscopic studies. An ACB is a supernumerary bronchus arising from the inner wall of the right main bronchus or intermediate bronchus opposite to the origin of the right upper lobe bronchus.

20.2.10 Bronchial Atresia

Bronchial atresia is an uncommon congenital anomaly usually associated with atresia of a segmental bronchus [26]. The apicoposterior segment of the left upper lobe is most commonly affected [27] although a recent large series from Japan reported a predilection for the right lower lobe [28]. This study also included two children with lesions involving two lobes. Occasionally the atresia involves a lobar bronchus. The blind ending atretic bronchus fills with mucous resulting in a bronchocele. The lung parenchyma distal to the atresia is aerated via interbronchiolar channels and the pores of Kohn. This is commonly associated with air trapping.

The classical findings on chest x-ray are a mass (the bronchocele) surrounded by hyperinflated lung with decreased vascular markings. Computed tomography will confirm the diagnosis: the obstructed atretic bronchus typically points toward the hilum and the segmental nature of the emphysematous lung parenchyma distal to the obstruction is evident [29] (Fig. 20.5).

The majority of patients with bronchial atresia are asymptomatic. Symptomatic patients usually present with recurrent chest infections, dyspnoea, wheezing, or chronic cough. Secondary spontaneous pneumothorax has been reported [30]. No treatment is necessary for asymptomatic patients. Surgical excision is reserved for patients with complications. Segmental or lobar resection may be necessary with the aim to preserve normal lung parenchyma [28].

Fig. 20.5 CT scan showing bronchial atresia

20.2.11 Congenital Tracheal Stenosis

The normal trachea is supported by 16–20 horseshoe shaped cartilages and a membranous posterior wall. Congenital tracheal stenosis is associated with compete rings of cartilage which replace all or part of the normal tracheal cartilages [31]. The incidence of congenital tracheal stenosis is unknown but the condition is almost certainly underdiagnosed.

Tracheal stenosis typically presents in infancy with progressive dyspnoea and biphasic stridor. Symptoms worsen during the first few months of life as the infant grows [32, 33]. The stridor will increase substantially during feeding and at times of agitation. Infants with severe stenoses present earlier because the resistance to airflow is inversely proportional to the fourth power of the radius of the airway. Occasionally complete tracheal rings are found coincidentally at endoscopy, usually following endotracheal intubation for an unrelated procedure when the airway is found to be unexpectedly small.

20.2.11.1 Classification

The classification of congenital tracheal stenosis has been refined over the years. In 1941 Wolman described two variants—segmental stenosis and funnel stenosis [34]. In 1964 Cantrell and Guild added a third variant—diffuse hypoplasia [1]. Grillo described four variants with in a classification which is useful in clinical practice [33] (Fig. 20.6). Recently a further variant, described as a cork-screw stenosis, has been reported [35].

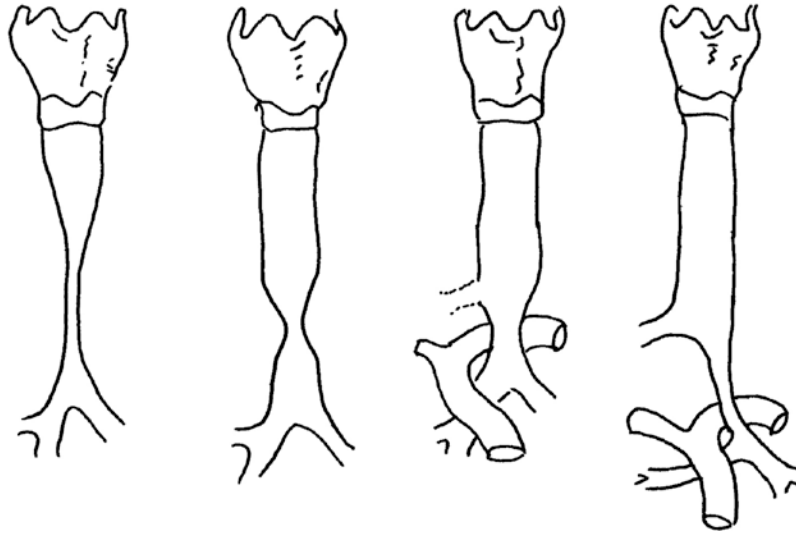

Fig. 20.6 Grillo classification of tracheal stenosis. Type I: Generalised hypoplasia. With the exception of the first 1–3 tracheal cartilages the trachea is diffusely narrow. Type II: Funnel stenosis. There is a progressive narrowing of the lower trachea. Type III: Segmental tracheal stenosis. The stenotic segment is frequently located below an anomalous tracheal bronchus supplying all or part of the right upper lobe. Type IV: Segmental tracheal stenosis associated with a bridging bronchus. A tracheal bronchus at the level of a normal carina supplies all or part of the right upper lobe. The airway continues as a stenotic bridging bronchus which supplies the remaining lobes of both lungs

Radial aplasia
Downs syndrome
Crouzon syndrome
Pfeiffer syndrome

20.2.11.2 Associated Malformations

Over 50% children with congenital tracheal stenosis will have other malformations, most commonly cardiovascular [33] (Table 20.4). The association with an anomalous left pulmonary artery (pulmonary artery sling) is particularly important because successful management requires simultaneous correction of both the vascular and tracheal anomalies [36, 37]. The discovery of one necessitates a search for the other [38]. The anatomical relations between PA sling and tracheal stenosis are shown in Fig. 20.7.

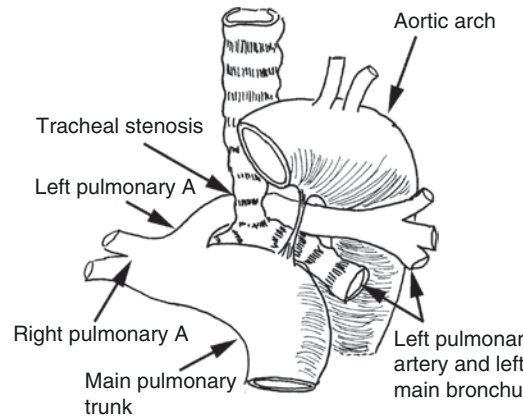

Fig. 20.7 Pulmonary artery sling diagram

The left pulmonary artery (LPA) arises from the posterior aspect of the right pulmonary artery. The LPA passes around the right bronchus and between the lower trachea and oesophagus en route to the hilum of the left lung [39]. Stenosis of the distal trachea and/or right main bronchus associated with complete tracheal rings is present in at least 50% of patients with pulmonary artery sling.

20.2.11.3 Assessment

Investigation and assessment of a child with congenital tracheal stenosis requires radiology and endoscopy. The tracheal air shadow may be abnormal on a plain chest X-ray but cross sectional imaging with contrast-enhanced CT or MR imaging is necessary to confirm the abnormality and determine the relationship of the airway to the major vessels (Fig. 20.8). Echocardiography should be performed to document intracardiac anomalies.

Bronchoscopy is an essential but potentially risky procedure in an infant with tracheal stenosis. Unintentional mucosal trauma may convert a stenotic airway into a critical airway and ideally this investigation should be postponed until radiological studies are complete. The aim of bronchoscopy is to confirm the extent and severity of the tracheal stenosis. Complete tracheal rings are relatively easy to identify (Fig. 20.9) provided the airway is not inflamed or oedematous.

20.2.11.4 Management

The management of congenital tracheal stenosis is complex and must be tailored to the patient [32, 33]. Successful results require a team familiar with the complexities of difficult airway management in young children. The outcome is invariably better if the stenosis is corrected before the airway becomes critical and the child is ventilator dependent. Medical treatment is futile, as is forcible dilatation. Tracheostomy has no role in the initial management of a child with tracheal stenosis.

Various surgical techniques have been used to correct congenital tracheal stenosis [40] (Table 20.5). Short segmental stenoses are potentially suitable for resection and direct anastomosis. In practice short segment tracheal stenosis is rare and there are better options for long segment stenoses. Approximately 25–30% of a child's trachea can be resected (roughly six rings) and followed by end-to-end anastomosis before excessive tension is likely to result in separation [41].

Pericardial patch tracheoplasty is relatively straightforward but the results are disappointing because of granulation tissue, malacia and recurrent stenosis. Cartilage graft tracheoplasty is technically difficult because of the inherent inflexibility of costal cartilage. Currently the technique used most widely to repair congenital tracheal stenosis is the slide

Fig. 20.8 MR scan showing long segment tracheal stenosis

Table 20.5 Surgical management of tracheal stenosis

Tracheal resection with end-to-end anastomosis
Patch tracheoplasty—cartilage, pericardium
Slide tracheoplasty
Tracheal transplantation procedures

tracheoplasty, first described by Goldstraw and colleagues in 1999 [42].

The stenotic segment of trachea is divided at the midpoint. The proximal and distal segments are incised vertically on opposite surfaces and then overlapped. Tracheal continuity is restored with a long oblique anastomosis (Fig. 20.10). The circumference of the trachea is effectively doubled and the stenotic segment shortened by half. Oxygenation is maintained during the procedure by either intubation of the distal airway through the operative field or by normothermic cardiopulmonary bypass. Follow up studies confirm good long term outcomes as the reconstructed airway grows with the child [43, 44].

The tracheal slide procedure can be adapted to treat complex variations in airway anatomy [45]. Tracheal stenosis associated with a pulmonary artery sling requires concomitant repair of both components [39]. The LPA is disconnected from

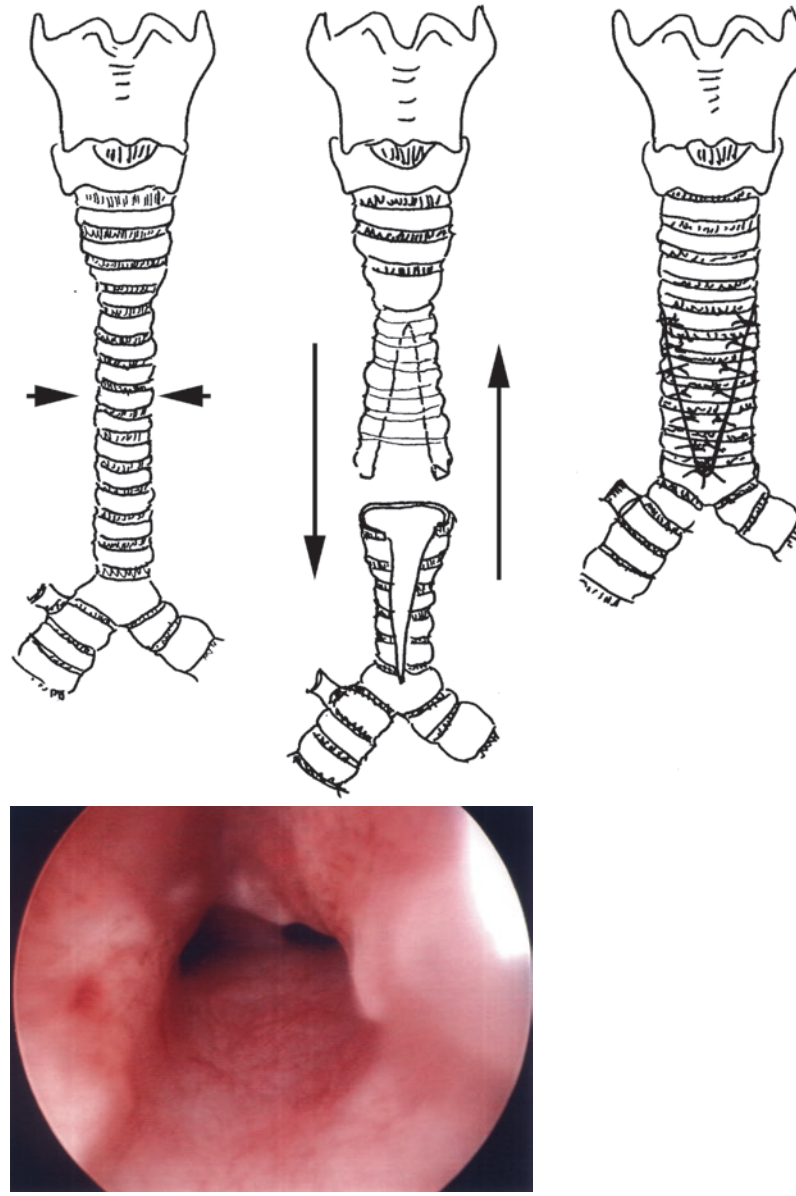

Fig. 20.10 Slide tracheoplasty including bronchoscopy photograph

the RPA and reimplanted into the main pulmonary artery at a site approximating the normal takeoff of the LPA. The associated tracheal stenosis is treated by a slide tracheoplasty (Fig. 20.11).

In recent years interest has focused on methods of tracheal replacement as a salvage procedure for children with inoperable recurrent stenoses. Attempts to reconstruct the trachea with prosthetic materials are doomed to failure [46]. Allogeneic transplantation of the trachea is not possible in the conventional sense because the trachea lacks the vascular pedicle necessary to permit reliable direct anastomosis to the recipient. Indirect revascularisation has been described by implantation of the allograft into the forearm of the recipient where it acquires a blood supply [47]. The graft is subsequently transplanted into the trachea as a free flap based on the forearm radial vessels. It seems doubtful that this procedure will ever be suitable for infants.

All or part of the trachea can be replaced with an acellular cadaveric homograft which then serves as a scaffold for host tissue ingrowth. Complication rates are high although a survival rate of 90% was reported recently [48]. It is possible to populate a cadaveric tracheal scaffold or a synthetic scaffolds with epithelial cells and chondrocytes in vitro derived from recipient stem cells and early clinical trials are underway in children [49, 50].

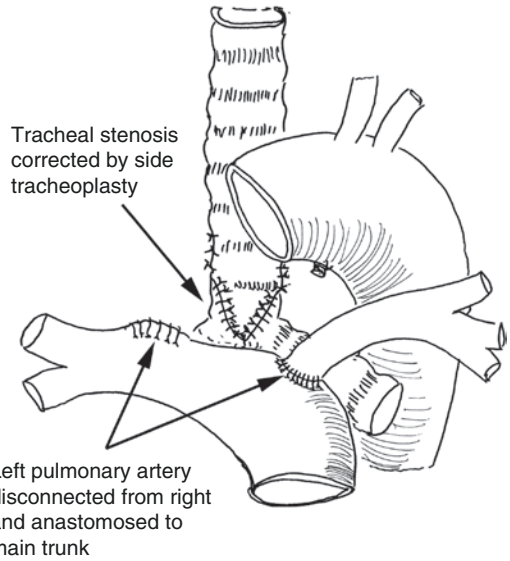

Fig. 20.11 Repair of a PA sling and associated tracheal stenosis

20.2.12 Tracheomalacia

The intrathoracic trachea dilates slightly during inspiration and narrows in expiration as a result of differences between intrathoracic and airway pressures during normal respiration. Tracheomalacia is characterised by a deficiency of the supporting cartilages which renders the airway susceptible to collapse [51, 52]. As a consequence changes in tracheal diameter during respiration increase substantially and the malacic segment collapses during expiration. This is most pronounced during forced expiration which occurs with crying or coughing.

20.2.12.1 Classification and Aetiology

Tracheomalacia most commonly affects the lower third of the trachea. Tracheomalacia can extend into the main bronchi (tracheobronchomalacia). Rarely the malacia is confined to the bronchi (bronchomalacia). Bronchomalacia is almost always associated with major cardiac anomalies [53, 54].

Tracheomalacia can be classified according to aetiology (Table 20.6). Primary tracheomalacia is caused by intrinsic abnormalities in the cartilage of the airway. Secondary tracheomalacia is the result of extrinsic compression of the airway,

Table 20.6 Classification of tracheomalacia

(A) Primary
1. In otherwise normal infants
2. In premature infants
3. Esophageal atresia and tracheo-esophageal fistula
4. Dyschonroplasias
(B) Secondary
1. Extrinsic compression
(a) Vascular rings
(b) Cardiac—enlargement of the pulmonary arteries
(c) Mediastinal masses (cysts, neoplasm, mediastinitis)
2. Prolonged mechanical ventilation

most commonly from vascular rings [55]. This distinction is convenient but simplistic. Cartilage first appears in the fetal trachea at about the seventh week of gestation. Differentiation of the paired aortic arches occurs at the same time and it seems reasonable to assume that malformations that result in vascular rings will also cause deformation of the developing tracheal cartilages during subsequent fetal development.

When tracheomalacia is seen in association with oesophageal atresia the tracheal cartilages are abnormal. Wailoo and Emery performed a detailed post-mortem study of the tracheas of 40 children born with oesophageal atresia [56]. The authors found abnormally short tracheal cartilages in 75% cases, resulting in poor support for the airway. More recent experimental work using the rat-adriamycin model has revealed a range of structural abnormalities in the tracheal cartilages, including bifid and fragmented cartilages [57].

Prolonged endotracheal intubation and tracheostomy predispose to tracheomalacia [58]. The mechanism is probably a combination of direct trauma from the tube and chronic airway inflammation. The tracheomalacia can be sufficiently severe in infancy to prevent decannulation of a tracheostomy.

20.2.12.2 Associated Conditions

Congenital cardiac abnormalities are found in up to 50% children with tracheomalacia [53]. Severe tracheomalacia is invariably associated with chronic lung disease and gastro-oesophageal reflux [59]. The latter is usually severe and many infants will require anti-reflux surgery.

20.2.12.3 Clinical Features

The symptoms and signs of tracheomalacia typically appear during the early months of life although they may be obvious from birth. Children with mild tracheomalacia may have no symptoms apart from a characteristic barking cough ('TOF cough'). Infants with more severe tracheomalacia will have intermittent stridor. Initially this is expiratory but as the tracheomalacia worsens this will become biphasic and signs of respiratory distress will appear. All the signs of tracheomalacia become more pronounced when the child is upset or suffering from a lower respiratory tract infection.

Severe episodes of airway obstruction may occur during feeding, especially with solids. This is most often seen in infants after oesophageal atresia repair although it also occurs in infants with a vascular ring. Passage of a food bolus down the oesophagus probably compresses the adjacent posterior wall of the trachea. The problem is exacerbated by an anastomotic stricture, oesophageal dysmotility and gastro-oesophageal reflux.

Hypoxia and cyanosis are characteristic of the "dying spells" seen in children with severe tracheomalacia. Usually these episodes are precipitated a bout of coughing or choking with a feed. Collapse of the trachea causes complete airway obstruction. The apnoeic child loses consciousness, collapses and becomes cyanosed and bradycardic. Once respiratory effort ceases the airway will reopen but serious hypoxia and cardiac arrest may occur if resuscitation is delayed.

20.2.12.4 Diagnosis and Assessment

The initial assessment of a child with suspected tracheomalacia is based on confirmation of the diagnosis and assessing the extent and severity of the disease (Table 20.7). The cause of the tracheomalacia may be obvious (e.g. oesophageal atresia) but if a child being investigated for stridor is found to have tracheomalacia then the underlying cause needs to be established (e.g. vascular ring).

Plain radiographs are of limited value. A barium swallow can be useful, particularly for the assessment of OA-related tracheomalacia. Changes in tracheal calibre during swallowing

Table 20.7 Investigation and assessment of tracheomalacia

can be marked and this is best seen on lateral screening. Gastro-oesophageal reflux, anastomotic stricture and oesophageal dysmotility, which all exaggerate tracheomalacia, may be identified.

An upper GI contrast study will often be the first clue to a vascular ring. The commonest vascular ring is a double aortic arch. This can produce characteristic indentations on a column of contrast in the oesophagus in the AP and lateral projections (Fig. 20.12).

Endoscopic examination of the airway is necessary to confirm the diagnosis of tracheomalacia and assess the extent and severity of the airway

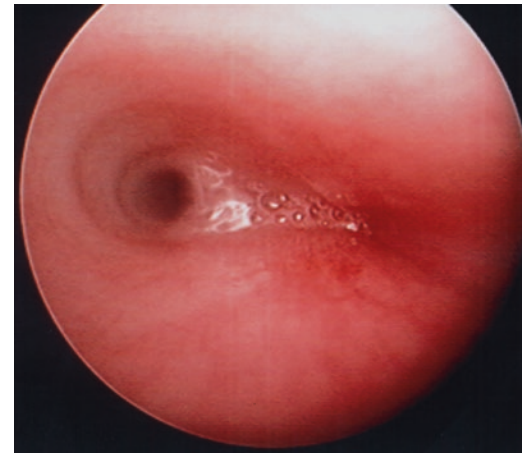

Fig. 20.13 Appearances of tracheomalacia at bronchoscopy

collapse [60] (Fig. 20.13). The examination should be performed under general anaesthesia with spontaneous respiration using a technique that minimises airway obstruction. The best methods are either fibreoptic bronchoscopy through a laryngeal mask or tracheoscopy using a Hopkins rod telescope and an operating laryngoscope.

In the 1960s Wittenborg et al. used fluoroscopy to study changes in tracheal diameter in healthy children [61]. During quiet breathing the airway calibre remained constant but crying or struggling reduced the diameter of the trachea by 50–80% in normal children. Collapse involving >50% of the diameter of the trachea during quiet breathing is abnormal. The majority of infants with symptomatic tracheomalacia will have 75–100% collapse.

Dynamic CT and MR are useful imaging techniques for suspected tracheomalacia [62, 63]. In cooperative children images can be acquired with breath-holding at full inspiration and end expiration to demonstrate changes in airway calibre and cine CT can be used to acquire images during phasic respiration. Virtual bronchoscopy is a novel CT-based imaging technique that allows three-dimensional evaluation of the airway although the quality of the images obtained in children currently lack sufficient resolution to replace conventional bronchoscopy [64]. At present none of these techniques is able to distinguish between dynamic

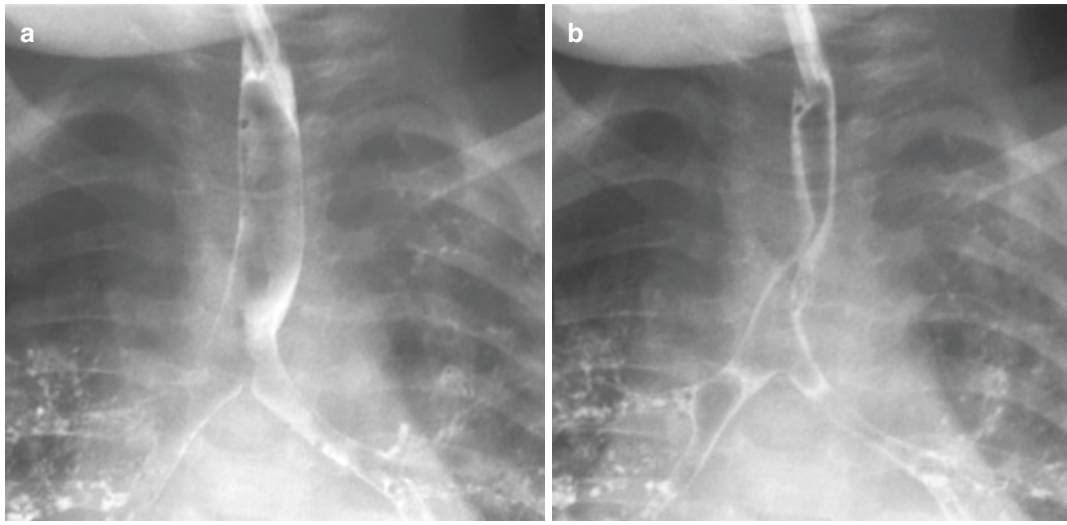

Fig. 20.14 Appearances of tracheomalacia during bronchography (**a**) inspiration (**b**) expiration

or static narrowing reliably and consequently bronchoscopy and/or bronchography remain essential investigations.

Bronchography involves injection of small volumes of water-soluble contrast into the trachea under fluoroscopic guidance [65]. The technique is capable of showing both structural abnormalities and segmental airway malacia. Images can be obtained with spontaneously respiration under anaesthesia with different levels of continuous positive airway pressure (CPAP) to determine the minimum pressure required to maintain airway patency (Fig. 20.14).

20.2.12.5 Treatment

When tracheomalacia is secondary to mediastinal pathology this should be treated. Mild to moderate tracheomalacia per se may not require any specific treatment although respiratory infections should be treated promptly. The trachea becomes more stable as the child grows and symptoms will usually abate during the first 2 years of life.

Untreated severe tracheomalacia in infancy is life threatening. In the past the mainstay of treatment was tracheostomy. Extended tracheostomy tubes were necessary to stent the distal trachea. Surgical options for tracheomalacia include aortopexy, segmental tracheal resection and stenting.

Aortopexy involves partial excision of the thymus to create a space anterior to the aortic arch. The aorta is then pexed to the back of the sternum without disturbing the tissue plane between the vessel and the trachea [66]. Intraoperative bronchoscopy is useful to ensure sutures are placed in the correct region of the aortic root and arch to provide optimum elevation of the malacic segment of trachea [67]. The procedure can be performed through a left anterior thoracotomy but safe exposure is more easily obtained through a partial upper sternotomy [68]. Apposition of the aorta and the under surface of the sternum lifts the anterior wall of the trachea forward widening the antero-posterior dimension of the airway and reducing the tendency to collapse (Fig. 20.15).

Aortopexy is not always successful and around 10% of infants will require further treatment [69]. Resection of the malacic segment is occasionally curative if satisfactory improvement in the lumen cannot be achieved by aortopexy but tracheostomy and long-term ventilation may be necessary. Procedures to increase the intrinsic rigidity of the tracheal wall by fashioning rings out of costal cartilage or wrapping the malacic segment in synthetic mesh to provide external splintage have been tried but the results are generally unsatisfactory.

Endoluminal metallic stents have been used to palliate malignant airway obstruction in adults

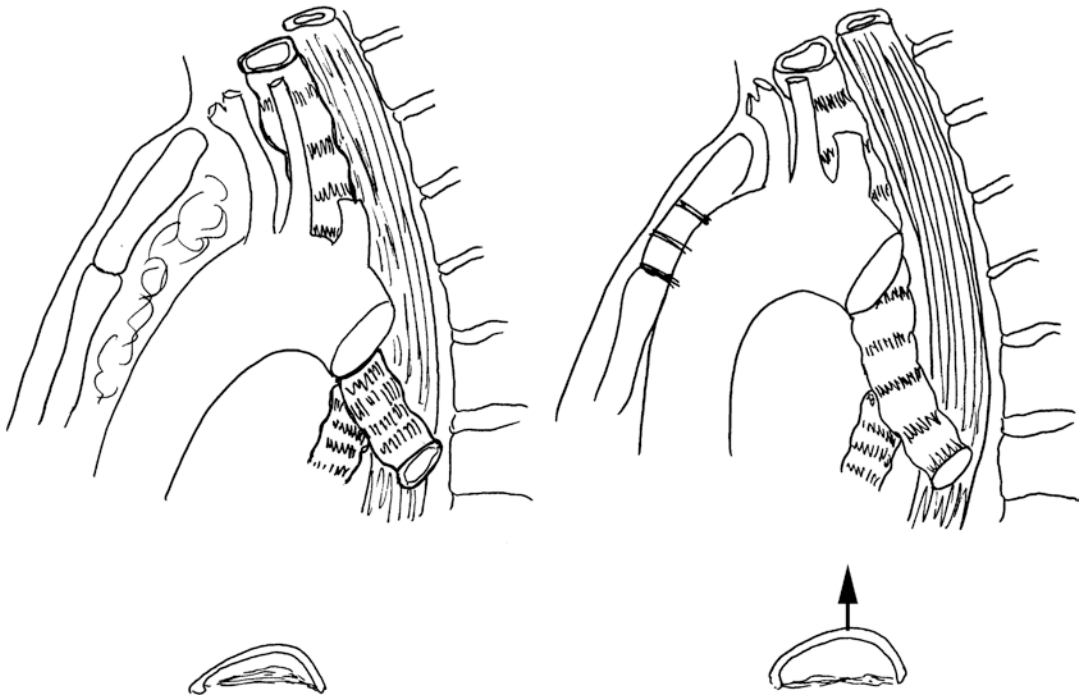

Fig. 20.15 Principles of aortopexy

since the 1980s. Bugmann et al. stented a malacic airway in an infant after cardiac surgery in 1994 [70]. Expandable metallic stents are relatively straightforward to insert using a combination of bronchoscopy and fluoroscopy. The stent is deployed over a balloon catheter which is inflated in the airway. The expanded stent is thus lodged inside the airway (Fig. 20.16). Stents can be deployed in the trachea and main bronchi. The lattice of the stent can be placed over a lobar bronchial orifice without compromising ventilation of the lung.

From a purely mechanical perspective stents are undoubtedly effective at supporting the malacic airway. However, complications from airway stenting in children are relatively common. Unless the stent is firmly impacted in the wall of the airway it is liable to migrate with loss of airway support. Airway stents do not become epithelialised in the way endovascular stents do and, as a consequence, excite the formation of granulation tissue [71]. Granulation tissue in the airway is liable to cause obstruction and bleeding. Stents can, and do, erode through the wall of the airway into adjacent large blood vessels [72]. These complications are important in the context of tracheomalacia because it is likely that the stent will become redundant as the child grows. Removal involves grasping the stent and twisting to

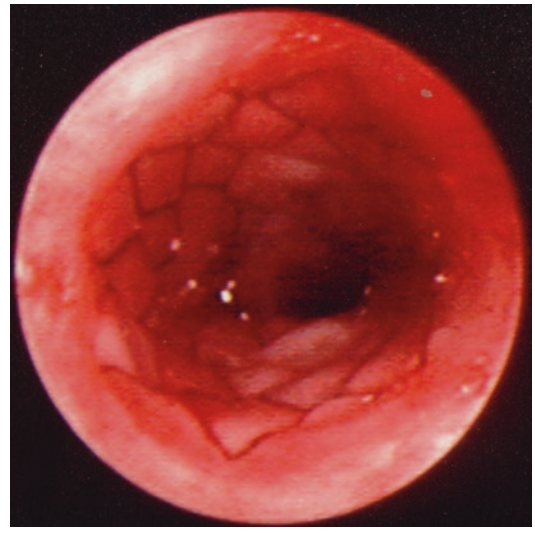

Fig. 20.16 Palmaz stent deployed in the trachea

disimpact the lattice from the wall of the airway and then retrieving the crumpled stent through a rigid bronchoscope. This manoeuvre is invariably associated with brisk bleeding from the trachea and risks loss of control of the airway. Fatalities have been recorded [73]. There is no data on the long-term consequences of stenting of the paediatric airway. Biodegradable stents have been developed for endoluminal use in the airway but these remain at an experimental stage [74].

The relationship between gastro-oesophageal reflux (GOR) and tracheomalacia is incompletely understood. Chronic respiratory disease in infancy is invariably associated with GOR as a result of increased work of breathing. Gastro-oesophageal reflux frequently exacerbates chronic respiratory disease. The mechanism is less clear but probably includes repeated microaspiration and vagal-mediated responses to acid secretions in the pharynx and oesophagus causing reflex alterations in bronchial tone. Aortopexy and fundoplication are frequently necessary to control symptoms in infants with oesophageal atresia and severe tracheomalacia and the main difficulty is deciding which operation to perform first [75].

20.3 Congenital Malformations of the Chest Wall

20.3.1 Embryology

In the future trunk region the paraxial mesoderm forms a series of block-like condensations, the somites, in a cranio-caudal progression of 3–4 somites per day from day 20 to day 30 of embryogenesis. These somites are the progenitors of the axial skeleton, trunk musculature, trunk dermis, endothelial cells and meninges of the spinal cord. The ventromedial somite undergoes an epithelial to mesenchymal transition into the sclerotome which develops into the vertebrae and ribs. The lateral portion of the sclerotome forms the vertebral transverse process and ribs, whilst the medial portion forms the vertebral body, arch and spine [76].

Small lateral mesenchymal condensations form the costal processes. Concomitantly, transverse processes grow laterally along the dorsal side of each costal process. In the thoracic region the distal tip of the costal processes lengthen to form the ribs. This process of lengthening of the thoracic costal processes begins on day 35 with the first seven ribs connecting anterior medially via the costal cartilages to the sternum by day 45. The cartilaginous precursors subsequently undergo endochondral ossification. Primary ossification centres arise in the region of the rib angle around the sixth week and progress distally along the ribs. Secondary ossification centres arise in the head and tubercles of the ribs but not until puberty [76].

The sternum develops from the lateral mesodermal plate. In the sixth week of development cells begin to migrate from parallel bars of condensed mesoderm in the lateral ventral chest. These sternal bands join first at the cephalic end at around the seventh week, progressing caudally to fuse along their length by the tenth week. The rate of fusion slows caudally. At around the same time the manubrium sternum arises separately from a cranial condensation of mesoderm, the presternum, which is associated with the developing shoulder girdle. The fused sternal bars join with the presternum cranially and the rib ends laterally. The mesoderm of the sternum chondrifies soon after migration is complete. Chondrification occurs as a continuous process whereas ossification arises from a series of ossification centres, with ossification in the manubrium and upper sternum in the 6 month of fetal life, the mid sternum in the seventh month and the lower sternum at around 1 year of post natal age. The xiphoid process at the lower pole of the sternum ossifies much later, between 5 and 18 years of age. Frequently the xiphisternum remains bifid. Complete fusion of the sternal ossification centres is not complete till after puberty [77–79].

20.3.2 Sternal Cleft

Sternal clefts are rare congenital anomalies. Early in gestation the lateral sternal primordia fail to fuse [80, 81]. The incidence is uncertain but sternal clefts are sufficiently rare to be reported in the literature as solitary or small

series case reports. Sternal clefts accounted for 0.15% of all thoracic wall anomalies seen over a 25 year period in one large paediatric thoracic practice [82]. Sternal clefts are reported to have a higher incidence in females, frequently quoted as a 2:1 female to male ratio [83].

The classical sternal cleft is a U or V shaped separation of the sternal bars to the level of the third or fourth costal cartilage. However, sternal clefts may be partial or complete and partial clefts may affect the cranial or the caudal sternum. Upper sternal clefts are typically isolated anomalies whereas lower sternal clefts are frequently associated with other anomalies, as classically seen in the Pentalogy of Cantrell [84]. Ectopia cordis is the protrusion of the heart out of the thoracic cavity in association with a sternal defect. In simple sternal clefts the heart remains in its normal position despite the overlying sternal defect. This displacement of the heart is very difficult to correct as attempts to reduce the heart result in kinking of the great vessels and disruption of blood flow. Shamberger and Welsh proposed a classification for clefts depending on the presence or absence of ectopia cordis [78, 85, 86] (Table 20.8).

The aetiology of sternal cleft deformity is unknown. A familial predisposition has not been described. Excessive alcohol ingestion during pregnancy and vitamin B_{12} deficiency have been proposed but there is no clear evidence to support this association [78]. A gene mapped to Xq25–26 has been implicated in the process of midline ventral fusion, being associated with the combination of sternal fusion, diaphragmatic, cardiac and ventral abdominal wall defects. Variable penetration giving rise to a lethal phenotype in males could explain the female predominance [87–89]. Embryological studies in mice have suggested a role for Hox genes, specifically HoxB4, in ventral fusion of this region of the thorax [90].

Table 20.8 Classification of sternal defects

Thoracic ectopia cordis
Thoracoabdominal ectopia cordis
Cleft sternum

Sternal clefts can be associated with craniofacial haemangiomas. The PHACE syndrome comprises **P**osterior fossa brain malformations, capillary **H**aemangiomas, **A**rterial malformations (especially on the carotid and vertebral arteries), Cardiac malformations (including the aorta and vena cava) and **E**ye abnormalities [91]. Sternal clefts and other midline raphe anomalies are seen in some of these patients and the acronym has been extended to PHACES syndrome. This has been reported to have an 8:1 female preponderance [92, 93].

Isolated sternal cIefts usually present at birth as a soft bulging mass in the midline with paradoxical movement on respiration and/or obvious cardiac pulsation. They are typically asymptomatic. Isolated sternal clefts can be identified on antenatal screening ultrasound [93]. Clefts associated with other midline anomalies as in Pentalogy of Cantrell have been detected in the first trimester of pregnancy by ultrasound [94, 95].

The indications for repair of a sternal cleft are shown in Table 20.9. Repair is best achieved in the neonatal period when the chest wall is most compliant because compression of the heart and lungs following closure is minimal [82, 96–98]. Correction of the sternal cleft may be deferred to allow concurrent repair of cardiac anomalies. However after about 3 months of age the chest wall becomes more rigid and this complicates repair [82, 96].

Preoperative assessment should include an echocardiogram and chest X-ray. A contrast enhanced CT scan of the thorax will demonstrate the extent of the bony lesion and may be useful to exclude vascular anomalies. If the child shows features of PHACES syndrome MRI of the head is necessary to exclude intracranial anomalies [91, 92].

Sternal clefts are best approached through a midline incision over the defect. The pectoralis

Cosmesis

muscles are reflected off the sternum. The edges of the defects are freed from the underlying pleura and pericardium. The edges of the sternal bars may be freshened by sharp dissection with a scalpel. Approximation of the sternum in an incomplete cleft is facilitated by excision of a wedge from the intact part of the sternum, particularly in U-shaped defects. The sternal bars are progressively apposed with a series of non-absorbable sutures around the sternum, through the medial intercostal spaces. This should be performed gradually allowing time to verify that cardiac and respiratory function is not being compromised [82, 96–99]. The presence of a distal sternal bridge of cartilage or bone makes primary repair more difficult [99].

In older children and adolescents surgical repair requires additional measures as the thoracic cavity is less compliant and the likelihood of cardiac and pulmonary compression is greater. A variety of approaches have been described. Sabiston proposed performing sliding chondrotomies, with bilateral oblique incisions through the costal cartilages to allow midline approximation of the sternal halves [100]. Alternatively, the sternal cartilages may be divided in half in the anterior posterior plane along their lateral border and the anterior portions then rotated medially and sutured together to cover the defect (*the door wing plasty*) [101–103]. Acastello et al. described closure of the defect with partial resection of the first three costal cartilages and disruption of the sternoclavicular junction to permit mobilization of the sternal bars for approximation [82]. However, disarticulation of the sternoclavicular joints gives a poor cosmetic result and risks chronic shoulder instability. Division of the medial third of the clavicles is a better alternative [103]. Various prosthetic grafts such as Teflon, polypropylene, silicone, and titanium have been used to cover sternal defects in adults. These materials have been used to cover sternal clefts in childhood with varying results [104]. In general the outcome of a sternal cleft is determined by the presence of other associated anomalies. Excellent long-term functional and cosmetic results are reported following repair of isolated sternal clefts [82, 102].

20.3.3 Pentalogy of Cantrell

Cantrell first described a syndrome of congenital defects involving the abdominal wall, sternum, diaphragm, pericardium, and heart in 1958 [84] (Table 20.10). Cantrell's pentalogy is a rare with an estimated incidence of 5.5 per million live births [87]. Not all patients are born with the full pentalogy and a revised classification was suggested by Toyama depending on the severity of the deformities [105]. A variety of other anomalies have been reported in association with Cantrell's pentalogy including cleft lip and/or palate, encephalocele, hydrocephalus, limb defects and abdominal organ defects such as agenesis of the gallbladder and polysplenia [106].

Cantrell proposed that failure of growth of the lateral plate mesoderm resulted in non-fusion of structures of the abdominal wall and ectopia cordis [84]. Other authors have suggested that amniotic bands prevent normal descent of the heart into the thorax which consequently prevents closure of the thoracoabdominal wall [107].

Van Hoorn et al. reviewed the literature in 2008 and found 37 of 58 patients with Cantrell's pentalogy had been terminated or died within days of birth. This 36% survival rate is likely to be an overestimate and the long term outcome of these patients is unclear [106].

Pentalogy of Cantrell can be detected as early as 12 weeks on antenatal scan [94, 95]. Zidere and Allan reported evolution of three cases during the course of fetal development with reduction of the heart into the chest after

20 weeks and resolution of a pericardial effusion. This highlights the difficulty of antenatal counselling for the parents [95].

Following delivery and stabilisation an echocardiogram should be performed to look for cardiac malformations as this is the main determinant of outcome. Once the decision is made to proceed with treatment, the ventral abdominal wall, sternal, pericardial and diaphragmatic defects should be closed in the early neonatal period. Corrective or palliative surgery for the cardiac malformations can be performed subsequently when appropriate clinically.

Cervical ectopia cordis is universally fatal. There are occasional reports of survivors of thoracic ectopia cordis but in the majority of cases attempts to reduce the heart into the thoracic cavity kinks the great vessels and causes cardiac failure. The heart is covered by the exomphalos membrane in thoracoabdominal ectopia cordis and can generally be reduced into the mediastinum.

Correction is attempted by first achieving skin cover, then reducing the heart in a staged procedure, and finally repairing the sternal defect [108].

Fig. 20.17 Neonatal pectus excavatum

20.3.4 Pectus Excavatum

Pectus excavatum is a depression of the anterior chest wall, most pronounced in the region of the lower sternum. Pectus excavatum is typically symmetrical although asymmetric deformities are seen. Excavatum deformities affect approximately 1% of the population and are four times commoner in boys than girls. A family history of chest wall deformity can be elicited in up to 45% cases [109]. Racial variation is documented, pectus excavatum being much commoner in white Caucasians (38 per 10,000 live births) than those of Afro-Caribbean descent (7 per 10,000). A study of 34 families showed pedigrees suggestive of a wide variety of inheritance patterns [110].

Pectus excavatum is rarely present at birth and most commonly develops during childhood with the deformity progressing, often markedly, during puberty. Where pectus excavatum is noticed in infancy this is usually secondary to either airway obstruction (e.g. laryngomalacia) (Fig. 20.17) or connective tissue disorders (e.g. Ehlers Danlos syndrome) [109]. If the deformity is secondary to airway obstruction it will often resolve as the airway disease improves.

Childhood interstitial lung diseases such as the surfactant deficiencies result in pectus excavatum in all patients surviving beyond infancy [111]. The EPICure study following survivors of extreme prematurity (26 weeks gestation at birth) found a statistically significant increase in the incidence of pectus excavatum at age 11 years compared to a control population (17% versus 2%) [112].

Pectus excavatum in early childhood is an asymptomatic deformity. The deformity causes significant anxiety to parents and children and can markedly affect self confidence as children grow older. The traditional approach to correction of pectus excavatum was described by Ravitch. The

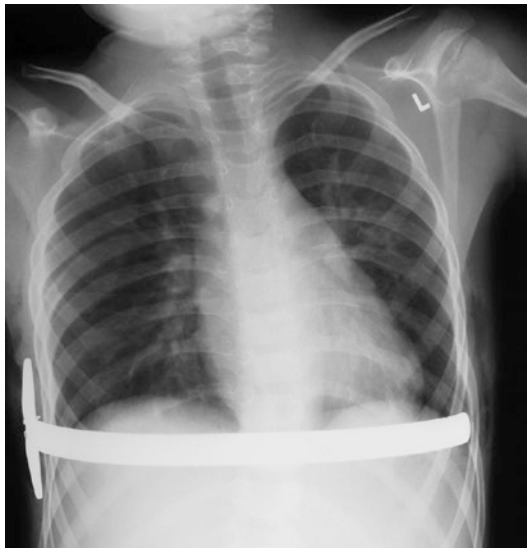

Fig. 20.18 Nuss repair pectus excavatum

anterior chest wall is exposed via a midline or transverse sub-mammary incision. The pectoral muscles are reflected. The deformed costal cartilages are removed by sub-perichondral resection followed by a sternal osteotomy to correct the sternal depression [113–115]. More recently Nuss described an alternative approach to the correction of pectus excavatum which has been widely adopted, the minimally invasive repair of pectus excavatum (MIRPE) [116]. This minimally invasive technique involves the placement of a curved metal bar, appropriately sized and shaped for the patient, through the chest, deep to the sternum in the region of the maximal depression exerting a continuous pressure, the sternum gradually becoming fixed in this new position (Fig. 20.18). The bar is removed after approximately 2 years [117, 118].

The ideal age for correction is 7–12 years whilst the chest remains malleable. Many patients present in later puberty after progression of the deformity and when they become more self-aware. There is no indication for correction of pectus excavatum in the neonate and indeed an acquired asphyxiating thoracic dystrophy has been described following correction in very young children using the Ravitch technique, ascribed to overzealous cartilage resection disrupting subsequent thoracic growth [119, 120].

20.3.5 Pectus Carinatum

Pectus carinatum is an anterior protuberance of the anterior chest wall. Pectus carinatum is not seen in infancy but tends to occur in older childhood and progress during the pubertal growth spurt. There is a four to one predominance in males and a family history of deformity can be elicited in 6.7% of cases [110]. No clear aetiological factors have been identified.

The deformity of pectus carinatum is quite variable. The protuberance of the sternum may be symmetrical or there may be torsion of the sternum resulting in an asymmetric protuberance with relative depression of the costal cartilages on one side and prominence on the other. Pectus carinatum is corrected using the Ravitch procedure with subperichondral resection of the involved costal cartilages and sternal osteotomy, in this case wedged open to create depression of the distal sternum [121]. Correction of torsion of the sternum can be challenging. Pectus carinatum is frequently associated with depressions in the lateral lower chest that persist after correction of the central deformity.

20.3.6 Jeune's Syndrome (Asphyxiating Thoracic Dystrophy)

In 1955 Jeune's described a familial asphyxiating thoracic dystrophy characterised by a small thorax and short limb dwarfism [122–124]. Jeune's syndrome affects 1 in 100,000 to 300,000 live births, with a similar incidence in males and females [125]. The cause is uncertain but familial studies have suggested an autosomal recessive inheritance pattern. A link with a locus at chromosome 15q13 has been described in some cases [126]. More recent reports suggest an association with the IFT80 gene on chromosome 3q24 which encodes an intraflagellar transport protein which is essential for the development of motile and sensory cilia [127].

The phenotype of Jeune's syndrome is variable but the chest is always involved with short horizontal ribs. Respiratory involvement is universal

but of severity from a rapidly fatal respiratory distress to minimal respiratory impairment. Restricted chest expansion causes alveolar hypoventilation. It is unclear whether there is also lung hypoplasia. Other skeletal features include dwarfism and short phalanges (thoracic-pelvic-phalangeal dystrophy). The retina, pancreas, liver and kidneys may also be involved [128]. Mild forms of Jeune's syndrome are associated with progressive renal failure. The diagnosis of Jeune's syndrome is confirmed by the classical X-ray appearances of short horizontal ribs, square iliac wings and a horizontal acetabular roof with a medial spur. Jeune's syndrome may be detected antenatally by the dimension and shape of the fetal chest [129].

A variety of surgical approaches have been tried to relieve the chest wall restriction and improve respiratory function. Median sternotomy with graft interposition has been performed to enlarge the thoracic cavity [130]. Lateral thoracic expansion has also been tried [131, 132] and, more recently, the vertical expandable prosthetic titanium rib procedure (VEPTR) [133, 134].

The vertical expandable prosthetic titanium rib (VEPTR) was developed by Dr. Robert Campbell in 1989 (Synthes Spine, USA) to treat patients with hypoplastic chest walls causing respiratory compromise. The use of this technique to treat Jeune's syndrome involves bilateral insertion of high radius curvature titanium prosthetic devices, as a staged procedure, the contralateral side being operated on approximately 2 months after the first thoracotomy. A customised device is made for each patient based on the cross-sectional imaging and planned surgery. A thoracotomy incision is made extending anteriorly to the region of the seventh/eighth intercostal space and myocutaneous flaps raised. The chest wall is mobilised by dividing the ribs anteriorly at the costo-chondral junction and posteriorly in the region of the transverse process. Usually the third to ninth ribs are divided. The vertical expandable prosthesis is attached to the 2nd and 10th to 12th ribs which have not been divided and then the free lateral rib segments are fixed to the prosthesis by K-wires, distracting the mobilised segment of chest wall laterally. The VEPTR device is then lengthened approximately every 6 months depending on the growth and well being of the child. The central segment of the prosthesis requires replacement approximately every 3 years depending on the lengthening achieved [133–137].

A review of 19 patients who had undergone VEPTR thoracic expansion for Jeune's syndrome found that four patients had died in the first year after surgery, all related to disease severity rather than surgery. Due to the rarity of the condition it is impossible to perform a randomised controlled trial of treatment. There is some suggestion of improved survival following surgery but this may reflect improvements in the general care of patients with Jeune's syndrome rather than to the effects of surgery [133].

There is anecdotal evidence that the respiratory restriction improves with age. Frequent respiratory tract infections in infancy become less problematic as the child grows. However, there is little documented evidence to support improvement in pulmonary function tests [125, 138] and indeed other authors dispute that any improvement occurs [139]. The classic form of Jeune's syndrome with severe respiratory involvement is almost universally fatal within the first year of life [133]. The long-term results of newer surgical techniques are awaited. Outcomes reported in recent series have been better than previously, with or without surgery [138].

20.3.7 Ellis-van Creveld Syndrome

Ellis-van Creveld syndrome (chondroectodermal dysplasia) is a further subtype of the short rib dysplasia syndromes. The cardinal features are short stature, short ribs, polydactyly, and dysplastic fingernails and teeth. Heart defects, especially abnormalities of atrial septation, occur in about 60% of cases [140–142]. The diagnosis is confirmed by the characteristic radiographic appearances of the slanting proximal tibial plateau and the carpus with abnormal size and shape of the carpal bones. The diagnosis may be suspected antenatally by the presence of short ribs, polydactyly and cardiac malformations [140].

Approximately 150 cases have been reported world-wide. The condition is inherited as an autosomal recessive trait with variable expression. Mutations of the EVC1 and EVC2 genes, located on chromosome 4p16, have been identified [140, 143].

The prognosis depends on respiratory function in infancy which relate both to the narrow thorax and cardiac malformations. The respiratory symptoms are often mild compared to Jeune's syndrome with most reported cases surviving to adulthood. Congenital cardiac malformations are the major determinant of survival [140].

20.3.8 Jarcho-Levin Syndrome

Jarcho-Levin syndrome is a rare genetic disorder characterised by multiple vertebral segmentation and formation defects affecting the majority of the thoracic and lumbar vertebrae. Two subtypes are recognised, spondylothoracic dysplasia and spondylocostal dysostosis.

Spondylothoracic dysplasia has an autosomal recessive inheritance pattern. The ribs are all fused posteriorly at the costovertebral junctions producing a small thorax with a typical "crab like" appearance on radiograph. Mortality from respiratory failure is high with 44% of cases dying in the first year in one recent series [144].

Rib involvement in spondylocostal dysostosis is asymmetrical and less severe. Multiple vertebral segmentation anomalies with unilateral rib malformations lead to a progressive thoracic scoliosis. Inheritance can be autosomal dominant or recessive [144]. Respiratory involvement is less severe and the long term prognosis are correspondingly better than spondylothoracic dysplasia [133, 144].

20.3.9 Poland's Syndrome

In 1841, Poland described a "deficiency of the pectoral muscles" in the cadaver of a convict who had reputedly been unable to draw his arm across his body. Poland's syndrome is a constellation of congenital defects comprising a unilateral deficiency of the pectoral and chest wall muscles associated with ipsilateral syndactyly [145]. The right side of the body is involved in 60–75% of patients [146].

Fig. 20.19 Poland's syndrome

The clinical manifestations are variable but absence of the sternal head of pectoralis major muscle is a constant feature (Fig. 20.19). The serratus anterior and latissimus dorsi muscles may be absent or under-developed. Abnormal breast development is seen in about one third of girls, ranging from mild hypoplasia to complete absence of the breast and nipple. In most patients the chest is sunken anteriorly due to hypoplasia of the third to fifth or more rarely second to fourth costal cartilages and anterior ribs. This may lead to an asymmetrical pectus carinatum deformity in later childhood [147]. In approximately 15% of patients there is aplasia of the upper costal cartilages causing a more severe chest deformity with lung herniation [147]. Significant reduction in pulmonary function has been documented in association with lung herniation [148]. Dextroposition of the heart is reported in association with left-sided involvement.

The incidence of Poland's syndrome varies from 1 in 7000 to 1 in 100,000 and the condition is 2–3 times more common in males than females [149]. The phenotype is variable and it is extremely rare for all features to be present in one patient. Isolated breast hypoplasia and absence of the pectoralis major muscle is relatively common in patients presenting for breast augmentation. The aetiology is believed to be due interruption of the embryonic blood supply in the subclavian

artery around the sixth week of development as the upper limb bud is forming [150–152].

Surgery for the thoracic components of Poland syndrome varies from cosmetic procedures for breast hypoplasia or chest wall deformity to chest wall reconstruction to improve lung function and protect the heart and lung [146, 149]. The shoulder girdle muscle deficiency is generally well compensated for. Chest wall defects due to rib aplasia may be corrected using split subperiosteal rib grafts or prosthetic mesh. Myocutaneous latissimus dorsi flaps are the most widely used method for reconstructing the soft tissue contours of the chest wall, combined with breast implants in female patients. If chest wall reconstruction is indicated in childhood, soft tissue reconstruction should be deferred until after puberty. In adults these procedures may be combined as a single stage procedure [146, 148, 149, 153]. Preoperative assessment with CT or MRI is important as the degree of soft tissue involvement particularly, can be underestimated by simple clinical examination [154].

Small children with severe deformity may require early surgery to improve respiratory function or manage rare associated anomalies such as ectopic liver tissue [148, 153]. Gore-Tex™, Prolene™ mesh and titanium mesh have all been used and must be sutured taut to the margins of the defect in order to correct the flail segment effect of the deficient ribs. Such repairs carry the dual problems of potential prosthetic infection and the need for revision as the child grows. There is little published data on the long-term outcome of patients requiring early surgery.

In the majority of patients the problem is cosmetic and repair can wait until after puberty when a combined operation to correct the bony and soft tissue deficiencies is possible. Depending on the size of the defect and development of the ribs adjacent to the defect, the anterior portion of adjacent ribs can be split along their length leaving the deep part in situ and the superficial segments moved as split rib grafts to fill the deficient rib spaces. Where there is an associated pectus carinatum deformity requiring resection of the anterior portions of the contralateral ribs, the resected fragments can be used to bridge the defect. In the absence of suitable ribs for grafting a prosthetic mesh repair is required. Contralateral rib grafts can be harvested but this is rarely done unless there is a specific indication for surgery to the contralateral chest wall. Grafts must be securely attached to the rib end laterally and sternum medially to prevent displacement. Mesh may be used to stabilise the repair in which case the rib grafts should be sutured to the mesh in addition to the margins of the sternum and defective ribs [146, 149].

Myocutaneous latissimus dorsi flaps can be used to provide both skin and soft tissue to reconstruct the anterior chest wall and create the anterior axillary fold. A prosthetic breast implant is often necessary in girls. Not infrequently the ipsilateral latissimus dorsi muscle is also deficient in which case free flaps from the contralateral latissimus dorsi or gluteal muscles have been used [146, 147, 149].

20.4 Acquired Chest Wall Deformity Secondary to Neonatal Thoracic Surgery

Long term follow up studies of patients undergoing neonatal thoracic surgery for conditions such as oesophageal atresia or congenital diaphragmatic hernia frequently fail to comment on chest wall morbidity resulting from these procedures. In the 1960s Freeman and Walkden noted two children with marked shoulder elevation attending for follow up following thoracotomy for repair of oesophageal atresia [155]. They traced 24 other patients, 19 of whom also reported shoulder deformities. The authors reviewed the variations in surgical approach and stressed the importance of preserving the function of the serratus anterior and lastissimus dorsi muscles to minimise complications. In 1985 Jaureguizar published a long term follow up study of 89 patients who had undergone a right thoracotomy for repair of oesophageal atresia. Twenty-nine of the patients (33%) had significant musculoskeletal deformities [156] (Table 20.11).

Table 20.11 Late complications of thoracotomy in the neonatal period

Elevation of the shoulder/winged scapula
Chest wall asymmetry
Rib fusion
Scoliosis
Tethered scars limiting shoulder mobility
Breast disfigurement

Table 20.12 Factors contributing to post thoractomy deformity

Congenital vertebral anomalies
Nature of incision
– Site
– Muscle cutting/splitting
– Rib resection
– Nerve injury—denervation of serratus anterior
– Tethering of scar
Multiple thoracotomies
Anastomotic leak causing pleural/mediastinal sepsis

Reviewing the experience of treating oesophageal atresia at Melbourne Children's Hospital, Chetcuti et al. identified a variety of risk factors that contributed to a 35% incidence of chest wall deformities in 285 patients [157, 158] (Table 20.12). Deformities identified included scoliosis, anterior chest wall asymmetry and breast deformities. Congenital vertebral anomalies were present in 19% of the patients (Fig. 20.20) and in this group the incidence of chest deformity increased to 42%. Denervation of the serratus anterior muscle with consequent muscle atrophy was identified as the major cause of anterior chest wall asymmetry, this was slightly commoner in males than females, potentially being masked by breast developed in the post-pubertal females. Poorly sited incisions are the main cause of breast deformity. Multiple thoracotomies significantly increased the risk of scoliosis. Other postulated risk factors for development of scolosis were rib resection thoracotomy and scarring of chest wall musculature resulting in vertebral malalignment. Other studies have found a strong link between anastomotic leak with resultant empyema and mediastinitis and subsequent development of

Fig. 20.20 Scoliosis associated with thoracic vertebral anomalies

scoliosis [159]. Interestingly in the Melbourne study, in the group with no underlying vertebral anomalies, two thirds of the scoliosis was convex away from the side of thoracotomy, other studies have had similar findings. Only two patients with a contralateral scoliosis had had an empyema. In a cohort study of 100 adults who had undergone surgery for oesophageal atresia, Sistonen et al. found 56% patients had a scoliosis >10° and 11% >20° Cobb angle. Risk factors included vertebral anomalies and rib fusion. The presence of associated anomalies e.g. VACTERL was also significantly associated with scoliosis. Many of the vertebral anomalies seen at adult follow up in the study were not apparent on the neonatal imaging [160].

A study of adult survivors or congenital diaphragmatic hernia (CDH) also identified a high incidence of chest wall deformity, being present

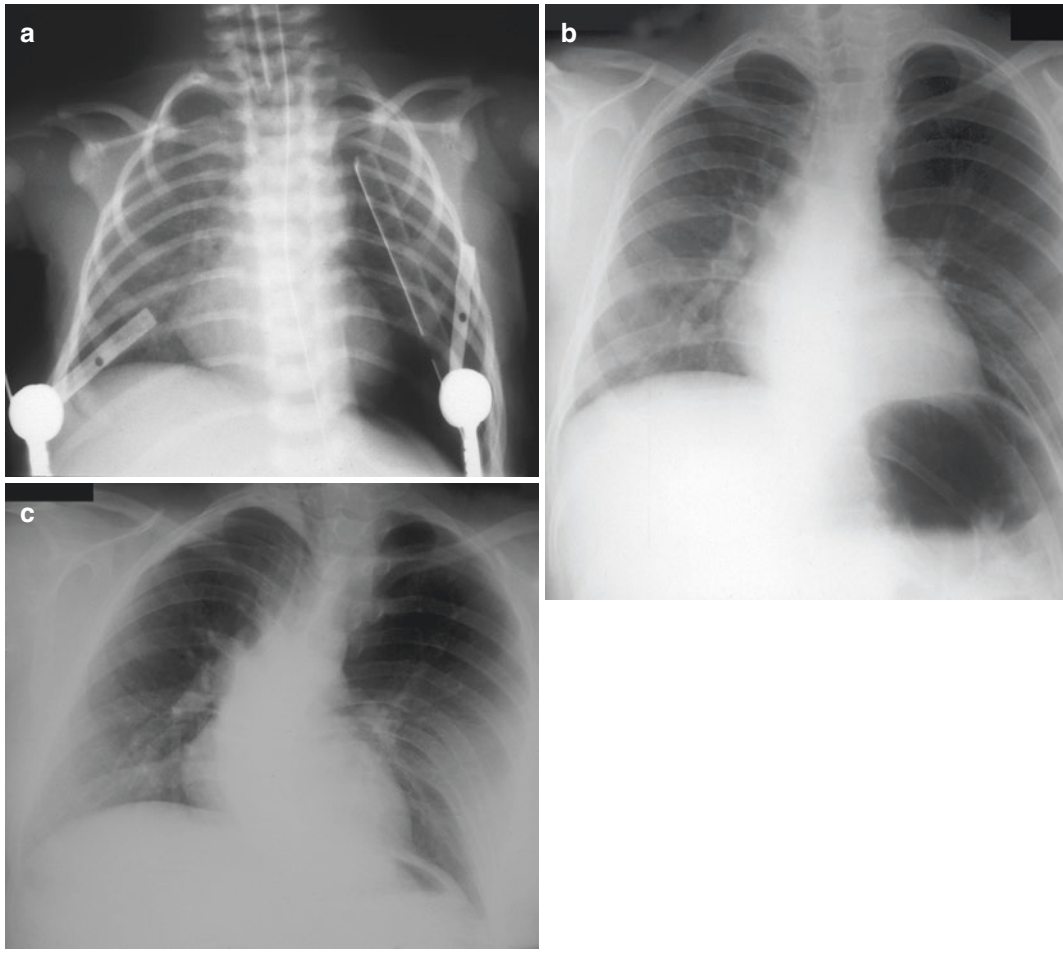

Fig. 20.21 (**a**–**c**) Progression of scoliosis following neonatal CDH repair

in 29 of 60 patients (48%). Deformities were felt to be commoner in patients who had had large defects. Eleven patients (18%) had pectus excavatum and one pectus carinatum, whilst 16 patients (27%) had significant scoliosis with a Cobb angle greater than 10%. Scoliosis was commoner in patients with documented impaired pulmonary function [161] (Fig. 20.21). The surgical approach used in these patients was not clear. Reviewing the published literature, Peetsold et al. estimated that 16–48% of CDH survivors have chest wall deformities, most commonly pectus excavatum and 5–10% have mild to moderate thoracic scoliosis [162]. It is difficult to differentiate the effects of the surgical approach from the underlying pulmonary and potential thoracic hypoplasia as the cause of these deformities though closing a large defect under tension appears to increase the incidence of long chest wall deformity [162].

Careful positioning of patients at the beginning of lengthy operative procedures is important to minimise traction on nerves and muscles which may have long term sequelae. A lateral muscle splitting thoracotomy taking care to preserve the nerve supply to the serratus anterior and latissimus dorsi muscles is crucial to normal long term function [163]. Care should be taken that the incision does not extend near the breast bud.

Assessment for chest wall deformity or scoliosis is an important part of the long term follow up of neonates who have undergone thoracotomy or repair of congenital diaphragmatic hernia.

Referral of patients with significant vertebral anomalies for assessment by a spinal surgeon should be considered.

Thoracotomy carries several risk factors for the subsequent development of thoracic deformity. Refinements in surgical technique over the decades have dramatically reduced the incidence of thoracic deformity but there remain significant potential long-term sequelae of thoracotomy. Advances in thoracoscopic surgical techniques and instrumentation over the last 20 years have permitted thoracoscopic techniques to be applied to a variety of neonatal thoracic problems including lung resections for the management of conditions such as congenital cystic adenomatoid malformations (CCAM), repair of oesophageal atresia and congenital diaphragmatic hernia [164, 165]. In theory there are advantages to this approach to reduce the long-term sequelae of chest deformity but long term follow up data is limited at present. None the less, these techniques are not without problems. The congenital diaphragmatic hernia study group found a significantly higher incidence of recurrent diaphragmatic hernia in patients whose repair had been performed using minimally invasive techniques, particularly by a thoracoscopic approach with a 7.9% versus 2.7% ($p < 0.05$) incidence of recurrence identified [166]. A multi-institutional study of thoracoscopic repair of oesophageal atresia concluded that this was a safe approach with equivalent outcomes to historical controls performed using an open approach [167]. The authors drew attention to the potential advantages of reducing musculoskeletal sequelae. Thoracoscopic repair of oesophageal atresia is performed by a transpleural approach. A recent follow up study of the open approach to oesophageal atresia repair specifically drew comparison of the thoracoscopic approach with a more contemporary open surgical approach. This study identified a 3% incidence of scoliosis, attributed to pre-existing vertebral anomalies and no other thoracic deformities [168]. More importantly the authors showed a higher incidence of anastomotic leak using the thoracoscopic approach (2.7% versus 7.6%), although this did not achieve statistical significance. This is a potentially important finding not just in terms of oesophageal function. Pleural and mediastinal infection has been identified as a significant factor in development of post-thoracotomy scoliosis [157, 159].

The importance of long-term follow up of children after neonatal thoracotomy cannot be overstated.

Extracorporeal Membrane Oxygenation

21

Arul S. Thirumoorthi and Charles J.H. Stolar

Abstract

Extracorporeal Membrane Oxygenation (ECMO) is a life-saving intensive care technology that uses partial heart and lung bypass for extended periods. Also known as extracorporeal life support (ECLS), it is not a therapeutic modality, but rather a supportive tool that provides sufficient gas exchange and perfusion for patients with acute, reversible cardiac or respiratory failure. This affords the patient's cardiopulmonary system time to rest, sparing them from the deleterious effects of traumatic mechanical ventilation and perfusion impairment.

21.1.1 History of ECMO

The Extracorporeal Life Support Organization (ELSO) was formed as a study group in 1989 by a collaboration of physicians, nurses, perfusionists, and scientists with an interest in ECMO. The group provides an international registry that collects data from almost all ECMO centers in the United States and throughout the world. Since the first successful use of ECMO in neonates in 1974 through July 2011, ELSO has registered 29,839 neonates treated with ECMO for a variety of cardiopulmonary disorders (see Tables 21.1, 21.2 and 21.3) [1].

21.1.2 ECMO Outcomes

The most common indications for ECMO in newborns are meconium aspiration syndrome (MAS), congenital diaphragmatic hernia (CDH), sepsis, persistent pulmonary hypertension of the neonate (PPHN), and cardiac support. Outcomes vary by disorder, but the overall neonatal ECLS survival for respiratory indications is 85% and for cardiac 61%. The mortality rate for these disorders without ECMO exceeds 80%.

21.2 Neonatal Patient Selection Criteria

Selecting potential ECMO candidates remains controversial. The selection criteria are based on data from multiple institutions, patient safety, risk of complications and mechanical limitations of equipment. All ECMO centers develop and maintain their own specific criteria based on their outcomes data.

21.2.1 Reversible Disease Process

ECMO is a supportive modality, not therapeutic therapy; therefore the baby should have a reversible disease process. Prior to ECMO, patients should be supported by mechanical ventilation for no longer than 10–14 days. Prolonged exposure to high concentration oxygen and positive pressure ventilation leads to the development of bronchopulmonary dysplasia (BPD) [2]. As few as 4 days of aggressive ventilation can lead to the development of BPD and prolonged ECMO runs (203 versus 122 h) [3]. Recovery from this type of irreversible lung injury may take from weeks to months to occur, if at all. Support with ECMO can be beneficial for reversible lung disease over a relatively short period of time (2–3 weeks). However, even a lengthy ECMO course is unlikely to be sufficient to permit recovery of the irreversible fibrotic changes that occur to the lung following sustained barotrauma and/or oxygen toxicity. In addition, with a longer ECMO run, the chance of infection, bleeding complications, thromboembolic events, and mechanical failure increase.

21.2.2 Gestational Age

The gestational age should be at least 34 weeks. Premature infants (<34 weeks' gestation) who were offered ECMO developed significant morbidity and mortality related to intracranial hemorrhage (ICH) [4]. The incidence of ICH appears to be directly related to gestational age, a 22% incidence of ICH at 32 weeks versus 12% at 36 weeks has been reported [5]. Ependymal cells within the brain may not be fully developed in preterm infants, thus making them susceptible to intracranial bleeding. Additionally the systemic heparinization necessary to maintain a thrombus-free ECMO circuit increases the risk of hemorrhagic complications.

21.2.3 Birth Weight

The birth weight should be 2000 g or greater due to technical consideration and limitation of cannula size. The smallest single lumen ECMO cannula is 6 French (Fr). Flow through the tube is inversely related to length of the tube as well as directly related to the radius of the tube by a power of 4. If the vein is small, then the cannula will be small, resulting in flow that will be reduced by a fourth power. If the baby weighs less than 2 kg, then the anatomical challenge of cannula placement in conjunction with the inadequate flow from small catheters make ECMO in these small babies challenging.

21.2.4 Hemorrhage and Coagulopathy Complications

There should be no active hemorrhage or major coagulopathy as these are relative contraindications to ECMO. Uncorrectable coagulopathy and uncontrollable bleeding have a high risk of bleeding complications while on ECMO. The need for continuous systemic heparin therapy while on ECMO adds to this risk of bleeding [6]. Hemorrhage should controlled and bleeding diathesis corrected prior to ECMO initiation.

21.2.5 Intracranial Hemorrhage

The infant should not have an intracranial hemorrhage (ICH). Patients with history of previous intracranial bleeds, cerebral infarcts, prematurity, coagulopathy, ischemic central nervous system injury, seizure or sepsis are particularly at high risk for ICH and severe neurologic consequences [4, 7]. Pre-existing ICH may be exacerbated secondary to the use of systemic heparin and altered cerebral blood flow while on ECMO. Infants with small intraventricular hemorrhages (grade I—restricted to germinal matrix and grade II—also inside ventricles) may be considered for ECMO on an individual case basis, but these cases should be closely monitored for worsening bleeding with frequent neurologic exam and daily head ultrasound. Pre-ECMO discussion with parents of these risks is especially critical.

21.2.6 Coexisting Anomalies

The infant should have no congenital or chromosomal anomalies incompatible with life,

i.e. trisomy 13 or 18. Many fatal congenital anomalies may initially present as reversible diseases including congenital alveolar proteinosis, alveolar capillary dysplasia and overwhelming pulmonary hypoplasia. A clear diagnosis prior to initiation of ECMO should be established as best as possible, as it is not intended to delay an inevitable death. Other treatable conditions, such as total anomalous pulmonary venous return (TAPVR), transposition of the great vessels (TOGV) and intact septum may initially manifest with respiratory failure. An echocardiogram should be rapidly obtained to determine the need for ECMO or cardiac surgery.

21.2.7 Bridge to Diagnosis

Despite best efforts, it is not always possible to establish a clear diagnosis prior to the initiation of ECMO and must be determined during its course. For example, pulmonary vein misalignment, a uniformly fatal anomaly of deficient alveolar capillaries and anomalous veins within the bronchoarterial bundles, presents with symptoms of persistent pulmonary hypertension unresponsive to treatment [8]. These children are often placed on ECMO. If the pulmonary hypertension is intractable despite support by ECMO, then the diagnosis of alveolar capillary dysplasia should be entertained [9]. The diagnosis is made via an open lung biopsy while on ECMO. If alveolar capillary dysplasia is confirmed, then withdrawal of ECMO support should occur. As mentioned in Coexisting Anomalies, some correctable cardiac conditions may present as respiratory failure and patients occasionally placed on ECMO before accurate diagnosis is made. Once established, appropriate therapy should be instituted.

21.2.8 Failure of Medical Management and Cardiopulmonary Criteria

Candidates for ECMO must have a reversible pathophysiologic process with a predicted mortality exceeding 80% and have exhausted maximum medical management. This is an admittedly subjective criterion, as conventional therapies will have great institutional variation. The term medical management encompasses ventilator and pharmaceutical modalities. Conventional medical therapy begins with positive pressure ventilation, vaso-dilatory or–constrictive agents and inotropes. These therapies may extend to administration of surfactant and alternative respiratory strategies including high-frequency ventilation, hyperventilation, hypoxia and induced respiratory or metabolic alkalosis [10]. Advanced medical strategies have been successfully employed for patients who otherwise met ECMO criteria. These strategies include high-frequency oscillation, permissive hypercapnea with spontaneous ventilation and nitric oxide. In 1985, Wung et al. used permissive hypercapnea in conjunction with spontaneous ventilation. This was employed in a series of 15 patients with persistent pulmonary hypertension [11]. A $PaCO_2$ of 50–80 mmHg and a PaO_2 of 40 mmHg were tolerated. Paralytics were not used and low-pressure ventilator settings were employed to provide adequate chest wall excursion. These patients survived with medical management alone. While some infants with reversible respiratory failure have been spared ECMO, many benefit and should be considered for ECMO if they meet criteria.

Objective criteria for assessing mortality risk in neonatal respiratory failure have been suggested [12–15]. The most commonly used measurements predictive of mortality are high-pressure ventilator settings, Alveolar-arterial oxygen gradient ($AaDO_2$) and the Oxygenation Index (OI) (see Table 21.4)

Alveolar-Arterial Oxygen Gradient:

$$AaDO_2 = (P_{ATM} - 47)(FiO_2) - [(PaCO_2)/0.8] - PaO_2$$

Oxygenation Index: $OI = MAP \times FiO_2 \times 100 / PaO_2$

where P_{ATM} is atmospheric pressure, FiO_2 is inspired oxygen fraction and MAP is mean airway pressure.

Criteria for cardiac failure include hypotension refractory to inotropes or volume resuscita-

Table 21.4 Predictive mortality alveolar-arterial oxygen gradient and Oxygenation Index

Measurement	Predictors of 80% mortality
$AaDO_2$	>625 mmHg for more than 4 h >600 mmHg for more than 12 h
OI	>40
High-pressure ventilator settings	Peak inspiratory pressure > 40 cmH_2O Positive end expiratory pressure > 7 cmH_2O Intermittent mandatory pressure > 100 FiO_2 of 1.0

tion, oliguria (urine output <0.5 ml/kg/h), decreased SvO_2 and decreased peripheral perfusion. It should be noted that survival benefit of ECMO during CPR (ECPR) and emergency cardiopulmonary bypass have not been clinically established.

21.2.9 Congenital Diaphragmatic Hernia

Patients with congenital diaphragmatic hernia who develop respiratory failure must meet unique criteria to be candidates for ECMO. The newborn must demonstrate adequate lung tissue to be able to sustain life. This includes a sustained preductal oxygen saturation ≥ 90% for at least 1 h (commonly referred to as the honeymoon period) and at least one recorded $PaCO_2$ < 50 mmHg before developing 80% mortality likelihood.

21.3 Methods of Extracorporeal Support

21.3.1 Veno-Venous ECMO

Veno-Venous (VV) support delivers oxygen for respiratory indications. In VV ECMO venous drainage is accomplished by cannulating the right internal jugular vein (RIJ) with the tip in the right atrium (RA) and reinfusion via a femoral vein. A variation is single cannula double-lumen veno-venous ECMO (DLVV) inserted via the RIJ with the tip in the RA. The double-lumen catheter both drains deoxygenated blood and returns oxygenated blood to the right atrium. Double-lumen catheters of 12–15 Fr gauge are available for use in neonates. Use of VV ECMO when indicated avoids arterial cannulation and carotid ligation while maintaining pulsatile flow. In DLVV there is mixing of oxygenated and deoxygenated blood in the RA. Oxygenated blood recirculates in the pump, artificially raising SvO_2 measurement and may limit oxygen delivery at higher flow rates.

21.3.2 Veno-Arterial ECMO

Veno-Arterial (VA) support not only delivers oxygen for respiratory failure but also provides circulatory support in the event of cardiac failure, difficulty weaning from cardiopulmonary bypass, or occasionally CDH anatomy. In these cases, VA support is provided by venous drainage of the right atrium through a cannula inserted in the RIJ (see Fig. 21.1). Oxygenated blood is returned through a cannula in the right common carotid artery (RCCA). Patients who present with profound lactic acidosis, hypoxic ischemia, and end organ failure often have a component of cardiovascular collapse and may also require the circulatory support of VA as opposed to VV ECMO. Patients with left ventricular (LV) failure are at risk of LV distension on ECMO and decompression via atrial septostomy is necessary. Preexisting atrial or ventricular septal defect may obviate need for mechanical septostomy and should be determined by echocardiogram prior to initiation of ECMO.

Transthoracic or open chest VA ECMO is common variation in patients unable to wean off intraoperative bypass or in the postoperative period. The venous cannula is in the right atrial appendage and arterial cannula in the ascending aorta. While large diameter catheters may be utilized, there is significant risk of hemorrhage and infection.

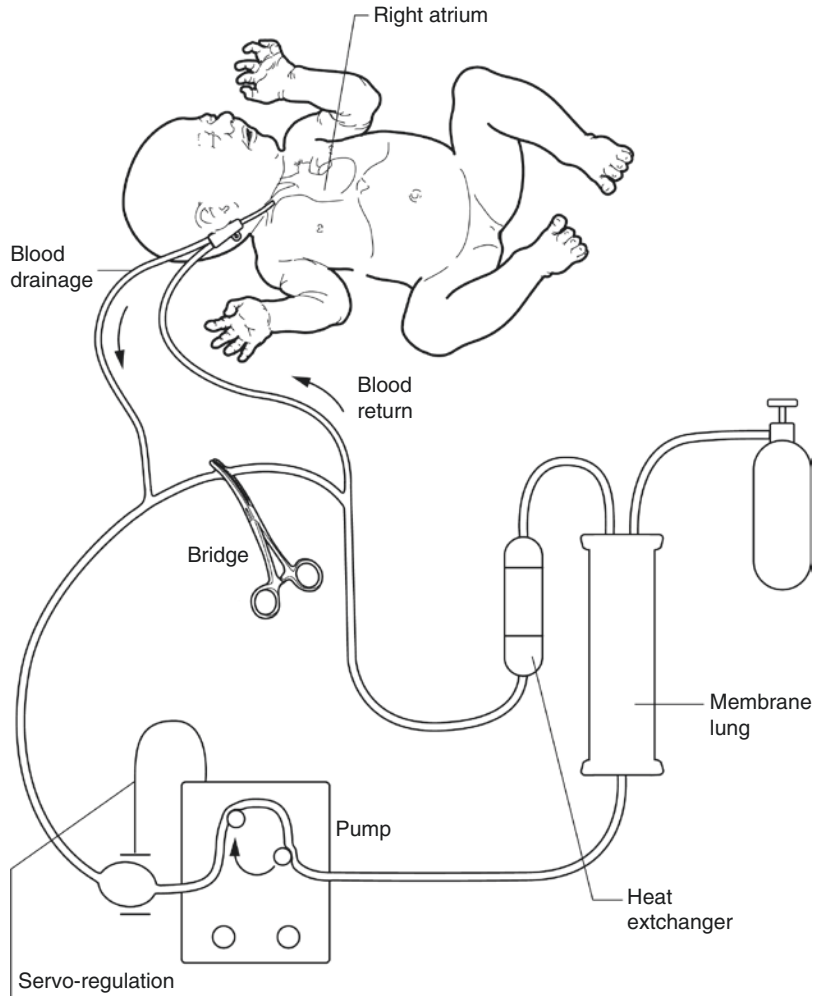

Fig. 21.1 ECMO circuit diagram. From Taylor & Francis UK. Published in Operative Pediatric Surgery 7th edition, Lewis Spitz and Arnold Coran, CRC Press, 2014 pages 196–198; used with permission

21.4 ECMO Circuit and Cannulation

21.4.1 ECMO Circuit

Venous blood is drained from the right atrium of the infant by gravity or negative pressure into a bladder reservoir. An inline oxymetric probe before the bladder accomplishes continuous monitoring of SvO_2. If venous drainage does not meet pump outflow the servo-regulator will shut off the pump. This limits risk of high negative pressures and possible damage to RA and air cavitation (entry of air into pump). Although hypovolemia is the most common cause of decreased venous inflow, occlusion of the venous line secondary to kinking or thrombus should be ruled out. A roller or centrifugal pump pushes blood through the membrane oxygenator. Continuous pressure monitoring pre- and post-oxygenator ensures that pressure in the circuit (negative and positive) does not exceed pre-set parameters. A bubble detector halts flow if air is detected in the circuit. The membrane oxygenator is either a silicone or hollow fiber with counter current flow of blood and gas providing a large surface area for gas and water vapor exchange. Post-oxygenator the blood is warmed

to physiologic temperature. Oxygenated blood returns to the baby via the RA (DDLV), Femoral Vein (VV) or aortic arch (VA) (Fig. 21.1).

21.4.2 Cannulation and Anesthesia

Cannulation can be performed in the neonatal intensive care unit with adequate sedation and analgesia. Neuromuscular blockade is critical at venous cannulation and decannulation to prevent ingress of air emboli due to spontaneous respiration, though it is not recommended during ECMO support. As with OR procedures, sterile technique is used. The cannulas are filled with heparinized saline, usually 8 Fr arterial and 10 Fr venous for neonates.

21.4.3 Patient Position and Incision

The infant is placed in the supine position with the head at the foot of the bed and turned to the left. The neck is hyperextended with use of a transverse shoulder roil. The chest, and right neck are prepped and draped. Local anesthesia is infiltrated over the right cervical neck incision site. A transverse incision is made one fingerbreadth superior to clavicle, 3 cm in length anteromedial to the right sternocleidomastoid muscle (Fig. 21.2).

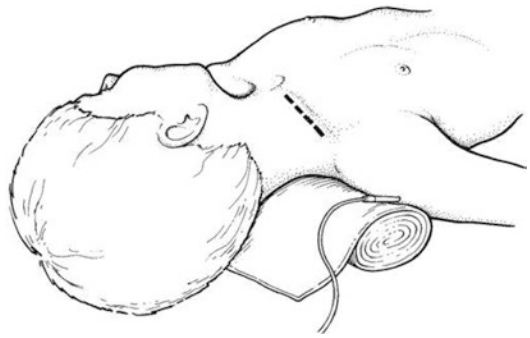

Fig. 21.2 Patient position and incision. From Taylor & Francis UK. Published in Operative Pediatric Surgery 7th edition, Lewis Spitz and Arnold Coran, CRC Press, 2014 pages 196–198; used with permission

21.4.4 Dissection and Vessel Exposure

The platysma muscle is divided, sternocleidomastoid retracted laterally and dissection carried down to the carotid sheet with electrocautery. The carotid sheath is opened and the right internal jugular, right common carotid and vagus nerve are identified. The vein is dissected first and isolated with vessel loops. Frequently the facial vein is present and must be ligated. The common carotid artery without any branches, lies medial and posterior, and is dissected and isolated with vessel loops. Once vessels are isolated, a heparin bolus of 100 units/kg is administered and allowed to circulate for 3 min. ACT level should be drawn prior to cannulation and be >300 s (Fig. 21.3).

21.4.5 Cannulation

Ligatures of 2-0 silk are passed proximally and distally on the artery and vein. For VA ECMO, the arterial cannula occurs first. The carotid artery is ligated distally and proximal control

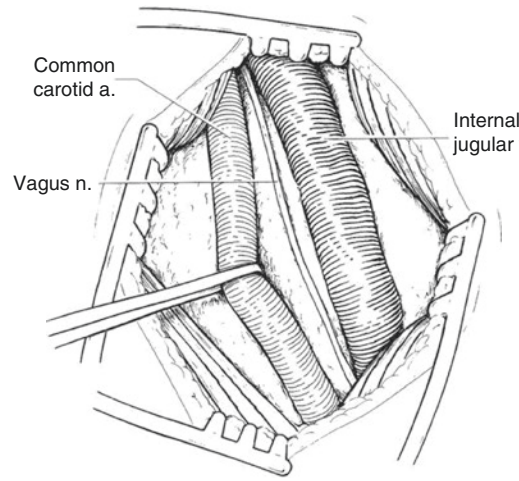

Fig. 21.3 Dissection and vessel exposure. From Taylor & Francis UK. Published in Operative Pediatric Surgery 7th edition, Lewis Spitz and Arnold Coran, CRC Press, 2014 pages 196–198; used with permission

obtained with a vessel clamp. A transverse arteriotomy is made near the distal ligature. Prolene stay sutures can be used to assist with retraction and prevent intimal dissection. The heparinize-saline filled cannula is inserted to its premeasured position, usually about 3 cm to the junction of the brachiocephalic artery and aorta. It is secured with the previously placed 2-0 silk ligatures and a small piece of vessel loop placed inside the ligatures anteriorly. These bumpers serve to protect the vessel from injury during sharp division during decannulation. Prior to venotomy, the patient must be paralyzed to prevent air embolus secondary to spontaneous respiration. Venous cannulation follows a similar pattern to arterial. The jugular vein is ligated proximally and a transverse incision made close to the ligature. The catheter is passed to the level of the right atrium, usually 5–6 cm, and secured as the arterial cannula. For VV and DLVV bypass, the RCCA is dissected and isolated with vessel loop in case conversion to VA ECMO is necessary. If using a double lumen cannula, the reinfusion port must be oriented anteriorly to ensure the oxygenated blood is directed across the tricuspid valve, minimizing recirculation. Bubbles are aspirated and the cannula(s) connected to the prep rimed ECMO circuit. Bypass is initiated. After achieving hemostasis, the wound is irrigated and closed in layers. The cannulae are secured to the skin, below the ear ensuring they remain unkinked. Cannulae positions are confirmed with chest radiograph and transthoracic echocardiogram (Fig. 21.4).

21.5 Clinical Management of Extracorporeal Support

21.5.1 Cannula Management

The preferred site for cannula placement is in the vessels of the right neck. The reason for this is that the femoral vessels are too diminutive for cannulation in a neonate. The internal jugular vein is accessed via an open procedure. During the open procedure, muscle relaxants are given to prevent the inadvertent aspiration of air into the vein. In the event of VA ECMO, the carotid artery is dissected and identified for catheter placement. After placement of the catheters and initiation of ECMO flow, the catheters are carefully secured with sutures to the blood vessel and skin (see Fig. 21.2).

The position of the catheter is confirmed in two ways. First, a chest radiograph is performed, which can grossly demonstrate catheter position. The tip of the venous cannula should be located within the right atrium, while the tip of the arterial cannula should be located in the ascending aorta. The second mode of confirming cannula placement is cardiac echocardiography. The double-lumen catheter should be visualized within the right atrium, venting the return oxygenated blood through the tricuspid valve to minimize recirculation. If there is persistent difficulty maintaining flow due to poor venous withdrawal, the possibility of a catheter problem must be entertained and further imaging should be performed to confirm the proper position.

21.5.2 Prime Management

The tubing of the ECMO circuit is initially circulated with carbon dioxide gas followed by the addition of crystalloid and 25% albumin solution when using silicon sheet oxygenators. The albumin coats the tubing to decrease its reactivity to circulating blood. The carbon dioxide gas dissolves into the fluid. Packed red blood cells are required for initial priming of the pump, which displaces the crystalloid and colloid in the circuit. Blood is washed before priming the circuit as preserved blood contains non-physiologic levels of electrolytes. Otherwise, upon initiation of ECMO, a massive transfusion of unwashed blood can significantly alter infant electrolyte concentrations and induce cardiac arrest. Calcium gluconate is added to minimize arrhythmias when going onto ECMO. Sodium bicarbonate and heparin are added to the circuit as well.

The initial pH, oxygen content and carbon dioxide content of the circuit are then measured and adjusted to physiologic parameters. If the prime blood is acidotic, this may exacerbate the infant's condition; or, if the primed circuit has a low carbon dioxide content, this may cause metabolic problems for the neonate. Additionally, a heat exchanger warms the prime to normal body temperature. The primed circuit must be physiologically compatible with life prior to initiating ECMO to maximize support and prevent exacerbation of the child's condition.

21.5.3 Pump Management

The goal of ECMO is to maintain adequate pump flow providing good oxygen delivery to the tissues and organs. Oxygen delivery is dependent on the speed or rotations per minute (RPM) of the pump. Full support on VA ECMO is considered a flow rate of 120–130 cc/kg/min corresponding to a cardiac index of 2.4. Adequate perfusion and oxygen delivery can be monitored by the pH and PO_2 of a 'mixed venous' blood sample (preoxygenator blood sample). The flow of the pump should be adjusted to maintain a mixed venous PO_2 of 37–40 mmHg and saturation of 65–70%. With VV ECMO, full support is 120–150 cc/kg/h. The 'mixed venous' sample may not be a reliable indicator of perfusion as recirculation may produce a falsely elevated PO_2. Therefore, other indicators of poor perfusion should be followed: persistent metabolic acidosis, oliguria, seizures, elevated liver function tests, and hypotension. If oxygen delivery is found to be inadequate, then the RPM of the pump may need to be increased to improve perfusion.

Roller pumps use a rotary vane to trap fluid in the tubing against the pump housing to propel the blood towards the oxygenator. They propel a fixed volume (length of tubing) at constant flow rate regardless of discharge pressure dependent on RPM. This area of contact is at risk for tubing rupture over time. To reduce the risk of rupture, the 'raceway' (tubing within roller pump housing) is advanced regularly after temporarily stopping the pump flow. Tubing rupture is a rare event, less than 1% of ECMO runs per year, due to modern materials such as Supertygon† (Norton Performance Plastics Corporation, Akron, OH, USA), a chemically altered polyvinyl chloride (PVC).1.

Another type of pump, centrifugal, is also commonly used for ECMO. Centrifugal pumps work by using a rotating impeller to create flow by adding energy to a fluid. Fluid enters the housing at the rotating axis, is accelerated by the impeller and discharged at the outer casing. They do not have a mechanical degradation of tubing integrity and are not susceptible to raceway rupture. Unlike rotary pumps, centrifugal pump flow rate is dependent on inlet and outlet pressure. Though flow rate is primarily dependent on RPM, there will be some variation in flow rate due to pressure.

21.5.4 Oxygenator Management

The silicone membrane (envelope) oxygenator has been critical to the success of ECMO and long-term bypass. The mechanism of gas exchange occurs when blood in the tubing enters a manifold region and is distributed around the envelope of a silicone membrane lung. Oxygen flows through

the inside of the membrane envelope in a countercurrent direction to the flow of blood. Oxygen diffuses across the silicone membrane into the blood as carbon dioxide is eliminated. The oxygenated blood drains into a manifold and is returned to the infant via a heat exchanger.

A thrombus may form in the oxygenator over time. As a thrombus extends, the membrane surface area is decreased, resulting in decreased oxygen and carbon dioxide transfer. This can lead to increased resistance to blood flow. The gaseous portion of the oxygenator may also develop obstructions, which may lead to air emboli. Long-term use may wear the silicone membrane, resulting in blood and water in the gas phase.

Most ECMO circuits measure a pre- and post-oxygenator pressure. The difference in these two pressures, the DP, can help determine when an oxygenator is failing. An elevated pre-oxygenator pressure with a stable post-oxygenator pressure, thus elevated DP, likely means that there is an obstruction to blood flow in the oxygenator, often from thrombus. There is no absolute DP value that mandates replacement of an oxygenator. However, a rapid increase in this value with the anticipation of continued ECMO support should alert the practitioner to the need for replacement of the oxygenator. In addition, a larger oxygenator may also be required if the gas and blood flow rating of the old oxygenator are exceeded in order to maintain adequate perfusion.

In increased use are hollow-fiber oxygenators, such as the Quadrox-iD† oxygenator (Jostra Medizintechnik AG, Hirrlingen, Germany) for neonates. The oxygenator uses less priming volume (80 mL) and has a smaller surface area. The decreased surface area allows for more efficient gas exchange and reduces the potential for thrombus formation [16]. Additionally, the resistance across the oxygenator is smaller than the silicone oxygenator, less than 50 mmHg. This may cause less disruption of red blood cells.

21.5.5 Volume Management

While on ECMO, maintenance fluids for a term newborn under a radiant warmer are estimated to be 100 cc/kg/day. Water loss through the oxygenator may approach 2 cc/m^2/h. For a baby weighing 3 kg, this would be about 10 cc/day. Fluid losses from urine, stool, chest tubes, nasogastric tubes, ostomies, mechanical ventilation, radiant fluid loss, and blood draws should be carefully recorded. Fluid management may become difficult in the baby on ECMO as fluid extravasates into the soft tissues during the early ECMO course. Therefore, strict measurement of the net fluid balance on ECMO should be maintained. Classically, the weight increases in the first 1–3 days as the patient becomes increasingly edematous. On the third day of ECMO, diuresis of the excess edema fluid begins, and can be facilitated with the use of furosemide. This diuretic phase is often the harbinger of recovery. In the event of renal failure on ECMO, hemofiltration or hemodialysis can be added to the ECMO circuit for removal of excess fluid and electrolyte correction. In a retrospective comparison of neonates on ECMO, use of hemofiltration was associated with shorter duration on ECMO and time on mechanical ventilation [17].

While on ECMO, the baby's hemoglobin is maintained at 13–15 g/dL to maximize the oxygen carrying capacity of the blood. Platelet destruction during ECMO is anticipated and is secondary to the flow through the oxygenator and exposure to plastic surfaces. In order to reduce the risk of bleeding during ECMO, the platelet count should be kept above 100,000/mm^3 [18]. The authors recommend using 'hyperspun/concentrated' platelets to avoid the excess administration of fluid, and thus preventing further problems with volume overload and edema.

21.5.6 Ventilator Management

Once the desired oxygen delivery is attained, the ventilator should be promptly weaned to avoid further oxygen toxicity and barotrauma. The optimal rest settings remain unclear [19]. At the authors' institution, the FiO_2 is decreased to 0.21, PEEP to 5 cmH_2O, PIP to 20–25 cmH_2O, a rate of 12 breaths/min and inspiratory time of 0.5 s if the infant's arterial and venous oxygenation are adequate.

If the baby remains hypoxic despite maximal pump flow, then higher ventilator settings may be temporarily required. Alternatively, hypoxic neonates on VV ECMO may need to be converted to VA ECMO for full cardiorespiratory support. On occasion, the chest x-ray will worsen in the first 24 h independent of ventilator settings and improve after diuresis. As the patient improves on ECMO and the pump flow is weaned, ventilator settings are then modestly increased to support the baby off ECMO. At our institution, if the oxygen saturation is greater than 93%, then an FiO_2 of 0.4, PIP < 28, PEEP of 5, and a rate < 30 as adequate settings for a trial off ECMO.

In addition, during the course of ECMO, pulmonary toilet is essential to respiratory improvement and includes gentle chest percussion and postural drainage. Special attention should be made to the ECMO catheters and keeping the head and body aligned. Endotracheal suctioning is also recommended every 4 h and as needed based on the amount of pulmonary secretions present.

21.5.7 Medical Management

After the initiation of ECMO, vasoactive medications should be quickly weaned if the blood pressure remains stable. In the event of seizures, phenobarbital is usually given and maintained to prevent further seizures. In addition, gastrointestinal prophylaxis with an H_2-blocker, such as ranitidine, is instituted. Fentanyl and midazolam are usually administered for mild sedation, however the use of paralytics should be avoided. Paralysis is avoided because muscle activity plays a vital role in fluid mobilization, preventing edema and loss of compliance. Neonates also tolerate ECMO well without paralysis and it prevents an accurate neurologic exam.

Infectious prophylaxis is provided by cefazolin, if no other antibiotics have been started at the author's institution. However, many neonates who are placed on ECMO are already on broad-spectrum antibiotics. If these are discontinued than cefazolin ore equivalent should be initiated. Due to the indwelling cannula and manipulation of the circuit at stopcocks, the risk of infection is a constant concern; therefore, strict observance to aseptic technique when handling the ECMO circuit should be maintained. Routine blood, urine, and tracheal cultures should be obtained to monitor for infection.

The caloric intake on ECMO should be maximized using standard hyperalimentation. For a newborn, total parenteral nutrition (TPN) should be started at 100 kcal/kg/day. Normally, this should be supplied as 60% carbohydrates (14.6 g/kg/day) and 40% fat (4.3 g/kg/day). Intralipid infusion may be used as a fat source, although there is some controversy with its use in the setting of severe lung disease. As a result, the percentage of fat in the hyperalimentation may be lowered. Amino acids may be added but must be considered in the setting of poor renal function and increasing blood urea nitrogen (BUN) levels. With normal renal function, approximately 2.5 g protein/kg/day should be provided in the TPN mixture.

Enteral nutrition is gaining acceptance in some centers. Initial concerns with feeding enterally on ECMO were that there was inadequate gut perfusion from the initial insult, which could lead to necrotizing enterocolitis when feeding was begun [20]. However, a retrospective study of 67 neonates supported with VA ECMO who were fed enterally, did not show any significant adverse effects [21]. While septic complications of enteral feeding appears to be low, many of these patients will have a gastrointestinal ileus. Of the previously mentioned 67 neonates, 21% had enteral feeding temporarily discontinued due to high gastric residuals.

In the setting of cardiopulmonary failure and large volume shifts it is essential to closely monitor electrolytes with potassium, calcium, and magnesium repleted as necessary. Sodium and phosphorus are usually not repleted as they are often provided in blood products and volume expanders.

21.5.8 Coagulation Management

Heparin is initially administered as a bolus (100 units/kg) followed by a constant heparin

infusion (30–60 units/kg/h) to maintain a thrombus-free circuit. The level of anticoagulation is monitored by the activated clotting time (ACT). The heparin infusion is adjusted to maintain an ACT of 200–240 s. After decannulating, the heparin infusion is stopped and not reversed with protamine sulfate.

21.5.9 Hemodynamic Management

Hypotension and hypertension are both seen in neonates on ECMO. Hypotension is common in both respiratory and cardiac failure requiring the use of inotropes even after being placed on ECMO. Cause can be hypovolemia as well as myocardial dysfunction from pre-ECMO hypoxia. Inotropes are readily weaned after correction of hypoxia and acidosis in conjunction with volume resuscitation and hemoglobin at 15 mg/ld. Hypertension is also common and should be aggressively treated after reversible causes such as pain, hypercarbia and hypoxia are ruled out. Hypertension increases risk of ICH and its sequelae.

21.5.10 Temperature Management

Thermoregulation is controlled by adjusting temperature of blood returning to patient. Selective hypothermia for cerebral ischemia/hypoxia may improve neurologic outcome. It is not yet clear if whole body or cap cooling provides significant improvement in outcomes on ECMO. It is possible to maintain temperature of 34 °C for 45 h on ECMO without increasing morbidity [22]. The largest study to date is underway in the UK. The Neonatal ECMO Study of Temperature (NEST) is a multicenter prospective randomized control trial of mild hypothermia versus normothermia in neonates with respiratory failure [23].

21.5.11 Pharmacology Management

ECMO alters pharmacologic management secondary to increased volume of distribution and drug absorption due to the circuit. While antibiotic, analgesia and sedation is calculated by age and weight, it should be noted that drug absorption by the oxygenator can be significant with lipophilic agents most extremely effected. Sedatives such as fentanyl and midazolam have extremely short half-lives, in the order of minutes, when administered to patients on ECMO.

21.5.12 Surgical Procedures on ECMO

ECMO may be used to stabilize patient prior to surgical repair of reversible diseases, i.e. CDH or TGOV. Operative procedures may be safely preformed while the child remains on bypass. However care must be taken to obtain meticulous hemostasis to avoid hemorrhagic complications. Pre-operatively hemoglobin should be transfused to 15 g/dL and platelets to 100,000/mm^3. Intraoperatively ACT level should be reduced to 180–200 s. The fibrinolysis inhibitor aminocaproic acid is administered as a 100 mg/kg bolus 1 h prior to incision with a continuous maintenance drip at 30 mg/kg/h for up to 72 h postoperatively.

21.5.13 ECMO Weaning and Decannulation

As the patient improves during the ECMO course, the flow of the circuit is weaned, based on improving postductal arterial and venous oxygenation. Neonates supported with VV ECMO should be weaned using the patient's SaO_2 as the SvO_2 will be artificially high from recirculation. Neonates supported with VA ECMO should be weaned maintaining the patient's SvO_2 with a target of 65–75 mmHg. From full flow support of 150 cc/kg/min, the flow is decreased to 30 cc/kg/min while maintaining adequate perfusion. As flow decreases it will be necessary to increase ventilator support. The ACT should be maintained at 220–240 at lower flows to prevent thrombosis. If the baby tolerates the low flow, then the ECMO cannula (VV) or cannulas (VA)

may be clamped while the ECMO circuit recirculates. During a clamping trial, the child is observed for up to 4 h to ensure hemodynamic stability and adequate saturation without acidosis. The authors prefer to wean patients onto moderate conventional ventilator settings, i.e. IMV 20, FiO_2 0.4, PIP 25, and PEEP 5. Higher ventilator settings, though, may be tolerated if the risks of continuing ECMO outweigh those of discontinuing ECMO.

If the recirculation is tolerated, then decannulation is performed. As with the insertion, decannulation should be performed as a sterile surgical procedure. Muscle paralytics should be administered to prevent air aspiration into the vein. Prior to decannulation, vasoactive medication and hyperalimentation should be switched from the ECMO circuit to other vascular access. Once the catheter is removed, the vein is ligated and not repaired. This is also true for the artery in the case of VA ECMO.

21.6 Complications on ECMO

21.6.1 Hemorrhagic and Thrombotic Complications

The most common complication during ECMO is bleeding and coagulopathy. Bleeding can occur at cannula site, surgical site, intracranial, intestinal, tracheal or urinary. Coagulopathy occurs due to activation of coagulation cascade by contact with foreign surface of catheters and ECMO circuit. Platelets are consumed by the circuit as discussed previously. Treatment includes transfusion of blood products as well as coagulation factors if necessary.

Oxygenator failure and thrombus formation within circuit tubing is common. Venous or pre-oxygenator clot can be observed unless pressure drop is excessive and adequate flow cannot be maintained. Segments of tubing or oxygenator can be replaced as necessary. Arterial or post-oxygenator clot are of significant concern as they can emblaze with pulmonary and neurologic complications. Post-oxygenator clot is an indication for replacement of the entire circuit.

21.6.2 Mechanical Complications

While hypovolemia is an important cause for poor venous return to the circuit and subsequent poor pump flow, other causes must be eliminated prior to volume infusion. These may include small venous catheter diameter, excessive catheter length, catheter kinks, improper catheter position, insufficient hydrostatic column length (i.e. patient height), and improper calibration or set-up of the venous control module system. In addition, pneumothorax, cardiac tamponade, and abdominal compartment syndrome may need to be considered if there is no readily appreciated mechanical reason for poor venous return.

Air embolism should be rigorously guarded against. Air can enter the circuit via connectors, stopcocks as well as at cannulation and decannulation. Pre-oxygenator air can be aspirated via stopcocks but arterial or post-oxygenator air is an emergency. ECMO should cease until the air is aspirated. If there is an air embolus becomes systemic, the patient should be placed in Trendelenburg and embolus aspirated via the arterial cannula.

After these causes have been excluded, small amounts of isotonic fluid (5–20 cc/kg) may then be introduced into the circuit to support higher pump flow rate. However, a large amount of volume infusion in conjunction with long-term muscle relaxants and venodilators can lead to anasarca, which in turn, can lead to poor chest wall compliance, compromised gas exchange and oxygen delivery. In some conditions, such as sepsis, there may be endothelial damage and capillary leakage, in which case anasarca may be unavoidable.

21.6.3 Neurologic Complications

The most serious long-term complications of the ECMO patient have been neurologic (e.g. learning disorders, motor dysfunction, cerebral palsy) and appear to be due to hypoxia and acidosis prior to ECMO. Neurologic complications on ECMO include ICH, stroke and seizures. Seizures are common among ECMO neonates but are associ-

ated with prior hypoxic insult. The incidence of ICH in neonates is 14% on ECMO and increased in premature infants. During the ECMO course, frequent neurological examinations should be performed, and paralytic agents should be avoided. The examination consists of evaluation of alertness and interaction, fullness of the fontanelles, reflexes, tone, spontaneous movements, eye findings, and presence of seizures. Intracranial hemorrhage is the most devastating complication on ECMO. Therefore, careful attention must be made to the rate of ECMO flow, rate of exchange of PCO_2, fluctuations in the ACT, and platelet count. Cranial ultrasounds should be performed every day to monitor ICH and after any major event, such as equipment malfunction, sudden worsening in oxygenation status, and pneumothorax. Electroencephalography (EEG) may also be helpful in the neurologic evaluation of the neonate. As previously discussed studies are underway to evaluate the benefits of selective hypothermia on ECMO to mitigate neurologic sequelae of hypoxia. Progression of ICH or worsening of neurologic status may require cessation of anticoagulation and removal from ECMO support.

21.6.4 Renal Complications

Infants on ECMO may sustain acute tubular necrosis (ATN) marked by oliguria and increasing BUN and keratinize levels. ATN may extend into the first 24–48 h of ECMO before improvement in urine output is seen. This may be attributed to decreased renal perfusion secondary to nonpulsatile flow in VA ECMO or capillary leak at ECMO initiation. If the renal condition does not improve, poor tissue perfusion should be considered. A combination of inadequate ECMO flow rate, low cardiac output, and intravascular volume depletion from diuresis may lead to decreased renal function. If after adequate volume resuscitation oliguria does not resolve, pharmacologic diuresis with furosemide may be utilized. If the infant remains in complete anuric renal failure and requires dialysis, a hemofiltration module can be added in series to the ECMO circuit to remove excess fluid and stabilize electrolyte abnormalities.

21.7 ECMO and Congenital Diaphragmatic Hernia

Neonates with CDH have abdominal viscera in the thoracic cavity, most commonly on the left side. This often leads to significant pulmonary hypoplasia and pulmonary hypertension. Pulmonary insufficiency can ensue, leading to hypoxemia, hypercarbia, and acidosis soon after birth; this can then lead to a vicious cycle of pulmonary vasospasm, pulmonary hypertension, right-to-left shunting of blood and worsening hypoxemia, hypercarbia, and acidosis. This cycle must be broken, if not medically, then with the assistance of ECMO. Medical management has improved greatly with the use of pulmonary vasodilators such as inhaled nitric oxide.

If a fetus is antenatally diagnosed with a CDH, plans should be made for delivery in a medical center with ECMO capabilities in case of potential rescue therapy. There is no surgical indication or benefit to early delivery by Cesarean section. In the delivery room, intubation should be performed immediately after birth. The baby should then be transferred to a neonatal intensive care unit and started on mechanical ventilation to stabilize oxygenation and hemodynamics.

21.7.1 Surgical Repair CDH

In the past, newborns with CDH have undergone repair as a surgical emergency. However, respiratory mechanics frequently worsen postoperatively, perhaps as a result of early repair [24]. In the 1980s, however, surgeons reported improved results with delayed surgery after postnatal medical stabilization [25–30]. A strategy of delayed repair in CDH patients after stabilization of respiratory and hemodynamic parameters with or without ECMO is the current standard of care.

21.7.2 CDH and ECMO Selection

Patient selection of newborns with CDH for ECMO support is particularly difficult. Neonates with CDH who present with overwhelming pulmonary hypoplasia that precludes gas exchange

should not be offered ECMO. This group is characterized by the inability to sustain a preductal oxygen saturation ≥ 90% for at least 1 h, a PaO_2 of 100 on a FiO_2 of 1.0 or a PCO_2 < 50. Their degree of pulmonary hypoplasia is incompatible with life and they would not be able to be weaned from ECMO. Appropriate candidates for ECMO will go through a 'honeymoon' period where they will maintain a PaO_2 > 100 on FiO_2 of 1.0 or a $PaCO_2$ < 50 for a period of time. Should they develop sustained hypoxemia (PaO_2 < 40), acidosis (pH <7.2) or an alveolar arterial oxygen gradient >600 for 10 h, then ECMO should be instituted. This period of adequate gas exchange followed by deterioration suggests that these patients have a degree of reversibility of their pulmonary hypertension. Applying this criteria, 85% patients with a CDH supported on ECMO survived to discharge [31].

21.8 Results and Outcomes

21.8.1 Survival

Mortality statistics for neonates supported by ECMO are increasing according to the ELSO registry [32]. The ability for critically ill babies to be managed medically has improved significantly over the last decade. Use of inhaled nitric oxide (pulmonary vasodilator), surfactant, high frequency oscillating ventilation, permissive hypercapnea and spontaneous ventilation have all contributed have increased the severity of illness of neonates placed onto ECMO. Despite advances in medical management, mortality has remained specific to the primary diagnosis prior to ECMO [32]. For example, ECMO patients with the diagnosis of CDH have a 51% survival rate while meconium aspiration syndrome has a survival rate of 94% [32, 33]. Neonates supported by ECMO for respiratory failure have higher rate of survival to discharge (75%) than for cardiac failure (39%) [32] (see Tables 21.1, 21.2 and 21.3).

The leading cause of infant mortality on ECMO, is due to severe hemorrhagic or coagulopathic complications. Prematurity and low birth weight, <2 kg, are another risk factor for mortality. It should be noted that newborns <2.5 kg still have a higher mortality. A retrospective study reviewed 300 newborns supported with ECMO, and the infants who weighed <2.5 kg, although meeting the criterion of 2 kg, had a relative mortality risk of 3.45% compared to ECMO neonates with birth weights >2.5 kg [34].

21.8.2 Feeding and Growth

ECMO survivors often faced delayed discharge from the neonatal intensive care unit due to poor enteral feeding. As many as one-third of post-ECMO neontaes struggle to attain goal feeds [35–37]. The root cause of feeding failure varies; possibilities include interference from tachypnea, generalized central nervous system (CNS) depression, poor hunger drive, soreness in the neck from the surgical procedure, sore throat from intubation, poor oral motor coordination, and manipulation or compression of the vagus nerve during the cannulation procedure [37, 38]. Pre-ECMO diagnosis points to different causes. Infants with CDH have a higher incidence of feeding difficulty than infants with MAS and RDS [38–40]. The CDH infants have a field defect, one aspect of which is foregut dysmotility, which leads to significant reflux, delayed gastric emptying, and feeding difficulties. Respiratory compromise and severe chronic lung disease also interfere with feeding. These babies may require prolonged nasogastric feeding or even a gastrostomy, fundoplication, and pyloroplasty to maintain adequate growth. However, ECMO infants generally do not have major long-term feeding complications.

Though the majority of post-ECMO children demonstrate normal growth, this population of infants has a higher incidence of growth problems compared to normal controls.

Head circumference below the fifth percentile occurs at a higher rate (10%) in post-ECMO children. Furthermore, poor head growth is associated with a major handicapping condition with a risk greater than 75% at 5 years of age [41]. Although controversial, there have also been reports of macrocephaly, which follows a pattern of venous obstruction secondary to internal jugular vein ligation observed on neonatal neuroimaging [41, 42].

Growth problems are most commonly associated with ECMO children who had CDH or residual lung disease [39].

21.8.3 Respiratory

Respiratory sequelae are a significant cause of long term morbidity in ECMO survivors with corresponding high rate of hospitalization in the first 2 years of life related to pre-ECMO care or PPHN [43, 44]. Approximately 15% of ECMO survivors require supplemental oxygen beyond the neonatal period. This cohort is twice as likely to be hospitalized for pneumonia as control children by age five (25% versus 13%) with a half of these hospitalizations occurring within the first year of life.

Of the ECMO-treated neonates, the primary diagnosis of CDH, in particular, has been found to be associated with chronic lung disease, defined by the need for bronchodilators, diuretics, or supplemental oxygen for the management of pulmonary symptoms. Specifically, the use of supplemental oxygen at discharge from the hospital has been reported in 22–80% of CDH patients [40, 45–47]. Aggressive ventilator management and lung injury prior to initiating ECMO leads these children to develop bronchopulmonary dysplasia. Persistent oxygen requirements are due to pulmonary hypertension.

The duration of aggressive mechanical ventilation prior to initiating ECMO is associated with supplemental oxygen requirement beyond 28 days [3]. Neonates with severe respiratory failure had an 11.5-fold increased risk of bronchopulmonary dysplasia if ECMO was initiated at later than 96 h of age correlating with duration of ventilation. Additionally, ECMO infants with birth weights of 2–2.5 kg have a greater risk for chronic lung disease than larger ECMO infants [34].

21.8.4 Neurologic

The most serious morbidity post-ECMO is neurologic. Multiple institutions have published sensorineural, neuromotor and developmental handicap at 1 year after birth.

The average incidence of sensorineural handicap such as cerebral palsy, blindness and hearing impairment is 6% [41, 48–60]. Auditory deficits are reported in more than 25% of ECMO neonates at the time of discharge [61]. The majority consists of mild-moderate deficit by brainstem auditory evoked response (BAER) testing which generally resolve over time. Iatrogenic injury may play a role secondary to alkalosis, furosemide administration or gentamicin ototoxicity. As a result, hearing screening is recommended at the time of NICU discharge. Overall sensineural hearing loss occurs in 5% of ECMO children [41, 53, 55, 57]. This rate is comparable to non-ECMO PPHN children [62–65].

Visual deficits in ECMO neonates are usually limited to infants <2 kg associated with immature retina in premature patients. This is uncommon in ECMO neonates weighing >2 kg. Concern about retinopathy of prematurity due to the hyperoxic condition of ECMO has not been borne out.

Severe developmental delay among ECMO survivors is 9% on average, comparable to other critically ill neonates. Extremely low birth weight neonates (<750 g) have a 15% rate of having major sensorineural handicap with 21% testing in the mentally retarded range [66]. Additionally, newborns with PPHN not supported with ECMO have an average sensorineural handicap rate of 23% [62–65, 67–70].

At 5 years of age, 50% of children supported with ECMO as neonates had a normal neurologic outcome as defined by lack of a developmental delay, epilepsy, or cerebral palsy [41, 48, 50, 53–60, 71, 72]. The disabilities of the remaining children fall on a spectrum with most being mild to moderate. Consistent with ICH complications, low gestational age and low birth weight were significantly associated with a negative neurologic outcome. At discharge home, most ECMO neonates will exhibit signs of general CNS depression, including lethargy, hypotonia, and weak primitive reflexes, an indication of moderate hypoxic ischemic encephalopathy. By 4 months of age, ECMO infants typically function in the normal range, though residual hypotonia and asymmetry persists in about 25%. Severe

neuromotor are found in approximately 10–15% of affected individuals and by age three, learning disabilities, particularly with language and perceptual functioning appear [37, 73–75].

The increased morbidity and mortality of low birth weight and gestational neonates supports the theory that factors present prior to a course of ECMO are the cause of negative neurologic outcomes rather than ECMO itself. The pre-ECMO diagnosis correlates with poor cognitive development. At 2.5 years, children with CDH who underwent ECMO were at greater risk of having an abnormal cognitive status as compared to non-CDH ECMO survivors [58].

Seizures, both clinical and electroencephalographic, occur in 20–70% of EMCO neonates [76–79]. Neonatal seizures are associated with neurologic disease and poorer long-term outcome, including cerebral palsy and epilepsy [80]. According to one study, the handicap rate following neonatal seizures is 8% [81]. Abnormal EEG are predictive of developmental delay. Only 18% of ECMO infants with normal EEGs have developmental delays; 35% with one abnormal EEG and 58% with two or more abnormal EEGs [77].

Reconstruction of carotid artery post-ECMO ligation and cannulation remains controversial. ECMO infants post carotid artery ligation compared to those with right common artery reconstruction show no significant differences in neurodevelopmental delays [82, 83]. An additional study of neonates with CDH supported by ECMO showed a 72% incidence of occluded or highly stenotic right common carotid artery, following reconstruction at 2 years of age. Similarly to previous studies, there was no significant difference in neurologic development when compared to controls [84].

21.9 Summary

Since 1974 the role of ECMO in the treatment of neonatal respiratory and cardiac failure has been clearly established. During that time, new methods of medical management have allowed many infants to recover without ECMO, yet numerous babies still benefit. As knowledge has been garnered and disseminated through the ELSO registry and centers gained experience and data, neonatal selection criteria and indications have been elucidated. Any patient with reversible cardiopulmonary disease meeting criteria should be considered. ECMO is an excellent supportive modality after the failure of medical therapy with a proven reduction in mortality. The selection criteria maximize neonatal survival while minimizing unnecessary ECMO for irreversible disease.

Congenital Lung Malformations

22

Emily R. Christison-Lagay and Peter C. Kim

Abstract

The development of the foregut, including the division of the esophagus from the tracheobronchial tree and the patterning and differentiation of the pulmonary anlage remains incompletely understood. Nonetheless, the last decade has made remarkable progress toward developing a more sophisticated model of the dynamic interactions of endoderm and mesoderm that give rise to the tracheobronchial tree, lung, and esophagus. Congenital cystic lesions such as congenital pulmonary airway malformation (alternatively congenital pulmonary adenomatoid malformation) (CPAM), bronchopulmonary sequestration (BPS), bronchogenic cysts, foregut duplications, and congenital lobar emphysema (CLE) arise from discrete perturbations within this interaction.

Keywords

Pulmonary sequestration • Congenital pulmonary airway malformation Congenital pulmonary adenomatoid malformation • Congenital cystic adenomatoid malformation • Congenital lobar emphysema • Foregut duplication

22.1 Introduction

The development of the foregut, including the division of the esophagus from the tracheobronchial tree and the patterning and differentiation of the pulmonary anlage remains incompletely understood. Nonetheless, the last decade has made remarkable progress toward developing a more sophisticated model of the dynamic interactions of endoderm and mesoderm that give rise to the tracheobronchial tree, lung, and esophagus. Congenital cystic lesions such as congenital pulmonary airway malformation (alternatively

congenital pulmonary adenomatoid malformation) (CPAM), bronchopulmonary sequestration (BPS), bronchogenic cysts, foregut duplications, and congenital lobar emphysema (CLE) arise from discrete perturbations within this interaction.

Historically, most cystic pulmonary lesions were discovered postnatally in the first weeks to months of life when they became infected or caused obstructive symptoms; now, however, they are diagnosed with increasing frequency by sonography during routine prenatal care. This early diagnosis not only provides an opportunity for improved prenatal surveillance, perinatal care, and a more comprehensive understanding of postnatal natural history, but also has posed some dilemmas surrounding the management of asymptomatic, incidentally discovered lesions whose behavior over time remains incompletely understood [1, 2].

22.2 Embryology

The human respiratory tract and primitive foregut begins development between 3 and 4 weeks of gestation and undergoes six separate stages: the embryonic stage (4–7 weeks), the pseudoglandular stage (5–17 weeks), the canalicular stage (16–26 weeks), the saccular stage (24–38 weeks), the alveolar stage (36 weeks to 2 years of age), and the microvascular maturation stage (birth to 3 years of age) [3].

Following the completion of gastrulation, the endoderm begins a complex reorganization to form the primitive respiratory and gastrointestinal tracts. Tracheal and lung bud precursors derive from different populations of cells. It is the lung buds that generate the bronchi and respiratory tree. Dynamic interactions of the endoderm (which will become the epithelium of the trachea, bronchi, and alveoli) with its surrounding mesoderm (which will give rise to muscle and cartilage) influence the location and pattern of branching. Paratracheal mesoderm inhibits branching while parabronchial mesoderm induces and supports the process. Aberrations in this process can lead to abnormal tracheal branching or the pulmonary agenesis [4].

More than 50 molecules have been implicated in lung morphogenesis. The process begins with the establishment of gradients of fibroblast growth factor (FGF) and FGF receptor mediated signaling that induce expression of the transcription factor Nkx 2.1 (thyroid transcription factor 1, TTF1) during the fourth week of gestation. The zone of expression of Nkx2.1 marks the future location of the thyroid gland and site of the midline laryngotracheal groove, the cranial extent of the respiratory system [4, 5]. Caudal extension of this groove forms the rudimentary trachea. The transcription factors T-box 4 and 5 (TBX4, TBX5) along with retinoic acid and its conjugate receptors RARα and RARβ induce FGF10 and transforming growth factor beta (TGFβ) stimulate lung bud development and initiate branching. Deficiencies in retinoic acid (vitamin A) and RAR signaling have been implicated in pulmonary agenesis, diaphragmatic hernia, lobar agenesis and tracheoesophageal fistula [6]. FGF-10 acts a tropic stimulus for epithelial cell proliferation while the secretion of BMP-4 initiates branching morphogenesis in the apical epithelial cells. Just beyond the elongating branch tip, sonic hedgehog (shh) stimulates mesenchymal proliferation and induces TGFβ1 which helps to stabilize the growing matrix and provides feedback inhibition of shh and FGF10. This inhibition allows at the tip allows epithelial proliferation lateral to the expanding bud to promote further branching. Subsequent formation of epithelialized ducts involves such molecules as Hoxb5 (larger bronchioles) and epimorphin (respiratory bronchioles and alveoli) [7]. Furthermore, the precisely controlled expression and interaction of the integrin family of transmembrane receptor proteins with E-cadherin and extracellular adhesion proteins such as laminin, fibronectin, and tenascin C contribute to tissue stability and homeostasis and organ morphogenesis [8].

22.3 Etiology and Animal Models of Cystic Lung Lesions

Because of the complexity of lung and foregut development, the spectrum of congenital cystic lung lesions likely results from innumerable local perturbations of the normal pattern of embryonic development. Studies of human resected CPAM

and BPS tissue have found that both Hoxb5 and an aberrant isoform of α2-integrin levels are abnormally increased [8, 9]. TTF1 and FGF9 overexpression and FGF7 underexpression have also been implicated in CPAM development without concomitant changes in FGF10 or FGFR2 expression [10]. Microarray analysis of resected CPAM specimens identified Clara cell marker 10 (CC10) and fatty acid binding protein 7 (FABP-7) to be much higher than in age matched controls, although any putative mechanism for their roles in lung dysmorphogenesis remains purely speculative [11]. Most authors feel that sequestrations arise from anomalous lung buds dorsal to the normal lung bud between the fourth and eighth week of gestation [12].

Animal models have found that overexpression of FGF7, 9, and 10 is associated with abnormal pulmonary morphogenesis and the development of cystic lung malformations [13–16]. Induced expression of the transcription factor Sox2 has also been shown to result in pulmonary cysts, "bronchialization" of alveoli, and "muscularization" of the airways and vasculature [17]. The adriamycin-induced model of foregut malformation also demonstrates abnormal lung budding with frequent anomalous connections between the respiratory and GI tract [18]. Recent research has noted increased platelet derived growth factor PDGF-B gene expression and protein production in in utero rapidly expanding CPAMs compared to normal lung or term CPAM specimens [19].

22.4 Prenatal and Neonatal Diagnosis and Imaging

The routine use of antenatal ultrasound has increased the frequency of prenatal diagnosis of congenital lung lesions. CPAM and BPS are now often sonographically diagnosed between 20–24 weeks gestation. Following diagnosis, antenatal surgical opinion is commonly sought. Most CPAM and BPS may be expectantly managed with planned term delivery followed by neonatal intervention if clinically warranted. It is not unusual for lesions identified during the second trimester to decrease in size over the remainder of gestation with some resolving altogether [20, 21]. The mechanism for this regression is not completely understood. One possibility is that the lesions outstrip their blood supply and involute. Another possibility is that the lesions decompress through small communications with the normal adjacent lung. Management of lesions which appear to regress is a source of controversy and will be discussed in detail below [22]. In the context of cystic lung lesions, the presence of nonimmune hydrops is the most important indicator of fetal distress and is strongly correlated to the incidence of fetal demise [23, 24]. Polyhydramnios, mediastinal shift, and a low fetal lung to thorax ratio are also markers for poor outcome [25]. A minority of CPAM cases present with antenatal fetal distress or with neonatal respiratory compromise. More commonly, infants with prenatally diagnosed CPAMs who do not undergo resection during infancy, present later in childhood with infectious complications.

Antenatal sonographic features of CPAM depend upon the size of the associated cysts. Multiple cystic lesions greater than 5 mm in diameter appear as an hypoechoic mass, microcystic lesions tend to be echogenic. Extralobar sequestrations tend to appear as well-defined, hyperechoic, homogeneous lesions similar to the appearance of a microcystic CPAM. In this case, the identification of a systemic blood supply can be crucial in making an appropriate diagnosis. MRI can be a useful adjunct to better delineate "hybrid" cases with features of both CPAM and BPS.

Subdiaphragmatic (intraabdominal) extralobar sequestration may appear as an echogenic suprarenal mass with a systemic blood supply and may be confused with a neuroblastoma or mesoblastic nephroma. Fetal adrenal neuroblastomas are frequently cystic, a feature which may be helpful in interpreting prenatal sonography [26]. On antenatal ultrasound, it is impossible to distinguish intrathoracic intralobar from extralobar sequestration.

An anteroposterior and lateral chest X-ray (CXR) is the often the first obtained postnatal imaging of CPAM and BPS. The lesions can be obscured by atelectasis or pneumonia if present. A CPAM most commonly appears as a radiolucent area on CXR. Large CPAMs and BPS can cause

mediastinal shift or esophageal displacement on barium swallow. Extralobar sequestrations are typically small and difficult to detect on CXR, they may be appreciated on chest or abdominal ultrasound to work up other organs. Intralobar sequestrations may appear as a triangle-shaped mass in the base of the lung. An air-fluid level may be present, suggesting either bronchial communication in hybrid lesions or the congenital bronchopulmonary foregut malformation (CBPFM) variant (see below). The latter diagnosis can be confirmed through demonstration of a communication of the pulmonary cyst with the esophagus or stomach by barium swallow. Ultrasound is the best screening tool. Sequestrations appear as echo-dense lesions on either side of the diaphragm with an identifiable systemic blood supply. CT imaging best defines the type of cystic lesion and its associated anomalies, although MRI is superior to CT in identifying systemic blood supply.

22.5 Congenital Pulmonary Airway Malformations

Congenital pulmonary airway malformations (CPAM), previously referenced in the literature as congenital cystic adenomatoid malformations (CCAM) are hamartomatous lesions of the lung characterized by terminal bronchiolar proliferation into cysts of various sizes (Fig. 22.1a). They are the most common congenital cystic lesions of the lung accounting for approximately 30–40% of developmental lung bud anomalies with an historically reported incidence of 1:25,000–1:35,000 live births [2, 27]. This is likely a substantive underestimation of true incidence. Macroscopically CPAMs appear as a multicystic intrapulmonary mass. Cysts are typically localized to a single lobe, with lower lobes more frequently affected than upper lobes and an equivalent left-right distribution. Bilateral disease is rare and is more likely to result in con-

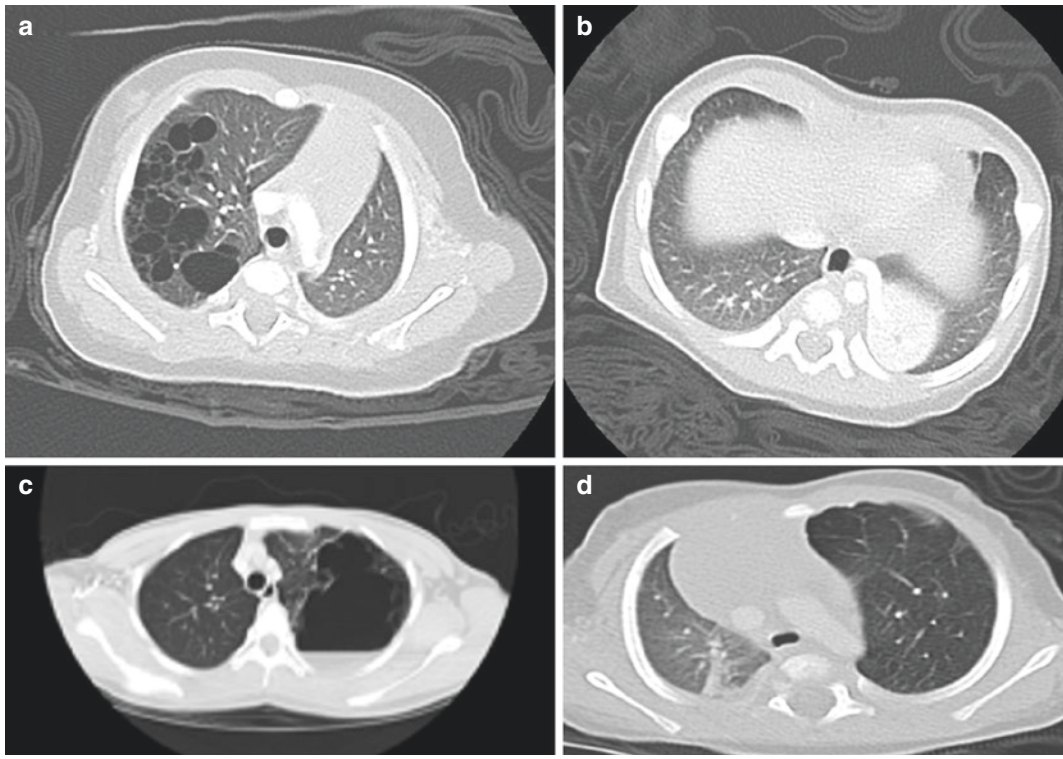

Fig. 22.1 (**a**) Right lower lobe CCAM; (**b**) left lower lobe pulmonary pleuroblastoma; (**c**) left lower lobe extralobar sequestration with a large aortic feeding vessel; (**d**) congenital emphysematous lung with left hyper lucent lung field is shown

genital high airway obstruction syndrome (CHAOS) [24]. Cysts can range in size from less than a millimeter to greater than 10 cm. Although many cystic lung lesions have been loosely encompassed under the moniker of CPAM, microscopically, CPAMs can be distinguished from other cystic lung lesions by five characteristics:

(1) Increased deposition of smooth muscle and elastin within the cyst wall, (2) the absence of cartilaginous remnants within the mass itself, (3) the presence of polypoid mucosal projections into the cyst, (4) the presence of mucus secreting cells with the cyst walls, and (5) a lack of associated inflammation [28]. CPAMs are not commonly associated with other congenital or genetic anomalies, although infants who are stillborn with CPAMs reportedly have a higher incidence of associated abnormalities including heart, renal, and neural tube defects as well as facial dysmorphia [2].

The historical classification of CPAM by Stocker based upon postnatal lung resections or autopsy results of stillborn infants divided the lesion into three types: macrocystic (Stocker I), microcystic (Stocker II), and solid (Stocker III) [28]. More recently this classification has been expanded to include tracheobronchial dysgenesis (type 0) and distal acinar dysgenesis (type 4, with an accompanying change from Roman to Arabic numbering) to encompass the complete spectrum of pathologic airway malformations extending from tracheobronchial to distal acinar malformations (see Table 22.1 and Fig. 22.2) [29]. Type 1 lesions account for the majority of cases (50–65%) and consist of a single or multiple large cysts surrounded by smaller cysts and compressed pulmonary parenchyma. The epithelium of larger cysts is pseudostratified and ciliated, while smaller cysts are lined by cuboidal to columnar epithelium [2, 29]. Type 2 CPAM are characterized by small cysts (0.5–2 cm) lined by cuboidal epithelium with an underlying fibromuscular layer. Occasionally, associated chromosomal or developmental anomalies may be seen with a Type 2 lesion. Type 3 lesions are rare (<10% of postnatal cases). They are often mixed solid-cystic adenomatous lesions, although on gross examination they appear solid. On histologic examination, the lesion resembles immature lung with an absence of bronchi. Cuboidal epithelial cells line irregular airway-like structures surrounded by alveolar ductules and saccules. Large type 3 lesions can exert a mediastinal

Table 22.1 Expand stocker classification of CPAMs

Stocker classification	Anatomic description
0	Acinar agenesis
I	Macrocystic (>5 mm)
II	Microcystic (<5 mm)
III	Solid
IV	Mixed solid-macrocystic

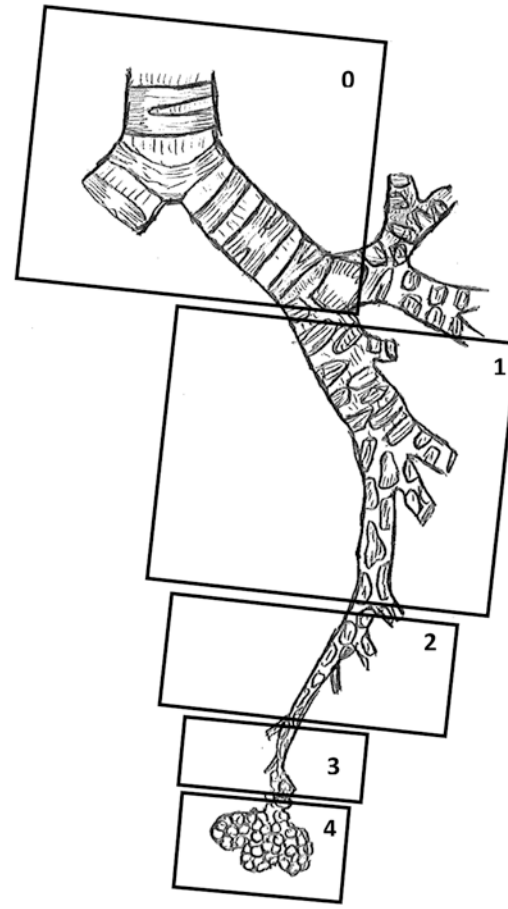

Fig. 22.2 Stocker reclassification of CPAMA based upon the presumed site of development of the malformation. 0 = tracheobronchial, 1 = bronchial, 2 = bronchiolar, 3 = bronchiolar/alveolar, 4 = distal acinar

mass effect causing contralateral lung hypoplasia or hydrops. Type 0 lesions are rare and are incompatible with life. Infants present with cyanosis at birth. There is an associated incidence of cardiovascular abnormalities and dermal hypoplasia [2]. Type 4 CPAMs are found 10–15% of the time and presents as a hamartomatous malformation of the distal acinus. Large thin-walled cysts are found peripherally and are lined by type I and II pneumocytes. They most closely approach Type I lesions and were previously classified as such.

Stocker's initial classification of CPAM reported a stillborn rate of 14%. Of those infants surviving to birth, approximately 80% presented with symptoms of infection or respiratory distress in the perinatal period through the first month of life [30]. Pulmonary hypoplasia in this population can contribute to cardiorespiratory compromise. Presentation later in childhood is rare, accounting for fewer than 10% of all presentations. Pulmonary hypoplasia is not a feature of these lesions which most commonly present with recurrent or persistent pneumonia, but may also present with lung abscess, pneumothorax, failure to thrive, and malignant transformation [2].

While Stocker's initial classification also attempted to attach prognostic value to these subtypes, clinically, it may be more practical to divide CPAMs on the basis of cyst size into macrocystic (>5 mm) and microcystic (<5 mm) categories. Macrocystic lesions tend to communicate with proximal airways and may lead to early air-trapping as the cysts fill but do not empty and compress adjacent normal lung. On the other hand, when diagnosed prenatally, it is rare for them cause hydrops. They are generally asymptomatic at birth and become symptomatic as amniotic fluid is exchanged for air. Microcystic and solid CPAMs are associated with anatomic abnormalities of the tracheobronchial tree including bronchial atresia and stenosis. They are more frequently associated with prenatal hydrops and pulmonary hypoplasia. It is the complications of hydrops and hypoplasia rather than the type of lung lesion alone that determine prognosis.

22.5.1 Prenatal Management and Fetal Surgical Considerations

Large fetal lung lesions can affect fetal development in several reproducible ways. Esophageal compression can cause polyhydramnios. Vena caval and cardiac compression results in fetal hydrops and death. While all prenatally diagnosed lung lesions should be approached with gravitas, they have a variable natural history. Approximately 15% of prenatally diagnosed CPAMs and up to 70% of BPS shrink during late gestation [31]. Several authors report complete sonographic regression [32, 33]. Crombleholme, Adzick and colleagues have developed a formula for the prediction of the development of fetal hydrops which uses a ratio of CPAM volume normalized against fetal head circumference [34]. CPAM volume is estimated as (length × width × height × 0.52). A cystic adenomatoid malformation volume ratio (CVR) greater than 1.6 is predictive of a greater than 80% chance of the development of hydrops. CVR reaches a plateau at approximately 28 weeks of gestation. For fetuses less than 28 weeks, twice weekly US surveillance is recommended to assess for hydrops. For fetuses with CVR <1.6, surveillance can be done weekly. Hydrops in this group occurs less than 2% of the time. An exception to this rule can occur in the event of a single dominant cyst. Such a cyst is at risk for acute enlargement and consideration should be given to shunt placement in if the CVR is less than 1.6.

Options for fetal intervention include shunt placement and resection. Fetal thoracentesis used as solo therapy is ineffective for treatment because of rapid reaccumulation of cyst fluid but it may serve as a temporizing measure prior to definitive therapy [35]. CPAMs presenting with a dominant large cyst without a solid component may undergo shunt placement. Successful delivery near term is possible in 75–80% of fetuses undergoing shunt placement with fetal loss occurring in approximately 10% [36]. Shunt placement prior to 20 weeks GA may result in an increased risk of chest wall abnormalities [37].

For patients with CVR >1.6 demonstrating evidence of hydrops, the firstline treatment of choice is a course of maternal steroids (betamethasone or dexamethosone) which has been shown to limit CPAM growth and diminish hydrops [38, 39]. Only after this option has been unsuccessful should any fetal intervention be entertained. Options for fetal intervention include shunt placement and resection. Fetal thoracentesis used as solo therapy is ineffective for treatment because of rapid reaccumulation of cyst fluid but it may serve as a temporizing measure prior to definitive therapy [35]. CPAMs presenting with a dominant large cyst without a solid component may undergo shunt placement. Successful delivery near term is possible in 75–80% of fetuses undergoing shunt placement with fetal loss occurring in approximately 10% [36]. Shunt placement prior to 20 weeks GA may result in an increased risk of chest wall abnormalities [37].

Open fetal surgery is an option at specialized centers for fetuses with microcystic CPAMs, a normal karyotype and no other abnormal anatomy on fetal sonography. Survival in the Children's Hospital of Philadelphia (CHOP) series is reported as 13 of 24 cases with resolution of hydrops at 1–2 weeks following resection, restoration of the mediastinum to midline and compensatory in utero lung growth [1]. In this series the majority of fetal deaths (6 of 11) occurred intraoperatively after the delivery of the mass from the chest. Maternal morbidity has been low and mostly related to uncomplicated wound infections. Occasionally, progressive hydrops can result in the "maternal mirror syndrome" in which illness in the fetus is reflected in the condition of the mother. Progressive symptoms of pre-eclampsia including vomiting, hypertension, peripheral edema, proteinuria and pulmonary edema can occur [40]. The only successful treatment of the mother is delivery of the fetus.

If significant respiratory distress is anticipated at birth, the Ex Utero Intrapartum Therapy (EXIT) procedure utilizes "placental bypass" during thoracotomy and lobectomy and may be considered in centers equipped to perform it.

22.5.2 Postnatal Management and Surgical Considerations

It is generally assumed that surgical resection is the management of choice of most pediatric surgeons today for symptomatic congenital cystic lesions. The management of asymptomatic lesions, however, is a clinical conundrum without broad consensus. The traditional argument favoring early resection cites avoidance of the long-term risk of pulmonary infection, an increased operative ease in the non-infected field, the potential benefit of long term compensatory lung growth and avoidance of the potential difficulty and expense of long-term patient follow-up. An opposing view is taken by surgeons who cite that operation on an asymptomatic patient poses significant and potentially morbid risks without clearly defined benefit. One study found that 10% of perinatally diagnosed patients undergoing excision of an asymptomatic CPAM experienced perioperative complications [31]. Moreover, several studies have suggested that resection of a complicated CPAM is not associated with any significantly higher morbidity than elective resection of an asymptomatic CPAM (although other studies have come to the opposite conclusion) [20]. Nor is there any definitive data suggesting that pulmonary function is improved in patients undergoing early resection (allowing a greater opportunity for compensatory growth) than later [21, 41].

More recently evidence has emerged that the risk for malignancy within the population of children with radiographically diagnosed CPAM may be higher than historically suspected. There is a known association between bronchoalveolar carcinoma and rhabdomyosarcoma and CPAM with over 25 case reports documented in the last three decades [42–45]. Ozcan reported 33 cases of primary pulmonary rhabdomyosarcoma; nearly 50% of these had cystic lung malformations and a quarter were associated with CPAM [46]. Furthermore, malignant transformation has been observed in incompletely resected CPAM [47]. Perhaps most concerning and convincing are the recent reports suggesting that

radiographic imaging is unable to accurately differentiate CPAM from pleuropulmonary blastoma (PPB) a high grade malignancy associated with a poor prognosis in advanced stage disease with little observed efficacy of adjuvant chemo- or radiotherapy (Fig. 22.1b) [22]. In our recent retrospective analysis of 129 CPAM resections, we identified three patients (2.3%) who had pathologically confirmed but clinically unsuspected PPB at the time of surgical resection [20, 22]. When counseling families at our institution, we approach discussion of the management of asymptomatic CPAM with these findings and now recommend surgical excision over expectant management. Patients who had previously elected to be followed conservatively are also now informed of these new recommendations.

22.5.3 Surgical Approach

The surgical approach to CPAM resection is by either open posterolateral thoracotomy or, more recently, a video assisted thoracoscopic (VATS) approach at 2–6 months of age to avoid neonatal anesthesia. The two techniques offer similar results and have a similar complication profile. Cosmesis, post-operative pain relief, and hospital stay is improved with VATS which is typically accomplished through the use of three or four 3–5 mm port sites. One of these must be enlarged sufficiently to extract the specimen from the thoracic cavity. A chest tube is typically left in place and may usually be removed on the first postoperative day.

The objective of surgical management is complete surgical excision of the entire cystic lesion. Most frequently this is performed via segmentectomy or lobectomy, very rarely it requires pneumonectomy [22, 48, 49]. If the CPAM involves adjacent lobes, lobectomy can be used to excise the principal lesion with segmentectomy reserved for the less involved lobe. In general, pneumonectomy should be avoided as it can lead to disabling respiratory symptoms and long-term complications including chest wall deformity, scoliosis, and abnormal systemic venous return [50]. Postoperative pulmonary function is excellent and infants are at no increased risk for respiratory infection than other children. If an infant has a significant degree of pulmonary hypoplasia, many centers encourage prophylaxis against RSV during the first year of life [2].

22.6 Bronchopulmonary Sequestration

Sequestrations are benign pulmonary lesions characterized by a lack of direct bronchial communication to the tracheobronchial tree and by a systemic blood supply. They are classified on the basis of the presence of a pleural covering. An intralobar sequestration is contained within the substance of the adjacent lung tissue while an extralobar sequestration is enveloped in its own pleural lining and is anatomically separate from the pulmonary parenchyma. The reported prevalence of sequestrations ranges form 0.15–1.8% in the general population, and intralobar sequestration is reported three times as commonly as extralobar sequestration in most series [51]. Both intra- and extralobar sequestrations are more commonly located on the left, and an extralobar sequestration may be located within the chest, within the muscle of the diaphram, or in a subdiaphragmatic position (Fig. 22.1c) [52]. Extralobar sequestrations are three times as common in males [2]. Rarely, the entire lung can be an extralobar sequestration. Approximately 80% of BPS have an aortic arterial supply, although other, and sometimes multiple, systemic sources have been reported. Venous drainage of extralobar sequestrations is typically into the systemic circulation, but up to 25% of extralobar sequestrations drain into the pulmonary circulation. In contrast, almost all intralobar sequestrations drain into the pulmonary venous system. While most BSP are asymptomatic, a few may present with respiratory symptoms, cardiac failure, infection, hemoptysis, or in conjunction with other congenital anomalies including congenital diaphragmatic hernia (CDH), cardiac and musculo-skeletal abnormalities, and

enteric duplications. Developmental abnormalities are much more commonly associated with extralobar than intralobar sequestration. Five to fifteen percent of infants with CDH have an associated extralobar sequestration [53]. Intralobar sequestration is more likely to present in older children with symptoms related to compression of adjacent, atelectatic lung or by infection secondary to inadequate drainage of secretions from the sequestered lung.

Although traditionally considered a different pathological and clinical entity from CPAM, BPS and CPAM can present as a hybrid anomaly with histologic features of a CPAM (most commonly a Stocker 2 or solid lesion) but a systemic blood supply [54–56]. As the process of tracheobronchial differentiation, budding, and branching is a complex one with the necessary synchronization of multiple elements, it is not altogether unexpected that patterning anomalies may overlap. Further complicating the nomenclature and easy separation of cystic lesions by pathology, a new term has been invented to define rare extralobar or intralobar sequestrations that communicate with the esophagus or stomach. These anomalies are termed congenital bronchopulmonary foregut malformations (CBPFM) and they are classified into four types according to their location and the level of communication between the alimentary tract and the tracheobronchial tree [57]. These lesions are more often located on the right side and have with equal gender distribution. Often there are associated congenital anomalies of the VACTERL spectrum, most commonly tracheoesophageal fistula/esophageal atresia and skeletal anomalies.

Like CPAM, the mass effect of BPS can cause fetal hydrops through cardiac and vena caval compression. Moreover, it has been speculated that shunting between a systemic arterial supply and the pulmonary venous drainage of a BPS may cause high-output cardiac failure and nonimmune hydrops [58]. Fetal mortality reaches 100% in untreated hydrops and 80% in fetuses who have significant pleural effusions [59, 60]. Placement of thoracoamniotic shunts improves outcome. Rarely BPS can cause esophageal or gastric compression resulting in polyhydramnios. Polyhydramnios can cause preterm labor and BPS associated with polyhydramnios has a survival rate of only 30% [61]. The role of reduction amniocentesis in the setting has yet to be defined.

With the prenatal sonographic identification of sequestration, a comprehensive sonographic survey and fetal echocardiography should be performed to attempt to identify any associated anomalies. Prior to consideration of fetal intervention, fetal karyotype must be performed. Fetuses with hydrops presenting after 30 weeks of gestation are candidates for preterm delivery while those less than 30 weeks may be considered for fetal intervention at specialized centers. Fetuses with large sequestrations that are not causing hydrops should be referred to a tertiary care maternal-fetal unit with the facilities for aggressive neonatal resuscitation and access to urgent surgical intervention. Large pleural effusions mandate emergent tube thoracostomy [1].

Neonates with respiratory symptoms should undergo urgent surgical resection. The arterial supply to the sequestration requires special attention. In up to 20% of cases, arterial supply comes from a branch of the infradiaphragmatic aorta. Loss of control of this blood vessel with subdiaphragmatic retraction can result in uncontrolled hemorrhage. It has also been reported that as many as 60% of right sided intralobar sequestrations may have scimitar syndrome in which the pulmonary veins drain into the vena cava [61]. Care must be taken not to inadvertently ligate the main branches of the pulmonary vein and therefore cause venous congestion of an entire lobe or ipsilateral lung.

Resection of asymptomatic sequestrations is generally advocated to prevent the later development of infection or hemorrhage (rare). Some surgeons elect to follow intraabdominal BPS citing the absence of any respiratory benefit and the rare instances of infection. The challenge remains with regard to inconvenience and methodology of follow up and persisting question of differential diagnosis in ruling out any tumorous lesions.

22.7 Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) is thought be a form of bronchomalacia in which dysplastic bronchial cartilage allows passage of air during inspiration but collapse during expiration leading to lobar hyperinflation (Fig. 22.1d). More rarely a similar picture may result from extrinsic compression from a vascular ring formed by abnormal pulmonary vessels or a large patent ductus arteriosus, or endobronchial obstruction from inspissated mucus. A third of cases remain idiopathic.

On prenatal ultrasound, CLE appears as an echogenic lesion without evidence of systemic blood supply. Fetal lung fluid trapping within the affected lobe may cause second trimester expansion of the lesion. Some cases of CLE regress during late gestation and become sonographically indistinguishable from normal fetal lung [62]. Despite sonographic regression, these lesions can still cause postnatal air-trapping and should be followed clinically.

The most dramatic presentation of CLE occurs when lobar hyperinflation causes compression of the normal ipsilateral lung and mediastinal shift leading to cardiorespiratory collapse. Emergency thoracotomy is lifesaving and the involved lobe often extrudes through the thoracotomy incision upon opening the pleural space. Less dramatically, CLE presents with increasing tachypnea progressing to ventilator dependence. A plain chest radiograph often demonstrates a hyperlucent lobe with mediastinal shift and compressive atelectasis of the contralateral lung. Resection of the involved lobe is curative and allows for restoration of mediastinal contents to the midline, lung reexpansion, and compensatory ipsilateral lung growth. Occasionally, CLE is detected radiographically and remains clinically silent. In this instance, a trial of expectant management may be appropriate, keeping in mind that the dysplastic bronchial cartilage may not allow normal clearing of secretions and the involved lung may be at increased risk of pneumonia.

Acquired emphysematous changes and parenchymal cysts may also result from long-term ventilator dependence of poorly compliant, premature lungs. If these changes cause mass effect then surgical management may be appropriate, with the caveat that most infants with acquired emphysema have marginal pulmonary function and may not tolerate resection. With time and growth of the child, most acquired changes resolve spontaneously.

22.8 Bronchogenic Cysts and Foregut Duplication

Bronchogenic cysts, foregut duplication cysts, and neurenteric cysts likely represent various presentations of aberrant patterning of the foregut anlage. These bronchopulmonary foregut malformations classically feature (1) a well-developed coat of smooth muscle, (2) a mucosal epithelial lining of either gastrointestinal or respiratory origin, and (3) an intimate attachment to some portion of the foregut [63]. Hybrid lesions with both respiratory and gastrointestinal epithelium and attachments have been described. Presentation may vary and depends upon the organ of origin and anatomic location of the malformation as well as the presence of mass effect or infection [64]. Newborn infants can present in respiratory distress secondary to bronchial obstruction or compressive mass effect of adjacent lung. In an older child, lesions are frequently detected on imaging conducted to evaluate nonrelated symptoms. Gastrointestinal duplications may have islands of acid secreting gastric mucosa leading to ulceration and hemorrhage.

Bronchogenic cysts are the most common cystic malformation of the mediastinum and are most commonly located near the carina or right mainstem bronchus although there are case reports of bronchogenic cysts presenting in the neck, pericardium, pulmonary parenchyma and intra-abdominally [65]. Histologically they have well defined wall of fibroelastic tissue, muscle and cartilage lined with ciliated respiratory epithelium. Often they share a wall with the tracheobronchial tree or esophagus, occasionally they arise as a saccular diverticulum off the airway and in this case may present with an air-fluid

level on imaging. Peripheral lesions are more likely to have a communication with the tracheobronchial tree and typically present with distal bronchial obstruction and pneumonia. More commonly however, a bronchogenic cyst appears as a spherical non-attenuating mass with Hounsfield units greater than water on CT. Once identified, bronchogenic cysts should be surgically resected via lateral thoracotomy or thoracoscopy due to their potential to become infected, or to present subsequently with obstruction or hemorrhage. Malignancy arising in a bronchogenic cyst has been reported in rare instances [66]. Care must be taken during the surgical dissection to avoid damage to any shared bronchial or esophageal wall. A direct communication can be ligated or repaired.

Most foregut duplication cysts are intrathoracic. Presentation may be indistinguishable from a bronchogenic cyst and is often secondary to mass effect. Compression of adjacent structures may cause respiratory (stridor, wheezing, cough, or cyanosis) or gastrointestinal (vomiting, dysphagia, obstruction) symptoms [64]. Gastric mucosa is found in approximately 30% of esophageal duplications and may cause hematemesis [67]. Imaging options include ultrasonography which may identify anterior duplications or be helpful in fetal imaging, CT, or contrast esophagogram. The latter may also help determine whether there is any communication with the esophagus and assist in surgical planning [68]. Like bronchogenic cysts, foregut duplications should be resected given their potential to present with secondary complications.

Neurenteric cysts are the least common of the foregut malformations. They are associated with vertebral anomalies (including scoliosis, hemivertebrae, and spina bifida) [64]. As with other congenital foregut malformations, an exact embryologic defect leading to the development of neurenteric cysts has yet to be uncovered, however it is commonly attributed to either a failure of normal separation of notochord and foregut or to aberrant herniation of foregut endoderm into the dorsal ectoderm [69]. Urgent surgical excision is indicated as complications include meningitis and paraplegia. Cystic communication into the spinal canal presents surgical challenges which must be addressed by a multidisciplinary team of pediatric surgeons and neurosurgeons. All children with posterior mediastinal masses should have adequate visualization of the spinal cord and canal. MRI is the preferred modality because of its ability to precisely define intraspinal anatomic relationships [68]. Surgical management often includes laminectomy or laminotomy with simultaneous surgical and neurosurgical excision of the cyst [63, 70].

Conclusion

Congenital pulmonary malformations comprise a clinically heterogeneous group of developmental anomalies with an overall favorable prognosis associated with expedient diagnosis and resection. Increasing evidence supports a role for early resection of asymptomatic lesions by experienced surgeons, which may often be accomplished safely through minimally invasive techniques.

Esophageal Atresia and Tracheo-Esophageal Fistula

23

Paul D. Losty

Abstract

Surgery for esophageal atresia (EA) is regarded as one of the greatest landmarks in newborn surgery. Advances have now led to greater than 95% survival for EA babies managed in the current era with much interest now focusing on health outcome(s), morbidity and quality of life (QoL) of survivors. Classical operation with muscle sparing thoracotomy, axillary skin crease incision and minimally invasive surgery offer a selection of management strategies for the pediatric surgeon and enthusiast alike. Debate continues with regard best practice and expert management of pure [long-gap] esophageal atresia without fistula, medical vs surgical treatment of gastro-esophageal reflux disease (GER), therapies for anastomotic stricture and tracheomalacia. Developmental biology and molecular genetic studies provide fascinating insight into the etiology of EA—TEF, with many key contributions emerging from animal models sharing striking similarity to the human phenotype.

surgeon and enthusiast alike. Debate continues with regard best practice and expert management of pure (long-gap) esophageal atresia without fistula, medical vs surgical treatment of gastro-esophageal reflux disease (GER), therapies for anastomotic stricture and tracheomalacia. Developmental biology and molecular genetic studies provide fascinating insight into the etiology of EA—TEF, with many key contributions emerging from animal models sharing striking similarity to the human phenotype [2, 3].

23.2 History

The history of EA-TEF is well documented in the literature [2, 3]. First survivors were not recorded until 1939 with Leven and Ladd achieving success with staged esophageal repair. Cameron Haight (an American surgeon working at Ann Arbor, Michigan) is credited with the first successful primary repair and survival of a 12 day old female newborn. Success in the UK followed with Franklin (1947) based at Hammersmith Hospital London, Denis Browne (1948) at Great Ormond Street Hospital For Sick Children, London and subsequently Peter Paul Rickham (1949) working at Alder Hey Children's Hospital Liverpool. By the 1980s pediatric surgery units in the developed world were achieving spectacular outcomes notably 85–90% survival with mortality falling to less than 10% defining the modern era of care [2].

23.3 Classification

In 1929 Vogt proposed an anatomical classification for EA and TEF based on radiology and post-mortem findings [4]. A variety of surgical classifications were thereafter suggested as treatment became more successful, the most frequently deployed system being that attributed to Gross [5]. The most detailed classification, however, is credited to Kluth and incorporates all the described anatomical variants of EA and TEF [6]. A working classification based on the frequency of each specific anomaly is of greatest practical value to the surgeon (Fig. 23.1).

23.4 Risk Categorization

Waterston's seminal paper describing the influence of pulmonary disease, birth weight and associated congenital anomalies on outcome of newborns with EA-TEF provided important contributions in the development of prognostic scoring systems [7]. Advances in neonatal intensive care have now rendered the Waterston classification outdated. In 1994 Spitz et al. proposed a new risk grading system based on birth weight and presence or absence of congenital heart disease that is widely applicable to the modern era [8] (Table 23.1). A Montreal classification places greater emphasis on preoperative ventilator dependence and associated major anomalies as survival determinants [9]. Many studies have recorded the negative influence of respiratory distress syndrome and pneumonia on outcome(s) with the burden of aspiration events contributing to morbidity and late death following operative repair [10, 11]. Variant anatomy also features as risk factor(s) for determining favourable outcomes. Babies with 'long gap' or 'pure' EA without fistula experience a high morbidity from anastomotic leak, stricture, fundoplication rate(s), 'failure'/'re-do' operations and esophageal replacement [10–12].

23.5 Epidemiology

In Liverpool and Mersey the incidence of EA and TEF is approximately 1 in 3300 live births [13]. Incidence varies widely across the world, e.g. 1 in 2440 Finland [14] to 1 in 4500 in Australia [15] and USA [16]. Sex ratio has been quoted as equal by many authors but some publications also refer to a male preponderance [17]. EA and TEF is more common in twin pregnancy. Exposure to teratogenic drugs during pregnancy has been implicated, these include thalidomide, progesterone and estrogens [18].

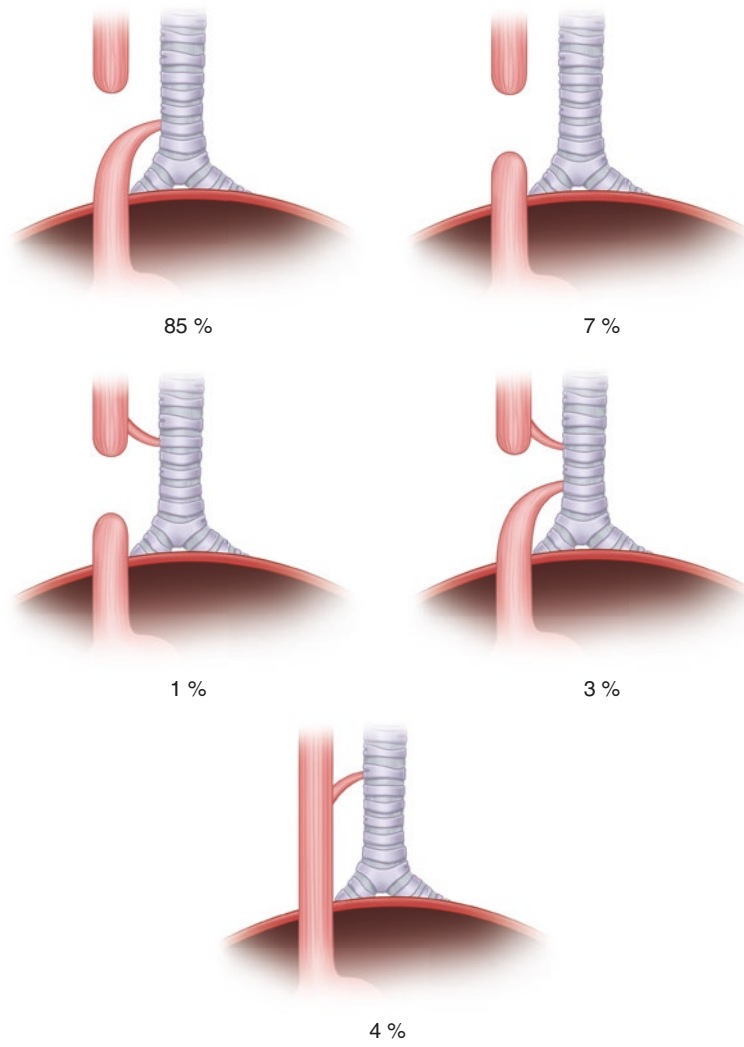

Fig. 23.1 Classification and frequency of esophageal atresia and tracheo-esophageal fistula. EA and distal TEF—85%; Isolated EA—7%; H-type TEF—4%; EA with proximal and distal fistulas—3%; EA and proximal fistula—1%

Table 23.1 Spitz prognostic classification scoring system [8]—Survival related to birth weight and congenital heart disease (CHD)

Group	Survival (%)
I birth weight > 1500 g without major CHD	97%
II birth weight < 1500 g or major CHD	59%
III birth weight < 1500 g and major CHD	22%

23.6 Genetics

Reports of familial cases of EA-TEF suggests a polygenic hereditary etiology. The best estimate of risk of recurrence for parents of a single affected child is 0.5–2.0%, rising to 20% if another sibling is born with EA. The vertical transmission risk is 3–4% [19]. A 10% incidence of non-specific chromosomal abnormalities (translocations, deletions and duplications) is recorded. Edwards syndrome (trisomy 18) and Down's (trisomy 21) are associated with the EA TEF phenotype. Recognition of a syndrome suggestive of a major chromosomal abnormality in EA and TEF should prompt urgent involvement of a clinical geneticist before corrective surgery is undertaken. EA-TEF has also been described in association with Feingold syndrome (autoso-

mal dominant), Holt–Oram syndrome, DiGeorge sequence, polysplenia, and in babies with Pierre Robin anomaly [19].

23.7 Animal Models

Contributions to understanding the embryology and genetic control of foregut development have evolved from laboratory research involving animal models of EA and TEF. The adriamycin rodent model was developed by Juan Tovar and colleagues in Madrid [20]. Timed pregnant rodents administered adriamycin (doxorubicin) in the prenatal period on gestational days 8 and 9, yield offspring with an EA-TEF variant phenotype [20]. These animals also have VACTERL spectrum anomalies—*v*ertebral, *a*norectal, *c*ardiac, *t*racheo-*e*sophageal, *r*adial/renal and *l*imb defects [21]. A murine model of the VACTERL syndrome has also been generated in mice with targeted deletions of the transcription factors Gli-2 and Gli-3 for the Sonic hedgehog (Shh) gene—pivotally linked with axial organogenesis. Gli-2−/−Gli-3−/−double mutants demonstrate the full phenotypic spectrum of VACTERL syndrome thus confirming a crucial role for Shh in genetic control of foregut development [21, 22].

23.8 Embryology

There is no unifying embryological theory which successfully explains all the anatomical variants of EA and TEF. In the developing embryo the ventral aspect of the primitive foregut is destined to become the tracheo-bronchial tree. A median laryngotracheal groove develops in the ventral aspect of the foregut of the 23 day old embryo. As the groove elongates with the growing esophagus it is postulated that lateral epithelial ridges fuse to bring about foregut septation. Whilst explaining the possible origins of tracheo-esophageal cleft and H type variant EA fistula, caudo-cranial separation of the ventral trachea from the dorsal esophagus by a mesenchymal tracheo-esophageal septum clearly cannot adequately explain all variants of EA-TEF.

The findings of an increased number of tracheal rings and a longer trachea in the adriamycin rodent model of EA-TEF, suggests localized abnormal proliferation and elongation of the ventral respiratory component of the common foregut tube. The preferential incorporation of tissue into the trachea may also result in esophageal discontinuity. The association of 13 pairs of ribs with long-gap TEF has also been postulated to strengthen the argument that abnormal forces, in this case hyper-somatization, results in a relative deficiency of tissue which is then preferentially absorbed into tracheal development at the expense of the esophagus [23].

Additional work in the adriamycin model has also shown that the notochord is implicated with signalling activity to determine the fate(s) of neighbouring cell populations. Shh protein, which is expressed in notochordal tissue is believed to be pivotal in this dynamic process [24]. Shh stimulates cell proliferation and inhibits apoptosis, via intermediary HOX gene expression. Shh binds to the cell surface protein 'Patched' (Ptc), which is upregulated by Shh, and thus limits the inductive capabilities of Shh. Ventral misplacement of the notochord may also result in an abnormal diffusion gradient for Shh and a localized imbalance of proliferation and apoptosis in the primitive foregut.

23.9 Associated Anomalies

Associated anomalies occur in over 50% of newborns with EA and TEF [2, 25, 26]. Although some of these are relatively insignificant, a high proportion can be life threatening contributing directly to the morbidity and mortality of this condition. The assessment of the newborn with EA-TEF should therefore be prioritised with some urgency to address social, ethical and surgical strategies relating to the co-existent anomalies. The incidence of co-existent anomalies appear to be highest in babies with EA without fistula and infants with oro-facial cleft defects [27]. Patients born with EA-TEF have a higher incidence of prematurity than that seen in the

normal healthy population. Congenital heart disease (27%) is the commonest co-morbid condition having the greatest impact on survival. Aortic arch anomalies occur frequently with 'long gap' EA-TEF variants. Other malformations include urogenital (18%), skeletal (12%), anorectal (12%) and gastrointestinal defects (9%) most notably duodenal atresia. The spectrum of associated anomalies encountered in 581 EA patients treated at Alder Hey Children's Hospital over four decades is shown in Table 23.2.

The VATER association [27, 28], now better referred to as the VACTERL sequence is defined by the presence of three or more anomalies. In a study from Liverpool, VACTERL associations were recorded in 19% of cases [26]. CHARGE association refers to—*C*oloboma, *H*eart disease, *A*tresia choanae, *R*etarded development, *G*enital hypoplasia and *E*ar deformities with deafness. EA-TEF is also apparent in the SCHISIS sequence—exomphalos, neural tube defects, cleft lip palate and genital hypoplasia [29–31].

Interestingly babies with EA and TEF have a higher than expected incidence of hypertrophic pyloric stenosis [32]. The almost universal association of gastro-esophageal reflux with EA may lead to delay in diagnosis if gastric outlet obstruction is not suspected from pyloric stenosis. Tracheomalacia of a variable severity is present in EA cases although the full spectrum of associated tracheo-bronchial and pulmonary abnormalities deserves closer scrutiny. Significant anatomical tracheo-bronchial variant anomalies can be seen in 47% of infants undergoing bronchoscopy [33]. Pulmonary agenesis, foregut duplication cysts, congenital cystic adenomatoid malformations, and sequestered lobe have all been described in association with EA and TEF. Other rare foregut pathology such as laryngotracheo-esophageal cleft and congenital esophageal stenosis may coexist with EA and TEF.

Table 23.2 Abnormalities associated with EA-TEF—Alder Hey Liverpool (1953–1997) [26]

Anomaly	1953–1997 (581 cases)
Cardiac	154 (27%)
Urogenital	105 (18%)
Skeletal	71 (12%)
Vertebral	64 (11%)
Anorectal	67 (12%)
Gastrointestinal	53 (9%)
Palate/Laryngotracheal	44 (8%)
VACTERL	25 (19%)

23.10 Antenatal Diagnosis

Fetal diagnosis is now possible in cases of EA and TEF [34]. This may be clearly advantageous, as delivery can be planned at or near a specialist centre with full neonatal surgical capability. Counselling by a skilled multidisciplinary team (obstetrician, paediatric surgeon, neonatologist) is essential. A careful search/screen for associated chromosomal or cardiac anomalies is important. The identification of a chromosomal abnormality may have potential implications for termination of pregnancy. Antenatal diagnosis of EA should theoretically reduce the likelihood of inadvertent newborn feeding and aspiration pneumonitis. Despite potential advantages of antenatal diagnosis, it is important to note that fetal sonography selects an 'at risk' group with a significantly worse prognosis [35–37]. Perinatal mortality (excluding termination of pregnancy) in a study from Newcastle, UK was reportedly 21% [35]. The classical sonographic features of EA and TEF in the fetus are absence of the stomach bubble and associated polyhydramnios [36]. Prenatal detection rates may vary widely in fetal medicine centres (9–24%). There is a high rate of false positive scans with almost 50% of all suspected cases on fetal ultrasound scanning later proven not to have EA after birth [35].

23.11 Clinical Presentation

Newborns with EA have difficulty clearing saliva. Episodes of coughing, choking and cyanosis may be witnessed shortly after delivery. Early attempts to feed an infant will result in respiratory distress. Diagnosis is confirmed by failure to advance a nasogastric tube into the stomach. A characteristic resistance is felt at the blind ending upper esophageal pouch and the tube cannot be introduced into the stomach. A plain X-ray film

Fig. 23.2 Chest X-ray film of newborn with EA and TEF. Nasogastric tube is coiled in the blind-ending upper esophageal pouch. Gas filled intestinal loops below the level of the diaphragm confirms the existence of a distal TEF

Fig. 23.3 Case of 'pure' EA without fistula. The nasogastric tube is lying in the upper esophagus pouch. Absence of air-filled abdominal intestinal loops suggests that there is no distal communicating esophageal fistula

should include the chest and abdomen demonstrating the nasogastric tube coiled in the upper pouch. The TEF is confirmed by the presence of gas-filled intestinal loops below the diaphragm (Fig. 23.2). In isolated or pure EA without fistula a featureless gasless abdominal X-ray is observed (Fig. 23.3). The presence of a double bubble on the abdominal plain film is highly suggestive of associated duodenal atresia (Fig. 23.4). A careful and thorough search for co-existent anomalies is essential specifically here also checking for imperforate anus. The cardiovascular system should be examined to exclude a major congenital heart defect whose treatment in some cases may take a higher priority over correction of the EA defect.

Having established a diagnosis of EA TEF intravenous fluids are started and a Replogle sump suction catheter inserted into the upper esophageal pouch to permit continuous suction of salivary secretions [38]. The infant should be nursed in a supine or lateral position. Arrangements should then be made for early newborn transfer to a specialist neonatal surgical unit. Surgery is best performed within the first 24 h after birth in an otherwise healthy baby, as pneumonitis is an ever-present risk from aspiration of saliva and reflux of gastric contents through the lower pouch TEF.

On admission to the newborn surgical unit, the infant should be fully re-examined and radiology reviewed. The X-ray study may be repeated with gentle downward firm pressure on the Replogle tube. On rare occasions a fine nasogastric tube may coil in the baby's oropharynx who has an otherwise normal patent esophagus. The successful

Fig. 23.4 EA and TEF with duodenal atresia. Nasogastric tube coiled in upper pouch. 'Double-bubble' appearance confirms duodenal atresia

passage of a Replogle tube into the stomach will prevent erroneous diagnosis and an unnecessary operation! When EA is diagnosed in the newborn an estimation of the length of the blind upper esophageal pouch seen on plain X-ray film can give the surgeon some useful clues as to the ease (or difficulty) of a primary anastomosis. Echocardiography should be performed before undertaking surgery as this will alert the surgeon and anesthetist of an underlying heart defect that may adversely influence prognosis and may importantly dictate operative approach by identifying the laterality of the aortic arch. Blood should be obtained for cross-match and a hematological and biochemical profile sorted preoperatively. Broad-spectrum antibiotics should be administered and intravenous fluids continued. Other investigations—whole-spine X-rays, renal and cranial ultrasonography can be deferred until after surgery. Contrast studies of the upper pouch to identify a rare upper pouch fistula have been superseded by preoperative bronchoscopy.

23.12 Surgical Management

Surgery for esophageal atresia is best usually performed in the stable newborn as a scheduled procedure during normal working hours [39]. Emergent operation in the middle of the night rarely benefits the baby unless the surgeon is confronted with a 'high risk' scenario, i.e. a ventilated patient with respiratory distress and gastric distension which indicates impending perforation. Here urgent transpleural thoracotomy with fistula ligation is life saving (see later). Most surgeons also like to perform bronchoscopy when planning elective repair of EA and TEF. We deploy flexible miniature bronchoscopy with scopes that can be steered through the endotracheal tube. Bronchoscopy allows precise confirmation of diagnosis and in most cases will demonstrate a common variant fistula just proximal to the carina. Occasionally the fistula may be seen arising at the level of the carina or higher in the main airway or from one of the main bronchi. Where possible a careful and thorough search should also be made to exclude a rare co-existent upper pouch fistula. The larynx should be examined to exclude a laryngotracheo-esophageal cleft lesion.

Following bronchoscopy the infant is positioned for operation. In the classical operation, a right thoracotomy is planned with the baby secured in a lateral position, with the right arm raised across the head so that the scapula can be easily manipulated (Fig. 23.5). The surgeon may find a working headlamp and optical loupe magnification greatly facilitate operation. A curved skin crease incision is made 1 cm below the angle of the scapula with a muscle sparing thoracotomy.

Bianchi has described an axillary skin crease incision, which gives excellent cosmesis, which we increasingly deploy at Alder Hey (Fig. 23.6) [40]. A retractor is used to lift the scapula off the chest wall and the ribs are counted down from the

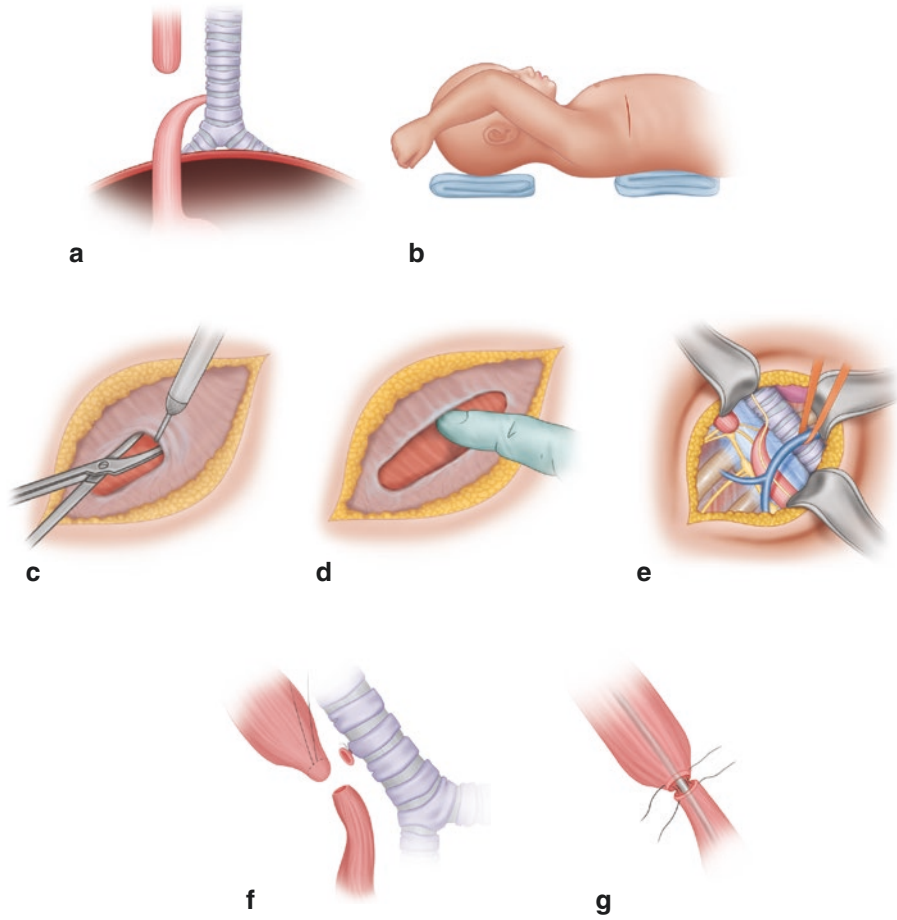

Fig. 23.5 (**a**) Operation EA TEF most frequent anomaly. (**b**) Newborn in lateral position with location of skin incision indicated. (**c**) Exposure of intercostal space with division of overlying muscles. (**d**) Gentle stripping of parietal pleura from chest wall to aid develop extrapleural space. (**e**) Operative field—lung with pleural membrane have been retracted medially. The azygos vein is easily visualized. Blind proximal esophageal pouch and the TEF fistula with distal esophagus and vagal fibers are seen lying on its exposed surface. (**f**) TEF fistula ligated and divided flush with trachea. (**g**) Lateral and posterior esophageal sutures in place and transanastomotic tube fed across anastomosis distally towards the stomach

Fig. 23.6 Axillary skin incision in newborn some weeks after EA–TEF repair

second interspace. The thorax is entered through the fourth intercostal space with a blunt haemostat and bipolar diathermy separating the intercostal muscles to the level of the parietal pleura. The pleura is gently freed from the inner aspects of the rib cage to then facilitate an extra-pleural dissection and locate the TEF. This procedure is best usually commenced with moist pledgets and having developed the correct plane may be continued by inserting a moistened gauze swab into the extra-pleural space sweeping the pleura away

from the chest wall superiorly and inferiorly. Exposure is improved by introducing a Finochettio rib retractor. Great care is required with the dissection as it is particularly easy to create a pleural tear in the anterior aspect of the incision. If a significant pleural tear occurs during the dissection it is wise to open the pleura widely converting to a transpleural approach. The practical advantages of an extra-pleural over transpleural approach, include the possibility of avoiding chest drain insertion, and in the event of an esophageal anastomotic leak, the potential containment of any leak/soiling within the extra-pleural space. The extra-pleural exposure is achieved and completed by retracting the posterior mediastinal pleura forwards with a malleable retractor until the azygos vein is clearly visualized as it enters the superior vena cava in the depths of the wound.

The azygos vein is mobilized and controlled with vascular sloops. The author advocates temporary occlusion of the vein before ligation, as venous return to the heart may rarely be critically dependent on the azygos system. Provided this maneuver does not affect cardiac output, the azygos vein may be safely ligated and divided as it enters the superior vena cava. Alternatively some surgeons elect to preserve the azygos vein [41]. Once divided, the site of the TEF fistula communication between the trachea and the distal esophagus is usually apparent. Having confidently identified the distal esophagus, a vascular sloop is carefully passed around it. Traction on the sloop controls the fistula and enables its junction with the trachea to be located precisely. Although it is possible to suture ligate the fistula, the author prefers to divide the fistula in stages and apply interrupted 5-0 or 6-0 monofilament prolene sutures to the tracheal component of the fistula. The distal esophagus is secured with a stay suture. The integrity of the TEF repair is checked by instilling saline into the thoracic cavity and requesting the anesthetist to exert positive airway pressure to ensure that no air bubbles leak from the suture line. Rarely difficulty can be encountered in locating the distal esophagus, and it is quite possible to mobilize the descending aorta in the erroneous impression that it is the esophagus. The surgeon should recognize the distal esophagus by following the vagus nerve as it courses distally, and by observing its rhythmic distension with ventilation.

Attention is focused on the upper pouch—a bulbous structure—which is identified by requesting the anesthetist to push firmly on the Replogle tube. The upper pouch should be secured with a transfixion suture which can be driven through the Replogle tube and becomes useful then for traction. Bipolar diathermy is ideal for mobilising the upper pouch which should proceed upwards to the thoracic inlet unless the gap separating the esophageal segments is short. Dissection of the tissue plane between the upper pouch and airway requires great care to avoid injury to the trachea. With adequate mobilization of the upper pouch it is usually possible for the surgeon to judge whether a primary anastomosis is feasible. In most cases of EA with distal TEF a primary anastomosis is achieved although occasionally considerable tension is required to complete repair.

To undertake primary anastomosis the upper pouch is opened at its most distal extremity. The posterior wall of the anastomosis is commenced by placing two 5-0 or 6-0 PDS sutures through all layers of the lateral margins of the distal esophagus, taking great care to avoid excessive tissue handling and trauma with fine forceps. Sutures are completed by including all layers of the corresponding aspect of the upper pouch taking mucosa so that the knots comes to lie on the inside. Additional posterior wall sutures are inserted. All sutures are individually tied drawing the esophageal ends together commencing first with the laterally placed sutures. Having completed the posterior wall of the anastomosis, a 6–8 Fr. fine bore nasogastric tube (TAT tube) is passed by the anesthetist through the infant's nostril to the suture line, where it is grasped by the operating surgeon and carefully positioned distally along the lower esophagus into the stomach. The anterior layer of the anastomosis is completed by placing sutures with knots lying on the outside. When the gap defect length proves wide primary anastomosis may be facilitated by creating a Livaditis (1969) myotomy on the upper

pouch or with an esophageal flap as described by Gough. Anastomosis created under tension require a chest drain. For straightforward extrapleural primary EA TEF repair a chest drain may be unnecessary [42]. Ribs are loosely approximated with absorbable pericostal sutures and closure of the chest wall/skin then performed. A chest drain (if present) should be attached to under-water drainage. The baby is transferred to the intensive care unit for ventilatory support and postoperative monitoring. Should additional surgical pathology be present, such as duodenal atresia or imperforate anus, these should be dealt with accordingly under the same anesthetic in the stable infant.

23.13 Upper Pouch Fistula

Rarely the surgeon may also encounter a coexistent upper pouch fistula (1%–2% cases). Clues here to alert the surgeon of a 'second' upper pouch fistula are finding a short upper pouch more adherent than usual to the normal plane of dissection with the airway. Once identified the fistula tract should be divided carefully and repaired with 5-0 or 6-0 interrupted nonabsorbable prolene sutures on the tracheal airway side. The esophageal tissue defect is closed with 5-0 or 6-0 interrupted absorbable PDS sutures. Surgery then proceeds as discussed earlier to complete oesophageal atresia primary repair. Upper pouch fistula may well go unrecognised and become only evident on a postoperative esophogogram study which some surgeons routinely undertake to evaluate the primary anastomosis. Recurrent chest infections and aspiration on oral feeding in the early weeks after primary repair provide clues here also. A prone dynamic tube contrast esophography study performed in the radiology department may help localise the upper pouch fistula. If the lesion appears to be in a proximal location beyond the thoracic inlet a cervical approach (see H fistula later) may be indicated to achieve repair. The author here recommends NG tube feeding the infant and delaying the repair of the 'second fistula' for a number of weeks to allow time for the thoracic primary anastomosis to fully heal.

23.14 Long-Gap EA with Distal TEF

The surgeon will encounter situation(s) where the gap between the upper pouch and the distal esophagus is clearly too wide to permit primary anastomosis after division and repair of the TEF fistula having fully mobilized both the proximal and distal esophagus. Under such circumstances, it is probably wise to proceed to cervical esophagostomy as a 'spit stoma' and feeding gastrostomy, accepting the need for esophageal replacement surgery at a later date [2].

23.15 Right-Sided Aortic Arch

The optimum surgical strategy for management of babies with EA TEF and a right-sided aortic arch (RAA) is widely debated. The anomaly is most often undetected preoperatively and surgeon decision making to safely undertake EA TEF repair is required at thoracotomy. The incidence of RAA in association with EA is 1.8%–2.5% [43, 44]. Chest X-ray may provide some clues. Preoperative echocardiography is at best 20% accurate in identifying this anomaly [43, 44]. If the surgeon's suspicion remains high, magnetic resonance imaging should be arranged for definitive diagnosis. If a right-sided arch is identified from preoperative studies, experience from specialist centers advocate left side thoracotomy. The presence of RAA with right side thoracotomy does not preclude a successful anastomosis but the procedure is significantly more challenging as evidenced by a 42% leak rate reported from Great Ormond Street Children's Hospital, London [45]. A trial dissection with operative repair of the TEF with right thoracotomy is acceptable and feasible [46]. When the surgeon encounters significant difficulty left thoracotomy is advised to achieve esophageal anastomosis with division of the fistula through the right or left chest as circumstances dictate.

23.16 Premature Infant with RDS

In premature often very low birthweight (VLBW) babies with lung immaturity, emergency surgery is vital when ventilation is markedly compromised by the TEF with abdominal distension and diaphragmatic splinting. The surgical priority here is urgent ligation of the fistula deploying a transpleural thoracotomy to rapidly locate the TEF. Should the infant's condition stabilize sufficiently after TEF repair, primary anastomosis of the esophagus may then be appropriate. Otherwise delayed repair of the esophagus is undertaken when the baby is physiologically stable at a later date. Sudden deterioration with gastric wall perforation is also a 'high risk 'event in these fragile VLBW babies. In such situations, emergent ligation of the fistula is life-saving. Needle paracentesis to relieve tension pneumoperitoneum with laparotomy, repair of the stomach perforation and feeding gastrostomy should follow [47, 48].

23.17 Postoperative Care

Babies should be nursed in the intensive care unit following repair of EA TEF. Weaning from ventilation need not be unduly prolonged in the stable infant with a satisfactory anastomosis. Where the anastomosis is under considerable tension, elective paralysis and ventilation for a period of 3–5 days is practised [49]. It must be conceded however, that there is no strong evidence to support the claim that this technique favorably influences anastomotic healing [50]. There is some experimental data indicating that the level of tension in the anastomosis correlates with the severity of GER [51]. It is the authors practice to commence all patients on H_2-antagonists (e.g. ranitidine) as prophylactic therapy in an effort to reduce the risks of anastomotic stricturing potentiated by GER. A contrast esophagogram is optional at the discretion of the surgeon after 5–7 days to evaluate the anastomosis, although major anastomotic leaks are clinically evident before this time. Minor 'radiological' leaks may be noted on postoperative contrast studies. These are almost always of no clinical significance and do not preclude the infant from being offered feeds [52]. In most cases TAT tube feeding can be commenced after 48 h, and slowly increased as tolerated by the infant.

23.18 Surgical Management of Isolated ('Pure') Esophageal Atresia

The diagnosis of isolated EA without fistula (pure esophageal atresia) is confirmed by the inability to pass a nasogastric tube together with a featureless 'gasless abdomen' on plain film radiology (Fig. 23.3). The absence of intestinal gas below the diaphragm does not always however completely exclude the presence of a distal fistula, as a small proportion of babies may have a thin fibrous like connection between the lower pouch and the trachea, which does not readily permit the passage of air [48].

Surgical management of isolated EA is challenging and open to debate. Many pediatric surgeons consider delayed primary anastomosis of the native esophagus the best approach. This strategy demands meticulous nursing care with regular suctioning of the bind ending upper esophageal pouch, chest physiotherapy and careful attention to nutrition by supervised gastrostomy feeding. A prolonged period of hospitalization (6–12 weeks) is required to achieve this objective. Delayed primary esophageal anastomosis is associated with its own attendant morbidity with further ongoing care required to manage esophageal strictures and significant GER [53, 54]. The desire to preserve the infant's esophagus must be counterbalanced by the humility of knowing when to accept defeat and abandon the esophagus in favor of a replacement procedure. Initial management involves creation of a feeding gastrostomy with attention taken to avoid injury to the small stomach of these vulnerable babies with placement of the G-tube [55]. We do not advocate assessment of 'gap length' at the time of this operation deferring to a later session when the baby is more stable.

After a period of approximately 3–6 weeks, the extent of the gap defect can be assessed

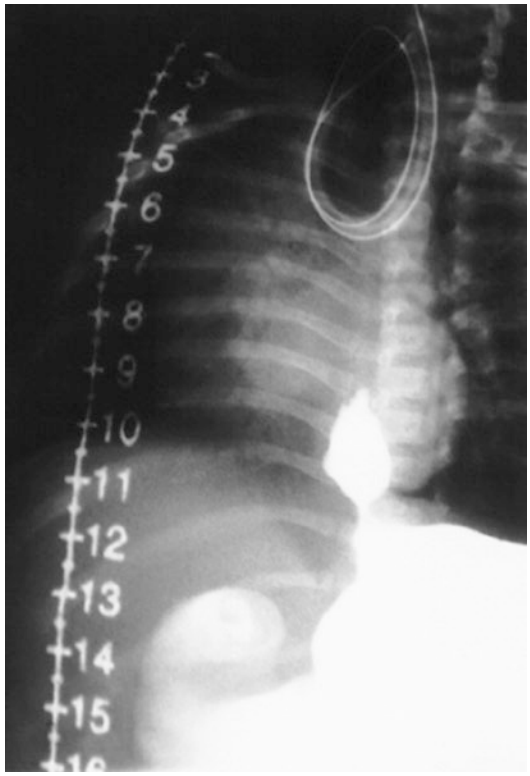

Fig. 23.7 Gap assessment in a case of isolated pure EA. The scale bar represents gap length (cm)

by fluoroscopy (Fig. 23.7). The radiopaque Replogle tube is advanced into the upper pouch and (1) contrast instilled via the gastrostomy or (2) a metal sound introduced through the gastrostomy site directed carefully towards the distal esophageal stump at the hiatus. This procedure can be repeated at 2–3 weekly intervals, to assess whether the ends of the esophagus are sufficiently close together to schedule delayed primary anastomosis [56]. Flexible endoscopy (under general anesthesia) can also be performed after several weeks when the G tube tract site is sufficiently mature to accept passage by steering the 'baby scope' to locate the blind esophageal stump. Images taken 'on table 'likewise provide an accurate gap length assessment with a radiopaque tube placed in the upper pouch. A distance of less than two vertebral bodies separating upper and lower pouches is ideal. However in practical terms there is little to be gained by the surgeon delaying attempts at surgery to reconstruct the esophagus beyond 12 weeks of age.

The operation of delayed primary anastomosis essentially involves the same meticulous approach by the surgeon. It is to be expected that the anastomosis may be created under considerable tension. The upper pouch should be fully mobilised proximally to the thoracic inlet. The distal esophagus is frequently a primitive stump not readily identified at thoracotomy without use of special aids. The surgeon can readily facilitate location of the distal esophageal stump by passing a flexible endoscope via the G-tube tract site towards the esophageal hiatus. A brightly illuminated stump is easily identified in the depths of the thoracotomy wound. A stay suture (5-0 or 6-0 prolene) should be secured on the distal esophageal segment to aid its mobilisation and dissection. Some surgeons still prefer passing metal bougies to identify the distal esophagus. The distal esophagus may be dissected to the diaphragmatic hiatus to help reduce tension on the anastomosis. A Livaditis myotomy or upper pouch flap may also be helpful [57–61]. The author prefers to perform a Livaditis myotomy over the inflated balloon of a Foley catheter passed by the anaesthetist via the mouth to the upper pouch. Extra length can also be obtained by proceeding to laparotomy and creating a lesser curve lengthening procedure as described by Scharli or a Collis gastroplasty [57–63]. If a primary anastomosis is still not possible using these techniques options are then proceed to cervical esophagostomy and schedule an esophageal replacement procedure when the infant is 18 months or older. A decision to convert to an immediate replacement of the esophagus is equally feasible provided the surgeon and team are sufficiently skilled. However caution is advised offering esophageal replacement to very young infants as risks of recurrent pulmonary aspiration are not insignificant in this young age group before walking and upright posture is established. Options for esophageal replacement include—gastric transposition, reverse gastric tube, colon replacement and jejunal interposition [2, 64]. Gastric transposition and colon graft interposition are the most popular operations currently.

Delays in restoring esophageal continuity have significant drawbacks. Firstly, there is the ever-present risk of aspiration pneumonitis, and secondly, the inability to feed the infant via the

normal oral route. Although the child's nutritional needs are met by gastrostomy feeding, the inability to establish oral feeds may lead to long-term aversive feeding behaviour. Spitz has recommended formally assessing the length of the gap when the gastrostomy is initially performed. A gap length > 6 vertebral bodies (6 cm), would prompt him to abandon the esophagus and perform a cervical esophagostomy [64]. This approach of early cervical esophagostomy and delayed esophageal replacement permits early sham feeding, which theoretically promotes neuronal maturation and development of the learning skills needed for feeding and later speech acquisition.

A number of other innovative approaches to the operative treatment of long-gap EA have been described. True primary repair has been performed with reported gap lengths exceeding 5 cm—the hypothesis tested by Foker was that a well-constructed esophageal anastomosis can withstand considerable tension [65]. The value added technique for esophageal reconstruction (VATER) operation involves mobilizing the gastric fundus and performing a limited Thal fundoplication. At thoracotomy the proximal stomach is drawn into the chest and a primary esophageal anastomosis is performed [66]. Staged neonatal colon esophagoplasty has also been described which involves the isolation of a short length of transverse colon based on the ascending branch of the left colic vessels at the time of open gastrostomy [67]. The conduit is positioned transhiatally in the posterior mediastinum to be retrieved at thoracotomy several days later, when continuity is restored.

Several well established operations are available to restore gastrointestinal continuity in long-gap EA, where the infant's own esophagus has been abandoned [64]. Colon replacement was originally popularized by Waterston. The colon conduit may be isoperistaltic (left colon based on the left colic vessels), or anteperistaltic (right colon based on the ileocolic vessels). The colon is best routed via the posterior mediastinum (via the hiatus), or through right or left chest cavities to the neck. Cervical esophago-colon anastomosis are prone to leak. Colon grafts also tend to dilate and kinking is not uncommon due to tortuosity. Respiratory problems are seen due to recurrent aspiration as the new food pipe created with colon is 'non refluxing'.

The stomach may be used to create an esophageal substitute graft. A gastric tube esophagoplasty can be fashioned from the greater curvature of the stomach, based on the left gastroepiploic (ante-peristaltic) or right gastroepiploic arcades (iso-peristaltic) preferentially using the posterior mediastinum as a route to the neck anastomosis. [68] The long suture line both of the tube created and greater curve suture line are susceptible to bleeding and leaking. Reflux is a problem and can predispose to anastomotic stricture formation. However, dilatation and kinking are not encountered with the graft. GER reflux may be controlled by performing a posterior partial wrap fundoplication.

Gastric transposition has been widely popularised by Spitz and has the merit of simplicity [64, 69]. The vascular supply is based on the right gastric and right gastroepiploic vessels, which allows full mobilization of the greater and lesser curvatures. After constructing a pyloroplasty, the stomach is routed through the posterior mediastinum via the diaphragmatic hiatus and the esophago-gastric anastomosis completed in the neck. Leakage from the neck anastomosis is reported in some 12% of cases and strictures requiring periodic dilatation in a similar percentage of patients [69].

Jejunal orthotopic interposition grafting re-emerged as a useful technique for esophageal replacement after the encouraging case series reports from the Netherlands by Klaus Bax and colleagues almost a decade ago [70]. Jejunal grafts do not dilate excessively and retain good peristaltic function which may explain why GER does not appear problematic for some of the patients [70, 71]. Use of jejunum substitutes has declined somewhat in recent years with gastric transposition and colon grafts now the popular choice of many surgeons worldwide today.

23.19 H-Type TEF

H-type TEF comprises 4% of all EA TEF variants [2]. It is perhaps more accurately termed N-type fistula as the track runs obliquely from

trachea to esophagus. Infants with H-type TEF usually present within the first few weeks after birth with a characteristic history of choking with feeds and cyanotic spells. Gross abdominal distension is an occasional presenting clinical feature which we have encountered as the belly 'accumulates wind' from the foregut fistula communication. Older children may have frequent chest infections with recurrent right upper lobe pneumonia(s) due to chronic aspiration.

Diagnosis may be readily established by a dynamic prone video esophagogram (Fig. 23.8). In this study, contrast is injected through a nasogastric tube which is slowly withdrawn from the esophagus. However, H-type fistula(e) may be missed in approximately 50% of contrast studies. Where suspicion remains, bronchoscopy should be scheduled. At bronchoscopy, a size 4 Fr. ureteric catheter is passed through the fistula into the esophagus to facilitate identification during subsequent neck dissection. A nasogastric tube is passed into the stomach, and broad-spectrum antibiotics commenced. A right transverse skin crease incision is marked a finger's breadth above the clavicle, before positioning the neck in extension with a roll placed under the shoulders. The sternomastoid muscle is split with the internal jugular vein and carotid artery mobilise laterally to expose the cervical esophagus and trachea. The ipsilateral recurrent laryngeal nerve should be identified and preserved. Flexible miniature bronchoscopy with a 2.2 mm calibre instrument (Olympus) can greatly aid precise localisation by brightly illuminating the site of the H fistula tract (Fig. 23.9) [72]. The esophagus is dissected at this point and slung with vascular sloops both above and below the fistula tract. Caution should be taken with the dissection as the contralateral recurrent laryngeal nerve is also vulnerable to injury. Traction on the esophagus enables the fistula to be secured with stay sutures. After withdrawing the ureteric catheter (and 2.2 mm bronchoscope if deployed), the fistula is divided and the tracheal component repaired with 5-0 or 6-0 interrupted non absorbable prolene sutures. The esophagus is closed with 5-0 or 6-0 PDS sutures. Some surgeons recommend tissue interposition between esophageal and tracheal suture lines to prevent recurrent fistula.

Fig. 23.8 Tube esophagogram study showing H TEF fistula

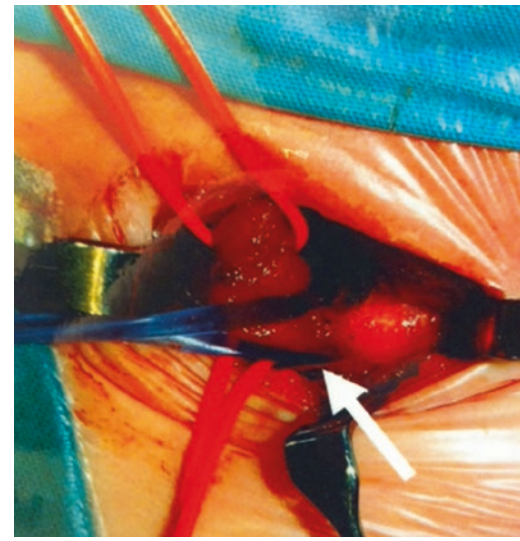

Fig. 23.9 Operative photograph showing a 2.2 mm flexible bronchoscope brightly illuminating a H fistula tract—[fistula marked with *arrow*]. Vascular sloops secure the mobilized esophagus clearly exposing the dissection plane between trachea and esophagus with H fistula

The infant should remain intubated and ventilated in the early postoperative period, as tracheal edema can result in a progressive stridor [73]. The vocal cords should be checked on extubation, given the significant risk of recurrent nerve palsy. Nasogastric tube feeding may commence after 48 h and oral feeds may be slowly introduced thereafter.

The Nd:YAG laser has also been successfully claimed to treat congenital H-type TEF. Repeated short duration pulses of laser light are used to coagulate the fistula [74]. Despite some success with this approach, the technique has not gained widespread acceptance and open repair remains the gold standard.

23.20 EA TEF—Complications and Special Considerations

23.20.1 Anastomotic Leak

The incidence of anastomotic leak following repair of EA and TEF ranges from 11%–21% [48, 75]. This is usually heralded with development of a pneumothorax and salivary drainage from the chest tube. It is rare for the anastomosis to be completely disrupted. Provided a trans-anastomotic tube (TAT) is in place, it is usually possible to control the leak with an adequately sized chest tube. With adequate drainage, broad-spectrum antibiotics and total parenteral nutrition, the esophagus will usually heal, although a prolonged period with a chest tube may be necessary. Some surgeons have used hyoscine patches in an attempt to 'dry up' the salivary leak. Others advocate early re-exploration (<48 h), with direct repair of the esophagus if possible, and the establishment of satisfactory chest drainage where a major leak is suspected [13, 75, 76]. When conservative management fails with uncontrolled sepsis establishment of a cervical esophagostomy and a feeding gastrostomy are essential. The child is then committed to esophageal replacement at a later date. A clinical anastomotic leak may predispose to the development of an esophageal stricture [77]. While this association seems entirely logical others contest such a correlation [75].

23.20.2 Gastroesophageal Reflux Disease—GERD

GER occurs in 40%–50% of babies following repair of EA TEF. GER may cause failure to thrive, predispose to recurrent aspiration episodes, and may lead to esophagitis and stricture formation [2]. Management of symptomatic GER initially requires aggressive medical therapy. Postural therapy and close attention to feeding regimes, with calorie supplementation may prove effective management strategies. Feed thickeners (e.g. Carobel), antacid preparations (e.g. Gaviscon), H_2-antagonists (e.g. Ranitidine), proton pump inhibitors (e.g. Omeprazole), and pro-kinetic agents (e.g. Domperidone), may be used in various combinations if vomiting is significant.

GER may contribute to recurrent pulmonary aspiration with frequent symptoms of respiratory distress including tachypnea, apneic episodes, cyanosis, and X-ray evidence of patchy pneumonic changes. Differential diagnosis in this clinical setting also includes swallowing incoordination, and respiratory distress from significant tracheomalacia. It is not uncommon to see infants in whom all of these factors are operating to a variable degree. It is important not to overlook the possibility of a recurrent TEF or ("double fistula "—see earlier) as a cause of repeated episodes of respiratory distress, although the history of choking and cyanotic episodes during feeding is usually much more evident in infants with a recurrent fistula. The selective use of esophageal pH monitoring, contrast studies, bronchoscopy, and assessment of swallowing by video fluoroscopy, may assist in evaluating the contribution of GER and other allied pathologies to respiratory symptoms. Failure to control GER despite full medical therapy is an indication for fundoplication.

Fundoplication rates following operation for EA vary widely between centers (6%–45%), reflecting the varied enthusiasm for anti-reflux surgery in the clinical setting of GER and esophageal dysmotility [2, 78]. There are several reasons for caution when considering fundoplication in EA patients. Dysphagia may be aggravated as a consequence of underlying foregut dysmotility. Fundoplication after EA repair has a higher failure rate (15%–38%) than is generally observed in otherwise normal healthy children with isolated GER [79]. Some authors recommend a partial wrap (Thal) fundoplication, because of the lower incidence of postoperative dysphagia [78].

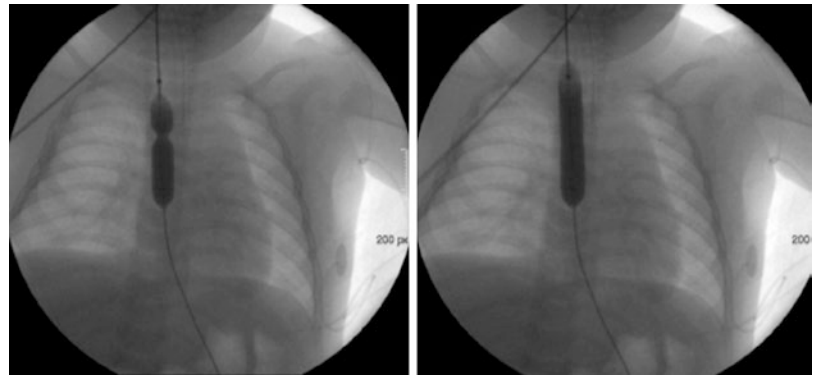

Fig. 23.10 Balloon dilatation of an esophageal anastomotic stricture—'wasting' appearance shows the region of stricture

Despite such concerns, many pediatric surgeons prefer a short (1.5–2.0 cm) 360° floppy Nissen wrap for its proven effectiveness in reducing GER [79]. The high failure rate of fundoplication and the significant complications associated with surgical treatment of GER, warrant careful follow-up in this group of patients.

23.20.3 Anastomotic Stricture

Definitions of esophageal stricture following repair of EA lack uniform consistency. The incidence of symptomatic strictures requiring therapeutic dilatation vary from 37%–55% [52, 77]. Some degree of anastomotic narrowing is invariably seen in all postoperative esophogram studies, but this is rarely of a sufficient degree to cause symptoms in the early period after operation. Parents should be counselled to report symptoms of prolonged feeding, incomplete feeding or associated respiratory difficulty to surgeons. Such symptoms prompt us to arrange surveillance endoscopy to assess the calibre of the esophageal anastomosis. Balloon dilatation is our preferred method of treating symptomatic strictures. The radial dilating forces generated during balloon dilatation are considered to be less traumatic than the longitudinal shearing forces caused by conventional esophageal bougienage [80, 81]. Balloon dilatation is performed under fluoroscopy imaging by passing a guide wire through the stricture over which a balloon dilator of appropriate size is introduced. Its accurate position is confirmed by partially filling the balloon with contrast medium, so that 'waisting' due to the stricture is centrally located with the device (Fig. 23.10). The balloon is then maximally inflated with volumes of dilute contrast to dilate the stricture. A contrast esophagogram is performed after removing the balloon catheter to ensure there has been no injury perforation. Some surgeons deploy steroid injections or mitomycin C to manage esophageal stricture(s). A tailored program of surveillance endoscopy/therapeutic dilatations may thereafter be scheduled for some patients. If a stricture requires frequent dilatation GER should be investigated by upper GI contrast, pH studies and endoscopy. Recalcitrant esophageal anastomotic strictures may require resection and fundoplication.

23.20.4 Tracheomalacia

Tracheomalacia is present to a variable degree in many patients with EA. It is thought to be responsible for the characteristically loud "barking" TEF cough [2]. Infants with severe tracheomalacia demonstrate expiratory stridor, which may result in episodes of desaturation, apnea, cyanosis and bradycardia (often associated with feeding), and life-threatening so-called 'dying episodes'. Tracheomalacia (if severe) may be evident in the early postoperative period when it proves difficult to wean the infant from ventilation.

Tracheomalacia can be assessed by bronchoscopy under conditions of spontaneous respiration. At endoscopy the tracheal lumen is

significantly compressed antero-posteriorly and assumes a narrow slit like appearance during expiration due to tracheal cartilage deficiency. Tracheo-bronchomalacia can extend beyond the carina into the main stem bronchi. As tracheomalacia may be self-limiting, surgical intervention is best indicated for patients with life-threatening symptoms [2]. Treatment options include continuous positive airway pressure (CPAP), aortopexy, tracheostomy and airway stenting [82, 83]. CPAP is a useful temporizing measure, but may be required for several weeks. Aortopexy is traditionally performed by anterior left thoracotomy through the third interspace. The left lobe of the thymus gland is excised to gain access to the root of the aorta taking care not to damage the phrenic nerve. A row of non absorbable pledgetted sutures are placed through the adventitia coat of the ascending aortic arch and then passed to the undersurface of the periostium of the sternum and tied hitching the aorta forwards and thereby relieving compressive forces on the trachea. Although this operation cannot resolve distal tracheobronchomalacia it often provides immediate dramatic symptomatic relief. Failure of aortopexy may be an indication for tracheostomy, although some authors advocate tracheal stenting in this situation [2, 82, 83].

23.20.5 Recurrent TEF

Recurrent TEF is estimated to occur in 5%–15% of cases [84]. Recurrent TEF may result from an anastomotic leak, but the possibility of a missed upper pouch fistula should always be considered. Symptoms include recurrent chest infections and choking attacks during feeding. A high index of suspicion is required if the diagnosis is not to be overlooked. Chest X-ray may sometimes reveal an air esophogram. The initial investigation of choice is prone video esophagography. If this study fails to demonstrate a fistula and the diagnosis remains strongly suspected, combined esophagoscopy and bronchoscopy should be performed. Rigid bronchoscopy is performed initially, and the site of the original fistula carefully examined. The fistula is gently probed with a ureteric catheter and methylene blue dye carefully instilled into the fistula pit. Synchronous flexible esophagoscopy is performed to see if blue dye can be seen entering the esophagus. Should this fail to demonstrate the fistula, an 'air/water test' is a useful supplementary investigation. The esophagus is filled with water and positive pressure ventilation applied to the bronchoscope. Occasionally, bubbles of air can be seen emanating from the fistulous opening into the esophagus.

Several strategies are detailed to manage recurrent TEF. The traditional approach is a formal 're-do' operation via right thoracotomy. At bronchoscopy, an attempt should be made to pass a fine ureteric catheter through the fistula into the distal esophagus. A flexible bronchoscope (2.2 mm—Olympus) may be useful to navigate, cannulate and brightly illuminate the fistula tract. The fistula is repaired using a similar strategy to that deployed for the H-type variant, i.e. isolation/slooping the esophagus repairing the fistula as described earlier. Tissue interposition between suture lines is sometimes advisable in an attempt to reduce the chances of further fistula formation. A 10%–22% risk of re-fistulation has been reported [84]. Other approaches described to treat recurrent TEF include diathermy fulguration of the fistula tract [84]. This technique has also been refined using the Nd:YAG laser to obliterate the epithelial tract communication. Sclerosing agents, Histoacryl, and fibrin glue(s) have all been injected subepithelially to occlude fistulae. A recent review of endoscopic therapies reported an overall success rate of 55% with several sessions required to effect permanent cure. A study from Oxford stated that surgical re-exploration should remain the treatment of choice [85, 86].

23.21 EA TEF Advances

Minimally invasive surgery is now feasible in EA-TEF. Rothenberg reported endoscopic repair in a personal series of eight newborns with EA-TEF ranging in weight from 2.1–3.4 kg. [87] This publication followed the first pioneering operation of EA in a 2 month old infant in 1998. Collaboration from members of the International

Pediatric Endoscopic Surgery Group (IPEG) led to a 2005 outcomes study which evaluated thoracoscopic repair from international centers located in the USA, Europe and Hong Kong [88]. One hundred and four babies with common variant EA and TEF (excluding H-type and long gap without fistula) were included. Of these, there were 5 (4.8%) conversions to open thoracotomy and a staged repair in one baby due to unforeseen long gap EA-TEF. Twelve infants (11.5%) developed early leaks and strictures and 32% required esophageal dilatation(s). Survival in this selected population was 97% with three deaths recorded of which one was directly related to the EA-TEF repair on the 20th postoperative day. Additional operations were required for associated anomalies. These included duodenal atresia repair, imperforate anus surgery, aortopexy and cardiac procedures. Twenty-five babies (24%) also underwent laparoscopic fundoplication for GER. In 2009, MacKinlay (Edinburgh) reported good outcomes in a study of 26 infants—88% survival, 27% leak rate—all minor not requiring operation and 35% acquired strictures needing dilatation(s) [89]. Long term benefits cited from minimally invasive surgery include a reduction in musculoskeletal morbidity notably winged scapula and unsightly skin scarring. MIS repair requires advanced technical skills in endoscopic surgery. For many centers not offering MIS repair, the axillary skin crease incision—(Fig. 23.6) popularised by Bianchi provides an excellent option with good aesthetic outcomes and comparable reductions in skeletal morbidity with all the benefits of classical open repair techniques [40]. MIS EA TEF vs open classical operation continues to remain widely debated in pediatric surgery and is perhaps best reserved for the MIS master enthusiast.

23.22 Quality of Life and Long-Term Outcome

The excellent survival of EA TEF babies born in the modern era has prompted detailed analysis of morbidity with emphasis on long-term outcomes [2, 90]. Several studies have examined respiratory function in EA children [91–94]. Symptoms of asthma and bronchitis are frequent, especially in the young child, and may persist into adolescence. Almost half of all children require future hospitalization due to ongoing respiratory morbidity. In a large Melbourne series comprising 334 EA children, episodes of pneumonia were seen in 31% of children under the age of 5 years, compared with 5% of those over 15 years [91]. The prevalence of annual attacks of bronchitis in these two age groups was 74% and 41%, respectively, with asthmatic symptoms reported in 40% of patients from each age range [91]. Spirometry studies have demonstrated both obstructive and restrictive abnormalities in over half the patients, and a similar proportion had a maximal working capacity below the normal range [92]. Tracheobronchial inflammation and airway narrowing have been demonstrated by bronchoscopy in one-third of patients, with histological evidence of inflammation in a further third [93]. It is plausible that abnormalities of bronchial anatomy, which are common in EA TEF, may contribute to respiratory morbidity. Clinical assessment by a respiratory physician with use of prescribed inhalers to manage reactive airway disease and antibiotics/physiotherapy for chest infections is recommended. The contribution of aspiration episodes, whether due to esophageal dysmotility or GER, to respiratory symptoms, should be actively investigated. Recognition of the long-term respiratory morbidity associated with EA patients, prompted the establishment of a specialist EA TEF clinic at Alder Hey Children's Hospital Liverpool almost 20 years ago staffed by pediatric surgeons, respiratory physicians, physiotherapists and dieticians. This multidisciplinary team approach ensures vigilant health surveillance is focused on all aspects of the child's welfare including the smooth transition to adult medical/surgical services [94, 95].

Esophageal dysmotility is a significant factor in long term patient morbidity [96]. It is clearly implicated in many cases of food bolus impaction when endoscopy reveals no significant anastomotic narrowing. Less severe symptoms of dysphagia have been reported in up to 20% of adolescents [96] and 48% of adults on long term follow up. Esophageal manometry and

fluoroscopy studies will demonstrate degrees of dysmotility in nearly all patients [92]. The dysmotility associated with EA may reflect intrinsic innervation abnormalities of the esophagus [97]. This may further contribute to respiratory morbidity through repeated 'silent' aspiration episodes.

GER may persist into adult life. Symptoms of heartburn and acid brash range from 18% to 50% in long-term follow-up studies [92, 93]. Clinical symptoms may underestimate the true incidence of GER as demonstrated by esophageal pH monitoring. An 8% incidence of Barrett's esophagus has been reported [98, 99]. The relative risks of esophageal cancer developing in the life time of a patient are uncertain though five cases have been recorded in the world literature [100, 101]. These findings further highlight the importance of comprehensive long term adult follow up [95, 102].

Various quality of life (Qol) scoring systems have been deployed to evaluate adult populations treated for EA and TEF. Using the Spitzer Index and a Gastrointestinal QoL Index, it has been shown that adults having primary anastomosis as newborns enjoyed an unimpaired quality of life. Quality of life metrics were also more favourable in patients who had native esophageal repair compared to colonic interposition [90]. Psycho-social studies show more learning, emotional and behavioral difficulties in EA adults than the healthy general population. Cognitive performance(s) were also significantly impaired in a high-risk patient group characterized by associated major congenital anomalies and/or the requirement for prolonged ventilation in the neonatal period [93, 103].

An energetic support group (TOFS)—a UK based charity was founded in 1982 for the benefit of children and parents. The organisation with over 1000 members (www.tofs.org.uk) provides a useful networking group for families together with a valuable handbook—'The TOF Child' [104]. With regular annual conferences attended by health care professionals and families opportunities therefore exist for knowledge exchange and practical advice. TOFS UK also raises valuable funds for research [2]. Similar support networks exist in other European countries, e.g. KEKS, Germany.

Congenital Esophageal Pathology

24

Steven W. Bruch and Arnold G. Coran

Abstract

Congenital esophageal stenosis is an intrinsic stenosis of the esophagus, present at birth, which is caused by congenital malformation of the esophageal wall architecture. Three forms of congenital esophageal stenosis exist: a membranous web or diaphragm occluding the esophageal lumen, fibromuscular hypertrophy of the esophageal wall, and tracheobronchial remnants embedded in the esophageal wall (Nihoul-Fekete et al., Pediatr Surg Int 2:86–92, 1987). The membranous web or diaphragm, the rarest of the three forms, consists of a partially obstructing lesion with an eccentric opening covered on both sides with squamous epithelium. These are located in the mid to distal esophagus. Stenosis due to fibromuscular hypertrophy exhibits normal squamous epithelium overlying a proliferation of smooth muscle fibers and fibrous connective tissue similar to that seen in hypertrophic pyloric stenosis, leading to narrowing in the mid to distal esophagus. This tapering is more gradual than the narrowing seen with tracheobronchial remnants. Tracheobronchial remnants, the most common congenital esophageal stenosis, results from abnormal separation of the esophagus and tracheobronchial tree during embryologic development resulting in cartilaginous remnants ectopically located in the esophageal wall. The narrowing occurs in the distal esophagus, is covered by normal mucosa, and is often abrupt in appearance due to a ring of cartilage in the esophageal wall. The cartilaginous remnants may or may not form a complete ring.

24.1 Congenital Esophageal Stenosis

24.1.1 Introduction

Congenital esophageal stenosis is an intrinsic stenosis of the esophagus, present at birth, which is caused by congenital malformation of the esophageal wall architecture. Three forms of congenital esophageal stenosis exist: a membranous web or diaphragm occluding the esophageal lumen, fibromuscular hypertrophy of the esophageal wall, and tracheobronchial remnants embedded in the esophageal wall [1]. The membranous web or diaphragm, the rarest of the three forms, consists of a partially obstructing lesion with an eccentric opening covered on both sides with squamous epithelium. These are located in the mid to distal esophagus. Stenosis due to fibromuscular hypertrophy exhibits normal squamous epithelium overlying a proliferation of smooth muscle fibers and fibrous connective tissue similar to that seen in hypertrophic pyloric stenosis, leading to narrowing in the mid to distal esophagus. This tapering is more gradual than the narrowing seen with tracheobronchial remnants. Tracheobronchial remnants, the most common congenital esophageal stenosis, results from abnormal separation of the esophagus and tracheobronchial tree during embryologic development resulting in cartilaginous remnants ectopically located in the esophageal wall. The narrowing occurs in the distal esophagus, is covered by normal mucosa, and is often abrupt in appearance due to a ring of cartilage in the esophageal wall. The cartilaginous remnants may or may not form a complete ring. The first description of this disorder was by Frey and Duschel in 1936 when at autopsy they found cartilaginous remnants in the distal esophagus of a 19 year old woman who died with the diagnosis of achalasia [2]. Congenital esophageal stenosis occurs rarely throughout the world with an incidence of one in every 25,000–50,000 live births [3]. In Japan, however, the incidence is higher for unknown reasons [4], with the fibromuscular form appearing more commonly. Most often, congenital esophageal stenosis occurs as an isolated malformation, but in up to 47% of the time it is associated with other congenital anomalies the most common being esophageal atresia with or without a tracheoesophageal fistula [5]. Other common associated anomalies include cardiac defects, intestinal atresias, malrotation, anorectal abnormalities, malformations of the head, face, and limbs, and chromosomal abnormalities, most commonly Down's syndrome [6]. The association between congenital esophageal stenosis and esophageal atresia with or without tracheoesophageal fistula was first described by Dunbar in 1958 [7]. The incidence of this association varies among reports from a low of 0.2% to a high of 14% [1, 8–12]. In a review of 187 tracheoesophageal fistula repairs, 21% of the H-type tracheoesophageal fistulas had an associated congenital esophageal stenosis [13]. The combination occurs often enough that distal esophageal narrowing should be looked for on the post-op esophogram obtained before feeds are started. In fact, many pediatric surgeons pass a tube through the distal esophageal segment before proceeding with an anastomosis in esophageal atresia patients.

24.1.2 Presentation

Children with congenital esophageal stenosis present in one of two ways. 10–20% will be identified on an esophogram obtained after a tracheoesophageal fistula repair [5, 14]. The other children are usually asymptomatic as infants until solid or semi-solid foods are introduced into the diet. They then develop dysphagia, vomiting, and solid food refusal. On occasion, a child with congenital esophageal stenosis will present with respiratory symptoms presumably from aspiration [5], or with foreign body obstruction [3]. In a review of 36 children with congenital esophageal stenosis, the average age at symptom onset was 7.4 months [5]. Since these symptoms occur commonly, there is an understandable delay in diagnosis. In the previous review, the average age at diagnosis was 1.8 years of age.

24.1.3 Diagnosis

With the clinical presentation of dysphagia and vomiting, a contrast study of the esophagus is often part of the initial evaluation. The stenosis is identified, but often attributed to other pathology. The initial thought is often a distal stricture due to reflux. If the symptoms have been more chronic, the proximal esophagus may have dilated making the radiographic picture similar to achalasia. The stenosis is usually in the distal portion of the esophagus just proximal to the gastroesophageal junction. With stenosis due to tracheobronchial remnants there is a thick abrupt narrowing as opposed to a smooth tapering "bird's beak" seen with achalasia, and it is almost always seen in the distal esophagus. The narrowing seen with fibromuscular hypertrophy may be somewhat more proximal but still in the distal esophagus and is a more gradual tapered narrowing as seen in Fig. 24.1. The radiologic picture of a web is a thin constricting band that may be in the mid or even upper esophagus [15]. Often other studies are required to differentiate congenital esophageal stenosis from a reflux stricture, or achalasia. Upper endoscopy with biopsy can be used. The endoscopy will show a distal narrowing with normal appearing mucosa as opposed to the inflammatory mucosa seen with a reflux stricture. The biopsies will not show inflammation with a congenital esophageal stricture. A 24 h pH probe may also help making this distinction. In a child with achalasia, the endoscope will fall through the distal esophagus in distinction to the congenital esophageal stricture which will exhibit significant resistance. More recently, endoscopic ultrasound has been used to assist in the diagnosis and also to distinguish between fibromuscular hypertrophy and tracheobronchial remnants as the type of congenital esophageal stenosis [16].

24.1.4 Treatment

The optimum treatment of congenital esophageal stenosis depends on the type of stenosis present. The membranous web is treated with dilation combined with endoscopic excision of a portion

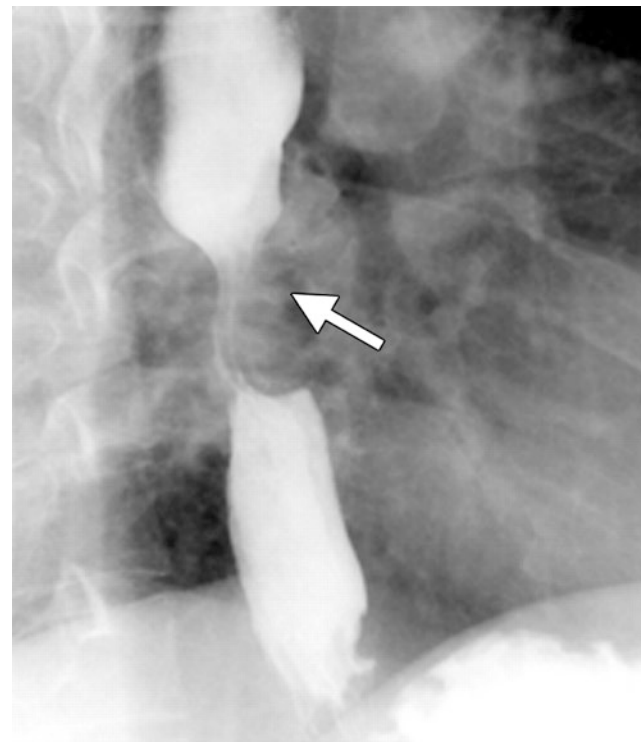

Fig. 24.1 Congenital esophageal stenosis secondary to fibromuscular hypertrophy in the mid esophagus

of the web. If dilation alone does not open the web adequately, the CO_2 laser may be used through the endoscope to excise the remainder of the web. In the previous review of 36 children, five had membranous webs and two required endoscopic CO_2 laser excision [5]. Fibromuscular hypertrophy is also amenable to dilation. The dilations can be performed with either hydrostatic balloon dilators or with bouginage. Theoretically, balloon dilators deliver the dilating force directly to the stricture and are therefore more effective and safer. However, in a retrospective series of 47 children with congenital esophageal stenosis who were all dilated using hydrostatic balloon dilators or Savory bouginage, the perforation rate was higher with balloon dilators (9.3%) compared to Savory dilators (1.7%). If dilation fails, there are two surgical options. The stenosis can be resected with a primary anastomosis, or a myotomy may be performed opening the hypertrophied esophageal muscle longitudinally and closing it transversely [5]. In general, the stenosis due to tracheobronchial remnants requires surgical resection. Often, dilations are initiated, fail, and then the child is brought to the operating room for esophageal resection. The stenosis is most often in the distal esophagus, thus requiring a left thoracotomy. A right thoracotomy is utilized for mid-esophageal stenosis. If the stenosis is just above the gastroesophageal junction, the best approach may be through the abdomen. It is often difficult to identify the stenosis visually or by palpation. Two techniques can be used to assist in finding the extent of the stenosis. A lighted endoscope may be passed from the mouth to the stenotic area. The other option is to pass a balloon catheter from the mouth past the stenotic area, inflate the balloon, and pull it back to find where it hangs up on the stenosis. The esophagus can be opened at that point, and the balloon catheter placed through the stenosis and pulled back to demonstrate the proximal extent of the stenosis [17]. In most cases the stenosis is less than 3 cm in length. A full thickness resection of the stenosis with a primary end-to-end anastomosis returns continuity to the esophagus. A circular myectomy has been described where the muscle wall of the esophagus is resected for the length of the stenosis removing the tracheobronchial remnants and leaving the mucosa intact. The two ends of the remaining muscle are then brought together in an end-to-end fashion [18]. Both of these techniques have been successfully described thoracoscopically [18, 19]. In any of these techniques care must be taken to avoid damage to the vagus nerves. In resections involving the area near the gastroesophageal junction, gastroesophageal reflux often results. Consideration should be given to adding an antireflux operation in these circumstances. In reality, unless the endoscopic ultrasound is utilized, it may be difficult to discriminate between the types of stenosis prior to initiating therapy. Often, dilations are begun and if they fail, it is suspected that the stenosis contains tracheobronchial remnants, and therefore requires resection. With this approach, some of the stenoses with tracheobronchial remnants may be treated with dilation alone, most likely the ones without circumferential cartilage. In a series of 47 children with congenital esophageal stenosis who all underwent dilation therapy, only two required operative intervention. They used predominately Savory dilators, dilated every 15 days until a caliber of 9–12.8 mm was achieved and then dilated as needed. Six of their children later in the study period had endoscopic ultrasounds showing tracheobronchial remnants. The mean number of dilations required was 3, with a range from 1–9. There were five perforations out of 147 dilations. Two of the perforations developed mediastinal abscesses, one was treated with CT guided drainage and antibiotics, the other required exploration, cervical esophagostomy, and eventual esophageal replacement. The other three were treated with antibiotics alone [14]. The algorithm for treating congenital esophageal stenosis begins with endoscopy and dilation for all stenosis with endoscopic CO_2 laser resection if needed for membranous webs. Only after a series of dilations fails should esophageal resection be undertaken [20].

24.1.5 Outcome

Overall the long term outcome for children with congenital esophageal stenosis treated with either dilations or resection is very good [6]. The complications associated with dilation are perforation and need for multiple dilations. A series of ten children were successfully dilated with 4.7 dilations over an average of 2.6 years [5]. Perforation rates vary from 10% in two series [5, 14], to 33% [10] and 44% [12] in two others. Following resection, complications include anastomotic leaks, stricture, and the development of gastroesophageal reflux if the resection is close to the gastroesophageal junction and not accompanied by an anti-reflux operation. Those children who had esophageal resection averaged 2.2 dilations over 2.1 months following the operation [5].

24.2 Esophageal Duplication Cysts

24.2.1 Introduction

Esophageal duplication cysts were first reported in 1711 by Blasius [21]. These duplications can occur in the cervical or thoracic esophagus, and on occasion the thoracic duplications will extend into the upper abdominal cavity. Cervical esophageal duplications are very rare. The first duplication cyst of the cervical esophagus was reported in 1964 by Bishop and Koop [22]. In an autopsy study by Arbona, the incidence of esophageal duplication cysts was 1 in 82,000, with a 2:1 male to female predominance [23]. Esophageal duplication cysts are defined by three characteristics: a cyst attached to the esophageal wall, covered by two layers of muscle and epithelium that represents some level of the gastrointestinal tract [21]. The epithelium contained in the duplication is most often esophageal, but up to one third contain gastric mucosa which may lead to ulceration, bleeding, or perforation. The majority of the esophageal duplication cysts, up to 80–90%, do not communicate with the esophageal lumen. Most, 60% are located in the distal esophagus [24]. Some esophageal duplication cysts referred to as neuroenteric cysts connect to the spinal canal and are associated with vertebral anomalies [25]. In addition to their association with vertebral anomalies (scoliosis, hemivertibra, and fusion), esophageal duplication cysts have also been described with small intestinal duplications, esophageal atresia and tracheoesophageal fistula, pulmonary abnormalities such as congenital cystic adenomatoid malformations, and pericardial defects [26, 27]. A recent literature review identified 12 cases of esophageal duplication cysts associated with esophageal atresia. Of those 12, five were not identified at the original repair [28]. The embryology of esophageal duplication cysts is unknown. Several theories have been presented including the failure of recanalization of the esophagus during the fifth to eighth week of embryonic life [29], and split notochord theory [30].

24.2.2 Presentation

Esophageal duplication cysts present in a number of different ways depending on their location and the type of mucosa that lines the cyst. Some, especially those of small size, remain asymptomatic. Of those that become symptomatic, the majority, 70–95%, are diagnosed before age 2 years [31]. The rare cervical esophageal duplication cysts most commonly present with respiratory symptoms due to tracheal compression [25]. However, they can also present with feeding difficulties or an enlarging neck mass due to infection, hemorrhage, or a build-up of secretions [29]. Thoracic esophageal duplication cysts can present with symptoms varying from respiratory symptoms, to dysphagia, to symptoms secondary to acid production of the gastric mucosa lining the cyst. The cysts in the mid to upper thorax generally cause respiratory symptoms due to tracheal compression. Cysts that lie in the vicinity of the mainstem bronchus can cause compression leading to

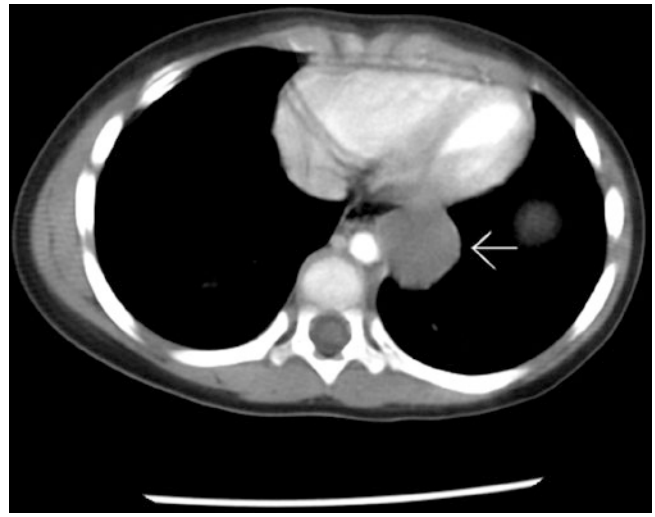

Fig. 24.2 Esophageal duplication cyst seen extending into the left chest from the posterior mediastinum

hyperinflation of the ipsilateral lung often requiring resection in the neonatal period [32]. Most of the cysts are located in the distal third of the esophagus and of these, 70% presented with dysphagia, 20% with epigastric discomfort, and the remaining 10% with retrosternal pain [25]. Gastric mucosa is found in up to one third of esophageal duplication cysts and can be responsible for a myriad of symptoms. Acid production from the gastric mucosa leads to ulcer formation. The ulcer can either bleed or perforate causing different symptoms depending on the location of the cyst. If the bleeding occurs in the esophagus it may present as hematemesis or as melena. Bleeding in the trachea leads to hemoptysis that may be life threatening. If the ulcer perforates into the pleural space it can cause a chemical pleurisy, an empyema, or a pneumothorax [33]. Esophageal duplication cysts are more and more frequently now being discovered prenatally with ultrasound or fetal magnetic resonance imaging [34].

24.2.3 Diagnosis

Imaging studies confirm the diagnosis of an esophageal duplication cyst. Plain films may reveal deviation or compression of the trachea or esophagus by a soft tissue mass. The esophageal deviation may be better seen with a nasogastric tube in place. Esophageal contrast studies reveal extrinsic compression of the esophagus from the mass effect and may show a communication between the cyst and the esophagus on the rare occasion when it is present [29]. With the diagnosis suspected from the plain film and contrast studies, further information regarding the size, exact location, and the anatomic relation to other mediastinal structures is useful prior to operative intervention. Ultrasound, computed tomography, and magnetic resonance imaging provide this information. The ultrasound exam reveals a cystic mass with a typical gut signature of the walls consisting of inner hyperechoic mucosa and outer hypoechoic muscle. It may also identify debris inside the cyst suggesting infection or hemorrhage. Computed tomography, as seen in Fig. 24.2, and magnetic resonance imaging better identify the location and extent of the cyst, such as extension into the abdominal cavity and mass effect on the airways. Recently, more magnetic resonance imaging rather than computed tomography is utilized to avoid radiation. Magnetic resonance imaging is favored if one suspects a neuroenteric cyst [32].

24.2.4 Treatment

Treatment of esophageal duplication cysts consists of complete excision. The cysts must be separated from structures in the mediastum, and

then dissected away from the common wall with the esophagus. The esophageal muscular wall is opened, and an extramucosal dissection is performed to remove the entire cyst while leaving the native esophageal wall intact. This may be performed through an open thoracotomy, or minimally invasively using thoracoscopy [35–37] or the surgical robot [38]. One of the difficulties when performing this operation in a minimally invasive fashion is ensuring the esophageal mucosa remains intact during the dissection. The use of intraoperative endoscopy with insufflation during the procedure helps prevent esophageal injury during the dissection [36]. The decision to remove the duplication cyst in a minimally invasive fashion should be up to the surgeon, but some situations that may require a thoracotomy include compressive subcarinal cysts with secondary lung hyperinflation and mediastinal shift and previously infected duplication cysts [34]. If for some reason the entire cyst cannot be removed it is important to remove all of the mucosa so the cyst cavity does not recur.

24.2.5 Outcome

With proper treatment, children with esophageal duplication cysts should have excellent surgical outcomes and overall quality of life.

24.3 Esophageal Perforation

24.3.1 Introduction

Boerhaave was first to describe a spontaneous perforation of the esophagus in 1724 [39]. In 1952, Fryfogle described a spontaneous perforation of the esophagus in a neonate [40]. In 1961, Warden reported the first iatrogenic perforation of the esophagus in a neonate [41]. The majority of esophageal perforations in children are iatrogenic in origin versus other etiologies such as spontaneous perforation and traumatic perforations from foreign bodies, caustic ingestion, and blunt and penetrating trauma. In a review published in 2006, spontaneous perforation or Boerhaave's syndrome has been described in 26 pediatric patients with half of these occurring in neonates [42]. Unusual causes of esophageal perforation include the ingestion of an eel [43] and of a shard of glass in a pancake [44], erosion of mediastinal necrotic tuberculous lymphadenopathy [45], and spontaneous perforation in a child with eosinophilic esophagitis [46]. Combining several pediatric series of perforated esophagi, 76.5% of perforations result from iatrogenic injury [47–49]. Most of the iatrogenic injuries occur during an endoscopic procedure in the older children, and with placement of naso- or oro-gastric tubes, endotracheal tubes, or the use of suction catheters in infants. In a series 39,650 endoscopies in children and adults, the incidence of perforation was 0.006%. When a therapeutic measure was added to the endoscopy, the incidence of perforation increased to 0.6% [50]. The most common therapeutic measure leading to perforation is stricture dilation, with strictures resulting from caustic ingestion being most at risk [51]. Other interventions leading to perforation include removal of foreign bodies, esophageal varix injection leading to focal necrosis [47], and perforation by a transesophageal echocardiogram probe during a cardiac surgery procedure [52].

24.3.2 Presentation

Signs and symptoms of esophageal perforation can sometimes be vague and nonspecific requiring a high index of suspicion to ensure early diagnosis and institution of treatment. Symptoms depend on the location and extent of the perforation. The most common area of perforation is the thoracic esophagus. These children develop dyspnea, chest pain, fever and vomiting most commonly, and may develop subcutaneous emphysema. Hammon's sign, a systolic crunching sound, can be heard over the cardiac apex and left sternal boarder and represents the heart beating against air filled tissues. With extensive soilage, tachypnea, tachycardia, and further signs of sepsis develop. Mackler's Triad classically represents spontaneous rupture of the esophagus and

includes emesis, chest pain, and subcutaneous emphysema [53]. Abdominal esophageal perforation leads to signs of peritonitis often associated with referred shoulder pain and dysphagia. Perforation of the cervical esophagus leads to cervical pain, subcutaneous emphysema, and pressure symptoms on the esophagus and trachea. The esophageal attachments to the prevertebral fascia limit the soilage following cervical esophageal perforation leading to localized retropharyngeal abscesses. Iatrogenic perforations in the neonatal population often take place in the cervical esophagus just proximal to the cricopharyngeal muscles. The nursing staff often has difficulty placing a nasogastric tube prompting a chest X-ray which identifies the abnormal course of the nasogastriac tube leading to the diagnosis of a perforation. If the perforation is not identified in that way, signs to be concerned with are respiratory distress, increased salivation, choking, cyanosis with feedings, blood in the nasogastric aspirates, and hypotonia [54, 55].

24.3.3 Diagnosis

When a perforation of the esophagus is suspected, work up should be expeditious. Plain films begin the evaluation. Findings depend on the etiology of the esophageal perforation. In a series of neonates with iatrogenic pharyngoesophageal perforations, plain film abnormalities included pneumothoraces, usually right sided, an abnormal position of the nasogastric tube, or pleural effusions [55]. In older children with iatrogenic or spontaneous perforation the findings on plain film include pneumomediastinum, pleural effusions, pneumothoraces, subcutaneous emphysema, and pneumopericardium [47, 54, 56]. A strong clinical suspicion and a normal chest X-ray should prompt further evaluation as 12–33% of esophageal perforations will have a normal initial chest radiograph [57]. The next step in the evaluation is a contrast esophagram. Initially, water soluble contrast is used to avoid the inflammatory response created in the mediastinum or pleural space if barium extravasates. The water soluble contrast exam has a 10% false negative rate [58], so barium should be used to pick up subtle perforations that the water soluble study can miss. Three abnormal patterns can be seen on the esophagram. The first is a retropharyngeal collection resulting from a cervical esophageal leak. The second is a contained submucosal perforation that results in contrast tracking parallel and posterior to the esophagus. The third pattern is a free perforation into the pleural space [54]. Computed tomography can be useful to define and drain intrathoracic fluid collections. Findings seen on computed tomography scan in children with esophageal perforation include mediastinal air and/or fluid and esophageal thickening. Computed tomography guides drain placement if fluid collections are present. The use of endoscopy is controversial in the diagnosis of esophageal perforation. When the perforation occurs during dilation, it is often first diagnosed with endoscopy. If this is the case, care should be used to minimize the amount of air insufflated into the mediastinum as it may cause pressure issues with mediastinal movement in the small children resulting in loss of venous return from vena caval obstruction. The use of endoscopy should be limited in the diagnosis of esophageal perforation as it is accurate in only 50% of cases, and may worsen the perforation [54].

24.3.4 Treatment

In the pediatric and neonatal setting, the majority of esophageal perforations can be treated successfully in a conservative manner. The principals involved include minimizing proximal flow of material through the esophagus, controlling contamination, maintaining downstream patency, and optimizing both clinical and nutritional status [59]. Patients are kept nothing per os, with placement of a nasopharyngeal or nasogastric tube to control secretions. Broad spectrum antibiotics covering gram positive, gram negative and anaerobic bacteria are used along with drainage of pleural effusions or mediastinal abscesses if necessary to control contamination. Mediastinal drainage can be performed with radiologic guidance or with the use of thoracoscopy [48].

Esophageal intraluminal stents have been used in pediatric patients but are usually not necessary [60, 61]. Nutritional status is optimized with total parenteral nutrition, or enteral feeds via a gastrostomy or jejunostomy tube. If these measure fail, the esophageal leak should be isolated with an cervical esophagostomy and gastrostomy placement which eventually leads to an esophageal replacement procedure.

24.3.5 Outcome

The outcome of esophageal perforation in the pediatric population is surprisingly good especially when compared to the adult population. In most cases conservative management allows the perforation to heal with little sequelae. Factors that predict a good outcome include early diagnosis and treatment, an iatrogenic origin, young age and absence of underlying disease [47]. Of these, the early diagnosis and treatment appear to be the most important with a 92% survival noted when treatment begins within 24 h of the perforation compared to 67% survival if treatment is initiated after 24 h [56]. In the most recent published series of pediatric esophageal perforations, all the perforations healed with conservative management and there was no mortality. After the perforation, the average antibiotic course was 10 days, the average time from perforation to an esophogram showing no leak was 10.2 days, the average time spent with nothing by mouth was 11.5 days, and the average hospital stay was 15 days [59]. A representative series of 19 esophageal perforations from multiple causes were initially all treated conservatively with nothing by mouth and antibiotics. Eighteen healed with conservative management. The one child who required esophageal diversion had portal hypertension and developed necrosis of the esophagus following sclerotherapy of an esophageal varix. Nine of the 18 did not require invasive management. There were 12 thoracic drains placed with some children receiving more than one, one pericardial window, six gastrostomies and two jejunostomies. One child required occasional dilations after the healing process was complete and two eventually went on to transhiatal esophagectomies due to their pre-perforation disease, but had no issues resulting from the perforation or its healing.

24.4 Achalasia

24.4.1 Introduction

Achalasia is an esophageal motor disorder resulting in increased lower esophageal sphincter resting pressure, incomplete relaxation of the lower esophageal sphincter after swallowing, and the absence of esophageal peristalsis. This leads to a dilated nonfunctioning esophagus with a functional obstruction at the gastroesophageal junction. Achalasia occurs infrequently in all ages, but only 5% of achalasia occurs in childhood. The incidence of achalasia in children has been on the increase. Large population studies of the incidence of achalasia in children have noted an increase from 0.11 to 0.18 cases per 100,000 children per year from 1988 to 2008 [62, 63]. In children, achalasia usually occurs in isolation during the teenage years, but has been associated in younger children with Trisiomy 21, Allgrove (triple A) syndrome consisting of achalasia, alacrima, and adrenal insufficiency and with familial dysautonomia [64]. Under the microscope an esophagus affected with achalasia will have a decrease in myenteric neurons, especially the inhibitory nitric oxide-releasing neurons in the distal esophagus and lower esophageal sphincter [65]. This is thought to result from an autoimmune mediated destruction of these inhibitory neurons in response to an unknown insult in genetically susceptible individuals [66].

24.4.2 Presentation

Although infants have been identified with achalasia, the symptoms most often develop in the early teen years. Several recent studies recorded the average age at diagnosis between 7.8 and 13 years of age with the earliest diagnosis at 1 month of age [63, 67–71]. Symptoms often

continue for a prolonged period prior to diagnosis with average times from symptom onset to diagnosis varying from 7.2 to 30 months [67–70]. Symptoms include dysphagia, vomiting and regurgitation most frequently. In addition, retrosternal chest pain, recurrent respiratory symptoms including cough or dyspnea after meals, nocturnal cough, failure to thrive or weight loss, drooling, and food sticking have been reported. In a review of 40 children with achalasia, 72.5% presented with dysphagia, 60% with emesis, 30% with food sticking, 27.5% with cough and 52.5% with weight loss [72].

24.4.3 Diagnosis

Achalasia is evaluated with a contrast esophogram, upper endoscopy and esophageal manometry. Most often all three examinations are obtained to cement the diagnosis, but some obtain manometry only when a question arises after the esophagram and endoscopy [67]. The contrast esophogram, seen in Fig. 24.3, reveals a dilated esophagus with retained contrast, smooth tapering of the distal esophagus accounting for the "bird's beak" appearance and lack of peristalsis in the body of the esophagus. These are classic findings, but a normal esophagram does not necessarily exclude early achalasia [64]. Endoscopy reveals a distended esophagus with retained food or secretions, but no obstruction at the gastroesophageal junction. Endoscopy can also be normal in up to 44% of cases of achalasia [66]. Esophageal manometry has the highest sensitivity of the three diagnostic studies [66]. Manometry reveals aperistalsis of the smooth muscle portion of the esophagus, incomplete lower esophageal sphincter relaxation, and an elevated lower esophageal sphincter resting pressure. Recently, esophageal high-resolution manometry, which displays manometric data as pressure contour plots, provides functional anatomy of the esophagus and can be obtained in children without sedation [73].

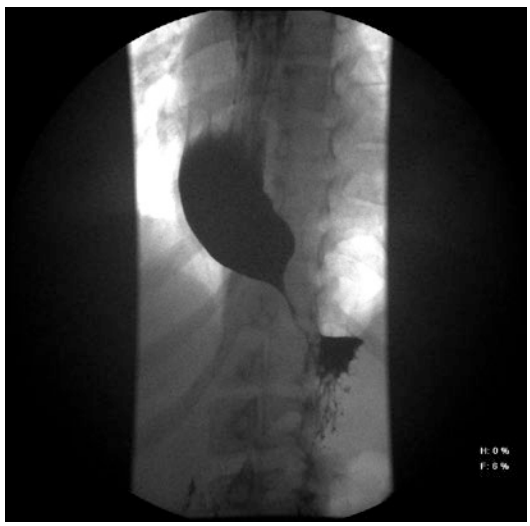

Fig. 24.3 Esophageal contrast study reveals dilated proximal esophagus and bird's beak appearance of the distal esophagus in achalasia

24.4.4 Treatment

Treatment for achalasia attempts to relax or disrupt the lower esophageal sphincter. There are three modalities commonly used: pharamacologic, endoscopic which includes dilation and injection of botulinum toxin, and surgical myotomy with or without a fundoplication to protect against gastroesophageal reflux. The pharamacologic agents used to achieve a reduction in lower esophageal sphincter pressure include calcium channel blockers, nitrates, and phosphodiesterase 5 inhibitors. These agents provide initial improvement in 50–90% of patients, but are short acting and have a significant side effect profile [74]. Pharmacologic treatment should be limited to patients unwilling or unable to undergo other procedures. Pneumatic dilation involves placing a dilating balloon in the lower esophagus and expanding the balloon to rupture the muscle fibers of the lower esophageal sphincter. The main risk of dilation is perforation which occurred in 1.6% of patients studied in a meta-analysis [75]. The long-term success ranges from 40–60% over 15 years [66]. Predictors of failure of dilation include younger age, male gender, pulmonary symptoms, failure to respond to 1 or 2 initial dilations, and manometric findings of a high initial lower esophageal sphincter pressure

(>15–30 mmHg), or reduction in lower esophageal sphincter pressure less than 50% of baseline after the first dilation [66]. Botulinum toxin is a neurotoxin that blocks the release of acetylcholine from excitatory motor neurons thus relaxing the lower esophageal sphincter. Occasionally, the initial injection does not provide relief, and if this occurs, future injections rarely if ever are effective. Repeat injections are often needed as the recurrence rate at 1 year is 50%, and patients are universally symptomatic at 2 years [66]. Given the need for long term results in children, surgical myotomy is often the first approach in this population. A Heller myotomy consists of division and dissection of the muscular wall of the esophagus from the mucosa for a distance of up to 4 cm from the gastroesophageal junction onto the esophagus, and 2–3 cm onto the stomach. This disruption of the lower esophageal sphincter may lead to postoperative gastroesophageal reflux and its complications, so a partial or complete fundoplication is often added to the myotomy. The operation can be completed in both an open or minimally invasive fashion from either the abdomen or the chest. The preferred approach is the laparoscopic abdominal approach. Adult data show that the risk of subsequent intervention for pneumatic dilation is 56% compared to 26% for surgical myotomy. Comparing pneumatic dilation to Heller myotomy with a Dor partial fundoplication at 5 year follow up, those treated with a myotomy had a good result in 95% compare to 65% for pneumatic dilation. However, the surgical success rate decreased to 75% at 15 years follow up. Of the patients treated with a myotomy that had a poor result 92% developed reflux symptoms and they were the cause of the poor outcome, not an incomplete myotomy [66]. The addition of a Dor partial fundoplication to the Heller myotomy decreased the incidence of postoperative reflux from 47.6% to 9.1%. Comparing a Dor partial fundoplication to a Nissen complete fundoplication, the reflux was similar, but those treated with a Nissen developed dysphagia 15% of the time compared to a 2.8% dysphagia rate with the Dor partial fundoplication [66]. At the time of surgery, endoscopy can be used to evaluate for a perforation and the completeness of the myotomy. The endoscope is placed, the distal esophagus is inspected, and gentle insufflation is used to open the lower esophageal sphincter. If the sphincter fails to open, a longer myotomy onto the stomach is required. Using this method, three of five patients required an extension of the myotomy after the endoscopy, and none of the five required further surgeries for achalasia [71]. Postoperative manometry may help predict which patients will develop postoperative symptoms. If the lower esophageal sphincter pressure was less than 12 mmHg after the myotomy, patients had no recurrent symptoms, while those that had postoperative pressures greater than 12 mmHg tended to develop symptoms [74]. When these modalities fail, esophagectomy and gastric pull-up remains an option.

24.4.5 Outcome

Less than acceptable outcomes with achalasia stem from three sources, the natural history of the disease, treatment related complications, and late consequences of successful therapy. The natural history of achalasia leads to problems related to aspiration, megaesophagus, and squamous cell cancer of the esophagus. Structural pulmonary disease thought to emanate from microaspiration occurs in 33% of patients with achalasia. A megaesophagus will develop in 10% of achalasia patients 18–21 years after the onset of symptoms. This may be related to a delay in either diagnosis or treatment. Treatment related complications include perforation with pneumatic dilation and with laparoscopic Heller myotomy. A large meta-analysis found that pneumatic dilation carries a perforation rate of 1.6% with a range of 0–8% in various series. Laparoscopic Heller myotomy had a 0.7% perforation rate with a similar range of 0–8%. The overall postoperative complication rate with the myotomy was 6.3% with a mortality of 0.1% [75]. Late consequences of successful therapy also lead to morbidity. Overall, 10% of patients with achalasia undergoing either pneumatic dilation or laparoscopic Heller myotomy will develop reflux esophagitis. Overall, 43% of patients following treatment for achalasia require acid sup-

pression therapy. Post procedure reflux is more common in those treated with a myotomy, 14% versus 5% in those undergoing pneumatic dilation. Of these patients who develop post procedure reflux, one half will develop late complications of reflux, most commonly a stricture [66]. Two types of esophageal cancer develop in achalasia patients, squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma occurs more commonly, and is thought to develop from stasis that leads to bacterial overgrowth, production of nitrosamines, chronic inflammation, dysplasia, and eventual cancer. Adenocarcinomas are thought to result from long standing reflux. A prospective study following achalasia patients for a mean of 15 years found a 3.3% incidence of esophageal cancer in the population. These cancers developed a mean of 11 years after the diagnosis of achalasia, and a mean of 24 years after the onset of symptoms. The hazard ratio for achalasia patients to develop esophageal cancer was 28 [76]. Using a pediatric quality of life instrument, children with achalasia were found to have a quality of life after being treated with a Heller myotomy that was lower than healthy children and children with inflammatory bowel disease, but comparable to children with chronic constipation [77].

25 Gastroesophageal Reflux in Newborns and Premature Infants

Juan A. Tovar

Abstract

Gastro-esophageal reflux (GER) is defined as the retrograde passage of gastric contents back into the esophagus where it does not belong. Food and gastric juice may damage the mucosa, interfere with respiratory function and impair nutrition. This phenomenon, which follows a failure of the anti-reflux barrier, is particularly frequent in infancy, a period during which it is considered a near-normal event. Episodes are usually short, occur after feeds and tend to decrease with the passage of time. When GER becomes bothersome, gastro-esophageal reflux disease (GERD) develops.

In this chapter, only GER and GERD in newborns and young infants are addressed. The mechanisms, symptoms, associated conditions, diagnostic procedures and treatment recommendations are summarized.

Keywords

Gastroesophageal reflux • GERD • Investigations • Fundoplication Gastrostomy • Outcomes

25.1 Introduction

Gastro-esophageal reflux (GER) is defined as the retrograde passage of gastric contents back into the esophagus where it does not belong. Food and gastric juice may damage the mucosa, interfere with respiratory function and impair nutrition. This phenomenon, which follows a failure of the anti-reflux barrier, is particularly frequent in infancy, a period during which it is considered a near-normal event. Episodes are usually short, occur after feeds and tend to decrease with the passage of time. When GER becomes bothersome, gastro-esophageal reflux disease (GERD) develops.

In this chapter, only GER and GERD in newborns and young infants are addressed. The mechanisms, symptoms, associated conditions, diagnostic procedures and treatment recommendations are summarized.

25.2 History

Interest in GERD is relatively recent. Only 100 years ago, reflux was linked to esophagitis and heartburn for the first time in adults when barium contrast studies were developed. A gastroesophageal barrier able to prevent retrograde passage of the bolus from the stomach was shown but its failures could not be investigated until the appropriate diagnostic tools became available. Esophagitis and Barrett's esophagus were characterized after development of endoscopy, esophageal manometry, pH-monitoring and miniaturized intraluminal impedance (MII), permitted understanding of the motor events involved in swallowing, GER and clearance. The number of publications on GERD increased enormously and it became a frequent diagnosis and a source of abundant medical consultation [1].

Unfortunately, knowledge on GER in infants and children in whom it is more frequent progressed more slowly, mainly because of the difficult application of these relatively invasive techniques to small individuals. Equipment size, lack of collaboration and ultimately, ethical problems for establishing normal values, made investigation difficult in them. In the fifties and sixties, GERD became a well-known pediatric disease in Europe whereas it was almost unheard of in North American children. When the current diagnostic tools were applied, this situation reversed and a flow of studies generated much interest and active, and sometimes hyperactive, therapeutic attitudes worldwide. GERD is currently considered as a highly prevalent condition in children, particularly in newborns and young infants, in whom medical and surgical treatments are often indicated.

25.3 Embryology

The esophagus and the stomach derive from the embryonal foregut [2] which is surrounded by mesenchymal cells that differentiate and arrange themselves into two concentric muscular layers, the internal or circular and the external or longitudinal ones. These muscle fibres are smooth except in the proximal end in which striated ones predominate. There are no anatomically defined muscle sphincters in the esophagus but the circular layer at both ends of the organ act as such. Early in embryonal life, neural crest cells invade the esophageal wall to form the submucosal and intermuscular plexuses of the enteric neural system that are widely interconnected. Sympathetic, parasympathetic and nitrergic elements mediate inhibition, stimulation and relaxation of muscle contractions and regulate gland secretion.

Embryogenesis of the diaphragm is related to that of the esophagus and stomach. Separation of the thoracic and abdominal spaces is effected by development of this muscle that maintains open orifices for the passage of the inferior vena cava, the aorta and the esophagus. The arrangement of the muscle fibres around the esophagus as a powerful sling contributes to the anti-reflux barrier.

25.4 Functional Anatomy of the Anti-Reflux Barrier

The stomach is located in the abdomen where positive pressures are maintained during the respiratory cycle even at rest. Recumbence, crying and movement further increase this pressure particularly during infancy, and so does gastric peristaltic activity. Conversely, the esophagus is located in the thoracic environment in which inspiratory negative pressures create a powerful pressure gradient between the abdomen and the thorax (and also between the stomach and the esophagus) that favours GER. Since the esophageal mucosa is not prepared for prolonged contact with digestive juices, an efficient anti-reflux barrier fights this phenomenon in normal individuals.

The components of this barrier are: (1) The infra-diaphragmatic location of the distal esophagus, that exposes it to permanently positive closing pressures; (2) The lower esophageal sphincter tone that maintains it permanently closed except during deglutition; (3) The diaphragmatic sling, that occludes the gastroesophageal junction during inspiration, when pressure gradients are stronger; (4) The gastric fundus that maintains

compression on the distal esophagus in the standing position and; (5) The distal rosette of mucosal folds, that contributes to cardial closure. This barrier is effective most of the time, but spontaneous non-deglutory relaxations or incoordination of its components allows reflux. Delayed gastric emptying might facilitate this failure.

Esophageal peristalsis acts as a second defensive line against GER. The normal esophagus is able to mount progressive peristaltic waves during deglutition that push the bolus into the stomach. These *primary* waves run all along the organ. Similar waves that occur when reflux has taken place and do not necessarily involve the upper level of the esophagus are *secondary* waves. In normal individuals, a few *tertiary*, simultaneous, non-progressive contractions, that are unable to clear the lumen, occur as well. Peristaltic activity is complemented by the permanent tonic closure of the upper esophageal sphincter that protects the respiratory tract from GER. During deglutition, both sphincters relax and primary waves propulsate the bolus. After reflux, salivary and esophageal gland secretions help primary and secondary waves to clear the lumen. In erect human individuals, gravity helps to achieve esophageal clearance, but this does not apply to recumbent newborns and infants.

25.5 Epidemiology

Regurgitation due to GER is recognized in more than one third of normal newborns and young infants, medical advice is sought in about one fifth of these cases and only a few of them have actually GERD [3]. All races and both genders are equally affected. Apparent differences in geographic distribution are probably due to variable degrees of interest in this condition that may look more prevalent in some areas than in others depending on the intensity of the diagnostic efforts.

25.6 Genetics

There is some evidence of the involvement of genetic factors in GERD because there are families in which several sibs suffer it. It was suggested that a genetic locus could in chromosome 13q14 and that a high-penetrance autosomal dominant mode of inheritance was likely in families with several members affected by severe GERD phenotype [4], but this was not fully confirmed [5].

25.7 Clinical Presentation and Diagnosis

Reflux can be visualized in the course of antenatal ultrasonography but it is doubtful that this can be of any clinical interest since it is a normal phenomenon. However, intrauterine esophagitis with haemorrhage responding to acid suppression has been reported [6].

Regurgitation and vomiting are the main symptoms of GERD in infants. They take place after feeds and are often partial and rarely explosive. Arrest of weight gain and growth may occur in a few cases, restlessness and nocturnal crying and, less often ground-coffee stained vomiting, are other expressions of esophagitis at this age. Occasionally, refusal to feed, dystonia or extreme irritability express esophageal sufferance [7]. Other symptoms, like repeated cough or recurrent atelectasis and/or pneumonia may be also due to GERD and several other respiratory symptoms like crises of asphyxia and cyanosis or difficulties for extubation in ventilated babies may have the same origin.

In the vast majority of infants, symptoms improve spontaneously or with some postural and dietary interventions during the first year. By 18–24 months most regular refluxers outgrow this condition and only a small proportion remain symptomatic.

The particular prevalence of GER in newborns and young infants and the trend of this phenomenon to improve were explained by the shortness of the intra-abdominal segment of the esophagus at this age and by the alleged immaturity of the anti-reflux barrier [8]. However, refined manometric studies demonstrated that the barrier and the esophageal peristaltic pump are operative since birth [9–12] and only partially undeveloped

in prematures [9, 13]. Spontaneous, transient, non-deglutory lower esophageal sphincter relaxations that account for GER in older patients are also their main mechanism in neonates [10–12, 14, 15]. Probably the relative large volume intake for weight, the crying pressures and the relative shortness of the esophagus in relation to gastric volume facilitate GER during this period of life, and the acquisition of the erect position could help to achieve the so-called maturation.

25.8 When to Perform Diagnostic Tests

This is particularly relevant in newborns and prematures in whom GER is so frequent and benign that the relatively invasive procedures used for its assessment tend to be avoided. All infants have episodes of reflux and therefore, demonstrating its presence only does not ensure its pathologic nature. Quantitation of acid exposure and assessment of mucosal damage become necessary whenever something more than symptomatic treatment is required and this means performance of more than one test.

Barium meal is still widely used for detecting GER but there is little doubt that it is scarcely specific or sensitive for this purpose [16]. In exchange, it is useful for ruling out malrotation and for assessing anatomical displacements (hiatal hernia) and gastric emptying (Fig. 25.1). Endoscopy and biopsy are possible with the thin fiberscopes currently available [17], but they are not routinely used, probably because mucosal damage does not always determine the severity of GERD at this age. Extended pH-monitoring remains the gold-standard for quantitating acid exposure [18–22] provided that some precautions are taken, like using double gastric and esophageal electrodes for detecting post-prandial gastric pH-buffering able to mask esophageal acidity [23, 24] and application of "normal" values that are different at this age are (normal reflux index close to 10% rather than the accepted 4% (22)) (Fig. 25.2). Prolonged multiple intraluminal impedance measurement (MII) coupled with pH-monitoring is rapidly replacing pH-monitoring alone because it informs about both acidic and non acidic episodes of reflux [25–27]. However, the equipment is expensive, interpretation of the tracings difficult and time-consuming and computerized analysis somewhat simplistic. Stationary and pull-through manometry with modern thin multi-lumen extruded catheters with high-pressure-low compliance perfusion is expensive, difficult to perform and requires specialized staff [9–15]. Scintigraphy is rarely used at this age and has its

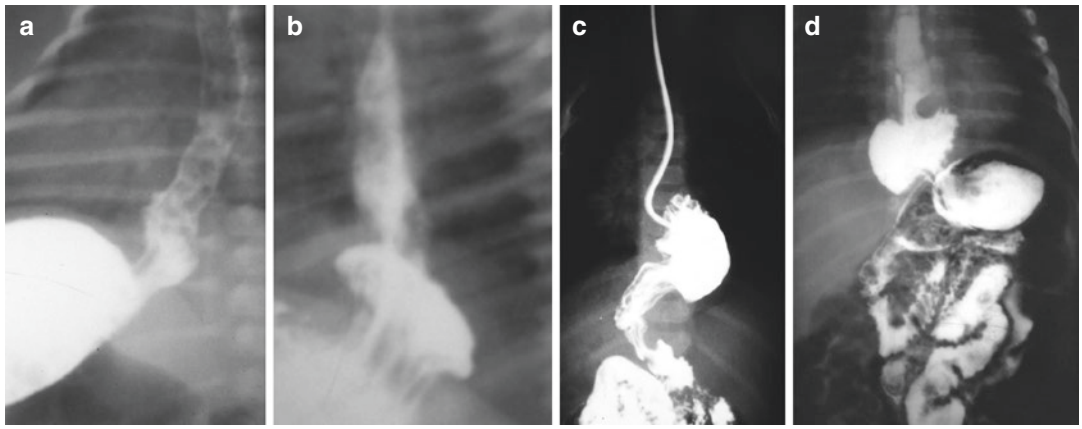

Fig. 25.1 Barium meal is a scarcely specific diagnostic method for GERD because in most cases, it only shows reflux that is to some extent a normal phenomenon (**a**). However, small displacements of the stomach into the thorax (**b**) or major hiatal hernia (**c**, **d**) are well illustrated by this widespread diagnostic method that also informs on duodenal position and gastric emptying

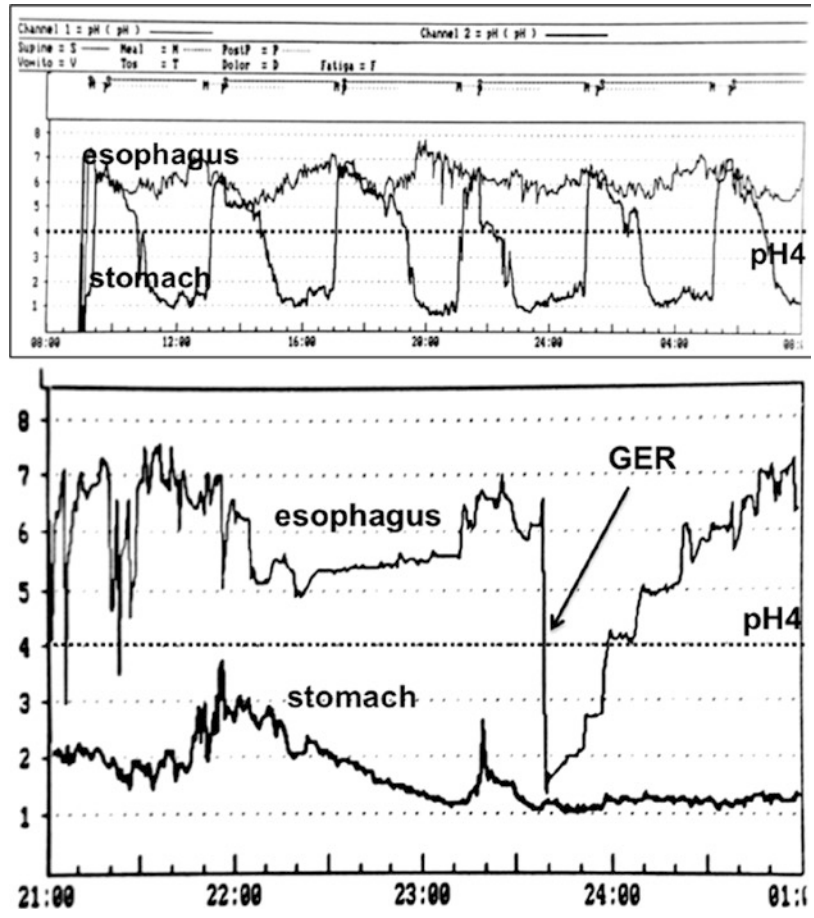

Fig. 25.2 Prolonged pH metering is the best method for quantifying acid esophageal exposure if gastric juice is acid. *Upper tracings*: With an electrode in the stomach and another one in the esophagus, it can be seen how postprandial buffering or alcalinization of the gastric juice for 2 h "blinds" the esophageal electrode six times in 24 h in this non-refluxing baby. *Lower tracings*: An episode of esophageal pH drop below 4 (*arrow*) while gastric pH remains low is indicative of an acid reflux episode

own limitations [28–30] and ultrasonography is probably under-used for this purpose. Indirect forms of relating symptoms to GER (search of either lipid-laden macrophages [31] or pepsin [32, 33] in broncho-alveolar lavage) may also be useful in cases with respiratory tract disease.

In the vast majority of refluxing newborns, diagnostic tests are deferred until demonstrated failure of postural, dietary and antacid treatments prescribed to assist the natural tendency of GER to improve with the passage of time. This failure takes place particularly often in babies with co-morbid conditions (severe respiratory disease, neurologic impairment, previous operations for esophageal atresia, congenital diaphragmatic hernia and abdominal wall defects) in which the anti-reflux mechanisms are damaged, as it will be shown later.

In these cases, and whenever surgery is contemplated, GER has to be convincingly quantitated with either pH-monitoring or MII. Damage caused by reflux has to be documented with endoscopy-biopsy and the anatomy investigated with a barium meal.

25.9 Co-Morbidities in Newborns and Prematures

25.9.1 Severe Respiratory Tract Disease and GERD

Delayed maturation, recumbence, upper airway obstruction, respiratory assistance with positive airway pressure [34, 35], xanthine medication [36], nasogastric tubes [37] and probably other

reasons, make GER particularly frequent and clinically relevant in premature babies and in those with neonatal broncho-pulmonary conditions. Conversely, microaspiration of gastric contents or esophago-bronchial reflexes caused by acid exposure [38] can cause the respiratory disease. Weaning off ventilator may be impossible until GER ceases and broncho-pulmonary dysplasia, that has other origins, is aggravated by GER [39].

On the other hand, apparent life-threatening events (ALTE), like pauses of apnea or cardio-respiratory arrests, are particularly common and dangerous in these tiny young infants. The relationship of GER with such events is difficult to demonstrate making this issue controversial. pH-tracings, poly-somnographic recordings [40, 41] and MII coupled with pH recordings [26, 42] clarified in part the extent of this relationship. Non-acidic reflux episodes are considerably more frequent than expected at this age on the basis of pH recordings alone [43]. ALTE could be related to both acidic and non-acidic reflux [44] although this interpretation is widely contradicted [45–47].

25.9.2 GERD in Neurologically Impaired Babies

Neurologically impaired (NI) infants have often GER. Abnormal neuro-enteric control, spasticity and constipation generate unfavourable conditions that exaggerate the GER-driving pressure gradient. Moreover, there is experimental [48] and clinical [49] evidence of lower esophageal sphincter pressure weakening after brain injury. Non-deglutory sphincteric relaxations are probably less determinant than sphincter insufficiency as a cause for GER in NI patients than in other refluxers [50]. For these reasons, NI children respond poorly to medical treatments and they are often candidates for surgery. Moreover, nutritional problems are common in this particular group of infants and a gastrostomy is often indicated in them in order to facilitate feeding. Gastrostomy itself has been shown to facilitate GER [51, 52] and some technical tips have been offered to prevent this [53]. NI infants constitute the group that requires more often surgical treatment for GERD during this period of life.

25.9.3 GERD After Treatment of Esophageal Atresia and Tracheo-Esophageal Fistula

Babies who survive neonatal repair of esophageal atresia (EA) and tracheo-esophageal fistula (TEF) have GER so often, that this is considered as a component of the original condition. This frequent association is explained by several reasons: (1) The esophagus is structurally abnormal and its extrinsic [54] and intrinsic innervations [55, 56] are deficient. (2) The hiatus and the position of the gastro-esophageal junction can be distorted as a consequence of the malformation [57] and/or of its repair [58] (GER is more frequent in long-gap cases [59–61]). (3) Some patients have upper airway obstruction due to tracheomalacia or tracheobronchial stenosis. (4) Innervation and function of the stomach are abnormal as well [62]. All these conditions create an environment in which the anti-reflux barrier fails while the peristaltic pump in charge of compensating for these failures is scarcely operative. Functional studies repeatedly demonstrated non-propagated peristalsis, weak propulsive force, particularly of the distal esophagus, and decreased lower sphincteric pressure [63–66]. Some of these dysfunctions were present prior to surgical repair [67]. Gastrostomy is occasionally used in the treatment of EA-TEF, and particularly in long-gap and in pure EA cases. This procedure by itself seems to facilitate GER [51, 52, 68].

EA-TEF patients have usually barking cough, often repeated atelectasis or pneumonia and sometimes chronic respiratory tract disease that may last for life. High proportions of survivors have restrictive, obstructive (or both) respiratory tract diseases that may interfere with school frequentation and impair their quality of life [69]. GER has been demonstrated to account in part for these symptoms.

Occasionally, recurrent anastomotic stenoses become refractory to bougie or balloon dilatation probably due to a peptic component [70]. This situation becomes manageable only after reflux is cured by fundoplication.

In EA-TEF survivors, GER tends to be clinically more expressive in the first months of life, but the actual incidence is difficult to estimate because it varies with the diagnostic tests employed reaching figures above 50% [71, 72] and tends to vary with time. In some series, it was almost constant in infancy and tended to decrease over time [73], whereas in others, it definitely increased [74]. It should be pointed out that the mechanisms that facilitate GER after EA-TEF persist for life and therefore, that little spontaneous tendency to improve should be expected. Esophagitis [65] and eventually Barrett's esophagus [75, 76] are found in a number of adolescent and adult patients after repair of EA-TEF and esophageal cancer has been reported in a few of them [77, 78] demonstrating that GER remains a long-standing problem.

Whenever symptomatic GER is shown in these patients, active treatment should be undertaken. Prospective assessment of reflux status and appropriate immediate post-operative medical treatment have been conducted in EA-TEF survivors with only limited proportions of anti-reflux procedures [73]. However, surgical correction of reflux is a widely accepted option [79, 80].

25.9.4 GERD After Treatment of Congenital Diaphragmatic Hernia (CDH)

CDH, a postero-lateral diaphragmatic defect that permits prenatal herniation of abdominal contents (bowel, liver, stomach, spleen or kidney) into the thorax, occurs in 1:3000 newborns. It is accompanied by lung hypoplasia with persistent pulmonary hypertension and often, by other malformations that cause mortality of up to 50% in population-based studies. However, 70–80% of babies treated in specialized units survive and many of them suffer subsequently respiratory tract disease, neuro-developmental deficiencies, hearing loss and GERD. The association between CDH and GERD was pointed out years ago [81] after a dysfunctional, dilated esophagus was described in some babies with CDH [82]. GERD was found more frequently in patients requiring ECMO [83, 84] and in those with large hernias [85]. It persists beyond childhood, causes problems in up to 54% of cases [74, 86] and produces esophagitis in more than 50% of patients and Barrett's esophagus in some of them [87].

There are several explanations for this: (1) The hiatus is under tension due to closure of the diaphragmatic orifice and/or by its replacement by a prosthetic patch. (2) Esophageal extrinsic and intrinsic innervations are abnormal, as shown in animals with CDH [88, 89] and in human autopsies [90] and consequently, the gastro-esophageal barrier and the esophageal peristaltic pump might fail. (3) The small lung, the flattened diaphragm [91] and the tight abdominal closure exaggerate the aboral pressure gradient that facilitates GER [92]. (4) Gastric emptying may be delayed [85] or the small bowel partially obstructed due to non-rotation or malrotation. (5) Gastrostomy is sometimes used for overcoming the nutritional difficulties that these patients experience post-operatively [93].

GER is frequent during the first year after CDH repair [94, 95] but it tends to taper-off in the ensuing years [74] unless chronic respiratory disease and/or neurologic impairment maintain it. Recent pH and manometric studies show that only a small proportion of patients maintain sphincteric and peristaltic dysfunctions over the years [96]. However, the severity of the respiratory disease in CDH patients and the difficulties for feeding make simultaneous performance of gastrostomy and fundoplication a relatively common indication.

25.9.5 GERD After Treatment of Anterior Abdominal Wall Defects (AAWD)

AAWD are developmental anomalies in which the body wall is incomplete or abnormal. In

omphalocele or exomphalos, the periumbilical wall is replaced by a gelatinous sac that contains the bowel and, sometimes, the liver. In Gastroschisis or Laparoschisis, there is a parietal orifice located on the right side, in the vicinity of the umbilical stalk, that allows the bowel, and sometimes other organs, to eviscerate. In both cases, the abdominal space is reduced at birth, and surgical reintegration of the viscera is invariably accompanied by increased abdominal pressure [97]. This, together with the difficulties for re-establishing intestinal transit after the operation and with the constant presence of non-rotation or malrotation, creates a pressure environment that facilitates GER and may even produce hiatal hernia [98]. The location of the hiatus itself, that is very anterior, sometimes substernal, may also facilitate some dysfunction of the anti-reflux mechanisms. Most often GER is a transient situation in this context that tapers off when abdominal contents re-accommodates itself into a progressively enlarged abdominal space but, in a number of cases, this does not happen. GER often accompanied by esophagitis has been found in 43% of omphalocele and 16% of gastroschisis patients [99]. Once again, some of these patients require gastrostomies for overcoming the first and sometimes long postoperative phase of gastrointestinal dysfunction and this may either aggravate GER.

25.10 Treatment

The concept of GER having a naturally-limited course in infants must guide all therapeutic actions except in those with co-morbidities in whom it may not apply. Orthostatic positions in prone [100] or left-lateral decubitus [101] have some limited effect although the alleged increased risks of sudden-infant death in prone position temperate this indication [102]. Formula thickening with rice starch or bean gums [103, 104] has been used with various degrees of enthusiasm although the cumulative evidence of its successes is scarcely convincing [105]. Prokinetics like Cisapride were extensively used [106] and then abandoned after some reports on their cardiac risks [107] that were probably exaggerated [108], but the evidence on their benefits in infants [109] and prematures [110] is weak. H_2-receptor inhibitors like Cimetidine [111], ranitidine [112] or famotidine [113] have also been extensively used for suppressing acid secretion until proton-pump inhibitors became the preferred medication. Omeprazole [114], esomeprazole [115] and pantoprazole [116, 117] are effective for acid suppression.

The need for randomized clinical trials for better defining the therapeutic guidelines in infants with GER has been repeatedly pointed out [118, 119] and the combined recommendations of the NASPGHAN [120] and ESPGHAN [3] on the management of GERD in children examine in depth all aspects of diagnosis and non-operative treatment of GERD limiting surgical indications to cases refractory to optimal treatment, those with intractable erosive esophagitis, intractable asthma or cases of ALTE with convincing evidence of temporal relationship between the episodes and reflux. However, these recommendations, that are less critical with some non-operative measures than with anti-reflux surgery [121], barely take into consideration some of the above-mentioned co-morbidities that are particularly relevant for pediatric surgeons.

Anti-reflux operations (Fig. 25.3) are based on reinforcement of the elements of the barrier. Some pretend to be more physiologic, like the anterior gastropexy designed by Boerema [122] or the anterior or Thal [123] fundoplication popularized by Ashcraft [124] and Boix-Ochoa [125]. In both cases the angle of His is exaggerated by elongation of the intra-abdominal segment of the esophagus and, in the anterior plication, half a fundal valve is sutured in front of this segment. However, the gold standard of anti-reflux operations remains the complete fundoplication devised by Nissen in which the fundus is wrapped around the lengthened intra-abdominal segment to act as a one-way pneumo-hydraulic valve [126, 127]. Provided that the wrap is loose enough, difficulties for burping are transient and the anti-reflux effect is powerful and achieves decrease of transient non-deglutory relaxations [128]. A minor modification is the posterior hemi-fundoplication

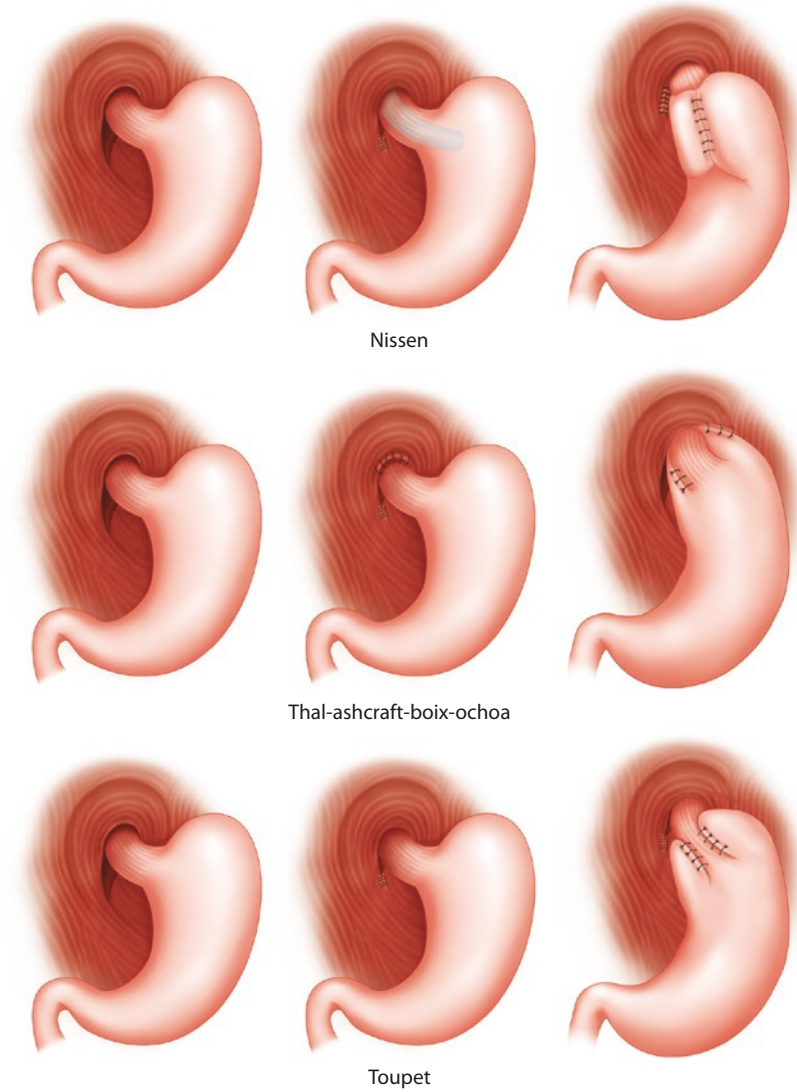

Fig. 25.3 Nissen fundoplication remains the gold-standard of surgical treatment of GERD. It consists (*upper drawing*) in replacing the distal esophagus below the diaphragm, passing the posterior wall of the fundus around the esophagus and suturing it to the anterior one in front of it. This one-way pneumo-hydraulic valve should be loose (a thick dilator is placed inside the esophagus during plication). Thal-Ashcraft-Boix Ochoa anterior plication (*middle drawing*) or Toupet posterior plication (*lower drawing*) may be as effective

of Toupet that achieves the same effect with only half a wrap [129, 130]. All these techniques can also be performed laparoscopically [131–143] and this approach is preferred in many cases.

It has been repeatedly shown that anti-reflux procedures work well in regular refluxers in whom the valve remains functional for long periods of time [142, 144]. However, this is not always the case when reflux-favouring conditions are present. In these patients, a full wrap is definitely stronger and is probably advisable [145].

Most surgeons agree on that anti-reflux operations are indicated only in cases in which symptoms cannot be managed by non-operative measures and when the naturally benign course of the disease is not any more a realistic perspective. However, pediatric surgeons are confronted with refluxing infants that were previously treated surgically for other conditions and this changes considerably their view of GERD for these specific groups [146].

The concurrent need for a gastrostomy in NI patients, and in some treated for EA-TEF, CDH or AAWD may also have some influence on the decisions since it facilitates reflux by itself [51] while at the same time can fight it by correcting malnutrition [147]. The performance of both

procedures during the same anesthesia motivates some indications. However, it should be taken into account that there is little evidence of the rationale for this attitude.

Fundoplication may be beneficial and even life-saving for infants with persistent respiratory tract disease in which GER has been demonstrated, particularly in those with broncho-pulmonary dysplasia and difficulties for extubation after prolonged mechanical ventilation [39, 148–151]. However, demonstration of the involvement of GER in the respiratory condition is difficult, and it is necessary to find better selection criteria for those eventually benefitting from anti-reflux surgery [42]. Operative decisions are particularly hard in infants with ALTE and apnoeic spells or cardio-respiratory events. Polysomnographic recordings have demonstrated that both these events and GER occur often in this particular population and are not necessarily related [47, 152] and that there are other causes for ALTE. This somewhat cooled a surgical indication that apparently stands by itself given the actual risk for life of these particular situations.

Anti-reflux surgery during infancy is relatively often indicated in NI individuals in whom dysfunction of both the barrier and peristalsis are irreversible and cause permanent regurgitation, malnutrition and respiratory tract disease. In addition, they often benefit from a feeding gastrostomy performed previously or concurrently [132, 153–155]. One third of fundoplications during this period of life are performed in NI infants and most have a gastrostomy [143]. However, it has been shown that a "protective" anti-reflux procedure is not necessary in all NI patients having a gastrostomy [156–158]. Complications and mortality after fundoplication are twice as frequent in them as in regular refluxers [155, 159, 160]. This is an important issue because the rates of fundoplication failure in NI patients range from 7% to 25% [159, 161, 162] in the long term.

After more than one failure of the anti-reflux procedure in NI children, alternative operations, like total esophago-gastric dissociation [163–165] or feeding jejunostomy [166, 167] can be offered as reasonable alternatives.

Infants with EA-TEF require anti-reflux surgery quite often and the operation in them may be more difficult than in regular refluxers. The esophagus (particularly the intra-abdominal portion) is shorter, the fundus is small, the angle of His is obtuse or non-existing and a gastrostomy might be already on site or else be required at the time of surgery. On the other hand, the compromised peristalsis in this condition makes any potentially obstructive manipulation less tempting. For these reasons, partial anterior (Thal, Aschcraft, Boix-Ochoa) [168, 169] or posterior (Toupet) [168] hemi-fundoplications are sometimes preferred to the classical Nissen. Anterior gastropexy has also been shown to be beneficial [122]. However, complete, loose fundoplication has been preferred by most authors [126, 144, 168, 170, 171] and there should not be reason for concern provided that it is actually non-obstructive. Lengthening of the intra-abdominal esophagus by Collis plasty followed by Nissen fundoplication has been found useful by some authors [172, 173].

The success of fundoplication in abolishing the GER of EA-TEF patients is, unfortunately, transient in a considerable proportion of cases ranging from 15% to 40% [79, 169–171, 174] due to wrap herniation or loosening. The persistence of all the causes for this dysfunction after fundoplication explains why it fails. In some cases, the severe consequences of GER have already been outgrown by the patient and, in others, redo plication is attempted. Chronic proton-pump inhibitors (Omeprazole) are indicated in these cases [175, 176] and, in some rare instances, more radical operations like esophago-gastric dissociation can be elected [177, 178].

Infants operated upon for CDH require anti-reflux surgery less often, but some cases with large defects and requiring ECMO support clearly benefit from it [85]. Abnormal hiatus, prosthetic patch, malposition or malrotation of the intestine and adhesions due to the previous operation can seriously interfere with the performance of an otherwise straightforward operation. A gastrostomy may be in place or is required at the same time. To circumvent these difficulties, prophylactic fundoplication during CDH repair

has been offered [179–181]. Hiatal refashioning and/or reconstruction may require prosthetic mesh patches in an attempt to reduce the incidence of recurrent reflux [182]. This may amount to 20% or more of operated patients [144].

Babies operated previously for AAWD like omphalocele and gastroschisis have sometimes GERD requiring surgical repair [98, 144]. Once again, this may be particularly difficult in them due to the abnormal arrangement of the intestine and the hiatus, adhesions and sometimes, to the need for a gastrostomy. In these conditions a prophylactic fundoplication during the initial operation has been proposed [183]. The approach to the hiatus can been found so difficult that a thoracic approach has been advised for these cases [184].

In summary, indications for anti-reflux surgery are scarce in newborns and infants, but they are clearly beneficial whenever non-operative treatment fails and especially when co-morbidities interfere with a favorable outcome. The higher number of complications and long-term failures in these particular patients should not discourage operative indications that may permit to overcome severe GER complications. Laparoscopic approach is indicated when feasible, and re-operation is necessary quite often.

Congenital Diaphragmatic Hernia and Eventration

26

Paul D. Losty

Abstract

Congenital diaphragmatic hernia (CDH) has an incidence of 1 in 2500 live births in the UK. CDH is a defect in the fetal diaphragm which allows the contents of the abdominal cavity to protrude into the thorax. CDH may be associated with other major anomalies. The defect may be diagnosed in the fetus, newborn or older child. Some forms of CDH may remain 'asymptomatic' for several years and not present until later life or adulthood. CDH is most often a sporadic and isolated birth defect (70%) though a number of gene mutations have been identified, e.g. chromosome 4p, 8q, 15q. Links have been made to environmental factors such as thalidomide, nitrofen and vitamin A deficiency. CDH may also be associated with the chromosomal disorders trisomy(s) 13, 18 and 21 including the inherited conditions—Fryn's and Pallister Killian syndromes.

26.1 Pathology

The precursors of the human diaphragm begin development during the fourth week of gestation in the form of the septum transversum and lateral folds of mesenchymal tissue(s). These partition the abdominal and thoracic compartments with the formation of the pleuroperitoneal membrane occurring by the eighth week. As development continues muscle fibres migrate into this membrane. Aberration(s) of these critical phases in early human development will result in a 'true' diaphragmatic defect (CDH) or a complete, yet hypoplastic, poorly muscularised diaphragm, i.e. diaphragmatic eventration. Closure of the right hemidiaphragm typically occurs before the left, which likely accounts for the higher incidence of left sided diaphragmatic defects (84%). Right diaphragm defects comprise some 13% of lesions and 2% cases are bilateral defects. Rarer forms include complete diaphragmatic agenesis. The commonest lethal form of CDH in humans is the defect occurring in the posterolateral regions of the developing diaphragm referred to as a Bockdalek's hernia [2]. Other variants encountered in clinical practice are the anterior diaphragm or sternocostal defect, i.e. Morgagni hernia.

Outcomes in CDH are highly variable with regard to prognosis in comparison to other major index neonatal surgical conditions, with reported mortality rates varying from 20%–60% across centres worldwide [1, 2]. Outcome data are here integrally link with the 'hidden mortality' of CDH when taking into account in utero deaths and perinatal fatalities. Morbidity and mortality in CDH is principally related to mechanical compression of the developing lung(s) by herniated intrathoracic abdominal viscera (gut, liver and spleen) resulting in pulmonary hypoplasia which also affects vasculature biology. Histological changes seen at human post mortem studies in the underdeveloped ipsilateral lung on the affected side of the hernia defect are also closely mirrored in the contralateral lung suggesting that whatever insult is responsible for the failure of the diaphragm to develop normally also potentially has wider impact on primordial development of the respiratory system. A primary anomaly affecting early human lung development is postulated [3]—the 'first hit' insult occurring with a 'secondary hit' resulting from later intrathoracic herniation—'dual hit hypothesis' [4].

26.2 Antenatal Diagnosis

Although CDH is not always diagnosed in the prenatal period—all cases detected antenatally must be referred early to a specialist centre. Antenatal diagnosis permits counselling by an experienced multidisciplinary team—paediatric surgeon, neonatologist and obstetrician—as well as allowing treatment and delivery planning [1, 2]. Antenatal diagnosis is reported as early as the 11th week of gestation, however, in the UK region, CDH is more often detected at a 20 week fetal anomaly scan. Within the wider European region—a multicentre study found that 60% of cases of CDH were identified antenatally at an average gestational age of 24.2 weeks [2].

26.3 Associated Anomalies

Antenatal detection should always make effort to identify other associated anomalies, to permit accurate parental counselling [1, 2, 5–7]. Survival of newborns with associated severe malformations (e.g. cardiac) remains dismally poor. Amniocentesis is recommended to identify chromosomal anomalies e.g. Trisomy(s) 13, 18 and 21, Donnai-Barrow, Fryns and Pallister Killian syndromes. Echocardiography is utilised to screen for cardiac anomalies, present in up to 18% of cases A thorough sonographic evaluation of the urinary, gastrointestinal and central nervous system should also be performed to detect further structural malformations (33%).

26.4 Predicting Outcome

Defining reliable antenatal predictors of outcome in CDH have been the subject of intense study over the last few years. Most current methods

rely on indirect techniques, e.g. US/MRI to make an assessment of fetal lung volume. Measurement of the contralateral fetal lung area to head circumference ratio (LHR), using 2D ultrasound (US) imaging, as a potential predictor of outcome was first proposed by Mike Harrison's group at UCSF in the mid 1990s [8]. LHR gained early popularity as a prognostic marker and indeed was incorporated into the NEJM randomised clinical trial to guide decision-making for fetal intervention in CDH—see later. A systematic review and meta-analysis study published from Liverpool (2007) showed absolute measurement of LHR was flawed and it was recommended better refinement was needed with procurement of comparative data in the normal healthy developing fetus [9]. LHR criteria have now been improved by fetal medicine specialists taking into account the fourfold relative increase of lung area to head circumference that occurs between 12–32 weeks in the normal developing fetus. The observed to expected predicted (O/E) LHR is now believed to be a better prognostic scoring tool [10].

Aside from determining fetal lung volume(s) with ultrasound other useful markers guiding prognosis antenatally include the presence or absence of liver herniation (designated 'liver up' CDH), and an emerging role for fetal MRI lung metrics. In a further systematic review study published from Liverpool it was later shown that fetuses with an increased volume of liver within the thoracic cavity—('liver up' cases) defined cases with (a) larger hernia defects, (b) a greater need for prosthetic patch repair and (c) worse survival [11]. Further studies to accurately predict survival have included real-time sonographic measurement of pulmonary artery dimensions to estimate risk(s) of postnatal pulmonary hypertensions [12].

26.5 Fetal Intervention

Fetal intervention for CDH was promoted and pioneered by Michael Harrison's group at UCSF, California, initially focusing on open surgical repair of the diaphragmatic defect deploying maternal C-section hysterotomy [13]. Early trials which evaluated open surgical repair of CDH were later abandoned due to problems with maternal preterm labour and adverse fetal outcome(s). Wilson's (1993) laboratory work explored and showed the dramatic changes seen in lung growth by occluding or 'plugging' the fetal trachea in the surgical CDH lamb model that led to the evolution of new fetal surgical approaches for CDH [14, 15]. Harrison then undertook the first randomised clinical trial in humans which explored the potential of fetal endoscopic tracheal occlusion. The trial showed equivalent survival outcomes in a treated cohort who underwent occlusion versus a control group of fetuses managed with conventional postnatal care in specialist centres [16]. For fetal surgery to have future clinical application selection of CDH fetuses with better prognostic 'high risk scoring' was needed. With the deployment of new LHR (O/E) and 'liver up' entry criteria (i.e. defining fetuses considered to have the very worst prognosis), fetal medicine programmes have now begun to explore the potential of FETO (a new minimally invasive operation 'fetoscopy guided balloon occlusion') in a prospective randomised clinical trial [17, 18]. The FETO trial outcome is eagerly awaited with findings expected to be published in the next few years.

26.6 Newborn Management

26.6.1 Delivery

With an increasing antenatal detection rate of CDH expert opinion regarding the mode of newborn delivery remains a subject of debate. In 2007 the International CDH study group reported a marginal (not significant) survival benefit for elective delivery by caesarean section [5, 19]. Further well designed randomised studies are required to draw any definitive conclusions here.

In order to maximise pulmonary development, delivery of the baby with CDH should be planned as near to term (more than 37 weeks) as

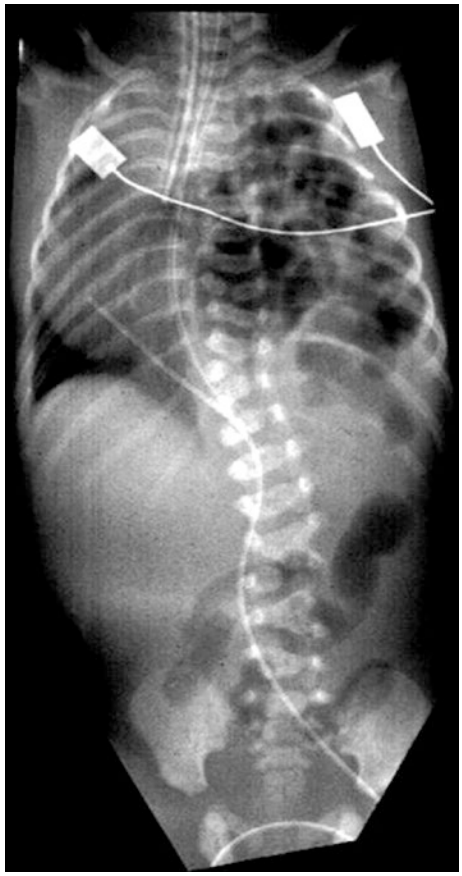

Fig. 26.1 Chest X-ray of newborn with left side CDH Bochdalek defect. Note bowel contents in left thoracic cavity, mediastinal shift and dextrocardia

possible [1, 2]. Delivery should be co-ordinated in a specialist centre equipped with full neonatal intensive care facilities and ready access to a multidisciplinary CDH team. Elective intubation following birth and 'gentle' ventilation (avoiding barotrauma) is recommended. All babies should have a nasogastric tube inserted to avoid gastric distension impairing ventilation and vascular access promptly secured to aid delivery of fluids and pharmacological/vasoactive agents. After initial stabilisation full clinical examination is essential to exclude associated anomalies and dysmorphism. Chest X-ray (Figs. 26.1 and 26.2) confirming the diagnosis and echocardiography is arranged screening for associated cardiac anomalies.

Fig. 26.2 Chest X-ray of newborn with right side CDH defect. Note marked opacification of the right hemithorax region as the liver and intestines (focal areas shown by gas shadows) were displaced in the thoracic cavity

26.6.2 Postnatal Diagnosis—'Late Presenting CDH'

Despite antenatal imaging almost 30% of patients with CDH may remain undetected until after delivery [2]. These cases may present emergently in the immediate newborn period or the first few days after birth whilst others may remain 'asymptomatic' until later life. Symptoms may include mild respiratory distress or laboured feeding problems. Delayed CDH presentation may occur with small diaphragmatic defects in which there is little or no herniated bowel at birth. Herniation of intestinal viscera into the chest may then occur as a later event following the introduction of feeds or accompany a respiratory tract infection. Clinical examination may reveal bowel sounds on chest auscultation. There may also be signs of decreased air entry on the affected side of the defect and mediastinal shift. Diagnosis is readily established by chest X-ray but occasionally may require an upper gastrointestinal tube contrast study to confirm the diagnosis of 'gut in the chest'.

26.6.3 Stabilisation

26.6.3.1 Permissive Hypercapnea/'Gentle' Ventilation Strategy

A major advance in the management of CDH particularly in the last 20 years has been the adoption of 'gentle ventilation' strategies (permissive hypercapnea) to reduce iatrogenic lung injury from barotrauma. Wung and Stolar—New York, introduced this therapy strategy which is characterised by preservation of spontaneous ventilation with permissive levels of hypercapnea ($paCO_2$ 60–65 mmHg or 9 kPa) and avoidance of high inspiratory airway pressures (ideally not exceeding 25 cm H_2O) [20]. Specialist centres worldwide are reporting improving survival (>80%) outcomes in CDH using this strategy with a declining utilisation of ECMO. High frequency oscillatory ventilation (HFOV) has also been deployed in management of CDH as a 'rescue therapy' prior to ECMO and as a primary ventilatory modality in an effort to reduce pulmonary barotrauma. Whilst several reports document improved survival of CDH using HFOV the recently published VICI trial has shown better outcome(s) with conventional ventilation in a prenatally detected CDH population as defined by (1) shorter duration of ventilation, (2) a reduced need for ECMO, (3) lesser requirements for iNO therapy also including (4) vasoactive agents notably sildenafil [21].

26.6.3.2 ECMO, Nitric Oxide, Sildenafil

ECMO (refer to Chap. 21) was introduced in the 1970s and used with modest success to treat cardio-respiratory failure in newborns not responding to conventional life support measures. ECMO was then later utilised in CDH to treat pulmonary hypertensive crisis. Pulmonary hypertension (PHT) associated with CDH is due to adverse physiologic events triggering abnormal pulmonary vascular resistance with right to left shunting, worsening severe hypoxemia and persistent fetal circulation. In the 1980s and early 1990s ECMO therapy expanded across intensive care units in clinical management of CDH. A 1990s UK multicentre randomised clinical trial and a Cochrane review later showed that no significant survival benefits were shown with ECMO use in CDH [22–24]. These findings have to some extent led to a steady decline in ECMO practice in many centres. Methods currently deployed for managing pulmonary hypertension associated with CDH now include use of inhaled nitric oxide (iNO) and the phospho-diesterase inhibitor sildenafil [25, 26]. A large multicentre randomised controlled trial (NINOS) and a Cochrane review failed to demonstrate significant sustained benefits with iNO therapy in CDH. In the studies that were published nitric oxide (iNO) therapy did not reduce (a) requirement for ECMO support or (b) improve CDH survival [25]. Sildenafil has emerged as a promising pulmonary vasodilator with some success recorded in CDH. Drug bioavailability and therapeutic efficacy from erratic gut absorption can be a problem. Intravenous sildenafil has been tested with encouraging early reports from Australia [27]. Randomised controlled trials are required.

26.6.4 Surgery

CDH was once regarded as a surgical emergency with operative repair performed early after delivery in an effort to improve ventilation by reducing the herniated viscera from the thoracic cavity [1, 2]. Currently preoperative stabilisation of labile physiology is paramount with delayed surgery scheduled during 'normal working hours' which permits optimisation of respiratory and cardiac status. A coordinated team approach is crucial with vital roles provided by cardiologists, intensivists and surgeons in selecting best therapies—(serial echocardiography monitoring of PHT, ventilator strategy(s)—CMV, HFO, iNO, ECMO) and timing of operation [1, 2, 22].

Classical operation is performed using a subcostal incision with the herniated contents returned to the abdominal cavity from the thorax and the defect in the diaphragm repaired with interrupted non-absorbable Ethibond sutures. A subcostal slide incising the upper margins of
